CHAPTER 81 ■ ANGER AND PAIN

JOSHUA WOOTTON

CULTURAL BACKGROUND

Aristotle, referencing Homer's *Iliad*, suggested that "Anger may be defined as an impulse, accompanied by pain, to a conspicuous revenge for a conspicuous slight,"[1,p54] emphasizing that "the angry man feels pain."[1,p63] There was no suggestion of the separation of emotional distress from its physical consequences. Unlike many of his contemporaries, Aristotle undertook a reasoned approach to the understanding of anger but nevertheless placed it clearly in the context of emotional and physical pain. In his essay *On Anger*, Seneca urged his elder brother Novatus to eschew anger and agreed that he was "right to have a particular dread of this most hideous and frenzied of all emotions,"[2,p17] even likening the emotional experience to "a brief insanity."[2,p17] It was a common thematic thread to philosophers and physicians in ancient Greece and Rome that anger tended to reveal itself as a form of madness and that attempts to control it reflected strength of character and spirit.[3] Attempts to control anger in antiquity, however, were usually concerned with altering its often dramatic appearance, not with regulating its impact on the body. The possible harmful effects of managing the expression of anger were paid little consideration.

Scripture, too, characterizes anger as being at the heart of sin or separation from God and admonishes against the dangers of its excesses. In Hebrew, Christian, and Islamic religious writings, God is often portrayed as angry toward those who oppose his will,[2] but the faithful are taught to suppress their angry impulses "for the anger of man does not work the righteousness of God" (Jas. 1:20). The Qur'an teaches that "Allah loves those who restrain anger" ('Al-'Imran 3:134), while the Psalms caution us to "Be angry, but sin not" (Pss. 4:4). In other passages, we are encouraged not only to avoid expressions of anger, but to resist even the emotion itself. In the Gospel of Matthew, we find that "everyone who is angry with his brother shall be liable to judgment" (Matt. 5:22), while elsewhere in the Psalms, we are exhorted to "Refrain from anger; and forsake wrath!" (Pss. 37:8), and in the Sunnah of Islam, the Prophet advises, again and again, "Do not become angry and furious" (Hadith-Sahih Al-Bukhari 8.137).

This deeply ingrained cultural awareness—that not only are angry actions dangerous, but the emotion of anger itself can be harmful—led to the inclusion of anger as one of the "seven deadly sins" in the religious West,[4] a theme popularized and later woven into the fabric of Western cultures through literature, drama, and art, including in European cultures the enduring and influential classics of Dante's *Divine Comedy* and Chaucer's *Canterbury Tales*.

PSYCHOANALYTIC BACKGROUND

One important difference between historical and more contemporary discussions of anger is that the former, while often concerned with the negative consequences of expressing anger, were seldom concerned with the possible harmful effects of its inhibition.[3] Anger in psychoanalytic theory does not carry the metaphysical weight of sin, but its expression through hostility and aggressive impulses often lies at the core of conflict, competing drives, and the formation of pathological symptoms, including pain. Although Freud was an atheist, his frequent excursions into the fields of religion, religious experience, and anthropology are testimony to his respect for the conscious and unconscious impact of culture upon the individual; he was the first to emphasize the idea that the individual and culture are linked dynamically and that disturbances may occur in the developmental interaction between the two, leaving behind a disposition to future neuroses.[5] He was also an astute observer of the phenomenon of pain from organic origins being maintained for intrapsychic reasons, long past the point of expectable physical healing and recovery.[6,7]

Early in his work, Freud arrived at the idea that pain is a common symptom of *conversion* and that, although there is usually an organic basis for the onset of pain, it can later be influenced and extended in duration and scope by a process through which mental conflict is displaced onto the body, resulting in the somatic expression of symptoms. Conversion, in this context, is closer to the contemporary term *somatization*, referring both to conversion and psychophysiological disorders. The repression of negative affects, such as anger, resentment, and guilt, is transmuted into the expression of physical symptoms. The defensive process of somatization continues until relief from the intrapsychic burden of intolerable affect is no longer necessary or desomatization takes place through support—often psychotherapeutic—of the individual's more mature defenses and coping strategies.

Freud's later work was focused more on patients whose pain was less directly associated with an original organic insult and more configured with mood disturbance. In *Mourning and Melancholia*, he delineated the intrapsychic origins of depression as a process through which aggression, originally directed toward the lost object, is turned against the self[8]—somewhat oversimplified in the popular formula "anger turned inward." According to this template, pain and mourning may be seen as affective responses to separation and as unconscious defenses against aggression.[8,9,10] Freud's successors related pain to aggression and hostility more directly, and the idea that the symptom of physical pain can be an unconscious defense against anger and aggression became a widely shared interpretation in psychoanalytic theory; however, as Merskey points out, the evidence has been largely anecdotal, with the relationship between anger and pain often being made more plausible by retrospective analysis.[7]

Like Freud, Engel acknowledged that pain may originate with actual physical injury, but his study of the "pain-prone patient" gave the most enduring and widely influential psychoanalytic expression of chronic pain as a symbolic displacement of anger and aggression.[11] He also suggested that patients are frequently unwilling or unable to acknowledge the hostility and aggressive impulses behind their pain, leaving them with the difficult task of attempting to adjust to symptoms that are borne of conflicts that they can neither recognize nor accept. The presence of chronic pain, then, may reflect underlying conflicts—in turn, giving rise to intolerable affects, which, when repressed, are given dynamic expression through the body. Szasz, as well, held that repression of emotional distress is often the principal mechanism underlying chronic pain and suggested that, by focusing their attention on their pain, many patients are coping with their distress symbolically and through a more socially acceptable expression of their conflicts.[12]

Burns summarizes the evidence supporting this view that repression of affect is the mechanism at the heart of chronic pain.[13,14] First, he cites the phenomenon of the "conversion-V"

profile on the Minnesota Multiphasic Personality Inventory (MMPI-2), depicted by clinical elevations on Scales 1 and 3, Hypochodriasis and Hysteria, with a comparatively lower score on Scale 2, Depression. The resulting V-configuration suggests the presence of somatic preoccupation and a hysterical constellation of defenses, deployed in the service of relieving depressed affect. Second, he further reports evidence of the link between the tendency to suppress anger and aggression and the symptomatic expression of chronic pain and disability. Finally, he points to the persistent observation that inhibition of emotion, particularly emotions arising in the context of traumatic events, has physiological consequences.

Where the first of these three lines of evidence is concerned, the conversion-V configuration of scores on the MMPI and MMPI-2 has been studied extensively, and applied to chronic pain, for more than 30 years.[13,15] The first scale of this "neurotic triad" of scores is Hypochondriasis (Hs). High scores on Hypochondriasis tend to reflect patterns of neurotic concern over physical health.[16,17] The third scale, Hysteria (Hy), was developed specifically as an aid to measuring the predisposition to develop symptoms of conversion or somatization and reflects a high degree of reliance upon hysterical defenses.[16,17] When these two scales are clinically elevated and the second scale, Depression (D), which reflects both mood and neurovegetative aspects of depression, is comparatively lower, the indication of the resulting V-configuration is that intolerable affect is being displaced onto somatic concerns, principally through the mechanism of repression.[14,15,16,17,18,19]

Where the second line of evidence is concerned, Burns' observations of trends in the scientific literature suggesting the link between chronic pain and the inhibition of anger[14] have been replicated and amplified by numerous subsequent studies, although not always with psychoanalytic theory in the foreground.[20,21,22,23,24,25] The suggestion is that patients with chronic pain are more likely to experience anger than those without pain and more likely also to inhibit their anger.[24] Burns' third source of evidence concerns the physiological response, both conscious and unconscious, to efforts at inhibition.[13] Suppression reflects the more obvious example of physiological cost; however, repression also has a dynamic element that must be balanced in the psychosomatic economy of mind and body interrelationship.[20,21,22,24] Within the framework of psychoanalytic theory, the physiological exertion demanded by inhibition was often seen as related to the persistence of conversion, as well as the intensity and duration of somatization.[8,10,26]

The following case of a young woman referred for evaluation of her chronic abdominal pain will serve to illustrate the psychoanalytic perspective on inhibition and its relation to anger and pain.

> Case 1: Ms. Ostrakova was a 20-year-old single library aide and part-time student at a nearby community college, who presented with a 2-year history of chronic abdominal pain. She had undergone two separate, complete gastroenterological work-ups at two different medical centers, without any positive findings. She associated the beginning of her difficulties with a chicken sandwich, prepared by her elder sister, in which the meat was apparently undercooked. She explained that she had become quite ill within a short time, with fever, nausea, and vomiting. These symptoms resolved after a few days, but her abdominal pain persisted and became progressively more debilitating until, by the time she arrived in clinic, she had taken a leave of absence from both college and her job and was attempting to manage her pain with a medication regimen that included short-acting opioids. Ms. Ostrakova was fit and slender and her demeanor, while somewhat subdued, was affable and cooperative. She had no psychiatric history or history of substance abuse, and her medical history was notable only for robust health prior to the onset of her abdominal pain. Her psychosocial history, however, was remarkable for early childhood trauma and abuse and a childhood household of domestic turmoil and violence. She described a history of fighting in school and finally being remanded at age 17 by the juvenile court system to a residential treatment facility for "anger management" in another state. When asked about the therapeutic aspect of her 1-year treatment program, she replied, "They just taught us how to keep our anger inside, not to let it out, so we wouldn't always get into fights. We had to avoid fighting to prove we had learned how to manage our anger."

As the interview progressed, it became clear that the patient had learned much about recognizing anger when she experienced it, and suppressing it in the moment, but little about the potential cost to herself and her body. A psychometric assessment reflected little endorsement of depressive symptoms on the Beck Depression Inventory or the MMPI-2 but clinically elevated scores on Hs and Hy, and her history reflected many of the psychosocial factors depicted by Engel as disposing toward "pain-proneness." The latter included parents who were abusive toward each other and toward their children, a father who was alcoholic and emotionally and physically domineering, and a mother who was often debilitated by pain of uncertain etiology.[11,27]

In her treatment program, the patient appeared to have gotten the message, right or wrong, that, if she showed no outward signs of anger, she would be considered successfully rehabilitated. The experience of anger, therefore, became an obstacle between her court-mandated residential treatment and her successful return home. Over time, the experience of anger was transformed by a developing awareness of intolerable affect—displaced onto her body in the more acceptable symptomatic expression of physical pain. When Ms. Ostrakova's elder sister provided the organic insult of an undercooked chicken sandwich, resulting in gastroenterological distress, the patient, who might previously have responded with anger leading to physical confrontation, began instead to experience the pain associated with simple repression of her affect—unconsciously "keeping her anger inside." This is the classic picture of somatization, depicted in psychoanalytic theory, which continues to be influential in our assessment of patients with chronic pain.

CURRENT RESEARCH IN ANGER AND ITS RELATION TO PAIN

The role of anger in exacerbating pain and in disposing toward the development of chronic pain is, in some respects, similar to that of other negative emotions or distressed affective states, such as anxiety and depression.[28] According to the prevailing gate control and neuromatrix theories of pain, negative emotions can increase the intensity and duration of pain by altering or dysregulating the descending and central pain modulation systems.[29,30,31,32] Precisely how this takes place remains an open question for further research, but an integrated neurobiological model is beginning to emerge with implications for treatment of both chronic pain and disorders of anger.

Physiological Mechanisms in Anger and Pain Research

Merskey noted that pain can make individuals aggressive for purely biological reasons, associated with the activation of the fight-or-flight mechanisms and high autonomic arousal.[7] He added that we may not need to look much further in our attempts to explain why patients with chronic pain become angry. Whereas angry responses can be adaptive, especially when they prompt the search for constructive solutions to problems within the medical setting, chronically angry reactions of the sort observed in some patients with chronic pain are often seen as maladaptive and disruptive—indicative not of discrete situations of fight-or-flight, but of sustained and simmering autonomic arousal.[32] Parsing the relationship here has proven challenging because of two related questions: Does chronic pain induce sustained sympathetic

arousal and therefore lead to continual expressions of anger? Does the situation of chronic pain arise more easily among individuals who are disposed to express anger and aggression?

Robinson and Riley outlined four models or mechanisms through which the relationship between pain and negative emotion has been usefully described, both from a clinical perspective and as a template for empirical design[28]:

- Negative emotion increases sensitivity;
- Pain is caused by negative emotion;
- Negative affect occurs as a result of chronic pain;
- Pain and negative emotion are concomitant.

The first of these is simply the observation that negative emotion increases somatic sensitivity. In other words, negative emotions increase awareness and recognition of pain. Evidence in support of this mechanism comes from studies in which induced changes in mood have been correlated with increased reports of pain and decreased tolerance for experimentally induced pain, as well as in the clinical observation that depressed patients tend to interpret sensations negatively, experiencing them more often as painful.[28]

The second mechanism—that pain is caused by negative emotion—is most closely allied with the psychoanalytic view of pain as a symptom of underlying or repressed conflict, but inhibition of negative emotion and affect can also result in elevations of autonomic and central nervous system activity, raising serum cortisol levels and leading to neurovegetative dysfunction and increased pain. Cacioppo et al.'s meta-analytic study of the physiological correlates of negative emotions concluded that the experience of anger, whether expressed or suppressed, tends to be accompanied by increased diastolic blood pressure, skin conductance, stroke volume, cardiac output, peripheral resistance, finger pulse, and heart rate, all suggesting a high sympathetic response.[33] Considering the impact of sustained autonomic arousal, negative emotions, not surprisingly, may also be seen as causal in the expression of stress-related illness and pain in which somatic reactivity can lead to musculoskeletal disorder.[28,34,35] Robinson and Riley's third mechanism echoes Merskey's suggestion that negative affect may be seen simply as a reaction to the situation of chronic pain, arising within a stress-diathesis framework,[7,28,36] whereas their fourth proposed mechanism posits that pain and negative emotion arise concomitantly from shared neurobiological pathways.[28]

Taken together, these four mechanisms are broadly consistent with the gate control and neuromatrix theories of pain; however, the last—that anger, anxiety, depression, and pain share neurobiological pathways—suggests a physiological context in which negative emotions can alter the descending and central pain modulation processes.[37] Serotonin, norepinephrine, and dopamine all play roles in the modulation of pain, as well as in the development of negative emotions. That pain and depression both respond to certain antidepressant medications has long been cited as evidence of common neurobiological pathways.[28,38,39] Relative cortisol levels and dopaminergic transfer and regulation have also been implicated in the relationship between anger and pain,[28,40,41,42,43] but the key neurotransmitter implicated in the modulation of anger is dopamine, with the focus of activity in the nucleus accumbens.[43,44,45,46]

From an evolutionary perspective, the emotion of anger is clearly primitive and derived from ancient limbic regions of the brain, as opposed to the cortex and prefrontal cortex, which assume a more modulatory role in its experience and expression.[44] The regions of primary activity for anger—along with its conceptual counterparts, appetitive impulsivity, drive, motivation, pleasure, and psychoticism—appear to be associated with the core regions of temperament: the amygdala and nucleus accumbens or ventral striatum, as well as the cingulate cortex.[44,45] Lara and Akiskal suggest that anger is influenced by dopaminergic transfer and regulation in these regions, with high anger being associated with either enhanced postsynaptic response to dopamine or increased synaptic dopamine concentration or both.[44] Wood outlines evidence to suggest that the inhibition of tonic pain is mediated by activation of mesolimbic dopamine neurons, arising from the ventral tegmental area and projecting to the nucleus accumbens.[43]

Ironically, anger may be associated both with an increase or a decrease in the experience of pain.[37,47,48,49] Acute stress may activate mechanisms of pain-suppression through the release of endogenous opioids and substance P within the ventral tegmental area, but prolonged exposure to stress—as in the case of sustained anger or proneness to anger—tends to result in a reduction of dopaminergic output in the nucleus accumbens, potentiating the subsequent development of hyperalgesia.[43] The outcome appears to be that inhibition of pain may occur initially when a painful stimulus is first perceived but that, upon further exposure and evaluation, sensitization may occur.[37] The experience of anger appears to undergo change over time, leading to associations with both traits and temperament—factors related to the thematic and serial evaluation of stimuli—an observation that has led to the study of anger-related features of both mood and personality disorders.[50,51,52] The influence of anger on the changes involved in mood states suggests a dynamic relationship associated with the tonic and phasic balance of dopaminergic activity.[43,44] In this case, the inhibition of pain may be principally related to physiological changes occurring in the initial or situational experience of anger, such as changes in cardiovascular reactivity and autonomic arousal that have been shown to modulate the experience of pain.[47] Pain sensitization, on the other hand, appears more associated with the ability to regulate anger and the emotional evaluation of the experience—individual differences that influence dopaminergic output.[37,44] This, in turn, suggests that the experience of anger, relative to personality and temperament, as well as how we manage anger, are important variables in the modulation of pain.[37,44,46,47,48,49,50,51,52]

Other physiological mechanisms under study include the effects of anger on muscle reactivity, the immune system, and endogenous opioid dysfunction.[32] Consideration of the last of these will be deferred to discussion of the related work on anger management, later in this chapter. Where the first is concerned, studies on muscle reactivity have suggested that anger may increase musculoskeletal tension in specific sites that contribute to pain.[53,54] The experience of anger, whether inhibited or expressed, and the trait of hostility have been associated with increased likelihood of reporting high levels of tension near the site of pain and injury.[55] A further mechanism through which anger may influence pain is distress-related immune dysregulation.[56] While brief, situational stressors involving activation of the fight-or-flight mechanisms have been shown to result in potentially beneficial changes to the immune system, exposure to prolonged stress and negative emotion, such as sustained anger and hostility, have been associated with deleterious effects in a broad range of health concerns, immunological suppression, and generalized inflammatory processes associated with chronic pain.[57,58,59,60] Because immunological changes must be observed longitudinally, this work has tended to emphasize the impact of sustained anger and hostility associated with enduring personality traits and temperament.[59,60]

Psychological Constructs in Anger and Pain Research

The etymology of "anger" is not the same for every modern language, but it appears to have come into modern English usage via Old Norse, *angra*, "to grieve, vex," later *angr*, "distress, grief," Old English, *enge*, "narrow, painful," influenced by the Proto-Indo-European root, *angh-*, "painfully constricted," and finally into Middle English, where its associations with pain endured.[61] The relative importance of the term in ordinary discourse can be illustrated through the frequency of its use: Of the

roughly 700,000 words in common English usage, "anger" is ranked 3,253rd in frequency of appearance in spoken and written communication.[62] Focusing on the logic underpinning the ordinary language use of the word "anger," Smedslund offered a contemporary definition of anger that depicts the psycholinguistic core of the construct, rather than emphasizing the characteristic features of its expression: "a feeling involving a *belief* that a person one cares for has, intentionally or through neglect, been treated without respect, and a *want* to have that respect re-established."[34,35,63] In Smedslund's conceptual framework, the "person one cares for," particularly in the context of pain, is ordinarily the self.

Fernandez emphasizes the dimensions of *action tendency* and *cognitive appraisal* in the study of the relationship between anger and pain.[34,35] The former concerns the behavioral tendencies associated with anger, including aggression and impulses directed toward the restoration of control, the removal of obstacles, and the seeking of redress. This becomes an important consideration in the context of whether action is expressed or suppressed and, if expressed, how adaptively. The latter suggests a framework within which the individual seeks to explain otherwise ambiguous interior experiences or changes in arousal. Both of these dimensions are anticipated by and subsumed under Smedslund's ordinary language definition of anger, and both have proven critical to the study of the relationship between anger and pain.

The cognitive appraisal theory of emotion—perhaps most elegantly and economically portrayed in Lazarus's cognitive-motivational-relational theory[64]—suggests that the experience of an emotion, like anger, is the joint effect of (1) the event of physiological arousal in response to incoming stimuli and (2) the cognitive appraisal of its meaning with respect to the particular setting in which the event occurs (Table 81.1). Cognitive appraisal, then, is the process through which physiological states, such as arousal, are interpreted in light of the perceived situation. This becomes critical in the management of anger and, by extension, to the psychotherapeutic treatment of patients with chronic pain, because how events are appraised tends to influence selection and deployment of coping strategies.[65,66] Lazarus further distinguished between primary and secondary appraisals, with the former referring to the interpretation of how a particular situation affects considerations of well-being and the latter, referring to considerations of how to cope with the situation.[64] Secondary appraisals, he suggests, can actually shape the experience of an emotion through the selection of a particular coping strategy.[64,67]

Anger Management Style

Much of the research on anger and its relationship to pain has highlighted the related constructs of hostility, aggression, and anger management style.[32] *Anger* is the term denoting the emotion, characterized by physiological arousal and accompanying conscious and unconscious impulses toward aggression. *Aggression* typically refers to the behavioral expression of the emotion, ordinarily through acts of vindication, punishment, and destruction, directed toward others or objects.[68] Freud's focus was ultimately less on anger than on aggression, as one of the two primary instinctual drives.[6,69] In psychoanalytic theory, aggression in its stimulation of defensive functions and coping strategies plays an important role in the development of personality. This distinction between anger and aggression suggests that, while anger is usually conceived as a transient state, aggression is a more durable and endogenously derived motivational force. The word *anger* can be used in this manner—to denote a more dispositional quality—but, frequently, the term *hostility* is used in reference to the tendency to make consistently negative cognitive appraisals regarding the motivations of others.[35]

Conceptual links with aggression and hostility further raise the distinction between state anger and trait anger, a critical consideration in researching the influence of anger upon chronic pain. A good starting point for the distinction is offered by Spielberger, who characterizes state anger as a transitory emotional episode, whereas trait anger is described as a more stable pattern of personality attributes, similar to hostility.[68] One way of representing this is that trait anger reflects a relatively stable dimension of proneness to anger in which individual differences are reflected in the frequency, intensity, and duration with which state anger is experienced over time.[70] This, in turn, suggests that characteristic defensive patterns and reliance upon particular coping strategies tend to result in what may be described as more enduring styles of anger management.

Anger management style is a term denoting the relative tendencies of individuals either (1) to suppress or internalize their anger or (2) to express or externalize their anger. The construct of anger management style is often represented in research as anger-in, anger-out, and anger-control.[32] *Anger-in* characterizes the tendency to inhibit the expression of angry thoughts and feelings, whereas *anger-out* describes the tendency to express angry thoughts and feelings directly, whether verbally, physically, or both. High trait anger, according to Deffenbacher, is more associated with the tendency to express anger negatively, less constructively, and with less control than with the tendency to suppress anger; he further notes that there is a stronger connection between the suppressed anger and anxiety than between suppressed anger and forms of expressed anger.[70] *Anger-control* refers to an individual's perceived control over the experience and expression of anger and is usually interpreted as positive, unless too much control approaches no expression at all.[32]

Although the International Association for the Study of Pain (IASP) appears to separate the sensory and emotional dimensions of the experience of pain, when it defines pain as an "unpleasant sensory and emotional experience associated with actual or potential tissue damage,"[71] several studies point to the simultaneous processing of pain in the somatosensory cortex and emotion-related cerebral systems.[37,72] Mollett and Harrison summarize the case for the application of emotional theories to the study of pain and propose that emotion may influence the processing of pain in several ways[37]:

- Negative emotion increases pain intensity and decreases threshold and tolerance;
- Positive emotion decreases pain intensity and increases threshold and tolerance;
- Pain may produce negative emotion or increase the memory for negative emotion.

This template emphasizes the relationship between anger and pain and strongly implicates anger in the development and maintenance of chronic pain. It further highlights the role of anger management style as a critical influence in how pain is experienced.

Anger-In

In his study of emotion regulation, Gross utilized a process model to illustrate two features of trait anger-in: First that, while the mechanism of suppression tends to decrease negative emotional expression, it also decreases positive emotional expression and second that, while suppression has little impact on the experience of negative emotion, it tends to decrease the experience of positive emotion.[73] In his analysis of emotion regulation, he concluded that, as a means of regulating negative emotion, cognitive appraisal is more adaptive than suppression and tends to decrease both the experience and expression of negative emotion, while increasing the experience and expression of positive emotion. He added that there may be times when cognitive appraisal cannot adequately be mobilized and suppression may be, in the moment, the best available means of regulating negative emotion, but such instances are more likely to involve evaluation in the moment of

TABLE 81.1

RS LAZARUS'S COGNITIVE-MOTIVATIONAL-RELATIONAL THEORY OF EMOTION*

Event (stimulus)	Physiological response	Setting/circumstances	Cognitive appraisal	Emotion	Secondary appraisal
Feeling oneself being pushed or shoved	Autonomic arousal, pain	A cashier's line in a busy store where customers are jostling for position	"A stranger has pushed me aside! *This is unfair!*"	Anger (increased pain associated with the unfair slight to one's identity or ego)	The setting may suggest that an angry outburst will prove less effective than a sympathetic, reasoned appeal to civility.
Feeling oneself being pushed or shoved	Autonomic arousal, pain	A pedestrian crosswalk at a busy urban traffic intersection	"A stranger has pushed me out of harm's way! *I was nearly struck by that automobile!*"	Relief, gratitude (reduced pain); if anger is experienced, it is likely directed toward the impatient motorist or toward oneself for being careless	The setting may suggest that a personal expression of gratitude toward one's protector is more appropriate than an angry outburst directed toward the fleeing motorist.

*The same or similar events and physiological responses may be interpreted or appraised differently, depending upon the setting or circumstances, resulting in different emotional responses.

state anger. The overarching conclusion is that suppression as a trait mechanism for modulating intolerable affect is problematic.

Engel noted that inhibition of anger, whether through repression or suppression, is a common attribute among pain-prone patients, but psychoanalytic theory offered little insight into the causal relationship or cognitive, emotional, and physiological mechanisms through which inhibited anger can affect pain.[11,24,25] More recent studies of anger-in as a form of emotional regulation confirm that suppression is a prevalent style of management among patients with chronic pain but also point to applications of Wegner's ironic process theory as a means of delineating the mechanisms involved.[24,25,74] According to this template, suppression of negative emotion requires the coordination of two distinct cognitive processes: the first represents a resource-dependent operating process that serves to eliminate awareness of unwanted thoughts and feelings, whereas the second represents a monitoring process that remains vigilant to the awareness of unwanted thoughts and feelings to be suppressed (Table 81.2). Under ordinary conditions, the monitor works to identify material to be suppressed, while the operating process performs the suppression; however, when under stress or high demand, the operating process may not have sufficient resources to perform its task. Stress, in this context, may be reflected in both cognitive and somatic symptomatology, with cognitive dissonance thwarting both suppression and cognitive appraisal and the corresponding demands on the body being expressed through cardiovascular and musculoskeletal symptoms. Burns et al. reported that patients with chronic low back pain who reflect an anger-in style of management are more likely than other groups to experience high levels of muscle tension at the site of pain and injury when experiencing anger and to show relatively high systolic and diastolic blood pressure.[55]

The irony implicit in Wegner's theory of mental processing is that, under such conditions, the monitor may be serving to bring unwanted thoughts and feelings into conscious awareness without sufficient resources for suppression to take place. The result is that unsuccessful efforts to suppress anger can paradoxically lead to heightened awareness of the cognitive and emotional experience of anger, thereby increasing sensitivity to pain and influencing subsequent perceptions and interpretations of pain according to the unsuccessfully suppressed, unwanted cognitions and intolerable affect.[24,25] Carson et al. conducted studies on constructs related to anger-in, including the construct of ambivalence of emotional expression (AEE) and the construct of forgiveness.[75,76] Their findings suggest that those who are ambivalent about expressing their emotions and those who cannot forgive others for perceived wrongs and insults may experience higher levels of low back pain and psychological distress, mediated by higher levels of anger. Where treatment is concerned, it is possible that psychotherapeutic interventions designed to resolve patients' ambivalence toward expressing their emotions and to encourage the development of cognitive reappraisals supportive of conciliation and forgiveness may facilitate the management of pain.

Anger-Out

Like anger-in, the emotional regulatory strategy of anger-out—managing anger directly with physical or verbal expression—has been shown repeatedly to be associated with increased responsiveness to pain and higher levels of chronic pain intensity and disability.[32,77,78] It must be noted, here, that anger-out, in this context, usually refers to the trait of immediately responding to the emotional experience of anger with expression of anger—not the same as the considered, constructive expression of anger signifying the mobilization of more mature defensive processes. Hostility and tendencies toward aggression are hallmarks of trait anger-out. Bruehl et al. have done the most complete review of anger-out studies to date and conclude that elevated trait anger-out is associated with heightened chronic pain intensity and low levels of improvement in individuals suffering from a broad range of medical conditions associated with chronic pain.[77] They examine a number of proposed mechanisms underlying the effects of trait anger-out upon acute experimental, acute clinical, and chronic pain, but the emphasis here will be upon chronic pain.

The authors submit that there is little evidence for the influence of either neuroticism or the psychoanalytic construct of repression.[77] The former—a willingness to over-endorse a broad spectrum of symptoms—has sometimes led to spurious correlations between elevated pain and indicators of an anger-out style of management, but the available evidence tends to suggest that the relationship of anger-out to pain is independent of the broader palette of negative affect, including depression and anxiety. Where the latter is concerned, one might expect that trait anger-

TABLE 81.2

DM WEGNER'S IRONIC PROCESSES THEORY OF MENTAL CONTROL*

Monitoring cognitive processes	Setting/circumstances	Operating cognitive processes	Mental control outcome
Vigilance toward unwanted thoughts or reminders of previous events leading to overwhelming anger	Stress-free or low-stress circumstances evoking occasional or random thoughts or reminders of previous events leading to anger Stress-laden or high-stress circumstances evoking frequent thoughts or reminders of previous events associated with harm or an unfair slight to one's ego or identity leading to anger	Effortful, conscious attempts at suppression of or distraction from unwanted thoughts and reminders	Successful suppression of or distraction from monitored thoughts and reminders Failed suppression of or distraction from monitored thoughts and reminders leading to preoccupation and rumination

*Note that when the operating processes are under high stress, the monitoring processes, which ordinarily serve to identify thoughts to be suppressed, can become the source of continual unwanted reminders of events leading to overwhelming anger.

out would be negatively associated with the classic psychoanalytic constructs of conversion and somatization and therefore consistently lead to an amelioration of pain. As previously noted, however, the hostility and aggression embodied in trait anger-out do not promote the mature and adaptive expressions of anger reflecting successful management that might lead to reduced pain intensity and sensitivity. Other behavioral mechanisms have been considered, including the observation that individuals whose scores are elevated on measures of anger-out show decreased cardiovascular reactivity when encouraged to express their anger versus suppress it and, among a high anger-out group of women, verbal expression of anger during provocation was associated with improved blood pressure recovery, following the stressful event. Although there are some indications that these findings are related to improvement in situations involving acute pain, Bruehl et al. point out that implications for the effect of behavioral anger expression upon chronic pain have yet to be fully delineated.

Although not specifically applied to the variable of management style, Greenwood et al. suggest several behavioral mechanisms that may influence the relationship between anger and pain.[32] First, anger may foster the development of pain behaviors associated with the negative consequences of expressing anger. The high correlation between hostility and absenteeism from work, for example, suggests that anger may contribute to the maintenance of pain-related illness. Second, the effects of anger upon marital functioning may lead to spousal responses that exacerbate and maintain pain and pain behaviors. Finally, anger can impact pain by contributing to conflicts and mistrust in relationships between patients and their medical providers. Studies by Burns et al. concluded that high scorers on anger-out and hostility were correlated with patients' reports of weaker alliances with their physicians and with interference in their abilities to improve with pain management.[79,80]

Proposed mechanisms underlying the relationship of anger-out and pain have also included a number of physiologically-based models.[77] Anger-out has been associated with greater visceral adipose tissue is some studies, a potential source of impact on lower spine mechanics. Like anger-in, anger-out has also been found to be correlated with increases in stress-induced muscle tension among patients with low back pain. Neither of these models, however, can account for the effects of anger-out on acute pain responsiveness and sensitivity. Genetic mechanisms have been suggested as well, but Bruehl et al. assert that none has been adequately investigated, to date, despite promising connections with genetic factors related to personality traits, emotional reactivity, and endogenous opioid system functioning. A related mechanism, referred to as "trait X," suggests that high anger-outs express their anger because they believe it is beneficial and it feels better to discharge it than the alternative. The idea is that behaviorally expressing anger for high anger-outs actually reduces arousal and restores emotional and physiological homeostasis more efficiently. The authors comment that trait X state interactions may well reflect some degree of functional regulatory benefit, especially in the immediate aftermath of expressing anger, but the more enduring trait anger dimension has yet to be sufficiently investigated.

Opioid Deficit Hypothesis

Bruehl, in collaboration with others, has also called attention to the role of endogenous opioid dysfunction in the relationship between anger-out and pain.[21,23,77,78,81,82] The essential premise is that mechanisms associated with anger-out may impose an excessive burden or strain on the body's ability to produce endogenous opioids, inhibiting the natural management of chronic pain. Bruehl et al. conducted studies in which subjects with low scores in anger-out reported increased acute pain intensity following opioid blockade with naloxone, versus following placebo blockade, whereas subjects high in anger-out reported smaller naloxone blockade effects.[21,23] The implication is that there is less effective endogenous opioid response among those who score high in anger-out, with opioid dysfunction partially mediating the positive correlation between anger-out and chronic pain intensity.[78]

Burns et al. further established that the use of exogenous opioid analgesics remediates opioid deficits such that anger-out is related to chronic pain severity only among patients not taking opioid medications.[82] The results suggest that regular use of opioid medications among those who are high in anger expression may compensate for overtaxed endogenous opioid mechanisms. In another, related study, Bruehl et al. investigated whether impaired central opioid inhibitory functioning, assessed via changes in plasma beta-endorphin release, could explain exaggerated pain responsiveness and anger expression in high anger-out subjects.[78] As with the opioid blockade studies and the study of the mediating effects of exogenous opioids, the results of this pain-induced endogenous opioid release study support the opioid deficit hypothesis and demonstrate that greater trait anger-out is associated with higher perceived pain intensity and less endogenous opioid release.

Taken together, these studies provide strong evidence for the idea that patients whose anger management style involves physical and verbal expression show comparative deficits in opioid analgesia because of endogenous opioid dysfunction. Bruehl et al. have taken this one step further with the opioid triggering hypothesis, suggesting that, for individuals high in anger-out, the dramatic expression of anger serves to activate endogenous opioid response that would otherwise remain quiescent when anger associated with pain and stress is either not expressed or only moderately expressed.[77] Those who are low in anger-out appear to elicit a sufficient endogenous opioid response without expressing their anger, but the expression of anger among high anger-outs may actually represent an adaptive mechanism designed to trigger the release of endogenous opioids. Patients high in anger-out may therefore have a higher threshold for the activation of endogenous opioid response, with the increased arousal of dramatic anger expression serving as a triggering mechanism.

MEASUREMENT OF ANGER

Anger, both state and trait, as well as the related constructs of aggression, hostility, and anger management style have been assessed for research purposes with a broad spectrum of tools, ranging from projective tests, like the Rorschach and TAT, to physiological measures principally associated with autonomic arousal.[35] Self-report questionnaires and inventories tend to predominate in anger-related research, however, both for their ease of administration and for their more readily documented validity and reliability. Several of the self-report instruments measuring anger that are more widely utilized in pain research are reviewed below. Extensive commentary on each, as well as critical reviews of many more instruments designed to measure some aspect of anger, are available in *Tests in Print VII*[83] and the *Mental Measurements Yearbook, 19th ed.*[84] The instruments discussed below are summarized in Table 81.3.

State-Trait Anger Expression Inventory-2 (STAXI-2)

The STAXI-2 was developed by Spielberger and is widely regarded as the most psychometrically sound and comprehensive tool in the assessment of anger and hostility.[35,68] It represents the integration and culmination of several precursors developed by Spielberger, including the State-Trait Anger Scale (STAS), the

TABLE 81.3

INSTRUMENTS DESIGNED TO ASSESS ANGER

Instrument	Format	Administration	Availability
State-Trait Anger Expression Inventory (STAXI-2)	57 items distributed across 6 scales, 5 subscales, and an anger expression index; ages 16 years and up	5–10 minutes; scored by hand	**PAR** Psychological Assessment Resources, Inc. (http://www3.parinc.com)
Targets and Reasons for Anger and Pain Sufferers (TRAPS)	10-point Likert scale assessing degree or intensity of anger toward 10 common objects of anger (e.g., self, significant others, employer, physician) and 10 common reasons for anger	10–20 minutes for an interactive administration; has been adapted for briefer self-administration; scored by hand	Fernandez E, Salinas N, Swift P, et al. Psychosocial factors that predict anger in chronic pain sufferers. *Annals of Beh Med* 1995; 17(Suppl.)S164. Fernandez E, Salinas N, Swift P, et al. Psychosocial factors that predict anger in chronic pain sufferers. Sixteenth Annual Scientific Meeting of the Society of Behavioral Medicine, San Diego, 1995. (Use by permission of primary author.)
Multidimensional Anger Inventory (MAI)	30-item instrument, with multiple variations, assessing the duration, frequency, and magnitude of anger, including differentiation between anger-in and anger-out expression and common situations leading to anger	10–20 minutes; scored by hand	Siegel JM. The multidimensional anger inventory. *J Pers Soc Psychol* 1986;51:191–200. (Use by permission of author.)
Novaco Anger Scale and Provocation Inventory (NAS-PI)	60 items distributed across 3 subscales (cognitive, arousal, behavioral) plus a 25-item inventory eliciting responses to specific situations	25 minutes; scored by hand	**WPS** Western Psychological Services (http://portal.wpspublish.com)
Anger Disorders Scale (ADS)	70 items distributed over 5 categories (provocations, cognitions, arousal, motives, behaviors)	short form, 5–10 minutes; long form, 10–20 minutes; scored by hand or software	**MHS** Multi-Health Systems, Inc. (http://www.mhs.com/mhs)
Minnesota Multiphasic Personality Inventory (MMPI-2)	567 true-false items distributed across multiple validity and clinical scales, with 6 assessing some aspect of anger, hostility, or aggression	60–90 minutes with a short form available; scored by hand or software	**Pearson** Education, Inc., Pearson Assessments for Educational, Clinical, and Psychological Use (http://www.pearsonassessments.com)

Anger Expression Scale (AES), and the first version of the STAXI-2. The instrument consists of six scales: Trait Anger, Anger Expression-Out, Anger Expression-In, Anger Control-Out, Anger Control-In, and State Anger, as well as five subscales and an Anger Expression Index. It can be administered in 5 to 10 minutes and is scored by hand, making it practical for clinical applications as well as research. The STAXI-2 purports to measure tendencies toward angry action, as well as more dispositional or trait-based hostility, along with tendencies to suppress or express the experience of anger. This makes the inventory well-suited for research in anger management styles and clinically well-adapted to assess the needs of patients for psychotherapeutic applications of anger management. Normative data are published for adolescents, adults, and psychiatric patients, and evidence for high reliability and validity are detailed in the testing manual.

The Targets and Reasons for Anger in Pain Sufferers (TRAPS)

Although the STAXI-2 is applied to the study of pain more frequently than other inventories of anger, it was not designed for use with chronic pain patients and does not assess specifically pain-related dimensions of anger. Fernandez developed a structured inventory, the TRAPS, later adapted for self-administration by Okifuji et al., that allows chronic pain patients to rate their

levels of anger on a Likert-type scale toward 10 common objects or targets of their anger: whole world, self, God/destiny, significant other, employer, insurance company, attorney or legal system, health care providers, person who caused the accident.[35,85] Patients may also be instructed to identify and rank their reasons for being angry toward these targets. The results, especially when the TRAPS is administered in a structured interview, allow clinicians and patients to explore together the relative importance of specific targets of and reasons for anger, suggesting interventions and strategies for reducing the impact of anger on pain. Normative data and information on reliability and validity are not yet available.

Multidimensional Anger Inventory (MAI)

Siegel developed the MAI as a brief instrument designed to assess responses to anger-eliciting situations in an attempt to increase sensitivity to the multidimensional nature of the construct.[35,86] Factor analytic solutions arrived at the following dimensions or factors: anger-arousal, hostile outlook, range of anger-eliciting situations, and anger expression, the last being divided into anger-in and anger-out. Although it was developed specifically to assess anger in cardiovascular patients, factor analytic replications in more heterogeneous populations suggest its utility on a broader scope, especially with other health-related groups. Reliability and scale validity information are available through the author's report.[86]

Novaco Anger Scale and Provocation Inventory (NAS-PI)

This inventory, developed by Novaco, consists of two principal sections: The Novaco Anger Scale (NAS) purports to measure the general inclination toward reacting with anger, whereas the Provocation Inventory (PI) asks patients to respond to descriptions of specific situations that tend to elicit anger.[87] The NAS contains 60 items divided equally over three subscales: (1) a cognitive subscale, measuring anger justification, rumination, hostile attitude, and suspicion; (2) an arousal subscale, measuring anger intensity, duration, somatic tension, and irritability; and (3) a behavior subscale, measuring impulsive reaction, verbal aggression, physical confrontation, and direct expression. The PI contains 25 items, each describing a situation that tends to elicit anger, with subjects being instructed to rate their degree of anger or annoyance on a 5-point Likert-type scale. The situations include scenarios such as "getting your car stuck in the mud or sand" and "being joked about or teased." The items are grouped into five subscales summarizing the theme of the provocation: disrespectful treatment, unfairness, frustration, annoying traits of others, and irritations. The NAS-PI attempts to characterize how an individual experiences anger and what sorts of situations provoke it. The instrument has been widely used to evaluate the role of anger in diverse environments, from community-based to correctional settings, and may prove useful in evaluating the role of anger in healthcare settings. Normative data, reliability, and validity are well-documented in the testing manual.[87]

Anger Disorders Scale (ADS)

The ADS is a self-report instrument consisting of 70 items distributed over five categories characterizing human emotion: provocations, cognitions, arousal, motives, and behaviors.[88] A short-form consisting of only 18 items may be used as a screening tool to obtain scores on three factors: reactivity/expression, anger-in, and vengeance.[89] The ADS is designed to assess and identify dimensions of anger that are associated with dysfunction and impairment in clinical populations. It yields information concerning the duration that an individual stays angry, the breadth of stimuli that may serve as triggers for an individual's anger, and the frequency of angry episodes. Information on reliability and concurrent and discriminative validity are available in the testing manual.

Minnesota Multiphasic Personality Inventory-2 (MMPI-2)

The MMPI-2 is a 576-item, true–false, self-report instrument designed to assess a broad range of psychopathology and personality traits and characteristics.[16,17] It is arguably the best known and most widely used psychometric assessment tool available, and it has been applied to the investigation of pain in hundreds of empirical studies.[15] Several MMPI-2 scales are relevant to the study of anger and its relationship to pain, including the Psychopathic Deviate (Pd) clinical scale, as well as the supplementary scales of Hostility (Ho) and Overcontrolled-Hostility (O-H) and the content scales of Anger (ANG), Cynicism (CYN), and Aggression (AGG). All of these scales are well-validated and are designed to reflect some aspect of trait anger, and some, like the O-H and Ho scales, have been distributed separately for convenience and shortened time of administration.

PSYCHOTHERAPEUTIC MANAGEMENT

When anger and problems with the management of anger are aspects of a patient's presentation with chronic pain, ignoring the indication for psychotherapeutic intervention may well jeopardize any chance of successfully treating or managing his or her pain.[90] As we have seen, trait anger and certain styles of anger management are fertile ground for the development of chronic pain, but anger may emerge as a critical factor in response to chronic pain, as well. The following case of a middle-aged patient with chronic headaches will serve to illustrate the mutually influential roles of anger and pain in the context of treatment:

> Case 2: Mr. Alvarez was a 45-year-old single man, referred to the Pain Center by his new primary care physician and his new neurologist for the treatment of longstanding chronic daily headaches with tension-type and migrainous features. He arrived for his initial evaluation more than an hour late but loudly insisted upon being seen, saying that the traffic was not his fault and that he had a severe headache requiring immediate attention. He was irritable in his exchanges with support staff and paced back and forth in the waiting area, to the discomfiture and consternation of other patients. When he was finally escorted to an examination room, he informed the nurse that he hoped he did not have to wait long to see the physician. Once his pain physician joined him for the evaluation, he seemed deferential and cooperative, as he related his medical history and the history of his headaches. His physician noted, however, that he expressed considerable anger toward previous providers, toward his wife and children, and toward his employer, none of whom, according to the patient, responded with adequate sympathy to his distress or provided any respite from his pain. As his physician rose to conclude the interview, the patient looked at the prescriptions he had been given as a first line of intervention and, tossing them onto the desk, said, "I didn't come here for more pills. I told you, I came for Botox injections, and I'm not leaving here without them." When it was explained that authorization from his insurance carrier had to be obtained and that he might well respond favorably to a less invasive procedure, the patient's anger became increasingly confrontational. When it became clear that he was not going to get what he wished, he vociferously decried "the incompetence of doctors" and stormed from the examining room, upsetting a chair and waste bin in the process.

In the succeeding days, as the patient's stricken pain physician consulted with Mr. Alvarez's referring providers and assembled

his medical records, several points became clear. This was not the patient's only reported angry exchange in healthcare settings and, indeed, it appeared that Mr. Alvarez frequently changed primary care physicians and specialists, whether by his own decision or mutual agreement.

It was a surprise when Mr. Alvarez made and kept a follow-up appointment, but less surprising when the outcome was much the same, with the patient discharging his anger and frustration toward staff and his pain physician. It was at the conclusion of his second appointment that he was referred to the pain psychologist to do biofeedback and learn relaxation techniques. This puzzled but did not threaten him, because the physiological benefit of treatment was emphasized, and he was affable enough during the initial visit and anamnesis, which revealed much about the relationship between his anger and his pain. He exhibited many of the behavioral mechanisms, previously mentioned, through which anger can exercise influence over pain.[32] His anger toward his employer led to frequent arguments and resulting exacerbations of his headaches, in turn resulting in high absenteeism, which led to further conflicts at work. His anger toward his wife frequently led to retaliation in various forms on her part, which, again, resulted in exacerbations of his pain and the development of pain behaviors designed both to justify his disability and to elicit sympathy. Finally, his anger in the medical setting led to inconsistent and poorly planned care that, in turn, thwarted his attempts to gain relief, allowing his headache and associated behavioral patterns to become firmly entrenched.

It was nevertheless an unexpected development to Mr. Alvarez when the pain psychologist suggested that his anger may be exerting a dramatic impact on his headaches. The patient characterized himself as "quick to anger but quick to get over it" and cited trends within his family of origin, especially his own parents, to be dramatically expressive of anger. He added with irony, "I thought that's what you psychologists were always saying—'to get it off my chest and not hold it in.'" He portrayed himself honestly and clearly as a high anger-out individual, a style of anger management shown repeatedly to be associated with increased responsiveness to pain and higher levels of pain intensity and disability.[32,77,78] In addition to doing biofeedback training and learning relaxation techniques, the goal of psychotherapy in this second case was to encourage the patient to adopt and practice more adaptive strategies for anger management. Neither Mr. Alvarez's anger-out style nor Ms. Ostrakova's anger-in style, depicted in the first case, was conducive to the successful management of their chronic pain.

Considerations in the Selection of Psychotherapy

Where the special practice of pain psychology is concerned, supportive and psychoanalytically-informed psychotherapies have been viewed as useful in the management of pain, primarily when behavioral and cognitive-behavioral treatments have failed to bring relief.[91,92] The psychodynamic approach may be a logical starting point, however, for patients whose anger, pain, and disability are sustained by intrapsychic conflicts or unconscious motives associated with childhood trauma or primary or secondary gain.[90,93] The drawbacks associated with pursuing such a course of treatment can be manifold, but there may be times when patients are unable to move forward until they are satisfied that their conflicts and motives are revealed and understood. A problem for the successful management of pain, however, is that psychotherapies focusing on the primacy of the experience of emotion are typically long-term and may require many months, if not years, to result in meaningful insight and progress. Such treatments, at least near their outset, can also lead patients to an uncritical acceptance of their feelings, further validating the experience of negative emotions such as anger; therefore, the selection of appropriate psychotherapy and the skill of the psychotherapist are perhaps most critical in cases where a psychodynamic or supportive approach is indicated.

If the principal obstacles to successful adjustment to chronic pain are factors such as anger management style and negative cognitions underlying anger and hostility, then a more direct approach to treatment would be to challenge the behaviors reflecting and maintaining anger, as well as the negative cognitions driving it. Challenging established behaviors with new, more adaptive ones is the goal of behavioral therapy, whereas identifying, examining, and restructuring the negative cognitions behind negative emotions is the work of cognitive therapy. Both are well established as offering greater efficacy in the implementation of change and the modulation of the effects of anger upon chronic pain, but both depend upon the patient's willingness to collaborate with treatment and his or her readiness for and motivation to change.[90,94]

The influence of any psychosocial risk factor, such as trait anger and hostility, may signal reluctance on the part of the patient to give up his or her pain and suffering or relinquish the refuge of disability.[90] In the first case study, Ms. Ostrakova complained of pain, but her symptoms were driven by powerful and enduring unconscious conflicts associated with her history of childhood trauma and abuse. The high correlations between histories of abuse and the subsequent development of difficulties with both anger and chronic pain are well documented in the psychoanalytic and scientific literatures.[11,27,95–99] For patients who have suffered abuse as children or who have been exposed as adults to situations involving catastrophic loss or harm, chronic pain may come to represent a means of psychologically symbolizing and organizing unbearable memories and intolerable affects.[90] In Ms. Ostrakova's case, coming to an understanding of the relationship between her history and the development of her symptoms may well represent an essential step toward taking an active role in her treatment, and the selection of treatment to facilitate this step is likely to involve a form of supportive and psychodynamic psychotherapy. Ironically, a year of inpatient treatment with behavioral and cognitive-behavioral interventions appears only to have altered the patient's style of anger management from anger-out to anger-in.

Investigators have found that patients vary widely regarding how prepared they are to collaborate in their own treatment and make the changes necessary to manage their anger and their pain more effectively. Assessing a patient's *readiness for change* is frequently a critical prelude to effective psychotherapeutic intervention and may shed insight into why some patients never seem to improve. Cognitive therapy often begins with the patient's response to two questions: What do you want (to change)? What are you willing to do to get it?[90,99] The first question is easy for most patients with chronic pain, but the second implies work and sacrifice and is not so easy when patients are prone to anger and preoccupied with their own suffering and deprivation. Assessing a patient's readiness for change is one way of answering the second question.

Kerns et al. applied Prochaska's transtheoretical model of the stages of change to the situation of chronic pain and arrived at four successive levels in patients' willingness to collaborate with treatment and undertake the behavioral changes necessary to manage their pain more effectively[100,101,102]:

- *Precontemplation*: patients who have no intention of changing their current patterns of behavior—"You're the doctor. Fix my pain!"
- *Contemplation*: patients who have begun to recognize the necessity of making changes in their behavior but have not yet committed to doing so—"I know it's up to me. I just don't know how to do it."

- *Action*: patients who have committed to a plan of action and are engaged in making changes—"I'm doing something about my pain."
- *Maintenance*: patients who are attempting to sustain the changes they have undertaken—"I'm using what I've learned in treatment to manage my pain better."

Angry and hostile patients, in particular, may be stuck in the precontemplative stage of readiness for change, and their often unrealistic expectations of their physicians may lead them to feel that effective treatment is being withheld. This was the case with Mr. Alvarez, whose anger was driven by his disappointment in providers who never seemed willing to do enough to help him manage his pain. Unlike Ms. Ostrakova, however, his style of managing anger did not reflect defensive inhibition of affect, and his chronic pain was not associated with unconscious conflicts. His anger, although more volatile, also proved more tractable to the psychoeducational component of cognitive therapy, and he was ultimately able to make the transition more easily from the precontemplative to the contemplative stage of readiness for change.

Behavioral and Cognitive-Behavioral Therapies

Templates for behavioral and cognitive-behavioral intervention in cases of chronic pain are offered in succeeding chapters. Here, their specific relevance to the treatment of anger will be explored. Behavioral approaches to the treatment of anger have tended to revolve around relaxation training and applications of relaxation techniques to reducing autonomic arousal and uncomfortable musculoskeletal tension. Suinn's template for anxiety/anger management training (AMT) represents one of the more enduring expressions of this form of treatment.[103,104] He proposes a brief, structured therapy involving six to eight sessions in which guided imagery directed toward arousing anger is subsequently and serially paired with relaxation techniques designed to deactivate arousal. Patients are first instructed in the elicitation of the body's natural relaxation response—which can be accomplished using meditation, progressive muscle relaxation, body scans or other forms of autogenic training, or diaphragmatic breathing techniques—and, once they have mastered this, the psychotherapist offers structured practice in the use of the technique to contain or defuse sympathetic nervous system reactivity cued by suggestions and visualizations of stressful images. The use of biofeedback technology in the assessment of progress can frequently hasten mastery of this strategy by presenting the patient with tangible evidence of progress.

Recall that in Lazarus's cognitive appraisal theory of emotion, the experience of anger is the joint effect of (1) the event of physiological arousal and (2) the cognitive appraisal of its meaning.[64] While much of behavioral therapy directed toward the management of anger is concerned with the former, cognitive therapy is directed toward the latter. As we have seen, anger, by Smedslund's definition, involves the appraisal by the subject that he or she—or a person for whom he or she cares—has been treated without respect.[63] This, of course, may actually be the case in a given situation, and therein lies the foundation of the biological basis for anger[43,44,73]; but anger, as our Greco-Roman and Judeo-Christian roots attest, does not necessarily conform to logic. The experience of anger can quickly and easily become associated with irrational, automatic thoughts and beliefs concerning the motives of others and the sources of threat to our well-being.

The approach of cognitive therapy is to offer a corrective process to the development and maintenance of errors in our thinking and beliefs.[35,90,105,106,107,108] Through the process of cognitive restructuring or reappraisal, patients are led to examine whether, in the process of trying to make sense of their anger and pain, they may be making fundamental errors in their thinking and relying upon mistaken beliefs. Patients are encouraged to challenge their automatic thoughts and uncritically held beliefs regarding their experiences of anger through the template of cognitive appraisal theory—that is, that situations are ordinarily neutral until we assign meaning to them. We are often unaware of this step of assigning meaning because we do not usually stop to examine the thoughts and beliefs that influence our emotional responses to certain situations and, even when we do, we may not consider the accuracy of these thoughts and beliefs. The essence of the cognitive model of treatment suggests that much of our emotional distress and self-defeating behavior is based simply upon inaccurate and irrational thinking and that, once our attention is drawn to these upsetting cognitions, we can test their veracity and value to see whether they form an appropriate basis for our emotions and behavior.

As they learn to identify negative cognitions, patients begin to monitor their cognitive appraisals more rigorously and critically, cognitively restructuring their primary and secondary appraisals of situations resulting in anger. Common reappraisals of the experience of anger might include reexamining the intention of the one toward whom our anger is directed, reconsidering the harm done by the perceived slight or insult, or reinterpreting the outcome of a situation to determine whether a perceived breach of respect actually resulted in harm or injury.[35] In the case of Mr. Alvarez, several negative cognitions were identified as being based on dysfunctional family-of-origin models and overrehearsed expression. His primary negative cognition—"Everyone is out to take advantage of me"—may have reflected some degree of utility in the gang-controlled streets of his childhood barrio, but was dysfunctional and even harmful in the medical setting, where his physicians and other providers were genuinely concerned to help him. Their response to his anger was to defend themselves by disengaging and retreating, often to the detriment of his care. A corollary negative cognition—"No one will help you voluntarily; you have to demand what you need from people"—was equally destructive of the medical alliance. Through cognitive reappraisal and the opportunity to test different interpretations, the patient ultimately proved to himself that people, especially people whose job is to take care of him, really are often willing to help and that consistently making demands of others tends to result in less return than welcoming their responses to reasonable requests. Mr. Alvarez's anger-out style, once a barrier to his receiving the best from his medical care, receded and was replaced by a more genuinely collaborative attitude toward his physicians.

SUMMARY

The cultural background of anger lays the groundwork for understanding its role both as an emotion and as a trait, as well as its relationship to pain. Psychoanalytic theory emphasized the harmful effects of inhibiting the experience and expression of anger, placing it at the core of conflicts between competing drives and the formation of pathological symptoms. More recent research has brought additional clarity to the relationship between anger and pain, suggesting a number of possible mechanisms through which state and trait anger can influence sensitivity to pain and the development and maintenance of chronic pain. This trend, in turn, has led to improved objective psychological measures of anger and the observation that style of anger management may be a principal modulating factor in the relationship between anger and pain. Anger management style has become a critical consideration in the development of effective psychotherapeutic treatments for anger-related psychopathology, with behavioral and cognitive therapies for anger often resulting in improved management of chronic pain.

CHAPTER 82 ■ COGNITIVE BEHAVIORAL THERAPY FOR CHRONIC PAIN

LUIS F. BUENAVER, CLAUDIA M. CAMPBELL, AND JENNIFER A. HAYTHORNTHWAITE

INTRODUCTION

The early foundations of modern cognitive–behavioral therapy for chronic pain derive from a rich history of scientific work in the behavioral and social sciences. In the 1960s and 1970s, Fordyce, working in a rehabilitation setting, applied established behavioral principles to the study of pain and pain-related behavior and demonstrated that patients' reports of pain and their daily activities could be changed using social consequences (the reader is referred to[1,2] for an excellent example of the application of behavioral principles for the management of pain). About the same time, the field of behavioral medicine formed and promoted a multifactorial conceptualization of physical health and illness in which psychological and behavioral factors reciprocally interact with biological factors. This approach was particularly suited to the study of pain, as cognitive and emotional processes had long been established as influencing pain (e.g., Beecher's work with soldiers returning from war[3] and Melzack and Wall's Gate Control Theory of Pain[4]). Albert Ellis'[5] work on irrational thoughts and Aaron Beck's[6–7] work on cognitive factors influencing depression had already gained prominence by the 1970s, and Turk et al.'s[8] influential book expanded these perspectives to include social learning principles and pain-specific cognitive pro-

cesses, synthesizing a cognitive–behavioral perspective on pain. These key developments and the concurrent explosion of research in the behavioral sciences changed treatment approaches for chronic pain, which had previously employed a largely biomedical approach, focusing on specific anatomy, physiology, and neurochemistry in order to modify nociceptive input.

Often, persistently painful clinical conditions require multidimensional treatment that targets pain reduction and a return to daily functioning. Cognitive–behavioral treatments (CBT) began receiving empirical support in the early 1980s,[8–10] and have become the most frequently used behavioral medicine approach for pain management, focusing on pain-related cognitions and behaviors. CBT for pain management is based on empirical work indicating that a person's beliefs about pain are associated with various functional outcomes[11–13] and that changes in patients' beliefs about pain are related to changes in functioning.[14,15] A substantial body of literature strongly supports the assertion that multifaceted pain treatment approaches incorporating cognitive-behavioral interventions are beneficial,[16,17] although not for every patient.[18] Specific underlying assumptions characterize CBT interventions for chronic pain.[19] People are viewed as actively (versus passively) engaged with their environment, processing both external and internal stimuli. Cognitive schemas are mental frameworks that represent an individual's understanding of the world. They develop from social and cultural experiences and are shaped by learning. Cognitive schemas are used to process external and internal stimuli from people's environments and guide behavior; therefore, these schemas become important targets for CBT. CBT for chronic pain also assumes that cognitions influence affective and physiological arousal, and these associations are viewed as reciprocal with affect, physiology, and behavior similarly influencing cognitions. The patient's active engagement with the environment includes changing his or her own behavior, manipulating the environment, and attempting to change others' behavior. Fundamental to this perspective is the tenet that people with pain are not helpless; they can and should replace maladaptive cognitions and behaviors (that precipitate, maintain, and exacerbate pain) to more adaptive ones. The concept of replacement is integral to a behavioral approach, in which consequences control behavior; in order for the behavior (or cognition) to change with any durability, it should be replaced with an alternative that is reinforced.

Cognitive, affective, and behavioral responses to pain are significant features of the pain experience because they influence long-term pain-related outcomes and therefore serve as key targets for psychosocial interventions directed at improving pain-related quality of life.[13,20,21] Thus, CBT for pain management involves the integration of cognitive, affective, and behavioral factors into the case conceptualization and treatment of patients. Psychological variables such as catastrophizing, negative thinking, maladaptive coping, pain behaviors (e.g., learned responses), and mood are of particular interest. Within the cognitive–behavioral framework of pain, patient perceptions and expectations of their circumstances significantly contribute to pain-related outcomes (e.g., health status, disability). Therefore, learning new cognitive and behavioral responses to pain and the factors that shape the pain experience (e.g., stress, social interactions) can enhance patient perceptions of control over pain, improve mood via changes in negative thinking, and replace maladaptive behaviors with adaptive ones, thereby decreasing pain and pain-related disability.

Cognitive–behavioral techniques have been applied and tested with a broad range of chronic pain conditions. Similar to pharmacological management of pain, the actual nature of the therapy is individually determined based on the clinical presentation. For example, some patients present with high levels of catastrophizing and an array of maladaptive beliefs about their pain and current life circumstances. For this patient, CBT may emphasize cognitive therapy more so than behavioral therapy. For another patient, inactivity and deconditioning may be primary, so goal setting and behavioral activation may receive more emphasis. The actual CBT intervention is specifically tailored to the patient's needs identified during a careful assessment of the presenting problem and clinical picture.

Some people are not good candidates for CBT, particularly because a significant level of motivation and commitment is required of patients.[22] For this reason, patients who are not interested in CBT are less likely to benefit since CBT requires the person to practice skills outside of therapy and attend treatment consistently. Sometimes these patients become more engaged after exposure to relaxation (see below) or use of biofeedback, but motivation (see discussion of readiness to change) and openness to considering the treatment are crucial. Patients who expect a "quick fix" or conceptualize their condition as purely "organic" and unaffected by psychosocial factors are unlikely candidates for CBT. Comorbid conditions, such as a personality disorder or substance abuse/dependence or a serious mental illness, may necessitate alternate mental health care and stabilization prior to initiating CBT for pain. Finally, the patient's social environment must be considered and incorporated into treatment whenever possible. The family, disability system, and other social forces can strongly influence the patient's ability to make behavioral, cognitive, and emotional changes. If not properly supportive of treatment goals, the social environment can undermine treatment efforts.

The typical modes of treatment delivery for CBT have historically been individual therapy or group treatment. Individual sessions are composed of one-on-one meetings in private and confidential settings where treatment is tailored to the patient. CBT approaches typically are structured according to individual need and are relatively short-term. Given the considerable practitioner time and often prohibitive cost associated with individual treatment, group therapy (see Chapter 86) has become an increasingly viable option.

The qualifications and training of the therapist providing cognitive-behavioral interventions for pain have not been studied or standardized to meet the standards used for the treatment of anxiety or depression.[23] In addition to basic skills in psychotherapy, the personal attributes of the competent clinician include placing a high priority on helping patients reduce symptoms quickly and valuing a collaborative working relationship in which both the practitioner and the patient collaborate in guiding the change process. A substantial period of theoretical training and supervised clinical experience is required for effective application of skills. Some essentials for the CBT practitioner include making case formulations/conceptualizations based on presenting problems and the factors that maintain them; developing a strong, active, collaborative therapeutic alliance; planning treatment sessions according to the conceptualization, continually monitoring progress and altering the course if appropriate; working toward patient goals; guiding the patient in identifying and modifying maladaptive cognitions; facilitating behavior change; working on treatment adherence; and strategizing with the patient for relapse prevention.

Unfortunately, few clinical trials of CBT in the pain literature adequately describe the expertise of CBT interventionists or document that they meet a minimal standard of expertise in administering these specialized interventions.[17,24] In many trials and most clinical settings, these interventionists are generally doctorate-level clinical psychologists with additional postdoctoral training in pain management. According to the American Psychological Association (APA), the doctoral degree in psychology with at least 1 year of supervised postgraduate work and completion of a state licensure exam is considered entry level for an independent professional and additional specialty certification in CBT is available to licensed psychologists through the American Board of Professional Psychology (ABPP). However, other countries (e.g., Australia) have outlined competencies for the non–doctoral-level

CBT practitioner in a number of disciplines including nursing and social work. While few CBT practitioners have additional specialized training in working with pain patients, a notoriously difficult population, training opportunities with experts in the field exist. For example, the International Association for the Study of Pain lists specific educational opportunities on their Web site.

TYPES OF CBT AND SPECIFIC TECHNIQUES

In this section we discuss traditional types of CBT, including coping skills training, cognitive restructuring, and some innovative modalities for treatment delivery (e.g., telephone and Web-based treatments). For a discussion of the application of contextual cognitive behavior therapy and exposure-based therapies, the reader is referred to Chapter 83. Although CBT therapist techniques and delivery systems vary by provider and/or program, the approaches are similar because they include some common ingredients: educational content; setting personalized treatment goals and identifying targets for intervention; refinement of existing pain coping skills and development of new skills; behavioral skill rehearsal during and between sessions; use of goal setting and homework; identifying and changing maladaptive beliefs and thoughts; and involvement of family or other sources of social support. Treatment sessions are structured (e.g., sessions often follow the same sequence: review of homework, new topic introduction and skill rehearsal, goal setting, and new homework assignment) yet personalized and substantial time in early sessions is devoted to education, as well as setting expectations for active participation on the part of the patient both during and between sessions.

Coping Skills Training

The objective of coping skills training is to shape the patient's conceptualization of chronic pain as a chronic illness, similar to diabetes, which requires self-management on a daily basis. Through education and skill development, patients develop an effective arsenal of pain coping skills. These skills typically include relaxation, cognitive restructuring, distraction, problem solving, behavioral activation and pacing, goal setting, and stress management, briefly renewed here.

Education and Rationale

Providing patients with education and information about the nature and course of an illness, available treatment plans, and the process and outcomes of diagnostic and therapeutic procedures is an essential aspect of CBT treatment. One of the goals of providing patients with information is to enhance their cognitive control over an aversive event by promoting control-enhancing reappraisals of the particular situation.[25] Preparatory information provided to patients facing stressful and painful invasive medical procedures reduces negative affect and pain.[26] Thus, education and information can increase self-management and feelings of control over pain.[27]

An integral educational component in coping skills interventions involves teaching patients about the gate control theory of pain.[4,28] Many patients find it helpful to know that experts conceptualize pain as a multidimensional experience consisting of sensory, affective, and evaluative components, and not simply a sensory event that signals tissue damage. This lays the groundwork for discussing the processing of pain as a dynamic sequence in which the cognitive and affective centers of the brain influence the transmission of nociceptive signals by activating descending systems that block pain through a gating mechanism located in the spinal cord. When described in everyday language, the concept of a gating mechanism in the spinal cord that modulates the experience of pain can be appealing to many patients. Some useful real-life examples that can be incorporated into the discussion of the gate control model include the common example of athletes performing while injured, the experience of phantom pain following an amputation, or the often experienced exacerbation of pain perceived during/following stressful events.

Early in treatment for many patients, it is important to establish a plausible rationale for the use of psychological interventions (i.e., CBT) to manage chronic pain because many patients are skeptical and quick to reject psychological approaches to pain management. The gate control theory of pain can be quite helpful in explaining the idea that in addition to biological factors, psychological factors play a role in shaping their pain experience. If pain is acknowledged as a personal/subjective experience influenced by thoughts, behaviors, and feelings, then the therapist can help the patient identify factors that maintain, aggravate, or alleviate their pain.

Relaxation and Imagery Techniques

Relaxation training is often one of the first skills taught in CBT for pain. There are a number of different relaxation techniques available for use in pain management (see Chapter 85 for more detail), including progressive muscle relaxation, imagery, deep breathing, hypnosis, yoga, and meditation. The common dimension of these various techniques is a neurophysiologic response referred to as the ''relaxation response.''[29] This response involves a reduction in the tone of the sympathetic nervous system that produces muscle relaxation along with attenuated neuroendocrine response to adverse external conditions, culminating with a general sense of well-being and decreased anxiety. Progressive muscle relaxation,[30,31] which involves systematically and progressively contracting and relaxing various muscle groups, imagery,[8] and deep breathing,[8] are methods frequently used in the treatment of chronic pain.

Relaxation methods are designed to enhance patients' stress-management skills by giving them different strategies to regulate cognitive–affective processes and autonomic responses associated with persistent pain. However, in order to achieve maximum benefit, relaxation exercises require a commitment from the patient to set aside time to practice consistently and ultimately implement the techniques. Relaxation strategies, particularly imagery techniques, can also serve to redirect the patients' focus away from their pain and onto the relaxation task at hand. Patients who become proficient at effectively implementing relaxation strategies can increase their perception of control over their pain. Once the general principles and exercises have been explained to the patient, the procedures can also be tailored to reflect the components that are most effective and most relaxing for the patient.

Though relaxation exercises can be time consuming and require motivation on the part of the patient, research supports the efficacy of relaxation therapy in augmenting improvement and minimizing or preventing potential relapses associated with conventional therapy alone.[32] Though some reviews find a lack of evidence supporting the analgesic effectiveness of relaxation exercises in chronic pain,[33] other reviews find evidence supporting the benefits of relaxation,[34] particularly with children and adolescents.[35] In general, there is very good evidence supporting the efficacy of relaxation in reducing the frequency of and pain associated with chronic headache, with outcomes comparable to those obtained with pharmacological treatments.[36,37] Furthermore, moderate to large effect sizes have been demonstrated with relaxation in the treatment of chronic back pain.[34]

Goal Setting

Goal setting is typically initiated in the first therapy session and goals are individualized to the patient based on their baseline level of functioning. Often the first goal in CBT treatment pertains to the practice of relaxation because the first session typically includes both educational information about the gate control theory and then the rationale and demonstration of relaxation. In setting a goal, patients are guided in identifying realistic, attainable goals that are measurable. For example, an appropriate goal for the patient who has just been taught relaxation might be to practice for a set period (e.g., 15 minutes) once each day until the next treatment session. For the unusual patient who already meditates daily, the goal might focus on monitoring pain before, during, and after meditation. Or the goal might include practicing new relaxation strategies as an "experiment" to see if different types of relaxation have different effects on pain. As the patient becomes more accustomed to and adept in the behaviors that promote goal attainment and as their level of functioning improves, goals can gradually become more challenging. However, the difficulty level of a goal should not be increased until the patient has demonstrated an appropriate level of skill and/or proficiency in the attainment of previous goals regardless of their level of pain. The sense of accomplishment derived from achieving one's goals can be quite rewarding for many people, though the social reinforcement received from family members, friends, and health care providers can also be very helpful. Furthermore, engaging in similar goal setting activities with other patients that share the experience of chronic pain can be very effective in motivating patients and reinforcing their behavior. This may be one of the advantages of participating in a group multidisciplinary pain management intervention relative to individual treatment.

Pacing

Pacing refers to the method of finding a manageable and realistic or optimal pace when engaging in specific behaviors and/or activities in order to not exhaust or deplete one's self or precipitate or aggravate pain. Due to the nature of chronic pain, it is often difficult for patients to predict when pain will flare up or, conversely, when they will have a relatively pain-free day. As a result, many chronic pain sufferers exert themselves and are overly active on days when pain is low to manageable. This is in contrast to alternating periods of under-activity during periods of high intensity pain. Unfortunately, periods of over-activity can potentially precipitate and/or aggravate a pain episode. This is particularly the case in low back pain, osteoarthritis, and many cases of complex regional pain syndrome. The patient engages in an activity until the pain prevents them from continuing and they are consequently forced into a period of rest and potential analgesic use secondary to the pain. This frequently repeated pattern often results in feelings of frustration, distress, and demoralization. Not surprisingly, patients may become avoidant and engage in maladaptive forms of coping, which leads to further decreased activity and resulting physical deconditioning accompanied by a loss of flexibility and strength.[38] Often, periods of increased activity tend to become shorter while periods of inactivity become longer. Behavioral techniques that can help with these alternating cycles of over- and under-activity include goal setting and pacing.[39]

Through proper planning and prioritizing tasks by importance, patients will be able to find an optimal pace at which to engage in identified activities and maintain a consistent level of activity over time as compared to cycling between periods of over- and under-activity. Once patients identify a desired activity, they establish a baseline level or rate of that activity which they are able to maintain daily regardless of other circumstances. Once a baseline is established, a goal is set to slightly increase the activity and, initially, the difficulty level of the goal should be minimal so that it is attainable regardless of whether the patient is in pain or not. Thus, the increase in activity early in the process should be easily managed and is expected to have minimal impact on pain. During this process, it is important for the patient to maintain the activity despite the level of pain; this way, activities are not contingent upon the patient's level of pain and goals are set and achieved regardless of the patient's pain level. Proceeding in a stepwise and systematic fashion will increase the patient's activity level and improve their self confidence.

Distraction

Distraction procedures, one of the many cognitive coping skills often promoted and refined during CBT, focus attention away from pain, allowing for a filtering process where some information reaches conscious attention and other information (in this case, pain) is suppressed.[40] Techniques using mental imagery, counting or even virtual reality are often used to distract.[41,42] Attention diversion can produce analgesia in laboratory settings,[43] during medical procedures,[44] and in the context of ongoing chronic pain.[45] These procedures may increase pain tolerance and decrease perceived pain intensity, as pain ceases to be the focus of attention potentially due to competing demands on the attentional system and/or other physiological processes. While these adjunctive treatments have been shown to be effective, when the distraction stops, pain often returns as the central focus of awareness and may subsequently be accompanied by greater pain.[40,45]

Distraction techniques may work best when pain intensity is constant or increases slowly[46] and may be more difficult to apply when pain intensity is high and accompanied by high somatic awareness.[47] However, distraction may be an effective strategy when pain is less intense. Nurses often use distraction to help patients manage painful or distressing procedures. Distraction is a very promising analgesic for brief medical interventions such as wound debridement for burn patients,[48] dislocations from fractures,[49] and for venous cannulation pain, which is often necessary prior to more invasive procedures.[50] The widespread clinical utility of distraction is an inexpensive, simple to apply method for reducing acute pain during medical procedures that has no known side effects, and which can reduce distress and be of great benefit to chronic pain patients when practiced regularly.

Cognitive Restructuring

Cognitive restructuring illustrates the essence of cognitive therapy[6] in which patterns of dysfunctional or negative thinking that can precipitate feelings of emotional distress (e.g., anxiety, depression, anger), physiological arousal, and maladaptive behaviors are identified. Patients are taught to identify and subsequently replace distorted cognitions in order to change negative mood states, lower and regulate physiological arousal, and replace maladaptive behaviors with behaviors that are likely to be associated with or result in positive outcomes. Hence, adaptive coping is encouraged through realistic appraisal of events. The basic premise behind cognitive restructuring is that patients' emotions and behavior can be greatly influenced by their thoughts. If people can actively change their "self-talk" or what they say to themselves along with the mental images they bring to mind, then they can change the way they feel. An extensive literature indicates that the thoughts and interpretations that people have in response to pain significantly influence their experience of pain (e.g., see Chapters 7 and 21). When these thoughts are negative, they may exacerbate the overall experience of pain, thereby increasing pain-related suffering; conversely, balanced, rational,

and realistic thoughts can serve to attenuate the pain experience and improve both psychological and physical function.

Cognitive restructuring is a vital component of chronic pain treatment. The first step in identifying distorted thinking involves developing awareness of these thoughts. Teaching the concept of automatic thoughts, which are the words and images that "automatically" pop into our heads throughout the day or when we are engaged in particular activities, lays the foundation for increasing awareness of negative thinking. It is then often helpful to illustrate for patients how thoughts can impact mood and behavior. One method of accomplishing this entails introducing the ABCD model, based on the work of Ellis[51] and Beck,[6] in which patients are taught to identify a precipitating event (A) when they notice that they are experiencing a negative mood (C). It is often challenging for many patients to distinguish the difference between thoughts (B) and feelings (C). Once a patient has identified thoughts, treatment focuses on identifying distorted thoughts (B) and accompanying maladaptive assumptions and beliefs (B) evoked by the event. Next, after identifying the negative thoughts and erroneous assumptions, several techniques are used to restructure or replace the distorted or irrational thoughts with more realistic and balanced thoughts. A commonly used approach is reality checking or hypothesis testing in which patients are taught to regard a distorted thought as a hypothesis (versus reality) that needs to be tested empirically. Patients are taught to challenge faulty thinking by examining the evidence supporting or refuting the negative thought. Following this, balanced and realistic thoughts that do not ignore the negative aspects of the situation but rather also include other aspects (i.e., neutral, positive) of the situation are developed in order to produce more balanced thinking (D) to replace the distorted thinking. Typically, these concepts are introduced in a therapy session and the patient is given a negative thought log to take home and use to identify precipitating events, distorted thoughts, emotional/behavioral consequences, evidence for and against their negative thoughts, and the resulting balanced thoughts generated to replace the negative thinking. The goal of cognitive restructuring is to recognize and modify negative thoughts in order to regulate emotional distress, physiological arousal, and/or maladaptive behavior.

Homework Adherence

Participation in homework assignments is one of the guiding principles inherent to CBT and has been repeatedly shown to have significant clinical importance in a variety of conditions.[52] While few studies examining the role of CBT homework in chronic pain populations exist, the use of homework in biofeedback treatment showed a trend toward greater improvement.[53] Homework facilitates the learning of new adaptive behaviors that can be generalized to the patient's natural environment. The more the patient practices the skills taught in treatment, the more proficient he or she becomes in successfully implementing these behaviors, which results in greater derived benefits. Successful implementation of the new adaptive behaviors reinforces the continued use of these skills for pain management. Consequently, it is crucial to emphasize to patients that homework is integral to their treatment success, because it facilitates the generalization and maintenance of these skills to situations outside the clinic setting. Many chronic pain patients take a passive approach to managing their pain, especially patients who seek care in tertiary pain care settings. As a result, it is important that homework assignments initially be a collaborative experience to help patients work toward taking responsibility for their pain management. Providing a rationale for homework, assigning specific (versus general) tasks, having a homework difficulty level that is reasonable and appropriate to the client, and reviewing homework completion and progress can help enhance patient compliance and improve long-term outcomes.[54] The reader is referred to a helpful resource for the practitioner by Johnson and Kazantzis[54] that discusses obstacles to the use of homework in chronic pain populations and provides strategies to promote homework compliance and overcoming/problem solving obstacles.

Relapse Prevention, Developing a Maintenance Plan, and Managing Flare-Ups

As previously noted, any intervention involving a cognitive shift or behavior change requires substantial dedication and work on the part of the patient. Continued dedication to maintenance of behavior change can be quite difficult for a patient without the weekly guidance and support of the interventionist. However, an important aspect of CBT includes discussion of relapse prevention and plans for any difficulty in maintaining treatment gains. The goals of relapse prevention include working to anticipate potential triggers of pain exacerbation, mood deterioration, or loss of physical function, identifying obstacles to maintaining behavior change, and noting any high-risk situations which may prompt relapse, as well as developing a plan for unanticipated challenges. The basic relapse prevention model includes components of behavioral skills training, cognitive interventions, and lifestyle change.[55] Identification of challenging situations and events (flare-up, new pain episode, re-injury, stress, psychological strain, etc.) and problem solving approaches to help the patient get back on track is essential. Little empirical literature exists on the best way to approach relapse prevention in chronic pain patients,[56] though suggestions are offered and discussed in CBT manuals for pain (see Table 82.1). Patients are encouraged to set realistic expectations about treatment, realize that setbacks both during and after treatment are expected, and create opportunities to practice new skills. It is also useful to have the patient keep track of situations that have exacerbated pain in the past in order

to anticipate and effectively plan for those situations in the future. Brainstorming between the therapist and patient can facilitate better management and implementation of appropriate skills in future situations.

Although relapse rates following CBT for psychiatric conditions are quite low compared to pharmacological therapies,[57,130] the examination of maintenance programs and relapse rates has been relatively neglected in the literature on CBT for pain, an omission that was noted in the early 1990s[56] and has not been adequately addressed since. A very recent editorial[131] emphasized the dearth of information on this important topic, which has not received increased attention since the original calls for action. While treatment gains following CBT generally maintain over 6 and 12 months following the end of treatment[132] and even improve (although some decline), efficacy is also seen over long periods of follow-up.[133] In a recent and innovative posttreatment relapse study, Naylor and colleagues[121] developed and assessed the effects of a Therapeutic Interactive Voice Response (TIVR) system (an automated, telephone-based tool they created for maintenance enhancement) in chronic musculoskeletal pain patients. Following 11 weeks of group CBT, patients received either standard care or TIVR, which included components of daily self-monitoring, review of coping skills, behavioral rehearsal of coping skills, and personalized feedback messages based on the patient's daily reported pain. Compared to standard care following CBT, the TIVR group showed continued gains at 4 months and reported reduced typical pain level, catastrophizing, and increased physical functioning/activity.[121] This innovative approach to maintaining and even enhancing treatment gains shows tremendous promise for CBT interventions.

OUTCOMES AND PREDICTORS OF OUTCOMES

Outcomes

Hundreds of studies demonstrate the effectiveness of CBT[57] and several meta-analyses specifically support the efficacy of CBT for chronic pain. One of the earliest meta-analyses found that CBT interventions for chronic pain reduced pain intensity, improved coping and reduced behavioral expressions of pain, compared with other active treatments.[17] Other reviews summarize positive outcomes for specific pain conditions including arthritis,[58] migraine/chronic headache,[59] chronic musculoskeletal pain,[60] chronic cancer pain,[61] rheumatoid arthritis and osteoarthritis,[62] myofascial temporomandibular disorders,[63,64] chronic low back pain,[21] carpal tunnel syndrome pain,[65] and chronic pelvic pain.[66] CBT benefits patients with chronic fatigue syndrome, irritable bowel syndrome[67] and works in children.[68–70] The outcomes appear more variable in fibromyalgia.[71] In an interesting review, Bradley and colleagues[72] compared patients with a "well understood" chronic pain condition (RA, osteoarthritis) to those without a specific origin (fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome), finding that CBT produced positive outcomes for all patients except those with fibromyalgia.

In a recent meta-analysis, Hoffman and colleagues[21] concluded that CBT for chronic low back pain produces dramatic improvements in pain (see section I) with additional benefits in pain-related interference, health-related quality of life, and depression. In another meta-analysis, CBT in arthritis patients was compared to a number of other treatment approaches (e.g., biofeedback, stress management, emotional disclosure, hypnosis, psychodynamic therapy) for improving outcomes related to arthritis pain.[58] This examination included 18 studies of CBT in arthritis patients and found that CBT produced a significant decrease in pain; however, the strongest findings were for quality of life related variables such as self-efficacy, mood, and pain coping. Unfortunately, the lack of studies examining interventions other than CBT precluded these authors from making meaningful comparisons between the effectiveness of CBT to other treatments.[58]

New studies are now being published addressing the cortical changes that occur following cognitive–behavioral interventions. For example, imaging studies have revealed changes in specific brain areas following CBT for a variety of psychiatric disorders.[73] More relevantly, in a positron emission tomography (PET) study in irritable bowel syndrome patients, Lackner et al.[74] found changes in cortical–limbic region neural activity subserving hypervigilance and emotion regulation after a brief course of cognitive therapy. Several authors have noted that changes in brain activity following psychological interventions often parallel those of pharmacological studies.[73]

Predictors of Treatment Outcomes

Not all patients complete treatment,[75] and among those who do respond there are differences in the degree of benefit experienced.[18,76] Understanding the factors that predict positive (or negative) treatment outcomes is important for programs to help tailor approaches or match patients to the most appropriate treatment,[13,76] control costs by funding the treatments most likely to be effective, and improve mechanisms that contribute to treatment efficacy.[77] Most studies have not found an association between response to CBT and age, sex, race, education, and pain duration,[15,77] suggesting that all patients potentially may be helped by this therapy. Similarly, multidisciplinary treatment for chronic back pain reduces pain intensity and improves return to work regardless of medical background, medical diagnosis, and physical impairment.[33,78,79] However, specific outcomes vary widely across patients exposed to CBT, yielding effect sizes in the small to moderate range.[17,18] Patients who are emotionally distressed engage in a high degree of negative thinking about their pain, or lack faith in their ability to effectively manage their pain; they may experience less favorable outcomes. For example, depression has been associated with poorer treatment outcomes.[80–83] On the other hand, stronger belief in one's ability to control pain[15,84–86] and less catastrophizing or negative thinking in response to pain[15,87,88] are associated with favorable treatment outcomes. Research examining associations between physical/sexual abuse history and pain-related treatment outcomes has been inconsistent, demonstrating both poor outcomes[89] and outcomes comparable to patients with no prior abuse history.[90]

In an interesting review article focused on back pain, McCracken and Turk[77] concluded that low expectations for returning to work, greater somatic focus, or greater perceived pain and disability predicted poorer outcomes and in some cases poor program compliance or early discharge from programs. More controlling, less organized, less cohesive, and less supportive family circumstances also were associated with less treatment benefit.[77] Secondary gain or when treatment has financial implications for the patient is a complicated concept that remains important to consider,[91] but a simplistic approach is clearly not validated.[92] The Minnesota Multiphasic Personality Inventory (MMPI) has frequently been used to predict who will benefit most from treatment; however, these studies also have mixed and confounding conclusions.[93]

Readiness to Change

The Transtheoretical Model of Behavior Change integrates theoretical models to explain how people may be more or less successful in treatments focusing on behavior change. One of the key constructs in this model, stage of change, speaks to the "readiness" of a person to modify a certain problem behavior. Five stages include (1) precontemplation: the person has no intention

of making a behavioral change in the near future; (2) contemplation: the person thinks about the possibility of making a change, but has not yet fully committed to action; (3) preparation: the person is considering making a change soon (within a month); (4) action: the person is actively working on changing behavior and modifying their environment to help implement change; and (5) maintenance: the person is working to maintain changes and using relapse prevention. These stages are thought to be important in treatment settings, as practitioners may be more successful if they tailor their intervention to the prominent stage of a given patient (thus helping catalyze movement and aiding the patient in progressing from one stage to the next). This model has been applied to pain and particularly the patient's readiness to adopt self-management therapies.[94] The Pain Stages of Change Questionnaire (PSOCQ) was developed to assess readiness to change in pain patients, which assesses both stage of readiness and acceptance of being personally responsible for pain control.[94] The validity[94,95] and clinical utility of the PSOCQ have been demonstrated.[75,96,97] The PSOCQ has been shown to predict treatment dropout,[75,96] and positive increases in attitudes regarding self-management as well as predict subsequent improvements in outcomes.[97] The interested reader is referred to reviews of this literature.[98,99] Noting limitations to the PSOCQ, the Multidimensional Pain Readiness to Change Questionnaire (MPRCQ[100]), and a more recent revised version, the MPRCQ2,[101] was developed to examine readiness to change a wider range of behaviors in multidisciplinary chronic pain management settings. These questionnaires have also been adapted for specific pain conditions, including osteoarthritis[102] and fibromyalgia (in a Dutch population[103]).

The assessment of these stages in pain patients has paved the way for additional research on motivating patients to engage in treatment and improving outcomes by tailoring treatment to the patient's level of readiness. Motivating pain patients in the early stages of readiness (precontemplation, contemplation) can be quite challenging. Jensen and colleagues[22] set forth a motivational model for pain self-management and others have found that motivation and adherence mediate the relationship between readiness to change and goal attainment.[104] Motivational interventions are discussed in detail in Chapter 87.

ALTERNATIVE APPROACHES TO TRADITIONAL CBT

Self-Help

Recent developments in technology, as well as an interest in the broader dissemination of CBT treatments, have encouraged the use of alternative modes of delivering treatment. Self-help interventions organized via group formats, workbooks, books, audiotapes, minimal contact formats, and telephone- and Internet-based delivery systems have been found to reduce pain, pain-related disability, depression, and anxiety in arthritis, low back pain, headache, and temporomandibular joint disorder.[105] Much self-help is provided through groups, and the use of lay leaders to facilitate such support/educational groups has contributed to the widespread application of the *Arthritis Self Management Program* (ASMP) through the Arthritis Foundation.[106] This program provides the strongest outcome data on the benefits of skill development as compared to disease education in order to enhance self-management. Self-management incorporates techniques designed to increase patients' confidence and skills in daily management of their arthritis. The ASMP has been found to be cost efficient in reducing pain and improving patient functioning in such areas as exercise, anxiety, depression, decision-making, and problem-solving.[106] Some of the latest work by Lorig and her colleagues[107] extends the use of written self help materials to include a tailored, written intervention based on the ASMP. Following completion of a one-page assessment, rheumatoid arthritis and osteoarthritis patients receive a tailored summary report with recommendations for developing a personal plan, as well as a variety of supportive materials including *The Arthritis Helpbook* and relaxation tapes. Quarterly written contacts included personalized feedback, encouragement about changes made, and recommendations for further changes. Participants receiving this personalized intervention reported increased self-efficacy and reductions in physician visits as well as reductions in global disease severity ratings. Compared to the ASMP, these participants also reported significant reductions in disability and greater increases in self-efficacy.[107] Overall, such self-help programs appear to achieve reductions in pain and disability primarily through increases in self-efficacy, and these changes can maintain over long periods.

The benefits of self-help may vary according to the structure of the program or the pain condition. Four group sessions of self-management led by trained laypersons supplemented with an educational book and video helped patients with chronic low back pain reduce worry or concern about back pain, increase confidence in self-care, and lower disability scores up to 12 months posttreatment.[108] On the other hand, when support groups are not well attended or sessions are spread over fairly long periods, little differential benefit of lay- or professionally-led support groups over treatment as usual has been observed.[109] Self-help has less clear benefits for patients suffering from irritable bowel syndrome (IBS), where self help was no better than a waiting list control group in reducing gastrointestinal symptoms and distress and both had less impact than CBT.[110] Even without symptom reduction, however, there is some indication that a comprehensive self-help guidebook can reduce IBS patient costs by as much as 40%.[111]

Limitations to self-help techniques are, as of yet, largely unknown, but include the potential for greater rates of attrition. Studies assessing the efficacy of self-help techniques often use highly controlled research settings for investigating treatments, and are selective in obtaining participant groups; these factors may further limit the generalizability to patients who are more medically or psychologically/psychiatrically complicated.[105] However, it appears clear that self-help may be particularly useful for patients with limited resources, who travel a long distance for specialty care, or are resistant to seeking mental health care. Thus, the development of brief, self-help-oriented interventions have the potential to vastly increase the number of patients who can successfully access and benefit from psychological interventions. Self-help workbooks for chronic pain are currently available, although none has been empirically examined to our knowledge, although the workbook by Lorig and her colleagues listed in Table 82.1 is based on their extensive research using similar materials. For patients seeking self-help, the workbooks and/or books listed in Table 82.1 can be recommended.

Home-Based and Minimal Contact CBT Treatments

The headache literature has a long history of demonstrating the cost-efficiency of minimal contact CBT interventions for managing chronic tension and migraine headache. An early meta-analysis concluded that home-based behavioral treatment for headache sufferers yields equivalent or superior benefits when compared to clinic-based treatments.[112] In minimal-contact therapy (MCT), CBT and self-management skills are introduced in the clinic typically by a specially trained professional, and training and practice occur primarily at home using written materials and audiotapes. Meta-analyses of the self-help literature suggest that some degree of therapist contact may have incremental benefits,[113] and in MCT the therapist contact can be delivered by

diverse methods, including infrequent meetings, telephone calls, and/or mailings and use of electronic contacts such as electronic mail. Issues of confidentiality need to be discussed and ground rules established before using electronic communication strategies. MCT may be more affordable for many patients seeking care and have been shown to be more cost-effective in the treatment of headaches.[114] MCT gains can be equally well maintained as intensive individual protocols.[115]

MCT has been examined in greatest detail within the headache and facial pain literatures. A meta-analysis of headache clinical trials indicated that home-based behavioral treatment yields treatment effects that are equivalent or superior to clinic-based treatments.[112] As a viable, cost-effective alternative for many chronic headache sufferers, minimal contact interventions for headache average a five-fold increment in cost-effectiveness.[112] The use of MCT in dental/facial pain is limited to two studies, both of which provide encouraging results. Following two group sessions supplemented with written materials and individualized therapist feedback temporomandibular joint disorder (TMD) patients reported reduced pain and interference in daily activities as compared to usual care.[116] Using MCT to teach principles of habit reversal, a small group of 10 TMD patients reported reductions in pain, pain interference, and life stress that were maintained 8 months posttreatment.[117]

The extension of home-based interventions to Web-based designs raises the potential for improving pain and other outcomes while being cost/time effective and broadly dispersed. Increasingly, CBT interventions are enhanced through use of advanced communication technology in order to expand access and reduce costs. For example, telephone psychotherapy has been successfully used as a supplement to antidepressant treatment in primary care[118] and is being tested for the treatment of depression in patients with multiple sclerosis.[119] Automated telephone contact that includes personalized messages enhances outcomes following group CBT,[120] possibly due to encouraging consistent use of skills or enhancing self-monitoring.[121] Work on Internet-based cognitive behavioral self-help treatment for pain management is just developing and early studies show good outcomes despite high rates of attrition.[122] The addition of telephone support does not seem to enhance outcomes,[123] but may substantially reduce dropout.[124]

Spousal/Caregiver Involvement in Treatment

The involvement of family members in CBT can be critical in helping the patient with chronic pain make substantial and enduring changes. A recent meta-analysis documents the beneficial impact of family involvement in CBT treatments for chronic illness, concluding that the involvement of family members in psychosocial treatment increased treatment effects on depression and, in some cases, reduced mortality.[125] While little research has focused on spousal/caregiver involvement in CBT for pain, there are undoubtedly bidirectional interactions between intractable pain and the psychosocial environment/familial relationships. For example, a strong concordance between the patient's perceived pain level and the spouse's rating of that pain may lead to improved outcomes.[126] Keefe and colleagues have extensively studied patient and caregiver interactions as well as novel interventions involving a spouse or other caregiver in treatment.[13] Spouse-assisted coping skills training shows a trend to reduce pain, pain behaviors, and psychological disability when compared to individualized coping skills training,[127] and these gains are generally maintained at 6 and 12 months.[128] The addition of exercise to spouse-assisted coping skills training improves physical fitness, strength, pain coping, and self-efficacy.[129] Keefe and colleagues[129] interpret these caregiver-assisted interventions as shaping the social context that influences pain and further suggest that the most appropriate patients for these interventions may be those who prefer a "communal style of coping" with pain, whereas those with a poor relationship or communication skills may benefit less from these treatments.[13]

NEW DIRECTIONS AND CONCLUSIONS

Prevention and/or Early Intervention

A significant body of literature documents the efficacy of CBT in the treatment of a wide range of chronically painful conditions. CBT reduces pain and improves pain-related psychological and physical function both alone and as an adjunct to other treatments. While potentially any patient can benefit from CBT, effect sizes are moderate at best and many people do not show substantial improvement. Continued research needs to identify treatment nonresponders and how to best address their health care needs. Most often, CBT is a treatment that is offered late in the course of chronic pain, often after the patient has experienced multiple treatment failures and continues to experience substantial pain, pain-related disability, and distress. As our knowledge of risk factors increases, a logical direction for clinical care and research is to identify which patients may benefit most from early CBT interventions. By capturing people early in their transition from acute to chronic pain, it may be possible to reduce or even stop the development of a clinical pain condition in part through the use of prevention strategies. An excellent example of this potential is provided by a study of CBT for patients with rheumatoid arthritis for less than 2 years.[134] As compared to medical management, the CBT group showed immediate reductions in depressive symptoms that sustained for 18 months, when additional improvements in disability and anxiety were also observed. Thus, CBT effectively altered the 18-month course of early rheumatoid arthritis. Linton found that a CBT group intervention prevented long-term sick leave and reduced health care use in at-risk people with subacute or recurrent spine pain.[135] A similar study with neck and back pain community residents with little disability showed similar positive outcomes in the CBT group, particularly with long-term sick leave.[136] Of note, these studies by Linton and his colleagues recruited patients from the community and early in the pain trajectory. Since studies of irritable bowel,[137] fibromyalgia,[138] and headache[139] indicate substantial differences in personality, mood, and psychiatric comorbidity between patients and community residing nonpatients, the recruitment processes used in existing studies of CBT likely influenced the strength of findings (i.e., small to moderate effect sizes). Prevention holds the potential to reduce the skyrocketing costs of health care and the significant suffering and disability associated with chronic pain. The cognitive behavioral conceptualization of chronic pain suggests that capturing patients at the primary care level, when a patient enters the health care system, may provide the best opportunity to improve coping skills and correct misperceptions about pain that contribute to persistent pain and pain-related disability.

Tailoring Treatment

Tailored treatment or treatment matching involves determining *a priori* which patients are most likely to benefit from a particular treatment. Although the heterogeneity of patient groups likely accounts for at least some of the limitations of CBT,[76] few studies have systematically evaluated treatment tailoring or matching prospectively. One of the more promising approaches to treatment tailoring utilizes profiles derived from the Multidimensional Pain Inventory,[140,141] which has been shown to predict differential response to CBT in some studies.[76]

The challenges of providing these specialized services in the context of escalating medical costs suggest a need to develop a more sophisticated, stepped care approach to providing CBT interventions, especially if these interventions are to be made available early in the transition from acute to chronic pain. A stepped care approach has been proposed for the management of back pain,[142] which might have broad applicability to many types of pain. Level 1 care recommends self-help via groups, workbooks, or the Internet; Level 2 care provides minimal contact CBT with a trained specialist; and Level 3 care provides intensive individual or group CBT with a trained specialist. Steps 2 and 3 are generally beyond the scope of current medical practice, but could be integrated into physical therapy or case management interventions.[142]

CONCLUSIONS

Chronic pain results from a complex interaction of biological, psychological, and social variables, and responses to pain are shaped not only by the pathophysiology of the underlying disease, but also by their inherent cultural and psychosocial contexts. CBT is an effective treatment for many patients who experience chronic pain, producing reductions in pain and pain-related interference, improvements in mood and coping, and reductions in negative beliefs and cognitions such as catastrophizing. Since we know so little about the characteristics of nonresponders and continue to face challenges in the health care system around access to these specialized services, studies that identify patient characteristics that enable treatment matching or test a stepped care approach to treatment are warranted. Whether the development of the next generation of CBT interventions and established exposure-based treatments (see Chapter 83) are differentially effective for subtypes of patients will need to be determined, as will new avenues for treating CBT nonresponders.

CHAPTER 83 ■ PAIN AND ANXIETY AND DEPRESSION

LANCE M. MCCRACKEN

INTRODUCTION

Chronic pain upsets, frightens, discourages, and demoralizes those who experience it. Chronic pain imposes limits on daily functioning and creates conflicts between what the individual and society expect and what the individual finds him or herself able to do. It presents diagnostic ambiguities and apparent contradictions, such as the oft-quoted notion that "hurt does not equal harm." It is essentially impossible to fully predict or control in many circumstances. As chronic pain continues, these experiences can create an accumulating sense of uncertainty, threat, loss, and helplessness, and can lead to the experience of significant anxiety and depression, among other emotions.

The purpose of this chapter is to describe and examine anxiety and depression in the context of chronic pain. It will briefly review the extent of these emotional experiences, the impacts they impose on patients, and processes by which they interact with other experiences of chronic pain to adversely influence patient behavior and overall functioning. It will also detail the nature of cognitive behavioral treatment approaches to anxiety and depression and describe new developments that may improve management of these conditions for chronic pain sufferers in the future.

PREVALENCE OF ANXIETY AND DEPRESSIVE DISORDERS IN CHRONIC PAIN

Identified rates of significant anxiety and depressive disorders in chronic pain sufferers depend entirely on the particular population under study, the methods used to collect the data, and the criteria used for defining cases (Table 83.1). Nonetheless, anxiety and depression appear significantly more among persons with chronic pain than those without. A recent national survey in the United States (N = 5877) found that among chronic pain sufferers, 35.1% experienced anxiety disorders and 20.2% experienced

TABLE 83.1

SELECTED PREVALENCE FIGURES FOR ANXIETY AND DEPRESSIVE DISORDER IN COMMUNITY AND CLINICAL SAMPLES WITH AND WITHOUT CHRONIC PAIN

Study	Sample	Diagnostic method	Prevalence anxiety	Prevalence depression
McWilliams et al.[1]	U.S. general population sample with chronic arthritis, bone, joint pain N = 5877	Composite International Diagnostic Interview—Short Form for Major Depression (CIDI)	35.1%	20.2%
Currie and Wang[6]	Canadian household survey N = 118,533 total (N = 10,600 with chronic pain)	CIDI		5.9% for those without pain 19.8% for those with pain
Von Korff et al.[2]	U.S. general population sample with chronic spinal pain N = 5692	CIDI	26.5%	17.5%
Kroenke et al.[17]	U.S. primary care clinic sample N = 965	Structured Clinical Interview for *The Diagnostic and Statistical Manual of Mental Disorders*, 4th edition	19.5% at least one anxiety disorder 8.6% Posttraumatic Stress 7.6% Generalized Anxiety 6.8% Panic 6.2% Social Anxiety	
Moussavi et al.[14]	Nationally representative samples from 60 countries N = 245,404 (4.5% diagnosed with angina, 4.1% with arthritis)	CIDI		3.2% overall 15.0% of those with angina 10.7% of those with arthritis 23.0% of those with two or more chronic medical conditions

depressive disorders in the past year.[1] In this study, chronic pain was defined as "severe arthritis, rheumatism, or another bone or joint disease."[1] A more recent study found similar rates of anxiety and depressive disorders in persons with "chronic spinal pain" at 26.5% and 17.5%, respectively.[2] They defined chronic pain as "chronic back or neck problems" in the prior 12 months. Both of these studies were based on data from a general population survey, the National Comorbidity Study,[3] and employed a standard diagnostic interview, the Composite International Diagnostic Interview (CIDI) from the World Health Organization (WHO).[4] For comparison purposes, the results from a nationally representative household survey in the United States (N = 9282), relying on precisely the same methods as those producing the data above, demonstrated 12-month prevalence estimates of 18.1% for anxiety disorders and 9.5% for mood disorders, regardless of the presence of pain.[5] Hence, from these data collected in the United States, rates of anxiety and depressive disorders in those with chronic pain in the community are roughly 1.5 to 2.0 times as great as those in the community in general.

Results from a large household survey in Canada show that depression is more than three times more prevalent in individuals with chronic pain compared to those without.[6]

A recent survey of community-dwelling adults carried out in 17 countries in Europe, America, the Middle East, Africa, Asia, and the South Pacific (N = 85,088), found that "mental disorders" are more common among persons with chronic back or neck pain than in those without. The pooled odds ratios were 2.3 (95% CI = 2.1, 2.5) for major depression, 2.8 (95% CI = 2.5, 3.2) for dysthymia, 2.7 (95% CI = 2.4, 3.1) for generalized anxiety disorder, 2.1 (95% CI = 1.9, 2.4) for agoraphobia or panic, 1.9 (95% CI = 1.7, 2.2) for social phobia, and 2.6 (95% CI = 2.3, 3.0) for posttraumatic stress disorder.[7] Other results from the same data showed that rates of depression and anxiety increase substantially as the extent of pain increases, nearly doubling in persons with pain in multiple areas of the body.[8]

Perhaps not surprisingly, data from chronic pain sufferers who present in clinic populations show generally higher rates of depression and anxiety disorders compared with those with chronic pain in the general population. Overall, current prevalence estimates in clinical samples range from 7.0% to 62.5% for anxiety disorders,[9,10] and from 30.0% to 54.0% for major depression.[10,11] In particular, the rate of current depression among individuals with chronic pain in clinical settings is at least six times the rate in the general population.

IMPACT OF ANXIETY AND DEPRESSIVE DISORDERS ON PATIENT FUNCTIONING

The high rates of anxiety and depressive disorders in chronic pain are worrying, particularly given the well-documented impacts of these disorders on health, impacts that are reflected clearly in the WHO slogan that there can be "no health without mental health."[12] Mental health problems are generally known to in-

crease risk for other diseases and injury and to impede access to health services for comorbid conditions.[12] This situation is more troubling still for the worldwide shortage of appropriate services for such conditions, most dramatically in the less developed countries, but also in Europe and the United States.[13] Even in developed countries, only about half of those with severe mental health disorders receive even minimal services.[13]

Out of the two sets of psychiatric conditions, it appears that depressive disorders have by far the largest impact on general ''disease burden'' worldwide. A recent WHO survey including observations from 245,404 participants in 60 countries[14] found a 12-month prevalence of 3.2% for ICD-10 depressive episode. In this survey, between 9.3% and 23.0% of participants with one or more chronic medical conditions also had depression. In comparison to persons with chronic asthma, angina, arthritis, and diabetes alone, those with depression had the lowest rated health. Those with depression comorbid with another chronic medical condition had much lower rated health than those with the chronic medical conditions alone. And, finally, those with two or more chronic medical conditions and comorbid depression had the lowest mean health scores overall.

Based on a recent large-scale study, persons without chronic spinal pain were estimated to function at an average of 93.5% of full role performance, compared to an average of 76.5% for persons with chronic spinal pain.[2] About one-third of this difference in role performance was associated with a combination of physical comorbidities and, importantly, anxiety and depressive disorders. Results from a large, representative, population-based survey in Europe (N = 21,425) showed that the presence of pain and depression was associated with more than twice as many days per month of decreased work productivity as in either condition alone, and more than five times as many days as in the absence of either condition.[15] Other data from primary care clinics in the United States similarly showed that ''disabling chronic pain'' is four times more prevalent in those with major depression compared to those without.[16] These data further showed that the presence of major depression brought with it a significant risk of alcohol abuse or dependence and six times the risk of significant anxiety-related problems.

Just as depressive disorders clearly add to the impact of chronic pain, anxiety disorders, based on somewhat fewer studies, appear to do the same. A study of 965 randomly sampled patients in primary care in the United States showed that 19.5% had at least one anxiety disorder.[17] Compared to the patients without anxiety disorders, the 188 patients with at least one anxiety disorder reported two to three times as many days in the past three months when their symptoms interfered with their usual activities and more then one and one half times as many physician visits.[17] The implication of these data is that those with chronic pain and significant anxiety-related problems would be expected to carry the added burden of anxiety-related interference with functioning and additional health care use.

The presence of anxiety and depression places patients with chronic pain at risk for a wide range of unwanted health-related outcomes in addition to the general effects on functioning detailed above. These include sleep disturbance,[18] complaints of cognitive dysfunction,[19] opioid abuse (OR = 1.46),[20] delayed seeking of treatment,[15] reduced treatment effects,[21] and dissatisfaction with treatment.[22] Suicide is relatively rare in chronic pain sufferers but appears to occur at twice or three times the rate of the general population.[23] It is nonetheless important as it is arguably the most limiting of all possible outcomes in chronic pain management. Here too, clear features of anxiety and depression, such as helpless, hopeless, or catastrophic thinking, and desire for escape or avoidance, are identified as key psychological processes that increase a patient's risk.[23]

For its part, the adverse effect of depression on pain treatment appears mutual in that, just as depression negatively impacts on treatment of pain, pain negatively impacts on treatment for depression.[24] Also, effective treatment for depression can reduce pain, reduce interference with daily activities due to pain, and improve overall health status, such as in older adults with arthritis.[25]

PROCESSES IN THE INTERACTION OF ANXIETY, DEPRESSION, AND CHRONIC PAIN

In the past, there was often debate about which came first: pain or the types of psychopathology associated with anxiety and depression. For some, this type of linear thinking may be beside the point, such as in clinical situations and treatment planning. It also belies the fact that the terms ''chronic pain,'' ''anxiety,'' and ''depression'' represent merely ways of speaking about conglomerations of underlying experiences, behavior, and circumstances that interact complexly. Certainly, the temporal order of these events can occur in any direction in any individual case. Most frequently, however, experiences of chronic pain are regarded as antecedent to the emergence of later anxious and depressive behavior. This is somewhat better demonstrated in the case of depression than anxiety.[10]

According to the commonly applied ''diathesis-stress'' model, individuals who later develop patterns of significant anxiety and depression do so, in part, as a result of particular pre-existing susceptibilities. The occurrence of chronic pain then ''activates'' these patterns by bringing with it stressors and emotionally pertinent circumstances.[10,11] As mentioned, experiences of uncertainty or threat are commonly associated with chronic pain and are typical occasions for anxiety and fear. Likewise, experiences of loss, broadly speaking, also are commonly associated with chronic pain and are typical occasions for depression.

Attempting to answer the question of which came first, pain or patterns of emotional suffering, may serve no practical clinical purposes. Patients may be better served by an understanding of how experiences of anxiety and depression maintain or worsen a pattern of suffering and disability associated with chronic pain, lend complications to the process of treatment, or contribute to excess health care use, for example. Perhaps the most useful task is to identify the key elements among the patient's problems that are most manipulable and most likely to yield large and durable improvements in health and functioning. In fact, the most manipulable circumstances in those with chronic pain may include the circumstances that give rise to anxious and depressive behavior patterns more so than the circumstances directly underlying the pain experience itself.

The Fear-Avoidance Model and Processes of Depression and Pain

For its part, anxiety has been incorporated into a well-integrated model of chronic pain and disability, the so-called ''fear-avoidance model,'' a model that has garnered a moderate degree of empirical support.[26,27] According to this model, when persons with chronic pain experience fear or anxiety related to their pain and act accordingly by avoiding their pain and related situations, the result is increasing emotional impact overall and greater disability. This pattern of behavior has been reliably demonstrated in a range of chronic pain conditions including both acute and chronic low back pain,[28,29] general musculoskeletal pain,[30] rheumatoid arthritis,[31] osteoarthritis,[32] and fibromyalgia.[33] Other studies have shown that reduction in fear and avoidance plays an important role in the process of successful multidisciplinary treatment for chronic pain.[34,35]

The proposed processes behind the fear-avoidance model include respondent and operant-based learning in tandem with

processes of physical deconditioning (loss of physical capacity) or disuse (reduced activity), hypervigilance, and possibly muscular reactivity. Cognitive processes, including catastrophizing, also figure importantly in the cyclical process of mutually reinforcing behavioral, cognitive, emotional, and musculoskeletal influences on reduced functioning.[26] However, the proposed processes of disuse and deconditioning in this model have so far evaded clear empirical demonstration.[36]

Anxious or fearful behavior patterns can vary greatly in terms of the nature of the specific situations that occasion the behavior, how many different situations there are that do so, or how generalized these are. The fear-avoidance model concerns fear and anxiety directly related to pain and activity or movement. Fear of pain from the particular pain problem and fear of movement (kinesophobia) represent the specific end of the continuum, health anxiety and fear of general pain perhaps represent points midway in the continuum, and generalized worry or "trait anxiety" represent the more general end. Studies suggest that measures of more specific, pain-related, movement-related, and possibly health-related forms of anxious behavior are most useful for understanding adjustment to chronic pain, while measures of non-specific, trait-like, or general anxiety appear less useful.[37,38]

The case for how depression contributes to the behavior disturbance of chronic pain is less formalized, as it has not been incorporated into a specific model of distress and disability, as has anxiety or fear. Clearly, the extent to which chronic pain sufferers also suffer with symptoms of depression is correlated with their level of disability or quality of life, both in the general population samples,[1,6] and in clinic samples.[30,39–42] The role of depression in the overall impact of chronic pain may include processes as negative automatic thoughts or attributional styles,[43] relations between depression and passive coping or avoidance,[44,45] or a mediating role of depression in relation to effects of insomnia on pain-related disability.[46]

Practically, by definition, persons with depression and chronic pain have a greater burden of discouraging, ruminative, and distressing thinking (e.g., "I am a worthless person," "My situation is hopeless," "My pain is unbearable") and will therefore experience greater overall emotional distress and greater limitations in functioning as a result, presumably, as they "believe" their thinking, feel the emotions provoked by the circumstances described in their thoughts, or act as if they were true. In addition, their negative thoughts may occasion behavior patterns that are punishing to others, such as complaining, crying, or irritable behavior. These may produce maladaptive social interactions, either alienating others, or gaining ultimately unhelpful forms of social support, an effect suggested in a number of studies on catastrophizing.[47] Behavior patterns of avoidance, which are implicated in the effects of depression, are well documented in their adverse affects on functioning.[45] These adverse effects arise quite straightforwardly because unnecessary or overgeneralized avoidance of unwanted experiences prevents participation in productive, satisfying, or healthy activities at least some of the time.[48] Finally, the effects of sleep-related behavior in relation to depression may be complex. These may include disabling effects of fatigue and other bodily symptoms from actual impaired sleep,[49] or perceptions of a need to rest or reduce activities based solely on the belief that sleep was inadequate,[18,50] or a combination of both.

Confounded Content in Anxiety, Depression, and Pain

Clearly anxiety, depression, and chronic pain have considerable overlap in their psychological and behavioral features. In the case of depression and chronic pain, for example, there is controversy over whether the "somatic features" of each might lead standard depressive inventories to overestimate the presence of depression.[51,52] Anxiety, chronic pain, and depression are each aversive psychological experiences. Each experience includes: (a) unpleasant feelings in the body and in emotions; (b) patterns in thinking that include a mixture of attempts to solve the problem, unproductive rumination, as well as the presence of distressing or discouraging content; and (c) behavior patterns acquired in the past because they limit contact with, or avoid, the experiences, even though the long-term workability of these patterns appears extremely limited. These behavior patterns will include the avoidance, escape, or corrective rituals associated with anxiety; the generally low activity and persistent treatment seeking of chronic pain; and the withdrawal, excessive sleep, and even the complaints, irritable behavior, or emotional blunting, of depression. These are patterns of behavior that are both topographically and functionally similar, and, again, predominantly avoidant. They may differ more in their originating circumstances than in the psychological processes that maintain them.

TREATMENT OF ANXIETY AND DEPRESSION

In a recent high quality review, it was reported that there are now over 325 published outcome studies on cognitive-behavioral therapy (CBT) and at least 16 "methodologically rigorous" meta-analyses of these studies.[53] There were several general conclusions from this review: large effect sizes were found for CBT for depression, generalized anxiety disorder, panic disorder, social phobia, and posttraumatic stress disorder, with an overall mean effect size of 0.95 (Cohen's *d*: >20 = small, >05 = medium, >0.08 = large). It was also concluded that CBT was "somewhat superior" to antidepressant medication in treatment of depression.

CBT is sometimes faulted for having limited evidence for the durability of its treatment effects. In the extreme, it is sometimes suggested that effects of CBT are short-term only. The research literature shows that this is not true, and that CBT produces relapse rates, in conditions such as depression and panic, that are half as large as those from pharmacological therapies.[53,54] Twelve-month follow-up data after treatment for depression showed that CBT responders were significantly less likely to relapse than medication responders who were subsequently withdrawn from medication (31.0% versus 76.0%) and no more likely to relapse than patients continuing on medication (31.0% versus 47.0%).[55] Data like these have led experts to conclude that "as effective as medications are for many psychiatric disorders, there is no evidence that they are anything more than palliative; that is, they suppress symptoms so long as they are taken, but often do little to alter the course of the underlying disorder or to reduce subsequent risk once their use is discontinued."[54]

More and more, it appears that antidepressant medications may have significant limitations. A Cochrane review of nine studies including active placebos (which mimic some of the side effects of antidepressants and may prevent "unblinding" effects) versus antidepressants revealed that just two of these showed statistically significant effects in favor of the active drug in terms of improvement in mood.[56] The nine trials produced a pooled effect size of 0.39. One positive trial result contributed to significant heterogeneity in the combined result. Removing this one trial led to a reduced effect size of 0.17. These trials were all relatively short duration, just 6 weeks on average and 12 weeks in the longest case, and, hence, tell us little about longer term results of interest in clinical practice. Recent analyses of published and unpublished trials, available through the Food and Drug Administration in the United States, suggest that the published literature on antidepressants may present an unrealistically high effect size, perhaps one third higher, compared to results that include unpublished trials.[57]

Results of studies with pharmacological therapies for anxiety

disorders tend to reveal a similarly sobering pattern as with recent studies of depression. For example, benzodiazepines appear inferior to CBT, particularly in the longer run (6 or 12 months after treatment), for generalized anxiety disorder[58] and for panic disorder.[59] From these results, CBT shows the lowest rate of referral for further psychological or psychiatric treatment in comparison to medication alone for patients with generalized anxiety disorders,[58] and benzodiazepines alone are not recommended for those who have access to appropriate forms of CBT for panic disorder.[59] Currently, serotonin reuptake inhibitor (SSRI) medications are considered the first line pharmacological therapy for anxiety disorders such as panic. There are data that show CBT and SSRI each used alone are about equivalent in efficacy 9 months following the start of treatment, but combined CBT plus SSRI therapy appears marginally better.[60] On the other hand, naturalistic SSRI use during CBT for panic disorder is associated at pretreatment with greater agoraphobia and at posttreatment with delayed reductions in panic severity.[61] Results from cost-efficacy analyses following a randomized trial of three monotherapies (CBT, imipramine, and paroxetine) and two combination therapies (each medication combined with CBT) for panic disorder demonstrated that CBT alone was the most cost-effective both at the end of the maintenance phase and 6 months after the termination of treatment.[62] Trials of SSRIs for panic disorder show relatively high dropout rates (i.e., low tolerability) of between 25% to 50% during 12 months.[63] Relapse of symptoms is relatively high following treatment with medications and especially so after discontinuation of medication, an effect that is reduced with the addition of CBT.[64]

Clearly the efficacy of CBT for anxiety and depression is well-supported by research. On top of this success, particular methods within CBT may be in a process of refinement. For example, there has been a gradual revolution afoot in the analysis of treatment components and treatment process. More than 10 years ago, a component analysis of CBT for depression (N = 150) showed that both the behavioral activation component of CBT (an approach to increasing behavior that yields a sense of pleasure and mastery) and combined components of behavioral activation and skills training for modifying automatic thoughts were as effective as the entire package of these components plus a component that focused on changing core cognitive schemas.[65] These results held both immediately posttreatment and at 6-month follow-up. Additional results showed that the behavioral activation condition was as effective as the full set of components at altering negative thinking and dysfunctional attributional styles. These results run contrary to the popularly accepted cognitive model of depression, as this model proposes that the modification of negative schemata is necessary for treatment effects in CBT. It appears that a relatively simple treatment for depression aimed at direct behavior change and not on changing the way people think can be as effective as a more complicated form of treatment that emphasizes cognitive change.

A recent randomized trial comparing behavioral activation to cognitive therapy and antidepressant medication (N = 241) found that, in severely depressed patients, behavioral activation produced similar positive effects as did antidepressant medication, and both of these treatments produced better results than cognitive therapy.[66] This version of behavioral activation was an updated version that highlights the role of avoidance and withdrawal in depression, seeks to promote engagement with activities consistent with long-term goals, and to redirect attention away from the content of rumination and onto direct experience. In a follow-up study, the research group found a subgroup of patients they deemed as experiencing an "extreme nonresponse" to cognitive therapy.[67] Through the use of logistic regression, they found that the extreme nonresponders to cognitive therapy were characterized by high baseline depression severity, functional impairment, and problems with their primary social support. These patients reported major life stressors or interpersonal problems and regarded themselves as having long-standing difficulties with depression. When patients with these same characteristics were identified among those treated in the behavioral activation condition, they did not evidence nonresponses to this treatment. Perhaps cognitive therapy is more complicated to deliver because of its focus on patient behavior, beliefs, and attitudes, as opposed to the smaller number of straightforward overt behavioral strategies included in behavioral activation. Perhaps a more limited focus is an advantage when the length of treatment is constrained.[67]

More than 16 years ago, Sullivan and colleagues[68] called for increased recognition of depression in chronic pain and for treatments specifically targeting depressive symptoms in chronic pain. Although we do know that CBT is effective for anxiety and depression and that treatments for chronic pain based on cognitive behavioral principles can result in decreased depression and anxiety,[69] this leaves the question still unanswered about how to most effectively treat anxiety and depression in the context of chronic pain or whether to do so will result in significantly better overall treatment results. The current literature leads one to assume this would be the case.

COGNITIVE BEHAVIORAL TREATMENT OF PAIN-RELATED FEAR AND AVOIDANCE

Unlike depression, the model connecting fear and anxiety-related processes to chronic pain has spawned specific treatment methods, primarily including exposure-based methods. Exposure-based treatments essentially include having the patient make contact with particular situations, involving movements and pain, that provoke fear and avoidance, but having them do so in a way that does not include avoidance and so that they do not attempt to control their fearful feelings by avoidance or escape. Exposure trials are typically performed along a graded hierarchy of fear-eliciting situations, from low levels of threat to higher levels. These treatments for pain-related fear and avoidance have typically also included a component called "behavioral experiments," which include methods to identify and challenge irrational expectations during exposure.[70] Repeated trials using these methods together are presumed to reduce fearful feelings and correct mistaken fearful beliefs or expectations.

In what was apparently the first published demonstration of exposure for treatment of pain-related fear and avoidance, Vlaeyen et al.[70] conducted a replicated, single-case, cross-over experimental design comparing in vivo exposure with methods designed to increase activity in a graded fashion. The participants in this study (N = 4) were selected for their high levels of fear of movement. Based on graphical and time series analyses of daily ratings of pain-related cognitions and fears, improvements only occurred during the graded exposure and not during the graded activity condition. These investigators also found that reductions in fear of pain correlated with reductions in catastrophizing and disability. These results from the Netherlands were essentially replicated by a group in Sweden.[71] In a subsequent study, the actual exposure component, and not educational sessions included with exposure, appeared responsible for improvements in daily activity, and that improvements from treatment maintained at a 6-month follow-up.[72] The results of graded exposure in vivo for fearful patients with chronic pain have been extended to patients with complex regional pain syndrome (CRPS).[73] Again, relative to baseline phases of randomly determined durations across patients, an exposure condition was associated with decreased fear, disability, and pain. Interestingly, the exposure condition also appeared to reduce patients' signs and symptoms of CRPS.

Until recently, all of the investigations of graded exposure for

chronic pain utilized single subject design methods and therefore small sample sizes. In what appears to be the first randomized controlled trial in this area, including 44 patients with chronic low back pain, Woods and Asmundson[74] showed that, relative to a graded activity condition, patients in the graded exposure condition had greater improvements in measures of fear of pain and movement, pain-related anxiety, catastrophizing, pain, anxiety, and depression. Improvements in disability, however, did not reach statistical significance. Improvements were maintained at a 1-month follow-up.

In a more recently reported trial including patients with "at least moderate pain-related fear" (N = 85), it was demonstrated that exposure-based treatment appeared roughly equal in efficacy to graded activity in terms of improvements in functional disability and physical activity-related complaints, immediately and 6 months following treatment.[75] On the other hand, the exposure treatment demonstrated clear superiority in reducing pain, catastrophizing, and perceived harmfulness of activities. Effects of the exposure condition on disability and physical activity-related complaints were mediated by decreases in pain, catastrophizing, and perceived harmfulness of activities. Although the results from both randomized trials are certainly not discouraging, they seem less definitive in asserting the specific efficacy of exposure-based methods than were results from the studies relying on single subject designs.

DEVELOPMENTS IN CONTEXTUAL COGNITIVE BEHAVIORAL THERAPY

Developments in the cognitive and behavioral therapies have been described as a series of "waves."[76] The first consisted of the application of laboratory-based principles to human behavior problems in what was simply called Behavior Therapy, or, in the field of chronic pain management, the "operant approach."[77] The second wave included the addition of cognitive therapy methods to behavior therapy to define what is now understood as CBT.[78] The "third wave" includes a number of approaches that integrate the behavioral and cognitive elements of the first two waves, but also expands these within a conceptual framework that is less mechanistic and more contextual. The methods that emerge within this wave include notions like acceptance, mindfulness, and values. Examples of these "third wave" approaches include Mindfulness-based Stress Reduction,[79] Dialectical Behavior Therapy,[80] Mindfulness-based Cognitive Therapy,[81] Acceptance and Commitment Therapy (ACT),[82] and an approach to chronic pain based on ACT called Contextual Cognitive Behavioral Therapy (CCBT).[83]

The therapeutic model underlying ACT and CCBT includes six core processes. These include acceptance, contact with the present moment (a feature of mindfulness), cognitive defusion (a loosening of the general role of verbal/cognitive processes in their influence on behavior and their blocking of nonverbal influences), committed action, self-as-context (as distinct from a verbally constructed sense of self), and value-based action.[83] In turn, these six processes entail an overall process referred to as "psychological flexibility," which is a quality of behavior that allows it to change or persist in line with long-term goals and values relatively free from restrictions on behavior based on interactions between verbally-based and direct (nonverbally-based) influences on that behavior.

Research supports the role of the core therapeutic processes described here in relation to the functioning of patients with chronic pain. For example, acceptance of pain is associated with emotional, physical, and social functioning, health care use in both retrospective[84,85] and prospective[86] studies in patients with heterogeneous pain problems, and in patients with rheumatoid arthritis[87] and low back pain.[88] Mindfulness,[41] values-based action,[89] and general psychological flexibility[90] are, likewise, significantly and generally related to key aspects of patient functioning. In relation to focus of this chapter, more than 20 studies of these contextual processes in chronic pain demonstrate that these processes are particularly strong in their correlations with anxiety (range r = -0.29 to -0.72) and depression (range r = -0.45 to -0.59).

There are at least seven treatment outcome studies that demonstrate the benefits of treatment methods for chronic pain related to the ACT and CCBT model. In these studies, both mindfulness-based methods alone[91–93] and broader packages of methods (including exposure, mindfulness, values-based methods, and other methods to increase psychological flexibility)[94,95] yield significant results across a range of domains, including results with clear clinical significance.[96] These latter results, for example, include effect sizes of 1.2 immediately post treatment (N = 171) and above 0.90 at a 3-month follow-up (N = 114) for both pain-related anxiety and depression, following a 3 or 4 week course of interdisciplinary residential treatment in the United Kingdom. Whereas the mindfulness-based methods for chronic pain have been analyzed in fully randomized controlled trials, the results regarding the comprehensive multicomponent packages of methods await a high quality, fully randomized, controlled trial. To date, published studies have included a small randomized trial of participants "at risk" for work loss due to pain or stress,[97] and a nonrandomized trial with a waiting phase comparison.[94]

The particular value in acceptance-based, contextual, and mindfulness-based methods for anxiety and depression in chronic pain sufferers appears to arise from their specific focus on processes for addressing rumination,[98] undermining avoidance, and reducing the impact of distressing and restricting influences in patterns of emotional thinking.[82]

SUMMARY

The suffering that comes with chronic pain is undeniable in the community and even more so in the clinic. This suffering takes many forms but commonly includes the experiences of anxiety and depression. Between 1 out of 5 and 1 out of every 2 individuals with chronic pain will meet criteria for an anxiety or depressive disorder or both. The added burden of anxiety or depressive conditions on top of chronic pain is important because this constitutes real human suffering, and because it significantly impacts on general health, work, and health care use. Despite the quite large burden imposed by anxiety and depression on individuals, the community, and national resources, these problems are not adequately addressed, even among the most advantaged countries around the world, where less than half of those in need receive even minimal services.

Talk of individuals in categories like chronic pain, anxiety, and depression is just a way of speaking, a way of organizing events in the world. This way of speaking has uses as well as limitations.[99] A more adequate analysis of the medical, psychological, and social processes responsible for the suffering and disability of chronic pain will require looking underneath these categories to the interrelated experiences and behavior patterns that constitute the problem and to the situations and history that determine and maintain these patterns. It is not an adequate technical analysis to say that depression "makes pain worse," or even to say that fear causes avoidance and that this avoidance causes disability and further distress.

What is remarkable about the categories of chronic pain, anxiety, and depression is all the psychological features they share in common. Each of these includes contact with aversive experiences particularly in the body and in the mind. Each of these includes thoughts and beliefs that, if taken literally, add considerably to emotional suffering, and, if followed, lead to behavior patterns

that restrict the individual's functioning further still. Each of these includes prominent patterns of avoidance, including both decreases in healthy overt activity and processes of struggling to control or limit contact with the many related, collateral, aversive experiences. While the particular history that gave rise to the chronic pain, anxiety, or depression may have unique features, such as the experiences of threat or uncertainty that lead to anxiety, or the experiences of loss that lead to depression, the psychological processes that maintain the suffering and life disruption they occasion appear largely overlapping. One day, treatments may focus not on symptoms of chronic pain, anxiety, or depression, but on underlying psychological dimensions of avoidance, loss of contact with reality, and general psychological inflexibility.[82]

Cognitive behavioral approaches to anxiety and depression are highly effective for reducing the symptoms of these conditions and for improving patient functioning. There is also evidence that cognitive behavioral approaches for chronic pain can generally effectively reduce the impacts of anxiety and depression. Still, cognitive behavioral methods develop and evolve. These developments emerge from theoretical advances and from research results. Among the particularly intriguing results, for example, it was recently concluded that perhaps it is *not* necessary to challenge irrational thoughts in CBT,[100] and that a modern version of behavioral activation, a method for changing behavior without first changing thoughts and feelings, can be more effective in treating depression than a more comprehensive cognitive behavioral approach that places a greater emphasis on changing thoughts.[66]

A short time ago, the remark was made that "these are interesting times to be doing depression research,"[101] by this it was meant that this is a time of potential controversy and a time for questioning notions, such as the notion that depression is primarily a function of altered brain chemistry, some personality-based vulnerability, or an irrational response. One might equally say that it is an interesting time to be doing anxiety or chronic pain research for the same controversies that emerge. Recent analyses suggest that the human suffering and lost vitality that arise with chronic pain, anxiety, and depression emerge not from a defect in the individual but from a somewhat arbitrary extreme within normal human functioning. Newer developments in the cognitive behavioral therapies that emerge from this way of thinking include processes like acceptance, mindfulness, and values, where in the past the key processes may have been "control," "coping," and "cognitive restructuring." As research results continue to accumulate, methods that derive from these processes may be shown to significantly expand the range and adequacy of our treatment methods for individuals suffering with chronic pain.

CHAPTER 84 ■ HYPNOSIS

JEANNE HERNANDEZ

HISTORY OF HYPNOSIS IN PAIN AND SYMPTOM CONTROL

Hypnosis is a word derived from the Greek word meaning "sleep." The fairly ancient practice was used by the Druids, the Celts, and by the Egyptians, who frequented "sleeping temples" for relaxation and healing. In the 1770s, the Austrian physician Franz Mesmer (1734–1815) was interested in the effect of physical energy and magnetism on the body and spirit. He placed his patients in a tub of iron filings and, with wide sweeps of his arm, made "passes" up and down the patients' bodies. The success of the practice, termed mesmerism, was attributed to animal magnetism, whereas the benefits were probably due to the hypnotic effect of his arm-waving ritual. In the 1830s, practical uses of mesmerism were discussed by Oliver in the U.S. and by the French Academy of Medicine. In Scotland, James Braid (1795–1860) termed the word "hypnosis" in 1843, thinking it to be a stage of sleep that influenced the nervous system, and distinguishing it from the state of mental concentration. Braid concluded that the relaxing suggestions diverted the patients away from critical thinking and led them into trance. In the early 1900s, Pavlov also viewed hypnosis as an incomplete sleep state that allowed patients to mentally separate from what was going on around them.

John Esdaile (1808–1859)[1] began using trance inductions with surgery patients in 1845 in India, where there were not anesthetics available; he found the hypnotized patients to have increased resistance to infection, greater comfort, and quicker recovery times. In Europe, the School of Hypnotic Study was being formed in Nancy, where the view was that suggestion led to hypnotic trance states that were quite normal phenomena. Neurologist Jean-Martin Charcot (1825–1893) also noted that hysteria was effectively treated with hypnotism; while he brought hypnotism into favorable light, he viewed it as a part of the hysteria process and not a normal healthy phenomenon. Interestingly, recent brain research shows us how he was correct in his assessment and that there is a link between the propensity to hysteria and high hypnotizability.

Pierre Janet (1849–1947) saw hypnosis as dissociation or a split away from cognitive consciousness, which was sometimes normal and healthy and other times related to dissociative states or multiple personalities. In the late 1800s, Freud became interested in accessing repressed memories through hypnosis, recognizing it as a pathway to the unconscious mind. However, he was not a good hypnotist and therefore abandoned it; in doing so, he led others away as well. Fortunately he did continue his interest in the hypnotic properties of dreams and free associations.

In the mid-1840s, the introduction of chloroform and ether into surgical practice was another reason for the apparent hiatus in the use and study of hypnosis in medicine. In the 1950s, its use in understanding the workings of the mind and its application to psychotherapy began to pick back up. In the U.S., psychologist Clark Hull[2] documented its use for anesthesia, posthypnotic amnesia, and pain relief. Milton Erickson conducted many of these experiments and went on to study the mechanisms of trance practices brought to him by Jay Haley and Margaret Meade. Erickson had an exquisite understanding of the mechanisms of the unconscious mind, and his personal understanding of its effectiveness for reducing physical pain left him well poised to research, practice, and teach hypnosis for symptom control and pain management. The American Society of Clinical Hypnosis (ASCH) was founded in 1957 as a spin off from the Society for Clinical and Experimental Hypnosis (SCEH), founded in 1949. Hypnosis was endorsed by both the American Psychological Association (APA) and the American Medical Association (AMA) in the late 1950s. The British Medical Association endorsed its use in 1958 as an anesthetic in certain surgical situations.

In a way, there is a great difference between the linear and precise thinking of modern medicine and the spiritual and imagination-rich mosaic thinking of the hypnotherapist, and yet they come together in this chapter in the discussion of pain as a psychological event, and of the role of expectancy and hope in pain management and general wellness. The early researchers and practitioners identified the spiritual and magical element of hypnosis having to do with the positive expectation noted in the early practices of Mesmer with his magnets, Freud with his dream work, and Erickson with his positive mindset of hope and respect for the patients. These men all identified the role of the unconscious mind in psychosomatic symptom formation and, in doing so, let down the Cartesian wall between the mind and the body. They also recognized that the highly hypnotizable may be more likely to develop psychosomatic symptoms but also may be more likely to benefit from hypnotic treatment. Upcoming sections will discuss pain as a psychological event that is moderately plastic and open to suggestion. Research shows that the triggered memory of pain and the expectation of future pain can be as painful as injury-induced pain.

In the 1970s there began to be an interest and upsurge in multidisciplinary pain management. Fordyce,[3] Bonica, and many others were at the forefront of the physicians, scholars, and researchers who moved the field forward in the 1980s. While the ideal was for patients to be holistically treated by all disciplines together, psychological management is still usually done separate from medical treatment. Recently, Turk[4] reviewed outcome data for patients receiving care from interdisciplinary chronic pain and rehabilitation programs (ICPRP) as opposed to other care. He found that pain reduction and activity level of patients in ICPRPs was as good as or better than that of patients receiving standard medical treatment and that iatrogenic complications, medication use, and health care use was less, with more patients returning to work. Other studies compare psychological treatment for chronic pain favorably to more invasive measures and to narcotic use. A recent systematic Cochrane review concluded that cognitive interventions combined with exercise is recommended for chronic low back pain.[5] There is also strong evidence that intensive multidisciplinary biopsychosocial rehabilitation improves function when compared with inpatient or outpatient nonmultidisciplinary treatments.[6] A recent study reconfirms the cost-effectiveness of perioperative hypnosis to patients or to their hospitals.[7] Given the evidence, we may expect that less invasive and less costly treatments may become the preferred options of patients, their providers, and insurance companies. An extensive review of the

research[8] found hypnosis to meet the APA's criteria as an effective treatment for pain, and superior to medication.

Hypnotic trance will be explained as a state of mind and its use in behavioral medicine in general will be described. The discussion will include the current understanding of how hypnosis works at the unconscious level in general and for pain relief, citing recent literature on brain mechanisms of pain. Recent research will be outlined, suggesting hypnosis' application to specific types and locations of pain, and some commonly used hypnotic maneuvers to treat them. Even though some studies discuss symptom relief (tension, twitches, allergies, anxiety, rashes) as separate from pain itself, usually symptom relief leads to pain relief down the road. The chapter describes both traditional and newer practices of pain hypnosis, and provides information on certification and training. The chapter is concluded with a discussion on chronic pain, where the emotional suffering related to pain is a notable dynamic.

HYPNOSIS BY DEFINITION

Hypnosis is a process of bypassing the critical thinking cognitive mind to access the unconscious processes. Without the critical thinking filters, the hypnotized person may be more suggestible and more easily influenced by the hypnotist. During hypnotic trance, a person can focus intently on just one aspect of an experience, or dissociate from the experience to the point of losing track of their body and whereabouts. Succinctly, hypnosis is simply a programmed entrance into "trance," which is itself a perfectly normal state that we engage in whenever we are totally absorbed in a task or experience and are not reviewing the characteristics of our experience. Formally, hypnosis is "a social interaction in which one person, designated the subject, responds to suggestions offered by another person, designated the hypnotist, for experiences involving alterations in perception, memory, and voluntary action,"[9] hopefully for the sake of some change the patient desires. Professionals should be thoroughly trained in hypnosis before practicing it, and should work only in the areas of their professional expertise. ASCH and SCEH train and certify professionals in medical hypnosis; certification requires a professional degree in health or mental health and specific training that includes the ethical uses of hypnosis.

Conscious, Unconscious, and Content of Consciousness

A brief review of the conscious and unconscious minds will serve as the groundwork for discussing the mechanisms of hypnosis itself as well as the psychosomatic process of logging an emotional experience as pain.

A. Consciousness: what you are oriented toward in the present
1. *Content of consciousness: perceptions and specific thoughts; what is on your mind and in your thoughts, including what is "on the back burner"*
2. *Selective consciousness: what you choose to have in the front rather than in the back or periphery of your mind*

B. Unconscious
1. *Long-term memory: which you may or may not access when necessary*
2. *Short-term memory: which has happened recently*
3. *Automatic functioning that usually but not always bypasses your conscious mind. This is sometimes called the primary process or body language that demonstrates when you are angry, happy, or frightened. It also includes behavior such as scratching an itch or catching yourself before you fall.*
4. *Programmed physiology that you have little or no access to in normal thinking state, such as your heart beating, breathing, allergic responses, healing rate, etc.*
5. *Deeper processes such as the essential self, spiritual self, soul, and body's core identity. Other parts of the self are the immune system, the neurological map, or the body and the core spiritual self.*

We might say that the conscious mind includes awareness and cognition, and the unconscious mind includes everything else, including your physical self. Cognition is a tool to help with survival and with the expression of the essential self; it is a small part of the whole self constellation, in a somewhat figure/ground relationship. The unconscious mind is adaptive and capable of profound change, potentially with both positive and negative outcomes.

When you are "associated" to a situation, you see it through your own eyes, and you are fully present to it; an example of this is the child who is involved in a task but is not monitoring himself and who needs an adult to oversee his behavior. In reflective thinking, you are of two minds at once, contemplating an idea or situation by looking into your unconscious mind to find new perspectives for viewing or approaching it. The conscious mind and the unconscious mind can operate autonomous of one another, in the condition of dissociation (dis-"associated"), occurring when ideas are split off from the normal (associated) experience and when, to some extent, you are not paying attention. When dissociated, you may take a global experience of the situation and break it down into parts, amplifying one part while diminishing concentration on the other part—when, for instance, you notice one aspect of the situation and no longer notice others. You may see the situation and also see yourself in the situation, or you may see the situation differently. This can occur during trauma or during hypnosis; for instance, during surgery, you can dissociate from pain by imagining yourself at the beach and seeing the beach at the same time, or dissociate from a body part during surgery and believe it to be having surgery or recuperating across the room. In an internally directed trance state, the patient may shut off pain and influence healing, immune functions, heart rate, blood flow, and autoimmune responses not commonly accessed in the normal conscious. Again, hypnosis is merely the programmed entrance into trance or dissociation at some level, and hypnotherapy is the programmed entrance into trance for therapeutic purposes.

Actually, the hypnotist or hypnotherapist is merely guiding the patient to self-hypnosis. Unless the state is induced with hypnotic medications or other psychoactive substances, the patient is the one to suspend vigilance, and their ability to do so is likely to depend on: (1) the relationship that they have with the hypnotist, (2) the skill of the hypnotist inducing the trance, (3) the safety of the situation and environment, (4) the patient's level of hypnotizability, (5) the patient's expectancy that they will receive benefit and relief, (6) the patient's need for the trance—pain itself can be a trance state to tap into, and (7) the patient's past experience with trance states, ranging from dissociative disorders leading from experienced trauma, to meditation and past hypnosis training.

Complementarity, the quantum physics concept of relativity, helps explain the use of hypnosis for pain control. Basically, it is impossible to be wholly in one state (fully present and focused in one perspective) and keep the other fully in mind at the same time; the difference is being *in* the moment, versus *thinking about* the moment. When you are fully locked into pain, you cannot get perspective to solve the pain problem; you need to dissociate from the pain somewhat to get a better perspective on it. Once you dissociate from it, you can no longer feel it. The hypnotherapist facilitates the process. Other examples of split consciousness or going back and forth between the conscious and the unconscious minds are the rewriting the endings of dreams (lucid dreaming), remembering that the stove is on while watching

television (split concentration), and accessing memories—all of which are normal functioning, but also, in a way, related to hypnosis. These principles of trance and hypnotic states are important to understanding hypnotic pain management. The more access to the unconscious mind one can gain by self or guided hypnosis, to imagine or create another way of being or feeling, the more control of pain and physiological symptoms one may have.

CENTRAL MECHANISMS

Central Mechanisms of Hypnosis

Hypnosis has been viewed as magical, energy-related, sleep-related (Braid and Pavlov), psychosomatic, pathological (Charcot), dissociative,[10–12] and the consequence of normal suggestibility[13]—all of which are partly true. Recent brain imaging research using functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) shed more light on the process. In general, the studies show that there are many brain areas involved in the hypnotic process, including simultaneous increased activities in some areas and selective shutting down of others. Some studies look at performance on certain tasks (learning, verbal, auditory) and in certain situations (pain, for example) before and during hypnosis, while others compare high and low hypnotizable patients or subjects.

Clinicians as far back as Freud have known that some people are more suggestible or susceptible to hypnosis than others. About 15% of people are highly suggestible, 65% are moderately, and 20% are not very suggestible.[11] While hypnotizability is a fairly stable trait and not related to intelligence, it can be taught and also modified according to situation, hypnotist skill, patient motivation level and expectancies, induction and trance relevance to the patient, and patient physical and psychological state. Experienced hypnotists help patients lower their vigilance by setting the appropriate conditions and by sensing and identifying the way their patients unconsciously process information.[14,15]

High and Low Hypnotizability

Over the last two decades, Gruzelier[16] has been involved in numerous experiments studying high and low hypnotizable brain responses to experimental tasks during pain episodes and other situations. His studies seemed to show that in a hypnotic state, subjects can selectively ignore what is in their perceptual field while still knowing what is there. This is important regarding pain, in that often the patient's focus is as much on misery and helplessness as it is on their physiology; the clinician may not be able to change the physical condition, but they may help the patient to selectively disregard the pain and the suffering. Gruzelier[16] found that, in general, highly hypnotizable subjects exhibit more neurophysiological and cognitive flexibility,[17] which include "superior abilities in absorption, creativity, dissociation, attention and vividness of imagery; these are all well known correlates of hypnotizability." Regarding hemisphere involvement, high hypnotizables under hypnosis demonstrate more right hemispheric frontolimbic influence. Further, there is more neuronal flexibility going from the right to left and from the left to right hemispheres, and, according to Gruzelier, "in stimulus repetitions, highs showed a shift from an initial right-sided preference, in line with the right hemisphere's role in global orienting, to a left hemisphere preference, in line with the left-sided involvement in the local orienting process,"[16,18] indicating absorption. One study found greater informational exchange in the prefrontal areas of highly hypnotizable patients during hypnosis.[18] High hypnotizables were better able to inhibit pain from their conscious awareness. fMRIs showed them to have a significantly larger rostrum area, the corpus callosum area involved in transferring problem solving information between the left and the right hemispheres. Gruzelier emphasized another difference between highs and lows during an auditory attention task: pre-hypnosis, highs increased ERP N100 activity (engaging frontal attentional circuits), while lows had little activity, indicating distraction; under hypnosis, highs had little activity, indicating disengagement of the frontal process, or distraction, while lows' activity progressively increased.[19]

Other studies involving mental tasks showed increased activity in the anterior cingulate under hypnosis in highs more than in lows (indicating that they were monitoring the task), and a decrease in the inferior frontal gyrus activity (indicating that they were disengaging from executive functioning).[16] In other words, highs under hypnosis are relatively better at actively not paying attention to what they still know is in the field; they seem to let go of attending it. This seems to represent frontolimbic inhibition on the left side and a shift to the right brain, engaging the patients' ability to feel or imagine things different than they were before. Hypnosis involves activation of the hippocampus and inhibition of the amygdala activity at the same time.[20] A fractal analysis of electroencephalographs (EEGs) in patients under hypnosis showed dissociation of centralized activity and a loss of the normal patterns of integrated physiological responses, which results in a trance state.[21]

Central Mechanisms of Hypnotic Analgesia

Price, Barber, and Hawkins[22] provided a statistical path analysis to show four necessary elements of hypnotic analgesia—relaxation; absorption; disorientation from time, space, or sense of self; and automaticity—and their relationship order. Automaticity is the condition in which the suggestion bypasses cognition and leads directly to the sensation or experience, such that the suggestion of sinking into a warm bathtub will allow you to relax your back muscles and smile, without your having to think about it or consciously relax or lower your shoulders. Studies show that imagining heat actually increases blood flow that relaxes muscles, thereby validating automaticity. The principle is similar to direct suggestion and to suggestion through expectancy and placebo.

Some suggest that hypnotic analgesia works by activating endogenous pain inhibitory systems that descend to the spinal cord, where it prevents transmission to the brain of pain coming from nociception. One study evoked experimental pain in subjects by stimulating the sural nerve, causing the nociceptive flexion reflex (NFR).[23] Hypnotic suggestion could both increase and decrease the NFR, leading the researchers to conclude that their hypnotic suggestion actually controlled the response at the spinal level by activating descending antinociceptive mechanisms. However, this does not appear to stem from the opioid system alone,[24,25] in that the administration of naloxone, an opioid antagonist, does not reverse hypnotic analgesia. It would seem, then, that there are nonopiate cortical fugal or brain-to-spinal-cord descending control mechanisms.

The relationship between pain and hypnotic or dissociative faculties of the brain are made clearer in recent studies of complex regional pain syndrome (CRPS), which begins with excruciating pain and can progress to include dramatic physiological changes and neglect or dissociation from the painful limb. According to studies, within moments of an injury or absence of sensory input, there is a reorganization of the somatosensory cortex representation of the injured limb that leads the patient to behaviorally isolate or "favor" the limb. fMRI studies show that the degree of change in the somatosensory cortex is directly related to the degree of perceived pain.[26,27] Even when there is painless stimulation in the CRPS patient's uninjured counterpart limb, there is pain-related activation all through the brain, including cerebral,

motor, parietal, bilateral S2, frontal lobe, and the anterior and posterior parts of the anterior cingulate cortex (aACC and pACC).[28] When the CRPS pain lessens, however, both the cortical reorganization and impaired tactile sensation return to normal.[29,30] Wobst[31] summarizes the PET, fMRI, and evoked potential studies on pain, concluding that the ACC, insular, frontal cortices, amygdala, S1 and S2, and the lateral thalamus are all involved in pain when the body processes the pain in regard to location and duration. The studies show that the affective (cognitive and evaluative) components of pain are processed in the medial thalamus and progress back to the ACC.[32–35]

At the same time, other areas of the brain work to calm and heal; following the awareness of physical or emotional pain, the right ventral prefrontal cortex is involved with soothing responses that are triggered by soothing hypnotic therapeutic suggestions and messages, which proceed to help the right parietal lobe to reorganize and to perceive the body intact and comfortable (see section later on CRPS and phantom limb pain).

In a hypnosis study of experimentally induced pain, high and low hypnotizables responded differently.[36] Under hypnosis with the low hypnotizable subjects, increased pain ratings corresponded with increased frontal gamma oscillations; however, gamma oscillations did not increase in high hypnotizable subjects as the pain ratings increased. The gamma frequencies were noted primarily in the bilateral anterior cingulum (within the limbic system), which supports the understanding of pain being tied in with a complex of emotional responses. The mid-cingulate cortex may modulate and influence sensory, affective, cognitive, and behavioral aspects of nociception at least in the hypnotic state.[37] Raij et al.[38] used fMRI to compare brain mechanistic responses to noxious stimulation perceptions versus hypnotically hallucinated pain; they found that both real and imagined pain produced similar brain responses, although perception of hallucinated pain was less than the actual induced pain. In both cases, there was activity in the rostral and perigenual ACC and in the pericingulate regions of the medial prefrontal cortex. They conclude that the medial prefrontal cortex is involved in monitoring real and hallucinated pain which then influences how noxious stimuli are experienced and processed. A study exposed subjects to pain (1) in the waking state, (2) with hypnotic relaxation, or (3) with hypnosis suggesting depersonalization (out of body experiences).[39] All the subjects showed somatosensory, insular, and cerebral activation with pain; however, the depersonalization group showed less activation in the contralateral somatosensory cortex, parietal cortex and prefrontal cortex, putamen, and ipsilateral amygdala. DePascalis, Magurano, and Bellusci[40] and others have shown somatosensory event-related increase during pain, followed by a reduction when subjects were administered hypnotic analgesia. DePascalis[41] found that highs experiencing hypnotic analgesia showed smaller total, delta, and beta amplitudes in the right hemisphere; they experienced more theta activity in the left hemisphere during pain and more in the right hemisphere with hypnotic analgesia, decreasing both the sympathetic activity and the overall experience of pain. Meier et al[42] showed that hypnotic hypalgesia decreased subjects' experimental pain; when suggestions about increasing pain were made, somatosensory evoked potentials, auditory evoked potentials, and EEGs remained unchanged from the hypalgesic state, indicating that the physical response to pain and its affective component can indeed be separated. Thus, hypnotizability level certainly appears to impact the ultimate outcome of hypnosis in general as well as for pain management.

PAIN AS A PLASTIC EXPERIENCE

Why is hypnosis particularly appropriate for acute and chronic pain management? How can it be that Jensen and Barber[43] showed hypnotic analgesia to be more effective than other analgesics, including morphine, for reducing pain? We can begin to answer it by viewing pain as a psychosomatic event and a complex interweaving of physiological, psychological events, and the memories and expectations of like experiences, interacting on two-way streets through the body. In other words, it is a perception or conclusion derived from a real physiological signal, expectations, and memories of similar past experiences; the perception itself generates feedback to the body. Physical injury and disease cannot fully predict the amount of perceived pain a patient experiences; other determining factors are anxiety and trauma, context of the injury, depression, expectation, social support, and numerous other personality factors and cognitive styles. Interestingly, as is discussed elsewhere in this chapter, those who are highly hypnotizable are often the most likely to experience psychosomatic symptoms of the overlap of psychological interpretation and nociception, but they are also most likely to benefit by hypnosis and other well applied psychological treatment.

Chapman[44] describes nociception as an unconscious messaging about tissue damage through the nervous system, not to be equated with pain, which is the conscious awareness of that nociception. He defines pain as "a complex, compelling unpleasant bodily awareness normally associated with tissue trauma." One purpose of pain is to engage the cognitive problem solving part of the brain in a plan to resolve the tissue damage. Biologically, pain is a cascade of neurotransmitter and biochemical responses to nociception involving the hypothalamic-pituitary-adrenal (HPA)-axis and the limbic system and causing changes in blood pressure and blood sugar, serotonin, and norepinephrine levels, thereby affecting concentration, mood, behavior, healing, and sleep. Pain can interfere with psychological and physical well-being. When the nociception is not medically treated and stopped, the body's unconscious responses to it can continue on to cause permanent change and damage in other physiological and psychological systems. At the same time, psychological stress and suffering can lead to the same cascade of physiological stress responses and even lead to the construction of the sense of pain where no damage exists, which helps to explain why some events, physical or otherwise, cause pain to some people more than others.[44]

Hypnotherapy for pain aims to disengage pain from suffering and soothe both the physical and emotional stress. In the case of acute pain during surgery or procedures and after injury, the patient's focus can be directed away from the experience, or the experience can be reframed as beneficial and healing, and one not to be feared. Directing the patient's focus away from the pain and back into them is also a way to alleviate suffering, in that the pain would then be differentiated from the patient's sense of self. Whereas pain is stressful, hypnotherapy is a relaxing and comforting experience that induces brain waves and levels of autonomic functioning that soothe the sympathetic nervous system and enhance healing and resistance to disease.[45] By changing the cognitive mind's and body's responses to nociception, patients may simultaneously alleviate pain, promote healing, and learn to manage future pain better, all within the same cost-effective applications. For a detailed review of techniques according to medical problems, see Brown and Fromme[46] and Hammond.[47]

TESTING HYPNOTIZABILITY

Hypnotizability level does appear to influence hypnotic pain management and the outcome of hypnosis in general, although there are ways for the experienced hypnotist to work with it successfully. Researchers may be more likely than clinicians to use hypnotizability scales before engaging in subject or patient interactions. Some say that testing for hypnotizability may actually interfere with the research, because testing itself is hypnotic training and subjects become more hypnotizable with practice.[48] Nonetheless, when hypnotizability is very important, such as before attempting intraoperative hypnotic analgesia, it may be wise

to use the Stanford Hypnotic Susceptibility Scale (SHSS), Form C,[49] which is a fairly long (over an hour) and stringent test with a broad sampling of hypnotic suggestions. The Stanford Hypnotic Clinical Scale (SHCS)[50] is a shorter version that gives scores for adults in 25 minutes; there are also versions for children. The Hypnotic Induction Profile (HIP)[51] gives scores for adults and children in 5–15 minutes; it is based upon a simple procedure (the eye roll) that goes beyond suggestibility to autonomic function. The Harvard Group Scale[52] may be read or administered by tape recording, and should be used when there is a need to maintain a pool of subjects of varying suggestibility. The Waterloo-Stanford Group Scale of Hypnotic Susceptibility (WSGC)[53] is a group version of the Stanford Hypnotic Susceptibility Scale, Form C that may best be used for measuring suggestibility. The Hypnotic State Assessment Questionnaire (HSAQ)[54] assesses patients' hypnotic state at one point in time, and may be used during clinical or experimental sessions. Weitzenhoffer[55] points out that suggestibility and hypnotizability are different and that some research has failed because subjects were not really hypnotized, but rather merely followed suggestions. To be sure of hypnotizability, he recommends administering the Stanford Profile Scales of Hypnotic Susceptibility, I and II,[49] or at least one of them, and the next best assurance that the patient is in a hypnotic state would be to use a score of 10 as a cut-off on SHSS:C.

Lynn, Council, and Green[56] outline various hypnotherapists views on assessing hypnotizability levels. Many[48] object to the use of such tests, stating that they are obtrusive, undermine the therapeutic relationship, and do not adequately measure hypnotic capacity or take into consideration change in hypnotizability over time. Other options to using tests are to assess the patient's success with the first induction[57] or to use a conversational assessment of hypnotizability.[58] A series of questions can give the clinician a good idea of how easy it will be to get a patient into a hypnotic state; for example, questions about past hypnotic states or trauma, dissociative tendencies in various realms of life, right/left brain characteristics.

A scale that may be informative to a psychologist treating pain patients is the Tellegen Absorption Scale,[59] a 34-item true-false test that correlates well with hypnotic susceptibility. Wickramasekera[60] found that patients scoring high on absorption scales or tests of hypnotic susceptibility and also scoring high on neuroticism as measured by the Marlowe-Crown[61] were more likely to develop psychosomatic pain or symptoms, by dissociating traumatic or undesirable experiences and converting them into somatic symptoms or pain, creating what Damasio termed "psychological markers." Wickram developed a 25-item scale to be used to identify patients who were more likely to somatize. He points to the neural flexibility and "ideational fluency" that Gruzeleir[16] suggested was related to a propensity to dissociate that can leave one vulnerable to schizotypy, affective distress, mood disorders, and somatic markers or memories that stay beyond conscious awareness. In simpler terms, highly hypnotizable patients are more likely to create a somatic marker for a psychological event, and are more likely to trigger a memory of previous pain when they experience a new pain.[44] A meta-analysis[62] shows classic, modern, and mixed forms of hypnosis to be effective for treating psychosomatic disorders (those which meet the criteria for somatoform disorder), which would include both hypersensitivity to pain, hyperawareness of symptoms and to body processes in general, and the transduction or conversion of emotions and memories into somatic markers. This is remarkable given the range of disorders and symptoms including: tinnitus, duodenal ulcers, asthma, irritable bowel syndrome (IBS), osteoarthritis, chronic pain, and dyspepsia. Also, DuHamel et al.[63] found that their high hypnotizable burn patients had significantly more intrusive avoidance and arousal symptoms with their injury-related trauma. Roelofs, Hoogduin, and Keijsers[64] showed that they could use hypnosis to induce catalepsy and altered perception of the cataleptic limb in high hypnotizable subjects, suggesting the formation of conversion disorders or psychosomatic illness. Younger et al.[65] show a linear correlation between hypnotizability and somatic complaints commonly assumed to be of a psychosomatic nature.

CURRENT RESEARCH AND APPLICATIONS OF MEDICAL HYPNOSIS FOR PAIN

The applications of hypnosis to medicine are numerous and go beyond the scope of this chapter, as not all involve pain; Table 84-1 outlines common applications of hypnosis in medicine in general. Information on the effect of hypnosis on emotional pain and on physical pain, related or not to medical conditions, is undoubtedly not best found in the medical research, but rather in books, articles, and trainings offered by the clinicians who regularly use it but who are not researchers. This is in part because every effective hypnotherapy session is, in research terms, an N of 1. However, research in hypnosis and its clinical use in medicine are increasing, due to the recent surge in brain research and the increased understanding of what pain is, and due to increased attention to the number of the people in chronic pain and in health care utilization and costs. Hypnosis research is important because, without published results, it is difficult for hospitals and insurance companies to justify reimbursing and endorsing its use in medicine.

Earlier research on psychological treatment of medical conditions often compares such treatment to standard care practices with and without the addition of cognitive behavioral therapy (CBT). CBT often consists of a standardized program that is more applicable to research than hypnosis. CBT differs from hypnosis in that the therapist intends to speak directly to the patient's cognitive conscious mind, without deliberately sending any direct or indirect messages to his/her unconscious. A hypnosis session may likely include behavioral suggestions in and out of trance, and messages to the conscious and the unconscious mind at the same time. Both may include homework. Kirsch, Montgomery, and Sapirstein[57] looked at 18 studies of CBT with and without additional hypnosis. The addition of hypnosis to CBT substantially enhanced treatment outcome, such that the patients who received additional hypnosis did better than 70% of those with just CBT treatment. In most cases the authors mean CBT administered in the medium of hypnosis.

As we go on to discuss the research on medical hypnosis, there

TABLE 84.1

COMMON APPLICATIONS OF HYPNOSIS IN MEDICINE

Headaches	Smoking cessation
Muscle cramps	Eating disorders
Pain disorders such as CRPS	Perioperative preparation
Chronic diseases	Post-operative pain and recuperation
Burns	Allergies
Minor procedures – analgesic or anesthetic	Wound care
Colonoscopies	Hypertension
Blood drawing	Chronic disease management
Dentistry	Cancer related anxiety and depression
Surgery – anesthetic	Nausea and emesis
Cancer	Dental and needle phobia
Labor and delivery	Skin rashes and warts
Bone growth and healing	Immune and autoimmune disorders

are some points to bear in mind. First, we expect there to be quite a difference between the methods and benefits of hypnosis in clinical practice and the process of studying it in research. We must assume that clinicians in their office would not exactly follow a research protocol, and that they would modify even a hypnotic script to fit their patient's situation. Also, pain hypnosis is used primarily for chronic pain, less often for procedural and least for surgical pain, where hypnosis is usually used as an adjunct to medicine. Under strict standards, for hypnosis to be considered the dependent variable in research, it must deliver suggestions that could not be just as well delivered to the patient cognitive-behaviorally (as in telling the patient what to do). However, some highly hypnotizable or well-trained patients have ready access to the unconscious mind and absorb even a CBT message quite deeply or literally; a good example of this is the patient who testifies that they always gets all the side effects mentioned on the inserts of their medications. Finally, most patients in severe pain or in traumatic conditions are already in a trance and in a manner of speaking hypnotized, so that the comparison between CBT and hypnosis is muddy at best. In effect, the strict standards of the research may dilute the power of hypnosis. Fortunately, clinical success with hypnosis does not depend wholly on the results of research studies.

Efficacy and Effectiveness

To move the practice of hypnosis in medicine along, research on effectiveness (how hypnosis works in the real world, in quasi-experimental design) should be as methodical as the research on efficacy (how a technique works within the controlled research situation).[66–69] A 1982 article[70] reported skepticism about the effect of hypnosis on pain due to the lack of controlled studies comparing hypnosis with credible placebos or other treatment methods. Hawkins[71] updated that article with a review of research articles up to the year 2000, and was able to conclude that hypnosis is effective for pain related to cancer, burns, gastrointestinal problems, and for invasive medical procedures. He also noted that poor-quality reviews were not more likely to produce positive conclusions about efficacy, and that there was a paucity of good studies in the areas of obstetrics, headache, and chronic pain. Montgomery, DuHamel, and Redd[8] did a meta-analysis of pain analgesia studies using healthy subjects and patient samples and taking into consideration hypnotizability levels; they concluded hypnosis to be effective in both arenas for 75% of their population. Hypnotic analgesia compared favorably in effect to standard care and to attention.[72] Hypnosis has compared favorably to empathic attention[73] and to autogenic training (AT) for psychosomatic and medical disorders.[74] Yapko,[48] however, suggests that AT is in itself a hypnotic induction and that the comparison of the two treatments presents a problem.

The research process itself raises some concerns. One is that research studies focus on the precise content of the intervention, not how it can be flexibly adapted to the real life patient situation. Another concern is the outcome measure itself: we intend for patients to be noticing pain less, but then we ask them to tune into it and rate it at the end of the study. Also, many studies do not account for hypnotizability, which would color research results. Another issue is expectancy—the patient's expectation that hypnosis will resolve their pain—which seems to predict pain relief. Jensen and Patterson[75] suggest that most of hypnosis studies lack adequate controls for expectancy and placebo effects, even though the studies find that hypnotic analgesia is effective in treating chronic pain. Clearly, raising the patient's expectancy is a good thing, as are raising their levels of self efficacy and curiosity about finding new ways to cope, and encouraging the placebo effect. A study looking at changes in various psychological responses to pain postoperatively and after 3 months found hypnosis to be effective; the positive effect was not significantly related to hypnotic ability, concentration of treatment (e.g., daily vs. up to weekly), or initial response pattern to treatment, but it was moderately related to the participants' expectancy ratings of treatment after the first session.[76]

All of this being said, Amundson, Aladdin, and Gill[77] point out that research probably underestimates the effectiveness of clinical hypnosis. Many are concerned about the randomized controlled trial (RCT) approach to hypnosis research that is so distinct from the patient-centered and cooperative relationship based nature of clinical hypnotherapy.[78,79] Clinical one-on-one hypnotic sessions take a patient's unique issues and personal variables into consideration, and scripted or standardized protocols cannot address the psychological and emotional issues intertwined with the pain. Spiegel and Kahn[80] discuss the difficulties inherent in using an outside hypnotherapist as the interventionist in research or therapy, which lacks the all-important therapeutic relationship; they also point out that the relationship between the hypnotherapist and the treating physician is important. It would seem that hypnotic protocols would be most effective when designed for each patient by a therapist who is interactively responsive to the patient; according to one extensive study, 30% of therapy outcome is based on the therapeutic relationship, even when the treatment is medication, while another 15% is due to expectancy.[81] Nonetheless, research showing the effectiveness of hypnosis must be stringent if it is to be widely available in medicine and adequately reimbursed by insurance companies. In fact, when comparing the delivery of hypnotic analgesia with the hypnotist present, manualized protocols, standardized audiotapes, or individualized audiotapes (as would be prepared for patients in clinical practice), a meta-analysis indicates that any delivery is better than none[82]; however, since clinicians understand the importance of being fully present and flexible in a hypnotic session, more research in this area is needed. Interesting delivery formats are now on the horizon. Patterson, Wiechman, Jensen et al.[83] have attempted to improve absorption that may be missing with audiotapes by creating virtual reality (VR) computer-based presentations that immerse patients in a three dimensional computer-generated environment, to absorb the patients' attention and divert it away from the pain experience. VR induces and sustains a hypnotic state without a therapist. Questions arise as to whether this intervention satisfies the research definitions for hypnosis, and whether the same effect could be accomplished by naturalistic absorption or with audiotapes alone.

Here is an example of a clinical application of hypnosis that is distinct from a research protocol. A female patient in her 30s had been extensively evaluated for her deep, sharp right side pelvic pain that came on for 15 to 20 minutes as often as every hour, even during the night. She rarely had pain when she was on birth control pills, other than after sexual intercourse. There was a small area of endometriosis, successfully removed, and one cyst that ruptured, but otherwise no diagnoses explained the pain. She and her husband were anxious to be off birth control pills in order to conceive, and she also exhibited generalized high vigilance. She asked a hypnotherapist to help find any unconscious motivations for the pain. She is highly hypnotic and motivated, with high expectancy. The therapist worked interactively with her on a wide range of techniques to find what worked uniquely for her in managing and accepting the nerve pain, which she practiced self hypnotically at home. Hypnosis helped with vigilance, and therapy helped other issues about trust. The therapeutic relationship supported the work on hyper vigilance, trust, and specific fears that related to pregnancy.

Clinically, and in research, even when patients do not receive pain relief with hypnotic analgesia, they seem to receive satisfaction from the sessions. Jensen et al.[84] reported that out of the benefits listed by subjects in their pain hypnosis study, 23% reported pain-related benefits as the reason for satisfaction, 58% reported other than pain benefits, 13% were neutral, and

8% reported a negative experience. Subjects cited increased sense of control and positive shifts in perspective, with no subjects reporting dissatisfaction. Dawson et al.[85] have said that pain treatment satisfaction in general has more to do with the provider–patient relationship than pain-related outcomes.

We will briefly mention two other variables. Both direct and indirect hypnotic suggestions for pain or symptom relief seem to be effective (e.g., progressively relaxing muscles versus imagining lying on a beach at a peaceful island, which would warm and relax muscles). In regards to whether hypnosis is more effective when labeled as hypnosis or introduced using other terms, Jensen and Patterson[75] concluded that in the short-term there is probably no difference, but over time, there may be a benefit for the patient in attributing improvement to hypnosis or self-hypnosis.

Review of Research Studies According to Pain Problems or Situations

Research on hypnosis has waxed and waned over the years and varied in focus. Many of the new studies are physician driven and are looking for nonmedicinal, noninvasive self-management treatments that improve medical outcome. Even though pain is common to most medical disorders and procedures, each carries its own unique cluster of symptoms and might indicate a different psychological or hypnotic approach for healing and management, differing lengths of treatment time, and varying depths of trance. Research and clinical reports show the importance of matching the appropriate protocol to the type of pain experienced.[86] The following sections will outline recent research on hypnosis when used as one of the treatment modes, grouped according to medical condition. Under each heading, research findings, primarily since the year 2000, are followed by some suggestions and techniques for use in clinical practice. Most of the articles address acute and procedural pain. Hopefully, the sections will serve as a background and a resource for hypnotherapists and clinicians, and for those planning to embark upon such medical research.

Perioperative and Procedural Uses

As described previously, hypnotic analgesia was first reported as successful in surgery before there were any chemical anesthetic alternatives. In this century, while there are sporadic reports of its successful use as the only anesthetic,[87] it is now most often used as an adjunct to chemical anesthetics or to analgesics. Studies have looked at improved well-being or enhanced healing and recovery time after surgery or procedures and reduction in hospital costs. Hypnosis successfully targets a number of surgical and postsurgical variables, such as anxiety, blood pressure, and patients' sense of control over their feelings[88]; pain, nausea, vomiting, blood loss, wound healing[89]; pain, knee strength, edema, inflammation, and postsurgical anxiety after anterior cruciate ligament (ACL) surgery[90]; both objectively and subjectively rated healing, when level of hypnotizability was controlled[91]; postoperative anxiety and pain level, even after a single session of hypnosis before surgery[92]; pain and distress, where the effects were mediated by patient expectancy[93]; shorter hospital stays; and less parenteral narcotic use.[94] A study showed hypnosis to lessen procedural pain and result in a speedier medical procedure; positive results did not correlate with hypnotizability, possibly because the hypnotist facilitated self hypnosis before and during the procedure, such that subjects received individualized treatment.[95]

Three studies used hypnosis as it might be used clinically. Enqvist and Fischer[96] aimed to reduce preoperative stress that might influence healing and recovery from a surgery, specifically to reduce medication use, inflammation, infection, postoperative pain, and edema. Using one surgeon who was blind to the grouping, patients were given a 20 minute tape containing an induction, suggestions of finding a safe place, having control of bodily responses to surgery, dissociating, and alleviating pain. Subjects were also asked to use their chosen way of relaxing for 2 minutes, and to let soft music bring them back to awareness. In a controlled study, Dyas[97] used a conversational induction containing positive language patterns and suggestions that included counting down (into trance), relaxing breathing, finding a safe place, and dissociating from the surgical procedure; reinforcing words were used during surgery, and posthypnotic suggestions addressed continued relaxation and comfort. Another controlled study used music with or without the audio taped voice of a hypnotherapist during surgery under general anesthesia[98]; the addition of hypnosis was beneficial, and the author suggests the results would be even more significant using individualized tapes and in situations where less anesthesia is used.

Obviously both physical and emotional pain during surgery can present a problem, as pain is both traumatic and stressful and relief from it can improve healing, save money, and make for happier patients and surgeons. The most important patient variable to consider for use in surgery as the sole or primary anesthesia seems to be hypnotizability. To be sure the patient is highly hypnotizable and can go into a deep state, stringent testing should be done.[49,56] The sole use of hypnosis should be reserved for the patient who is highly hypnotizable, experienced with hypnosis, and for whom the payoff is likely to be great. Preoperative preparation for surgery described by Kessler and Dane[99] is also effective and satisfying to patients. Kessler found that the most significant variable related to the anxiety in surgery that can affect the surgical outcome variables related previously was the expectation of negative surgical outcomes, coming from previous experiences of either the patient or to those close to them; he designed a short screening questionnaire to identify patients who are in most need of hypnotic preparation (Kessler, personal communication, 1996). Subsequent perioperative hypnotic treatment can be done with any level of trance, even conversational,[58] to assure that the anxiety level regarding the procedure is optimally low and that the mind set is positive; this can speed up healing and recovery and allay concerns about procedure and recovery processes. During such perioperative preparations I have twice discovered male patients who fully expected to die because they were grieving the death of fathers who died during the same procedure or at their like chronological age; we took the time to work through those issues before surgery took place.

The most important factors regarding preparation for surgery involve positive expectancy and the positive interpretation of the surgical events and sounds the patient may unconsciously notice. The optimal protocol will include some critical details of the surgery that the patient can interpret positively: "when you feel the surgeon touch your stomach with a knife, that will be an indication that he is finding the best place on your belly for the smallest opening to allow him to remove the part of your intestine that needs to come out so that he can reattach the healthy tissue and allow your intestines to work normally again" and "when you feel a little tugging, that will be an indication that he is closing the opening with a nice line of little stitches," "since you will be hungry from not eating before surgery, you can begin to look forward to your favorite food soon after surgery," and "you can let your thoughts be on that beach you love so much, and you can listen only to sentences from your own doctor and that begin with your first name." In that way, the surgeon can request the patient to lower their blood pressure, divert blood away from the surgical site, and the surgeon can prepare the patient for any changes in the surgical plan, and even imbed suggestions to lose interest in unhealthy food or cigarettes. For a review of other "patient-friendly" terms see Bennett and Disbrow.[100]

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) is one of two pain syndromes responsive to hypnosis that are particularly interesting

because they demonstrate the brain mechanisms of pain. CRPS is a complicated condition wherein the pain is disproportionate to the injury or event leading up to it; the continuing acute-level pain has no confirmed mechanism.[101] Even when there is neuropathology, the symptoms, which can lead to muscle atrophy and bone demineralization, appear to be sympathetically driven. Treatment usually includes some psychotherapy to manage anxiety and often to disclose a series of emotional events that trigger a flight/flight or psychophysiologically defensive response. The psychological meanings attached to a nociception or to perceived pain may trigger the brain to temporarily rewrite the neurosensory map of the pain area. This in turn leads to a relative neglect syndrome of that limb, which can establish, in lay terms, a ''cry for help'' in the form of pain and distress symptoms.[26,102,103]

Treatment should include psychologically working through the incidents in the patient's life that led to the need for the defensiveness,[104,105] addressing anxiety and stress management, and counteracting the neglect of the injured limb in order to reintegrate it back into the body. This can be done using mental imagery,[106] desensitization training,[107] or hypnosis, which can accomplish all of the above at the same time. The process of neglect is a dissociative process beginning at a deep level. Given other work on hypnotizability and psychosomatic disorders, we can hypothesize that highly hypnotizable people may be more likely to develop CRPS under the right conditions, and also assume that hypnosis would more readily help them resolve the complex syndrome.

Phantom Limb Pain

The other pain disorder responding to psychologically addressing brain mechanisms is phantom limb pain. Pain in an amputated limb can come from damaged nerve endings that are at the stump or that connect with the neurons in the spinal cord. It can also come from a change in the somatosensory cortex map of the body that results either from lack of sensory input from the missing or paralyzed limb, or from a peripheral nerve injury that leads to lack of sensation.[108] This may lead to a neurological need or a cry out to find the missing limb that takes the form of pain sensation.[109]

Long before there were fMRI studies, Erickson said ''If you can have phantom limb pain you can have phantom limb pleasure''; implying the power of the unconscious mind to change the interpretation of information from the periphery or the somatosensory cortex, from negative to positive. The patient can do this with self-hypnosis or with deep trance hypnotherapy, to resolve pain by creating a more positive mind/body messaging system (to counteract pain) and a better transfer of information between the cognitive and the unconscious areas of the brain (this may counteract neglect due to changes in the somatosensory mapping). Giraux and Sirigu[110] have patients imagine that they are still using the missing or paralyzed limb to relieve pain. This is similar to the positive rehabilitative effects found when asking patients to imagine doing the physical therapy if they are not yet ready to actually do it. Flor et al.[111] had patients touch the stump for sensory stimulation; both studies[110,111] demonstrated pain relief. This works along the same lines as having CRPS patients gently stroke and soothe (desensitize) their limbs that were previously too painful to touch, in order to restore the somatosensory map that was altered due to excruciating pain.[112] Evidence for the relationship between the somatosensory cortex and pain comes from research where the somatosensory map was reorganized back to the original somatosensory map by using an electrical prosthetic limb[113] or by use of a mirror-image of the remaining limb to ''trick'' the mind into thinking there were two functioning limbs.[114] Hypnosis may also be used to accomplish the end goal of resolving the need to find the missing limb. Older and more traditional hypnotic trances for phantom pain may be found in Hammond.[47]

This author used hypnosis to assist a young college student patient who had lost his leg in an automobile accident. He felt positional pain leading him to believe that his leg was bent in a painful position under his body. First, we discussed the actual cause of the pain as a somatosensory reorganization that was his mind's first attempt to help him survive that he could now revise; this mini-lecture was partly informational and partly a hypnotic confusion technique and an induction into trance. He was guided to imagine moving the leg to a more comfortable position and then soothing it so that it would recover from the bent position. This reduced some but not all the pain. In the next session, we used a technique of connecting spiritually with the limb as a valuable part of himself.[112] He was hypnotically guided to bring his attention into his leg (''go down your leg to the injury'') and gently nurse and soothe the injury. He was guided to recognize that his leg was a valuable part of himself that he could always have relationship with (as he did with elders who had passed on) and he was guided to watch his leg go to a spiritual place to rest outside of his body where he knew it would be safe in the universe and would wait for the rest of his body in the future at the end of his life. He was then guided to visualize the perimeter (the map) of his body at present (without the leg), and to see and feel the body moving without the leg, and to practice this in his mind, free from pain. His guided imagery had him sensing himself going to class and doing in the future the things he had done in the past. This lengthy set of sessions helped with the majority of his pain; his keen focus on getting back to his life and on to his active career certainly helped him to take positive suggestions. The treatment is in line with the research on the brain mechanisms discussed previously and in line with trends toward success reported by Oakley et al.[115]

Burns

There is a relatively long history of using hypnosis for burn pain, which can be very intense for an extended period of time. Wound care procedures necessary for recovery from burns is painful as well, and pain medication usually does not cover all of the pain. Burn pain is often severe enough to evoke a negative trauma-related trance state in itself, if not shock, at the very same time that a positive mind set is important for recovery. As mentioned previously, distraction is a useful pain management technique for certain situations, but hypnosis appears to afford more pain relief than distraction alone during dressing changes. Frenay[116] also found it more effective for pain reduction than stress reducing strategies for decreasing pain and anxiety during wound care; in that study, the wording was individualized according to the hypnotherapist's observations and their judgment of the patient's clinical needs. One case study has experimented with immersive virtual reality (VR) (mentioned earlier in this chapter).[83] In that study, patients engaged in the VR during wound care; those who remained with the program enjoyed the experience, had no medication side effects, and their pain and anxiety significantly dropped with the VR.

Clinicians will appreciate the work of Ewin,[117–119] a teaching surgeon and psychiatrist who, in addition to using hypnosis during procedures and surgery, also used hypnotic imagery to prevent the symptom formation after skin is burned. He would immediately give suggestions to counteract the body's response to a burn (reddening and blistering) such as swimming in a cold stream in the evening, and he took advantage of the trauma-induced trance state after a burn incident. I used the technique for a hand burn resulting from picking up a frying pan that had been on the stove. I imagined moving my hand in a cool mountain stream visited during childhood, and when that cold was fully re-experienced, I imagined a sequence of events that included swimming in a pool that day, and moved through time to the very near future (watching TV in the next room), skipping the episode of the burn completely; I rehearsed the sequence a few

times, letting the unconscious mind do the work of deleting the burn experience. Also, to regain my body's trust and prevent avoidance or resistance in the future, I immediately telepathically sent my hand an apology and an assurance about taking better care of the hand from then on.

For debridement and healing of burns, good techniques might include hallucinating anesthesia or numbness in the area, and displacing the limb or area of the body that is in pain to another side of the room, or to a special imaginary healing place, so that the body can rest easy and be ready for its return after trance; trance can be extended by posthypnotic suggestion to last as long as is necessary. There may be a place as well for amnesia for the more painful and traumatic events of the accident, which would have to be addressed in trance individually. Trance phenomenon will allow for the conscious and unconscious minds to work together to know that an accident occurred while conveniently forgetting about parts of it, both at the same time; it is also possible for a patient to know they are being treated for an injury and to forget the pain, both at the same time.

Dentistry

Hypnosis has been successfully resolving pain and anxiety surrounding dental work for over 80 years, and was arguably used as much for dental work as for other purposes through World War II. Kay Thompson, a dentist who was also an Ericksonian hypnotherapist, pointed out potential psychosomatic element of pain in the oral cavity, as the mouth is the first infant connection to the mother, the first source of gratification, and the first experience of getting attention to one's needs (through crying).[120,121] For whatever reasons, pain in or near the head may be more likely to result in anxiety and a loss of self-control and efficacy, and patients are relatively quick to appreciate caring support and attention.

A study comparing Ericksonian hypnosis to progressive muscle relaxation tapes, education about procedures, and a control group showed the Ericksonian hypnosis group to have less anxiety about dental procedures; in the protocol, negative thoughts were restructured (the sound of the dentist drill as a suggestion to go deeper into trance) and patients were to visualize success over pain and to use age-regression to a painless time in the past.[122] A study comparing patients' pain before and after dental work offered five hypnosis sessions which included relaxation, imagery, catalepsy, analgesia, and anesthesia, with posthypnotic suggestions to patients; they were also given self-hypnosis tapes.[123] The patients showed less pain frequency and duration and an increase in daily functioning compared to baseline, even at 6-month follow-up. A study comparing educational sessions or occlusal appliances to hypnorelaxation for temporomandibular joint (TMJ) pain showed that the hypnosis group reduced current and worst pain significantly more than the control groups did.[124] Hypnosis has been shown to be an effective adjunct in dental surgery to reduce pain, pain medication use, and anxiety,[82] and pre- and intraoperative hypnosis audiotapes used for third molar extraction with anesthesia reduced anxiety and pain medication use.[96]

For surgery and procedures, a depth of hypnosis is often used wherein the patient is responsive to the dentist's requests (to open wider, close, etc.) but does not feel the procedure itself. Hypnotic suggestions may be for relaxation, for creating numbing, for going by trance to another place while safely leaving the tooth with the dentist, and for feeling pressure rather than pain. In addition to dental procedural pain and anxiety, many dentists learn hypnosis for needle phobia, gagging, bruxism, saliva control, and TMJ, all of which will necessitate specific suggestions.

Pediatric Pain

Children are in general more hypnotizable than adults for a number of reasons. They have much richer fantasy lives, are relatively more curious, and are encouraged to use imagination in play; there are fewer parameters and fixed interpretations of the world in general, as they are still learning and are relatively trusting of adults and authority. Critical thinking develops as the brain matures, and it is only in adolescence where society demands more realistic and responsible thinking. In general, peak hypnotizability may be as late as latency (8–12 years of age), when children are the most open-minded, curious, imaginative, and willing to suspend judgment and when they are reasonably knowledgeable. Learning pain management and self control early can help children tolerate medical procedures (shots, fracture settings, etc.) and eliminate negative associations to pain that may remain with them as adults. Children are not reflective thinkers, and so they are more likely to be psychosomatic in their presentation of emotional or situational problems; the bank of literature on childhood stomach aches tells us that for them, stomach aches may be a benchmark for distress that may otherwise go unexpressed.

Training in self hypnosis improved children's functional abdominal pain 80%,[125] and self-hypnosis tapes improved the respiratory functioning of anxious children in a pulmonary center by 95%.[126] A prospective controlled trial explored the efficacy of adding self-hypnosis training to the use of analgesic cream for lumbar puncture-induced pain and anxiety in 6- to 16-year-old cancer patients[127]; the additional hypnosis led to a decrease in anticipatory and procedure-related pain and anxiety. A retrospective study found a significant decrease in self-reported pain intensity, duration, and frequency of headaches, with no adverse effects, after adolescents were taught self-hypnosis.[128] An hour of self-hypnosis training given to children, along with instructions to practice several times a day, led to less stressful and speedier urological procedures, by both parental and staff report.[129] Manual-based clinical hypnosis has been found more effective than distraction,[130] cognitive-behavioral treatments,[131] and play and distraction.[132] Hypnosis can also help children undergo acupuncture.[133] However, reviews of the research still found hypnosis to be not robust enough to fall within best practice guidelines for managing procedure-related pain in pediatric oncology;[66] several researchers call for more randomized control trials for the clear-cut benefits of hypnosis and other psychological interventions to be shown, although no studies refute the likelihood that it is beneficial and shows a better side-effect profile.[134–136]

Designing trances or trance experiences for children will of course involve taking their developmental age into consideration, as well as the degree of trauma and fear involved in what they will be experiencing. First, it is important to remember that children are highly suggestible, and are still vulnerable to trauma long before they can understand its context or verbalize their problem. On the other hand, even babies can be lulled or stroked into a soothing situation and be spoken to in reassuring words, songs, and sounds. Olness and Gardner[137] suggest framing therapeutic suggestions and stories in the context of what they know, such as bubbles, pop-up books, dolls, and stories, and utilizing story book figures as the characters of the stories. Nature, favorite pleasant places, cars, magical travel, music, and repetitive action such as ball bouncing or yo-yo tossing can be used in inductions. For adolescents and older children who are more interested in relationships, stories and images could include peer groups. All aged children may be quite intrigued with some of the classic induction techniques such as the pendulum, arm levitation, and the coin drop. It is particularly important to speak to the child in language he/she can understand, to consider play as a way to make the experience more pleasant, and to speak with a tone of voice that allows the child to feel supported and respected, and to add suggestions about self control and self-efficacy and safety. For detailed discussion of hypnosis with children, see Olness and Kohen.[138]

A case example is a 13-year-old patient who broke his nose while playing baseball; his mother brought him to a facial trauma

doctor I was working with at the time. Concern for his anxiety was relatively great since the same surgeon in the same hospital had previously done surgery on the youngster's throat after a near-fatal small airplane crash. Before trance, any fears or discomfort were discussed so that he would be safe in the procedure room. As the room was being set up for him, we discussed any of his concerns and his baseball game. I hypnotically coached him to go back in his mind to complete the game as he wanted it to end, and along the way, and I suggested to him that he could forget about whatever parts of the whole afternoon that would make him more comfortable, and that he did not need to remember. I gave him permission to suggest to me how to make the experience safer and more comfortable for him. He proceeded to ask one resident to leave, because she was talking about trivial personal issues and not paying attention to his procedure. To our surprise, when the patient woke up the next morning, he removed all the bandages and packing and went down to breakfast without mentioning or questioning the bandages or the hospital experience, but he did remember some pretty girls he saw on the way there. Since that incident, the author includes suggestions to follow his doctor's instructions, so that any necessary aftercare does not also go by the wayside!

Irritable Bowel Syndrome

Most IBS patients have low thresholds of pain in their bowels, along with abnormal autonomic nervous system functioning and considerable symptom discomfort.[139] Hypnotherapy has been shown to improve pain, autonomic symptom dysfunction, and well-being,[140] even at follow-ups beyond 5 years.[141] The Manchester Model[142] hypnosis protocol has been consistently effective for treatment of bowel and other physical symptoms, depression, and anxiety[143,144]; improvement in symptom scores is associated with improvement in IBS-related thoughts.[145] When Palsson's North Carolina hypnotic protocol[146] is administered to IBS patients, their daily diary reports show an approximate 50% reduction in pain.[147] In a study comparing the North Carolina protocol[147,139] administered with the manual presentation versus with individually tailored presentation, the manualized induction group had less emotional stress after the treatment, but the individualized induction group continued to improve and did better at 10 months than the group who received the scripted trance, and showed less emotional distress.[148]

Hypnotic suggestions to improve gut symptoms and IBS pain can include those to warm hands, progressively relax, move attention away from gut symptoms, and to calm and comfort the gut, in addition to suggestions for enhanced overall well-being, self-efficacy, self management, and control. The North Carolina protocol is lengthy; it includes all the previously listed elements and also suggests dissociation away from the pain and to a carefree place. This appears to break the cycle of pain, and patients reset their perceptions of pain. The protocol includes seven scripted, therapist-guided sessions and an audiotape for home use. The Manchester Model[142] now has 12 scripted sessions and an audiotape for home use; the scripts include suggestions to warm the hands and transfer the warmth mechanically to the gut, for control and normalization of gut functions, as well as suggestions for ego-strengthening and self control in handling IBS symptoms.

Headaches

In general, migraine, tension, and mixed headaches respond to hypnosis.[149] Migraine headache frequency, duration, and severity decreased in one study when patients were given one group hypnosis session and 12 weeks of follow-up with hypnosis audiotapes.[150] Tension headache pain, vitality, and mental health improved when patients were offered guided imagery audiotapes.[151] There have been many comparisons of autogenic training (AT) to hypnosis for headache control. AT focuses specifically on relaxing muscles, which is in part what hypnosis would address, so that similar effectiveness is expected. Studies show AT to be more effective,[152] less effective,[153] or equally effective for headache pain.[154] Both treatments seem to help patients perceive more self control of pain[155]; improvement in pain scores seems to be related to hypnotizability, and formal hypnosis with a formal induction seems to improve the chances of success.[153]

To treat a headache it is usually important to know whether the patient has tension, migraine, or cluster headaches. For tension headaches, direct suggestions could be to breathe in and out through the skin in the head and neck, to loosen the scalp, to let the hair fall naturally directly from the scalp, or to cool or warm the inside of the head (depending on the type of headache). Indirect suggestions might be to imagine being in a relaxing place or in a cold place, with cool wet rag at the neck. For migraines, Gibbons[156] suggests diving into water, as this lowers blood pressure and heart beat and may alleviate circulatory congestion in the head. Suggestions for cold (skiing, hiking in the snow) may also be helpful. Patients may also constrict blood vessels by imagining them to become tight, cool, and narrower. Tension headaches may respond to suggestions that help to open the blood vessels, such as warm climates, relaxation, or warm water. Hammond[149] finds self-hypnosis effective for tension headache management; he suggests that patients who report daily morning headaches may respond well to the use of self-hypnosis tapes at bedtime, which aim to allay tension while they are sleeping.

Cancer

Caner pain may be distinct from other long-term or chronic pain, in that changes or increases in pain may trigger end of life concerns, grief, depression, and anxiety. In addition, there are very often painful and bothersome side effects to cancer treatment, such as nausea, vomiting, tissue or nerve damage, weakness, and fatigue, many of which respond to hypnosis quite well. The feedback loop between diseases such as cancer, negative cognitions, and suffering are discussed elsewhere, as is the effect of stress and distress on immunosuppression, which can compromise patients' recovery times and resistance to secondary illnesses.

Hypnosis is particularly effective in reducing stress through direct and indirect suggestions to relax, and through enhancing patients' sense of self-efficacy and self-control. Spiegel and Bloom[157] showed positive effects with hypnosis in terminal cancer patients, possibly including giving patients a slightly longer lifespan; the latter benefit was not replicated in the recent study, possibly due to the improved medical treatments that extend the lives of all patients who were subjects.[158] This does point out the importance of alternative medicine therapists ensuring that patients are not discounting or ignoring medical care.

A number of studies compared hypnosis to cognitive behavioral therapy (CBT) for control of cancer pain. One showed bone marrow transplant patients to benefit more from hypnosis than from CBT or attentional control, as they had less pain at worst times, and for shorter durations.[159] Other studies show the benefits of hypnosis over CBT for pain, anxiety, and overall distress.[93,130,160] A prospective randomized study with advanced stage cancer patients showed that a manualized presentation of four weekly hypnosis sessions with addition audiotapes for home use significantly decreased pain; suggestions were comprehensive, including relaxation, comfort, dissociation, and more specific pain control techniques.[161]

Quality of life is particularly important with cancer because end-of-life patients may have grieving to do as well as personal, relationship, and spiritual business to tend. To address this, one study randomly assigned patients to 10 minute self-hypnosis audiotapes teaching either progressive relaxation (a passive coping strategy) or breathing exercises (an active coping strategy), to be used three times a week.[162] Positive attitudes increased and negative attitudes and anxiety decreased in both groups, with more improvement shown with the active coping strategy; this

may have had to do, again, with perceived self control. Quality of life, particularly vitality, improved for metastatic breast cancer patients who were given 4 weeks of self hypnosis training, in comparison to those offered 4 weeks of training in a Japanese healing method called Johrei and to wait-list controls[163]; both treatment groups improved in mood and anxiety scores. Other studies have shown quality of life improvement for cancer patients using hypnosis.[164,165] The latter study's protocol looks similar to what might occur in a clinical setting; it offered four 30-minute sessions of hypnosis weekly, using traditional inductions and individualized suggestions for symptom management and ego strengthening. Hypnotic suggestions that foster or support existential, religious or other beliefs about life after death for patients, and for those who socially support them, might be given early in treatment.[166]

Osteoarthritis

The research literature on the use of hypnosis with arthritic pain is sparse. One study found Erickson hypnosis to compare favorably to Jacobson relaxation and control conditions for treatment of osteoarthritis pain.[69] Pain relief was directly related to imagery and hypnotic susceptibility, but not to expectancy. Hypnotic suggestions addressed relaxation, positive imagery and age regression to a more comfortable time; the authors used the words of "mental imagery" rather than "hypnosis," and the words "pain" and "analgesia" were not used.

Clinically, suggestions to alleviate arthritis pain may include warm water, warm blankets, warm sun, and stroking the area with arm hands. Also, suggestions to initiate moving arthritic parts or walking while exhaling and to keep the breath flowing, can alleviate unnecessary tensing. The patient may self-hypnotically rehearse moving the arthritic area, thereby limbering the body before actually moving, to help the mind and body work together. Patients might move around while keeping in mind the image of themselves at a much younger age and at pain-free times. They might also focus more intently on the *goal* for moving (specifically what they will do on the other side of the room once they get there) rather than on the sensation of moving. Time distortion to a pain-free time in the past or future, and getting involved with increased focus on what they are doing, may also distract them from physical feelings. Other suggestions might be to let go of the sensation of gravity in the body, and to lighten their steps.

There are references to anger as a psychosomatic link to some arthritis pain. As with other emotional links to pain, hypnotic treatment is likely to be even more successful when such psychological or emotional components are addressed. Often, defensiveness or fear underlie the anger and can lead to body tension; the extent of this would be relatively easy to discover during the very important pretreatment assessment.

MEDICAL HYPNOSIS TECHNIQUES

Principles of Preparation, Induction, and Suggestions

The traditional hypnotherapy session may be divided into four phases: induction; a period of deepening involvement of the unconscious mind while lessening involvement of the conscious mind; the therapy itself; and then a gradual transition back to conscious awareness. Beforehand a pretreatment assessment should include learning the patient's analogies or metaphors about the pain (stabbing, slicing, cold, daggers, or tingling) and learning what the pain means to the patient in terms of suffering, insult, guilt, religious beliefs, associations to past traumas, future expectations and fears, and social, cultural, or familial losses. That information will help the therapist know the extent of the patient's fears and concerns and the nature of their suffering, and determine the appropriate therapy and support that is needed. It will also tell the therapist what specific words or metaphors to use in their messages and suggestions to the patient, and what overall approach to use. The better the therapist understands the mechanisms of the unconscious mind, particularly where pain, stress, and memories are concerned, the easier it may be to do effective pain management work.

Ethics for using hypnosis are even more stringent than when using other psychological techniques, in that trances allowing access to unconscious processes can potentially leave the patient more vulnerable. ASCH guidelines also include preparing the patient for hypnosis by dispelling myths about what hypnosis is and is not, advising them of what they might experience, and ensuring that hypnosis is not against their religious beliefs or that it will not violate safety boundaries; this protects both the patient and the clinician. They should know that the therapist will not shield them from any pain they should keep in order to protect themselves; it is sometimes best to allow patients to keep a certain small percentage of their pain, and to recognize any pain that they might need to address. Patients should be advised and comforted to know that the therapist is guiding them into a condition of self-hypnosis, and is not *doing* hypnosis *to* them. They should also be advised that everyone has their own level of susceptibility that is independent of intelligence and emotional or moral fortitude, and that can vary according to day or time. They should also be given permission to stop the session and to talk to the therapist whenever they need to do so.

One variable to consider is the level of involvement in treatment the patient desires. Some patients are proactive in their treatment and cope best by knowing everything there is to know about the process and prognosis, while others avoid knowing the clinical details. Giving the patient the amount of detail he or she wants to keep them comfortable will help in keeping good rapport. In one study, researchers found that over time, patients who attributed the pain control to themselves did better with pain.[155] For the benefit of positive expectancy, using the word hypnosis may benefit the patient outcome, because some patients prefer handing over the pain management to the clinician (as in the often heard phrases "Just hypnotize me and make me stop [smoking] or [eating] so much." That mindset signifies an external locus of control, which is not a good indicator of pain management in general or for therapeutic success; however, it may indicate success with hypnosis in that the patient may be willing to suspend vigilance with little resistance.

It is best to provide a quiet, pleasant, and emotionally safe space for the hypnosis sessions, which, of course, may be compromised in many clinical, surgical, and emergency settings. Again, the most important element is the patient/clinician relationship, and there are techniques health care providers can use to gain rapport and help anxious and traumatized patients relax in emergency rooms, operating rooms, and busy clinics (see http://www.anodyne.net). In the clinical setting, proper posture helps patients truly "let go" and relax; they may do best when sitting with both feet on the floor and with hands resting on the knees, so that they are not likely to fall asleep but they do not have to work at balancing. An emotionally safe one-on-one session would facilitate the patient's recovery of memories and hidden associations to the pain. Setting up positive expectancy, including the clinician's and the rest of the treatment staff's positive belief in success, also improves the success of hypnosis; this is the variable that confounds many research studies, according to Jensen and Patterson.[75]

Styles of hypnosis vary depending on the preferred approach of the therapist, the context, and the needs of the patient. Research indicates that all therapy techniques work more or less equally well, and that the most effective is the one the therapist feels most comfortable using, as they direct their attention to-

ward the patient's chosen outcome and remain flexible about changing approaches as the patient's needs change.[167] In hypnosis, the patient is suspending vigilance and giving over access into his or her unconscious mind, so that the onus is on the therapist to choose words carefully and to maintain the safe therapeutic space. That being said, the inductions, certainly the messages, and the length of the sessions will necessarily differ according to the circumstance of pain—chronic, acute, surgical, or trauma-induced pain. Emergency situations are often best handled with a very direct authoritarian approach. In emergencies and where pain is suddenly acute, the patient may be anxious and may want someone to take charge, and they may need suggestions for quick relief; indeed, the pain and trauma involved may already have induced a trance state. Depth of trance is not necessarily related to outcome; the purpose of the trance is to get suggestions to the unconscious mind efficiently, and hypnosis aims to facilitate that at whatever level. Hypnotic anesthesia for surgery demands a deep trance and a longer induction. For other medical procedures where the patient is to be conversant (such as with epidural injections or spinal cord stimulator placements or brain surgery), a lighter trance may be in order. Light trances may allow patients to observe and learn self-hypnosis, while the therapist can gain information on how the work is going and even explore sensations in the pain area to gain more diagnostic information. Conversational trances can occur when the therapist establishes very good rapport with the patient, when the patient is already in an altered state of mind, and when the therapist talks directly to the unconscious mind using hypnotic language and techniques (for example, the Ericksonian techniques described later). Hypnosis may bring up unexpected memories or associations that should be addressed and resolved when they occur or when they are recognized; this might necessitate varying levels of trance during the session.

Common Induction Procedures

Inductions can be done conversationally, naturalistically, using rituals or chanting, by directing the patient inward, or by using objects such as a coin or crystal on a chain. In general the induction involves fixating or narrowing the patient's attention and deepening their involvement while at the same time suggesting dissociation from conscious awareness of the field. Good rapport-building skill and the use of hypnotic phrasing and words allow a seamless transition from induction into therapy. Therapy can begin during induction or after the patient is at the necessary level of trance.

A number of classic induction procedures are often taught in hypnosis training:

- Chiasson induction: The patient is asked to hold their hand out in front of them, and to notice their arm or hand move slowly toward their face. The therapist suggests that the patient's eyes feel so heavy that they want to close. When the hand comes closer to the face and as the fingers open, trance will also occur.
- Reversed arm levitation induction: the patient starts with their arm out in front of them, and as it slowly drops to the table (lap, chair arm) and rests there, they will go deeper into trance.
- Catalepsy induction: the patient holds the arm out in front of them and is given the suggestion that they will lose the feeling of it being there and that they will not be able to move it.
- Chevreul pendulum technique[168]: the patient holds a shiny object at eye level, and has their eyes follow the swinging movement; the therapist suggests that the arm is getting tired and will slowly sink to the table. The moment the pendulum hits the table, the patient will go deeper into trance and may close their eyes for comfort.
- Coin technique: The patient holds a coin in their fist out at arm's length. The therapist may suggest that the coin is a balloon that expands, so that the hand opens; eventually the coin drops, which the patient knows is the signal to enter into trance.
- Magnetic hands: the patient holds two hands out in front of themself, with the suggestion to watch how they slowly come together like magnets, eventually touching one another, which is the invitation into trance.
- Imagery induction: The patient is asked to go in their mind to a personally ideal, specific place or location and to hear, sense, smell, and totally be *in* the setting.
- Going down a staircase: The patient is guided to walk slowly down a flight of stairs (often 20); as the therapist talks, inducing trance, the therapist will imbed a count-down of the number of stairs until the patient gets to the bottom, when they will drop into trance. The lead out of trance will be to reverse the numbers (from 0 to 20) as the patient walks back up into the conscious mind.
- Progressive relaxation: The patient is guided to relax muscle groups progressively, starting at their feet and working upward or starting at their head and working down. The advantage of this technique is that it is easily used self-hypnotically.
- Eye fixation: The patient is asked to watch something intently until they cannot anymore, and when the eyes decide to close they may go into trance.
- Rapid eye roll[169]: The technique is also an indicator of hypnotizability. The patient is asked to take a deep breath and hold it, then to roll the eyes upward to look into the top of the eye sockets, then to close the eyes, as the patient slowly breathes out, they will relax into a trance.

When there is a sufficient level of trance, therapy can continue to help the patient feel better and give them tools to forget pain, change the perception, put it into perspective, or view the sensations constructively.

Suggestions and Imagery

The link between thoughts, feelings, behaviors, physiological state, and pain can allow any of them to change when any of the others does. Curiosity and imagination can be essential keys to change, and change can happen for the patient when they imagine that they are in the state of mind or body that will allow the change to occur. For instance, when I want to be relaxed, I can imagine being at the beach, to put me in the right frame of mind, or I can go to the beach. If I want someone to like me, I can imagine that they already do, to show them how to treat me. If I want to dance gracefully, I can imagine myself gracefully gliding across a dance floor, to access body memories. Body states, behaviors, and feelings are modified more easily in trance than out of trance. When the patient uses their own images, those images are more likely to be relevant and more likely to be successfully used in future self hypnosis sessions. To encourage dissociation away from the body, the suggestion may be a very detailed trip up in the air in a balloon, off into the clouds, on a row boat in a magical lake, on a magic carpet over a peaceful place, up on a mountain top, or down on a beach. Any of these can help move the focus out of the here and now and out of the body. Turning inward, but still dissociating away from pain, suggestions might be to take a journey from the top of the spine all the way down the back to the sit bones,[170] to go inside the organ or area of the body that has pain and do something soothing, (expand the space, add a healing potion, stroke the inside walls of the area) according to the patient's image of the pain problem,[171] or to go into (working with) the inner workings of the brain to change the interpretation or sensation of pain.[172] All these utilize the complementarity principle, to be discussed below.

For hypnosis to be effective, the message or suggestion needs to go (1) from the conscious to the unconscious mind, reflectively or by self-hypnosis; (2) directly to the unconscious mind while the conscious mind is in deep trance; or (3) indirectly to the unconscious mind by confusing the conscious mind or by some otherwise subliminal technique. Techniques to do the latter include (1) imbedded commands (If **you** are like me you **will feel** that the couch is **better** than the chair for going **in**to **trance**); (2) suggestions of dissociation (‘‘While you are aware of the pain at a conscious level, your unconscious mind is already beginning the healing process all by itself without you having to do anything’’); (3) the ‘‘yes’’ set, wherein the therapist says a series of truisms the patient will endorse, and then presents the therapeutic message that the patient may have otherwise doubted (‘‘You did well last week and you did well yesterday, and you are doing well now, and you will continue to do well tonight as well’’); (4) implied causatives, which assume that when the patient does **A, B** will follow (‘‘Whenever you begin the healing you will probably notice the pain that leads to the automatic healing responses in your unconscious mind that know how to resolve pain all on their own’’); and (5) confusion, which forces one to suspend the conscious mind so as to think through and resolve the cognitive conflict the confusion created (see Erickson section later). Direct versus indirect style of suggestion is exemplified by whether the patient is told, for instance, to ‘‘Lower your shoulders’’ or ‘‘Take the creases out of your forehead’’ as opposed to ‘‘You may remember the pleasure of a very warm shower on your back and shoulders at the end of a winter day’’ or ‘‘If you have ever had a soothing massage, would your shoulders remember that now?’’ and ‘‘Does your forehead remember how it was so smooth when you were a baby, sleeping peacefully in your cradle?’’ or ‘‘As your eyes slowly begin to close, it is as though you can feel the day’s tension roll right down your face, from your hair and all down over your chest and onto the floor in front of you.’’

The unconscious operates more in machine language than the sophisticated conscious mind, so keeping language extremely simple, using metaphors and sparing words, is usually more effective, unless you are accessing the patient’s unconscious mind by using a confusion technique, imbedding two conversations and hidden messages at the same time, or creating a state of boredom so that the patient will go deeper into unconsciousness. Whatever the purpose for the trance, it is usually a good idea to add in suggestions to enhance self-esteem and self-efficacy. *Convincers* can assist the effect of therapy by raising the patient’s level of positive expectancy that hypnosis works. Traditional ways to do this might include glove anesthesia, wherein the therapist guides the patient to create numbness in one hand, catalepsy or the arm raise as discussed previously, or simply calling attention to the lost sense of time that occurs during trance. Finally, *fractionation* involves changing the patients’ depth of trance, coming out and back into trance, which effectively deepens the trance; may make the trance more effective and may show the patient that he is an interactive partner in the process.

For surgical and procedural anesthesia or analgesia and for trauma situations, acute pain relief is the primary concern. However, the suggestions made for trust and emotional comfort during and after surgery, speedy recovery, ease with the hospital and healing processes, reduction in anesthetic and pain medications, self-confidence, amnesia for presurgical pain, and future well-being can be posthypnotic and address postsurgical issues. With chronic pain, posthypnotic suggestions can help the patient process and reframe nociception that continues to occur after the hypnotic session. The suggestions can be general or specific, suggesting that whenever the patient feels *x*, the patient can automatically do *y* (‘‘In the future, whenever you feel tension in your head, you can automatically say your special releasing words to yourself, release and relax,’’ or ‘‘Whenever you want relief from daily tension you can say the word ‘ease’ to yourself, and you will automatically feel the wave of release throughout your neck area.’’)

Finally, the patient can be guided out of trance with suggestions that encourage more cognitive thought and less unconscious processing. References to recognizing time, temperature of the room, the therapist’s voice (‘‘as distinct from your own’’), or feeling the heart beat, as the therapist picks up the pace and volume of their speech, can all guide the patient back to conscious awareness. There may be side effects to trance which are not convenient, such as foggy thinking, lethargy, disorientation, slow heart beat, lack of vibrancy, and a temporary amnesia for what was going on before the trance. They may be erased with another brief series of suggestions so that the patient feels refreshed and in control at the end of trance.

CHRONIC PAIN MANAGEMENT

Jensen and Patterson[75] reviewed 19 studies on the efficacy of hypnosis for chronic pain, and outlined the control conditions used for comparison. Eight studies involved headache pain alone; and others included cancer, sickle cell, low back, temporomandibular, and mixed chronic pain problems. There were six types of control conditions: measuring change from baseline; hypnosis versus standard care; hypnosis added to another treatment, including physical therapy, medication, education or advice, or an occusal appliance; hypnosis versus biofeedback; an attentional control condition; and minimal effect control conditions (this allows for passage of time and patient expectancy that a change could occur). They also addressed conditions (or independent variables) that effect success with hypnosis, namely suggestibility, frequency of treatment sessions, frequency of self-hypnosis practices, patient-rated outcome expectations, initial treatment response, and diagnostic group. The overall conclusion was that hypnotic analgesia was significantly more effective than no treatment and than other standard care conditions, although other hypnotic-like treatments, such as progressive relaxation and autogenic training, produced similarly effective pain control.

We have mentioned chronic pain as distinct from acute and procedural pain throughout this chapter, although almost all the techniques mentioned also may apply to chronic pain. Chronic pain carries the expectation that it may never go away, and the extra burden of itself as a prolonged physiological stressor. In addition, its emotional suffering component may magnify with time.[172–174] To that aim, Hilgard and Hilgard[173] asked their patients to rate their suffering and pain separately so that they might learn to differentiate them. Chronic pain is of the type that the patient can well afford to disregard, forget or modify; there are hypnotic techniques for all those possibilities. Treatment may include dissociation from the nociception and from the awareness of pain; time distortion, which allows the patient to mentally ‘‘be’’ in the future or the past when they do not feel good; selective amnesia for the original injury that caused the pain; displacement of the pain to a place outside the body, imaginary numbing of the pain, and altered perception of the pain that recognizes nociception as just a signal and nothing more.

Brown[175] outlines group pain therapy sessions, which may be done in 8–12 week formats. The techniques are taught to the patient through personal experience during sessions, and then the patients practice them for home use. Brown classifies pain management techniques in four categories—alleviation, alteration, attenuation, and awareness.

1. Alleviating the sensations or symptoms involves making direct or indirect suggestions to make the pain go away, to substitute pain sensations for other sensations or for different ones, to create numbness, or to imagine analgesia.
2. Alteration involves changing the overall experience of pain by temporary forgetting it or losing sensation of it, by altering

the meaning of it, such as aching after winning a sports event, or changing the sensation (from pain to pressure or tingling), or by dissociating from the pain or by depersonalizing from the body.

3. Avoiding involves taking pain away using distraction, engaging in fantasy, distorting time, age regression or progression, by getting absorbed in a mental task, or by imagining the pain somewhere else in the body.
4. Awareness techniques include focusing the conscious mind on the component parts of the pain, and studying the component parts of one's pain awareness, or the component parts of the mind and body's nociception process itself.

Brown's awareness techniques also highlight complementarity, in that when a patient thinks about their thinking, they tend to go into trance and cannot pay attention to pain. Brown suggests having patients pinch the skin between the thumb and the forefinger[51] to induce just enough pain to test out each of the listed techniques and to find out which ones work best; in subsequent practice sessions, each patient will hone the techniques that worked the best for them personally. Brown suggests beginning with secondary pain areas (for instance, the leg pain that accompanies back pain, or compensatory pain) before working with the primary one. Finally, pain management training should include a section on relapse prevention, to be sure that patients know how to manage the psychological and behavioral triggers in their lives that exacerbate pain, and that they have a variety of techniques to use for different situations, types, and levels of pain.

Spira and Speigel[176] discuss practical ways hypnotherapists can work with patients' varying levels of hypnotizability, presenting a tabular outline of techniques to use according to the patients' hypnotizability (low, moderate, and high) and pain levels (mild, moderate, or severe). The table shows strategies that help low hypnotizables, who will do best learning to release tension for mild pain, differentiate pain from their responses to moderate pain, and distract themselves during severe pain bouts. Moderately hypnotic patients may best attend to their own positive coping resources to managing pain and other problems; as pain increases they may imagine themselves to be in a positively resourceful state. Patients who are highly hypnotizable can alter mild pain directly by triggering memories of past successful alterations to go directly to that state; as pain progresses, they may dissociate from the experience.

Ericksonian Naturalistic Approaches to Pain and Symptom Management

Erickson was an expert at pain management from personal and professional experience; his techniques and philosophies are taught worldwide and through the Milton H. Erickson Foundation. Neurolinguistic programming (NLP) was developed as an attempt to understand how and what Erickson knew about the unconscious minds of his patients; a good part of NLP's focus is on getting into rapport with the patient's unconscious processes, to help them make changes that other parts of their mind are resisting (see http://www.NLPU.com for more information on medical and pain related applications). Erickson believed that hypnotic trance should be cooperative and interactive and that induction should guide the patient inside him- or herself. He believed patients were unique and resourceful in resolving their own pain and suffering, if they could become "unstuck" and open up to doing so. He oriented patients toward positive change, and his rapport with patients was a study in and of itself. He spoke directly to the patient's unconscious mind (or body processes) and bypassed conscious *and* unconscious resistance by utilizing the patient's language, posture, mood, words, and thinking patterns; this requires the attentive listening and observation skills. To treat pain and symptoms, particularly psychosomatic pain, he stressed the importance of seeing the symptom as a valid part of the patient's experience with some positive purpose that the therapist must welcome in order to work with it.

Erickson managed his own pain by absorbing himself deeply into the awareness of his pain and verbalizing his perceptions of it; this advanced technique diverted his attention away from the sensation itself. His other pain management techniques included altering or reinterpreting the signal, reframing it as a positive thing, eliciting positive early memories to replace the present feelings, or disregarding conscious awareness of pain signal. He was also a master at introducing confusion at the cognitive level, to send the patient into trance, and then confusing perception of pain signals. He disengaged the conscious mind with techniques the conscious mind could not follow. Examples of confusion techniques include:

- Including syntactical errors into conversation ("wondering how *you will* it will happen for you . . . to *go into trance*")
- Putting two opposing ideas in the same sentence ("You can use self-hypnosis or I will lead you there"), or offering like alternatives ("You can go into trance all by yourself or you can go into self-hypnotic trance".)
- Distracting with strange wording ("Isn't it always the way it is when you think you have control")
- Making blatant suggestions and negating them ("Maybe you were kind of hysterical, or that really doesn't make sense at all")
- Using double meanings (such as in a story about shattering window panes or taking them out to let air through the frame)
- Interspersing an important suggestion into a sentence ("It's apparent (*as a parent*) that *you do a good job* at work anywhere.")
- Leading the patient away from their train of thought with surprise or humor ("Wow, I just remembered . . . sorry to interrupt . . . and you were saying . . . or is there another way you wanted to feel?)
- Suggesting the obvious ("Sooner or later you will feel relaxed and drop into trance," or "You may not yet know how you will get relief, but as your pain waxes and wanes. . . .")
- Reframing the experience ("You know you are still alive when you are lucky enough to still feel your pain.")
- Paradoxical states of being, to make feeling pain inconsistent with some other state of mind the patient can remember expereincing
- Describing the pain in a sentence and saying it backward
- Reversing the perceived direction or pathway of the pain

Lankton and others use a number of Erickson's tools for treatment of pain that include metaphors, stories, and anecdotes or jokes to pull attention away and disconnect from cognitive control. Lankton and Lankton[177,178] devised the triple imbedded metaphor technique that begins with a naturalistic trance induction and then progresses deeper with the use of three concurrent stories. The technique relies on excellent rapport and the design of stories and language specific to the patient and imbeds suggestions for cognitive, behavioral, emotional, and physiological changes at deep levels. The use of metaphors fosters a shift to the right side (more hypnotic and feeling) of the brain. Lankton's hypnotic trances for treatment of physical pain highlight confusion of the pain perception, time distortion, humor for distraction and rapport, and posthypnotic suggestion.[179]

Kay Thompson,[180] an Ericksonian who was also a dentist, used distraction techniques with children, and played many word games, such as "panes" of glass that could shatter and be disposed of, seeing through a pain of glass, "untying the knots to not feel" pain, and her famous phrase to start the process of pain management, "When everything that can and should be done about the pain has already been done, you can forget about the pain now."

Obviously there is overlap in the pain management tools that

practitioners use; what differs is the style of presentation, the particular suggestions for physiological healing according to the specific type and site of pain. Above all, the patient needs to know that their pain and suffering are acknowledged by the therapist; trust, rapport, safety, confidence, and expectancy are all beneficial to the outcome.

CONCLUSION

Trance is a natural phenomenon, and health care providers have been using hypnosis to guide the patients into pain relieving trances for over 200 years. Recent research on the central mechanisms of pain and of hypnosis has highlighted a role for hypnosis in many medical disciplines, concluding that patients prepared hypnotically for surgery do better than 89% of other patients, and that 75% of both healthy subjects and patients respond positively to hypnotic analgesia, even when hypnotizability is not controlled. Ongoing efficacy and effectiveness studies on hypnosis have improved techniques such that even in the wake of the improved medicines and procedures that modern pain clinics have to offer, hypnosis is still poised to take a respectable role in interdisciplinary pain medicine.

CHAPTER 85 ■ RELAXATION AND IMAGERY TECHNIQUES

KAREN L. SYRJALA AND JEAN C. YI

Relaxation with imagery (R&I) is one of the most widely used methods for nonpharmacologic relief of pain, with strong empirical support.[1,2] A form of R&I is nearly always a component of multidimensional chronic pain treatment and is typically part of broader cognitive behavioral treatment programs for chronic pain. In addition, R&I is effective with acute and cancer pain problems. Beyond efficacy in reducing reports of pain, R&I can be beneficial in limiting the impact of pain on function.[3]

Numerous techniques and terms are used within the rubric of R&I, including progressive muscle (tense–release) relaxation, autogenic relaxation, imagery, visualization, and meditation. Although it is possible to separately describe relaxation methods versus imagery methods in practice, nearly all relaxation incorporates a form of imaging, whereas nearly all imagery begins with a form of relaxation. Consequently, clinicians need to understand and be able to use both components. Relaxation is used to pull focus away from pain and to induce a physical state of decreased muscle tension, as well as decreased autonomic and affective arousal. In theory, this state is inconsistent with the pain experience and, in itself, may reduce pain perception. Imagery provides a directly competing cognitive focus, which can block perception of pain during total concentration on imagery. After imagery is completed, pain reduction may continue through a shift in cognitive interpretation of nociceptive signals or through more direct neurochemical mechanisms. Both relaxation and imagery disrupt the pain–dysfunction feedback loop by increasing patient focus on feelings of well-being, thereby decreasing the focus on pain, as well as the tension, anxiety, depression, and inactivity related to pain.

As described in this chapter, R&I has been shown to be effective in the treatment of chronic low back pain, cancer pain, rheumatoid arthritis, childbirth, and acutely painful procedures. Headache and temporomandibular disorder (TMD) pain have been treated successfully with relaxation alone or combined with imagery. In this chapter we first consider some basic information, including a historical perspective of R&I techniques, theoretical bases including physiologic effects, and advantages and disadvantages of the methods. We then detail clinical methods and efficacy, as well as possible complications that a clinician should be prepared to manage. For further details on the application of specific approaches, the reader is referred to several books with useful information for professionals.[4–8] In addition, Bernstein and Borkovec[9] have a widely used manual for training professionals in progressive relaxation. For reviews of research or practice of R&I, see articles by Fernandez and Turk,[10] Keefe and Caldwell,[11] McCaffery and Beebe,[12] the NIH Technology Assessment Panel,[13] Syrjala and Abrams,[14] Syrjala and Roth-Roemer,[15] Turner and Romano,[16] Vessey and Carlson,[17] and Wallace.[18]

With the increased public attention to self-help and alternative therapies, bookstores are full of books and audiotapes instructing patients how to use imagery on their own. Clinicians will find several that they can recommend for patient use, along with professional care, in treatment of specific pain problems. *Books and audiotapes should not be considered adequate treatment alone. Most patients require initial professional assistance to adapt methods to their individual needs.*[19,20] *Tapes alone can bias patients against trying R&I with a professional, because they believe "it doesn't work for me."*

BASIC INFORMATION

History

Relaxation was in use by the 1930s as a technique for reducing tension and anxiety. Progressive muscle relaxation (PMR) was introduced by Jacobson,[4] who found that by extensive practice with systematic tensing and releasing of muscle groups, anxious patients could learn to discriminate the resulting sensations and produce an experience of deep relaxation. Wolpe[21] modified the procedure into a program that could be completed in six 20-minute training sessions with twice-daily home practice. He then incorporated relaxation into his systematic desensitization therapy for phobias, reasoning that relaxation would provide a response incompatible with fear. The relaxed state was paired with gradual exposure to the feared stimulus. The patient first imagined the exposure while relaxing and then actually confronted the feared object in real life. This method of treatment for phobias is still used today.

Autogenic training (AT) originated with a Berlin psychiatrist, Johannes H. Schultz, and was popularized in North America by Luthe.[22] AT does not require tensing of muscles but instead consists of turning attention to each muscle group in turn, suggesting sensations of heaviness and warmth. After progression through the muscle groups, attention is turned to slowing the heart rate, developing a regular respiration pattern, and regulating the viscera and cooling the forehead. The objective of AT is autonomic regulation as well as muscle relaxation. In its passive concentration, AT resembles meditation. In its content it incorporates the use of imagery, although these images are limited and intentionally repetitive.

Benson[5] has described the relaxation response as a form of meditation without the religious or lifestyle connotations of transcendental meditation, Zen, or yoga. In the two most tested meditation strategies for pain, the relaxation response and mindfulness meditation, patients are taught awareness in the moment, without judgment. Procedures vary, but awareness can focus on breathing, a phrase, or on a detached observation.[6,8,23]

Although relaxation began as a treatment for anxiety, since the time that behavioral psychologists began working with pain patients, R&I techniques have been a key element of standard treatment.[7] A sequential combination of PMR and AT is most frequently taught, with deep breathing and guided imagery often incorporated. Although not technically included in any of the original versions of relaxation already mentioned, deep breathing can be the first step toward helping patients focus attention before proceeding with further relaxation. Guided imagery serves as a distraction technique and, more important, as an effective means of introducing alternative thoughts, images, or ways to perceive

pain. As such, the imagery component can be critical to the success of relaxation as a pain relief tool.[10]

Theoretical Bases

The mechanisms through which R&I reduces pain are still under debate, except for consensus on the obvious mechanisms of tension relief and altered sympathetic arousal.[13] Little is known about brain physiologic changes in response to relaxation, but more is known about peripheral physiologic change. Even brief PMR training has produced significant reductions in heart rate, respiratory rate, and electromyographic (EMG) forearm muscle tension.[24] Furthermore, during relaxation, physiologic changes have been greater than those observed during hypnosis for systems not under voluntary control (e.g., heart rate and tonic muscle tension). Other documented physiologic responses to relaxation include decreases in oxygen consumption, blood pressure, and serum lactic acid levels; increases in skin resistance; and alterations in blood flow.[25] Investigators have found that plasma norepinephrine levels either increase or do not change after relaxation.[26] It has been hypothesized that these peripheral changes, which indicate a decreased arousal of the sympathetic nervous system, are related to decreased end-organ responsiveness to norepinephrine.[25]

Reduced sympathetic activity after relaxation does not fully explain the pain reductions found in a substantial number of conditions.[16,27–29] In tension headaches and TMD pain, the reduction in reported pain may be due, at least in part, to muscle relaxation effects[30] and decreased sympathetic arousal, although not all studies have supported this finding. Altered blood flow may account for some of the effect with migraine headache. Other physiologic and cortical processes almost certainly are involved in accomplishing the pain relief reported with imagery in some acute and chronic pain conditions.

Measured brain responses to relaxation include increased electroencephalogram alpha and theta waves,[25] but research has confirmed few other brain activity changes. Theorists have speculated that relaxation and meditation shift areas of brain activation or that pain relief is a function of changes in catecholamines, endorphins, or other neurochemical systems.[13,25] Some data suggest that a spinal–thalamic–frontal cortex–anterior cingulate pathway influences subjective response to pain, whereas a spinal–thalamic–somatosensory cortex pathway influences pain sensation. Noxious signaling may be modulated through a descending pathway that involves the periaqueductal grey. At the dorsal spinal cord, serotonin and norepinephrine appear to play important roles in sensory modulation.[3] Although these mechanisms have been hypothesized for some time, they remain difficult to test. Another area of the brain that has been implicated in pain has been the rostral anterior cingulate cortex (rACC).[31] Using imagery strategies, deCharms and colleagues were able to demonstrate that teaching healthy volunteers or chronic pain patients to control activation of the rACC, as monitored with real-time functional MRI, led to a decrease in pain perception.[31]

Advantages

R&I has three primary advantages over the similar but more complex technique of hypnosis (see Chapter 84): (1) Patients can be trained in the use of the skills with relative ease; (2) no special equipment or extensive training of the therapist is required; and (3) patients readily accept R&I techniques, whereas they are more likely to reject hypnosis.[32]

Although it can be difficult to predict who will benefit from R&I, the lack of serious complications and the relative ease and low cost with which it can be tried make this a method with minimal risks.[33] Unlike the practice of hypnosis, R&I is essentially a skill that can be learned. It also does not depend to any extent on the "susceptibility" of the patient, although it does require willingness to practice. If a patient is unable to visualize images, PMR can be taught with potential benefit, and methods can be adapted to the particular capabilities and preferences of a patient. Thus, the flexibility within the method leaves room for adaptation to a wide variety of styles or needs. Expectations of patients tend to be more realistic than for hypnosis. While hypnosis may benefit from positive expectations and wishes for a "magic cure," higher levels of fear of loss of control can work against patient receptiveness, whereas fear is rarely aroused by R&I utilization.

Disadvantages

R&I requires the participation of the patient. To optimize benefit, patients must practice outside the trainer's office. Although self-control is one of its appeals to patients, lack of practice is one of the greatest problems in its use.[30] Further disadvantages follow as corollaries to R&I's advantages. These include the lack of implied "magic cure" that can be hoped for with either a medical intervention or hypnosis. Ease of use and lack of cost can be associated in patients' minds with lower expected efficacy. The effects of R&I may not be immediately apparent but can accumulate over time, as will be discussed in the studies to follow, thus requiring not only practice but also patience. R&I is a subjective experience not unlike pain; as such, its effects can be difficult to measure and confidence in their benefits may be low. In addition, imaging ability may be a moderator of reduction in pain when using guided imagery.[2] Finally, for most conditions, R&I is not an adequate stand-alone treatment for pain, but must be considered a complementary method used in combination with appropriate medical treatment.

CLINICAL INFORMATION

Indications

Indications for treating pain vary with the type of pain and the condition of the patient. Relaxation is recommended for any patient for whom tension is a significant cause of pain or for whom tension and fear may be augmenting the pain problem. In acute pain situations such as childbirth, trauma, or procedural pain, R&I may be combined with meditation and other distraction strategies that decrease the focus on discomfort and speed the passage of time. Relaxation is clearly indicated in the treatment of tension, migraine, and cluster headaches and in TMD pain. In other chronic conditions and in cancer pain, clinical trials have indicated that R&I and meditation reduce pain.[14,20,28,34] With the limitations of time in the current medical practice environment, R&I is most strongly recommended for patients who have chronic conditions that cannot be adequately relieved with medical intervention alone. In addition, patients will benefit from R&I training if they must regularly repeat acutely painful procedures because fear and phobias can increase over time with exposure to these stimuli.

Contraindications

Contraindications are few and usually relate more to the mental status and characteristics of the patient than to the pain condition itself. Pain or sedation that prevents a patient from focusing attention, or a delirium that disrupts cognition, needs to be treated with other methods until concentration is possible. Then, briefer images with a short relaxation component can permit participa-

tion by a patient who otherwise could not sustain the mental effort needed for more extended training. Sometimes these patients feel ease of intense discomfort by combining images with physical massage or pressure on a part of the body (shoulder, hand, lower arm, or calf muscles) that is not in pain. Of course, clinicians must be cautious and should consider having someone else in the room if they decide that physical touch with imagery is needed to help a patient with pain that cannot be relieved with medical methods alone.

Certainly religious objections,[14] intense fear of loss of control, or resistance to trying the method for any reason should be respected. Skepticism is not a reason to withhold treatment if the patient is willing to give the technique a valid try—clinicians can encourage a healthy skepticism and empirical testing attitude. Similarly, patients who ask for biological explanations for why mental strategies might work usually respond well to information about physiologic mechanisms behind R&I. These patients also may do best with PMR in the beginning because this helps to enhance awareness of physical changes that occur as the body relaxes. The same is true for patients who seem out of touch with their bodies and unaware of tension or for patients who are action-oriented "doers not thinkers."

Intense anxiety or preoccupation that prohibits focus on imagery must be attended to pharmacologically or with discussion before beginning R&I. Because anxiety can increase during imagery, the clinician should assess a highly anxious patient and ensure that emotional expression is tolerable. Usually a patient presenting with extreme anxiety needs to express thoughts and feelings first. Then the clinician can re-evaluate the patient's ability to focus. Ability to engage in a discussion of places that the patient enjoys should indicate adequate ability to participate in imagery.

Two additional circumstances can complicate the use of R&I: One is the patient who is feeling very out of control; the other is the patient who has a strong need to be in control. For patients who feel completely out of control of their experience and environment, a clinician can appropriately take charge of the situation and let patients know the clinician is going to ensure their safety during the process. Clinicians need to convey to patients that the situation is manageable and the pain can be relieved. If these messages seem to reassure and calm the patient, the clinician should be able to move into imagery. For patients who give indications that they must be in control, clinicians will want to assess whether these patients might respond best to permissive, indirect imagery versus more structured PMR methods. PMR helps in this situation because patients can be told exactly what steps the clinician will take. Generally, patients feel safest with PMR because it is clear that patients control their own responses. Alternatively, if imagery is used, the clinician can encourage patients to select as many features of the imagery as possible and can incorporate options and permission to have other thoughts or experiences during the imagery. Another strategy is to have patients tell the clinician what they see, feel, hear, and do in their imagery, with the clinician asking questions rather than leading the imagery process.

Techniques

Preparation of the Patient

Relaxation may be learned and practiced by virtually anyone. The techniques can be taught by those who have had relatively limited training, but clinicians should be aware of and prepared to handle possible complications. Before relaxation training begins, the clinician should explain to pain patients the rationale for the particular procedure being used. Also, the clinician should assess for treatment expectancy as these are related to outcome measures of pain management.[35] In a recent study, pretreatment negative expectancies predicted negative affect and poorer health-related quality of life a full year after R&I plus cognitive–behavioral treatment.[35] Many patients view relaxation as irrelevant to their pain problem, or even as an indication that their doctors think the pain is "just tension" or "all in my head." Most patients are helped in their disbelief by a brief discussion of the physiologic pathways of pain perception, hypothesized neuroendocrine effects, and the feedback loop between pain and tension or fear. Patients can also be told that relaxation training is harmless and, if nothing else, will leave the patient feeling relaxed. The clinician can then suggest that the procedure be tried as an "experiment," with nothing to lose. This approach is preferable to promising patients dramatic pain relief because this rarely occurs initially. Patients also need to understand that R&I is a skill, like learning to read. Benefits take time to reach their peak, and daily home practice is necessary to become adept at the procedure and to maintain benefits. Audiotapes can be helpful in supporting home practice.

To prevent surprises and help patients feel secure, clinicians should describe the basic steps involved in the technique and estimate the length of time required to complete the procedure. Although increased comfort can be achieved in as little as 5 minutes, deep relaxation requires at least 20 minutes for new practitioners and may continue for up to 45 minutes. Patients can be advised that they will likely be most comfortable with their eyes closed, although this is not mandatory, and that they are free to move at any time to make themselves more comfortable. Use of a reclining chair with a headrest is desirable, or patients can sit on the floor or a regular chair. They should not lie on a bed, unless the goal is rest for a sleep-deprived patient in pain. Lying on a bed tends to evoke falling asleep rather than completing the imagery. When using imagery, it is critical to assess for images that would be helpful as what one patient considers relaxing might not be so for another patient.[14] Unplugging the phone and minimizing other noises or disruptions are helpful. In hospital rooms this is not always possible. Therefore it is helpful to add a statement such as "and just allow any sounds around you to fade to the distance, part of the background that adds to your feeling of being in a different place, a place all your own right now." Surprisingly, after imagery, patients often indicate that they were unaware of any sounds or disruptions even though they may seem intrusive to the clinician.

Training Procedures

Deep breathing is the most rapidly learned of the relaxation techniques. Very little training is needed to obtain benefits. Controlled breathing also can be quite effective in capturing and holding a very distressed patient's attention and may be the first step toward using imagery to further distract the patient from the distress. One component that is often not stressed but can be quite valuable in relieving pain is making a sound while breathing, usually just emphasizing the sound of air leaving the lungs and mouth. Another component of deep breathing that can improve effectiveness when panic is a component of acute pain, is to remind the patient to exhale first, not inhale. Shallow breathing is a feature of panic, reducing available oxygen volume. Exhaling first allows oxygen to be inhaled more fully. Variations on this method are commonly used in childbirth preparation.[34] Typical instructions for deep breathing are given in Table 85.1.

PMR is the most routine of the techniques. Because it requires the patient to tense and release muscle groups, it provides feedback to the clinician (as well as the patient) on the participation of the patient. The tense–release format provides momentum from which the patient can achieve relaxation well below usual levels of tension relief. Before implementing this technique with a patient, clinicians are urged to read the manual by Bernstein and Borkovec[9] or another in-depth "how–to" for this method.

Autogenic relaxation is similar to PMR in that it progresses through the body, focusing attention on relaxing each area of

TABLE 85.1

INSTRUCTIONS FOR DEEP BREATHING[a]

I. Perform the following steps in sequence:
   A. Deep breathing may be done in any position. If possible, sit, lie, or stand comfortably, with a straight spine.
   B. Exhale the air in your lungs.
   C. Inhale through your nose while counting slowly to four as you:
      1. First fill the lower section of your lungs. Your diaphragm will push your abdomen outward to make room for the air.
      2. Second, fill the middle part of your lungs as your lower ribs and chest move forward to accommodate the air.
      3. Third, fill the upper part of your lungs as you raise your chest and shoulders slightly and draw your abdomen in a little to support your lungs.
      4. With practice, these three steps can be performed in one smooth, continuous inhalation.
   D. Hold your breath for a slow count of three.
   E. Exhale through your mouth, making a relaxing, whooshing sound like the wind as you blow out to a slow count of 4.
   F. As you exhale, follow the same order as the inhalation:
      1. First, pull your abdomen in.
      2. Next, exhale from your middle chest.
      3. Finally, exhale from your upper chest as you allow your shoulders to sink and relax and your abdomen to puff out again slightly.

II. As the pattern becomes automatic, scan your body for other areas of tension, then return to the sound and feeling of breathing as you become more and more relaxed.

III. Imagine all the tension from your body being pulled into your lungs and being exhaled with your breath.

IV. Continue deep breathing for 5–10 minutes at a time. If you become lightheaded at any point, alternate six regular breaths with six deep breaths.

V. As you continue deep breathing, scan your body for any area that may remain tense, focus on this place and imagine breathing directly through this area.

VI. When you have learned to relax yourself using deep breathing, practice it whenever and wherever you feel yourself getting tense.

[a]Following the instructions provided results in the most complete relaxation, but the steps can be shortened or adapted depending on the clinical situation.
Adapted from Davis M, Eshelman EF, McKay M. *The Relaxation and Stress Reduction Workbook*. Oakland, CA: New Harbinger Publications, 1982.

the body in turn. Autogenics, however, does not require tensing muscles first. The focus is on imagining a feeling of warmth and heaviness in each area. Imagery may be inserted after completion of the relaxation phase or may be combined with the relaxation phrases. This technique is useful with patients who are quite fatigued and uncomfortable. The imagery component may relate only to feelings of warmth, heaviness, and sensations that accompany relaxation or may be augmented at length depending on the will and interest of patient and clinician.

Incorporating imagery into relaxation can greatly enhance efficacy as a pain relief tool.[10,20,36] Imagery also increases the enjoyment of patients and therefore the likelihood that they will use the technique. Activating all the senses in the mind can create distraction as well as hypnotic-like experiences of comfort, well-being, and mastery of a problem. For instance, patients can be asked to choose a place where they have felt most at ease or joyful. As patients recapture the familiar experience of a place with sight, sound, taste, smell, and touch, they also recapture the feelings of comfort. Clinicians can then suggest to patients that by imagining themselves in that place, patients can once again be comfortable and in control of how they feel. The content of images can vary greatly, from going to pleasant places to modifying the pain experience directly.[14,37] Patients without these abilities may respond more to the relaxation component of R&I. Choice of images may be the most important factor in the success of imagery. Pleasantness may be more important to encouraging use of the imagery than in enhancing its effect on pain.[40] Pain reduction is greater when patients can choose their images and when they make statements to themselves in the imagery that they are able to tolerate or modify the pain.[39] More success in using imagery may be achieved by patients with greater ability to generate images and those who have a capacity to experience images as if they are real.[38,39]

An alternative imagery strategy is more akin to meditation. This approach involves focusing on the pain rather than away from it and picturing details of the pain location.[41] There is some indication that for more extreme, unremitting types of pain such as with terminal cancer, focusing on the pain rather than away from it is more effective in achieving pain reduction.[42] Table 85.2 lists some of the more commonly used imagery strategies for pain control. These can be incorporated into imagery of going to a favorite place or can be combined with deep breathing.

In execution, meditation most resembles deep breathing. Instead of focusing sequentially on each part of the body, meditation requires a cultivated "detached observation."[6,8] Two similar approaches to meditation have been useful in medical settings. One involves repeating a phrase or word to oneself and is referred to as the *relaxation response*[5]; the other is called *mindfulness meditation*.[8,23] Mindfulness meditation is similar to the imagery approaches that transform painful sensation.[41] Attention is fo-

TABLE 85.2

IMAGERY OPTIONS FOR PAIN CONTROL—STRATEGIES

I. Escape or distraction by having the patient go to a favorite place

A. Use multisensory imagery: color, shades of light, texture of objects, sensations against the skin (e.g., air temperature), smells, taste, sounds, physical sensations

B. To increase absorption, change the surroundings, have the patient move deeper into the place or on to another location that moves the person further away from the pain, and find something unexpected.

C. Introduce another person or object with a "message" the patient most needs to hear right now; have the patient connect with that person in a caring way (look into the other person's eyes, touch hands, hear the words that are most helpful right now).

D. For pain relief through distraction, include physical action in the imagery; have the patient walk, run, feel the strength and power of his or her muscles, how well the body works, how healthy and comfortable it feels to move.

E. Use positive suggestions—what is felt.

1. Pain or discomfort is not mentioned.
2. Talk about "moving attention to that area of the body that you would like to feel more comfortable, more at ease."

Advantages

Most enjoyable so patients are more likely to practice

Takes less effort from the patient

Disadvantages

Provides distraction, but without analgesic suggestions it may not extend pain relief past the period of the imagery

II. Block pain with images of analgesia or anesthesia.

A. Numbness via ice or anesthetic

B. Flip switches to change the channel so the pain message cannot connect to the brain.

C. Turn down the signal of the pain message to the brain; count down the numbers (using the 0 to 10 point scale for pain) to a pain number that is acceptable to the patient.

Advantages

Provides direct analgesic suggestions

Gives patients control over the pain and the use of imagery at any time, thus extending relief past the period of imagery

Disadvantages

Takes more active participation by the patient

Patients may feel they have failed if it "doesn't work"

May be easier for more suggestible patients

III. Sensory transformations

A. After relaxing, go to the pain location with the mind; as a neutral observer, explore the pain and watch as it changes. Have patients notice what the pain says to them and how they can respond to ease the pain.

B. Use images that can change as the pain changes and have the patient observe these changes in color, shape, density, texture, size.

C. Use images that compete with the pain description.

1. Blow cold arctic air through a burning pain.
2. Take a knotted cramping pain, gather the knot into a fist and throw it away, or loosen the knot, watch as it softens, smoothes, eases.

Advantages

Takes less energy than blocking pain

Goes with the patient's focus rather than fighting against it

Can be done quickly without lengthy relaxation for patients in acute pain

Can be very successful in easing pain and greatly reducing tendency to tighten around pain

Disadvantages

Less likely to eradicate pain; instead teaches the patient to modify and work with the pain

Pain may initially seem worse because of the focus on it, scaring the patient

IV. Additional strategies can be used with hypnotic trance (see Chapter 84)

cused not on changing pain perception but on insight developed from distinguishing all sensations as they occur moment by moment. Thoughts about pain are observed from the position of a neutral observer. Although relaxation response training is easy to implement, data do not clearly document its effectiveness as a pain reduction method. Mindfulness meditation, on the other hand, has been shown to reduce pain in chronically ill patients.[23,28] In a feasibility study comparing mindfulness, massage, and control groups of patients recruited from an internal medicine practice, the two treatment groups did not differ, and both groups had reductions in pain compared with controls.[43] Differences appeared at the 12-week follow-up when the massage group was unable to maintain gains whereas the mindfulness group was able to do so.[43] In another study using pain-free volunteers, pain tolerance increased after mindfulness practice.[44] For meditation, an experienced clinician is recommended as a trainer. Instructions for using the relaxation response and instructions for mindfulness meditation are detailed thoroughly in the Kabat-Zinn book.[8]

Related to mindfulness-based approaches, McCracken and colleagues have promoted using acceptance to treat chronic pain.[45–48] The utility of acceptance is that people are taught to acknowledge the pain they are experiencing while continuing to live their lives rather than avoiding activities because of fear of re-injury or worsening pain.[45] In one study of this method, participants were less depressed and reduced the amount of time resting due to pain.[46] Caution should be used in interpreting these findings as a randomized controlled trial has yet to be done testing acceptance. However, it may be a promising new approach in pain management.

Effectiveness

Comparisons have been made between R&I strategies and hypnosis or biofeedback, as well as between different relaxation techniques. Numerous studies have also tested packages of cognitive–behavioral skills training that have included a form of R&I. Each of these interventions, including hypnosis, biofeedback, and cognitive–behavioral packages, elicits similar physiologic responses and subjective reductions in pain when compared with no treatment.[1,16,20,25,27,29,36,49,50] In general, research results indicate that R&I demonstrates greater effect size than other strategies alone and that packages of cognitive–behavioral skills are not always superior to R&I alone.[10,11,49] Hypnosis, biofeedback, and audiotaped relaxation are less effective than live PMR in achieving reductions in sympathetic arousal.[24,51] However, a taped version of guided imagery has been found to be effective.[52] An exception may be frontalis EMG levels, which have shown greater reductions with autogenic relaxation than with tense–release relaxation, although both approaches produce some decrease in EMG.[53] This finding may interest clinicians choosing between relaxation techniques for the treatment of tension headache.

Much of the research on the effectiveness of relaxation alone for pain reduction has been conducted with tension headache patients. In general, the results of these studies suggest that relaxation is effective and that benefits are maintained at follow-up.[16] Relaxation training alone appears to be a reasonable first step for headache sufferers, with the addition of biofeedback for those patients who are unsuccessful with relaxation alone.[54] Similarly, research with TMD pain patients suggests that many can be treated successfully with relaxation alone, although some patients may benefit from the addition of biofeedback.[55] With other conditions, relaxation is best implemented in combination with imagery.

Pain reduction is not the only goal of many treatments. R&I may target health-related quality of life and not just pain.[56] R&I has achieved superior results in return to work rates when compared with medication alone.[50] Health care visits also have decreased in the year following R&I interventions.[50] The next sections discuss efficacy of a single method of R&I within specific medical conditions, as this is how most clinical trials of R&I methods are tested.

Chronic Conditions

R&I is usually one element in a set of cognitive–behavioral treatments for chronic pain, rather than an independent pain control technique. Research indicates that R&I can contribute to reduced pain levels, reduced medication use in a number of chronic conditions, and reduced disability, although the role of R&I versus other cognitive methods is not yet clear.[29,49,50] The evidence for sustained improved function is less consistent but more often than not supports improvement in disability after treatment.[29,49,57–59] Chapter 82 presents a thorough review of the effectiveness of cognitive–behavioral strategies that usually include R&I.

Kabat-Zinn and colleagues[8,23,28] have used mindfulness meditation to successfully treat a variety of chronic problems, including pain located in the low back, neck, shoulder, arm, leg, face, head, chest, peripheral nerves, and multiple sites. About 10% to 20% of patients refuse to use this strategy for pain control. A majority (72%) who are willing to try are able to reduce their pain by 33% or more. In addition, improvement has been noted in body image, activity, mood disturbance, and medication use. Compliance both during and after participation in the program has been high. These results support the contention that meditation may have a generalized beneficial effect for chronic pain patients.

Headache. Tension headache research dominates the literature and generally reveals relaxation to be as effective or more effective than biofeedback.[16,27,60,61] The same results have been found with migraine headache, although fewer studies are available. The most careful explorations into the relative roles of relaxation and biofeedback in relieving headache have been reported by Blanchard et al.[54,60,62] and Andrasik et al.[63] (see Chapter 61). In terms of both cost-effectiveness and success, the optimal therapy for tension, migraine, or mixed tension and migraine pain appears to be a two-step treatment beginning with PMR. For those patients who do not show substantial reduction in headache activity with PMR, the second step is instituted. For vascular headache patients, the second step is thermal biofeedback; for tension headache patients, frontalis EMG biofeedback is the second step. Blanchard et al.[64] found that with this two-step therapy 73% of tension headache patients and 52% of vascular headache patients were much improved. While all groups improved with relaxation, tension headache patients improved the most.

Philips and Hunter[65] tested the effects of PMR versus PMR with calming imagery for tension headache patients. The two groups showed similar improvements in pain. The authors suggested that the addition of imagery produced a larger improvement in pain based on several outcome measures even though no individual measure showed significantly superior effects.

The superiority or equivalence of relaxation and biofeedback has not been consistent across studies. LaCroix et al.,[66] for instance, found that thermal biofeedback was superior to frontalis EMG feedback and relaxation for migraine patients, although all groups improved. However, Vasudeva et al.[67] conducted a randomized control trial with people who had migraines with aura using biofeedback and relaxation and found that those in the biofeedback condition had significant reductions in pain, anxiety, and depression compared to the control group that was told to relax without any further instruction.

With regard to home practice, Andrasik et al.[63] reported that posttreatment practice was unrelated to maintenance of effects. It should be noted, however, that all patients in this study were provided with regular therapist visits.

Low Back Pain. Studies comparing relaxation with other techniques for low back pain indicate that relaxation is an effective treatment[68,69] but that combining relaxation with other cognitive–behavioral strategies may be advantageous (see Chapter 82). Turner[70] compared PMR treatment with PMR plus additional cognitive-behavioral therapy or no treatment. The two treatment groups both reported reduced pain intensity and disability immediately after treatment and at 1.5- and 2-year follow-up. The cognitive–behavioral group, however, showed some superiority in maintaining treatment gains and in hours worked per week. A number of other studies by Turner et al. support the use of relaxation as one component of effective cognitive–behavioral treatment for chronic pain.[16,29,49,70,71] McCauley et al.[72] compared PMR with hypnosis in the treatment of low back pain and found that both treatments were similarly effective and superior to a placebo EMG treatment.[73]

Though studies indicate that relaxation contributes to the efficacy of combination treatments for low back pain, the value of adding specific components to treatment packages remains unclear. In particular, the usefulness of combining imagery with relaxation training for treatment of chronic conditions needs to be examined. Furthermore, outcome variables other than symptom relief, such as employment status, medication, and health care use need to be evaluated when considering the utility of R&I for low back pain.[68]

Temporomandibular Disorder Pain. The research on relaxation and cognitive–behavioral packages that include PMR for TMD pain supports the conclusion that relaxation is effective in reducing pain and is at least as successful as biofeedback, the most commonly compared treatment.[71] Funch and Gale[55] reported that biofeedback and audiotaped relaxation training were equally effective in reducing TMD pain. Patients who were more successful using relaxation were generally younger, had experienced TMD pain for a shorter period of time, and reported other psychophysiologic disorders. The differential effect of relaxation and biofeedback with different patients also was found in a single-subject, multiple-baseline study by Moss et al.[74] In this study, relaxation with EMG feedback was most effective for three out of four patients tested. In a large, randomized, controlled clinical treatment, Dworkin et al.[71] compared patients receiving usual treatment for TMD with patients receiving usual treatment plus a package of cognitive–behavioral skills that included relaxation training. The skills-trained group reported continued improvement over 12 months of follow-up and overall lower pain scores. Researchers also found a strong trend toward reduced pain interference with function. Turner et al.[59] compared PMR to self-care, consisting of dispensing general health information but no advice or treatment, and found that participants in the PMR condition made clinically significant changes in pain level, activity interference, depression, and jaw function. These gains were maintained over a 1-year follow-up.

Arthritis and Autoimmune Diseases. The benefits of self-management strategies that include relaxation for coping with arthritis pain and dysfunction are well documented.[75–82] Educational strategies that may or may not include relaxation exercises are widely used in arthritis and are cost-effective and pain relieving over and above the efficacy of medication alone.[11,77,83] Even more so than with low back pain and other chronic conditions, arthritis and autoimmune diseases are not treated with R&I alone, but rather with R&I as a component of educational and other cognitive skills training.[11,84] Consequently, it is difficult to know to what extent R&I is an essential component of these techniques. There is no reason to believe that patients with arthritis pain or autoimmune diseases would respond differently than patients with other chronic illnesses such as low back pain or cancer, even though each disease has its own unique characteristics and therefore stressors that tax coping.

Cancer Pain. Cancer patients may experience acute treatment-related pain or chronic pain (see Chapters 41–49). Chronic pain with cancer may be stable (e.g., postmastectomy pain) or progressive (e.g., tumor invasion pain). R&I is commonly used in the management of cancer pain and is effective.[84,85] Successful treatment depends to some extent on tailoring therapy to the type of pain. In clinical reports, R&I, sometimes called *hypnosis*, is touted.[86,87] However, there are few controlled trials on the efficacy of R&I with adult cancer patients.[88] As noted by Jay et al.,[89] adult research has focused on persistent pain, whereas pediatric research has focused on procedural pain. Spiegel and Bloom[90] provided group "self-hypnosis" training to breast cancer patients and reported an additive analgesic effect of hypnosis, with smaller increases in pain and suffering over time. Syrjala et al.[36] provided three groups of bone marrow transplant patients with training in "hypnosis," cognitive–behavioral training including PMR, or support with no training. The group receiving hypnosis reported lower average levels of oral pain after chemoradiotherapy than the other two groups. In a follow-up study, Syrjala and colleagues[20] tested R&I against three other groups: a standard treatment control, a supportive psychotherapy intervention, and a cognitive–behavioral package, which included R&I. Again, in this clinical trial R&I was the most effective treatment for pain, with cognitive–behavioral methods showing no mean additive effect over and above the R&I alone. There was an indication that some patients who may not have benefited from the R&I alone benefited from the cognitive–behavioral package. However, power was not adequate to test this hypothesis. These data indicate a valuable role for imagery in helping cancer patients cope with pain. Results also suggest a need to individualize patient treatments.

Relaxation with EMG was found to be an effective means of pain reduction in a sample of Taiwanese patients with advanced cancer.[91] EMG data indicate that relaxation not only decreased pain but also anxiety and physiological arousal. This study also demonstrates cross-cultural validity for the use of relaxation techniques.

Acute Conditions

Childbirth. Preparation for childbirth usually includes breathing exercises with a visual focus and sometimes includes formal relaxation training (see Chapter 56). As Tan[34] noted in his review, studies on the effectiveness of these strategies in reducing pain in childbirth are supportive but equivocal. Many studies do not include actual measures of pain level in reporting favorable outcomes. Despite the equivocal data on pain reduction associated with childbirth preparation, the reduced distress resulting from such programs probably supports their continued use.

Acute Traumatic, Procedural, and Postoperative Pain. A number of sources confirm the benefits of relaxation training before various procedures and surgery.[92] Only anecdotal evidence was found for the use of deep breathing, relaxation, and imagery during acute trauma, although hypnosis has been demonstrated effective during burn debridement.[93] In a review of nonpharmacological interventions for burn patients, relaxation was found to be effective in reducing pain.[94] This is a difficult area to research because of the unpredictable availability of patients and the wide variety of possible injuries. By and large, support for the use of R&I strategies in trauma situations must be extrapolated from research on other acute pain conditions.

Relaxation training before stressful procedures has been shown to be effective in reducing a number of measures of pain and distress. For example, patients trained in PMR and deep breathing before sigmoidoscopy rated themselves as less anxious and made fewer requests to stop the procedure than patients who were not trained in relaxation.[95] Both relaxation and information have been reported to reduce heart rate and observer ratings of

distress during endoscopy. Only relaxation also increased positive mood.[96] Even greater effect size was seen in a study of imagery and self-hypnosis during radiologic procedures. In this randomized controlled trial, patients receiving the R&I and hypnosis treatment reported less pain, used less analgesic medication, reported less anxiety, and had fewer procedural interruptions due to hemodynamic instability.[97] In a departure from using specialists to provide R&I to patients, Lang and colleagues[97,98] have trained radiology nurses and technicians to provide R&I during painful procedures. Patients receiving R&I reported lower pain scores, with a strong trend toward less drug use.[98]

Laboratory and clinical studies have found that the effectiveness of relaxation training in acute situations may depend on the coping style of the patient. In the laboratory, it has been reported that patients who were more external in their "locus of control" were better able to use relaxation training than were patients who were more internal—that is, saw themselves as the agent of control.[99] During procedural discomfort, patients who reported that they preferred to avoid thinking about unpleasant things were helped more by relaxation than by information, whereas the reverse was true of the nonavoiders.[96] In addition, patients who indicated that they were less independent benefited from both relaxation and information, whereas those who were more independent benefited from neither. Relaxation and information were not demonstrated to be harmful to patients who were not matched on intervention and coping style. Finally, with postoperative patients, Scott and Clum[100] found that brief relaxation training was profitable for those who had "sensitizing" coping styles that focus on problems, but not for those who were avoiders. In sum, avoiders and "external locus of control" patients may do particularly well with escape-oriented pleasant imagery, whereas other patients may respond well to all types of R&I.

Pediatric Applications

Research on the use of relaxation techniques with children is less extensive and well controlled than the research with adults. Lavigne et al.,[101] Vessey and Carlson,[17] Rheingans,[102] and Eccleston et al.[103] provide reviews of painful pediatric conditions and the interventions that have been successful. The terminology used in much of the published research is inconsistent. For example, treatments are interchangeably defined as active fantasy, guided imagery, breathing, hypnosis, relaxation, or imagery.

Children are generally able to participate in imagining as a distraction from pain or fantasy to modify the pain experience from approximately 5 years of age.[17] Initially, imagery differs from play or active fantasy and storytelling only in its intention. We have found it particularly effective to use stuffed animals or soft puppets onto which the child can transfer the pain, fear, or anger that accompany pain. When left with the child, these toys become an object with which the child can repeat the imagery when the clinician is not present. As children mature to adolescence, imagery and relaxation methods increasingly resemble those used with adults. However, adolescents and children are closer to fantasy than many adults and therefore require little or no time in relaxation and need to move to fantasy imagery more quickly. Adolescents respond well to imagery with themselves as heroes and the agents of change and success. Pain transformations can be included in these images of mastery.

In research with pediatric cancer patients, interventions have focused on procedure-related pain and distress.[89,104–106] Effective treatments have included breathing and imagery, sometimes incorporated into a cognitive–behavioral package. Although numerous studies demonstrate that R&I can reduce distress related to procedures, and sometimes pain, light sedation has largely supplanted a need for R&I with repeated invasive procedures such as lumbar punctures and bone marrow aspirations.

A small number of case studies suggest that relaxation, particularly if coupled with imagery, can be effective in treating other pediatric pain problems. Distraction and breathing exercises have received some support as useful techniques for relieving pain during debridement for pediatric burn patients.[101] Weydert et al.[107] compared guided imagery with PMR to deep breathing for treating recurrent abdominal pain in children. Participants in this study improved more in the guided imagery with PMR condition than in the breathing condition. In addition, participants were able to maintain their gains over a 2-month follow-up. Unlike relaxation research with adults, which has focused on tension headache, pediatric research has focused on autogenic relaxation for migraine. This research clearly supports the use of autogenics for relief of migraine in children.[101]

Because children are easily engaged in active imagery, this component can be successfully introduced into most interventions with children in pain. Clinicians interested in the use of imagery are also referred to the literature on hypnosis, as many researchers using imagery with children have termed their interventions "hypnosis."

Complications

Minor Problems. One of the advantages of relaxation techniques in comparison with more invasive therapies is the lack of lasting adverse effects. Most complications are rare, harmless, and can be quickly resolved. Muscle cramps can develop with PMR, in which case the patient can be asked to generate less tension in problem areas for shorter periods of time. If necessary, a pause can be taken while the patient massages cramped muscles. Unless the patient comments or appears uncomfortable, spasms should simply be ignored. Patients can be reassured that muscle spasms are common when people relax and occur in many people when they fall asleep. Movements are common and not disruptive. They can be normalized by the clinician including suggestions for shifting to a more comfortable position at any time. Talking and laughter usually stop if they are ignored. Alternatively, they can be casually acknowledged, such as "and just notice that different thoughts or feelings may come up and that's fine, just a part of letting things flow through your mind and away, feeling even more at ease."

Because some patients experience intrusive thoughts as disruptive, they should be told ahead of time that such thoughts are to be expected. Suggest that as thoughts arise, they can be allowed to "float through the mind, knowing that anything important will still remain later, but that right now there are no other things to focus on or to do but to let these normal thoughts just drift away."

If a patient falls asleep, the therapist might need to speak in a progressively louder voice until the patient is again awake. Patients who report falling asleep regularly during home practice should be instructed to practice earlier in the day and in a sitting position, not lying down.

Problems Requiring Attention. Problems requiring the therapist to be more careful and attentive are infrequent. The more common difficulties and some solutions are described in Table 85.3. For certain patients, tension or pain can be localized in an area not sufficiently covered by the standard relaxation of body parts. TMD pain, as an example, benefits from exercises and relaxation targeted to the jaw area.[71] If residual tension remains, it is helpful to develop a tension or relaxation strategy that specifically targets the localized area. This might involve taking time after relaxing to go to any place in the body that continues to feel tight or uncomfortable, going to that place with the mind and watching while imagining breathing through that place and noticing the changes in sensations. Sensory transformation imagery may be used to expand on this experience.

Pain patients commonly have an initially greater awareness of the pain as attention is focused on internal states. In this case, patients can be instructed to observe the pain in a detached man-

TABLE 85.3

PROBLEMS AND SOLUTIONS ENCOUNTERED IN CLINICAL PRACTICE

Problem	Solutions
Fatigued or in severe pain	First Use medications for better pain control. Consider medication options for fatigue or depression. Then Use brief images; little induction is needed. As appropriate, use touch on the hand, foot, or shoulder to help the patient focus, to anchor the patient away from the location of the pain, and to provide a competing sensation to the pain. Begin simply, do only what is possible (e.g., breathing with an image of pain changing).
Lack of concentration	Use brief images. If preoccupied, talk about preoccupations. Perhaps try at a later time.
Highly distressed	Need to talk out feelings first. If feeling out of control, need signs that you are in control and believe the situation is manageable. Patients can relax because you are in control and will make sure they are okay.
Unsupportive family	Talk to the family. Involve the family in helping the patient. Help the patient solve the problem.
Not practicing	Review what gets in the way. Problem solve barriers. Try to remove guilt or "homework" associations so patient will claim the activity, not see it as externally imposed.
Skeptical patients	Encourage an experimenting attitude—"see what happens."
Religious patients	Explore whether faith and help of God can be incorporated as a focus of imagery. Discuss but defer if patient thinks imagery violates beliefs. Ensure that patient is always in control, can stop any time. Offer an option to observe or listen to a tape first.
Crying, increased anxiety, or other negative effects	Ask if patient is okay and wants to stop or continue. Talk about it; start again if patient is comfortable. Open eyes if feel safer.
Falling asleep	For patients in severe pain with sleep deprivation, encourage to continue with a deep, restful sleep. Raise the tone of voice and incorporate suggestions for more active imagery. If patients complain of falling asleep during home practice, suggest practice sitting up and at a time of day when more alert.
Unresponsive patients	Explore whether the patient has control fears or other barriers. Discuss what was experienced. Decide if worth trying again or if change in method is indicated. Reassure the patient that it often takes practice and gets easier with practice or that you may need to try several approaches to find the one that works best for him or her.

Reprinted from Syrjala KL, Abrams JR. Hypnosis and imagery in the treatment of pain. In: Turk DC, Gatchel RJ (eds.) *Psychosocial Approaches to Pain Management: A Practitioner's Guide*, 2nd ed. New York: Guilford Press, 2002:187–208, with permission.

ner (as described for meditation). Usually the intensity will lessen. Alternatively, the clinician can move the patient's attention to another part of the body or to images away from the body.

Patients who have been particularly out of touch with body sensations can suddenly become aware of any number of strange, unfamiliar sensations while relaxing and focusing on the body. Patients might feel as though they are floating and disoriented to such an extent that they must open their eyes until they once again feel comfortable. If this sensation or others are frightening, the clinician will need to respond with reassurance. Other discomforting sensations can include tingling, nausea, lightheadedness, or a sense of losing control.

Patients who fear losing control require perhaps the greatest care in designing an appropriate intervention. These patients often respond initially to PMR because the procedure feels most in their control. Explaining the steps of the procedure also helps to ease their fears. Another strategy is to offer choices for what they would like to try. With these patients, it is particularly important to include statements that they are in complete control of their experiences and what they choose to do, that at any time they can choose to change their experience or even to stop.

An increase in anxiety has been reported in some patients learning relaxation.[108] In our experience, this occurs in approximately 2% of patients. Switching to a different relaxation (e.g., PMR) that more fully occupies the patient's attention may help reduce such anxiety. Discussion of the nature of the anxiety may reveal an alternative set of thoughts or images that can provide a more neutral focal point for the patient. Often patients feel some relief from expressing pent-up feelings. However, other patients may feel embarrassed or reluctant to try imagery again. This circumstance requires the use of clinical skill in deciding the best approach for each individual.

Sexual arousal can occur from the relaxation and rarely from perceived seductiveness in the setting. If treated matter-of-factly as similar to other normal intrusive thoughts, this usually resolves on its own.[9]

Failure to practice relaxation strategies is by far the most common problem encountered. Clinicians can remind patients of other learning experiences, such as reading or biking, in which practice led to mastery. Discussion of changes in the home environment that would assist practice may also be helpful. Above all, clinicians must emphasize that practice is an important element of learning and using any relaxation technique successfully.

CONCLUSIONS

R&I techniques—including PMR, AT, deep breathing, imagery, and meditation—can be valuable in the treatment of both acute and chronic pain syndromes. The number of randomized controlled trials that demonstrate efficacy of R&I for many types of pain are sufficient to conclude that this is an effective strategy for pain treatment. The advantages of R&I include its relative cost-effectiveness and lack of lasting adverse effects. Although the specific physiologic mechanisms through which R&I reduces pain have not been proven, relaxation reduces muscle tension, quiets the sympathetic nervous system, and provides a cognitive distraction from distress and pain sensations. R&I may also lead to neuroendocrine changes that inhibit pain perception.

For headache and TMD pain, relaxation appears to be the treatment of choice, with biofeedback instituted for those patients who do not benefit from relaxation. For other chronic conditions, R&I may be as effective as biofeedback or any other packages of cognitive–behavioral skills. Furthermore, R&I is difficult to distinguish from hypnosis either in procedure or in effect. Similarly, with acute pain, R&I is as effective as other cognitive–behavioral approaches that have been studied.

There are no populations that should be excluded from using R&I, except for those with religious or other firm objections. Children and adults equally benefit from the methods. Older adults also benefit.[109] Although R&I would rarely be used for painful conditions without considering appropriate medical treatments as well, R&I helps patients to be active participants in their health and should be considered whenever medical care alone is not adequate to alleviate pain.

Continuing challenges are to make this method less dependent on people with highly specialized expertise and to facilitate the incorporation of R&I into routine practice through training of nurses, technicians, and physicians providing front-line care. Other strategies are being tested that would combine video, printed, and audiotaped materials to patients who do not have access to experts or to provide these same types of materials through World Wide Web treatment groups. Matching patient characteristics to specific R&I techniques may also improve use. The survival of R&I as a pain strategy to combine with medical treatment may depend on these efforts to make R&I widely accessible.

CHAPTER 86 ■ GROUP THERAPY FOR CHRONIC PAIN

BEVERLY E. THORN, REGINA MCCONLEY, AND BARBARA B. WALKER

Group treatment has become a common method of helping patients manage chronic pain.[1] First appearing in the pain management literature in the early 198Os, case reports[2] and open clinical trials[3,4] focused on adapting individual treatments for small-group formats and exploring the acceptability of a group format to patients. Since that time, numerous controlled research trials have established the efficacy of group treatment for helping patients manage chronic painful conditions.

Although case reports and open clinical trials continue to accumulate in the literature and provide valuable information, in an evidence-based practice, randomized controlled trials (RCTs) provide stronger support.[5] As a result, findings presented in this chapter are based on searches of the scientific literature that were performed as recommended within the practice of evidence-based medicine.[6] Specifically, Medline, PsycINFO, and the Cochrane Collaboration Databases were searched dating back to 1980 using combinations of controlled vocabulary terms, keywords, and methodological filters in an effort to identify the highest level of evidence currently available on group treatment of chronic pain. Details of these searches may be found in Appendix A.

These literature searches revealed that controlled trials have primarily centered around four different types of groups: (a) cognitive-behavioral therapy (CBT) groups that focus on teaching pain self-management skills; (b) mindfulness-based pain reduction groups that are sometimes included as part of CBT but often delivered separately; (c) education groups; and (d) supportive/expressive groups. The vast majority of well-controlled trials have found that group CBT is efficacious for treatment of chronic pain; as a result, the focus of this chapter is on group CBT for the management of chronic pain conditions.

BASIC CONSIDERATIONS OF GROUP TREATMENT FOR PAIN MANAGEMENT

Rationale for Group Treatment

Evidence for Efficacy of Group Treatment for Chronic Pain

To find the best available evidence in an evidence-based practice, one searches specifically for meta-analyses and systematic reviews that synthesize the evidence quantitatively. To our knowledge, no meta-analyses or systematic reviews of group cognitive–behavioral treatments (CBT) as a treatment for chronic pain have been published to date. Our literature search did reveal numerous controlled studies (both randomized controlled trials [RCTs] and

nonrandomized controlled trials) that have compared (1) group treatment to individual treatment and (2) group treatment to wait-list controls, to treatment as usual, and to other kinds of group treatment (e.g., relaxation or education/support groups) and (3) behavioral group treatments to group exercise and physical therapy treatments. These are reviewed below.

Group vs. Individual Treatment. Table 86.1 summarizes the controlled studies that have directly compared the efficacy of group-administered treatment to individually-administered treatment for chronic pain.[7–12] Although relatively few studies have compared group to individual treatment, they have consistently demonstrated few meaningful differences in outcome between the two treatment modalities.

One of the earliest RCTs comparing group to individual treatment[8] found no differences in outcome between the two modes of treatment for headache patients with the exception that at the 6-month follow-up, participants in the group condition showed less of a tendency to drift back toward baseline levels of pain ratings. Since participants knew prior to treatment that they would be randomly assigned to group or individual treatment formats, posttreatment interviews queried their perceptions regarding the treatment modality to which they were ultimately assigned. Patients in group treatment highlighted the benefit of being able to share openly with other headache sufferers and to discuss their progress with others in the group. Patients in individual treatment valued the personalized attention given via the dyadic therapeutic relationship and expressed concern that group treatment would not have offered sufficient therapist time for each individual. Thus, participants who participated in each treatment modality seemed to highlight the positive aspects of the treatment modality to which they were assigned as the reasons why this would be the preferred mode of treatment.

Another early RCT focusing on patients with pain in the upper extremities also demonstrated minimal overall differences between individual and group treatment.[10] At 6-months and 2-year follow-up, those who received the group treatment reported less pain-related interference than those who were treated individually, and treatment outcome was otherwise equally efficacious.[10,11] It is interesting to note that posttreatment satisfaction ratings were higher for individually-treated patients, and individual treatment was more effective than group treatment on the outcome measure of self-reported coping strategies. One limitation of these early RCTs, however, was the relatively low number of participants in each condition, which limited the statistical power. A benefit of the studies was the collection of patient satisfaction data.

Several more recent trials have confirmed these general findings. In patients with chronic low back pain, Rose et al.[9] reported few differences in an RCT comparing patients treated individually and those treated in groups. In a sample of patients with mixed chronic pain, Frettloh et al.[7] also found few statistically significant differences in treatment outcome between individual and group modalities, although the effect sizes in improvement at follow-up suggested that group treatment may have been superior to individual treatment.[7] In another RCT of mixed chronic pain patients, Turner-Stokes et al.[12] compared outpatient group and individual therapies and found that both treatments resulted in improvements on measures of depression, anxiety, medication consumption, general activity, and pain severity. Those treated in a group showed greater initial gains than those treated individually, but these treatment differences were not sustained over time. Patients treated individually showed slower initial gains, but evidenced the same benefits as those who had been treated in a group at the end of treatment. These authors also reported less of a tendency for the treatment gains made by individually-treated patients to drift back toward baseline over time. In this study, however, group treatment was delivered for more hours at a time and over a shorter duration (8 weeks) than individual treatment (spread over 16 weeks), and this difference could explain the slower treatment gains witnessed with the individually-treated patients. These few distinctions notwithstanding, these authors and others have generally concluded that there are very few meaningful differences between outcomes resulting from group and individually administered treatments for chronic pain.

Group CBT vs. Wait-List, Treatment as Usual, or Other Group Treatments. Table 86.2 summarizes the controlled studies that have compared group-administered CBT to wait-list control conditions, treatment as usual conditions, or other group treatments such as relaxation, education, or supportive/expressive group therapy.[13–47] There are an impressive number of controlled trials that have been carried out by different research groups focusing on different populations of pain patients that together establish the efficacy of CBT for chronic pain. In most cases, RCTs that compared group CBT to other types of group treatments also included a wait-list condition to control for the natural progression of the chronic pain disorder. Below we highlight findings from studies comparing group CBT to other types of group treatment because they have played an important role in identifying specific mechanisms responsible for treatment efficacy.

CBT is a generic term used to describe a complex and multifaceted treatment. Although the general principles associated with CBT are likely consistent across studies (i.e., teaching pain self-management strategies and that one's thoughts and feelings influence one's ability to cope with pain), the specific treatment components vary across studies. CBT almost always includes one or more modules on recognizing and modifying maladaptive or distorted pain-related cognitions and beliefs, enhancing cognitive coping, learning relaxation strategies (including one or more types of relaxation techniques such as biofeedback, autogenic relaxation, progressive or passive muscle relaxation, meditation, and/or self-hypnosis), and completing regular homework assignments for skills acquisition. Frequently, but less consistently, CBT includes modules focusing on stress management (sometimes referred to as stress inoculation), paced physical activity, assertive communication, pleasant activity scheduling, and coping self-statements.

Because of the varied approaches that have all been subsumed under the label of CBT in the literature, it has been difficult to identify the specific treatment components that account for treatment efficacy. Controlling for nonspecific treatment effects (e.g., attention from therapist, expectations of health care provider and patient) is an important step toward determining the specific components of treatment efficacy. Comparing patients receiving group treatment for chronic pain to those on a wait-list does not allow for this type of analysis although wait-lists do control for the natural progression of the disorder over time and potential reactivity associated with self-monitoring or keeping pain diaries (if included as part of the study). The social context in which the treatment is administered is of particular relevance for the study of the active components of group treatment approaches. Therefore, studies comparing one type of group treatment to another type of group treatment provide better evidence for the nonspecific treatment effects of group treatment (e.g., social support from group members, group problem solving).

There are a limited number of studies in which one group treatment for pain has been compared to another. One study in patients with mixed chronic pain, for example, compared group education plus CBT to group education plus group discussion to control for attention.[27] These authors found that both groups showed equal improvements in pain coping and knowledge, and both were superior to a wait-list control condition. An economic evaluation of the treatments resulted in the authors' suggestion that the extra health care costs associated with the addition of the CBT modules were not warranted based on the outcomes.[27,48] It is important to note that the education modules that were offered to all participants included structured physical fitness

(text continues on page 1275)

TABLE 86.1

INDIVIDUAL VS. GROUP THERAPY

Authors	N	Study	Treatment type	Treatment components	Duration	Outcome measures	Results	Limitations	Follow-up (f/u)
Frettlöh & Kröner-Herwig, 1999	102 mixed chronic pain	Non-randomized Controlled Trial*	Group CBT (N = 34) vs. Individual CBT (= 34) vs. control (TAU = 34)	Education, relaxation, imagery, cognitive restructuring	12 weeks	Subjective disability, catastrophizing (katastrophisierende Kognitionen), depression (Depressivitat), coping (kognitives Coping), pain diary	Group & individual >control for majority of outcomes. Group = individual for depression and most other measures. Larger effect sizes for group compared to individual at f/u	Session duration not specified *Information obtained from English abstract only	6 mos.
Johnson & Thorn, 1989	22 Headache	RCT	Group CBT(N = 7) vs. Individual CBT (N = 7) vs. Wait-list Control (WLC) (N = 8)	Psychoeducation, Cognitive Coping Strategies, Relaxation	5 weekly 90 minute sessions	McGill Pain Questionnaire MPQ, Brief Symptom Inventory (BSI), Self-monitoring cards (for pain intensity, no. of prescribed medications, no. of OTC medications, no. of prescribed pills consumed, no. of OTC pills consumed)	Improvement in pain ratings and decrease in anxiety across groups from Times 1 to 2. Decreases in number of times individuals took medication and in number of different medications taken. GCBT = ICBT overall	Small sample size, limited power	1, 3, & 6 mos.
Rose et al., 1997	84 chronic low back pain	RCT	Part 1: Group CBT (N = 26) vs. Individual CBT (N = 24) Part 2: compared 15-hr (N = 22), 30-hr (N = 22), or 60-hr duration treatments	Education, Cognitive therapy, graded aerobic exercise, relaxation	15, 30, or 60 hours duration	VAS pain severity scale (0 to 100), Roland & Morris Disability Questionnaire, Modified Somatic Perception Questionnaire (MSPQ), Modified Zung Depression Inventory, Pain Locus of Control Scale, Pain self-efficacy Questionnaire	Individual = group treatments on outcome measures. Individual tx more strongly associated with changes in disability and on MSPQ. No differences in program duration on outcome.	No control for baseline differences on some variables	6 mos.
Spence, 1989, & Spence, 1991 (2-yr follow-up)	45 Chronic work-related pain of the upper extremity (19 followed at 2 yrs)	RCT	Group CBT (GCBT) (N = 13) vs. Individual CBT (ICBT) (N = 14) vs. WLC (N = 15)	Goal setting, cognitive restructuring, relaxation, cognitive skills training, dealing with sleep problems, assertiveness training	9 weekly sessions at 1.5 hours	BDI Spielberger State-Trait Anxiety Inventory (STAI) Coping Strategies Questionnaire (CSQ) McGill Pain Rating Index (PRI) Sickness Impact Profile (self-report & other-report) Daily Self-Monitoring	GCBT & ICBT> WLC for reductions on all outcome measures. Improvements maintained at f/u GCBT = ICBT 2 yr f/u: Less relapse for GCBT for pain ratings and interference, GCBT = ICBT for other outcomes	Small sample size, Limited power	6 mos., 2 years
Turner-Stokes et al., 2003	113 mixed chronic pain	RCT	Group cognitive-behavioral therapy (CBT)(N = 66) vs. Individual CBT (N = 47)	Group and individual: relaxation, cognitive coping strategies, activity pacing, encouraged to exercise by building up with achievable goals	Group: 1 full afternoon per week for 8 weeks Individual: 1 hour sessions every other week for 8 weeks	West-Haven Yale Multi-dimensional Pain Inventory (WHYMPI), State-Trait Anxiety Inventory (STAI), Beck Depression Inventory (BDI), General activities, analgesic medication consumption, and pain severity	Both groups: significant improvements in pain interference, control over pain, and depression. Group = individual at follow-up. Rapid improvements in Group, slower improvements in individual. Differences leveled off at f/u Group = individual overall	Treatment intervals differ according to group or individual assignment	6–12 mos.

TABLE 86.2

GROUP COGNITIVE AND BEHAVIORAL THERAPY STUDIES

Authors	N	Study	Treatment type	Treatment components	Duration	Outcome measures	Results	Limitations	Follow-up (f/u)
Thorn et al., (2007)	34 Headache	RCT compared order of treatment modules	Cognitive-behavioral therapy (CBT) (N = 22) vs. WLC (N = 11)	Cognitive restructuring, cognitive coping, relaxation, assertiveness, behavioral pacing, homework	10 90-minute group sessions	Pain Catastrophizing Scale (PCS), Pain Anxiety Symptoms Scale (PASS), Beck Depression Inventory – II (BDI-II), Headache Management Self-Efficacy Scale(HMSE), Pain and Medication via pain diaries	CBT>WLC for improvements in catastrophizing, anxiety, headache management self-efficacy. 50% treated patients showed clinically significant reductions in h.a. frequency, medication use no difference in outcome based on order of treatment	Small sample size rendered limited power to detect potential differences in order of treatment modules	6 mos, 12 mos.
Li et al., 2006	64 with work-related injuries	RCT	Training on Work Readiness (T) (N = 34) vs. Control (C) (N = 30)	T: individual vocational counseling (3 sessions), CBT, pain and stress management, relaxation, stages of change assessment, job acquisition, pre-employment training	T: 3 weekly group sessions at 2–3 hours, 3 one hour individual sessions	Spinal Function Sort (SFS), Loma Linda University Medical Centre Activity Sort (LLUMC), Chinese Lam Assessment of Stages of Employment Readiness (C-LASER), Chinese State Trait and Anxiety Inventory (C-STAI), Short form Health Survey (SF-36)	T>C for improvements in anxiety, work readiness, readiness to change, and perceived health status T: within-group improvements from baseline for most SF-36 subscales & physical capacity	Lack of f/u, stages of change may require longer time period for assessment	None specified
Linton et al., 2005	185 workers with back/ neck pain	RCT	CBT (N = 69) vs. CBT and physical therapy (CBT + PT) (N = 69), vs. Minimal treatment (N = 47)	CBT: problem solving, homework, skills training, stress management, relaxation CBT + PT: CBT plus personalized exercise program Minimal: medical visit and advice, educational booklet	6 weekly 2 hour sessions	Sick absenteeism, health care visits, Outcome Evaluation Questionnaire, VAS pain ratings, HAD, Pain Catastrophizing Scale (PCS), Tampa Scale of Kinesophobia (TSK), ADLs, Roland Morris Disability Questionnaire (RMDQ)	CBT + PT = CBT for most measures. CBT + PT >Minimal for reductions in health care visits. At f/u: CBT + PT fewest sick days, followed by CBT and Minimal. Both treatment groups 5 times less likely to be on long term sick leave than Minimal.	Different intervention lengths	1 year
Gold et al., 2004	185 women with vertebral fracture	RCT	Part 1: Intervention (I)(N = 94) vs. Education control (EC) (N = 91) Part 2: Crossover: EC becomes I group after 6 mos. Initial I group self maintenance	I: exercise, coping skills (relaxation, stress reduction) EC: education of health issues for women	Part 1: I: 5 weekly exercise & coping sessions (225 min) EC: 1 weekly session at 45 min Part 2: I: self-maintain EC = I group	Trunk extension strength, Functional Status Index (FSI), Global Severity Index of Hopkins Symptom Checklist-Revised	Part 1: I >EC for improvement in trunk extension & psychological symptoms EC: worse for all three outcomes Part 2: EC showed within-group improvements in trunk extension & psychological symptoms after intervention I: decrease in back strength from post-tx, improvement in psychological state maintained	Different session lengths for I & EC, no control group at F/U. I group did not receive education in cross-over design	6 mos.

TABLE 86.2

CONTINUED

Authors	N	Study	Treatment type	Treatment components	Duration	Outcome measures	Results	Limitations	Follow-up (f/u)
Van Lankveld et al., 2004	59 rheumatoid arthritis	RCT compared couples to patient only group	Couples (C) (N = 31) vs. Patient only (P) (N = 28)	Education, cognitive restructuring, encouragement to use active coping skills	C: 2 weekly 1.5 hour sessions for 4 weeks	Disease Activity Score (DAS): swollen joint count Impact of Rheumatic Diseases on General Health & Lifestyle (IRGL), Coping with Rheumatoid Stressors Questionnaire (CORS), Maudsley Marital Questionnaire (MMQ)	Sample improvements in disease activity, cognitions, coping, physical & psychological function (C = P). At f/u: C >P for improvements in disease related communication with spouse	Possible selection bias of highly invested couples because of study design	6 mos.
Ersek et al., 2003	45 elderly with chronic pain	RCT	Self Management (SM) (N = 17) vs. Educational booklet Control (EB) (N = 23)	SM: education, self-monitoring, communication, relaxation, individualized goals, homework EB: booklet with information about pain, medications, instructions for self-management, and pain resources	SM: 7 group sessions at 90 min	SF-36, Graded Chronic Pain Scale, Geriatric Depression Scale, Survey of Pain Attitudes (SOPA), survey assessing use of pain management strategies, treatment usefulness scales	SM >EB for improvements in pain intensity and physical role function (pre-post change); Clinically significant improvement in 43% SM & 13% EB; SM = EB at f/u.	Brief follow-up	3 mos.
Tkachuk, 2003	28 Irritable Bowel Syndrome (IBS)	RCT	CBT (n = 14) vs. Home based symptom monitoring with weekly telephone contact (SMTC) (n = 14)	CBT: Education, relaxation, cognitive restructuring, assertiveness training SMTC: daily symptom monitoring, discussion of symptom patterns	10 90 min sessions for 9 weeks	Daily monitoring IBS scores, BDI II, cognitive emotional distress (CSFBD), trait anxiety (STAI-T), discomfort with assertion (AQ), quality of life (SF-36)	CBT >SMTC for pain relief ratings, improvement in GI Symptoms, quality of life. Maintained at f/u. 1/3 treated patients experienced clinically significant improvement	Brief f/u	3 mos.
Leibing et al., 1999	55 rheumatoid arthritis	RCT	CBT (N = 19) vs. Treatment as Usual (TAU) (N = 36), change in medication matched control group (CN) (N = 20)	CBT: Education, relaxation, cognitive restructuring, pain management, pleasant activity scheduling	CBT: 12 weekly sessions at 90 min	C-reactive protein (CRP), blood sedimentation rate (Westergren), swollen joint count, Hannover Functional Ability Questionnaire (HFAQ), Medication types, VAS pain intensity, Affective pain score, pain diary, STAI, Depression Scale (DS), Arthritis Helplessness Scale (AHI), Bernese Coping Modes	Overall increase in disease activity across sample. CBT less progressive inflammation than TAU. CBT >CN for pain reduction, improvements in depression, anxiety, helplessness. CBT: improved depression, helplessness, positive coping from baseline	Potential Type I error from multiple significance tests. Lack of f/u	None specified

Potts et al., 1999	60 non-cardiac chest pain	RCT	CBT (N = 34) vs. WLC (N = 26)	CBT: Education, relaxation, biofeedback, graded exercise, challenging automatic thoughts, homework WLC: delayed treatment	6 sessions at 2 hours	HADS, Nijmegen hyperventilation scale, Sickness Impact Profile (SIP), Nottingham Health Profile (NHP), Chest pain diaries, Hyperventilation: portable carbon dioxide monitor, Exercise electrocardiography (ECG)	CBT >WLC for improvements in chest pain frequency, pain free days, anxiety, and depression, disability, and exercise tolerance. Similar results for delayed treatment group once treated. Overall, 76% had improvements in chest pain. Maintained at f/u	Lack of control group at f/u	6 mos.
Cole, 1998	113 mixed chronic pain	Non-randomized controlled trial	CBT (N = 88) vs. TAU (N = 25)	Coping skills pain self-management, adjustment, stress management, relaxation, self-esteem, positive thinking	75 min, 1 per week for 16 weeks	Multidimensional Pain Inventory (MPI), Minnesota Multiphasic Personality Inventory-2 (MMPI-2), Beck Depression Inventory (BDI) Reported narcotic medication usage, health care visits, work status	CBT: decreases in BDI and MPI scores, & health care visits from baseline, increase in return to work F/U: medication decreased from 75% at baseline to 44%, health care visits decreased from 5 per month to 1 per month. Work status increased from 10% to 31%	Patients not randomly assigned. No direct comparison between CBT and control groups	1 year
Keel et al., 1998	27 Fibromyalgia (FM)	RCT	CBT (N = 14) vs. Autogenic (N = 13)	CBT: stress inoculation, cognitive restructuring, activities for pain diversion, information, relaxation, group discussion, stretching, aerobic exercise Autogenic: practice relaxation	15 weekly sessions lasting 1–2 hours.	Feiburg Personality Inventory Locus of Control Scale Rosenzweig Picture-Frustration Diary (of active hours, resting hours, sleep index, pain intensity, and medication consumption) General Symptom Checklist	2 CBT clients vs. 1 autogenic had clinically significant improvement in medication consumption, physical therapies, sleep, pain scores, general symptoms At f/u: CBT >autogenic for improvement in pain ratings. 4 CBT vs. 0 autogenic had clinically significant improvements at f/u	Small sample size; Statistical analyses not described	3 mos.
Keel et al., 1998	411 low back pain	Non-randomized controlled trial	Experimental (E) (N = 243) vs. Standard physiotherapy (S)(N = 168)	E: coping strategies, stress management, relaxation, simulated work situations fitness training, education and group activity, individual physiotherapy or psychotherapy for acute pain, S: mostly individual physiotherapy	E: 4 week (27 day) inpatient program S: 3 week (20 day) inpatient program	Work situation, physical activities, pain history, VAS pain rating, pain drawing, RMDQ, Psychological General Well-being Index (PGWB), health costs, quality of life, impairment	E = S for improvements in functional ability, limitations in daily life, health care visits E: higher proportion of individuals in work rehabilitation (23% work incapacity decrease), E >S daily hours worked, decrease in professional handicaps. At f/u: larger proportion of S worsened	Pre-existing differences between groups on demographic variables. Different predominant treatment modalities in each condition (E = group, S = individual)	3 mos., 1 year
Basler et al., 1997	94 low back pain	RCT	CBT (N = 36) vs. TAU (N = 40)	Education, relaxation, modifying thoughts and feelings, pleasant activity scheduling, postural training	12 weekly sessions at 150 minutes	Pain diary (pain intensity, control over pain, medication consumption), Heidelberg Coping Scale (HCS), Dusseldorf Disability Scale (DDS)	CBT: decreases in pain intensity, improvements in coping with pain, mental performance, and disability Gains maintained at 6 month f/u TAU: Little or no change	High attrition rate at f/u	6 mos.

(*continued*)

TABLE 86.2

CONTINUED

Authors	N	Study	Treatment type	Treatment components	Duration	Outcome measures	Results	Limitations	Follow-up (f/u)
van Dulmen et al., 1996	45 IBS	Non-randomized controlled trial	CBT (N = 25) vs. WLC (N = 20)	Patient education (e.g., roles of cognitions, behaviors, in IBS), homework, discussion, progressive muscle relaxation	8 weekly sessions lasting for 2 hours	Diary (duration of pain, daily avoidance behavior, GI complaints), Abdominal Complaint Inventory, Symptom Checklist 90 (SCL-90)	CBT >WLC for improvement in Daily Abdominal Complaint Score (DAC), duration, avoidance, and number of successful coping strategies delayed treatment group: decreases in DAC, Improvements maintained at f/u	No WLC at f/u, wide range of f/u assessment times (6 mos. to 4 years)	Mean = 2.25 years
Vlaeyen et al., 1996	131 FM	RCT	Cognitive educational intervention (ECO = 47) vs. Attention control condition of education & discussion (EDI = 39) vs, WLC (N = 40)	ECO: imaginative transformation of pain, relaxation & biofeedback, homework EDI: education, sharing thoughts with group members, listening to music, homework	ECO & EDI = 12 90 minute sessions conducted in 6 weeks	Pain cognition list, Coping Strategies Questionnaire (CSQ), Behavioral Approach Test, Pain Behavior Scale, McGill Pain Questionnaire (MPQ) Multidimensional Pain Locus of Control Scale, Checklist for Interpersonal Pain Behavior, Fear Survey Schedule, BDI	ECO = EDI for improvements in pain coping and knowledge EDI >WLC on knowledge and pain control. At 12 month f/u, ECO = EDI, although ECO had an increase in pain intensity	Potential confounding of treatment (EDI group shared thoughts, completed homework). Low education level of participants may have made ECO difficult	12 months
Newton-John et al., 1995	44 chronic back pain	RCT	CBT (= 16) vs. Electro-myographic Feedback (EMGBF = 16) vs. WLC (= 12)	CBT: education, goal setting, relaxation, cognitive restructuring, homework EMGBF: education, diaphragmatic breathing, adaptation, homework	8 sessions at 1 hour (2 sessions per week)	BDI, STAI, (CSQ), Pain Disability Index, Pain Beliefs Questionnaire (PBQ)	CBT & EMGBF >WLC for improvements in intensity, disability, adaptive beliefs, & depression. Improvements maintained at f/u, along with improvements in anxiety and active coping	Small sample size per group	6 mos.
James et al., 1993	33 headache	RCT	CBT with Goals (Goal Group) (N = 13) vs. CBT with no goals (Open Group) (N = 13) vs. WLC (N = 7)	Both CBT groups: education, coping, developing appropriate self-talk, generalization of skills, relaxation Goal: specific time goals for coping with pain/stress Open: instructions to cope as long as possible	6 weekly sessions at 90 minutes	Goal specificity: coping with daily stressors and pain, daily self monitoring, pain index, medication intake, downtime, Pain Behavior Questionnaire, SCL-90, SIP, BDI, STAI, Cognitive Coping Index	Goal & Open groups >WLC for improvements in pain coping skills, Goal group >Open & WLC group for reduction of headache and non-narcotic medication use	Lack of f/u period	None specified

Turner & Jensen, 1993	102 low back pain	RCT	Relaxation (R) (N = 17) vs. cognitive therapy (C) (N = 21) vs. cognitive therapy & relaxation (CR) (N = 16) vs. WLC (N = 18)	R: imagery, progressive muscle relaxation (PMR) C: identify negative thoughts, counter negative automatic thoughts CR: combined treatment	6 weekly sessions at 2 hours	VAS pain ratings, SIP, BDI, Observed Pain Behaviors, Cognitive Errors Questionnaire, BDI	R, C, & CR >WLC for improvements in pain ratings, and disability. At f/u: all three patient groups improved. At both f/u, patients in all groups improved R = C = CR	No comparison to control group at f/u, attrition rates for control condition	6, 12 mos.
Kneebone & Martin, 1992	35 headache	Non-randomized controlled trial. Compared couples to standard non-couple and control groups	Partners involved (PI)(N = 12) vs. No partners (NPI)(N = 10) vs. No treatment control (NTC)(N = 13)	PI & NPI: self-monitoring relaxation, cognitive restructuring, assertiveness, group process (e.g., support), homework PI: partners educated in reinforcement principles	10 weekly sessions at 1.5–2 hours	Headache activity, intensity, medication usage, relaxation practice, Partner Involvement Questionnaire, Dyadic Adjustment Scale (DAS), self-monitoring forms	PI = NPI for relaxation time, PI >NPI for partner involvement: spouse assisted with relaxation PI: decrease headache activity from baseline NPI: decreased medication usage from baseline. NTC increased medication usage. At f/u, NPI >NTC for reductions in medication. Other measures: PI = NPI at f/u	Potential for Type 1 inflation. Low motivation across treatment groups to practice relaxation	2 mos., 12 mos.
Nicholas et al., 1991	58 low back pain	RCT	Cognitive Therapy (CT) + relaxation (N = 8) or CT (N = 10) vs. Behavior Therapy + relaxation (N = 9) or BT (N = 10) vs. attention (ATC N = 10) & no attention control (N = 11)	All groups: physiotherapy, education, exercise CT: cognitive restructuring, distraction, imagery, self-monitoring BT: activity pacing, medication reduction, reinforcement Relaxation: PMR ATC: group discussion about back pain	5 1.5–2 hour sessions twice per week	Pain Rating Chart STAI, PBQ, CSQ, SIP, SIP-Others (SIP-O), Medication intake, report of alternative treatments, visits to health care facilities	Sample improved on affective distress, functional impairment, medication use, and active coping. Both CBT groups & both BT groups >ATC & control for improvements in pain intensity, self-reported disability, pain beliefs, and active coping. BT >CBT for improvements in impairment. Improvements somewhat maintained at f/u	Physiotherapy included as part of all treatments Small sample size	6, 12 mos.
Subramanian, 1991 & Subramanian, 1994	39 mixed chronic pain Long term F/U = 22	RCT	Structured group therapy (N = 19) vs. WLC (N = 20)	Therapy: stress management, relaxation cognitive restructuring (coping thoughts, self-defeating, self-enhancing thoughts), assertiveness training	8 weekly 2 hour sessions	SIP, Pain level (0–10 scale) used a control variable Profile of Mood States (POMS), social support questionnaire	Therapy >WLC for improvements in physical and psychosocial dysfunction, negative mood states. Within-group improvements also apparent. Long term f/u: Improvements maintained, improvement in pain severity observed, 77% improved from post to f/u, 36% reduction in prescription medication usage	No comparison group at long term f/u	6 mos. Long-term: 18–22 mos.

TABLE 86.2

CONTINUED

Authors	N	Study	Treatment type	Treatment components	Duration	Outcome measures	Results	Limitations	Follow-up (f/u)
Peters & Large, 1990	68 chronic pain	RCT	Group inpatient program (IPMP)(N = 29) vs. Group outpatient program (OPMP)(N = 23) vs. control (C)(N = 16)	IPMP: education, pain management, relaxation, cognitive restructuring, exercise, vocational counseling, reinforcement OPMP: education, activity goal setting, exercise, medication & stress management, relaxation	Inpatient: 4 weeks Outpatient: 9 weekly sessions at 2 hours	BDI, MPQ, General Health Questionnaire (GHQ), SIP, Pain Behaviour Checklist, pain drawings, VAS ratings, VAS stair climbing test, physiological measures, physical endurance	Sample improvements in disability, GHQ scores, BDI, & MPQ scores IPMP & OPMP >control for improvements in disability, VAS pain ratings, and pain behavior	Results may have been influenced by timing of the assessments, lack of f/u	None specified
Turner et al., 1990	96 chronic low back pain patients	RCT	Group behavioral and aerobic exercise (BE) (N = 18) vs. Behavioral Therapy only (B)(N = 18) Aerobic exercise only (E)(N = 21) vs. WLC (N = 23)	BE: behavioral intervention followed by exercise in each session B: reinforcement role-playing, discussion, homework, communication E: Exercises 5 times per week	BE & B: 8 weekly 2 hour sessions E: 5 weekly sessions	McGill Pain Questionnaire (MPQ), SIP, Pain Behavior Checklist (PBC), PBC-spouse ratings, Physical Work Capacity (PWC), Center for Epidemiological Studies Depression Scale (CES-D), recorded pain behaviors	All 3 groups improved more than the WLC from pre to post treatment (tx), BE >WLC from pre to post tx on self-report and observer rated pain behavior measures, BE >E on PBC Spouse ratings Follow-up: all tx groups improved over time	Interaction with therapists varied by condition	6, 12 mos.
Linton et al., 1989	66 nurses with back pain	RCT	Physical and behavioral preventive intervention (PBI)(N = 36) vs. WLC (N = 30)	PBI: physical therapy, ‘‘low back school’’, relaxation, pain control instruction, goal-setting, problem-solving, coping, identifying high-risk situations	PBI: 8 hours per day for 5 weeks	Daily pain diaries, VAS intensity, fatigue, anxiety, sleep, pain behavior, activities of daily living (ADLs), BDI, AHI, marital satisfaction, absenteeism, medication intake	PBI >WLC for improvements in pain intensity, fatigue, pain behavior, sleep, ADLs, helplessness Most differences maintained at f/u	Use of non-standardized measures of sleep quality, ADLs, marital satisfaction	6 mos.
Puder, 1988	69 mixed chronic pain	RCT	Stress inoculation training (SIT) (N = 31) vs. WLC (N = 38)	SIT: explaining treatment, reviewing progress, problem solving	10 weekly 2 hour group sessions	Daily pain diary, non treatment technique usage: psychological support, exercise, heat/cold, massage, TENS, injections	SIT >WLC for improvements in pain interference, coping, decreased analgesic intake, discontinuation of heat/cold, and home traction technique. No diff. according to age Improvements maintained at f/u	Use of non-standardized measures	1, 6 mos.

Bradley et al., 1987	53 rheumatoid arthritis	RCT	Biofeedback assisted CBT (N = 17) vs. Structured group social support therapy (SGT) (N = 18), No adjunct treatment (NAT) (N = 18)	CBT: thermal biofeedback, education, relaxation, behavioral goal setting, self-reward SGT: education, discussion of coping strategies, encouragement to develop improved strategies	CBT: 5 thermal sessions, 10 family/ friend meetings SGT: 15 sessions family/ friends	STAI, Depression Adjective Checklist (DACL), Health Locus of Control Scale (HLCS), AHI, pain behaviors, rheumatologist ratings of disease activity level, rheumatoid factor titers, sedimentation rate (Westergren)	CBT >SGT & NAT for decreases in pain behavior, pain ratings, rheumatoid activity (RAI), NAT: lower RAI scores than SGT SGT & NAT increased in depression and rheumatoid factor titer across assessments, CBT & SGT >NAT for improvement in anxiety CBT maintained improvement at f/u	Session duration not specified	6 mos.
Larsson et al., 1987	36 high school students with tension/ migraine headaches	RCT	Self Help Relaxation (SHR) (N = 12) vs. Problem Discussion Condition (PDC) (N = 10) vs. Untreated Self Monitoring Condition (SM) (N = 12)	SHR: relaxation programs, rapid cue controlled strategy, homework, help solving problems during relaxation PDC: discussion of conflicts in everyday life, role-play, identifying stressors, assertiveness	5 weekly sessions SHR = 3 hours PDC = 7 hours	Headache Diary: frequency, duration headache free days, peak intensity, modified Depression Scale for Female adolescents, Children's Manifest Anxiety Scale, Social Relationship-Competence Questionnaire (SRCQ)	Headache Activity: Greatest reductions for SHR group, SHR >SM and PDC Headache sum and peak intensity: SHR >PDC during pre-follow-up interval Headache duration and headache free days: SHR >SM and PDC	Small sample size, different therapist interaction for two interventions.	5 mos.
Bradley et al., 1985	33 rheumatoid arthritis (RA)	RCT	Thermal Biofeedback and group cognitive behavioral (CB = 11) vs. Social support (SS = 10) vs. NAT (= 12)	CB: thermal biofeedback, education, skills acquisition, self-instructional training, application SS: education, support, encouragement to develop own coping strategies, NAT = control	CB: 5 individual thermal sessions, 10 family meetings SS: 15 family meetings	STAI, DACL, VAS ratings of pain intensity, unpleasantness, severity of morning stiffness, pain behaviors, HLCS, rheumatoid factor titers, Westergren, rheumatologist ratings of disease activity.	CB >NAT group for significant decreases in pain intensity, Pre to Post: CB less pain behavior from pre to post, less rheumatoid activity, and rheumatoid factor titer. CB & SS less anxiety and depression. SS increase in sedimentation rate NAT: sig. reduction in morning stiffness	Small sample size, lack of f/u	None specified
Linton et al., 1985 & Melin & Linton, 1988	28 chronic pain	RCT Long-term f/u	Regular treatment (RT) vs. Applied Relaxation and operant activities (RT + BT) vs. WLC	RT: prescribed treatment plan RT+BT: plan and relaxation training, operant training, reinforcement of well behaviors, decrease in medication	12 sessions	BDI, Activities of Daily Living questionnaire, self-monitoring of pain, medication consumption, sleep f/u measures also included pain, health, activity, level, sleep, occupation	RT + BT >RT & WLC for improvements in pain level and leisure activity. Improvements maintained at f/u	Small sample size Long term f/u: WLC group received individual treatment prior to assessment	14–16 mos.

(*continued*)

TABLE 86.2

CONTINUED

Authors	N	Study	Treatment type	Treatment components	Duration	Outcome measures	Results	Limitations	Follow-up (f/u)
Moore & Chaney, 1985	43 mixed chronic pain	RCT	Couples group therapy (CBT)(N = 17) vs. Patient only group Therapy vs. (N = 14) WLC(N = 12)	Couples & patient only: education, goal-setting, problem solving, relaxation and controlled breathing, direct pain reduction method, coping strategies, homework.	16 hour program, Couples: 8 bi-weekly 2 hour sessions	VAS pain severity (patient and spouse) MMPI Hs, D, & Hy scales only, SIP, PARS IV Community Adjustment Scale (spouses) Locke Marital Adjustment Test (LMAT) Utilization of medical resources medication usage	Couples and patient only groups >WLC for improvements in VAS ratings, pain severity & pain behavior ratings, somatization, & PARS (spouse rating) Patient only groups >controls on LMAT & SIP scores Treatment gains maintained at f/u Couples = patient only therapy	Small sample sizes for each condition	3, 7 mos.
Cohen et al., 1983	25 Chronic Low Back Pain	RCT	Behavioral Intervention (BT)(N = 13) vs. Physical Therapy (PT) (N = 12)	PT: pain control strategies, relaxation, exercise, pool therapy, use of body mechanics, BT: goal setting, activity pacing, problem-solving, assertiveness	10 weekly 2 hour sessions	Physical Abilities & Walking Abilities testing, Knowledge and Functional Measure of Body Mechanics, CES-D, Psychological Adjustment to Role Scale (PARS-V)	PT: Greater low back control and decreases in CES-D score. BT & PT: Lower anxiety and depression per patients and sig. others on PARS-V, others. Decreases in physical and activity limitations for both groups.	Small sample size, validity data for some instruments not provided	None specified
Figueroa, 1982	15 tension headache patients	RCT	Behavior therapy (BT)(N = 5), psychotherapy (P)(N = 5), self-monitoring (SM = 5)	BT: problem solving, relaxation, anxiety management training, stress inoculation P: discussion, conflict resolution, discussion of stressful events	BT: 7 ninety minute sessions P: 7 ninety minute sessions (twice weekly)	Headache questionnaire, Headache checklist (e.g., level of relaxation, number of headaches, duration, severity, medication usage, disability), self monitoring forms	Pre to f/u: BT >P and SM for improvements in perceived disability. BT >SM for reductions in headache frequency and duration, medication usage, level of relaxation, and pain severity.	Small sample size, use of non-standardized measures	Time not specified
Turner, 1982	36 Chronic low back pain patients	RCT	CBT (N = 13), vs. Relaxation (N = 14) training, WLC/attention conditions (N = 9)	CBT: stress inoculation, behavioral goals, cognitive and affective responses to pain, coping self-statements, relaxation Wait list/attention: gave daily pain ratings to therapist in weekly phone calls	5 weekly 90 minute sessions	SIP, SIP Significant Other (SIP-O), VAS ratings, Self-ratings of improvement, Beck Depression Inventory, Work hours, health care usage	CBT and Relaxation groups >WLC for improvements in pain, depression, disability, and spousal ratings of physical and psychosocial function At f/u: CBT improved on SIP, SIP Significant Other, pain severity, Relaxation: worse pain severity 1.5–2 year f/u: both groups retain improvements, CBT >in hours worked per week	Small sample size	1 month, 1.5–2 years

training after each of 12 sessions, and this behavioral component may have served to increase the overall outcome efficacy of both groups. Furthermore, the discussion modules (attention control) included weekly homework assignments, which is typical of CBT groups but atypical of control conditions. The authors suggest that the homework assignments may have served as a form of graded exposure for the fearful participants, thereby resulting in treatment gains in the control group. It is also important to mention that both treatment groups in the above study used limited therapist time in an effort to reduce treatment costs. It may be that the principles associated with cognitive–behavioral change require some threshold amount of therapeutic intervention in order to be successfully implemented. These findings and others led Vlaeyen and colleagues to raise the important point that the active components of group treatment need further careful study.

Another study assessed the efficacy of group CBT for pain using education booklets as the control condition[18] and found significant pre- to posttreatment differences in favor of the CBT self-management groups. Although the use of education booklets do not control for the nonspecific treatment effects of group interaction or support, this study suggests that merely offering facts about pain and pain management outside a therapeutic context does not appear to be efficacious.

Several other studies have compared group CBT to relaxation training or another group condition. In one study of patients with low back pain, patients receiving group CBT and those receiving relaxation training improved compared to wait-list controls, although at follow-up, those who received CBT showed greater treatment gains than those receiving relaxation training.[47] In a similar study with fibromyalgia patients, those who received group CBT showed greater improvement in pain ratings than those who received autogenic relaxation training.[23] Focusing on high school students with migraine and tension-type headaches, Larsson et al.[40] compared self-help relaxation groups to problem discussion groups and untreated self-monitoring groups and found self-help relaxation to be superior to the other two conditions. Together, these studies suggest that CBT groups are superior to relaxation-only groups and that relaxation groups alone are superior to groups offering only education or discussion.

A specialized subset of studies comparing one type of group treatment to another are those that have compared group CBT offered only to the patient to group CBT offered to both the patient and his or her partner. Moore and Chaney[44] found that among patients with mixed chronic pain syndromes, couples group therapy and patient only group therapy were both superior to a wait-list control group, but the patient-only groups showed significant improvement on more outcome variables than did the couples groups. Another study found similar improvements in physical and psychological functioning, cognitions, and coping among both couples groups and patient-only groups, although at 6-month follow-up, patients in the couples groups reported greater improvement in communication with their spouse than did patients in the patient-only groups.[17] Patients with chronic headache differ in some ways from those with other chronic pain syndromes, and therefore it is interesting to note that one study found that partner involvement in chronic headache management groups actually reduced efficacy compared to nonpartner involvement.[31] Further research is necessary to determine whether this finding is unique to chronic headache patients or if other variables are associated with this outcome.

Behavioral Group Treatment vs. Exercise and Physical Therapy Group Treatments. Physical therapy has long been considered an essential component of chronic pain management, and as a result it is important to consider its role in treatment groups for chronic pain. Although most studies have focused on the efficacy of physical therapy and exercise in individual chronic pain patients, we located two RCTs specifically comparing group behavioral approaches to group physical therapy. In one study, chronic low back pain patients who received group behavioral treatment and those who received group physical therapy both showed significant decreases in activity limitations, anxiety, and depression.[45] In another study, Turner et al.[36] examined the differential efficacy of group behavioral therapy alone, group aerobic exercise training alone, group behavioral therapy plus group aerobic exercise, and a wait-list control group. The three treatment groups showed greater improvement than the wait-list control group, and all groups showed increasing improvement over the 6- and 12-month follow-ups. It is important to note that in this study, the combined behavioral plus exercise group treatment showed the greatest improvement overall, suggesting that physical activity may be an important component to incorporate into group treatment for chronic pain.

Although it did not compare *group-administered* physical therapy (PT) to group CBT, the results of one additional study may shed light on this issue because it explored the incremental benefits of adding individual PT training to 6 sessions of group CBT in recently injured patients with low back pain.[15] Random assignments were made to a minimal treatment condition (physical examination, reassurance and encouragement to stay active, informational brochure), CBT alone, or CBT plus PT. The treatment gains were similar between those patients who received CBT alone and those who received CBT plus PT although the CBT plus PT group incurred fewer health care visits after treatment. Both treatment groups showed large reductions in risk for developing long-term sick disability leave compared to the minimal treatment group.

To summarize, converging lines of evidence described above and in Table 86.2 provide strong evidence that chronic pain patients benefit significantly more from group CBT than from being on a waiting list or receiving medical treatment as usual. The specific mechanisms of treatment efficacy have yet to be clearly identified, but studies to date have shed some light on these mechanisms. As efficacy research moves from open trials to RCTs designed specifically to compare group CBT to other active group treatments, future studies are likely to emerge that will help identify the active components of efficacious treatment.

Mindfulness-Based Approaches to Pain Management. There is a small but growing literature of controlled trials on mindfulness-based pain and stress-reduction or other meditative therapies for chronic pain. A meta-analysis of controlled studies of mindfulness for a wide range of clinical populations (including, but not limited to chronic pain) reported significant, moderate effect size improvement on standardized measures of physical and mental well-being.[49] Regarding group meditation treatments specific to chronic pain, we were able to locate two RCTs[50,51] and three non-randomized controlled trials.[52,53,54] (See Table 86.3 for a summary.) Most of these studies compared group meditation to standard care and found meditation to be more beneficial with respect to pain perception, pain coping and measures of affect immediately post-treatment and also at follow-up.

The studies cited above studied mindfulness as a stand-alone treatment, but mindfulness-based pain and stress reduction groups are also sometimes included as part of an integrated CBT package. In an open clinical trial comparing a group of highly disabled patients with pain (n = 53) to a group of less-disabled patients (n = 234), McCracken and colleagues[55] found that mindfulness training plus CBT (referred to as "Contextual Cognitive-Behavioral Therapy"- CCBT) resulted in large decreases in psychosocial disability and depression, and large increases in acceptance of pain in both groups, with treatment gains maintained at 3-month follow-up. Even in highly disabled patients, CCBT resulted in statistically significant and clinically meaningful treatment gains. Clearly, well-controlled trials with adequately powered samples are needed, but the literature to date suggests that group meditation treatments may prove to be efficacious for chronic pain management.

TABLE 86.3

MINDFULNESS BASED GROUP INTERVENTIONS

Authors	N	Study	Treatment type	Treatment components	Duration	Outcome measures	Results	Limitations	Follow-up (f/u)
Carson et al., 2005	43 low back pain	RCT	Loving-kindness meditation (Medi)(N = 18) vs. standard care (TAU) (N = 25)	Medi: silent mental phrases to direct positive feelings toward others attend to feelings of love instead of anger/ resentment, discussion, practice	8 weekly 90 min sessions	McGill Pain Questionnaire (MPQ), Brief Pain Inventory (BPI), State-Trait Anger Expression Inventory (STAI), Anger Expression & Control, Brief Symptom Inventory (BSI), diary, VAS ratings of pain & anger, affect, pain, & fatigue	Medi: improvement in pain intensity, usual pain, psychological distress, and anxiety from baseline. TAU: little change Pre to f/u: Medi improved in usual pain, anxiety, psychological distress, and the phobia scale of the BSI	No direct comparison between intervention and TAU group.	3 mos.
Plews-Ogan et al., 2005	30 musculo-skeletal pain	RCT	Mindfulness Based Stress Reduction (MBSR)(N = 10) vs. Massage (N = 10) vs. standard care (TAU)(N = 10)	MBSR: meditation and yoga, nonjudgmental awareness, practice Massage: Swedish, deep tissue, neuromuscular, pressure point	MBSR: 8 weekly 2.5 hour sessions Massage: 8 weekly 1 hour sessions	Pain intensity, pain unpleasantness, Short-Form Health Survey 12 (SF-12)	Post treatment (tx): Massage >TAU for improvements in unpleasantness & mental status. MBSR = TAU At f/u: MBSR >TAU for improvement in mental health score	Small sample size limits statistical power	4 weeks
Grossman et al., 2007	58 females with Fibromyalgia (FM)	Non-randomized controlled trial	Mindfulness-based stress reduction (MBSR = 39) vs. Active Social Support (= 13)	MBSR: mindfulness practice, awareness during yoga, stressful situations, social interactions, homework Support: social support, relaxation training, stretching exercises, discussion, homework	8 weekly 2.5 hour sessions plus one all day session	Quality of Life Profile for the Chronically Ill (QoL), Hospital Anxiety and Depression Scale (HADS), Pain Perception Scale (PPS), Inventory of Pain Regulation (IPR), Visual analog ratings (VAS)	MBSR >support for improvements in VAS pain, QoL subscales, pain coping, depression, and somatic complaints Improvements maintained at f/u	Unequal n limits statistical power	3 yrs
Sagula & Rice, 2004	57 mixed chronic pain	Non-randomized controlled trial	Mindfulness meditation (MM)(N = 39) vs. Control (C)(N = 18)	MM: 20 min daily meditation (body scan, mindfulness on breath, hatha yoga), meditation log, development of resources for self-healing	8 weekly 90 min sessions	Response to Loss Scale (RTL)(e.g., Growth, Cope/ Awareness), Beck Depression Inventory (BDI), STAI	MM >C for reductions in depression, state anxiety, and intensity of grief from loss associated with pain. Growth: MM = C	Unequal sample sizes limits statistical power lack of f/u	None specified
Kabat-Zinn et al., 1985	90 mixed chronic pain	Non-randomized controlled trial	Stress Reduction and Relaxation (SR & RP)(N = 69) vs. Pain Clinic control group (PC)(N = 21)	SR & RP: meditation training, Hatha yoga, homework, 45 min daily meditation	10 weekly 2 hour sessions	McGill-Melzack Pain Rating Index (PRI), Body Parts Problem Assessment (BPPA) scale, medically oriented symptom checklist (MSCL), Profile of Mood States (POMS), revised Hopkins Symptom Checklist (SCL-90R)	Sample improvements in pain indices, mood, and psychological symptoms. SR & RP >PC for improvements in anxiety, hostility and somatization. SR & RP: Larger proportion of individuals with clinically significant improvements. Maintenance at f/u	Wide range in f/u assessments	2.5–15 mos.

Advantages of Group Treatment

Efficiency and Cost-Effectiveness

Given the general lack of difference in treatment outcomes between group and individual CBT, it could reasonably be argued that group treatment is a more efficient modality of therapy for chronic pain disorders. Certainly, group treatment is more cost-effective in terms of practitioner time and patient expense.

Social Proximity and Support

There are several other advantages to using a group modality with patients who have chronic pain-related conditions: A group approach provides social interaction and support from others who share common distressing experiences including the pain itself as well as secondary stressors associated with the pain such as frustrating interactions with the healthcare system, economic hardship, and deteriorating family relationships. Individuals struggling with chronic pain often feel isolated and misunderstood. Disclosing thoughts and feelings to others who share similar concerns offers patients a greater sense of legitimacy than might be experienced by sharing thoughts and feelings with a therapist or significant other who does not experience pain. A qualitative study of previously treated group members confirmed that being listened to, understood, accepted, tolerated, and affirmed were highly valued perceived benefits of the group approach for pain management.[56]

Beyond the social support provided by others who share similar concerns (which is considered a non-specific treatment factor), group CBT seems to offer additional benefits. Studies have shown group CBT to be superior to group relaxation sessions[47] and to group discussion sessions,[40] both of which offer the type of social support received in group CBT. Maunder and Esplen[57] reported that a supportive-expressive group for patients with inflammatory bowel disease did not improve symptoms of GI distress/pain, patient quality of life, anxiety, or depression, and they concluded that, at least for this population, supportive-expressive group therapy alone is not efficacious.

Vicarious Learning and Modeling of Collaborative Approach

Group treatment provides clinicians with multiple scenarios to choose from and build upon during group discussions, which is helpful when illustrating a particular teaching point. Taking advantage of a salient example and using it for the benefit of the entire group maximizes the likelihood that patients will understand the intervention through vicarious learning (i.e., other group members observing a therapeutic interaction between an individual patient and the therapist).

Moreover, group treatment provides a fertile venue for modeling a collaborative approach to treatment between the patient and the practitioner. Early in the group process, the leader establishes the expectation that patients will actively participate in group discussions, self-monitor their activities, and complete homework assignments. Through selective reinforcement of patients who actively engage in their treatment by participating in the group and completing the homework assignments, the leader can strive to increase active coping in all of its members. A qualitative study of group CBT treatment with women suffering from chronic pelvic pain revealed that this collaborative approach facilitates a therapeutic progression beginning with developing self-knowledge, followed by assuming responsibility for self-management, and ending with increasing self-control and personal mastery of emotions.[58]

Interpersonal Group Process

A final potential advantage of group treatment is the use of group process to facilitate treatment gains (i.e., utilizing the interpersonal exchange between group members in addition to the exchange between therapist and the patient). A group of patients provides an opportunity to capitalize on the moment-by-moment interchanges among group members as well as the interpersonal relationships that develop over time. It is noteworthy that group members will often accept positive feedback, negative feedback, and confrontation from other group members better than from the group leader. This may be due in part to feeling more understood by a fellow patient (someone who has "walked in my shoes"), but may also be due to the power of the interpersonal process that occurs in group settings.

Practical Issues

Open vs. Closed Groups

Most controlled studies in the literature have focused on time-limited, closed groups. In research, this is a necessity to control for a number of confounding variables that ongoing, open groups would introduce into a research design. There are also clinical advantages to running a closed group where all members start and end group treatment at the same time. From a practical perspective, however, running closed groups can prove difficult in some clinical settings because new patients would be required to wait until a new group starts to begin treatment. In response to this, some clinics have begun experimenting with a hybrid model which involves running revolving closed, time-limited groups but allowing new members to enter the group once each month so no patient has to wait longer than 3–4 weeks to start treatment. The effectiveness and feasibility of this model for treating chronic pain patients in groups is currently being explored by the third author of this chapter (BBW) as part of a collaborative effort between Indiana University and Volunteers in Medicine of Monroe County (www.vimmonroecounty.org). If both effective and feasible, this group model for helping patients manage chronic pain will hopefully be adopted by other clinics in addition to other members of the Volunteers in Medicine Alliance (www.vimi.org) across the country.

Length of Group

The length of the groups varied in the RCTs reviewed for this chapter, ranging from 5 to 12 sessions, with a modal number of 10 sessions. Most RCTs reported meeting weekly for 90-minute sessions. Time-limited groups are the accepted standard in research trials because treatment manuals are usually highly structured, and demonstrating fidelity of treatment through therapist adherence to the protocol is an important component of treatment implementation.[59] Furthermore, treatment groups of varying lengths would introduce variance that would reduce the statistical power required to detect real differences between treatment and control groups. On the other hand, clinical realities often necessitate varying the length of a particular treatment component based upon whether or not the intervention has been understood by the group members. In clinical settings, there may indeed be some situations in which it would be well advised to repeat a particular unit, continue coverage of a particular topic, or adapt the treatment protocol in some other way. As an example of this, when faced with an opportunity to treat pain patients with very little education, the first author of this chapter (BET) recognized the need to adapt the written materials used in group CBT for this population. An RCT is currently being conducted to test the efficacy of this adapted protocol in this subset of chronic pain patients with low literacy. If shown to be efficacious, the adapted materials could then be used in other clinical trials and in clinical settings with similar populations.

Number of Participants

A group composed of approximately five members is of sufficient size to facilitate interaction among group members, accommodate the absence of a member without jeopardizing group cohesiveness, and provide enough time to attend to each patient during the individual sessions. Most CBT groups will have more women than men, since women have more chronic pain problems, present more frequently for pain treatment than men,[60] and may be more receptive to group interventions based on their tendency to cope via a communal support process.[61] Differences in age, ethnicity, and cultural background do not appear to jeopardize the group process, perhaps because chronic pain serves as a unifying factor, making other potentially divisive issues less important. We were unable to identify any studies addressing the issue of whether it is important to racially match group leaders with participants. In an unpublished follow-up qualitative study using post-treatment key informant interviews with African American members of a CBT headache management group two years after the RCT had been completed,[13] those interviewed thought that including therapists of different racial and ethnic backgrounds as group leaders would enhance the comfort level of participants and thus increase both their willingness to participate and their chances of treatment completion. In mixed race groups, it is probably preferable to have at least one of the co-therapists be a person of different racial and/or ethnic background.

Individuals Who May be Inappropriate for Groups

Almost anyone deemed appropriate for individual CBT for pain management is appropriate for group treatment, but there are a few exceptions. Patients with moderate to severe dementia or other cognitive impairment, psychosis, or chronic interpersonal relationship problems are inappropriate for group treatment. In addition, it is not unusual for chronic pain patients to have problems managing anger, and in some cases the degree of anger and hostility may be a contraindication for group treatment. In these cases, however, it is often possible to help the patient learn to regulate their anger and hostility in individual treatment and then invite them to participate in a group at a later date. Keefe et al.[1] noted that they sometimes use a "time-out" strategy for group members whose anger is disruptive or in other ways counter-therapeutic, in which patients meet individually with group leaders while continuing to attend the group but remaining silent for two to three sessions. Clearly, if a patient expresses a strong preference for individual treatment or if his or her schedule prohibits involvement at the prescribed group time, an individual approach will need to be employed.

CORE COMPONENTS OF GROUP CBT FOR CHRONIC PAIN

As mentioned earlier, CBT is an umbrella term for a variety of treatment components. The core principles behind CBT involve the conceptualization that one's thoughts, feelings, and behaviors are critically important components in helping a patient engage in appropriate pain self-management. Common treatment components frequently include training in cognitive restructuring, cognitive coping, relaxation, paced physical activity, and assertive communication.

Overview of CBT Rationale and Components

The purpose of group CBT, like individual CBT, is to teach non-medication based methods of reducing pain and distress and to increase overall level of functioning despite the presence of pain. During the cognitive modules of CBT, patients are taught to identify the habitual thought patterns that exacerbate their pain and related distress. These thought patterns take the form of situation-specific automatic thoughts (e.g., "I might as well quit my job because I'm missing so much work."), more global attitudes and beliefs about their pain and the way they think it should be treated (e.g., "If I have back pain, I should lie down and rest as much as possible to let it heal."), and deep-seated core beliefs about the self (e.g., "I am basically useless now."). These distortions in thinking are associated with negative emotions (anxiety, depression, anger) and maladaptive coping behaviors (e.g., inappropriate reliance on pain medications). Cognitive coping techniques often include training in positive coping self-statements and cognitive distraction techniques. The behavioral modules of CBT teach patients specific stress management techniques such as relaxation, assertiveness, and pacing oneself instead of doing too much or too little in response to pain cues. Sometimes expressive writing is also included to help the patient process strong negative emotions. Behavioral approaches teach patients how to manage stressful events that cause pain, exacerbate pain, and/or are caused by pain. The distinction between "cognitive" and "behavioral" modules is somewhat artificial, since both cognition and behavior are involved in each component of treatment.

Example of a Typical CBT Group Program

Since there is considerable variability in the number and content of group CBT modules, no one treatment description captures all CBT programs. In general, however, each session consists of a review of what was learned the previous week, an introduction to a new skill or concept, and a homework assignment designed to reinforce the use of new techniques and promote understanding of new ideas.

The first session is designed to provide the rationale for a CBT approach and introduce the ground rules, including those regarding confidentiality. The second through the ninth sessions typically involve teaching specific cognitive and behavioral skills. The tenth session is used to promote a sense of closure and help patients begin to generalize what they have learned in past sessions. This is achieved by discussing how all of the techniques and concepts taught in the group can be integrated and maintained over time. See Table 86.4 for an outline of a 10-week CBT program. See also Haythornthwaite (Chapter 82) for a discussion of CBT for chronic pain not necessarily focused on group treatment.

Example of Cognitively-Focused Group CBT

Below we offer a more specific discussion of the cognitive aspects of our group CBT program. The manual covering the basic structure and detailing the cognitive components of treatment is available in Thorn.[62] Since the emphasis on cognitions is greater in this program than many other CBT programs for pain management, the four core components of the cognitive focus are featured below and the distinctive aspects associated with group treatment are highlighted when relevant.

Stress-Appraisal-Pain Connection

The first core component in cognitively-focused group CBT introduces the group to the importance of understanding the Stress-Appraisal-Coping Model of Pain. Group leaders help patients understand that pain produces stress, stress increases pain, and managing stress reduces the negative impact of pain on one's life. Moreover, stress itself can trigger and/or exacerbate pain. Thus, it is crucial that patients with chronic pain learn about stress and how to manage stress more effectively.

After reviewing the physiological mechanisms of the stress

TABLE 86.4

MAJOR OBJECTIVES OF TEN GROUP CBT SESSIONS

Session number	Major objectives
1	Establish rapport, explain therapy rationale, goals, format and rules, introduce the connection between stress and pain, and introduce the concept of stress appraisal
2	Introduce the stress-appraisal-coping model of pain, begin identification of automatic thoughts or images, recognize connection between automatic thoughts and emotional/physical shifts
3	Evaluate automatic thoughts for accuracy, identify sources of distorted thoughts, challenge negative, distorted automatic thoughts, construct realistic alternative responses
4	Identify underlying beliefs about the cause, treatment, and control over pain, challenge negative distorted beliefs, construct new beliefs
5	Identify core beliefs, challenge negative, distorted core beliefs, construct new, more adaptive beliefs
6	Introduce passive muscle relaxation techniques; construct and use positive coping self-statements; incorporate coping self-statements into relaxation
7	Introduce the principles of behavioral pacing (i.e., planned use of discrete periods of time engaging in productive, but potentially stressful, activities [“uptime”], alternating with periods of restful, relaxing activities [“downtime”], and the benefits associated with use of pacing)
8	Learn and practice expressive writing or verbal narration of expressive writing exercise
9	Introduce the principles of assertiveness (e.g., making direct, simple, nonapologetic requests; saying no to a request without hostility or guilt); plan an assertive communication
10	Review concepts and skills learned, provide feedback about helpful and challenging aspects of the treatment, continue to practice and use skills in everyday life

response, group leaders introduce the concept that judgments about and reactions to situations are more important than the actual situations themselves and that stressors are typically appraised as threats, losses, or challenges. The concept of “appraisal” is introduced as a determinant of “coping,” which is comprised of thoughts, feelings, and behavior. As part of the session, group members are asked to generate a list of stressors that are both pain-related and non-pain-related and then share them with the group.

As homework, group members are asked to add to their list of pain-related and non-pain-related stressful situations daily throughout the week. Beside each stressor, they are asked to record the type of appraisal (threat, loss, or challenge), and then to note how their appraisal of those stressors influenced their coping (thoughts, images, feelings, behaviors, and pain).

Recognizing, Evaluating, and Changing Automatic Pain-Related Thoughts

The second core component in cognitively-focused group CBT teaches patients to recognize, challenge, and then reconstruct maladaptive automatic thoughts. Group members are taught that automatic thoughts are the ongoing, internal stream-of-consciousness dialogue that often occurs just below one’s immediate level of awareness. Patients must first learn to recognize their own automatic, pain-related thoughts, especially those that are negative and/or irrational. To accomplish this, group members are asked to consider thoughts or images that run through their mind when their mood or sense of well-being worsens. For example, in response to a worsening of pain while standing at work, a patient might have the automatic thought: “I might as well apply for disability since I can’t work the way I used to.” Patients are often surprised by the large number of negative and irrational thoughts that occur just outside of their immediate awareness. Group leaders explain that these thoughts have a powerful impact on their emotions, behaviors, and other thoughts whether the individual is aware of them or not. Bringing these thoughts into one’s awareness provides greater control over the thoughts because once one is aware of a thought, one can evaluate it. It is emphasized that all thoughts contain at least a grain of truth and some are completely true, but many thoughts are distorted. These distorted thoughts, especially negative ones, coincide with negative emotions and can lead to or exacerbate feelings of helplessness and hopelessness. Once group members learn to identify common cognitive distortions, they can begin to recognize how their own negative, distorted automatic thoughts influence their moods, behavior, and pain. Next, group members are guided through a process of Socratic questioning to help determine whether their distorted thoughts are completely true, partially true, or not at all true. Socratic questioning is a “tell me more” technique where patients are taught to ask themselves a series of questions that will ultimately guide them to the answer. In the case of automatic thoughts, patients ask themselves, “what are the facts that support this thought?” and “what are the facts that do not support this thought?” Evaluating the rationality of their distorted automatic thoughts provides a segue into learning to construct alternative thoughts that are more realistic and adaptive. The purpose of focusing on distorted thoughts is not so much to change the *content* of the thought as it is to uncouple the emotion from the thought. The thought becomes “just a thought” by removing the power of “truth” from it.

Identifying and Evaluating Intermediate Pain-Related Beliefs

The third core component of cognitively-focused group CBT teaches group members to recognize thought processes such as underlying beliefs that are more deeply ingrained than situation-specific automatic thoughts. With intermediate beliefs, the focus is on those beliefs that are pain-related. Patients are taught that their pain-related intermediate beliefs are beliefs related to the cause of pain (e.g., “My pain is bad because I have collapsed discs in my spine.”), beliefs about appropriate treatment of their pain (e.g., “When I’m in pain my family should take better care of me.”), and beliefs about their ability to influence their pain (e.g., “The only thing that can help my pain is strong pain medication.”). Intermediate beliefs are often represented by rules and assumptions that patients make about the way things “should,” “must,” or “ought to be” in the situations in which they find themselves. It is thought that intermediate beliefs give rise to automatic thoughts.[63]

In order to help patients recognize these attitudes and beliefs about pain and the way it should be treated, group leaders first ask patients to identify key automatic thoughts (ones that come up repeatedly), explaining that they may be linked to underlying beliefs. Using a “downward arrow” technique described by Burns,[64] patients are asked to consider: “if that (automatic) thought is true, what does it mean to you?” Patients often need help identifying the underlying belief systems that are driving the irrational automatic thoughts. Intermediate beliefs may be harder

to identify because they are not as easily recognized as irrational by the patient. For example, the automatic thought "I might as well apply for disability, because I can't work the way I used to" could be driven by the belief that "I should be able to lift the same amount of freight that I could before the accident, in the same way, in the same amount of time." The self-expectation held by the patient giving the above example feels completely true to the patient when he first identifies his belief. Using a process of Socratic questioning similar to that used to examine automatic thoughts (e.g., "What are the facts supporting this belief?" "What are the facts not supporting this belief?"), group leaders can help patients begin to question these attitudes and assumptions about the way they (and the world) "should" be.

In many cases, patients' intermediate beliefs promote the attitude of a passive patient receiving a diagnosis, treatment, and cure. Here, the group leader can take advantage of the group process to help patients understand how their attitudes and beliefs about the cause and treatment of their pain impact what they choose to do (or not do) to help themselves. For example, with very little therapist intervention, one group member can open the door to considering alternative beliefs by saying something like, "So . . . none of these surgeries and none of the medicines have worked to cure our pain, and we've been trying it for years. Maybe it's time to try something else." As the group leaders help patients realize that beliefs and attitudes, like automatic thoughts, are also *just thoughts* and not necessarily absolute truths, they become more receptive to the idea of taking more responsibility for pain self-management behaviors rather than relying on the belief of a cure and the attitude that their health and well-being are in the hands of physicians.

Identifying and Evaluating Core Pain-Related Beliefs

In the fourth core component of cognitively-focused group CBT, group members learn that core beliefs are rigid, long-held beliefs about one's basic worth or lovability as a human being. For most people, most of the time, negative core beliefs do not predominate over positive core beliefs. However, it is thought that during times of significant stress (e.g., a pain flare-up), underlying beliefs often become negatively distorted, which in turn negatively impacts thoughts, feelings, and behavior.[63] Core pain-related beliefs reflect the patient's sense of self as an individual in pain. Unfortunately, with increasing pain duration and mounting associated problems, patients with chronic pain often adopt the core pain-related belief that "I am a disabled chronic pain patient" and assume the role commensurate with such an identity.

Core beliefs are probably the most difficult to change because they are so deeply ingrained and often thought to be indisputable facts. However, building on previous sessions and patient success with mastering automatic thoughts and intermediate beliefs, group leaders teach that core beliefs are not absolute truths; rather, they are ideas that can be altered. Again utilizing the Downward Arrow Technique[64] patients are asked to identify a frequently occurring automatic thought, perhaps stemming from a previously identified intermediate belief. They are then asked to consider, "If that automatic thought is true, what does it mean *about* me?" Building from a previous example, the automatic thought "I might as well apply for disability," driven by the belief "I should be able to work the same as I used to," might in turn be driven by the pain-related core belief "I am a worthless chronic pain patient." It is also sometimes useful to get at pain-related core beliefs by having patients ask the "Why me?" question. Often patients feel that they are in pain because they deserve some sort of punishment, are basically unlovable anyway, or have always felt unworthy.

Challenging and changing patients' negative core pain-related beliefs are a formidable challenge. Here the group process is invaluable as patients will more readily accept confrontation about the belief "I am unlovable because I have chronic pain" from a fellow pain patient than from a group leader. It is also useful to help patients examine the disadvantages as well as the advantages to holding on to negative core pain-related beliefs. With help, patients often recognize that adopting their negative core beliefs gives them permission to give up and no longer try to cope. Patients are often motivated to challenge their beliefs when they come to this recognition. Another tool used to help patients challenge their core pain-related beliefs is to experiment with the "acting as if" exercise.[63] In this exercise, group members are asked to consider what specific things they would do differently if they did not hold their core pain-related belief. Ideally, the treatment component examining core pain-related beliefs will ultimately help the patient dissociate pain from both disability and suffering, allowing the patient to adopt a new identity that "I am a well person with pain."

FACTORS AFFECTING PSYCHOTHERAPEUTIC OUTCOME

Although there are many potential factors affecting group treatment outcome for pain management, we have chosen to highlight four: the importance of changing cognitions, the importance of practicing skills to maintain treatment gains, the need for sufficient therapist contact to promote change, and the role of the group process itself.

The Importance of Cognitive Change

The CBT approach is based upon strong evidence that thoughts influence emotions and behavior, and this has been found to be particularly true with regard to the experience of pain. Highly negative cognitions regarding a patient's pain and its sequelae are predictive of poor patient coping with chronic pain.[65] For example, negative pain-related cognitions have been shown to be a robust predictor of higher perceived pain intensity, lower tolerance of painful procedures, greater psychological distress and psychosocial dysfunction, higher analgesic use, and greater pain interference, disability, and inability to work.[66–68] In addition, negative cognitions are a better predictor of poor coping (and therefore, poor adaptive outcome) than disease severity, perceived pain intensity ratings, age, sex, depression or anxiety.[66,67,69–75] Given this evidence, the basis of cognitively-focused CBT for pain is on helping patients become aware of, examine, and gain control over the thoughts that influence their feelings, coping behavior and physiology. Furthermore, with CBT, early changes in pain catastrophizing and perceived helplessness are related to later treatment changes in pain severity and functioning.[76,77]

Compliance with Homework and Skills Practice to Maintain Treatment Gains

When considering whether a valid clinical trial has been conducted, there must be some demonstration that adequate levels of independent treatment components have actually been given.[60] Treatment enactment refers to the extent that clients actually apply what they have learned out of the treatment session. Homework or practice of skills learned in treatment is one way to measure treatment enactment. Scharff and Marcus[78] found that headache participants who practiced the skills taught in treatment (which included physical therapy, headache-free diets, and relaxation) were more likely to maintain their treatment gains when measured at follow-up. Likewise, completion of homework assignments were significantly related to treatment outcome in IBS patients participating in group CBT.[19] Vlaeyen et al.,[27] compar-

ing group education plus CBT to group education plus attention control (group discussion), noted that in the CBT group, compliance with completion of homework assignments was quite low. The researchers noted that the education level of their participants was low and that the homework assignments might have been too difficult for them to complete. Ironically, failure to understand or complete the homework may result in an unintended decrease in self-efficacy, which would certainly limit the efficacy of the intended treatment.

Importance of Therapist Skill and Adequate Time with Therapist

Vlaeyen et al.[27] also noted that the treatment in their clinical trial was designed to be low-cost and therefore included minimal therapist interventions. It is quite possible that the complex cognitive and behavioral skills that must be acquired by patients prior to treatment gains require a threshold level of therapist intervention in order to be comprehended by the client. Thus, without a skilled therapist guiding the acquisition of cognitive-behavioral change in the CBT group, subsequent lack of understanding may have resulted in unintended frustration and reduced overall efficacy.

Importance of Group Process

In our review of the group pain management literature, we located one open clinical trial that offered interesting qualitative information regarding the importance of group process. Moore, Berk, and Nypaver[79] studied 51 patients completing multidisciplinary inpatient pain management programs in small groups (3–4 individuals). Overall, patients showed a decrease in pain, disability, and hypochondriasis after treatment, and at 6-month follow-up, treatment gains were maintained and more patients were employed. Failure to improve depended in part on whether other members of the same treatment group also failed to respond. The authors noted that each group seemed to quickly acquire a temperament unique to that group, with some evolving toward positive cooperation and some being more adversarial or negative in nature. Examination of the group data showed that if one individual failed to benefit from treatment (or left the program prematurely due to dissatisfaction) others in the group were also more likely to have not improved. This study highlights the importance of social factors in chronic pain and underscores the caveat that group treatment should be designed to capitalize on these social influences.

SUMMARY AND CONCLUSIONS

Group treatment approaches for pain management have been clearly established as efficacious, and the vast majority of controlled research studies have focused on CBT group approaches. The available research suggests that there are few differences in treatment outcome between group and individual CBT for chronic pain. Thus, since group treatment is more efficient in terms of therapist time and more economical for patients, we suggest that group treatment is generally the favored modality. Certainly, not all patients are appropriate for group pain management, and logistical difficulties in organizing and running a group prevent the universal adoption of group treatment as the only method of appropriate treatment. Relatedly, some patients may need more intensive psychotherapy than what the typical group approach has to offer. It is therefore quite appropriate to refer certain patients for individual treatment after the completion of group treatment.

FUTURE DIRECTIONS

It is important to note that although the extant research literature has established the efficacy of group CBT for pain management, the external validity of research-based efficacy trials has yet to be studied (i.e., effectiveness studies). Since the efficacy studies cover a wide range of pain problems and come from a variety of research laboratories both inside and outside the United States, we may feel more confident in the generalizability of the results. Future research exploring appropriate adaptations for local populations with special needs will help establish the effectiveness of group (GBT) approaches for real-world settings.

Two other areas in need of more research are cost-effectiveness studies and research examining the specific mechanisms associated with treatment efficacy. Regarding cost-effectiveness, such research is particularly difficult to carry out in health care settings without readily available (electronic and universal) health care utilization information. Regarding the identification of specific treatment factors responsible as the agent of change, the research conducted up to this point offers a promising start that efficacious group CBT is more than simply therapeutic and social support.

Finally, there is a clear need for a systematic review and meta-analysis of group treatments for chronic pain. As health care practitioners of all disciplines become more and more reliant upon systematic reviews to support evidence-based practice, a thorough systematic review and meta-analysis of group treatments for chronic pain would represent a certain contribution to the literature.

APPENDIX A

Search Strategies

Medline and Cochrane Database searches were performed in March 2007 using OVID as an interface to search for group treatments for (1) gastrointestinal disorders, (2) back, facial, neck, neuralgia and intractable pain, (3) pelvic pain, dysmenorrheal and vulvar diseases, and (4) headache disorders.

1. Database: Ovid MEDLINE(R) <1950 to March Week 2 2007> Search Strategy:
   1 exp psychotherapy, group/ (18366)
   2 exp Colonic Diseases, Functional/ (5158)
   3 1 and 2 (12)
   4 limit 3 to (humans and english language) (10)
2. Database: Ovid MEDLINE(R) <1950 to March Week 2 2007> Search Strategy:
   1 exp psychotherapy, group/ (18366)
   2 back pain/ or facial pain/ or neck pain/ or neuralgia/ or pain, intractable/(24526)
   3 1 and 2 (22)
   4 limit 3 to (humans and english language) (20)
   5 limit 4 to case reports (1)
   6 4 not 5 (19)
3. Database: Ovid MEDLINE(R) <1950 to March Week 2 2007> Search Strategy:
   1 exp Psychotherapy, Group/ (18366)
   2 exp pelvic pain/ or exp dysmenorrhea/ (3924)
   3 exp Vulvar Diseases/ (10719)
   4 2 or 3 (14610)
   5 1 and 4 (3)
4. Database: Ovid MEDLINE(R) <1950 to March Week 2 2007> Search Strategy:
   1 exp group psychotherapy/ (18366)
   2 exp Headache Disorders/ (17650)
   3 1 and 2 (17)
   4 limit 3 to (humans and english language) (12)

5 limit 4 to case reports (3)
6 4 not 5 (9)
7 from 6 keep 1–9 (9)

PsycINFO was also searched in March 2007 using CSA Illumina as an interface, and this search yielded 40 records focusing on group treatment for pain:

Database: PsycINFO/ CSA Illumina
Query: DE=("pain" or "aphagia" or "back pain" or "chronic pain" or "headache" or "migraine headache" or "muscle contraction headache" or "myofascial pain" or "neuralgia" or "trigeminal neuralgia" or "somatoform pain disorder")AND DE=("group psychotherapy" or "encounter group therapy" or "marathon group therapy" or "therapeutic community") NOT DE= ("neoplasms")

In November 2007, these searches were repeated and broader, more sensitive searches were also performed by incorporating keywords in addition to controlled vocabulary to minimize the possibility of missing relevant studies and to include studies on mindfulness. These broader searches in both Medline and PsycINFO are detailed below.

Database: Ovid MEDLINE(R) <1950 to November Week 2 2007>
1 pain.mp. or exp Pain/ (353317)
2 headache.mp. or exp Headache Disorders/ (49645)
3 1 or 2 (379062)
4 "group treatment".mp. (1467)
5 "group psychotherapy".mp. or exp Psychotherapy, Group/ (19229)
6 4 or 5 (20189)
7 3 and 6 (318)
8 cancer.mp. or exp Neoplasms/ (1982859)
9 7 not 8 (281)
10 limit 9 to (humans and english language) (224)
11 limit 10 to yr="1980–2008" (195)
12 limit 11 to "therapy (sensitivity)" (88)

Database: Ovid MEDLINE(R) <1950 to November Week 2 2007>
1 pain.mp. or exp Pain/ (353317)
2 exp Meditation/ or mindfulness.mp. (696)
3 1 and 2 (52)
4 limit 3 to (humans and english language) (51)
5 limit 4 to "therapy (sensitivity)" (19)
6 limit 3 to evidence based medicine reviews (1)
7 limit 3 to "review articles" (15)

Database: PsycINFO / CSA Illumina
Query: DE = ("pain" or "aphagia" or "back pain" or "chronic pain" or "headache" or "migraine headache" or "muscle contraction headache" or "myofascial pain" or "neuralgia" or "trigeminal neuralgia" or "somatoform pain disorder") and DE = ("mindfulness")
Records retrieved = 14.

CHAPTER 87 ■ MOTIVATING PAIN PATIENTS FOR BEHAVIORAL CHANGE

AKIKO OKIFUJI AND DENNIS C. TURK

INTRODUCTION

Motivation is perhaps the primary determinant of human behavior, influencing the initiation, direction, intensity, and persistence.[1] Historically, motivation has not been a central issue in the biomedical world as the modal biomedical approach to treat illness appeared to require very little active participation from patients. However, as our understanding of how patients' behaviors impacted their illness and influenced their adherence to treatment regimens increased, it has become of a significant issue and concern. This is especially true for treatment and management of chronic illnesses, such as chronic pain for which there often is no cure, since these diseases require patients to become actively involved in the self-management of their symptoms and lifestyles. Moreover, self-management and adherence to recommendations will likely be required for extended periods of time.

There is a large volume of literature indicating that even relatively simple behaviors, such as taking medication in the prescribed manner, is problematic. Studies have reported that depending on how it is defined and measured, the rates of nonadherence to medication range from 30% to 60%.[2] In general, one-third of patients can be expected to be nonadherent.[3]

For chronic pain patients, rehabilitation rather than complete

cure is most realistic. One of the critical requirements for successful rehabilitation is that patients adopt an active, participatory role in their treatments. Literature consistently acknowledges that multidisciplinary pain care that includes an activating therapy is helpful for restoring functioning and improving the quality of life.[4] However, such a treatment requires patients to make significant lifestyle changes including the incorporation of various functional activities in their daily routines. Maintaining these changes over long periods of time is often difficult even for healthy individuals. For example, a report by the U.S. Surgeon General[5] noted that 50% of those who sign up with gyms at the beginning of a year drop out within the first 6 months. Thus, it is hardly surprising that pain patients find it difficult to adhere to regular physical activity regimens and ones that may actually cause some exacerbation of their symptoms. In the one study that directly examined the issue of compliance with pain rehabilitation, Lutz et al.[6] followed patients 8 months after they had been successfully treated at pain rehabilitation and found that, based on self-report, the overall rate of adherence with the recommendations of the treatment program was only 12.2%, and the rates of adherence with each of the specifically recommended behaviors (e.g., progressive ambulation and stretching exercises, regular application of ice and heat, relaxation) averaged approximately 42%.

Another dilemma for successful implementation of activating therapy is that it can be contrary to the very nature of pain where the motivating drive is to avoid or escape from any activities that might increase pain or that patients anticipate will induce pain. Yet another disincentive is that most people have learned "if something hurts, don't do it." That is, they have come to equate hurt with harm. Combined with our culture dictating the notion that we should not have to tolerate discomfort and pain, patients may perceive activating therapies as a counterintuitive approach. Certainly, pain plays a protective role; in a case of acute injury, for example, resting and inactivity facilitates the healing process but may be inappropriate when pain is persistent.

Thus, clinicians are frequently faced with the challenge of how to motivate patients to actively engage in the treatment protocols. Long-term treatment success depends on regular adherence to recommended self-care regimens for people with chronic pain conditions.[3,7,8] Historically, clinicians would invest less energy in patients who show little commitment to therapies. "You can lead a horse to water, but you can't make it drink" was a typical way of conceptualizing the issue.[9] However, as noted earlier, motivation to commit to the treatment plan and adherence with regimen are essential in successful pain rehabilitation (pharmacologic as well as rehabilitative), and this makes how we can motivate patients for behavioral change a critical clinical issue in pain management.

CONCEPT OF READINESS TO CHANGE: TRANSTHEORETICAL MODEL OF BEHAVIOR CHANGE

The transtheoretical model of behavior change was developed in an attempt to understand motivation to adhere to the health care regimens. The transtheoretical model offers an integrative framework describing the process of behavior change.[10] The transtheoretical model was originally developed to understand how people change their addictive behaviors. The model, however, has been extended to many medical problems including chronic pain.[11] The basic assumptions underlying the model are the notions that people differ in their readiness and willingness to take on behavioral change and that there are certain processes of changes that facilitate the advancement of one's readiness. The model is organized around a major construct: stages of change.

According to the model, patients attempting to change health-related behavior move from one stage to another, often in a cyclic fashion (see Fig. 87.1; descriptions of each stage is in Table 87.1), although the movement through these stages is not necessarily linear. Some behaviors are easier to change than others; it is reasonable to assume that several attempts may be necessary to achieve significant behavioral change. A good example of the nonlinear change of stages may occur in smoking cessation where average smokers take 7–8 attempts to quit before succeeding.[12] The description of each stage as well as typical patient behavior seen at each stage point is listed in Table 87.1.

There are three critical parameters of the model that determines the likelihood of advancing one's readiness.

1. **Processes of change** are one of the dimensions of the transtheoretical model that enables understanding of *how* shifts in behavior may be achieved. Change processes involve both covert and overt activities and experiences that patients engage in when they attempt to change their behavioral patterns. Each process is a broad category and an eclectic collection of techniques, methods, and interventions can be recommended to facilitate the change process. Ten processes, cluster into two groups: the cognitive–experiential cluster of processes and the behavioral processes (Table 87.2). As can be seen, there are various strategies that come from the disparate theoretical orientations to target each process (right-hand column of Table 87.2).
2. **Self-Efficacy** is defined as personal confidence in the ability to change problem situations.[13] If people think that there is no way that they can do the prescribed activities, it is highly unlikely that the treatment will be successful.
3. **Decisional Balance** is defined as a personal "balance sheet" of gains and losses for changing and not changing their behaviors.[14] People are likely to advance their change stages when they perceive themselves to have adequate skills to cope and feel confident in executing those skills (i.e., high efficacy belief) and when they perceive more gains of changing and losses of not changing than more losses of changing and gains of not changing (decisional balance). We will discuss the decisional balance process later in the chapter as a part of reviewing the motivational enhancement techniques.

Some of the behavioral strategies such as counterconditioning and stimulus control are generally a major part of the multidisciplinary rehabilitation for chronic pain. The cognitive-behavioral self-management skill training that is generally a part of the pain rehabilitation also improve self-efficacy[15]; however, baseline levels of self-efficacy vary across patients, and there is a linear relationship between the baseline level of self-efficacy and posttreatment level of self-efficacy and subsequent treatment benefit self-management skill training.[16] Strategies targeting experiential processes are recommended as the primary approach to help people with low level of treatment readiness and self-efficacy.[17] Thus, using the concept of the change process seems a promising way to optimize the clinical outcomes of pain rehabilitation.

Motivation Enhancement Therapy

Motivation enhancement therapy (MET), developed by Miller et al.,[18] is one of the therapeutic methods to target motivation and readiness. It shares the assumption with the transtheoretical model that people vary in their readiness to adhere to treatment regimen and provides a problem-focused, patient-centered, clinician-directed approach with the aim of helping patients move through the stages of change. Although some of the techniques and approaches overlap with those of cognitive–behavior therapy (CBT), one of the most prevalent behavioral medicine approaches in treating chronic pain patients, the two therapy approaches have some distinct characteristics. The nature of the therapy course is no doubt variable depending upon the personal styles

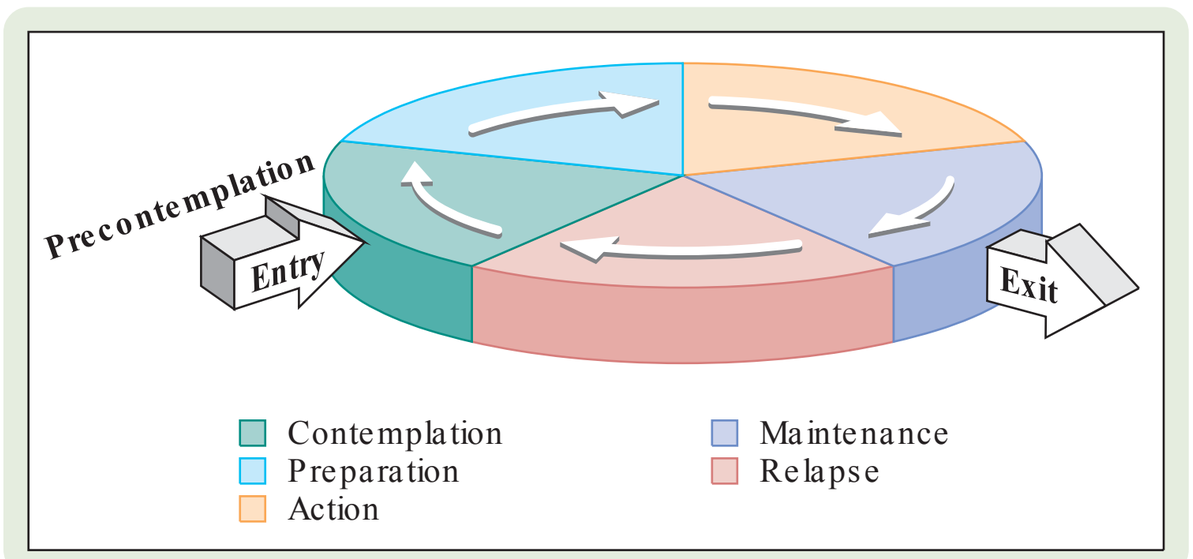

FIGURE 87.1 Stages of changes.

of the clinicians, and there is a danger of oversimplification of complex therapy modalities; however, for the sake of comparison and contrast, we summarize the characteristics of MET as compared to CBT in Table 87.3.

MET is broadly grounded in the Rogerian tradition of psychotherapy[19] in conjunction with behavioral analyses. It is nonconfrontational and patient-centered, exploring and reaching resolution of ambivalence toward behavior change. As in the Rogerian practice, a MET clinician helps patients explore their inner phenomenology that is explored without judgment or criticism. In order to facilitate this process, MET encourages a clinician to exercise empathetic listening and to ask open-ended questions.

Empathy is often confused with sympathy or agreement. In the Rogerian approach, empathy is expressed as understanding and acceptance without imposing the clinician's own perspectives. The patient's thoughts and feelings can be acknowledged through reflective comments no matter how much the clinician considers those maladaptive. Such acknowledgement is not achieved by simply repeating what the patient has just said. Rather, the clinician reflects back to the patient what the clinician "thinks" the patient meant. The term "active listening" or "reflective listening" is often used to describe the skill. Such empathetic atmosphere creates a sense of security for the patient which, in combination with a feeling of being understood and accepted, is considered critical for facilitating intrinsic motivation for behavioral change.

Asking open-ended questions helps the clinician to better understand the individualized phenomenology of the patient regarding the problem that is the target of behavior change in a nonthreatening manner. It also aids the patient to achieve a clearer view on the issue. Asking open-ended questions, however, is not time-efficient; asking questions that can be responded with a short "yes" or "no" answer can save time. As you can see in the following sections describing the MET techniques, however, asking open-ended questions is vital in successful implementation of MET. Some examples of open-ended and close-ended questions are listed in Table 87.4.

The MET offers a collection of therapeutic techniques to help patients: (1) clearly recognize their problems, (2) perform decisional balance work, and (3) produce self-motivational statements and internalize those motivational statements via improved self-efficacy. MET also provides the guidance for how to handle resistance and setbacks. In the following section, we will describe the basic MET methods, including how to deal with resistance and what not to do while engaging in MET.

TABLE 87.1

STAGES OF CHANGE

Stages	Descriptions	Patients' behaviors
Precontemplation	Patient does not perceive a need to change and actively resists change.	• Unwilling to discuss • "Who? Me?"
Contemplation	Patient begins to see a need for change and may consider making a change in the future	• Somewhat ambivalent or fearful of change • "Yes, but. . ."
Preparation	Patient feels ready to change and takes a first concrete (behavioral) change	• Sees more pros for change than cons • "I'll start this on Sunday!"
Action	Patient actively engages in behaviors consistent with regimen	• Feels more confident
Maintenance	Patient executes plans to sustain the changes made	• Feels comfortable with the change • Identifies self as the changed entity
Relapse	Some patients fail to sustain the effort	Variable

TABLE 87.2

PROCESSES OF CHANGE

Processes	Definition	Therapeutic strategies that may help targeting the process
Experiential Processes		
Consciousness raising	Increasing information about self and problem	Observations, confrontations, interpretations, bibliotherapy
Self-reevaluation	Assessing how one feels and thinks about oneself with respect to a problem	Value clarification, imagery, corrective emotional experience
Dramatic relief	Experiencing and expressing feelings about one's problem and solutions	Role playing, psychodrama, grieving losses
Environmental reevaluation	Assessing how one's problems affect the physical environment	Empathy training, documentaries
Social liberation	Increasing alternatives for nonproblem behaviors available in society	Advocating for rights of repressed, empowering, policy interventions
Behavioral Processes		
Counterconditioning	Substituting alternatives for problem and anxiety related behaviors	Relaxation, desensitization, assertion, positive self-statements
Helping relationships	Being open and trusting about problems with someone who cares	Therapeutic alliance, social support, self-help groups
Reinforcement management	Rewarding oneself or being rewarded by others for making changes	Contingency contracts, overt and covert reinforcement, self-reward
Stimulus control	Avoiding stimuli that elicit problem behaviors	Adding stimuli that encourage alternative behaviors, restructuring one's environment, avoiding high risk cues, fading techniques
Self-liberation	Choosing and committing to act or believe in ability to change	Decision-making therapy, resolution

HELP PATIENTS RECOGNIZE THE PROBLEMS AND GOALS

Patients come to clinics with various expectations and goals. Some patients expect to be pain-free, whereas some patients focus on improving the quality of life even if pain is not totally resolved. However, many patients are often unaware of what should happen to achieve their goals and what their role should be for meeting the expectation. The next step to help patients become more aware of what needs to happen is to delineate the gap between where they are now and where they want to be when they get better. For example, the discussion may start with questions such as:

- How is your life different from your life before pain began?
- How has your pain stopped you from doing what you want to do?
- What are you now doing to cope with your pain problem? How are they working for you?
- How do you think your pain and disability impact your relationship with your spouse/family?
- What do you miss most about your life before the pain began?

Then the discussion should be turned into what patients want to see happen through treatment. For example,

- What would your life look like with better pain management?
- What change would you like to see most?
- What are you doing now that is helping you to make these things happen?

TABLE 87.3

MOTIVATION ENHANCEMENT THERAPY VERSUS COGNITIVE–BEHAVIORAL THERAPY APPROACHES

	MET	CBT
Orientation	Patient-centered	Goal-oriented
Therapist–patient relationship	Collaborative	Top-down
Focus	Stage change	Action
Therapist's task	More listening	More talking
Dealing with ambivalence	Explore ambivalence	Direct persuasion
Approaches to reasons for change	Elicit reasons for change	Give reasons for change

TABLE 87.4

CLOSE-ENDED QUESTIONS VERSUS OPEN-ENDED QUESTIONS: EXAMPLES

Close-ended questions	Open-ended questions
Are you having a problem exercising?	Tell me about the problem you are having about exercising
Do you overuse your pain medications when your pain is really bad?	What do you do when your pain is really bad?
Would you be able to come to the clinic every week for trigger point injections?	How would you feel about coming to the clinic for trigger point injections?

- What other things could you do, or do more of, to help your goal come true?

This line of discussion can also help identify specific discrepancy between what a patient wants from therapy (e.g., "I want to get well") and what he or she is doing (e.g., "I can't do my exercise because I am not well"). The process facilitates the realization of the possibility that patients' own behaviors contribute to the maintenance of pain and prevent them from obtaining their goal of getting better. Such realization in turn forms a background on which motivation for behavioral change can be built.

Not only can clarification of the gap between a present state and a goal state help drive the motivation to change, but it also creates the opportunity to move to specific plans. A clinician and patient can start "brainstorming" as to what possible ways there are to make the change probable. Plans can be prioritized by patients' preference and practical concerns as well as perceived effectiveness of the actions. Possible problems and obstacles should also be thoroughly explored to better prepare the patient.

It is common to find that the patient, after years of functional impairment and other related problems, feels very helpless and convinced that there is nothing they can do to manage their plight. Such resistance can seriously arrest the process of behavioral change. We will discuss how to deal with resistance later in this chapter.

Decisional Balance

Motivation for behavioral changes is rarely linear. Often, we may understand the need for behavioral change but remain reluctant to commit ourselves to do the things needed for the change. People experiencing persistent pain are no exception. Nearly all pain patients would want to improve, and many of them may intuitively understand how behavioral changes can help their pain. Despite this, many patients may remain feeling ambivalent or conflicted about committing themselves for behavioral change. One often hears comments like "I know I need to be more active, *but*. . ."

To a large extent, activating rehabilitation and self-management pain care recommends daily practice of the learned skills and modification of lifestyle, aiming at the long-term, gradual improvement. Thus, activities required for these approaches typically do not pay off immediately despite substantial work involved. This tends to lead patients to focus more on immediate "cost" of self-management activities, such as postexercise soreness and time commitment. Decisional balance helps patients explore all sides of the story on the consequences of not only "doing" but also "not doing" activities that they think need to be done.

The decisional balance procedure involves creating a personal "balance sheet" of both advantages and disadvantages of committing to change compared to not committing. For example, suppose that a clinician would like to facilitate a more active lifestyle for a patient who has dealt with pain by staying in bed or resting for years. The patient will be asked to list what they think are good things and not so good things about maintaining the status quo; in other words, not changing and keeping doing what they have been doing. The patient will also be asked to list good and not so good things about changing their way to be more active and keep functioning despite pain. An example of a "balance sheet" is shown in Table 87.5. The clinician can help patients explore the impact of the change and no change on various life domains and the emotional and cognitive consequences of their action (or nonaction). The sheet will help facilitate the resolution of the potential "I want to, but. . ." conflict. The section of "not so good" things about change can also help the clinician see what areas of coping and other supportive care can be implemented to increase the sense of self-efficacy for the change.

Self-Motivational Statements

Self-motivational statements or "change-talks" by patients represent an important step toward better readiness for behavioral change. In MET, it is critical that thoughts reflecting their intention to change are discussed and help them internalize such thoughts. There are three steps in this phase. First, such thoughts should be elicited and verbalized. Then the thoughts need to be elaborated, as such thoughts, if remaining abstract, may result in perpetual wishful thinking with no actual behavioral change. And finally, elicitation and elaboration of such thoughts are reinforced. Going through this process helps patients identify problems and goals, and they then explore what it would mean to change versus not change. At this point, the patients may spontaneously come up with statements reflecting their willingness and intention to commit themselves for behavioral changes. If so, the therapy can start with the second step. However, for many chronic pain patients whose maladaptive habitual patterns are so ingrained in their lifestyles, some time may be devoted to help patients feel comfortable with change talks.

In order to guide a patient through this process, the clinician may ask questions such as:

- What encourages you that you can change if you want to?
- What do you think would work for you, if you decided to change?
- What will make (engaging in exercise program, etc.) it easier for you?

One of the supportive yet effective methods for the elicitation of self-motivational statements is to review past success. By recognizing that they were able to commit to change and were successful in doing so, it breeds the ground for optimism and improves the sense of self-efficacy. For example, in the earlier phase in treatment, the clinician may ask patient to list what and how they were able to change something in their lives, and guide the patient by asking

- What do you remember when you were able to. . .?
- What was it like when you changed. . .?
- When else in your life have you made a significant change? How did you do it?

Some patients may have a tendency to disregard past success and instead focus on past failure. It is also common to encounter the extremely negative cognitive style in which patients generalize past failure to all future actions. In a case like this, it is helpful to explore their past failure and help them reframe the experience. Provision of education regarding outcome literature and how certain behaviors increase their probability of recovery may also be beneficial.

It is extremely important for a clinician to recognize self-motivational statements. Typically, initial self-motivational statements are rather only vaguely directed toward the perceived needs

TABLE 87.5

DECISIONAL BALANCE SHEET

Staying in bed or resting every time I feel pain (status quo)		Trying to stay active (change)	
Good things	**Not so good things**	**Good things**	**Not so good things**
• Helps me rest • I will not get tired or sore	• Life has to come to a halt • I do not feel that good anyway • I may get even more deconditioned • I have to ask for help from others • Cannot participate in social things • More depression • May gain weight • Will never be able to go back to work	• Things can get done • Keep in touch with friends • Feel better about the day • Feel more independent • May gain physical strength • Less burden on family	• I may feel worse • I may feel stressed out

(e.g., "I know I really need to take the home exercise program more seriously," "I am wondering if I should start thinking of how I can manage my anxiety better," "It may not be a bad idea for me to go back to work"). How such statements are responded to by the clinician can determine whether they can be transformed to more concrete motivation and actual behavioral actions. Basic responses by the clinicians should clarify the issue at hand in terms of how the change can be made based upon what concerns. The statements can further be elaborated with responses like:

- Tell me in what ways you think you can do that.
- Sounds like you have some thoughts about it. What other concerns have you noticed about this problem?
- What are some reasons why you want to do this?
- How do you think you can enjoy this change?

The clinician must remain cautious during the process of elaboration. It is common to see that premature or presumptuous encouragement by the clinician can result in undue pressure for the patient. A discouraged patient is likely to become resistant to change. It is important to remember that MET is clinician-directed but patient-centered.

The attempts at self-motivational statements and subsequent elaborations should be positively reinforced. The clinician's encouraging responses can significantly impact the patient's frame of mind about the change. Simple comments such as "I think it's a wonderful idea," "I see how important this is to you," and "You have a point there" can help the process of eliciting self-motivational statements conclude in a positive and productive manner.

WHAT NOT TO DO IN MOTIVATION ENHANCEMENT THERAPY

One of the important aspects in MET is to avoid placing a patient in a passive role in the clinician–patient interaction. This is a very easy trap for the clinician to get in. For example:

> *Clinician*: How long have you had this pain?
> *Patient*: Seven years.
> *Clinician*: Where does it hurt?
> *Patient*: My back.
> *Clinician*: Are you working now?
> *Patient*: No.
> *Clinician*: Are you receiving disability?
> *Patient*: Yes.

The process like this is counterproductive for activating rehabilitation because it sets a tone of the treatment where the clinician is the expert who can tell what to do, whereas the patient is the passive recipient of the treatment.

We are not saying that a clinician should never provide advice. As an expert, a clinician can provide options and choices. What is important here is to emphasize that there are options and to help the patient achieve their own conclusion of what would work for him or her. Ultimate responsibility of behavioral change lies with the patient, and it should be communicated clearly through the MET process.

Value judgment by the clinician can also be detrimental in helping the patient increase motivation for behavioral change. Consider the following interaction:

> *Clinician*: It seems that you are only interested in getting medications from us. You have not done anything we asked you to do such as exercise, habit change, and mood monitoring; no wonder you are not doing so well.
> *Patient*: Well, I need my medicine because it takes some edge off my pain. I am not doing that badly. I am doing fine.

Value judgments by clinicians can elicit defensiveness, often leading patients to discount the very problem that needs to be addressed. "Oh, it's no big deal," and the change stage could return all the way back to the precontemplative stage (see Table 87.1 for the description of the stage). When the patients consider the problem "no problem," it is very hard, if not impossible, to motivate them for behavioral changes.

DEALING WITH SETBACKS AND RESISTANCE

Changes are hard to make. As noted earlier, patients are likely to hold some ambivalence about committing to change, particularly when the change involves the fundamental part of their lifestyle. Resistance is expected, can occur at any phase of MET, and may take various forms such as arguing, interrupting, denying, ignoring, challenging, minimizing, and sidetracking. Some example behaviors of these resistance forms are listed in Table 87.6. One of the hallmarks of MET is that a clinician does not fight resistance but works with it. Too often, an eager clinician gets overdriven to argue for the change, only to find that the patient backs off from the previous self-motivational stance and becomes reluctant to commit. MET requires a clinician to direct a patient to move toward the behavioral change without imposing, ordering,

TABLE 87.6

EXAMPLES OF RESISTANCE

Resistance	Behaviors
Arguing	Contests the accuracy of information or the clinician's expertise
Interrupting	Interrupts the clinician in a defensive manner
Denying	Shows unwillingness to admit/recognize problems
Ignoring	Does not follow the discussion or conversational direction
Challenging	Challenges the accuracy, effectiveness, or applicability of what the clinician says
Minimizing	Minimizes the risk of problem behaviors (or not doing something) or minimizing the benefit of change
Sidetracking	Changes the direction of the conversation away from the direction that the clinician was pursuing
Blaming	Blames others for the problem and does not acknowledge any responsibility for him/herself
Non-answering	Gives a response that is no answer to the question asked
Disagreeing	"Yes, but. . ."—disagrees with a suggestion without offering any constructive alternative

or arguing for it. How do we do this? The approach here is to stay on the same side with patients yet help them to argue for change. There are several specific techniques that a clinician can employ to work with resistance.

Simple Reflection

In simple reflection, clinicians express their acknowledgement of the patients' comments that reflects resistance in a nonconfrontational manner. For example, patients may argue that they are too exhausted and sore to do the home exercise program after taking care of the household chores; the clinician may respond:

- I see that you are frustrated for not being able to make the change you want.
- It is hard for you to work out after a long day.

The simple reflection method is to provide the sense that the patient is heard and understood. Notice that the reflection does not have any hint of value judgment (e.g., "It is really too bad that you cannot save any energy to exercise because we are not asking you to do that much, you know"), which would defeat the purpose of the simple reflection technique that is to be used to signal that the patient's concern was heard and taken seriously.

Amplified Reflection

Amplified reflection is an applied variation of simple reflection in which the clinician reflects back the patient's comment in an overexaggerated manner. With the example of not being able to do the home exercise above, the clinician may respond: "It is absolutely impossible for you to do the exercise."

The amplified reflection adds the core meaning or intensity of the emotion associated with the patient's statement. By doing so, it helps patients better see the balance of their ambivalence. Facing the exaggerated form of their own statement often helps them focus more on the other side of their original comment. Consider a case where a patient complains of postexercise soreness.

Patient: I am so sore after doing those exercises that I cannot do anything but lay in bed for the rest of the day. The house is a mess and I do not feel better.

Clinician: There is absolutely no way that the exercise can help you get better.

The amplification must be done in an empathetic manner. There can be a fine line between empathetic amplification and sarcasm. The same statement above, with a slightly different tone, can be delivered as a sarcastic criticism. If the patient feels that the clinician is being sarcastic or inpatient, the reflection will likely encourage further resistance and retard the process of change.

Double-Sided Reflection

Double-sided reflection is used to highlight the ambivalent feeling that the patient has expressed. With the example above, the clinician may respond: "On the one hand, you find it very difficult to incorporate exercise in your life, and at the same time, it is frustrating because you really want to do it."

Miller and Rollnick[20] recommend the use of "and" rather than "but" to bridge the two sides of the ambivalence. It also seems advisable that one ends the reflection with the motivational side, perhaps reflecting the motivational statement the patient has previously used.

Agreement With Twist

This is another variation of the reflection in which the clinician initially reflects and then reframes the patient's statement. Initial reflection is typically presented as an empathetic agreement, affirming that the patient was well heard. Then the clinician offers a reframed perspective on the same subject in a nonthreatening manner. For example:

Patient: I know I do not do all the stuff the physical therapist wants me to do. But it is so hard, and I don't think she (the physical therapist) understands how hard it is for me to do the program everyday.

Clinician: You have a point there. It is so frustrating for you not to be able to do the exercise, even though you are so anxious to find a way to do it and move forward with your program.

This subtle change in the direction can help the patient move further toward change while maintaining the therapeutic relationship.

Personal Choice and Control

The psychotherapy literature suggests that one of the conditions in which resistance tends to arise is when a patient perceives a loss of, or a threat of losing, personal choice and control.[21] Typically, resistance is stronger when the importance of the threatened freedom is greater, often resulting in people asserting their option by doing something counteractive to the required behavior. In MET, it is essential that the affirmation of personal choice and control be reminded throughout the course of treatment that it is ultimately their choice to follow through the treatment recommendation. For example:

Patient: All of you keep telling me to do the home program, even though I keep telling you I do not want to do it.

Clinician: It is your choice, of course. It is your health after all. We can only make the recommendations and the rest is up to you.

Such an interaction can help the patient understand that the choice is theirs; at the same time, it fosters a sense of responsibility for the patient to commit to the treatment regimen.

Shifting Focus

Some patients, particularly those with tendency to "catastrophize" (i.e., a cognitive and emotional process that involves magnification of pain related-stimuli, feelings of helplessness, and a negative orientation toward pain) and use the black–white cognitive styles, tend to get trapped into the mode of "cannot do because. . ."; there is always a reason why they cannot do what they need or want to do. For them, obstacles and barriers to advance behavioral changes can become so great that those could be the only thing they would focus. A clinician can defuse such intense focus and help the patient move out of the trap and onto the step necessary to make the desired change. For example:

Patient: There is absolutely no way I can do those exercises. You do not know how much it hurts for me to even lift my 2-year-old. I have not been able to do anything I want for years, and how can I possibly do what they want me to do?

Clinician: I see your frustration. It sounds like pain really influences your life. Tell me more the kind of things you would like to do in your life.

Shifting focus can help defuse the resistance and instead focus on something that can be workable and supportive for behavioral change.

RESEARCH OUTCOMES

A growing body of research supports the conclusion that MET is effective in promoting healthful behaviors. Past research has shown that MET has been effective for facilitating change to reduce problem behaviors, such as smoking,[22–24] alcohol abuse,[25,26] problem gambling,[27] behaviors related to eating disorders,[28] and high-risk sexual behaviors.[29,30] MET has also been shown to increase wellness behaviors such as promoting exercise in myocardial infarction patients[31] and cancer survivors,[32] adherence with glucose control regimen in diabetics,[33] and attendance for mammography screening.[34] MET has become a popular method to address obesity and research shows its efficacy for children[35] as well as adult diabetic patients.[36] MET has been shown to help normalize the lipid profiles of hyperlipidemic individuals via increased fitness.[37]

MET can easily be integrated in various clinical settings. Brief MET counseling in a primary care setting may reduce substance use among high-risk adolescents.[38] In a busy clinical setting, clinicians may regard a full course of MET impossible to implement. There is some evidence, however, that implementing even a small part of MET can be efficacious in promoting behavioral change. A recent study has reported that a brief decisional balance session can promote safer sexual practice and reduce problem drinking among high-risk college men.[39] MET can also be implemented through phone counseling. Phone MET has been shown to help adherence for osteoporosis medication[40] and reduce alcohol abuse.[41]

Unfortunately, MET has not been extensively tested for pain patients, although there are some excellent chapters describing MET,[42–44] reflecting the growing awareness of the importance of motivation in pain treatment. Available evidence strongly suggests that the state of motivation for change is critical in better treatment outcomes for pain patients.[45,46] Furthermore, a recent study suggests that implementing MET prior to the initiation of the CBT-based self-management skill training for pain patients may enhance the treatment attendance,[47] and similar results have been shown with cocaine users.[48] A recent pilot, single-group study also shows significant symptom reduction in fibromyalgia patients undergoing a brief exercise program with phone-based MET.[49] They found a dose-response trend with those who received more than four MET calls showing greater symptom reduction than those who received less than four calls.

CONSIDERATIONS FOR AND POTENTIAL PITFALLS OF MOTIVATIONAL ENHANCEMENT THERAPY

Although research consistently shows the effectiveness of MET for promoting behavioral change in various clinical settings, it is important to remind ourselves that it certainly is not a panacea for pain patients. MET primarily places a focus upon specific changes to either increase or decrease certain types of behaviors to further the effectiveness of pain treatments. If the treatment itself is too complicated or too difficult for the patient, behavioral change would not yield satisfactory outcomes, therefore de-reinforcing the behavioral change itself. Once discouraged, it is reasonable to assume that resistance to another type of behavioral change would become greater. The effectiveness of MET, therefore, partially depends upon the reasonableness of the pain treatment itself. The MET clinician needs to be actively involved in the pain treatment team to assure the successful interaction of MET and the pain regimens recommended by the team.

As some MET experts have pointed out,[42,50] MET is neither for every patient or for every clinician. For example, MET assumes a fairly equal balance of power between a clinician and a patient (i.e., clinician $\neq$ expert), and some patients may be uncomfortable or feel even threatened by such relationship with the health care provider. In a case like this, MET may prove to be detrimental rather than helpful, and the clinician may do better with the traditional top-down approaches to aim at behavioral change. Similarly, although MET is certainly a learnable skill, it may not be so for some clinicians. Some may feel more at home with more directive, confrontational style and find it more effective for their practice. Like any other behavioral modalities, the goodness of fit between a patient and clinician is critical for successful execution of MET for pain patients.

Finally, the outcome literature of MET for pain patients is scarce at this time. In addition, MET is a flexible approach with various techniques; how different parameters influence patients' behaviors is not well understood. MET also involves different formats (e.g., individual, group, phone, mail) as well as intensity of the program (e.g., number of sessions). The effectiveness of MET may depend upon various other factors such as target behaviors, clinical context, and overall pain treatment plan. Future research needs to take these factors in consideration to further our understanding of how we can optimize the effectiveness of MET for pain patients to achieve behavior change for more adaptive lifestyles.

Perhaps the most effective way to help people change is to encourage and assist them in accomplishing improvements based on their own efforts. Coercing and encouraging by themselves may be ineffective, whereas behavioral experience and success will have the greatest likelihood on increasing a sense of self-efficacy.[13] The emphasis is on the "self." Obtaining "evidence" demonstrating that one can actually bring about changes, especially changes that are important to patients, will provide the greatest incentive and motivation to continue to engage in necessary self-management behaviors.

CONCLUSION

In this chapter, we have noted the importance of motivation for behavior change, particularly for patients who have chronic pain. For these individuals, self-management and adherence to pre-

scribed regimens over long periods of time are essential. We reviewed the theoretical basis of behavioral change and the basics of the therapeutic approaches to enhance motivation for change, MET. There are multiple areas of treatments that require significant behavioral, cognitive, and emotional changes for pain patients. Pain clinicians, across disciplines, often face behavioral issues, such as maladaptive behaviors related to medication use and resistance and nonadherence to exercise and other self-management behaviors, all of which become a significant hindrance for optimal treatment implementation. MET is one approach that has been designed specifically to target motivation and to help clinicians help patients commit to behavioral change that should facilitate the overall pain therapies. Although there is limited empirical evidence for MET in pain medicine, there are a growing number of studies in other areas demonstrating the efficacy of MET in reducing maladaptive behaviors and increasing wellness behaviors, suggesting that MET can be a powerful tool for pain clinicians as well.

CHAPTER 88 ■ BASIC CONCEPTS IN BIOMECHANICS AND MUSCULOSKELETAL REHABILITATION

JAMES P. MCLEAN, GARY P. CHIMES, JOEL M. PRESS, MICHAEL L. HEARNDON, STUART E. WILLICK, AND STANLEY A. HERRING

INTRODUCTION

For the clinician treating patients with painful conditions, it is common practice to focus attention on the anatomic region of a patient's chief complaint (e.g., they present with right shoulder pain). Oftentimes, however, while they may complain of pain in a certain region, the underlying cause of the pain may lie elsewhere. For example, for many patients who present with shoulder pain related to rotator cuff tendonopathy, it would be unusual for the main cause of the rotator cuff to be because of some underlying pathology with the rotator cuff (although this certainly can occur with some conditions, such as a proximal myopathy). Rather, more commonly, the rotator cuff is the victim of suboptimal biomechanics elsewhere along the kinetic chain (whether that be at the scapula, thoracic spine, or hips), and therefore has been asked to perform in a manner for which it had never been designed.

The goal of this chapter is to provide an overview of the biomechanical approach to assessing and managing patients with musculoskeletal pain generators. The initial section will focus on the principles of biomechanical analysis, including assessment of range of motion, strength, and endurance. Further, we will explore more biomechanical function with a discussion of neuromuscular control, muscle balance, neural tension, and kinetic chain theory. We will also review the distinction between prehabilitation and posthabilitation, as well as detailing the nature of a patient-therapist relationship.

The second section will focus on the clinical application of these basic principles. These include therapeutic exercise, flexibility training, and strength training. We will also discuss manipulation, spinal traction, and the physical modalities. In the final section, we provide three clinical cases to demonstrate how the biomechanical assessment of peripheral musculoskeletal pain complaints can be used to better manage and treat our patients. It is our hope that these sections will help the pain physician to include a functional biomechanical assessment as part of their comprehensive pain management regimen.

By emphasizing biomechanical principles, the contents of this chapter represent a fundamental change from the customary emphasis on the use of physical therapy and physical modalities in treating musculoskeletal pain. Patients are often treated for musculoskeletal disorders with passive modalities such as hot packs, cold packs, massage, electrical stimulation, and deep heat. Unfortunately, these passive therapies are overused. While they certainly can play an important role in providing symptomatic relief of musculoskeletal pain, passive modalities should be used only as methods to facilitate *active* rehabilitation. The patient most needs to become actively involved in a therapeutic exercise program specifically designed to improve musculoskeletal functioning.

Musculoskeletal rehabilitation is a process whereby poor posture, muscle imbalances, and other biomechanical deficits are corrected using specific exercises to gain better static and dynamic control of the musculoskeletal system. The physical restoration process may involve passive therapeutic modalities to facilitate the exercise program. Clinicians treating musculoskeletal pain and dysfunction must identify and work to correct deficits in the patient's biomechanics.

This chapter introduces general concepts in clinical biomechanics that are crucial to the understanding of musculoskeletal rehabilitation. The first section, Basic Considerations, presents an overview of these biomechanical concepts. In the second section, Clinical Considerations, specific techniques used to treat musculoskeletal pain are reviewed. In keeping with the philosophy that lasting improvements in biomechanical functioning are due to exercise programs prescribed specifically for each patient's pain symptoms and biomechanical deficits, therapeutic exercise is emphasized; passive therapeutic modalities are given less attention. The concepts presented here can be applied to soft tissue injuries throughout the body. The diagnosis and treatment of specific injuries are covered in the final section of this chapter.

BASIC CONSIDERATIONS

This section introduces basic concepts in musculoskeletal rehabilitation. Using specific examples, we review the importance of optimizing range of motion, strength, endurance, and neuromuscular control. The role of muscle agonist/antagonist interactions and adverse neural tension (ANT) is included. There is a certain degree of overlap between the various biomechanical concepts that are presented. For example, although strength and endurance are related, they are presented separately because clinical pain syndromes related to deficits in strength differ from those related to deficits in endurance.

Range of Motion

Lack of adequate range of motion is probably the most common biomechanical deficit seen and one of the easiest to address. Deficits in range of motion can cause pain directly or may lead to pain elsewhere. An example of a range-of-motion deficit that causes pain directly occurs when electricians experience shoulder pain while doing overhead work because of limitations in glenohumeral forward flexion. An example of a range-of-motion deficit that leads to pain in a distant body segment occurs when electricians with limited glenohumeral forward flexion experience low back pain while performing overhead activities because they must increase their lumbar lordosis to compensate for the lack of shoulder elevation (Fig. 88.1). The compensatory increase in lumbar lordosis is an example of a maladaptive substitution pattern due to a biomechanical deficit (e.g., decreased latissimus dorsi length).

The musculoskeletal clinician must have adequate examination skills to identify all range-of-motion limitations, decide which of these contribute most significantly to patients' symptoms, and implement appropriate therapies to correct the deficits.

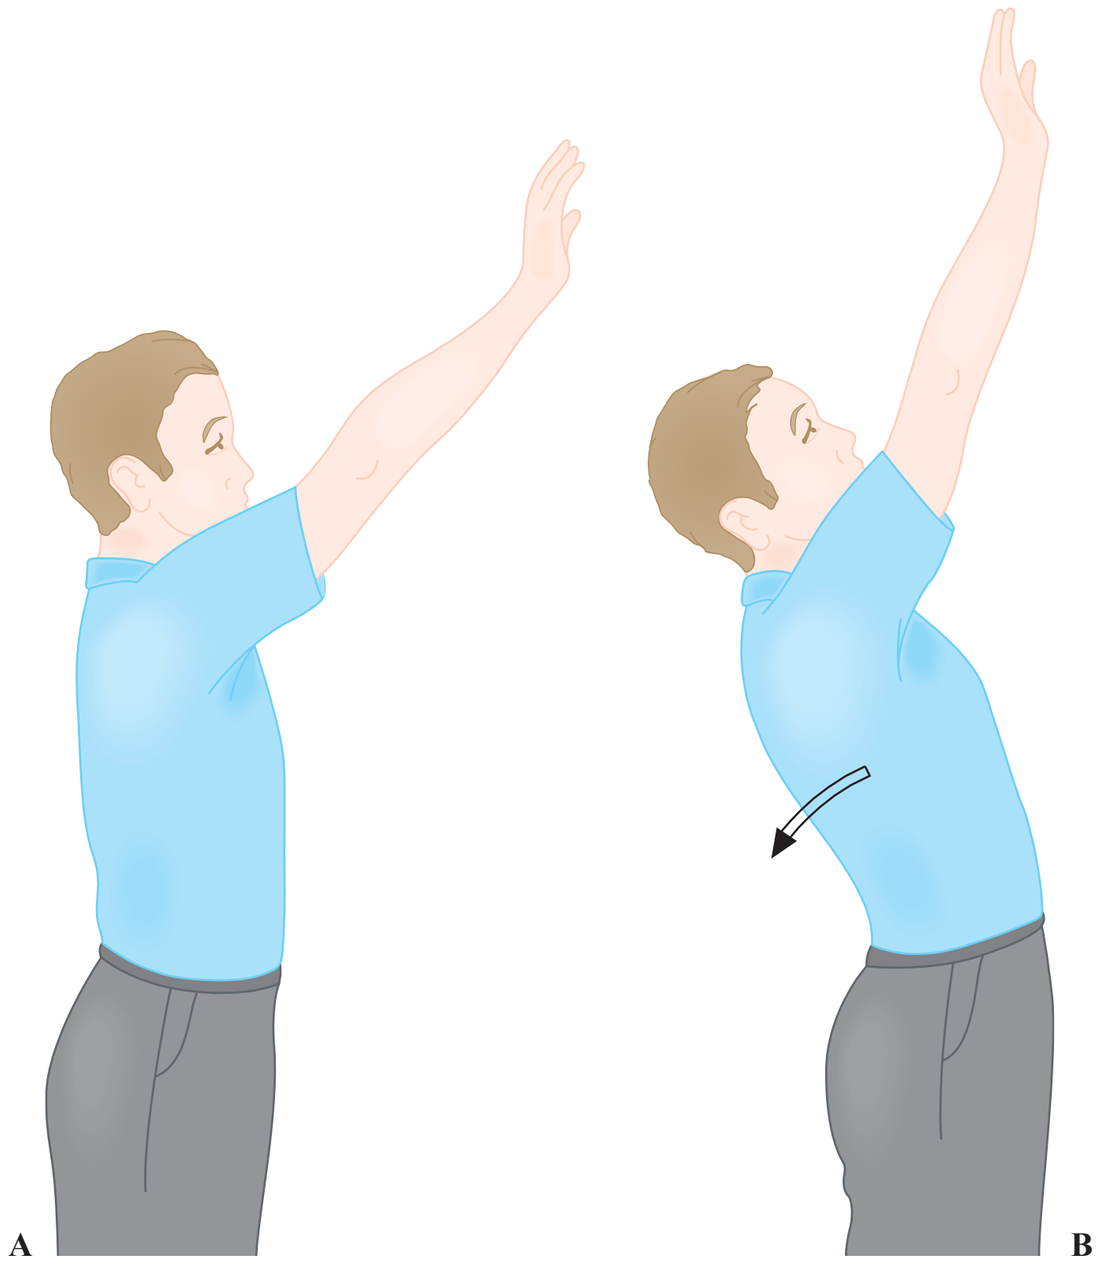

FIGURE 88.1 The individual with limited glenohumeral forward flexion **(A)** compensates with exaggerated lumbar lordosis during overhead activities **(B)**. This maladaptive substitution pattern can lead to low back pain.

Range-of-motion restrictions can be due to shortening of muscle-tendon units, restrictions in joint capsule distensibility, ANT, or bone-on-bone contact at joint interfaces. The first three conditions are almost always amenable to specific stretching techniques. These are discussed later in this chapter under Clinical Considerations. Range-of-motion deficits due to bone-on-bone contact are not improved with therapeutic exercise or physical modalities.

Strength

Strength assessment is part of the comprehensive examination of the patient, whether it is through manual muscle testing (MMT), or a more formal dynamometric assessment. As a general rule, the patient should be examined in muscles surrounding the region that is painful. In addition, assess strength in the regions immediately proximal and distal to the painful region. For example, in a patient with elbow pain, the clinician should evaluate strength in the shoulder, elbow, and wrist.

Additionally, since many pain complaints may have an underlying spine etiology (e.g., a radiculopathy), it is often useful to examine the key myotomes in the affected region. Using the same example of elbow pain, the clinician would evaluate muscle strength of the C5-T1 myotomes bilaterally to assess for focal weakness. A useful set of muscles for assessing specific myotomes are those that are used as part of the comprehensive assessment for spinal cord injury, as per the American Spinal Injury Association guidelines, as these key muscles have been tested to assure their reliability in assessing specific myotomes (Table 88.1).

If the clinician finds that a patient has what appears to be weakness, the next delineation is whether the weakness is a "true" weakness or is pain-limited. While this is obviously challenging,

TABLE 88.1

AMERICAN SPINAL INJURY ASSOCIATION MYOTOMES

Mytome	Movement tested
C5	Elbow flexion
C6	Wrist extension
C7	Elbow extension
C8	Finger flexion (at the DIP joint)
T1	Fifth digit abduction
L2	Hip flexion
L3	Knee extension
L4	Ankle dorsiflexion
L5	Long toe (hallux) extension
S1	Ankle plantarflexion

there are a few clues that may help the clinician determine whether a patient is limiting their effort secondary to pain. First, the clinician is able to elicit a more vigorous effort if the patient knows that maximum effort will only be required for a moment. Second, it is unusual for patients to be able to exert a submaximal effort in a smooth manner; instead, they will often exert an initial effort and then stop further exertion (i.e., "give-way" weakness, or "catch-and-release"). If the patient has pain-limited weakness, this is of course clinically important, because it demarcates a painful range of forceful motion. However, it is important to distinguish pain-limited weakness from a true focal weakness, which may be a harbinger of a potentially serious neurologic cause.

Two primary factors contribute to relative strength deficits in ambulatory patients without major nerve or muscle injury. The first might be considered a relative disuse weakness. In relative disuse, the body part is not immobilized but is infrequently used in a manner that develops strength. Triceps weakness in sedentary office workers is a good example of this. Although these individuals may be "pushing papers" all day long, they may go for decades without ever performing elbow extensions against enough resistance to prevent gradual weakness from developing. On MMT, they will likely earn an elbow extension grade of 4/5 to 5/5. This relative weakness may never be symptomatic unless the workload required in that individual's triceps muscle suddenly increases. This would occur, for example, if the person decided to build a deck onto the back of the house and began hammering for long periods.

Similarly, many of us do not maintain full strength in our hip extensors (especially for extension past the neutral position) or the muscles that help elevate the upper limbs, especially those that upwardly rotate the scapula. These simply are not movements that we do against resistance very often during routine activities of daily living. Mild strength deficits due to relative inactivity are frequently asymptomatic. They become symptomatic if the individual has a rapid increase in activity or if age-related changes such as loss of motor units or decreasing activity level further weaken muscle groups that already have mild strength deficits. Mild or relative weakness of the hip extensors and abductors has particular relevance in the setting of low back pain due to the functioning of the hip extensors and abductors as lumbopelvic stabilizers. Mild weakness of the scapular rotators has particular relevance in the setting of shoulder pain, due to the role of these muscles in overhead activities.

The second primary factor that contributes to relative strength deficits in ambulatory patients without major nerve or muscle injury is a process sometimes referred to as muscle de-education.[1] This is a process in which the individual fails to activate, or abnormally activates, a given muscle because of pain, fatigue, maladaptive biomechanics, or psychologic reasons. Over time, the normal

neuromuscular engram for the intended movement becomes harder to retrieve, and the neuromuscular control system has essentially "forgotten" the normal pattern of use for that muscle. Most often, muscle de-education involves the patient losing the ability to fire a muscle with the correct timing, or strongly enough, for the movement intended. The patient adopts a maladaptive neuromuscular firing pattern and substitutes other muscles to perform the task. Sometimes the muscle de-education process consists of the patient firing a muscle too strongly or losing the ability to relax the muscle appropriately.

An example of a patient substituting one muscle for another is the individual who preferentially fires hamstrings to perform hip extension, rather than using the strongest hip extensor, the gluteus maximus. If this maladaptive firing pattern continues over time, the gluteus maximus becomes de-educated and weak. This can result in poor pelvic control and secondary low back pain. The concept of muscle de-education emphasizes the close interaction between neural control mechanisms and musculoskeletal function in the development of musculoskeletal pain.

A classic example of a patient losing the ability to appropriately relax a muscle is the individual who presents with unilateral upper back and posterior neck pain. This is often due to the patient holding the scapula in an elevated position. The levator scapulae and upper trapezius are short and tight, and there are pain and tenderness in these muscles. This hiked-shoulder posture is assumed when people work hunched over a desk or when they are tense. Some individuals do not bring the scapula back down to its normal position, and over time they "forget" how to relax the scapular elevators, and forget where their scapula should be normally positioned.

The clinician treating musculoskeletal pain must identify all strength deficits, decide which ones are clinically relevant to the patient's symptoms, and implement an appropriate rehabilitation plan to correct those deficits and re-educate muscles that have lost their normal patterns of firing.

Endurance

Endurance refers to the capacity to continue to functionally exert oneself. While patients with pain complaints may occasionally be limited by cardiovascular endurance, the more common context for assessing endurance in a pain patient is muscular endurance.

As an individual bears weight during a functional activity, the forces of their activity (e.g., the ground reaction force while walking) have to be borne by the different structures throughout the kinetic chain. These include bone, joints, articular cartilage, ligaments, and muscles. Ideally, muscles bear a substantial amount of these reactive forces, which reduces the forces transmitted across other structures. However, with repetitive iterations, muscles may fatigue, and therefore, while muscles may be able to bear reactive forces initially, with each repetition, forces are then transmitted to other structures.

The phenomenon of muscle fatigue has important implications both diagnostically and therapeutically. Oftentimes, patients will complain of pain presentations that are initially mild, but worsen with increased activity. They may initially appear normal on physical examination. Therefore, it may be necessary during examination to exercise a patient to fatigue to simulate those circumstances when the patient is having pain. For example, if a patient complains of knee pain that worsens with walking long distances or climbing stairs, a component of the pain complaint may be poor muscular endurance in the quadriceps muscle. When testing knee extension by MMT, the strength may appear normal, since the patient's limitation is muscular endurance rather than peak torque production (which is what one tests with MMT). Therefore, the patient may be better assessed by performing repetitive single leg squats, which can fatigue the quadriceps relatively quickly within the time frame of the examination, and allow the clinician to assess whether poor muscular endurance is contributing to the patient's pain complaint. Similarly, if the clinician assesses that poor muscular endurance is contributing to a patient's pain complaint, then improving muscular endurance should be a focus in the patient's physical therapy protocol.

Neuromuscular Control

Motor control is often overlooked in musculoskeletal rehabilitation. A muscle or muscle group may be quite strong, but if it does not fire at the appropriate time, it might as well not fire at all. Neuromuscular control is a combination of sensory feedback from the body part, premotor planning, and motor execution.[2,3] Impairments in any of these pathways can lead to musculoskeletal dysfunction and pain. Normal neuromuscular control can be lost through injury or disuse and can be regained through appropriate retraining.[4] For some movements, proper neuromuscular control is an easy task. For other movements, motor control requires practice.

For example, if you ask patients to fire their biceps muscles, they will be able to flex their elbows without any difficulty. But if you ask patients to fire their multifidus or lower trapezius muscles, they may not be able to do so even if you show them pictures of those muscles in an anatomy text and explain their actions.[5,6] Multifidus and lower trapezius are under voluntary control just like biceps, but our ability to consciously use them to gain fine control over segmental spine motion and scapular rotation, respectively, is far less than our ability to consciously activate biceps to precisely flex the elbow. Specialized exercises can improve one's ability to execute fine control of the neuromusculoskeletal system.

When trying to gain fine motor control, one needs to maximize control of individual muscles and smoothly integrate the actions of different muscle groups in succession during dynamic activities.[7–9] For example, when lifting an object, a person must first fire the foot and ankle muscles to stabilize the feet on the ground. Then one must fire the thigh muscles to stabilize the knee. Next, the hip girdle muscles must stabilize the pelvis before the spine extensors can elevate the torso. If the gluteus maximus fails to kick in before the erector spinae fires, the pelvis will remain anteriorly tilted and abnormal motion will occur in the lumbar spine.

Normal motor sequencing is a highly synchronized process that can easily break down. Several causes of deficits exist in neuromuscular control. One is a lesion in the motor pathways, either centrally or peripherally. This can be dramatic in obvious cases such as cerebellar lesions or cerebral palsy. Subtle nerve injury, however, can cause subtle loss of neuromuscular control. For example, mild irritation of the C5 nerve root can cause abnormal firing patterns of the shoulder girdle muscles and result in upper back and shoulder pain.[10] Mild irritation of the L5 nerve root can cause abnormal firing patterns of ankle and lumbopelvic stabilizers and lead to ankle or lumbopelvic instability and pain. For optimal success, a comprehensive rehabilitation program addresses biomechanical deficits in both the musculoskeletal and neuromuscular systems.

Another cause of impairment in neuromuscular control is loss of sensory feedback from a body part. This can be dramatic in obvious cases such as occur with a lesion of the sensory portion of the internal capsule or severe vitamin B_{12} deficiency. More subtle loss of sensory feedback can also alter normal neuromuscular firing patterns, however. A common example of this is the inversion ankle sprain. One can strengthen the foot and ankle indefinitely, but if proprioception retraining is not added to the rehabilitation plan, the patient may have persistent ankle pain due to poor fine motor control of the ankle stabilizers.[11,12] Proprioception and fine motor control training is crucial for many

injuries involving the spine, knee, and shoulder, as well as the ankle.[2,13–18]

The clinician must recognize deficits in neuromuscular control that may be contributing to the patient's musculoskeletal pain and implement a rehabilitation plan that includes correction of those deficits.

Muscle Balance and Agonist/ Antagonist Interactions

When a patient has a pain complaint in a specific peripheral structure (e.g., the shoulder), pain in that region can be a function of suboptimal biomechanics at that joint. One cause of suboptimal positioning is an imbalance between agonist and antagonist muscle groups.

One of the most common examples of agonist and antagonist muscle groups occurs about the shoulder. For various postulated reasons, the flexor/adductor/internal rotator muscles of the shoulder girdle are often more active than the corresponding extensor/abductor/external rotator muscles. When this is the case, the glenohumeral joint sits in a plane that is suboptimal for many functional activities, particularly overhead activities.[19,20]

There are several mechanisms for the relative imbalance of agonist and antagonist groups. First, some activities, such as sitting at a desk using a laptop computer, will emphasize positioning that activates one agonist group (in this case, a slumped posture that internally rotates, adducts, and flexes the shoulder girdle) and de-emphasizes the corresponding antagonist group. Second, muscle balance theory states that a strong, tight muscle group will reflexively inhibit the antagonist group.[1,21] The clinical implications of such agonist/antagonist interactions are important. If a patient is having trouble strengthening a muscle group during a physical therapy program, simultaneous stretching of the antagonist muscle group may be necessary to facilitate strengthening of the target muscle group. Similarly, if the patient is not progressing with correcting range-of-motion deficits in a particular muscle group, the rehabilitation plan may need to include strengthening of the antagonist muscle group.[22] This concept is best illustrated by the following common examples of muscle imbalance that are clinically associated with painful musculoskeletal dysfunction.

The first example is that of the patient with subacute or chronic posterior neck pain. This patient often presents with cervical hyperlordosis due to tightness of the long cervical extensors and weakness of the cervical flexors.[23] Both of these biomechanical deficits need to be addressed to restore proper cervicothoracic posture and movement. Similarly, one contributor to abnormal motion at the patellofemoral joint, with subsequent patellofemoral arthralgia, is muscle imbalance in the structures that control the patella. Typical biomechanical deficits in this case are tightness of the laterally situated iliotibial band (ITB) and weakness of the medial thigh muscles, including hip adductors and vastus medialis obliques.[24] In treatment, it is necessary to stretch the lateral patellar stabilizers and strengthen the medial patellar stabilizers to improve patellofemoral tracking.

Another common area of muscle imbalance is the shoulder girdle, where one frequently finds tightness of the strong anterior shoulder muscles, including pectoralis minor, pectoralis major, and latissimus dorsi, with associated inhibition and weakness of the posterior shoulder muscles, including middle and lower trapezius and rhomboids.[25] This forward-rounded shoulder posture (Fig. 88.2) can be a cause of interscapular pain, rotator cuff pain secondary to abnormal scapular movement (Fig. 88.3), and upper limb pain due to ANT in the brachial plexus.

Similar symptoms can be seen with imbalance between tight scapular elevators, principally levator scapulae and upper trapezius, and inhibited, weak scapular depressors, including lower trapezius and serratus anterior. This pattern of muscle imbalance causes the patient to have a shoulder-elevated posture and is also

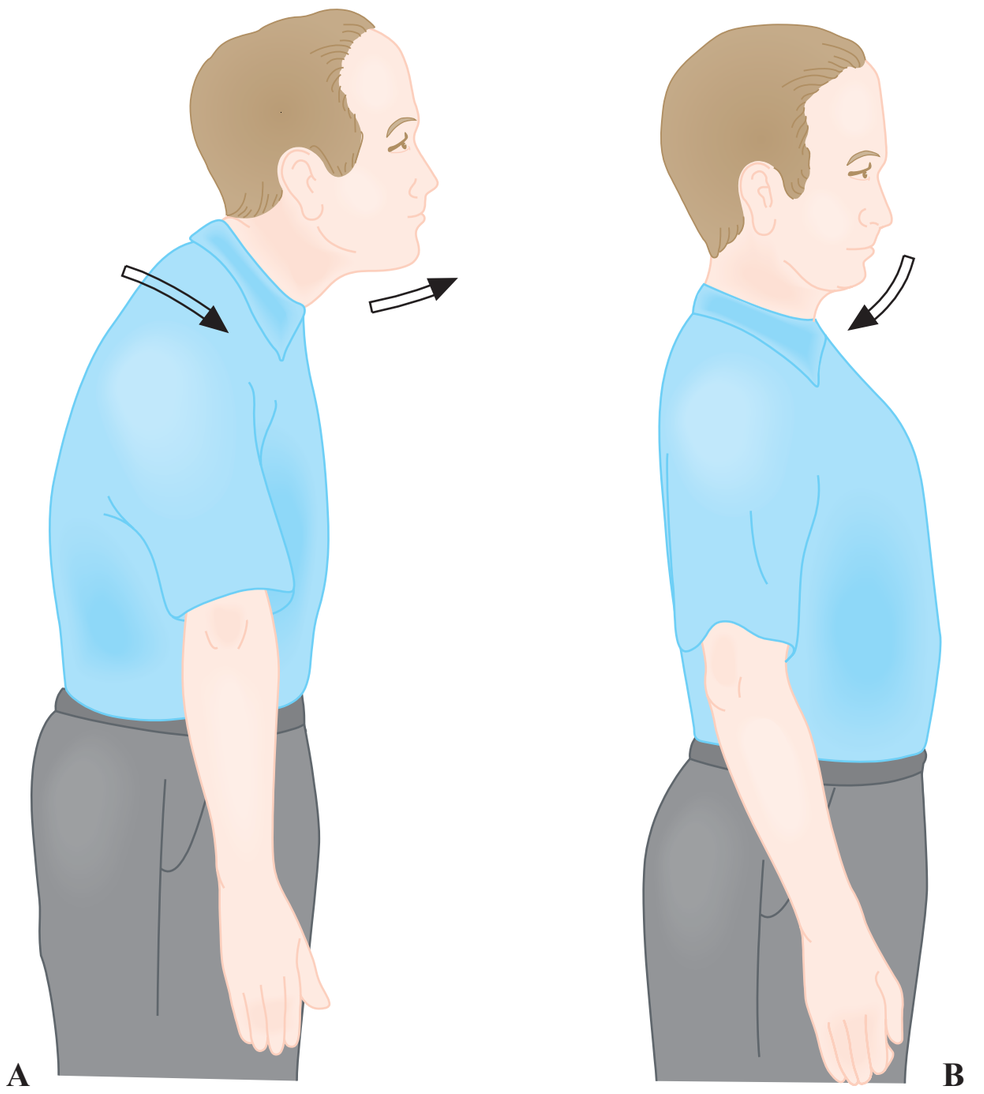

FIGURE 88.2 The forward-rounded shoulders posture offers a prime example of muscle imbalance that can lead to musculoskeletal dysfunction. The anterior shoulder muscles are tight and the neck and posterior shoulder muscles are put at mechanical disadvantage. **A.** Excessive cervicothoracic kyphosis necessitates a compensatory cervico-occipital extension to keep the eyes level. **B.** Posture rehabilitation includes stretching the anterior shoulder girdle, strengthening the scapular retractors, and chin tucks to improve cervicothoracic alignment.

often seen in patients presenting with posterior neck and shoulder pain. The rehabilitation plan should include stretching of the tight muscle groups with simultaneous strengthening of their antagonists to restore normal muscle balance.

A fourth common site of muscle imbalance is the hip girdle, where tight hip flexors are often seen clinically with inhibited, weak hip extensors.[1] Perhaps the most important clinical sequela of this type of muscle imbalance is not hip dysfunction per se. Instead, poor pelvic control by gluteus maximus results in an increase in anterior pelvic tilt, which leads to lumbar hyperlordosis and low back pain.[26] The rehabilitation of low back pain almost always includes restoration of neutral lumbar posture. In this case, that would necessitate restoring full range of motion of the hip flexors as well as full strength of the hip extensors.[27]

A few instances of agonist/antagonist interactions pose particularly troublesome problems for the neuromuscular control system. Consider again the relationship between the upper and lower trapezius. Working together, they couple forces to stabilize the scapula in a retracted and upwardly rotated position, a function crucial for all overhead activities. Yet, they also have antagonistic roles in that the upper trapezius is a scapular elevator while the lower trapezius is a scapular depressor. Such a complex relationship between two different parts of the same muscle, innervated by a single nerve, cannot always be accommodated by the neuromuscular control system and can result in scapulothoracic dyskinesis. In this case, the lower trapezius tends to become inhibited and weak.

An equally complex relationship exists between the tensor fascia lata and gluteus maximus, the two muscles that insert into and control the ITB. Working as agonists, the two muscles serve as hip abductors. Yet they are also antagonists in that the tensor fascia lata is a hip flexor and internal rotator, whereas the gluteus maximus is a hip extensor and external rotator. As in the above

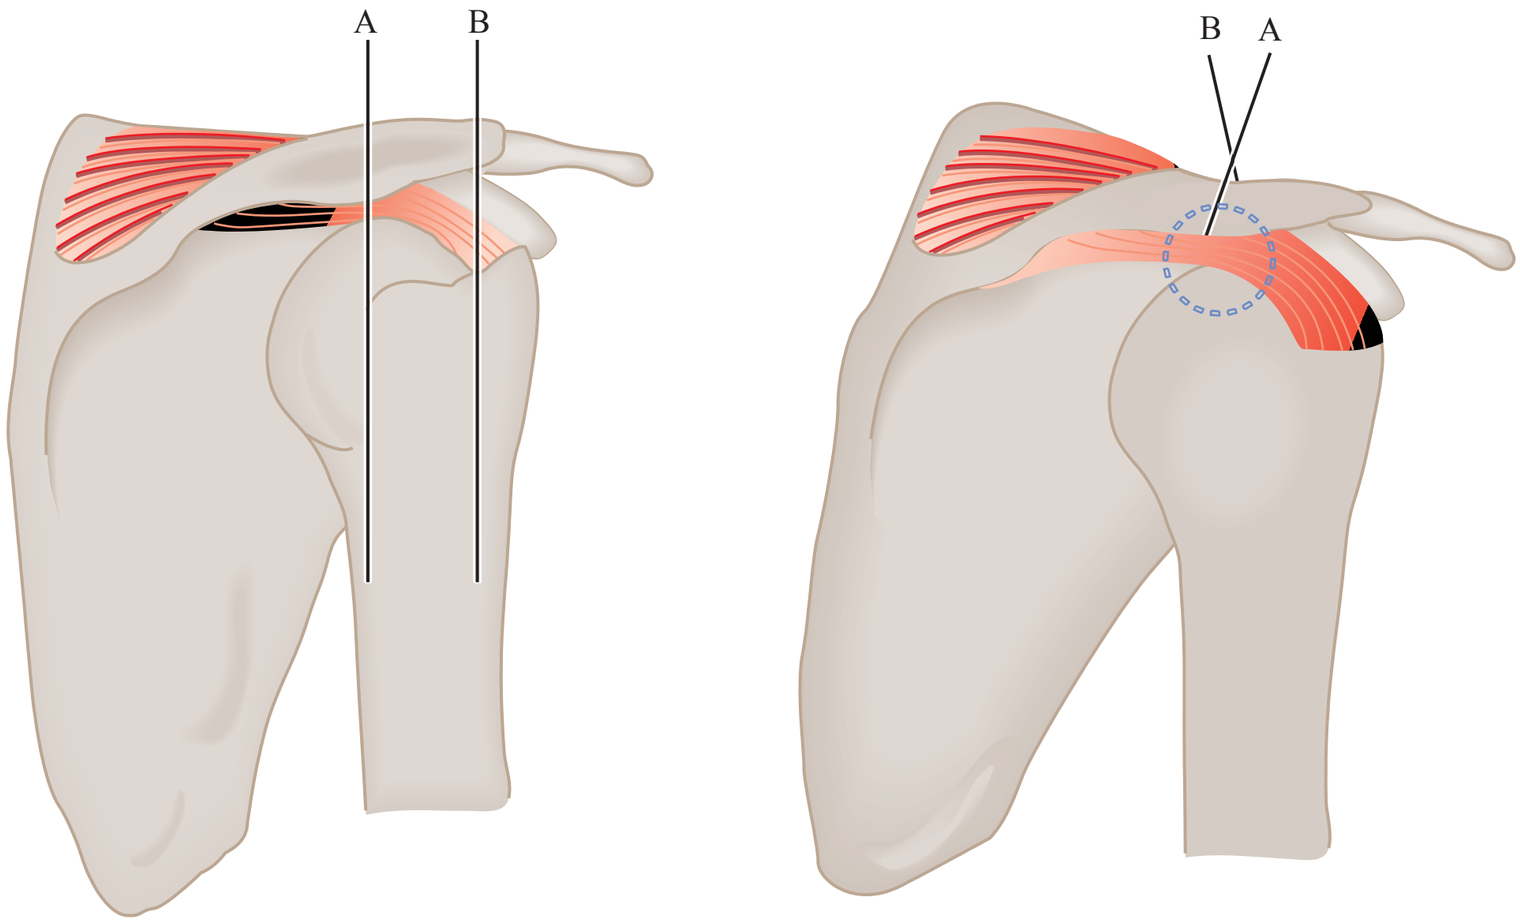

FIGURE 88.3 Line A represents a vertical line drawn through the angle of the acromion and Line B represents a line through the long axis of the humerus. The left figure represents the positioning of the humerus and scapula in anatomical position, whereas the right figure represents the same system with the scapula malpositioning from tightness/overdevelopment of the anterior muscles (pectoralis minor). As a result, the scapula is placed into a position of protraction and anterior rotation. In the right figure, the scapula (line A) is rotated, while the humerus (line B) due to effects of gravity, remains fixed in place, therefore resulting in an angle between the scapula and humerus. This angle creates a new dynamic for the supraspinatus tendon. The insertion of the supraspinatus tendon on the superior-anterior aspect of the greater tubercle of the humerus is now more closely approximated to inferior aspect of the acromion. The aberrant positioning of the scapula will predispose the supraspinatus tendon to impingement.

example, this can tax the resources of the neuromuscular control mechanisms that dictate appropriate firing patterns. In this example, the tensor fascia lata usually dominates, with the gluteus maximus becoming inhibited. If fine control of the ITB is lost, hip pain (trochanteric bursopathy) or knee pain (ITB insertionopathy) can result.

Other examples exist where muscles serve paradoxic functions. The tibialis anterior and tibialis posterior (TP) muscles work together to invert the foot and support the arch of the foot. Yet they are also antagonists in that the latter is an ankle plantar flexor, whereas the former is a dorsiflexor. At times, during normal walking gait, running gait, and going up or down stairs, both muscles must be active for dynamic arch support, but we need one or the other to stop firing because we need the action of its antagonist. Abnormal firing patterns of TP can lead to TP tendinopathy. Inhibition of either the tibialis anterior or TP can lead to arch collapse, plantar fasciitis, or foot pain.

Similarly, the extensor carpi radialis brevis (ECRB) and longus cooperate with the extensor carpi ulnaris to extend the wrist. But the ECRB is left in a quandary during wrist extension movements that require radial deviation, such as hitting a backhand in tennis, or repeatedly loading luggage onto a conveyer belt. At these moments, ECRB must fire to produce wrist extension and radial deviation. But the extensor carpi ulnaris, an ulnar deviator of the wrist, abandons its partner in wrist extension to allow radial deviation of the wrist to occur. This neuromuscular predicament impedes the ability of the wrist extensors to adequately concentrically generate or eccentrically absorb forces, and leads to ECRB overload (called lateral epicondylopathy or tennis elbow).

In each of the above examples of contradictory agonist/antagonist interactions, there exists a common, associated overuse injury such as rotator cuff tendinopathy due to scapulothoracic dyskinesis, ITB friction syndrome, posterior tibial tendinopathy, or forearm extensor tendinopathy.

The clinician must recognize muscle imbalances that contribute to the patient's musculoskeletal pain and implement a rehabilitation plan that restores proper balance by treating both the agonist and antagonist muscle groups involved. Neuromuscular control must be optimized through specific muscle education and training.

Neural Tension

Neural structures in the central nervous system (CNS) and peripheral nervous system (PNS) move when body parts move. Like muscles, tendons, and joint capsules, the connective tissue associated with the nervous system can lose its normal elasticity and range of motion. If symptomatic, this condition is called ANT. Alternative names include adverse neurodynamic tension or, sometimes, dural tension. ANT can be defined as abnormal physiologic or mechanical responses of the nervous system as its tissues are taken through a range of motion.[28]

ANT is most commonly recognized as the condition that produces a positive straight-leg raise test. It is also commonly recognized as the entity that produces a positive Kernig's sign in a patient with meningitis. Less commonly recognized, however, is that ANT can exist in areas other than the lumbosacral roots that contribute to the sciatic nerve. Even in the absence of meningitis, it can exist in the spinal cord and the surrounding connective tissue, the cervical roots, brachial plexus, and peripheral nerves. ANT can cause range of motion restriction, pain with movement, paresthesias in the distribution of the nerves affected, and diminished neuromuscular control.

Normal and abnormal movement of neural structures during movement of the musculoskeletal system has been partly characterized. The posterior part of the human spinal canal increases between 5 and 9 cm in length as the spine goes from full extension to full flexion.[29–31] Thus, trunk and neck movement is associated with gliding movements of the spinal cord within the canal. The

dura is connected to the bony and ligamentous structures of the spinal canal via the ligaments of Hoffman.[32] Abnormal adhesions between the dura and surrounding structures may form, however, and have been implicated in enhancing pain consequent to disc herniations.[33] Upper and lower limb movements also have mechanical consequences for the spinal cord and its roots.[34] The median nerve elongates 20% as the upper limb moves from elbow and wrist flexion to full elbow and wrist extension.[35] Further stretching of the nerve fibers in the brachial plexus is obtained by adding ipsilateral shoulder depression and contralateral cervical flexion.[36]

The nervous system is linked to the musculoskeletal system in several ways. First, neural movement is mechanically coupled with musculoskeletal movement. Second, the nervous system is physiologically connected to the musculoskeletal system at the neuromuscular junction. Third, the nervous system itself can be considered to be in part a connective tissue. Myelin possesses elastic features that allow the myelin sheath to change conformation as nerves stretch, with opening of the clefts of Schmidt-Lantermann.[37–40] The endoneurium, perineurium, and epineurium surrounding peripheral nerves all contain collagen,[41] the common substrate of all connective tissue.

The connective tissues within peripheral nerves allow for the necessary gliding of adjacent fascicles against each other during limb movements, especially when the limb goes through its full range of motion. Also built into the neurodynamic system is an allowance for a considerable amount of motion between the peripheral nerve and the surrounding tissues in which it lies.[35,42] Tunturi[43] demonstrated the presence of elastin in the dura mater of dogs, suggesting that dura possesses the capability of distensibility.

Certain regions of the body exist in which the connective tissue of the nervous system is more abundant. For example, the fibular nerve (also called the peroneal nerve) has 17% more connective tissue associated with it as it passes around the fibular head than as it courses through the popliteal fossa.[44] The amount of connective tissue in peripheral nerves ranges from 21% to 81%, with greater amounts present when the nerve passes a joint.[45] The connective tissue elements associated with the CNS and PNS protect neural tissue from injury during gliding movements and compressive events.

The spinal nerve roots lie at the junction of the CNS and PNS and are at particular risk for mechanical stress and ANT for three reasons. The first is that the connective tissue covering the roots is at a transition between the CNS and PNS and is not as well developed as its more proximal or distal counterparts.[46] Second, the spinal nerve roots are more tightly adherent to the walls of the intervertebral foramen than in other places.[47,48] Third, stenosis of the intervertebral foramen, which can cause abnormal neural gliding, is a common occurrence.

Often, a close association exists between ANT and muscle tightness. A prime example of this is patients with lumbosacral nerve root tension who also have marked hamstring tightness. Both the nerve root and the muscle must be mobilized if normal biomechanics in the region are to be restored.[49,50] ANT and muscle tightness often coexist and can easily be mistaken for one another. Careful physical examination is required to distinguish between the two.

Several special physical examination maneuvers that test for ANT in the spine and limbs are described later in the chapter. The clinician treating pain syndromes must be able to identify when ANT is contributing to the patient's symptoms and then implement an appropriate neural mobilization program.

Kinetic Chain Theory

Kinetic chain theory states that biomechanical deficits in one region can be responsible for symptoms in a distant body part. A corollary to kinetic chain theory is the concept of force distribution. A biomechanical system functions optimally when all its parts are able to absorb and generate forces appropriately. Loss of optimal function in one region of the kinetic chain may predispose to overload in another region. The following two examples illustrate this idea. First, if a volleyball player is generating inadequate hip extension or ankle plantarflexion moments during jumping, the athlete's quadriceps can become overloaded and patellar tendinopathy may result as the quadriceps is forced to compensate for the deficiencies of its kinetic chain partners. Second, if a golfer lacks adequate hip rotation, there will be a compensatory increase in lumbar axial rotation during the driving swing that may result in low back pain. Thus, the clinician must assess function in parts along the kinetic chain both proximal and distal to the painful area.

Kibler and colleagues[51–53] have eloquently synthesized a grand unifying theory of kinetic chain functioning. They describe how for any injury, there are five separate elements that make up the musculoskeletal injury complex that may be identified as contributing to the production or continuation of symptoms (Fig. 88.4). These elements include (1) the tissue injury complex—the actual area of anatomic disruption; (2) the clinical symptom complex—the group of symptoms the patient experiences, such as pain, stiffness, and impaired performance; (3) the functional biomechanical deficit—the set of muscle inflexibilities, weakness,

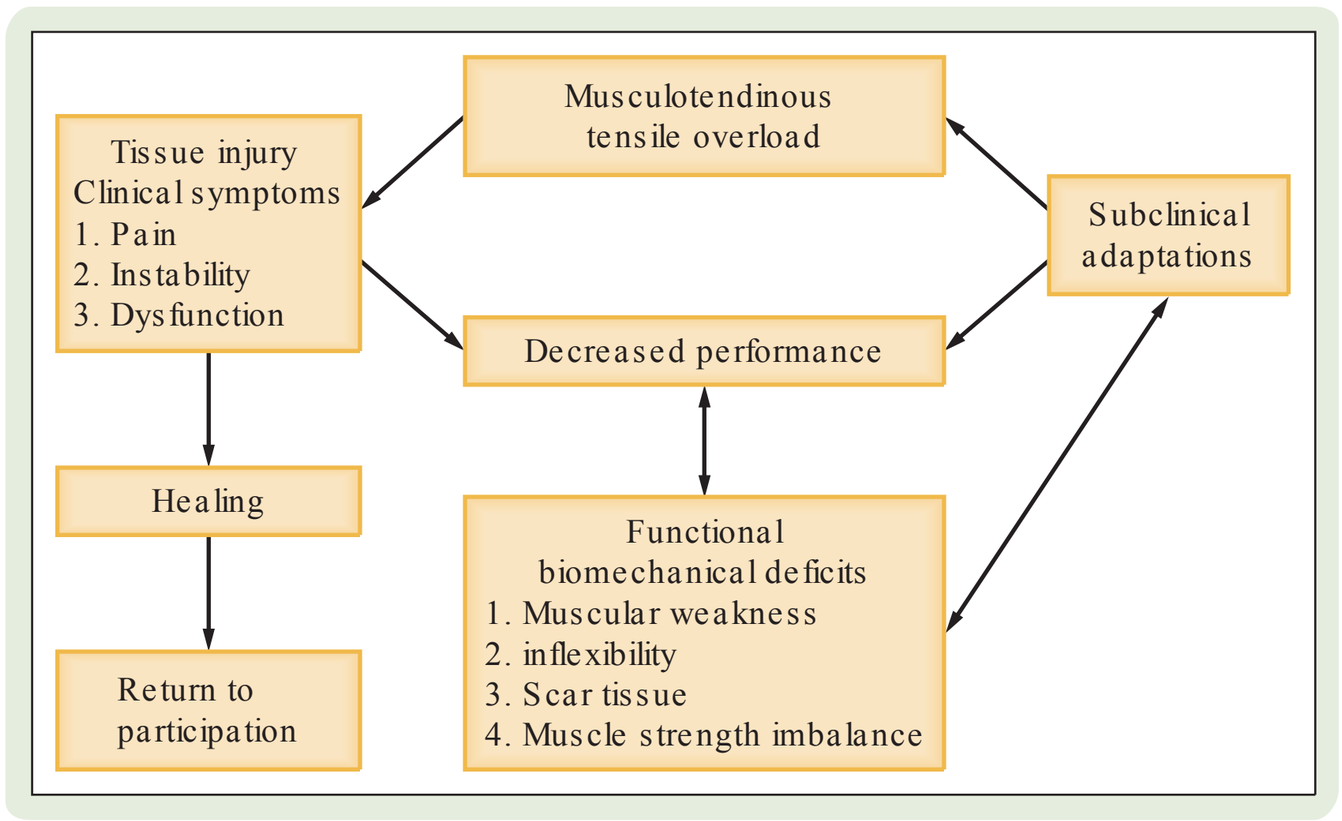

FIGURE 88.4 The vicious cycle: Tissue injury can lead to maladaptive biomechanical alterations, which in turn can lead to further tissue injury.

and imbalance that cause inefficient mechanics; (4) the functional adaptation complex—the set of functional substitutions that the patient uses in an attempt to reduce pain and maintain performance; and (5) the tissue overload complex—the group of muscles and other soft tissue structures that are subject to overload injury secondary to the initial injury or maladaptive biomechanics, thus causing or prolonging symptoms. These five elements are often interactive and additive, setting up a vicious cycle of continuing musculoskeletal problems.

Prehabilitation and Posthabilitation

The focus of the management of a patient with an acute pain complaint is typically targeted on resolving their current symptoms. However, given that pain complaints are often caused by suboptimal biomechanics, it is important for the clinician to rehabilitate beyond the resolution of the symptoms. This is termed posthabilitation. If the suboptimal biomechanics that led to the pain presentation are still present, then it is likely that the patient may have another exacerbation of the same pain complaint in the future. Indeed, for many common peripheral musculoskeletal pain complaints (e.g., ankle sprains), the best predictor of a future pain episode is a prior episode of the same condition.[11,54–57]

While it is certainly valuable to address a patient's pain complaints at the time of injury through rehabilitation and to prevent recurrences afterward via posthabilitation, the ideal scenario would be to prevent injuries from occurring. Prehabilitation is a focus on preventing injuries before they occur, primarily focusing on optimizing biomechanics to prevent those injuries associated with identifiable biomechanical deficits.

For example, Frank Noyes and his colleagues[58,59] have developed the Sportsmetric program as a systematic training program designed to reduce the incidence of ACL tears in female athletes. This is based on the biomechanical studies of Mary Lloyd Ireland and others who have demonstrated a clear causality between suboptimal biomechanics and increased incidence of ACL tears in female athletes.[60–66] It is important to remember that the absence of symptoms does not imply absence of pathology in the musculoskeletal system. The pain accompanying overuse injuries presents well after there are pathologic changes in the tissues and disappears before those tissues have fully healed. Therefore, the rehabilitation process must be comprehensive and continue after pain resolution. The goal of posthabilitation is prevention of injury recurrence.

Identifying Predisposing Factors

The astute musculoskeletal clinician searches for the reasons the patient developed an injury. In the case of acute trauma, the cause is obvious. In the case of soft tissue overload injuries, however, the clinician will need to look further. If the underlying precipitants of tissue overload are not addressed, the patient is at risk for recurrence.

Patient-Therapist Relationship

The relationship that the patient and therapist develop from their first session together and throughout treatment is crucial to the outcome of the rehabilitation process. The therapist must gain the trust of the patient and develop an exercise program that fits his or her musculoskeletal, cognitive, and psychologic needs. Some patients require more information or more reassurance. Other self-motivated patients may simply need to be shown how to do their home exercise program correctly and require less attention from the therapist.

Regardless of the specific needs of the patient, the therapist and physician must empower the patient to become an active participant in the rehabilitation process. This is done by educating the patient about his or her particular musculoskeletal pathomechanics and ensuring that the patient is involved in a home exercise program designed to make lasting biomechanical improvements. It is the additional responsibility of the therapist to help motivate the patient to be conscientious about performing the exercises (see Chapter 87). Should the patient-therapist relationship hinder the rehabilitation process at any time, consideration should be given to having the therapist adopt different strategies for that particular patient or to changing therapists.

CLINICAL CONSIDERATIONS

Therapeutic Exercise

The musculoskeletal rehabilitation clinician uses therapeutic exercise like the cardiologist prescribes antihypertensive medication or the surgeon uses a scalpel. The goal of therapeutic exercise is to correct biomechanical deficits that are contributing to the patient's injury and restore and maintain normal structure-function relationships in the musculoskeletal system. Although it is appropriate for the exercise program to be overseen by a physician and therapist, patients should do the majority of exercises independently, either at home or in a gym setting. The importance of promoting patient independence in a home exercise program, with regular reevaluation and advancement of the rehabilitation program, is critical in our changing health care environment. The principal components of therapeutic exercise are flexibility, strength, and neuromuscular control training.

Flexibility Training

An individual's flexibility results from a combination of genetic factors (primarily collagen type) as well as musculoskeletal usage patterns. Injury and lack of use predispose to contracture of soft tissues. Potential benefits of flexibility training include increased range of motion, decreased risk of musculotendinous injuries, decreased soreness, and improved musculoskeletal performance.[54,55] Several methods exist to improve flexibility. They include static stretching, ballistic stretching, contract-relax stretching, neural stretching, and manual mobilization. Each of these techniques is reviewed. Which technique to choose depends on the tissue to be stretched and the preferences of the physician, therapist, and patient.

Passive, Assisted Active, and Active Range of Motion

The terms passive range of motion (PROM), active assisted range of motion (AAROM), and active range of motion (AROM) refer to different levels of therapist and patient involvement in flexibility exercises (Table 88.2). PROM entails the therapist moving a joint through its range of motion with the patient maximally relaxed. The patient does not actively participate. PROM is often used in the early stages of rehabilitation and should be complemented with subsequent active participation by the patient.

TABLE 88.2

PHYSICAL THERAPY CATEGORIES

PROM	Passive range of motion
AAROM	Active assisted range of motion
AROM	Active range of motion

PROM is also used when the patient is unable to actively participate, for example, when trying to improve range of motion in a plegic limb. In AAROM, the patient actively moves the joint through its available range of motion as much as he or she is able, and then the therapist assists with overpressure at the end range of motion to make further gains in flexibility. AAROM is used when the patient is able to move the body part being targeted but not well enough at the end range of motion to improve flexibility. The goal of a progressive flexibility program is to enable the patient to perform the exercises independently. When possible, therefore, the patient should be advanced to AROM exercises without hands-on assistance from the therapist.

In static stretching, the length of the muscle-tendon unit is slowly increased until the patient feels a mild to moderate pulling sensation in the belly of the muscle being targeted. Sometimes the pulling sensation is felt at the musculotendinous junction or at the tendon-bone junction if there is overuse soreness or other pathology in these areas. If the patient feels pain or a severe pulling sensation, then the muscle-tendon unit is being overstretched and is at risk for injury. Severe discomfort during stretching is a signal that either the muscle should be relaxed by a few centimeters or a different stretch should be tried. During the course of a sustained static muscle stretch, the inverse myotatic stretch reflex is initiated, resulting in relaxation of the muscle.[67,68] It is important to take advantage of this phenomenon by extending the stretch by a few degrees or centimeters every 10 seconds. Thus, "static" stretching is not truly static when appropriately performed. This slow, controlled method of stretching is generally considered the safest way to improve flexibility of muscle-tendon units.

Some debate exists over the optimum amount of time that a muscle should be placed on stretch to effect lasting elongation of the tissue. Most clinicians advocate that a stretch should be held for a minimum of 30 seconds[69]; others prefer 120 seconds.[70] Also, no clear guidelines exist on the frequency with which a muscle should be stretched to effect lasting elongation of the tissue. Generally, two or more stretches per day, each held for at least 30 seconds, are required to improve range of motion. Some prescriptions might call for stretching a muscle every 2 to 3 hours.

Ballistic Stretching

Ballistic stretching is a higher-level technique used to increase the length of the muscle-tendon unit. In ballistic stretching, the muscle is positioned near the end of its range of motion and then repetitively brought just past the point where it provides natural resistance. These repetitive "bouncing" motions can be low or high amplitude and low or high velocity. Repetitive low-velocity movements up to and just past the muscle's end range of motion are called on-off stretching. The primary advantage of ballistic stretching is that, when performed correctly, rapid and significant gains in flexibility can be achieved.[71] The primary disadvantage is that it often requires the assistance of a qualified therapist or trainer. Another disadvantage is that the risk of over-stretching is greater than with static stretching. A session of ballistic stretching should be followed by static stretching of the target muscles.

Contract-Relax Technique

Contract-relax stretching is also considered a higher level stretching technique. Like ballistic stretching, the contract-relax technique has the potential to provide rapid gains in flexibility and it also often requires the intervention of a qualified therapist or trainer. This technique takes advantage of a period of muscle relaxation that follows muscle contraction. The patient firmly contracts the target muscle isometrically against resistance for approximately 5 seconds. Immediately following the contraction, the muscle is stretched. This contract-relax cycle can be repeated several times. Contract-relax stretching is sometimes referred to by the less descriptive term proprioceptive neuromuscular facilitation and is a form of the so-called muscle-energy stretching techniques.

Neural Tension Assessment and Mobilization

Restricted motion of neural elements can coexist and be interrelated with other soft tissue biomechanical deficits. Several reasons exist for this interrelationship. First, motion restrictions in the musculoskeletal system can cause secondary motion restrictions in the anatomically-related neural elements. One example of this includes tight, hypertrophied scalene muscles that restrict normal gliding of the brachial plexus as they pass out of the neck. Second, soft tissue edema or hematoma from acute trauma or chronic overuse can cause irritation of a nerve passing through the injured area. For example, sciatic ANT has been associated with repetitive hamstring strain.[49,72] Third, primary nerve irritation, for example, from a discogenic inflammatory process, can cause abnormal neuromuscular control that leads to secondary biomechanical deficits in the muscles served by that nerve root. Thus, ANT is rarely seen in isolation and should not be treated in isolation from other biomechanical deficits.

Before adding neural mobilization to the rehabilitation program, the clinician must determine whether ANT is present and, if so, whether it is relevant to the patient's symptom complex. Several physical examination maneuvers can be performed that assess for ANT in the lower and upper limbs.

The best technique for assessing ANT in the lower limbs is the slump test (Fig. 88.5). The starting position for this test has the patient seated with hands placed behind the buttocks, palms up on the examination table. The patient then places the chin on his or her chest and slumps the torso forward. This motion draws the spinal cord cephalad.[73] The examiner then sequentially extends the knee and dorsiflexes the ankle. These steps pull the lumbosacral nerve roots caudad.[74,75] At each stage, the examiner asks the patient what he or she feels. If the maneuver reproduces the patient's usual leg pain, and having the patient extend the neck relieves symptoms, the test is considered positive for ANT. It is crucial that the geometric relationship between the thighs, pelvis, and thoracolumbar spine remains constant so as to avoid tensing and relaxing myofascial structures and thus better isolate movement in the neuraxis. A crossed slump test occurs when extending the asymptomatic leg reproduces pain in the patient's symptomatic leg. This is analogous to a crossed straight-leg test.

The slump test is preferred over the better known straight-leg raise test for several reasons. First, the slump test is more sensitive because it adds cephalad gliding of the spinal cord, while the straight-leg raise maneuver only offers caudad gliding of the nerve roots. Second, the slump test adds specificity because neck flexion and extension help distinguish motion restrictions in neural tissue from other soft tissue inflexibilities. Using the standard straight-leg raise test, it is often difficult to distinguish between ANT and hamstring or gastrocnemius tightness. Both the straight-leg raise and the slump test can be modified to preferentially test tension in the peroneal/L5 nerve fibers versus the tibial/S1 fibers by inversion and plantarflexion of the foot.[74]

The brachial plexus tension test is the upper limb homologue to the slump test. First, the cervical roots are pulled distally by sequential shoulder depression, shoulder abduction, and external rotation, forearm supination, and elbow, wrist, and finger extension. The examiner asks the patient what he or she feels at each stage. Reproduction of pain or paresthesias in the limb is considered a positive test. If the neck is side bent to the contralateral side, thus drawing the cervical cord away from the limb being tested, symptoms should be exacerbated. If the neck is side bent toward the ipsilateral side, symptoms should be alleviated (Fig. 88.6). Side-to-side comparisons should be done. The brachial plexus tension test was first described by Elvey[76] and has been subject to cadaveric and clinical verification.[77]

Brachial plexus tension testing maneuvers with median, ulnar,

FIGURE 88.5 The slump test for adverse neural tension. Full spine flexion causes cephalad gliding of the spinal cord. Sequential knee extension and ankle dorsiflexion cause caudad gliding of the lumbosacral nerve roots. The examiner checks for reproduction of symptoms, side-to-side differences, and alleviation of symptoms with cervical extension.

and radial nerve bias have been described.[28] Because it can be difficult to differentiate between tightness in neural elements versus inflexibilities of myofascial structures along the kinetic chain, some clinicians refer to these physical examination maneuvers by the more generic term upper limb tension tests rather than brachial plexus tension tests. If the maneuvers reproduce neurologic symptoms, then the clinician can feel more confident that ANT is present.

The results of the neural tension maneuvers guide the initial neural mobilization maneuvers. The therapist instructs the patient to place the limb in the position where neural tension is first noted. Then the patient is instructed to slowly relax the limb a few degrees to a more comfortable position and then stretch a few degrees back toward the position of symptom reproduction. By gently repeating this maneuver with ever larger amplitudes, the connective tissues associated with the nerve gradually regain normal gliding motion.

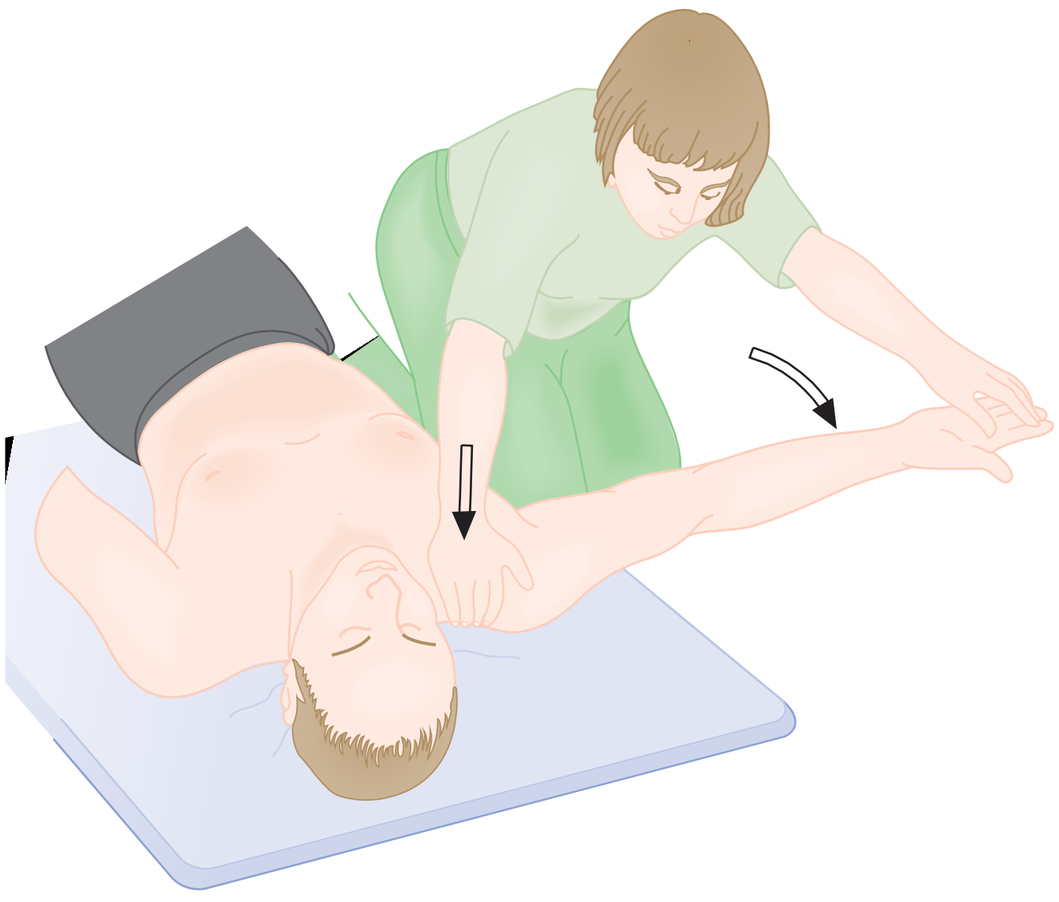

FIGURE 88.6 The brachial plexus tension test: The examiner sequentially performs shoulder depression and abduction, forearm supination, wrist and finger extension, and elbow extension. After each movement, the patient is asked about symptom production. Contralateral cervical lateral flexion should increase limb symptoms, and ipsilateral cervical lateral flexion should alleviate limb symptoms.

Manual Joint Mobilization

Joint mobilization is a technique applied by a therapist to a spinal or peripheral joint in which an oscillatory movement is performed to restore full range of motion in the joint. Manual joint mobilizations differ fundamentally from the previous types of range-of-motion techniques discussed. Mobilizations are aimed at improving accessory movements rather than voluntary movements. Voluntary movements are movements that individuals can perform themselves, such as glenohumeral joint flexion, interphalangeal joint flexion, and lumbar flexion. In contrast, accessory movements are joint movements that individuals have no ability to perform and only occur passively. Examples of accessory joint movements include anterior-posterior gliding of the glenohumeral joint, interphalangeal joints, and individual vertebral segments. Accessory movements can be gliding, rolling, spinning, or compression/distraction motions of the joint. Joint mobilization maneuvers target range-of-motion restrictions in the joint and joint capsule itself, rather than the muscles that span the joint. Joint mobilizations can be diagnostic as well as therapeutic: They can help distinguish capsular versus muscular patterns of tightness.

Joint mobilizations are classified into four categories of increasing aggressiveness. Grade I mobilizations are small-amplitude movements performed in the middle of a joint's normal range of movement. Grade II mobilizations are large-amplitude movements performed within the free range of the joint but not moving into any resistance or stiffness. Grade I and II mobilizations can prevent further loss of joint range of motion but do not increase range of motion. They almost always precede grade III and IV maneuvers during a therapy session. Grade III joint mobilizations are large-amplitude movements performed up to the limit of the available joint range of motion. Grade IV mobilizations are small-amplitude movements performed at and just beyond the limit of the joint's range of motion. Manual joint mobilizations should only be performed by a therapist or clinician with advanced training in these techniques. Experienced manual therapists can mobilize virtually any joint in the body.

Common Stretching Errors

Probably the most common cause of ineffective stretching is not holding the stretch long enough or not performing it frequently enough. Improper technique is another common cause of ineffective stretching. Often, individuals will fail to make gains in flexibility because the stretches target the single joint muscles in a muscle group, rather than the more important biarthrodial muscles. A

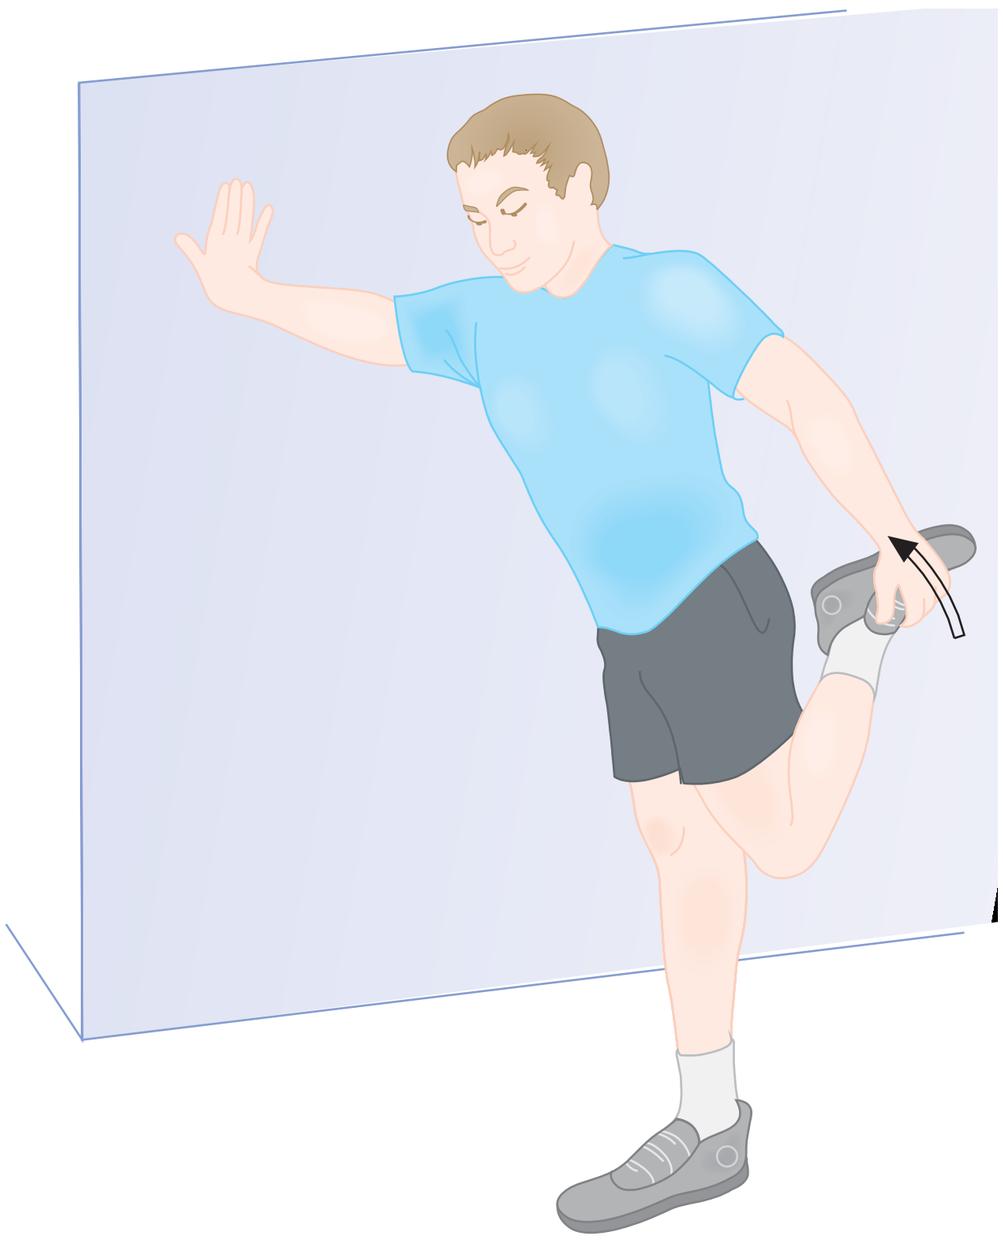

FIGURE 88.7 A common error in quadriceps stretching is failure of the patient to stabilize the pelvis. The position shown here provides pelvic stabilization and greater stretch to all four of the quadriceps muscles.

prime example of this is the classic standing quadriceps stretch, which might address the vastus lateralis, vastus intermedius, and vastus medialis but neglects the rectus femoris, which crosses the hip joint as well as the knee joint (Fig. 88.7). Sometimes a stretching position inadvertently stretches tissues other than the target tissue. Finally, the flexibility program must address all the relevant structures contributing to the inflexibility. Joint capsule mobilization maneuvers alone will not be successful if the muscles crossing that joint are also tight. Similarly, muscle stretching alone will not be successful if an underlying motion restriction exists in neural structures. Carefully documenting an exercise history will help determine whether the exercises are being performed correctly.

Strength Training

Strength deficits often contribute to musculoskeletal pain. Strength deficits can cause pain in one of two main ways. First, a muscle can be a primary pain generator if it lacks adequate strength or endurance to perform a given task and therefore fatigues. Second, a muscle group lacking sufficient strength to properly control a joint may cause abnormal, painful motion in that joint. Many ways exist to improve muscle strength.

Exercise Prescription

A strength training prescription should include the patient's diagnosis, the muscles to be worked, the modality of strength training, the frequency, the number of repetitions per set and number of sets per workout, the intensity of the exercise, and precautions. Exercise prescriptions should be flexible. The clinician must reevaluate the patient at appropriate intervals and modify the program as necessary.

Specificity of Training Effects

Training effects tend to be very specific to the type of exercise performed. For example, strengthening the biceps in isolation does not increase triceps strength. Training for quick, explosive power does not improve endurance, and vice versa. Training muscle groups to generate force does not necessarily increase their ability to absorb force. Strength training for the lower limb does not improve balance unless it is done in a manner that challenges balance. Therefore, the goals of the rehabilitation program must be clear, and the prescription must be written to fulfill those goals.

Neural Versus Muscular Mechanisms of Strength Gains

Physiologically, strength gains come about through neural and muscular mechanisms. It is well established that neural mechanisms play a significant role in strength gains during training. As early as 1967, researchers showed that rats on a training program improved muscle strength without a concomitant increase in muscle bulk.[78] The ability of muscle to undergo strength gains without hypertrophy has been confirmed in humans.[79,80] The mechanism of strength gains without muscle hypertrophy has been shown to be improved synchronization of motor unit firing. Neural mechanisms are more important than muscular mechanisms in the early stages of training, before muscle hypertrophy has had a chance to occur.[79–82] Later in the course of a training program, muscular mechanisms predominate. The quantitative electrodiagnostic techniques used to investigate changes in neural synchronization during strength training have been shown to be reliable and sensitive[83–85] and continue to be used to investigate training effects on the neuromuscular system.[86–88]

Static Versus Dynamic Strength Training

Static Strength Training. Strength training can be broadly classified into static or dynamic exercises. Static strength training is more commonly referred to as isometric exercise. In isometric exercise, a muscle or group of muscles works against a resistance without any change in muscle length or joint angle. Isometric exercise is the strength training method of choice in the earliest stages of rehabilitating injured muscle, tendon, ligament, or joints. Isometric exercise offers the primary advantage of avoiding movement in painful or frail structures, while allowing strength gains to occur. Isometric exercise is used in patients with osteoarthritis, if putting joints through a range of motion may be painful or impossible. Isometric exercise is also used in the initial stages of the rehabilitation of strains and sprains and advanced tendinosis, when movement of the injured structure puts it at risk for further injury.

Isometric exercise of any given muscle or muscle group should be varied in several ways. First, the joint angle should be varied. For example, in the earliest stages of rehabilitation for forearm extensor tendinopathy, the patient should be given a light hand weight to hold for a set amount of time with the wrist in a neutral position. Then the patient should statically hold the weight with the wrist in varying degrees of flexion and extension. The exercise should be gradually advanced by adding weight and by increasing the length of time of each repetition. The position should be held until mild to moderate fatigue develops in the target muscles.

Isometric exercises can be performed to either isolate a single muscle or work several segments of the kinetic chain simultaneously. In the rehabilitation of forearm extensor tendinopathy, for example, the wrist extensor strengthening can be done with the entire upper limb supported except for the hand. Alternatively, the upper limb can be unsupported to simultaneously work the shoulder girdle. The latter method offers the advantage of working proximal parts of the kinetic chain, where relative weakness may have predisposed to distal overload. At appropriate times during the rehabilitation course, the patient's program should be

advanced to short arc and then longer arc dynamic strengthening exercises.

Dynamic Strength Training. Dynamic exercises have various classifications. One can speak of concentric versus eccentric exercise, isokinetic versus isotonic exercise, closed kinetic chain versus open kinetic chain exercise, and plyometric exercise.

Concentric and eccentric exercise. Concentric muscular contraction refers to an action in which the muscle shortens to move a body segment. An example of concentric movement is shortening of the quadriceps muscle as one extends the knee while ascending stairs. An eccentric muscle contraction is one in which the muscle lengthens while resisting a force. An example of an eccentric movement is controlled lengthening of the quadriceps muscle as the knee flexes while descending stairs. The muscle has to lengthen to accommodate the normal mechanics of descent and also has to fire to prevent the knee from buckling. Eccentric exercise works muscles harder and is more likely to cause muscle overload than concentric exercise.[89–93]

Frequently, strength training regimens include both concentric and eccentric exercise. When rehabilitating a particular injury, however, one should emphasize the movement that overloaded the structure in the first place. For example, if a furniture mover suddenly overloaded his elbow flexors by trying to stop a falling couch with his forearm, the initial strength retraining program should progress from gentle isometric exercises to slow, gentle eccentric elbow flexor exercises. In normal human movements, one often finds an eccentric contraction preceding a concentric contraction in the same muscle. This sequence of eccentric and concentric contractions forms a natural pattern called the stretch-shortening cycle.[94]

Isokinetic and isotonic exercise. In isokinetic exercise, the target muscle moves a joint through a range of motion at fixed angular velocity, but the torque generated by the movement may vary. This is accomplished with the use of specialized equipment that can be programmed to provide resistance to joint movement at any predetermined fixed rate, usually measured in degrees per second. Although isokinetic exercise is useful for quantifying strength for research purposes, or quantifying a patient's progress during the course of rehabilitation, it is a type of movement that is rarely performed during real-life activities.[95] The applicability of isokinetic movements performed in the laboratory is further limited because of the dissociation between joint angular velocities and muscle shortening.[96,97] Therefore, rehabilitation protocols should emphasize more functionally relevant exercises.

Isotonic muscle contraction refers to a muscle contracting through a range of motion while maintaining either a constant tension within the muscle or a constant torque applied against a resistance. Like isokinetic movements, isotonic movement is rarely reproduced during daily activities and is therefore more of an academic concept than a practical one.

Closed and open kinetic chain exercise. Closed kinetic chain exercise refers to work done with the distal end of the limb fixed in space. Open kinetic chain exercise refers to work done with the distal end of the limb free in space. When a person does push-ups, for example, the hands are fixed on the floor, and the upper limbs function in a closed kinetic chain situation. When someone throws a baseball, however, the hand moves through space and the upper limb functions in an open chain fashion.

Advantages and disadvantages exist to both open and closed kinetic chain exercise. In general, if the movement to be trained is an open chain movement, such as lifting boxes, then the clinician should prescribe open kinetic chain exercises. Closed kinetic chain work is preferred when the patient needs to strengthen muscles that are primarily used in closed kinetic chain situations, for example, when strengthening knee and hip extensors in a post-polio patient who is having difficulty arising from a chair. Closed kinetic chain work offers several additional advantages over open kinetic chain exercise. Closed kinetic chain exercise promotes cocontraction of multiple muscles that cross a joint, thus providing greater joint stability. It also tends to work more segments of the kinetic chain, thus providing a more complete workout while also promoting improved sequencing of movements. Finally, closed kinetic chain work generally demands greater proprioceptive feedback than open kinetic chain exercise, thus improving this important sensory modality.

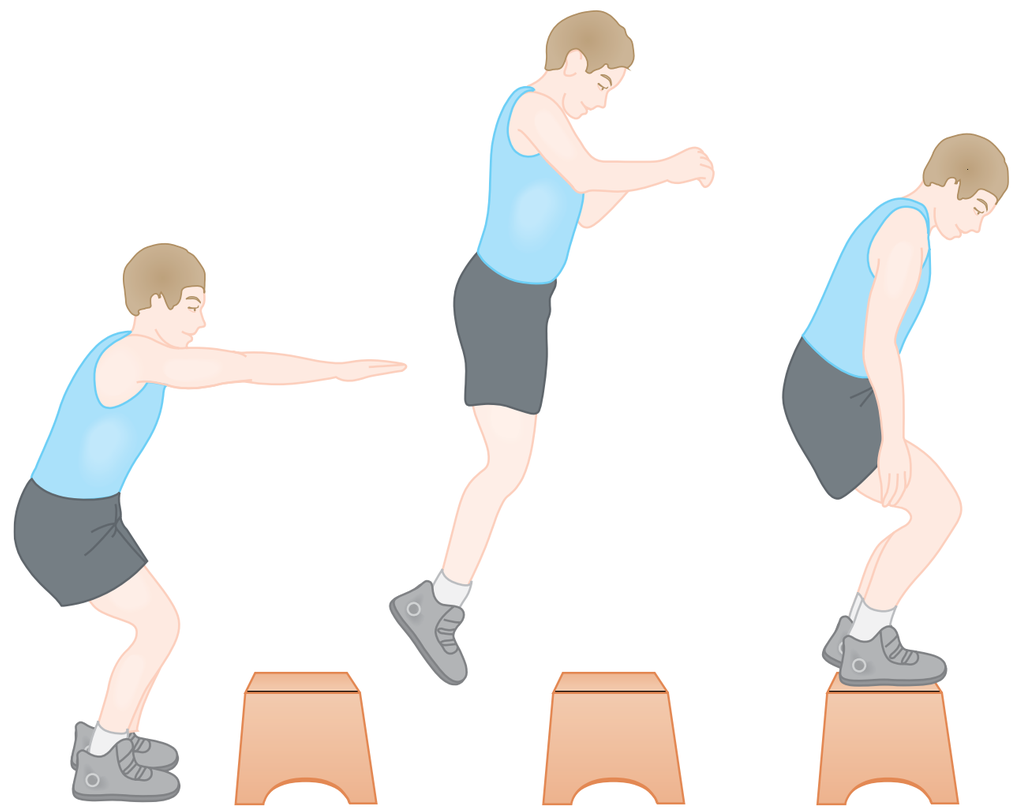

FIGURE 88.8 Lower body plyometric exercise: Step jumping builds strength, endurance, balance, and agility.

Combination strengthening exercises. A current trend exists to simultaneously work multiple muscle groups throughout the kinetic chain, rather than strengthen individual muscles in isolation. Two primary advantages exist to exercising multiple body parts at once. First, it is more time efficient. Second, most normal activities involve activating multiple muscle groups simultaneously or in sequence. Therefore, combination exercises are considered more functional than exercises that isolate individual muscles. An advanced form of combination exercise is plyometric exercise.

Plyometric exercise is a higher level dynamic form of exercise that can combine strength, endurance, power, balance, and agility training. Plyometric maneuvers simultaneously bring multiple muscle groups through a rapid stretch-shorten cycle. A simple example of lower body plyometric training is step jumping (Fig. 88.8). In this exercise, the hip extensors, knee extensors, and ankle plantar flexors rapidly fire concentrically. On landing, they fire eccentrically while lengthening. An example of upper body plyometric exercise could be throwing a basketball at a target while balancing on one leg. To avoid injury, an individual must attain an adequate baseline level of strength and flexibility before starting a plyometric training program.

Manipulation

Manual manipulation of the musculoskeletal system dates back at least to the times of Hippocrates and Galen.[98,99] After a long period of obscurity, manipulation reemerged at the end of the last century with the founding of osteopathy in 1874[100] and chiropractic medicine in 1895.[99] Manipulation enjoys widespread popularity today, with an estimated 12 million Americans undergoing 90 to 120 million manipulations per year.[101–103] Joint manipulation differs from joint mobilization in that manip-

ulation employs low-amplitude high-velocity thrusts, while mobilization employs higher-amplitude, low-velocity movements. Theoretically, if a manual therapist or chiropractor can improve a patient's joint alignment through manipulation, then biomechanics will also be improved.[104–106]

Despite its popularity, the exact mechanism of action whereby manipulation alleviates pain remains unclear. Manipulation of the musculoskeletal system is postulated to have several beneficial effects. First, it is believed to help restore joint symmetry, particularly in reference to the spine.[107–109] Second, it may aid in mechanical restoration of muscular and fascial range and ease of motion.[110,111] Third, manipulative techniques have been theorized to induce sensory afference, which may diminish pain through a gate theory effect.[111–113] Fourth, some authors have postulated that manipulation increases endorphin release.[104,109,111] These theories have not been subjected to rigorous scientific testing, however. Many believe that manipulation benefits patients primarily through a placebo effect.[114]

In the past, many practitioners of manipulation have extended the benefits of this modality to areas beyond the musculoskeletal system, such as the endocrine, immune, and digestive systems.[99] Such leaps in logic have led those in conventional medicine to question the practice of manipulation. Fortunately, a greater percentage of practitioners of manipulation now rely on this technique to restore structure-function relationships only in the musculoskeletal system.

Clearly, no current consensus exists on the mechanism whereby manipulation improves musculoskeletal function. Furthermore, there is no consensus on whether manipulation is beneficial at all, due to a lack of well-designed randomized controlled studies. One meta-analysis,[115] two reviews,[116,117] and two controlled clinical trials[118,119] indicate that manipulation decreases spine pain in selected populations, at least for short periods (e.g., less than 1 month). A review of randomized controlled trials found limited evidence that manipulation is better than placebo but not superior to other conservative measures for acute low back pain.[120] The same review found strong evidence that manipulation is better than placebo and moderate evidence that it is better than analgesics, rest, and massage for chronic low back pain.[120] Further study is needed to determine whether and how manipulation is effective.

Contraindications to high-velocity thrust manipulation include progressive neurologic impairment, unstable vertebral segments, severe osteoporosis, rheumatoid arthritis, bone or spinal cord tumors, spondyloarthropathy, bleeding diathesis, and poor manipulative skills. Risks are greater with cervical spine manipulations and include injury to nerve root, spinal cord, vertebral artery, and other soft tissue and osseous structures.[102,121]

Spinal Traction

Like manipulation, spinal traction techniques date back to ancient times[122] and are widely used today but are not universally accepted in conventional medicine circles. Also like manipulation, the literature on spinal traction is fraught with inconsistencies and methodologic flaws.[120] Reviews of randomized clinical trials have failed to find proof of efficacy for spinal traction,[120,123–126] particularly for lumbar traction. However, numerous reports of positive results of traction exist,[127–133] primarily in uncontrolled and/or nonrandomized clinical trials.

Proponents argue that if correctly performed, spinal traction can aid by widening the intervertebral foramina, decreasing intradisc pressure, allowing migration of herniated disc material back into place, decreasing facet joint friction, stretching paraspinal musculature, and straightening spinal curves, both in the lumbar[134–136] and cervical[137–139] regions. Three studies, two using epidurography[130,140] and one using computed tomography[133] to visualize disc herniations, have demonstrated reduction in disc prolapse following traction. Long-term maintenance of the reduction has not been demonstrated, however. In fact, disc material has been observed to return to its prolapsed state following traction therapy.[140] It has been speculated, but not proven, that traction improves nutrition of the disc by decreasing intradisc pressure and facilitating imbibition.[141] Traction has been advocated in the treatment of facet arthralgia and muscle spasm.[142] Some argue that the primary benefit of traction is from immobilization rather than the traction itself.[143]

Many ways exist to apply traction to the axial skeleton. Devices can be accommodated for use in a regular bed or hospital bed. There are also specially constructed, mechanical, single piece, and split traction tables.[110] Motorized and hydraulic traction tables are also available.[143] A therapist can manually apply traction,[100,107,144] although duration and force are more difficult to control when compared to mechanical or motorized traction. Some degree of traction can be obtained simply with positioning—for example, right side-lying on several pillows to provide left axial distraction. Autotraction is a technique that relies on patients' pulling their torsos cephalad with their arms, while the pelvis is fixed. Autotraction can be inexpensive and provides built-in protection against overdistraction because the patient controls the force applied. The patient's upper limb strength may be inadequate to generate the force necessary for distraction, however, and the time frame is limited by the patient's endurance.[145,146] Furthermore, autotraction puts the patient at risk for shoulder injury. Some prefer gravity traction, in which the patient is suspended from a crossbar either in a fully inverted position or in an upright position. Both orientations provide distraction forces of approximately 50% body weight through the axial skeleton.[147]

Traction devices can apply longitudinal, rotational, and sidebending forces. In addition to specifying the type of traction device used, traction prescriptions differ in terms of frequency of application, time per session, and force applied. No standardization of these parameters exists and prescriptions vary widely among practitioners.

Contraindications to traction are similar to those for high-velocity manipulation and include fracture, spine instability, osteoporosis, tumor, infection, pregnancy, hiatal hernia, and claustrophobia.[148]

Physical Modalities

Physical modalities such as heat, cold, and electrical stimulation can be useful adjuncts to the physical restoration program. The primary goals of physical modalities are to decrease pain and inflammation to facilitate the exercise program. They should rarely, if ever, be used in isolation without an appropriate exercise program.

Heat

General Physiologic Effects of Heating Modalities. Many different heating modalities are available to raise the temperature in superficial and deep tissues. The physiologic effects of tissue heating can be broadly classified into hemodynamic, neuromuscular, joint and connective tissue, and analgesic effects.

The hemodynamic effects of tissue heating are related to increased blood flow. Forearm blood flow increases two- to threefold following application of heat.[149] Vasodilation is postulated to speed healing of nonacute soft tissue injuries by increasing local metabolism and ingress of nutrients, leukocytes, and antibodies and increasing egress of breakdown products.[150,151] Heat also increases nerve conduction velocities in most peripheral nerves.[149,152] The clinical significance of this effect in musculoskeletal rehabilitation is unclear. A more relevant neuromuscular effect of tissue heating is the inhibition of group II muscle spindle

fibers.[153] Inhibition of spindle fibers can relax muscle and facilitate stretching.

Tissue heating facilitates stretching of muscle-tendon units by direct effects on connective tissue as well as by indirect effects via the muscle spindles. Lehmann and colleagues[154] showed that tendon distensibility increases with increasing temperature. They further showed that heat combined with stretching produced greater gains in tendon distensibility than heat or stretching alone. Heating superficial joints such as metacarpophalangeal joints can decrease stiffness in these structures and facilitate a stretching program.[155]

Although heat is often used for its analgesic effect, the mechanism whereby heat reduces pain has not been clarified. Possible mechanisms include general relaxation effect, endorphin release, vasodilation causing washout of pain mediators, and vasodilation leading to a decrease in ischemic pain.[156–158]

General Precautions for the Use of Heat. Heat use should be avoided in patients who are unable to provide feedback about their tissue temperature. This includes insensate patients and those whose cognitive condition impairs their ability to accurately warn the therapist of adverse effects—principally burns. Heat should also be avoided in patients with arterial insufficiency. The vasodilation produced can cause metabolic activity to exceed the ability of the arterial system to deliver oxygen to the area, resulting in tissue ischemia.[150,159] Vasodilation can also result in increased bleeding in patients with a bleeding diathesis. Heat is contraindicated in acute musculoskeletal injury because it can increase acute hemorrhage and edema. Theoretical objections have been raised against the use of heat near tumors due to the fear of increased rate of tumor growth or hematogenous spread.[158]

Superficial Heat. Heat may be transferred to body tissues by means of conduction, convection, or conversion. The first two are forms of superficial heat, while the last is used to heat deeper tissues. Superficial heat modalities are most useful for facilitating range of motion exercises in the hands and feet, where the target tendons and joints are superficial and not well protected by an insulating subcutaneous fat layer.

Hydrocollator packs, which transfer heat by conduction, are a commonly used modality to heat superficial tissues. They are made of silicon dioxide enclosed in canvas. These packs are heated to 65° C to 90° C and are applied to the skin over insulating towels for 20 to 30 minutes.[160] Hydrocollator packs have been shown to raise tissue temperatures up to 3° C at a depth of 1 cm below the skin.[161] The ability of hydrocollator packs to significantly elevate the temperature of tissue deeper than 1 cm is questionable.[161,162] Hot water packs, electrical heating pads, and chemical packs heat by convection. Hydrocollator packs have the advantage of offering greater temperature control than most of the convection modalities. Whirlpool and Hubbard tanks, however, provide superficial heat by convection and offer very good temperature control. Heated water tanks should not exceed 40° C.

Perhaps the most common misapplication of superficial heating modalities occurs when it is used in an attempt to heat deep structures. Studies have shown that the modalities listed in this section do not raise the temperature in tissues deeper than the subcutaneous fat, which serves as an excellent insulator against heat.[161,162]

Deep Heat.

Ultrasound. Ultrasound is the safest and most commonly used of the deep heating modalities. Ultrasound employs sound waves above the frequency threshold of human hearing to heat deep tissues. The ultrasound frequencies used range from 0.8 to 1.0 MHz. Although ultrasound produces some nonthermal effects on biological tissues, such as streaming, microstreaming, cavitation, and standing waves, the effects of the nonthermal effects are not thought to be clinically significant.[163–166] It is the thermal effects that are important.

The literature on the clinical benefits of ultrasound remains mixed. One group found no difference between exercise plus ultrasound and exercise plus sham ultrasound in a randomized, double-blind study in patients with lateral epicondylalgia, although both groups showed improvement over time.[167] Similarly, ultrasound plus exercise showed no benefit over exercise alone in a randomized, double-blind, placebo-controlled study on patients with painful knee osteoarthritis.[157] A review of the ultrasound literature concluded that most positive studies lacked adequate controls and that additional research was required to determine efficacy.[157]

Shortwave and microwave diathermy. Ultrasound has largely replaced shortwave and microwave diathermy as the deep heating modality of choice. They are included here largely for historical reasons only.

Shortwave diathermy employs radio waves to heat deep tissues. The Federal Communications Commission has restricted medical use to specific frequencies and most shortwave diathermy machines in the United States operate at 27.12 MHz.[160] Temperature elevations of 4° C to 6° C can be attained in muscle.[168] Thermal effects tend to be greatest in water-poor tissues, however, and subcutaneous fat may be heated up to 15° C.[169] Shortwave diathermy has been used to heat connective tissue in nearly every part of the body, including pelvic floor structures via transvaginal and transrectal application.[170] Pulsed shortwave diathermy has produced statistically significant pain relief in patients with rotator cuff tendinopathy,[171] neck pain,[172] and other soft tissue injuries.[173]

In addition to the general precautions of heat mentioned above, shortwave diathermy is also contraindicated in the setting of implants such as pacemakers, stimulators, surgical implants, contact lenses, and metallic intrauterine devices. Such devices can cause excessive heating to occur in the tissues immediately surrounding the implant. Additionally, shortwave diathermy can cause excessive bleeding if applied to the menstruating uterus. The safety of shortwave diathermy has not been established in those with immature skeletons and therefore is not recommended in the pediatric population.

Microwave diathermy differs from shortwave diathermy in that it employs electromagnetic radiation of much greater frequency. The Federal Communications Commission has approved microwave frequencies between 915 and 2456 MHz for medical use. Lower frequencies penetrate to deep tissues better than higher frequencies.[174,175] At 915 MHz, subcutaneous fat temperature may be increased 10° C to 15° C, with deep muscle temperature elevations of 3° C to 4° C at 2 to 4 cm below the skin.[176]

The contraindications for other forms of deep heat application hold for microwave diathermy as well (see Fig. 88.1). Microwaves can produce cataracts, so both patients and therapists should wear protective goggles.[177] Although human fetuses have been exposed to microwave diathermy without deleterious effects, the overall safety in fetuses and children has not been established and its use is therefore discouraged in pregnant women and young children. Because tissues with a high water content are selectively heated, application of microwave over fluid-filled cavities, cysts, or blisters can produce unacceptable local heating.[178] The use of microwave diathermy has, however, been used to speed resolution of hematomas.[179] Most clinicians feel that the presence of an acute inflammatory condition such as inflammatory arthritis is a contraindication to microwave diathermy.[180] There are some reports, however, of improved patient comfort after application of microwave to rheumatoid joints.[181,182]

Cryotherapy

Cryotherapy has several benefits in the treatment of musculoskeletal pain. Its ability to slow nerve conduction[149,183–185] and pro-

duce local analgesia[186] is well known. It has also been shown to improve tendon distensibility[154] and modify muscle stretch reflexes.[187–191] In combination, these effects can greatly facilitate a stretching program aimed at restoring full range of motion. Chilling a body part initially stimulates local reflexes to enhance sympathetic tone and produce vasoconstriction.[192,193] Vasoconstriction reduces blood flow, slows local metabolism, and lessens swelling.[194]

Technique. Ice packs, iced compression wraps, iced whirlpools, frozen steaks, and frozen bags of peas all work equally well in cooling body parts. The preferences of the therapist and patient usually determine the specific method of cryotherapy. Iced compression wraps offer a few advantages. Compression wraps help reduce swelling and can also add proprioceptive feedback for the individual who is exercising while icing (cryokinetics) or stretching while icing (cryostretching). Commercial products are available that are specifically designed for different body parts and that allow the individual to apply ice and compression simultaneously. These usually allow people to participate in other activities such as working or doing household chores because they do not have to fumble with a clumsy plastic bag of ice cubes. The recommended duration of cryotherapy is 20 to 30 minutes. This can be repeated up to once per hour. Longer periods of application increase the risk of local tissue damage and reactive hyperemia.[195]

Precautions. The most common adverse reaction of cryotherapy is local tissue damage from overzealous icing. Skin burns, frostbite, and nerve injury can occur.[196] Delayed tissue healing may occur if cryotherapy is used for extended periods because of reduction in blood flow and slowing of local metabolism.[197] Cryotherapy should be used judiciously or not at all in the extremities of patients with Raynaud's disease, cold urticaria, cryoglobulinemia, and atherosclerotic disease, because of the risk of inducing limb ischemia. As is true with heat therapy, cryotherapy is contraindicated in insensate patients who are unable to provide feedback on the status of the treated area. Properly applied ice treatments of less than 30 minutes in healthy individuals will not cause injury.[186,191]

Functional Electrical Stimulation and Surface Electromyography

Transcutaneous electrical stimulation for the treatment of pain is discussed in Chapter 91. In the rehabilitation of muscle dysfunction, functional neuromuscular electrical stimulation (NMES) and surface electromyography (SEMG) are sometimes used to aid the muscle reeducation process. Muscles can become de-educated or lose their normal firing patterns for several reasons, including partial denervation, disuse from prolonged immobilization or bed rest, and maladaptive substitution patterns. Specialized muscle reeducation techniques are often useful after tendon transfers as well, when the muscle is being asked to fire in a new pattern.[198] Electrical stimulation of muscle can help maintain muscle bulk during a period of disuse. It can also assist in the early stages of a muscle reeducation process, by giving the muscle a "jump start."[199–201] Once the patient feels the muscle firing with electrical stimulation, it is easier to start voluntarily firing the muscle. Feedback from the muscle can be transmitted to the patient using SEMG recordings. The patient can see the EMG signal recorded from the muscle undergoing reeducation and try to improve the firing pattern to make those tracings match a set of normal tracings.

The use of functional NMES/SEMG to help patients self-regulate the activity of motor units started in the 1960s.[202–204] It has been used fairly extensively in the functional rehabilitation of stroke patients.[205–208] In the nonstroke population, it has been used to reeducate muscles around the shoulder,[209,210] forearm and hand,[211–213] lumbar spine,[214,215] and knee.[216–221] As the benefits of functional NMES/SEMG become more widely appreciated, there will be greater elucidation of normal and abnormal firing patterns of muscle groups during dynamic activities. Functional NMES is contraindicated in patients with pacemakers, local infection or malignancy, recent fracture or serious muscle/tendon disruption, local skin lesions, seizure disorder, and pregnancy.[198]

Miscellaneous Physical Modalities

Numerous other physical modalities have been used through the millennia in the treatment of musculoskeletal pain ranging from aromatherapy to snake venom to healing touch. The majority of these alternative modalities are not discussed here due to a lack of scientific literature about their efficacy. Two less mainstream modalities that are becoming popular, vibration and low-energy laser therapy, warrant brief mention, however.

Vibration. A wide variety of vibration therapy products are commercially available. Physical therapists prefer models that operate with frequencies around 150 Hz and amplitudes around 1.5 mm.[222–224] In uncontrolled studies, vibration therapy has been reported to be 70% successful in the treatment of sinusitis and musculoskeletal pain.[225–227] These effects were not reversed by naloxone, suggesting that the mechanism of action did not involve stimulation of the natural opiate system.[228]

French investigators have also reported success with vibratory stimulation in the treatment of chronic pain.[229,230] In a prospective controlled study, Guieu and colleagues[230] found vibration to be more effective than sham treatment for short-term relief of chronic pain. Another arm of the same study found the combination of transcutaneous electrical nerve stimulation plus vibration to have additive effects for short-term relief of chronic pain.[230] In a series of experiments, the same group of investigators has explored possible roles of vibratory stimulation in modulating the Met-enkephalin and substance P pathways via activation of large afferent nerve fibers.[231–235] The definitive mechanism of action whereby vibration therapy reduces pain remains under investigation.

Low-Energy Laser. While low-energy laser treatments are available outside the United States for treating pain from osteoarthritis, back pain, headache, and neuritis, they are not yet approved for clinical use in this country. Energy levels used are usually in the range of 1 to 100 mW.[236,237] Pain relief has been reported to be as high as 60% to 80% of subjects, although other investigators have found no benefit.[237]

One double-blind controlled trial of low-energy laser versus sham treatment found it to be associated with decreased pain and improved grip strength in patients with lateral epicondylitis 4 weeks after treatment.[238] Other randomized, placebo-controlled studies failed to find benefit from low-energy laser treatments in this condition[239,240] and in ankle sprains.[241] A randomized, double-blind study evaluated the effect of low-energy laser versus sham treatment on chronic low back pain. Both treatment groups were also placed on an exercise program. Both groups had a decrease in pain, but there was no difference between those who received laser treatments and those who received sham treatments.[242]

The mechanism of action of low-energy laser remains unproven. Proponents of this modality report that it accelerates wound healing by stimulating DNA synthesis and collagen production and improves the function of damaged neurologic tissue.[236] Further research is needed to definitively assess its efficacy and indications.

CASE STUDY

We examined a 26-year-old runner with left anterior knee pain. She complained that she had developed the pain over the past

several months as she had been increasing her mileage and intensity in anticipation for a 10k road race. The pain tends to worsen as she progresses in her runs, bothers her when climbing up and especially down stairs, and is also bothersome when she sits for prolonged periods, such as when she drives or sits in a lecture hall or movie theater.

Her history is classic for patellofemoral syndrome, the most common cause of anterior knee pain in young, female runners. In working through her assessment, we used a kinetic chain evaluation to assess her biomechanics and help her develop a treatment plan. The starting point of the kinetic chain evaluation was to determine whether the location of her pain (in this case, the knee) was the culprit of her pain, or merely a victim of suboptimal biomechanics. Given that most young females do not have primary problems related to the patellofemoral articulation, most cases of patellofemoral syndrome are related to asking the patellofemoral articulation to do more than it is anatomically designed to do. The most common kinetic chain deficits are asking a relatively small structure to absorb forces that are better absorbed by a larger, more powerful structure, or asking an anatomic structure to range beyond its normal arc of motion to compensate for lack of range of motion at another joint. Therefore, our investigation focused on determining which structures above or below her knee were inadequately absorbing forces or were limited in their range of motion.

Upon further history, she noted that she did all of her training along the left side of a local crowned road (so as to be running against traffic). Because she is running on a sloped surface, this predisposes her to muscle imbalances about the hip, both in terms of the forces exerted and the amount of ranging at each joint. Interestingly, she did note that she had fewer symptoms when running on flat surfaces.

On physical examination, she also exhibited relative muscle imbalances. When examining her performing squatting maneuvers and single-leg squatting maneuvers, she initially performed without any lapses in form. However, after sufficient repetitions to fatigue the muscles, she started to have alterations in her biomechanics. What was most noticeable was that when she was viewed from the front, her knee appeared to track medially.

This is a common phenomenon in patellofemoral syndrome, namely that the femur was medially rotating and adducting her thigh relative to her patella. If one were to look at the patellofemoral articulation in isolation, it may appear that the patella was tracking laterally relative to the femur. This is sometimes compared to a train falling off a track. However, the motion of the patella relative to the femur is an illusion largely created by focusing only on the site of pain (the patella), and not focusing on the larger biomechanical system. The patella itself remains relatively fixed, but because the femur is displacing medially (from internal rotation and adduction at the hip), a better analogy would be the track slipping out beneath the train (Fig. 88.9).

One explanation for the malpositioning of the femur is relative disuse of the gluteus maximus, which is an external rotator, abductor, and extender of the femur at the hip joint. Therefore, if one performs a closed kinetic chain activity such as a single leg-squat or running (which is a series of successive and coordinated single leg squats), relative disuse of the gluteus maximus will result in the opposite motion of the thigh, namely internal rotation, adduction, and flexion. This is indeed what we saw with our patient (Fig. 88.10).

Armed with this insight, we were able to develop a treatment plan aimed at correcting her biomechanical deficit, particularly focusing on activation of her gluteus maximus during closed kinetic chain activities. These exercises included lunges and squatting activities. One exercise that we have found particularly helpful in helping cue the patient to activate her gluteus maximus is the "belt squat." We placed a belt just above the knee of the patient while she performed squatting maneuvers. The belt serves as a reminder to maintain the thigh in a position of abduction and external rotation throughout the range of motion. If the thigh were to slip into internal rotation or adduction, the tension in the belt would ease, and may even drop to the floor. In addition to the physical therapy program, we worked on her running hygiene, particularly focusing on having her run on flat surfaces to minimize her developing muscle imbalances about her pelvic girdle.

This case highlights several key points that were addressed elsewhere in this chapter. First, when a physician interacts with a patient who has a pain complaint, one has to consider whether the site of pain is the culprit or merely the victim of suboptimal biomechanics at another region within the kinetic chain. Second, if there is a kinetic chain deficit, one should look for a body part being asked to compensate for force absorption or range of motion that is inadequately addressed at another body part. Finally, once the kinetic chain deficit is identified, a targeted physical therapy program should be designed to compensate for

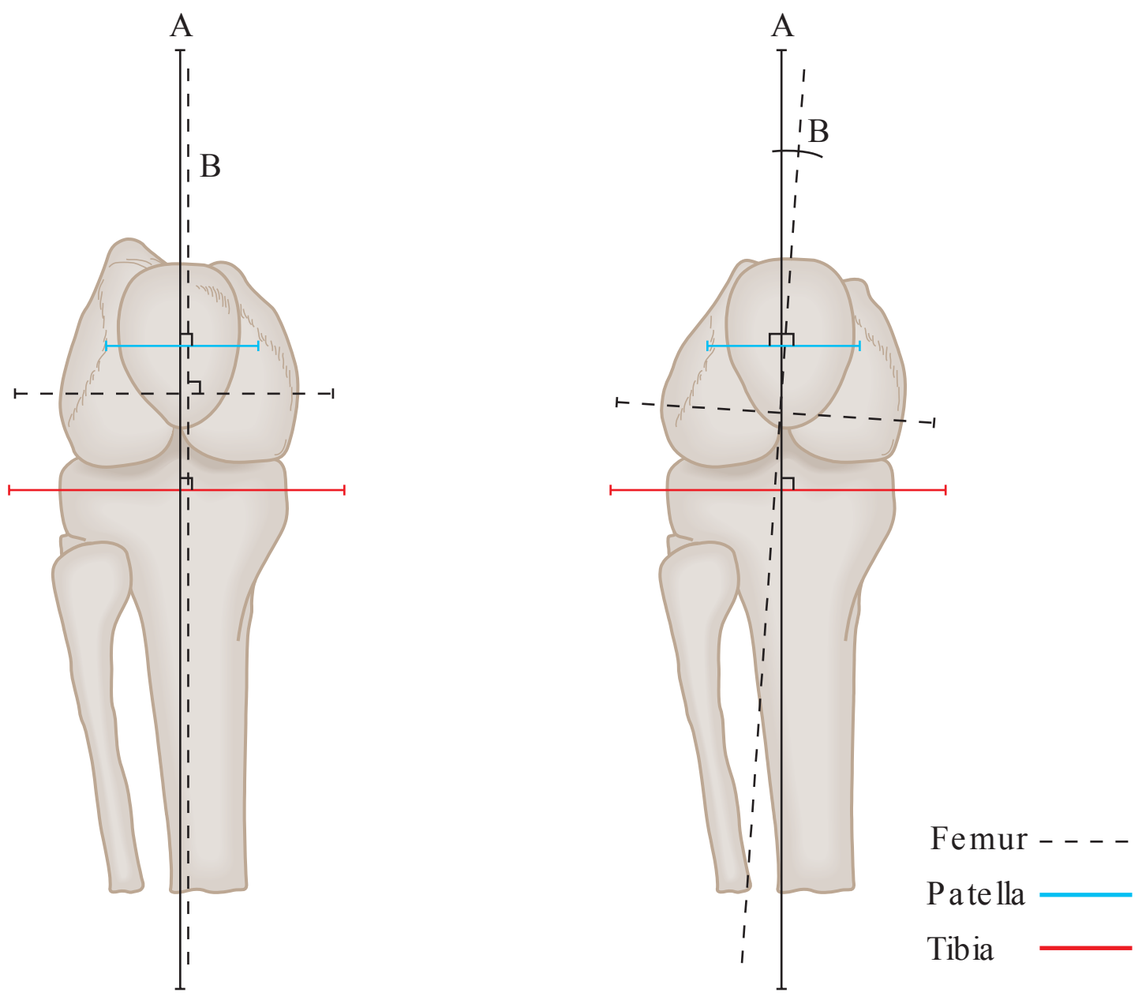

FIGURE 88.9 Line A is a line connecting the midpoint of the patella and the tibial tuberosity. Because of the strong attachment of the patella to the tibia via the patellar ligament, this line remains relatively fixed in place in both open kinetic chain and closed kinetic chain biomechanics. Line B represents long axis through the patellar groove of the femur. In open kinetic chain biomechanics, because the distal limb segment is not fixed, any motion of the femur (line B), will be matched by a corresponding motion in the patella and tibia, and therefore Lines A and B will remain parallel, as seen in the left panel. In closed kinetic chain biomechanics, the distal limb segment is fixed, and therefore the tibia and patella (line A) are not free to rotate with the femur (line B). Therefore, any motion of the femur will not necessarily be reflected in the position of the tibia and patella, and therefore an angle will develop between lines A and B. More specifically, when the femur internally rotates or adducts (as is seen when the gluteus maximus is not sufficiently activated), the patellar groove of the femur tracks medially relative to the patella and tibia, and it will appear that the patella is tracking laterally relative to the femur.

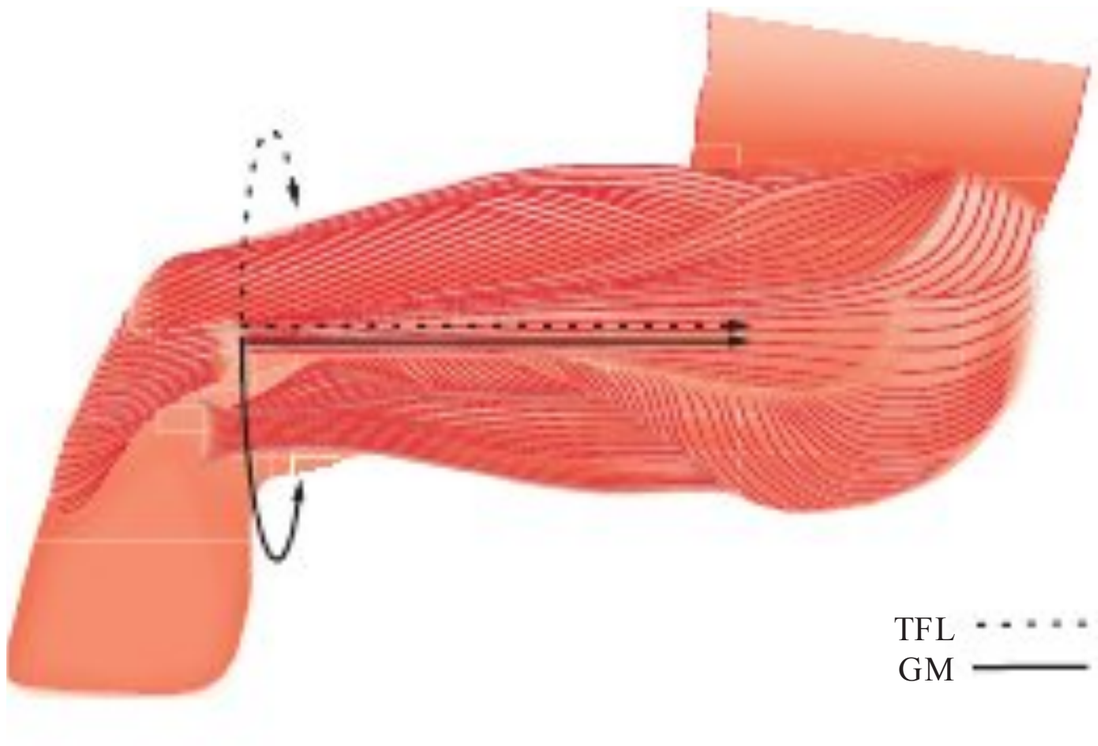

FIGURE 88.10 The ITB and the muscles attaching to it proximally, namely the tensor fascia lata anteriorly and gluteus maximus posteriorly. The tensor fascia lata acts on the femur to induce internal rotation (dotted arc), whereas the gluteus maximus induces external rotation (solid arc). When both muscles act together, the rotational forces cancel out, and their combined moment applies traction to ITB, resulting in pure hip abduction (solid and broken lines).

the kinetic chain deficit, which will allow the patient to resume their prior activities without re-exacerbating their initial pain complaint.

CONCLUSION

The goal of physical rehabilitation is to maximize the functioning of the patient's neuromusculoskeletal system. Therapies are directed at correcting pertinent biomechanical deficits by restoring full, pain-free range of motion, adequate strength and endurance for the patient's desired activity levels, and proper neuromuscular control. The mainstay of treatment is therapeutic exercise. Most exercises can be done by the patient in a home exercise program after careful instruction by a therapist. Manual techniques by a specially trained therapist can be very helpful, especially in the early stages of the rehabilitation program. The patient's progress should be reevaluated at appropriate intervals, and his or her therapeutic exercise programs should be upgraded as needed. Therapeutic modalities such as ice and ultrasound can be helpful to facilitate the exercise program. The majority of the work in most successful programs is done by the patient, not the therapist.

CHAPTER 89 ■ PAIN REHABILITATION

STEVEN STANOS

"Rehabilitation is a continuous process."[1]

Rehabilitation may be described as a "return to ability . . . the return to the fullest physical, mental, social, vocational, and economic usefulness that is possible for the individual."[2] The focus is placed more on one's abilities rather than their disabilities.[2]

HISTORICAL OVERVIEW: PAIN REHABILITATION AND FUNCTIONAL RESTORATION

History of Pain Rehabilitation

Early evidence of a rehabilitation approach to the injured person or worker dates back to the Egyptians under Ramses II in 1500 BC where organized treatments of injured workers, fees for treatment, and compensation for injury were established.[3] The development of more expertise and a more rational treatment and management approach of pain was delayed until the birth of the field of anesthesia in the 1840s and the isolation and synthesis of morphine by Serturner in 1806 and salicylates from willow bark in the late 1800s.[4] The modern development of a rehabilitation model evolved only after World War I and World War II with the birth of the fields of physical and occupational therapy as a means to "rehabilitate" injured returning soldiers.[5] Pain rehabilitation developed in the context of evolution of the medical specialties of physical medicine and rehabilitation, anesthesia, psychiatry, and occupational medicine during the twentieth century. John Bonica championed a more comprehensive "multidisciplinary" approach in the United States in 1947 and later at the University of Washington in 1960.[6] Wilbert Fordyce, a psychologist and collaborator of Bonica, incorporated operant conditioning and other behavioral approaches with more specialized 8-week inpatient programs in the late 1960s. In 1982, John Loeser formalized a more "structured program" at the University of Washington, a 3-week daily program, which has become a model for "interdisciplinary" treatment. A more biopsychosocial approach to pain rehabilitation has also been facilitated by the merging of behavioral and cognitive fields and the subsequent cognitive-behavioral approach to the assessment and treatment of pain in the 1980s and 1990s.[7–9] A proliferation of pain treatment facilities was seen between 1980 and 1995 and included the advancement of interventional procedures.[10] A more recent conceptualization of pain focuses on behaviors within the pain system, a biopsychomotor model of pain, which incorporates three interdependent behavioral subsystems: (1) communicative, (2) protective, and (3) social response behaviors.[11] This model assumes that a pain system can only be adaptive if the sensory component of the pain system is accompanied by behaviors designed to act on the source or cause of injury or illness. This may help to explain the wide variability observed in pain behaviors seen across different patients despite relatively similar levels of reported pain intensity and objective tissue pathology. The biopsychomotor model of pain can be extended to include behavioral factors such as communicative behavior (grimacing), protective behaviors (i.e., withdrawing a limb from the fire), and behaviors designed to elicit social responses (i.e., empathy and solicitous behavior from others). This model, like the biopsychosocial one, emphasizes that dysfunction may develop in behavioral systems separate from pain sensation, and subsequent treatments targeting pain behavior would more likely lead to greater clinical outcomes and provide a more pragmatic and inclusive model for the spectrum of pain rehabilitation (Fig. 89.1).

History of Functional Restoration and Work Rehabilitation

Functional restoration (FR) programs, based on a return-to-work model, evolved along with advancements in occupational medicine beginning in the 1970s. Prior to this, programs of "habit training" focused on restoring workers affected by disease or injury in the 1920s and later by the incorporation of vocational rehabilitation mandated at the federal level in 1923 and the Vocational Rehabilitation Act. In the 1950s, more objective measures were used to track progress and measure outcomes and served as the starting point for more formal work conditioning and work hardening programs championed by Lillian Wegg and Florence Cromwell.[12,13] In the 1970s, work hardening emerged as a formal industrial management service[14] and adopted a similar multidisciplinary approach used in the management of chronic pain and disability. Standardized work stimulation equipment, assessment, and treatment protocols were incorporated into standard practice in the 1980s and led to formal accreditation by the Commission on Accreditation of Rehabilitation Facilities (CARF) in the late 1980s and early 1990s.[15–17]

Gatchel et al.[18] described eight classic critical elements of a functional restoration approach which serves as the foundation for most multi- and interdisciplinary rehabilitation based programs. Elements include quantification of physical deficits on an ongoing basis, psychosocial and socioeconomic assessment used to individualize and monitor progress, and an emphasis on reconditioning of the injured area or body part. The team-centered FR approach also includes generic simulation of work or activity, disability management with cognitive-behavioral approaches, psychopharmacologic management focusing on improving analgesia, sleep, and affective distress, many times detoxifying patients from medications (i.e., opioids or benzodiazepines).[18]

What Is Pain Rehabilitation?

A pain rehabilitation model can be applied to the entire spectrum of pain conditions, from acute musculoskeletal injuries, to subacute and recurrent injuries aggravated by poor ergonomics and/or physical impairments, to more complex chronic pain conditions where interplay of biologic, psychologic, and social influences is more apparent. Pain rehabilitation is based on a structured, individualized approach. The formal assessment identifies specific problems and needs most relevant to the patient and relates the problem to impairments and psychosocial factors, selecting appropriate measures to monitor progress and treatment. The rehabilitation program includes planning and coordinating various interventions with a focus on treating the specific impairments by restoring function and identifying compensatory strategies. Additionally, addressing activity limitations by addressing environmental and personal factors may help in restoring patients to previous levels of functioning and preventing or limiting disability.[1]

A traditional definition of rehabilitation, based on a biomedical model, places the concept of rehabilitation as a secondary intervention, used to restore patients to their previous level of (residual) physical, psychologic, and social functioning, and if possible, return them to (modified) work.[19] Waddell and Burton[20] question this assumption in that the biomedical definition assumes that disability is a "matter of permanent impairment," that sickness and disability imply an incapacity to work, that rehabilitation focuses on "irremediable permanent impairment," and that rehabilitation is a second-stage process following acute medical management and only is carried out after treatment ceases. Waddell and Burton[20] have implied this may be inappropriate in that in many chronic pain conditions (i.e., low back pain) objective factors (pathology and impairment) accounts for a small part of the incapacity. These chronic conditions are characterized more by "symptoms and distress" than tissue abnormality.[20] A number of biopsychosocial risk factors (i.e., lower level of education, higher preoperative pain, low work satisfaction, longer duration of sick leave, somatic complaints, and passive avoidance coping) have been identified as predictors of poor outcomes after surgical interventions contributing to loss of function, increased disability, and persistent elevated levels of subjective reports of pain.[21,22] These biopsychosocial risk factors may serve as important and potential targets for pain rehabilitation.

Stakeholders in Rehabilitation

Pain rehabilitation also involves the coordination of a number of important stakeholders involved in the care of the individual patient or worker. Stakeholders may include various health care providers, managed care organizations and insurers, the workers' compensation carrier, society, the individual patient, and family members. This complex health care process and related list of stakeholders involved may sometimes add, as described by Shultz and Gatchel,[23] a political dimension to the individual patient's assessment and treatment process. Success in treatment may vary depending on stakeholder and may indirectly lead to antagonistic, confrontational, and misinterpreted feelings by the patient suffering with pain. Criteria of success may vary significantly depending on whether it is assessed by the patient or by society in general (Fig. 89.2). Many times, contrary to what is seen in other areas of clinical medicine, the pain rehabilitation clinician may find himself or herself in a potentially conflicting role in the treatment of patients with chronic pain (Table 89.1). The focus of care should remain on providing appropriate clinical services, serving as a patient advocate or adjudicator, without crossing ethical boundaries resulting in harm to the client.[24]

This chapter will focus on an overview of assessment and treatment strategies included in a pain rehabilitation-based approach to acute and chronic pain conditions. As part of the clinical continuum, the more comprehensive and integrated treatment approaches commonly referred to as multidisciplinary, interdisciplinary, and/or FR[25] will be examined. Important psychologic factors related to chronic pain and disability, the continuum of treatment models from more acute to integrative approaches,

specific responsibilities of members of a pain rehabilitation team (i.e., physical and occupational therapist, psychologist, relaxation therapist, and vocational specialist), and an overview of more specific work rehabilitation approaches including work conditioning, work hardening, and functional capacity testing will be reviewed.

MODELS OF REHABILITATION

Conceptual models of pain rehabilitation are based on historical advances that initially described pain as a purely sensory phenomenon evolving to include a more mind body approach to understanding disability and function (Table 89.2). Hippocrates and Galez (c. 150 AD) described an imbalance of bodily "humors" as a means of developing chronic pain and distress as a model for understanding suffering.[26] In the 1600s, a dualistic mechanistic model emerged. René Descartes (1596–1650) theorized damage to the body would stimulate specific neural pathways, giving rise to the sensation of pain.[26] Through the mid nineteenth century, medicine focused on the individual's unique manifestations of the disease process. In the mid 1800s, the expanding understanding of pathologic anatomy shifted the focus to a more biomedical model. In 1965, Melzack and Wall[27] proposed the gate control theory of pain which proposed that pain experience was determined by physical, motivational, cognitive, and emotional factors, and transmission of nerve impulses could be modulated by spinal gating mechanisms at the level of the dorsal horn. Melzack[28] elaborated on this more dynamic role of pain networks further with the "neuromatrix" model, arguing that the brain and central nervous system play a dominant role in the pain experience.

Biopsychosocial Approach Versus Biomedical Model for Pain Management

The biomedical model assumes a causal relationship between a specific physical pathology and the presence or intensity of pain symptoms. It emphasizes the importance of eliminating pain by restoring normal function in the organ or body part from which pain is thought to emanate. Although the more disease-based biomedical model enabled the medical sciences to flourish and improved our ability to treat infection and other disease processes, its fundamentally limited scope led to less profound success and relative treatment resistance in the treatment of many chronic pain states. A biomedical model may be more advantageous in treating more acute pain states, where interventional procedures, pharmacotherapy, and surgical interventions may lead to recovery of pain or hasten time to recovery. But the biomedical model poorly addresses related mental health issues and frequently relies on dualistic decision pattern whereby if the patient does not respond to an intervention, then the pain may be not be "real" or just "in their heads."[29] Many more complex pain conditions remain resistant to a purely biomedical approach (i.e., chronic low back pain, neuropathic pain, and fibromyalgia).[30] George Engel helped to shift the thinking from a purely biomedical model of disease management to a more comprehensive biopsychosocial model of illness.[31] Recently, the World Health Organization has embraced a biopsychosocial model of disability (Fig. 89.3) which incorporates a dynamic interaction between the individual health condition and contextual factors.[32]

The pain rehabilitation approach is based on a fundamental understanding of the individual's unique condition as it relates to (1) impairment, (2) disability, and (3) functional limitation. Impairment is the loss of normality psychologically, physically, or functionally at the level of the organs and body systems.[33] Examples of physiologic impairments include muscle weakness, loss of range of motion, and pain. Disablity is a restriction or lack of ability to perform activities due to related impairments such as inability to function in a specific vocation, as a spouse, student, or parent. Functioning has been described as an umbrella term for body functions, body structures, activities, and participation, denoting a positive interaction between the individual or patient and contextual factors (i.e., background of the individual's life and current situation). Functional limitation is a deviation from the normal behavior of performing activities of daily living (ADLs) and may include problems with transfers, standing, ambulation, running, and stair climbing.[33] A formal model proposed by the International Classification of Functioning, Disability, and Health integrates the individual components into a biopsychosocial based model where a "health condition" is substituted by

TABLE 89.2

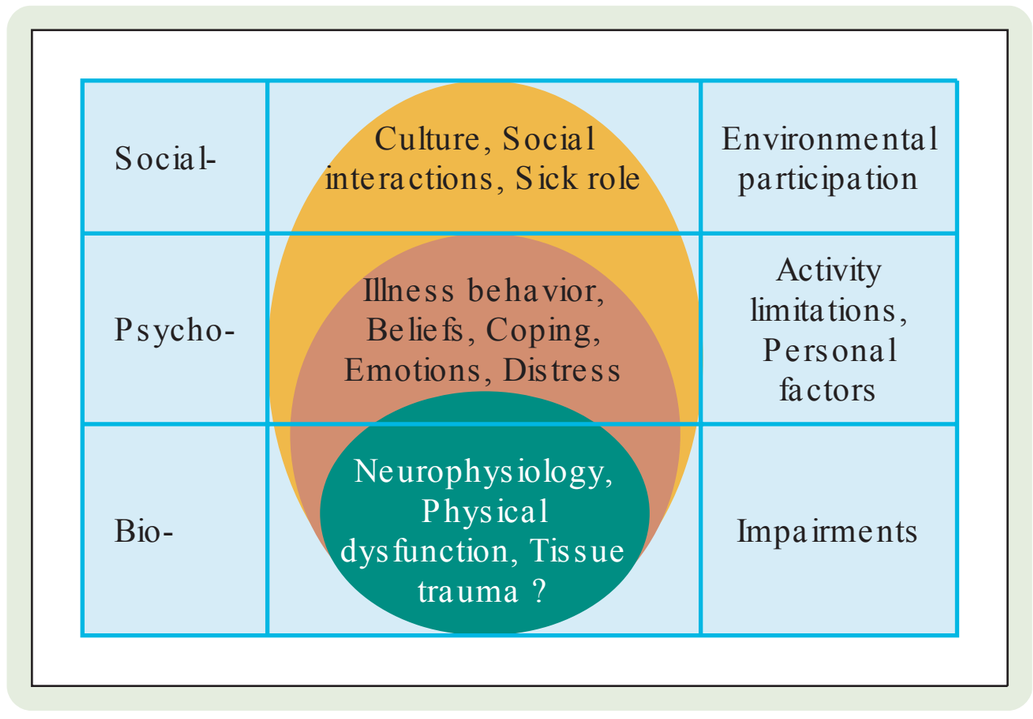

FIGURE 89.3 Domains of the biopsychosocial approach to pain rehabilitation. (Redrawn from Waddell G, Burton AK. Concepts of rehabilitation for the management of low back pain. *Best Pract Res Clin Rheum* 2005; 19:655–670, with permission.)

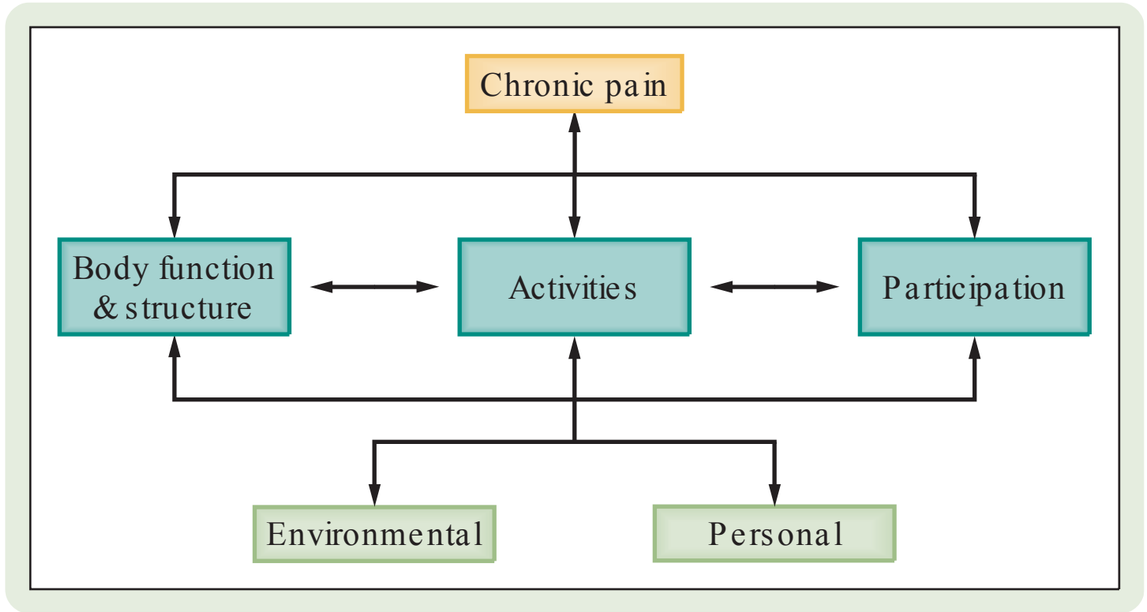

FIGURE 89.4 A formal model demonstrating the relationship among individual components that affect an individual's function was proposed by the International Classification of Functioning, Disability and Health. This model was proposed for any "health condition," and here we have substituted "chronic pain" for the more generic term. (Redrawn from Weigl M, Cieza C, Cantista P, Stucki G. Physical disability due to musculoskeletal conditions. *Best Pract Res Clin Rheum* 2007;21:167–190, with permission.)

"chronic pain" (Fig. 89.4). Chronic pain is affected by body function, activities, and participation as well as influences from the environment and personal factors.

A patient-centered approach is necessary if one is to effectively address these important individual concepts. A team-centered approach focuses on helping patients to achieve individual goals which enable them to improve physical and psychosocial function, decrease pain, and improve quality of life. By working together, the rehabilitation team is able to help patients achieve better outcomes than could be achieved by an individual practitioner or intervention (i.e., surgical procedure, injection, pharmacotherapy). Basic treatment goals of both acute and chronic pain rehabilitation programs focus on functional improvement, improved abilities to perform ADLs, return to leisure, sport, or vocational activities, and improved pharmacologic management of pain and related affective distress (Table 89.3).

Treatment Approaches: Pain Rehabilitation

A pain rehabilitation approach encompasses a wide range of treatment options including more directed therapies for acute pain conditions to more comprehensive and collaborative multi- and interdisciplinary approaches (Table 89.4).

Acute Rehabilitation

An approach to managing acute pain conditions relies on a more focused understanding of causative and aggravating factors, changes to affected tissues and related overload stresses, and includes three important phases: (1) acute, (2) recovery, and (3) functional. Within each phase, specific treatment focuses are applied by the therapist or clinician and tools or skills are taught by the treating therapist with a goal of ongoing self management and practice. Acute management may involve relative rest, passive modalities (ice, heat, ultrasound), interventional procedures (i.e., trigger point injections, epidural, and facet injections), and oral and topical analgesics. Recovery phases focus on more advanced stretching and strengthening, increasing endurance, and assessing and treating postural changes that may be contributing to chronic pain.[34]

More Comprehensive Team Models: A Pain Continuum

Rehabilitation treatment models include a continuum of care based on patient severity and needs with increasing complexity of treatment philosophies, a need for greater communication, and decreasing individual team member autonomy.[35] Each of these models occupies a position along a continuum of care based on increasing levels of coordination, diversity of philosophies, and decreased hierarchical structure and practitioner autonomy. The left side of the treatment continuum (Fig. 89.5) shows the least collaborative model, parallel practice, where health care providers function quite independently. As one moves to the right, services become more coordinated with decreasing level of autonomy and increasing diversity of philosophies. From a structure standpoint, moving left to right increases the complexity of care while reliance on hierarchy and clearly defined roles decreases. Complexity and diversity of outcomes increases while from a process perspective, communication, participants, synergy, and importance of consensus building increases. Multi- and interdisciplinary treatment is even more structured, usually involving a number of specialties with less evidence of practitioner autonomy.

With parallel practice, independent health care practitioners are working within their defined scope of practice such as in an emergency room setting or an acute cardiac unit (i.e., nurse, phlebotomist, physician, radiology technician) where the goal is rapid assessment and treatment in the most efficient manner. Consultation may include a pain physician referring a patient to an addiction specialist or surgeon for recommendations and shared treatment responsibilities. Collaborative practice may include the use of a case manager to help coordinate treatment between the patient and physical therapist. In a collaborative approach, information is shared on an ad-hoc basis; practitioners normally practice independently sharing information regarding

TABLE 89.3

PAIN REHABILITATION GOALS

1. Functional improvement
2. Improvement in ADLs
3. Relevant psychosocial improvement
4. Rational pharmacologic management (analgesia, mood, and sleep)
5. Return to leisure, sport, work, or other productive activity

Integrative

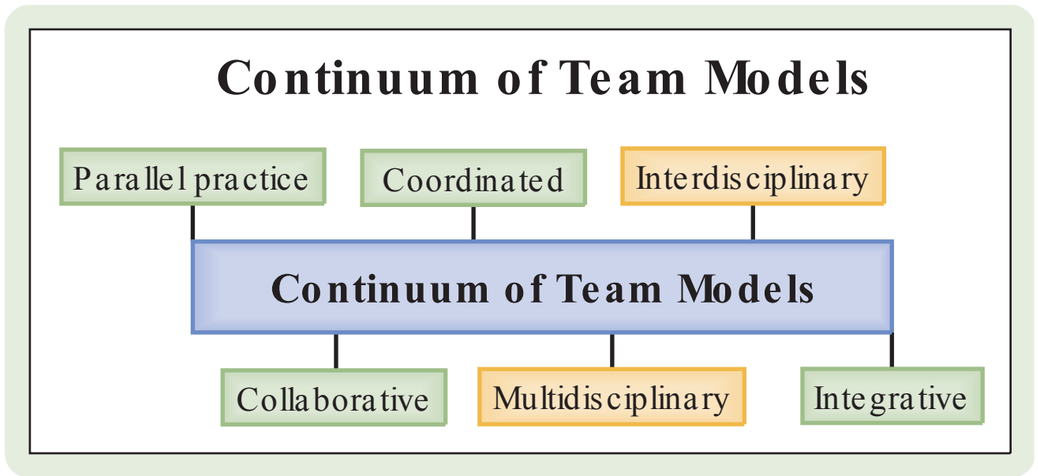

FIGURE 89.5 Continuum of team models. The most common practice model is parallel practice in which each practitioner oversees only the problems within their isolated discipline with little or no interaction with other practitioners caring for the same patient. The most effective models for caring for those with chronic pain involve programs designed to allow for frequent, direct, and repeated interactions among the providers caring for each patient in the form of multidisciplinary and interdisciplinary treatment programs. (Redrawn from Boon H, Verhoef M, O'Hara D, et al. From parallel practice to integrative health care: a conceptual framework. *BMC Health Service Research* 2004;4:15, with permission.)

a particular patient. In coordinated treatment, patient records are shared among clinicians providing treatment for a specific therapy where the case coordinator or case manager is responsible for ensuring information is transferred to all team members. Differentiating between multi- and interdisciplinary treatment will be reviewed in greater detail below. Although commonly used interchangeably, the terms inter- and multidisciplinary have important distinguishing features.

Multidisciplinary Treatment

Focused treatment programs for acute conditions may involve individual physical therapy directed by the pain physician, followed by a coordinated program including ongoing communication with the patient's case manager and therapist. With chronic pain conditions, more diverse assessment and treatment teams include multi- and interdisciplinary programs. In the multidisciplinary model, patient care is planned and managed by a team leader, usually a pain specialist (anesthesiologist, physiatrist, neurologist, psychiatrist, or primary care provider) or a psychologist, and is often hierarchical with one or two individuals directing the services of a range of team members, many with individual goals. Treatment may be delivered at different facilities or centers where individual patient progress is not regularly shared between distinct disciplines. The growth of multidisciplinary pain treatment centers in the 1980s led to the need for development of standards and formal accreditation processes. A committee on standards for Pain Treatment Facilities was established by the American Pain Society in the early 1980s and a process was subsequently developed to accredit multidisciplinary pain centers (MPCs) by the Commission on Accreditation of Rehabilitation Facilities (CARF). Non-CARF accredited programs also exist. Further, the International Association for the Study of Pain delineated four levels of pain programs[36]: multidisciplinary pain centers, multidisciplinary pain clinics, pain clinics, and modality-oriented clinics. Multidisciplinary pain clinics and centers, many of which include an even more integrated comprehensive interdisciplinary approach, include similar basic treatment disciplines; however, the MPC centers are usually associated with major health science institutions with an additional focus on pain-related research and outcomes.

Interdisciplinary Treatment

Even more collaborative, the interdisciplinary model involves team members working together toward a common goal. Team members are able to communicate and consult with other team members on an ongoing basis, facilitated by regular face-to-face meetings. Incorporation of the cognitive and behavioral psychologic approaches along with the development and emergence of the field of health psychology led to the development of more interdisciplinary models under the more general "multidisciplinary" umbrella. Interdisciplinary pain programs may also be referred to as functional restoration programs, which provide outcome-focused, coordinated, goal-oriented services. FR as an approach implies an emphasis on quantification and graded increases in function versus pain reduction, cognitive-behavioral therapy, occupational therapy, and work conditioning. FR programs were developed in the mid-1980s by Mayer et al.[37] in the United States and have been incorporated with the basic program structure of interdisciplinary programs. The basic treatment model is based on Fordyce's classic contingency management techniques and graded activity related to operant learning processes. FR aims at decreasing or eliminating learned pain behaviors.[38]

The interdisciplinary model provides practical strategies for assessing and treating pain-related deconditioning, psychosocial distress, and socioeconomic factors related to disability. An interdisciplinary team model is characterized by team members working together for a common goal, making collective therapeutic decisions, and having face-to-face meetings and patient team conferences to facilitate communication and consultation. Importantly, in this model, team members possess a combination of skills that no single individual demonstrates alone. Interdisciplinary teams may be led by a physician (medical director), psychologist, or nurse and include comprehensive assessment including pain medicine, pain psychology, and vocational rehabilitation. In some institutions, physical and occupational therapy assessments are also included in the formal assessment. Interdisciplinary programs are usually housed in one facility with periodic interdisciplinary team meetings to assess and adjust treatment progress, program coordination, and discharge planning. Programs primarily focus on restoring joint mobility, muscle strength, endurance, and conditioning and cardiovascular fitness. Coordinated vocational and therapeutic recreation services are also important aspects of care and focus on aiding patients in returning to work, improving behavioral factors (i.e., coping, catastrophizing, and problem solving) in the workplace, clarifying return to work level of functioning, and many times, individual occupational therapy.

In general, formal interdisciplinary programs vary in intensity, and may include 3–8 weeks of 4 to 8 hours per day programs with tailored group and individual therapies usually provided in an outpatient or, less often, in an inpatient hospital setting. Long-term follow-up studies of interdisciplinary treatment programs have demonstrated improved return to work rates, pain reduction, and quality of life.[39,40] The reader is referred to the chapter on Interdisciplinary Pain Treatment (Chapter 105).

Outcomes of Multi- and Interdisciplinary Treatment Programs

An early prospective trial documented high rates of return to work versus control subjects with improved physical capacities, self-reported disability, depression, and pain scores.[41] Maintained posttreatment improvements in pain, perceived health, and psychological and physical function have been demonstrated in long-term studies (6 months and 5 years).[42,43] The interdisciplinary treatment approach is supported by evidence suggesting these programs are more cost-effective and provide at least equal or greater efficacy than other pain treatments (i.e., spinal cord stimulation and implantable devices, conservative care, and surgery).[44] Additional evidence-based studies have demonstrated outcomes and treatment cost-effectiveness data supporting FR

treatment which included multidisciplinary and interdisciplinary treatment programs.[45–47] A recent analysis examined the cost utility of interdisciplinary treatment of chronic spinal pain.[48] Cost utility involved the calculation of cost of the specific treatment relative to desired treatment goal (increased functioning and decreased pain) relative to pharmacologic treatment with or without anesthetic interventions. Interdisciplinary treatment was associated with better cost utility supporting interdisciplinary treatment as both less costly and more effective.[48] Although early intervention and referral for pain rehabilitation treatment should intuitively favor greater outcomes as compared to referrals late in the treatment process, studies have demonstrated that patients with long-term disability, many of whom have a greater incidence of pretreatment surgery, may still benefit from comprehensive treatment with similar improved return to work rates and decreased lost time rates.[49] Rehabilitation-based multidisciplinary treatment has demonstrated high cost-benefit with regards to decreasing treatment costs and increasing workplace return to work.[50,51]

TEAM BUILDING AND STAKEHOLDER COORDINATION

Case Management

Case management involvement is an important resource in the management of work-related injuries. Case management has been conceptualized as a system-based approach based on Bronfenbrenner's systems theory[52] which incorporates an interaction of microsystems (worker factors), mesosystems (workplace, health care utilization, insurance system factors), and macrosystems (economic, social, and legislative). Case managers are primarily assigned to injured workers' cases to help facilitate communication between stakeholders and medical providers and coordinate and clarify issues related to return to work and job description, respectively. A practical problem-based approach in rehabilitation management process is the rehabilitation cycle and includes four important interdependent steps: assessment, assignment, intervention, and evaluation (Fig. 89.6).[53] Case management assessment includes identification of patient problems and modification and adjustment of goals. The assignment step involves the assignment to specific health care professionals who understand intervention principles and goals. Intervention more specifically refers to treatment disciplines and interventions with specific goals and milestones. Finally, evaluation refers to the evaluation of goals and level of achievement.[54]

Tate et al.[55] suggested success of any collaborative workplace rehabilitation relationship is contingent upon (1) company policy endorsing a commitment to rehabilitation, (2) educational opportunities offered or available for the injured worker by the employer, and (3) identification of key decision-making points involved in the ongoing relationship. Training the nurse case mangers in basic fundamentals led to improved work placement as compared to untrained case managers who were more likely to place the injured worker in a sedentary or light duty job position.

Applying a continuum of care model, many times facilitated by strong case management presence, includes a coordination of disciplines, services, providers, and care levels. A continuum of care model developed in Canada for the treatment of musculoskeletal conditions included medical management, active physical therapy, chiropractic management, and multidisciplinary assessment and rehabilitation. Implementation of the program resulted in more rapid and sustained recovery, greater patient satisfaction, and dramatic cost savings as compared to usual care.[56]

Applying Team Values

Decision-making in pain rehabilitation has been found to incorporate common decision values shared by the team members, worker, and stakeholders. Shared "general values," as described by Loisel et al.,[57] are those that stress work is therapeutic, pain is multidimensional, and interventions should be graded. These values should in turn be shared by the team members, the worker, and stakeholders facilitated by reassurance and the delivering of a single message as a way of more successfully returning a patient to work or previous level of function.[57] Theses same values can be applied to the many barriers presented to the individual patient and stakeholder (Table 89.5).

ASSESSMENT, GOAL SETTING, AND PROGRESSION THROUGH TREATMENT

Pain Rehabilitation Principles

Assessment of patients prior to entering a rehabilitation program is based on a comprehensive examination of physical, psychologic, and social or relevant vocational factors. Also, the evaluating clinician must work to develop trust and rapport with the patient in order to understand barriers to recovery (i.e., contentious relationships involving family, employer, case manager, and/or the legal system) that may potentially lead to a delay or reduction of clinical improvement. Many times, the success of developing that relationship starts at the initial evaluation. Understandably, patients undergoing a rehabilitation program are

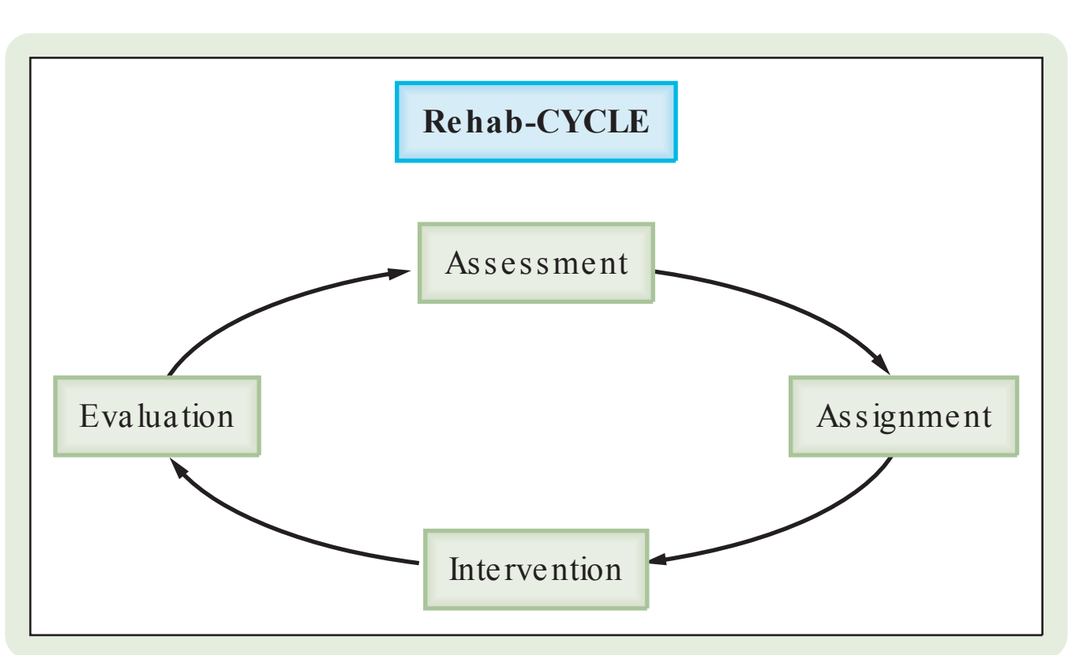

FIGURE 89.6 The rehabilitation cycle. (Redrawn from Stucki G, International Classification of Functioning, Disability, and Health (ICF): a promising framework and classification for rehabilitation medicine. *Am J Phys Med Rehab* 2005;84(10):733–740, with permission.)

often asked to make significant changes in the ways they cope with pain and function. Readiness to make such important changes has been found to be associated with treatment success[58,59] and readiness to self-manage pain increases from pre- to post-MPC treatment.[60] Based on the transtheoretical model of behavior change, individuals are seen to progress through a number of stages involving decisions about change and include precontemplation, contemplation, action, maintenance, and acceptance phases.[61] These basic concepts are important for the physician to explore during the evaluation and often become a focus of discussion between other potential treatment disciplines (i.e., pain psychologist, physician, and vocational counselor) when deciding whether the patient is an appropriate candidate for treatment. The pain rehabilitation clinician must be consistent and clear in promoting exercise and activity as essential, safe, and effective for the correction of functional impairments. The clinician must also be aware of various fears, negative attitudes, financial and vocational stressors many chronic pain working and nonworking patients are sometimes struggling with, and be able to confront the patients on these issues in an open and understanding manner (Table 89.6).[62]

REHABILITATION SPECIALISTS: ACTIVITIES AND CONCEPTUAL MODELS

A pain rehabilitation team may include a pain physician (i.e., anesthesiologist, physiatrist, psychiatrist, neurologist, and/or primary care physician), physical and/or occupational therapist, a pain psychologist, relaxation (biofeedback) therapist, vocational and therapeutic recreational therapists, social workers, and nurses. Ongoing communication between treating disciplines, including monitoring of progress and adjustment of patient goals, is coordinated by the pain physician. A rehabilitation model is based on a clear, concise, and consistent therapeutic message which focuses on the patient assuming a more active role in self management, flare up management, and exercise progression. Goals of treatment remain somewhat consistent across all disciplines and focus on improving function and decreasing pain. More specialized roles of individual therapists (i.e., physical and occupational therapy, pain psychology, and vocational rehabilitation) and treatment goals will be reviewed below based on a FR approach.

The Therapist's Role: Building an Effective Therapeutic Relationship

Besides obvious clinical skills and application of therapies by specific disciplines, the relationship between treating therapist (i.e., physical therapist, occupational therapist, psychologist, etc.) and patient is based on an ability to establish a mutually effective relationship based on ongoing respect, collaboration, and exchange of ideas. A successfully established working alliance will only help to improve outcomes. A process model for patient-practitioner collaboration includes a four-component model based on initially developing a therapeutic relationship, followed by mutual inquiry, problem solving, and negotiation.[63] The therapist must also be cognizant of the patient's beliefs, skills, emotional state, and expectations in effectively developing and adjusting a specific treatment plan and subsequent interventions.[64] A therapeutic relationship involves the establishment of clear and attainable short- and long-term goals, the therapy intervention and training, and discharge planning (i.e., home exercise program). Therapists involved in pain rehabilitation treatment must be adept in their ability to assess initial levels of functional ability and then monitor and progressively increase the individual patient's level and complexity of therapeutic exercises. Therapists assess secondary impairments in addition to their primary pain-related diagnoses (i.e., general inflexibility, deconditioning, regional myofascial pain and dysfunction, and other related postural abnormalities), which expands the area of treatment. Physical and occupational therapists apply a more functional cognitive and behaviorally mediated therapeutic approach and help the patient slowly integrate other aspects of the program into his or her home program.

The basic principles of cognitive-behavioral therapy are also introduced and facilitated by the physical and occupational therapy team members and may include goal setting, education, monitoring and documenting exercise and conditioning progress, and ongoing challenging and redirecting of maladaptive thoughts and behaviors.[65–67] The integration of these approaches may help foster patient optimism, decreases the fear of reinjury, and maximizes patient compliance. Common cognitive-behavioral objectives may be applied across disciplines as well as by pain psychology professionals in helping the pain rehabilitation patient change maladaptive thoughts and behaviors and include helping patients to combat demoralization, view pain as more manageable, alter

TABLE 89.6

PATIENT PERCEPTIONS

Pathways to becoming injured	Seeking treatment	Seeking return to adequate work	Living as an injured worker
Work, workplace, and degree of unsafe practices lead to injury	Desperate for a diagnosis; difficulty accessing appropriate and timely treatment	Returned to modified work yet disillusioned to find accommodations short-lived or nonexistent	Financial hardships; loss of marriages; change in family structure
Fear of unemployment; continued hazardous job	Negative attitudes by doctors and other health practitioners toward the injured worker	Lack of choice and control over vocational issues	Legal action with compensation system drained of financial resources, adding to distress
Lack of knowledge about reporting injuries	Medical uncertainty led to different diagnoses from different specialists; uncertainty led to more doctor shopping and inconsistent message regarding level of activity and restrictions	Workers believed employer-based actions on the need of company rather than the workers	Psychological deterioration; limitation in self-care activities led to feelings of dependency and social isolation

From Beardwood BA, Kirsh B, Clark NJ. Victims twice over: perceptions and experiences of injured workers. *Qual Health Res* 2005;15:30–48, with permission.

or unlearn maladaptive thoughts or behaviors, bolster confidence, and improve problem solving (Table 89.7).

Incorporating Behavioral Approaches in Pain Rehabilitation

Pain rehabilitation approaches rely heavily on incorporating behavioral principles and approaches (i.e., operant, cognitive, and respondent) into active therapies. The cornerstone of operant therapy is graded activity. The basic premise of a graded activity program is based on Fordyce's combined use of graded activity progression and contingency management techniques. This treatment targets helping patients to increase healthy behaviors with positive reinforcement while at the same time decreasing maladaptive pain behaviors and beliefs and increasing tolerance for activity.[68,69] Often, graded activity programs are also incorporated with exercise therapy and problem-solving training.[70]

TABLE 89.7

PAIN TEAM SHARED PRIMARY OBJECTIVES OF A COGNITIVE-BEHAVIORAL APPROACH FOR PAIN PATIENTS

1. To combat demoralization by assisting patients to change their view of their pain from overwhelming to manageable
2. To teach patients the coping strategies and techniques to help them to adapt and respond to pain and the resultant problems
3. To assist patients to reconceptualize themselves as active, resourceful, and competent
4. To learn the associations between thoughts, feelings, and behavior and subsequently to identify and alter automatic, maladaptive patterns
5. To utilize more adaptive ways of thinking, feeling, and behaving
6. To bolster self-confidence and patients' attribution of successful outcomes to their own efforts
7. To help patients anticipate problems proactively and generate solutions, thereby facilitating maintenance and generalization

Physical Therapy

Physical therapists specialize in gait training, locomotion, core strengthening and stability, joint deficiencies, and proper biomechanics. Active treatments include instruction in strengthening, postural re-education, and related therapeutic exercise (see Chapter 92). Passive treatment modalities (i.e., local application of heat, cold modalities) may be more efficacious for acute injuries; they are used more judiciously with chronic pain conditions. The use of modalities with chronic pain rehabilitation should shift to an emphasis on facilitating increased activity before or after formal treatment sessions or exercise and as a means of managing pain flare-ups more independently.

Manual therapy, the manipulation of soft tissues, continues to occupy a large part of the modern physical therapist's scope of practice. Not necessarily new to medicine, manual techniques were described by Hippocrates (460 BC) with traction and immobilization as a means of reducing fractures.[71] Galen[72] later recommended techniques to treat "outwardly dislocated" vertebrae. Modern physical therapy's use of manual techniques is based on principles of osteopathic medicine introduced by Andrew T. Still in 1871 and chiropractic treatment pioneered by Daniel Palmer in the late 1800s. Today, many therapists receive special training and certification from a number of "schools" of manual therapy including Maitland, Paris, Kaltenborn, and McKenzie (Table 89.8).[73,74]

Therapeutic Exercise

Therapeutic exercises targets muscle and joint deficiencies (i.e., weakness, decreased conditioning, and contracture) and serves as the basis for rehabilitation of patients with acute or chronic musculoskeletal, postoperative, and posttraumatic rehabilitation

TABLE 89.8

MANUAL THERAPY

Manual Therapy school	Basic principles	Key terminology
Maitland (Australian)	Graded oscillatory movements to evaluate and treat joint stiffness and restore lost mobility	"S.I.N.S." algorithm *S*everity, *I*rritability *N*ature of the complaint *S*tage of the pathology
Paris, Stanley B. (New Zealand)	Focus on examination of spine, facet joint primary source for dysfunction in spine	Incorporates Maitland and Kaltenborn principles
Kaltenborn (Norwegian)	Arthrokinematics principles (e.g., concave-convex, closed-loosely packed positions), treat hypomobility even if asymptomatic	
McKenzie, R (Australia)	Directional preference • "centralization" vs. "peripheralization" of symptoms • Over pressure	
Cyriax, James (England)	Identify "lesion" Heat and friction massage for contractile structures and forceful manipulation with manual distraction to treat intra-articular displacement	

protocols (Table 89.9). The pain clinician must be cognizant of basic principles of physiology and guiding a patient through an individualized active strengthening program. This section will review important definitions and concepts related to therapeutic exercise. With rehabilitation of any injury, strength and endurance are important targets for assessment and treatment. Muscular strength is the ability of a muscle to generate force against resistance. Maintenance of strength of one's muscle or, more importantly, muscle groups, will help to improve function and prevent new or reinjury. Strength training also incorporates balance and coordination of movement. Muscular endurance is the ability to perform repetitive muscular contractions against some resistance over time. Endurance will tend to increase with strength. Improvements in muscular endurance may be more advantageous with regards to improving daily function.

In general, skeletal muscular contraction can be divided into three types of contractions: isometric, concentric, and eccentric.[75] Isometric contraction occurs when the muscle contracts without changing length. Isometric or static strength is necessary for performing many ADLs and in functional tasks or sports activities where a stable base of support is necessary for effective and efficient movement of joints. In pain rehabilitation, isometrics may be useful when joint motion is painful, a joint or joints are immobilized, or muscle or muscle groups are weak. In concentric contraction, the muscle shortens in length while tension increases to overcome or move some resistance. With eccentric contraction, resistance is greater than the muscular force being produced, lengthening the muscle while producing tension. This type of muscle activation may be associated with a higher incidence of delayed onset muscle soreness after exercise.[76] Thus, concentric exercises may be the focus of the program prior to progressing to more eccentric, unloaded ones.

Strength and muscular endurance are dependent on size of muscle or muscle groups, number of muscle fibers, neuromuscular function and efficiency, and biomechanical factors. Neuromuscular training (NT) is a growing area of practice with most work in rehabilitation of musculoskeletal injuries including anterior cruciate ligament reconstruction. NT can include balance exercises, plyometrics, agility training, and joint mobility exercises. Plyometric exercise, initially used to enhance sports performance, may also be used in later stages of an active therapy program as a means of returning the patient to previous levels of sport or work. Plyometric exercise causes a lengthening of the muscle-tendon unit followed immediately by shortening, hence called the stretch-shortening cycle. Plyometrics are used with various demands placed on the musculoskeletal system, usually initiated at lower intensity and progressed to more difficult and physically challenging higher intensity levels. The higher intensity levels may serve to resolve postinjury neuromuscular impairment and prepare the body to respond more effectively and safely to rapid changes in position and movement as well as greater levels of force seen in higher intensity exercise and physically demanding work tasks.[77]

Exercise Prescription

Exercise prescription for the patient with pain should include four basic goals[34,78]:

1. Changing sedentary behaviors to more active ones
2. Modifying risk factors for disability (e.g., obesity, hypertension, deconditioning)
3. Maintaining or improving exercise capacity as it relates to strength, aerobic capacity, balance, and flexibility
4. Enhance psychosocial function

Exercise prescription and focus may vary depending on the patient's age, medical comorbidities, and individual pain-related impairments (i.e., muscle strength, joint pain, joint contracture). Endurance exercise may help to reverse the cycle of deconditioning and weakness commonly seen with chronic pain patients and is an important part of the pain rehabilitation program. The phys-

TABLE 89.9

COMMON THERAPEUTIC EXERCISES

Exercise type	Description	Therapeutic uses
Closed kinetic chain	Proximal segment of the extremity moves on a fixed distal segment (e.g., leg press, squats, elliptical walker)	Shoulder and knee rehabilitation, dynamic stability
Concentric	Muscle contracts as it shortens (e.g., flexion phase of a biceps or hamstring curl)	Increase muscle mass and strength
Core stability	Targets low back, trunk, and abdominal muscles (e.g., sit up, back extension, abdominal crunch, Pilates)	Relief of low back pain or pregnancy-related pelvic pain
Eccentric	Muscle contracts as it lengthens (e.g., extension phase of biceps or hamstring curl)	Sport-specific strengthening to prevent injury
Isometric	Muscle contracts, but its length stays the same (e.g., holding a weight in a stationary position for a few seconds)	Muscle toning and strengthening when joint mobility is not advised; quadriceps exercises to treat patellofemoral pain syndrome
Isotonic	Constant resistance applied to a muscle through a joint range of motion (e.g., free-weight lifting)	General muscle conditioning
Open kinetic chain	Distal segment of the extremity moves about the proximal segments (e.g., long arc quadriceps extension, most weight-lifting exercises using the arms)	Functional improvement in ADLs

iologic effects of exercise have been shown to have analgesic effects, enhance mood, and improve self-efficacy. Circuit exercise programs, popular with the elderly population, have been shown to provide significant improvements in cardiorespiratory fitness, muscular strength, body composition, and serum cholesterol levels.[79]

Occupational Therapy

Activities of Daily Living

Occupational therapy focuses primarily on functional mobility and ADLs, as well as activity tolerance and ergonomic retraining. Occupational therapists typically concentrate on educating patients regarding proper posture and ergonomics related to upper limb functional activities such as lifting and computer usage as well as proper standing, sitting, carrying, and lifting postures. In general, occupational therapists address upper extremity related ADLs including feeding, hygiene, grooming, bathing, and dressing. Occupational therapists spend considerable time with the patient, educating them on the potential for increases in pain with reinitiation of movement early in the treatment process. Focus may later change to lifting training and tolerance building. Coaching on proper body mechanics could include a basic assessment of maladaptive movement patterns, restriction in joint and soft tissue structures, as well as abnormal postures and bending or lifting techniques which may exacerbate and/or be the cause of ongoing pain and dysfunction. Occupational therapists are also responsible for managing and directing more individualized work conditioning and work hardening programs as well as administering functional capacity evaluations many times in coordination with the vocational rehabilitation team and employer.

Pacing

Another important concept occupational therapists are primarily responsible for is directing and instructing patients on activity, work, and leisure pacing. Pacing may be either an appropriate or a maladaptive behavior. Good pacing may include activity scheduling, taking breaks to complete a pain-inducing activity as compared to over-doing activities, and the "crashing and burning" approach with prolonged periods of rest and "down time" in order to recover from activity related flare-ups (Table 89.10).

The therapist is then able to work with the patients in improving their daily routines, incorporating pacing, taking appropriate breaks, and prioritizing activities while incorporating self-management skills learned in other disciplines such as relaxation techniques and stretching into the patient's daily routine at work, at home, and in leisure activities. Occupational therapists may also provide job site interventions which include assessing ergo-

TABLE 89.10

PACING: USEFUL VERSUS MALADAPTIVE RESPONSES

Useful	Maladaptive
1. Gradual increase in activity	Overdo activities
2. Increase on a quota system	Increase activity until "intolerable" pain
3. Varies mixed activities and rest	"Crash and burn": take extended periods of rest or prolonged down time after an activity or pain flare up
4. Realistic and manageable	Too busy to incorporate

nomics and monitoring for job site safety issues. Services may also include job site training where a trained occupational or physical therapist accompanies the injured worker.

Pain Psychology

Psychologic interventions as part of a pain rehabilitation program have been shown to enhance recovery, decrease disability, and enhance psychosocial functioning.[80–83] Psychologic interventions focus on addressing maladaptive cognitions, passive avoidance, depression, anger, and pain-related anxiety. Initial focus of psychologic treatment includes challenging patients to change maladaptive thoughts and behaviors. As stated earlier, an individual's readiness to make important changes has been hypothesized to be an important factor in treatment success and serves as an important initial clinical question posed by the treating psychologist.[84–86] Over time, patients are also challenged to consider taking a more active role in management and incorporating nonpharmacologic and pharmacologic therapies into their individualized program. Problem solving training may help to teach patients to choose more effective responses to pain and improve function.[87] Incorporating group pain psychology interventions with an active physical therapy program has been shown to enhance posttreatment outcomes as compared to physical therapy alone on measures of functional impairment, employment of active coping strategies, medication use, and self-efficacy beliefs.[88]

Combining group cognitive-behavioral therapy and relaxation therapy with an individually based multidisciplinary treatment (cognitive-behavioral therapy, physical and occupational therapy, and social work) program demonstrated an additive effect with greater improvement on measures of pain, sleep, activity levels, and medication use.[89,89a]

Relaxation Training

Further, incorporating relaxation techniques (i.e., deep breathing, progressive muscle relaxation) with therapeutic stretching can help the patient progress in the exercise program and improve activity tolerance. Biofeedback is a treatment that has been shown to be quite effective in the management of pain.[90] The treatment serves to help a patient become more aware of their physiologic responses to pain or other stressors. In general, relaxation training focuses on helping the patient to acquire self-management tools for reducing tension and decreasing pain. Initial treatment involves basic education explaining how biofeedback-assisted therapies work and helping the patient to understand they are able to control or modulate physiologic functioning of their own bodies by "seeing" or "hearing" their own physiologic function (i.e., breathing, limb temperature, and sweat).

Skills training includes training with basic biofeedback technologies such as respiratory biofeedback, surface electromyography, and/or thermal biofeedback. Techniques include diaphragmatic breathing, progressive muscle relaxation, and autogenic techniques. Patients are encouraged to log their practice sessions in their relaxation practice log. Relaxation training is provided in one-on-one and in group settings usually provided by a health psychologist, biofeedback specialist, or physical or occupational therapist. At the conclusion of formal treatment, patients should be independent with relaxation self-management techniques and be able to incorporate practice and technique integration with normal daily activities and during times of symptom flare-up or elevated levels of distress.

WORK REHABILITATION: WORK CONDITIOING AND WORK HARDENING

Work conditioning and work hardening are an important core component of work therapy in the field of industrial and pain rehabilitation. This field of modern occupational therapy developed after World War II with a focus of FR in wounded veterans as a means of securing employment in the civilian world after returning from duty. Work therapy also includes acute treatment, job analysis and placement, and functional capacity evaluation. Multidisciplinary principles were applied to occupational therapy based work rehabilitation in the 1950s with the development of improved assessment tools and systems and the addition of vocational counseling, medical management, and industrial engineering. In the 1970s, work hardening and conditioning programs were combined with behavioral medicine approaches that focused on reducing abnormal illness behaviors in a more comprehensive treatment of injured workers primarily with low back pain. Eventually, standards were established and subsequently updated by CARF in the late 1989s and early 1990s, respectively. Work rehabilitation usually begins once a patient has reached a treatment plateau in active physical therapy and is unable to return to work due to pain-related impairments (Table 89.11).

TABLE 89.12

COMPONENTS IN A TYPICAL WORK HARDENING PROGRAM

Step I Job analysis	Step II Establishing work tolerance baseline	Step III Individual work hardening plan/goals
Understand worker's specific job requirements Critical Job Tasks Physical Job Demands Psychosocial Demands High-risk Job Factors *If job analysis available: review and validate primary job functions *If job analysis not available: on site job task analysis	Medical History Worker Interview Job Description with Critical Job Demands Pain Assessment Physical Assessment Work Posture and Mobility Strength, Sensation, Coordination, Lifting, Reaching, Carrying, Pushing and Pulling, Stooping, Bending, Kneeling, Sitting and Standing, Work Task Stimulation	1. Increase duration of daily participation 2. Increase physical tolerances to the level of critical job demands 3. Improve body mechanics and postures 4. Develop pain management strategies 5. Develop problem-solving skills for self-management at the work site 6. Facilitate appropriate worker behaviors

Work conditioning is usually concentrated on the physical components of flexibility, strength, coordination, and endurance and involves one discipline of treatment (i.e., physical or occupational therapy). A more multidisciplinary approach is seen with work hardening, which incorporates behavioral and vocational components with a formal focus on return to job-specific tasks or positions. Work conditioning is routinely coordinated with acute medical management as compared to work hardening, which is usually provided later in therapy within the rehabilitation phase of treatment.

Work hardening programs were initially described by Matheson at Rancho Los Amigos Hospital[91] as a work-oriented program focused on improvement in the client's productivity versus symptom reduction or increased physical capacity. A "client" can be described as an injured worker with impairments that do not match their job position, a worker with disease-based impairments with diminishing physical capacity, a job applicant who may not have the physical abilities to perform the intended job, or a currently employed worker in transition to a job requiring higher physical function.[92]

Work hardening is an individualized, work specific, multi- and interdisciplinary program centered primarily on returning patients (i.e., the injured worker) to their previous level of work or work demands. Work hardening uses real or simulated work tasks and progressively increasing conditioning, flexibility, neuromuscular control, and tolerances (Tables 89.12 and 89.13). Goals of work hardening include (1) attaining optimal physical tolerances and abilities, (2) maximizing cognitive and psychosocial functioning, (3) developing appropriate worker behaviors, (4) reducing fear and increasing confidence for the resumption of productive work, and (5) identifying problems that may necessitate placement in an alternative job.[93,94]

An individualized work hardening program incorporates a three step process which includes an initial formal job analysis to determine specific duties, completion of a baseline work tolerance evaluation, and establishment of the individual work hardening plan. Work hardening standards have been established by a number of groups and may vary depending on the state or the federal governing body.[95]

Occupational therapy manages most work conditioning and work hardening treatments as part of the pain rehabilitation program. Assessment of the injured worker is more comprehensive than the assessment done during standard occupational therapist evaluations. Patients are placed in programs of a set number of days, usually 4 to 5 days per week over a 4 to 8 week period. Both programs are highly based on objective measures obtained during the program evaluation which includes tolerances and capacities for lifting, pulling, standing, sitting, reaching, climbing, kneeling, and/or crawling. The treatment program is based on the individual patient's own job demands and work level (sedentary, light, medium, heavy) and developing improved conditioning and tolerances for activities (Table 89.14). Although formal psychologic counseling is not a core discipline, these programs are based on helping patients work through and unlearn fear avoidance beliefs and movement patterns, pain-related fear, catastrophizing, and pain-related anxiety.

TABLE 89.13

WORK HARDENING PROGRAM STANDARDS

1. Improve strength and endurance in relation to return to work goal
2. Simulation of critical work demands, tasks, and environment of the job worker will return to
3. Education: body mechanics, pacing, safety, and injury prevention, promoting worker responsibility and self-management
4. Assess for need for job modifications (i.e., equipment changes or additions, ergonomic modification). Availability for on site job modification assessments
5. Individualized written plan which includes observable and measurable goals
6. Safe work or therapy environment that is appropriate for reaching vocational goals
7. Quality assurance system, outcomes based on program and worker goals
8. Documentation or reporting system that includes initial plan, regularly scheduled team conference notes with monitoring of progress, record of attendance, and compliance
9. Evaluation and modification of work behaviors (i.e., timeliness, attendance, interpersonal relationships)
10. Criteria for admission includes physical recovery sufficient to allow for progressive reactivation and participation for a minimum of 4 hours a day for 3 to 5 days a week along with a defined work goal
11. Criteria for discharge clearly stated (i.e., patient met goal stated in plan, patient did not participate according to program plan, goals not feasible to attain)

Outcomes of Work Conditioning and Work Hardening Programs

Reviews of work conditioning and work hardening programs have found evidence of improved return to work rates and fewer work days off in treated patients versus controls.[96–98]

MEASURING PHYSICAL CAPACITY

Functional capacity testing provides a means of measuring function by obtaining objective and subjective data with performance-based testing. Testing can be divided into two groups of tests including examining isolated parts of the body or "functional units" (i.e., lumbar spine, shoulder) and the ability of the functional unit to interact with other bodily functional units or activities such as lifting capacity. Lifting capacity many times involves the interplay of the biomechanical chain of a number of systems. A common example of the biomechanical chain includes transferring forces from a simple lifting task from the ground. Here, forces of the biomechanical chain include transferring forces from the hands through the elbow and shoulder (upper extremity functional unit) to the lumbar spine and hips (lower extremity functional unit) to placing the object and transmitting forces to the floor.

Functional Capacity Testing

Functional capacity evaluation (FCE) is a process where the individual's ability to perform a specific task or physical demands of a job is assessed, bridging the gap between observed physical impairment and work capacity. Matheson[99] describes the FCE as "a systematic method of measuring an individual's ability to perform meaningful tasks in a safe and dependable basis." FCEs have three specific purposes: (1) to improve the likelihood that the patient will be safe in a job task, (2) to assist in improving role performance through assessing and identifying functional decrements as a means of providing appropriate treatment or therapy, and (3) to determine presence of disability for bureaucratic or legal entities that may assign a quantifiable level of impairment or apportionment or deny monetary or medical disability benefits.[100]

The FCE is a valuable tool for the physician, vocational counselor, therapist, or employer to establish a specific attainable work goal based on objective data. In theory, by comparing performance demonstrated on the FCE to the required physical job demands of the individual worker, meeting or exceeding all job requirements simulated during testing will help to determine if the patient is safe to return to work.[101] Better performance on a FCE, many times defined by lower number of failed tasks during testing, may be associated with lower risk of recurrence after return to work.[102,103]

Various types of FCEs can be performed as a means of obtaining specific vocational goals including establishing functional goal setting, disability rating, job and occupation matching, and work capacity evaluation.[104] In general, the FCE can be done before treatment and usually once a patient has reached a treatment plateau or has completed a formal acute or subacute therapy program. As a means of determining impairment of disability, a FCE may compare measured functional capacity either to the patient's preinjury baseline abilities or population norms. Accurate measurements of a worker's preinjury capacities rarely exist, and health care providers are many times inaccurate in estimating the worker's preinjury functional level or physical capabilities.[105]

The FCE is used to establish a final level of functioning and includes a statement regarding validity, effort, and pain behaviors. A number of validated FCE tests and programs are available from a number of vendors and are individually designed for specific disorders such as low back pain or upper extremity conditions. These tests can be incorporated into a larger battery of tests used in the formal FCE.

Strength testing may include assessing lifting, carrying, pushing and pulling, work stimulation, and circuit testing (Table 89.15).

Common assessment and job simulation devices include the Purdue Pegboard Test, the Crawford Small Parts Dexterity Test, and the Jebsen Hand Dexterity Test. Testing usually lasts between 2 to 6 hours and may also be performed over a number of days to observe for fluctuations in performance depending on change in pain or to make sure the patient meets the demands of more continuous work-related physical activity.

Performance reliability is used to determine performance credibility based on the assumption an individual will produce similar outcomes in a series of trials.[106] Additional objective measures may also be assessed including increase in heart rate during and immediately following performance of a strenuous task. Perfor-

TABLE 89.15

FUNCTIONAL CAPACITY EVALUATION LIFTING PROTOCOLS

Test	Test of	Specific tests	Progression	
Isoinsertional Lifting Evaluation	Occasional lifting tolerance	4 lifts: floor to knuckle, 12 inch to knuckle, waist to shoulder, shoulder to overhead carry	Weight increased in 10 lb increments, if too much pain, decrease by 5 lb	
Dynamic Carrying, Pushing and Pulling Tests		1. Carrying 2. Pushing (sled) 3. Pulling (Sled)	Resistance increased in 10 lb increments	
Progressive Isoinertial Lifting Evaluation (PILE)	Frequent lifting capacity	Lumbar PILE: (floor to 30 inch high shelf) Cervical PILE: (30 inch shelf to 54 inch shelf)	Starting weight 13 lb (male), 8 lb (female)	End Points: 85% of max predicted age adjusted heart rate, 55% to 60% body weight

mance credibility can be subjectively determined by assessing for consistency and incongruity between specific tasks and tests. Reports of pain and pain behavior should be specific to the body part and correlate with the level or area of injury.[107] Performances that do not follow normal or expected patterns may also be indicative of less than sincere effort.

Subjective credibility measures may include the individual's perceived physical strain or effort and may be rated on a number of Ratings of Perceived Exertion scales. In one example scores range from 6 to 19 (e.g., 6 [no exertion], 7 [''very, very light''], 15 [''hard''] to 19 [''very, very hard'']) and increase linearly with exercise intensity. Values of the scale correlate to heart rate (0.8–0.9), ranging from 60–200 beats per minute.[108]

Grip strength assessment in the FCE serves two important purposes: to assess hand grip strength and to document performance of maximum voluntary efforts. A common test used in many clinics and mentioned in FCE reports is the Jamar hand dynamometer (Sammons Preston Rolyan, Bolingbrook, IL), a calibrated hydraulic hand dynamometer, which measures static grip strength at five grip spans. The therapist is able to produce a graphical representation of the forces produced at five grip positions, revealing a classic ''biomechanical curve,'' with the lowest force values occurring in positions one and five and the highest at positions two, three, or four. Inability to produce this bell-shaped curve could cast doubt on the individual's sincerity of full maximal effort. Force variability of multiple trials can be applied to normative data and can also be used to indicate noncredible performance.[109]

Functional Capacity Testing Utility

An important and controversial area of FCE results lies in its ability to demonstrate validity, reliability, and accuracy.[110,111] Lemstra et al.[112] examined the tester's ability to judge maximal effort in a standard lifting protocol. They found high specificity but low sensitivity (62%) with only a small number of commonly used maximal lifting tests (5 of 17) able to differentiate between maximal and submaximal effort.[112] Results of a functional capacity test can be used in conjunction with a more detailed understanding of the individual's job description as a means of establishing return to work restrictions and formal levels of work (see Table 89.14).[112,113]

What Does an ''Invalid'' Test Mean?

In clinical practice, ''invalid'' test results may be related to the patient demonstrating less than full effort in performance. Although not always consistent with malingering, a number of other causes (i.e., physical ability, disability, pain intensity, and fear of reinjury) have been identified and should be considered when interpreting and making clinical decisions based on an invalid test or test with evidence of less than ''full'' or ''maximal effort'' (Table 89.16).[114–118]

The result of an FCE can have far reaching consequences including injured workers having compensation terminated or losing their job or seeing a reduced medico-legal settlement in patients believed to be exhibiting submaximal effort.[119] In order to establish one's functional capacity, the injured worker must perform at his or her maximal ability or effort. A number of tests have been used as a means of validating effort. Methods used to assess sincerity of effort include Waddell nonorganic signs, pain behavior description, symptom magnification, coefficients of variation, correlations between physical evaluation and function, grip measurements, and temporal relationship between heart rate and increased levels of pain with activity.[119]

TABLE 89.16

CAUSES OF INVALID FUNCTIONAL CAPACITY EVALUATION TESTS/LESS THAN FULL EFFORT

1. Malingering syndrome
2. Factitious disorder
3. Learned illness behavior
4. Conversion disorder, pain disorder, or other somatoform disorders
5. Depressive disorders
6. Test anxiety
7. Fear of symptom exacerbation or injury
8. Fatigue
9. Medication and psychoactive substance effects
10. Lowered self-efficacy expectations
11. Need to gain recognition of symptoms

Washington, DC: American Institutes for Research; 1999.

ROLE OF OPIOID MANAGEMENT IN PAIN REHABILITATION

The role of chronic opioid management in pain rehabilitation remains a controversial topic. Pain rehabilitation programs as early as the 1960s focused primarily in reducing and or eliminating opioids secondary to fears of tolerance and development of iatrogenic addiction. This approach still characterizes many interdisciplinary programs today. However, the shift to more liberal use of opioids for chronic noncancer-related pain in the1990s and the assumption that risk for addiction was minimal led to increased use of opioids in the treatment of chronic pain.[120–123] The more recent reappraisal of the benefits and potential harms of chronic opioid use has also led to more questions regarding the accuracy of predicting aberrant behavior, and quantifying rates of addiction[124–127] use has been complicated by an appreciation for not only the potential risk for developing aberrant behaviors and addiction in a small percentage of patients but also for the development of other potential opioid-induced adverse effects, including cognitive impairment, endocrine function (sexual dysfunction and opioid induced hypogonadism), and mood.[128–131]

Risk stratification for determining potential risk for abuse and misuse and more comprehensive screening prior to initiating an opioid trial is finding greater acceptance in the evolving field of pain management.[132] Unfortunately, many patients referred for pain rehabilitation treatment may include a greater number of opioid treatment "failures" and/or patients additionally managed with other controlled substances (i.e., benzodiazepines and hypnotics). A number of reasons for "failing" should be considered during the evaluation and subsequent treatment planning and include ruling out improper or maladaptive opioid or controlled substance use, poorly designed opioid and/or pharmacologic regimen, poor or limited analgesic response with adverse effects, opioid induced pain sensitivity, or a combination of these factors (Table 89.17).

A pain rehabilitation approach may also offer a patient self-management treatment tools with potentially similar or even greater clinical outcomes than those achieved by his or her opioids. Concurrent pharmacologic management may include a structured taper off the currently used opioid, conversion to methadone, or conversion to buprenorphine products. Use of U.S. Food and Drug Administration-approved buprenorphine products for opioid dependence (i.e., buprenorphine and buprenorphine and naloxone) requires specialized licensure by clinicians. Treatment of withdrawal signs and symptoms primarily includes the use of oral or transdermal clonidine, an α_2-adrenergic agonist,[133] and adjuvants for withdrawal-related myalgias, insomnia, anxiety, and gastrointestinal distress.[134]

TABLE 89.17

POTENTIAL SCOPE AND SPECTRUM OF USE OF OPIOIDS IN PAIN REHABILITATION

1. Rule out improper or maladaptive use of opioids for their non-analgesic reasons (i.e., depression, psychologic tolerance, anxiety)
2. Adjust regimen, limit short-acting, limit total daily dose while patient learns additional nonpharmacologic skills to manage pain and pain-related disability
3. Detoxification secondary to failed analgesia, poor functional outcomes related to use
4. Slow taper down in total daily dose while monitoring for changes in mood, cognition
5. Detoxification secondary to development of possible opioid induced hyperalgesia
6. Detoxification secondary to pain condition not fully or partially responsive to opioid analgesics

TABLE 89.18

BEHAVIORAL TREATMENT TECHNIQUES FOR THE CHEMICALLY DEPENDENT PATIENT

- Psychotherapeutic Strategies
  - Supportive-Expressive Psychotherapy
  - Multidimensional Family Therapy
  - Motivational Enhancement Therapy
- Mind-body Therapies
  - Cognitive-Behavioral Therapy
  - Relaxation Techniques
    - Meditation, guided, or self-guided imagery, progressive muscle relaxation, deep breathing

Adapted from Wooten J. Behavioral Medicine Treatment in the Management of the Chemically Dependent Patient. In Smith HS, Passik SD, eds. *Pain and Chemical Dependency*. New York: Oxford University Press; 2008:253–258.

The advantage of a structured and relatively controlled environment of most multidisciplinary and interdisciplinary treatment programs is that it offers an opportunity for patients with limited or maximized improvement on chronic opioids to reduce or eliminate opioids while at the same time learning to apply new nonpharmacologic approaches to management of their pain. This structured environment is ideal for more successfully integrating a more rational polypharmacy approach.

Behavioral medicine treatments can be effectively incorporated into a structured multi- or interdisciplinary rehabilitation based program. Treatment of the chemically dependent patient can include two types of therapies: (1) psychotherapeutic strategies and (2) mind-body therapies.[135] Psychotherapeutic strategies include supportive-expressive psychotherapy, drug counseling, family therapy, and motivational enhancement therapy. Mind-body therapies, in general, include cognitive-behavioral therapy, group support and education therapy, and relaxation therapy (i.e., deep breathing, imagery, hypnosis, and biofeedback) (Table 89.18).

Patients can be successfully weaned or have their opioid dose decreased during a FR rehabilitation-based approach. Active opioid withdrawal did not adversely impact short-term outcomes following a 3-week outpatient pain program,[136] and physical and emotional functioning were favorable in a fibromyalgia cohort that completed an interdisciplinary pain rehabilitation program which included withdrawal of opioids, nonsteroidal anti-inflammatory drugs, benzodiazepines, and muscle relaxants.[137]

CONCLUSION

Rehabilitation is a continuous process, relying on a comprehensive, pragmatic approach that focuses on an individual's physical impairments and function-related disability. The field of modern pain rehabilitation developed along with the growth of a number of medical specialties (i.e., anesthesia, rehabilitation medicine, psychiatry, neurology, and occupational medicine), physical and occupational therapy, and health psychology. Pain rehabilitation assessment and treatment is based on a biopsychosocial model. A narrower dualistic biomedical model may fail to adequately assess and help patients to manage the complexities of ongoing pain, affective distress, and environmental and social issues. Treatment goals in pain rehabilitation programs include improving psychosocial functioning, decreasing pain, improving aerobic conditioning, and facilitating safe and successful return to work

status, return to leisure pursuits, and activities at home and in the community.

A pain rehabilitation approach includes planning and coordinating various medical interventions (i.e., pharmacologic and nonpharmacologic), educational activities, and coordinating a patient's participation with specific rehabilitation-based disciplines (i.e., physical and occupational therapy, pain psychology, relaxation and other mind body therapies). Vocational rehabilitation can serve as an additional treatment option and may be coordinated in patient-specific work-based therapies such as work conditioning and work hardening programs. Work conditioning and work hardening may be more specific levels of treatment for the injured worker as a bridge to progress patients after completing acute rehabilitation and more closely simulating work activities, respectively, prior to returning to previous levels of sport, function, or work. Functional capacity testing may be used as a more objective means of establishing a baseline level of function, establish treatment and work goals, or finalize return to work level of functioning. Validity measures may also help to identify physical and psychosocial factors that are contributing to the injured worker's level of functioning and clarify discrepancies in tolerances and effort.

The pain rehabilitation clinician must work with the patient in conjunction with various stakeholders (i.e., case managers, insurance providers and adjustors, legal personnel, and family members). The clinician's role may include additional responsibilities beyond only working to help patients decrease pain and increase function, but also as an advocate for the patient with insurers, employers, and rare circumstances as adjudicator, helping the insurer or employer to decrease or identify inconsistent or fraudulent patient behavior. Optimal patient outcomes are facilitated by the clinician and team members establishing a therapeutic environment with the patient characterized by ongoing coordination of care, communication between treatment team members and the patient, providing consistency of message, and collaboration between team members.

CHAPTER 90 ■ ASSESSMENT AND TREATMENT OF CHEMICAL DEPENDENCY

ANDREW J. SAXON, JAMES P. ROBINSON, AND MARK D. SULLIVAN

INTRODUCTION

This chapter on assessment and treatment of chemical dependency provides guidance, particularly for practitioners interested in pain medicine, on how various forms of substance dependence are diagnosed and managed clinically. Since detection and management of opioid addiction pose a major concern for physicians using opioids to treat patients, and since diagnosis of opioid addiction in this context is often confounded by pain issues, the chapter focuses special attention on this complex clinical conundrum. More specifically, the chapter focuses on patients with chronic nonmalignant pain (CNMP) because issues related to opioid addiction are more vexing in these patients than in patients with cancer or other life-threatening illnesses.

Various surveys indicate that individuals with chronic pain disorders are more likely to have substance use disorders than are individuals in the general population,[1,2] and individuals with substance use disorders also have high rates of pain disorders.[3] Therefore, practitioners treating pain disorders are likely to encounter patients with substance use disorders and will need to know how to screen for and recognize these disorders, diagnose these disorders, make appropriate referrals for and/or treat these disorders, monitor for these disorders during ongoing pain treatment, and how to manage therapy for chronic pain in the context of these disorders.

The first section of the chapter presents the assessment and treatment of all major forms of chemical dependency from the perspective of addiction medicine. The second section focuses on assessment and treatment of opioid addiction from the perspective of the pain specialist.

ASSESSMENT AND TREATMENT OF CHEMICAL DEPENDENCY—ADDICTION MEDICINE PERSPECTIVE

The panoply of substance use disorders includes intoxication, withdrawal, abuse, dependence, and substance-induced psychiatric disorders (for example psychosis, mood disturbance, or anxiety caused directly by the use of the substance). Substance use disorders occur with a variety of commonly used substances such as alcohol, cannabis, cocaine, opioids, sedative/hypnotics, stimulants like amphetamines and methylphenidate, inhalants, psychedelic agents, and nicotine. A standardized set of criteria characterizing these disorders is provided in the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV TR*).[4] Intoxication and withdrawal differ by substance and can generally be diagnosed through history and physical examination. The criteria

for abuse and dependence, which will be covered in greater detail below, are identical across substances.

The use of the term "dependence" has generated some confusion and controversy. In contrast to a commonly held conception of "dependence" as notating purely physiologic changes that occur in response to repeated exposure to a substance, in *DSM-IV TR*, "dependence" refers to a syndrome of physiologic signs and symptoms combined with an array of behavioral disturbances. Some have suggested that the phrase "substance dependence," referring to the *DSM-IV TR* syndrome, be replaced with the term "addiction" to avoid confusion between purely physiologic dependence and the syndrome of substance dependence.[5] Others feel that the term "addiction" has negative connotations leading to stigmatization. In any event, it should be understood that the terms "addiction" and "substance dependence" are essentially synonymous and interchangeable.

TABLE 90.1

QUANTITIES OF ALCOHOL THAT DEFINE A STANDARD DRINK (14 GRAMS PURE ALCOHOL)

Beverage	Percent alcohol	Quantity in standard drink (in fluid ounces)
Beer	5%	12
Malt Liquor	7%	8.5
Table Wine	12%	5
Fortified Wine	17%	3.5
Liqueur	24%	2.5
Brandy	40%	1.5
Spirits (gin, vodka, whiskey)	40%	1.5

Screening and Recognition

Some initial evidence must arise through screening to suggest that a patient has a substance use disorder to trigger a thorough diagnostic assessment. In many cases, screening and diagnostic evaluation may overlap. Recently, the idea of "universal precautions" in pain medicine has been advanced to detect potential substance use problems in all pain patients so there may be some value in routine use of some or all of these screening procedures.[6]

History

Generally, a thorough history of substance use obtained through a matter-of-fact, nonjudgmental interviewing style will provide a great deal of information or even a formal diagnosis. Most patients are not aware of guidelines for safe quantities of alcohol consumption and will readily divulge the amount of their drinking. Many patients are more reluctant to discuss use of illicit substances, but some will freely admit to such use if they do not fear sanctions or punishment. Oftentimes, this openness is more likely to occur during initial intake. Patients may be less forthright during the course of treatment if they believe they have something to lose by admitting to use. If time allows, it is worth asking explicitly about frequency and quantity of use for each class of substance along with route of administration. It is also quite important to ask about any history of current and past problematic substance use as such problematic use is known to increase the risk of recurrence in the context of pain management. It is useful to know what types of substance use disorder treatments have been useful for the patient in the past.

Recommended safe quantities of alcohol use consist of no more than 4 standard drinks per day (or more than 14 total per week) for men and 3 standard drinks (or more than 7 total per week) for women.[7] The recommended quantities are less for women because women tend to have less total body water and thus a lower volume of distribution for alcohol.[8] Quantities of different forms of alcohol that define a standard drink are listed in Table 90.1. If patients acknowledge regularly consuming more than the recommended amounts or describe heavy drinking such as 5 or more drinks on one occasion for men or 4 or more for women, a more thorough diagnostic evaluation for alcohol abuse or dependence should be pursued.

For illicit substances, any suggestion of more than occasional recreational use of marijuana should prompt a more thorough diagnostic evaluation. It is also important to look for nicotine dependence, as this has been associated with increased risk of opioid misuse in a number of studies.[1,9]

Physical Examination

Signs of possible substance use problems evident on physical exam include hypertension (common with excessive alcohol use), track marks indicative of recent or past injection drug use, pupillary constriction or dilation, inflamed nasal turbinates from intranasal substance insufflation, wheezes or rhonchi on lung exam from substance smoking, enlarged, tender liver from excessive alcohol use, other substance toxicity or hepatitis, or any stigmata of excessive alcohol use such as flushed facies, spider angiomas, palmar erythema, etc. Any of these findings should trigger further screening and a possible thorough diagnostic evaluation.

Laboratory

Routine blood work can provide an indication of excessive alcohol use. Suggestive findings include elevations in liver transaminases or macrocytic, hyperchromic red blood cells related to alcohol's interference with folate absorption and subsequent folate deficiency. Positive serologies for past or current hepatitis B or C infection or human immunodeficiency virus infection would raise concerns about a substance use related mode of transmission.

In addition, specific laboratory testing to detect presence of substances in body fluids offers a convenient component of screening. Typically urine is tested,[10] though tests can also be readily performed in oral fluid or blood.[11,12] Substances that have been used are likely to remain present in urine for a longer period than they will in other body fluids (Table 90.2). For urine testing, a screening test is typically performed via immunoassay. When needed, confirmatory tests using gas chromatography/mass spectrometry can be ordered. It is important to note that the routine urine assay for opioids does not detect oxycodone, which requires a specific screening test. Likewise methadone is not detected by the opiate assay and necessitates a specific screening test. Heroin can only be detected shortly after use if its intermediate metabolite, 6-monoacetyl morphine, is present. Subsequently, 6-monoacetyl morphine is rapidly metabolized to morphine. If morphine appears in a urine toxicology specimen, it could represent either pharmaceutical morphine use or heroin use. It is difficult to detect alcohol in urine, blood, oral fluid, or breath unless the use has been quite recent.

Self-Report Questionnaires

A number of self-report questionnaires have been designed to help in screening for substance use disorders, and these can be utilized prior to, concurrent with, or subsequent to the history, physical, and laboratory evaluation to help determine whether a patient warrants more thorough diagnostic evaluation. Although the instruments described below have definite utility in primary care and general populations as well as selected samples such as psychiatric patients, they have not been tested in pain patients.

In screening for alcohol use disorders, the most frequently

TABLE 90.2

DRUG DETECTION TIMES IN URINE AND DRUG PLASMA HALF-LIVES

Drug	Detection time in urine (based on standard cut-off values)	Plasma half-life
Amphetamine	2–3 days	12 hours
Cocaine Metabolite (Benzoylecgonine)	2–3 days	7.5 hours
Opioids		
Morphine Glucuronide	2 days	7.5 hours
Codeine Glucuronide	3 days	12 hours
Heroin Metabolite (6-mono acetyl morphine)	2–4 hours	20 minutes
Methadone	3 days single use 7–9 days maintenance dosing	24 hours
Oxycodone	2 days	5 hours
Hydromorphone	1–2 days	2.5 hours
Hydrocodone	1–2 days	4 hours
Barbiturates		
Short-Acting	1 day	25 hours
Intermediate-Acting	2–3 days	38 hours
Long-Acting	≥16 days	100 hours
Benzodiazepines		
Short-Acting	1 day	1.5 hours
Intermediate-Acting	2–4 days	10 hours
Long-Acting	≥7 days	48 hours
Cannabis single use	3 days	20 hours
Cannabis chronic use	≥30 days	20 hours

used instruments are the Alcohol Use Disorders Identification Tests (AUDIT)[13] and the Michigan Alcohol Screening Test (MAST).[14] The AUDIT has 10 items related to quantity and frequency of alcohol consumption and to maladaptive behaviors associated with alcohol use and can be completed in about 5 minutes. Each item is scored 0 to 4. A score of 8 or more for men under age 60 or 4 or more for women or men over age 60 are considered positive screens indicative of need for further assessment. The MAST contains 25 questions and focuses more on problem behaviors associated with alcohol use. Each item counts for 1 point, and a score of 6 or more indicates a positive screen with need for further assessment. There are shorter versions of the MAST which also appear to function as adequate screening instruments.

In the context of managing pain patients where urine toxicology should be readily available, self-report instruments to screen for drug use problems are probably less useful than a positive urine toxicology. However, if use of a self-report screening instrument is desired, the most commonly used instrument is the Drug Abuse Screening Test (DAST).[15] The DAST is based on the MAST and has 28 items concerning both intensity and frequency of drug use and problematic behaviors associated with drug use. As with the MAST, each item counts for 1 point, and a score of 6 or more points to the needs for further assessment. Shorter versions of the DAST also exist.

Diagnostic Assessment

As noted above, criteria provided in *DSM-IV TR* represent the most standard way to make a diagnosis of a substance use disorder. Substance abuse is considered a less serious disorder and substance dependence more serious. Abuse and dependence are mutually exclusive. Once a patient has progressed to dependence, the patient can no longer be diagnosed with abuse, even if the substance use has become less problematic. In that circumstance, a diagnosis of dependence in partial remission would be made. At times, it proves fruitful to interview family members if the patient is not forthcoming.

Substance Abuse

Table 90.3 contains *DSM-IV TR* criteria for substance abuse. The presence of one or more of four possible criteria is needed

TABLE 90.3

DSM-IV TR **CRITERIA FOR SUBSTANCE ABUSE**

A. A maladaptive pattern of substance use leading to clinically significant impairment or distress as manifested by one (or more) of the following, occurring within a 12-month period
   (1) Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home
   (2) Recurrent substance use in situations in which it is physically hazardous
   (3) Recurrent substance-related legal problems
   (4) Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance
B. The symptoms have never met the criteria for substance dependence for this class of substances

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed, text revision. Arlington, VA: American Psychiatric Publishing Incorporated; 2000.

to make the diagnosis. The essence of substance abuse involves the repeated use of the substance in risky situations or in situations in which the use results in legal problems or interferes with social or occupational functioning. The use need not be frequent, and withdrawal usually does not occur. Individuals usually begin with substance abuse and may then progress to dependence. To determine the presence or absence of the diagnosis, the interviewer should focus one by one in turn on each substance of potential relevance and systematically go over each of the criteria with the patient for each substance.

Substance Dependence

Table 90.4 displays the *DSM-IV TR* criteria for substance dependence. There are two physiologic criteria, tolerance and withdrawal, and five behavioral criteria. Three or more of the seven criteria must be present at any one time over a 12-month period to make the diagnosis. Thus, an individual could meet both physiologic criteria but would not be diagnosed with dependence unless she or he met at least one behavioral criterion. This situation could occur, for example, with a pain patient treated chronically with opioids who might display tolerance to the effects of opioids and withdrawal signs and symptoms if the medication is stopped but has no behavioral evidence of dependence, with an attention deficit hyperactivity disorder patient treated chronically with stimulants, or with an anxiety disorder patient treated chronically with benzodiazepines. Conversely, an individual might not have either tolerance or withdrawal but could have the *DSM-IV TR* defined substance dependence if she or he meets at least three of the behavioral criteria, although this scenario occurs rarely in clinical practice. As with diagnosing abuse, the interviewer should go systematically through each of the criteria with the patient and cover each substance separately. Inspection of the criteria reveals that questions about each criterion are unlikely to be interpreted by patients as critical or threatening and unlikely to engender resistance or deception, particularly if posed in a matter of fact, nonjudgmental fashion. Although this procedure sounds time consuming, it frequently can be accomplished in a matter of minutes for each substance of concern. As mentioned at the outset, the diagnosis of opioid dependence in a patient with CNMP being treated with opioids may not be as straightforward as simple application of the *DSM-IV TR* criteria and will be discussed in detail below.

Diagnosis of a substance use disorder certainly should not preclude appropriate interventions for a pain problem and, in many instances, with appropriate monitoring and safeguards may not preclude opioid treatment of chronic pain.

Co-Occurring Psychiatric Disorders

Mental health disorders frequently co-occur with substance use disorders.[16,17] It is likely that chronic pain patients who have substance dependence will have another nonsubstance related co-occurring psychiatric disorder.[18] Oftentimes co-occurring psychiatric and substance use disorders interact with negative synergy so that exacerbation of one disorder in turn exacerbates the other.[19] Thus, if a pain patient does have a substance use disorder, it is imperative to evaluate that patient for other co-occurring psychiatric disorders and provide appropriate clinical intervention (including pharmacotherapy and/or psychotherapy) for any that are diagnosed.

Monitoring During Ongoing Pain Treatment

Even if a patient does not manifest a substance use disorder at the onset of chronic pain treatment, a disorder can certainly arise during the course of treatment. Maintaining vigilance for the development of a disorder involves both observation of the patient for behavioral evidence and routine monitoring techniques.[6] Behaviors that may increase the index of suspicion include missing appointments, having medication shortages, failure to pay bills, or a markedly changed affect during appointments.

Depending on the setting and resources available, it may prove worthwhile to establish routine monitoring procedures for all pain patients even in the absence of concern. This approach normalizes these procedures, allows patients to expect them, and creates structure that may actually help the patient to feel supported while removing any sense of stigma or accusation that may supervene if the procedures are applied only for cause. The procedures that will be utilized should be specified at the outset of treatment in a written treatment agreement. One routine monitoring procedure to consider is urine toxicology testing as described above.[20]

Another potential procedure is unscheduled medication call backs. For this procedure, patients are telephoned and asked to return to the office within 24 hours with all their outstanding medication. When the patients come in, pill counts are performed to insure that all expected outstanding medication is accounted for. It is also possible to obtain a urine toxicology specimen at that time.

Treatment and/or Referral

Some general comments about treatment and referral will be made and then specific interventions for dependence on each particular class of substances will be outlined. Most physicians get virtually no training or experience in treatment of substance use disorders and, therefore, often feel helpless or hopeless in the face of these disorders. Although most patients with these disorders who do get treatment get it in specialized settings that operate in parallel to and oftentimes outside of mainstream medicine, many patients will refuse a referral to such settings, and a growing body of literature supports the efficacy of brief physician intervention as a reasonable first attempt at treating these disorders.

Brief Interventions

Brief office interventions conducted by physicians have demonstrated efficacy in reducing alcohol consumption for patients with problematic alcohol use that does not rise to the level of alcohol abuse or dependence and may also have some benefit in these latter disorders.[21,22] Motivational interventions (see below) which can be incorporated into brief office interventions have demonstrated modest efficacy in drug dependence.[23]

Brief interventions should be delivered in a manner that is matter-of-fact, nonjudgmental, supportive, and empathic and definitely not in a manner that is confrontational. The first step consists of stating concern about the patient's level of alcohol use (or any level of illicit drug use). It is helpful to give the patient direct examples from his or her medical record including bothersome symptoms, physical findings, specific diseases, or lab abnormalities. The next step involves giving direct advice to cut down (or quit) the substance use along with an offer to help. If the patient is not receptive to this advice and the situation is not emergent, the physician can encourage her or him to consider it carefully and reflect on why she or he considers ongoing use to be a reasonable course of action. A follow-up can be arranged for further discussion.

If the patient appears receptive to advice to cut down or quit, the physician can help the patient to establish a specific goal to cut down or abstain (for abuse or dependence). Also, the physician can provide explicit behavioral suggestions such as avoiding acquaintances who use, avoiding places where use has previously occurred, or seeking social support for quitting, including attending mutual-help groups such as Alcoholics Anonymous or Narcotics Anonymous. A follow-up appointment should be scheduled to monitor progress.

TABLE 90.4

PROBLEMS IN THE APPLICATION OF DSM-IV TR CRITERIA OPIOID DEPENDENCE TO PATIENTS WITH CHRONIC NONMALIGNANT PAIN

DSM-IV TR **criterion for drug dependence**	**Problem in application to CNMP patients**
1. Tolerance	Pain specialists expect their patients to develop some tolerance to opioids and do not consider opioid tolerance to be an indicator of addiction or inappropriate use. Many believe that there is no inherent limit to opioid dosing, so that it is easy to compensate for tolerance by increasing a patient's opioid dose.
2. Withdrawal	Pain specialists expect their patients to be at risk for withdrawal reactions in response to abrupt opioid tapers and do not consider such reactions to be an indicator of addiction or inappropriate opioid use.
3. Substance taken in larger amounts or over a longer period of time than was intended	The "amount" criterion is ambiguous because many pain physicians maintain that there is no definable ceiling for opioid dosing, and, therefore, no definite way to determine that a patient is taking too much of a drug. The "duration" criterion is ambiguous, because CNMP can last indefinitely.
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use	CNMP patients express a desire for opioids and explain this by maintaining that the opioids are needed to control their pain. Similarly, patients attribute difficulties in tapering opioids to pain increases during tapers, rather than to addiction. It is difficult for the treating physician to know whether these explanations represent rationalizations for addictive behavior or are accurate portrayals.
5. A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects	This is ambiguous in two ways. First, CNMP patients often do not have to go to great lengths to get opioids because their physicians prescribe them at office visits. Second, if a CNMP patient does engage in drug-seeking behavior, his or her behavior might be construed as evidence of pseudoaddiction. This term implies that the patient's behavior is attributable to inappropriate prescribing on the part of the treating physician, rather than to addiction on the part of the patient.
6. Important social, occupational, or recreational activities are given up or reduced because of substance use	CNMP patients often give up these activities but routinely report that they are forced to do so because of their pain, rather than because of opioid addiction. Treating physicians generally do not have reliable methods to determine why the patients fail to engage in work and social activities.
7. Substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance use	CNMP patients routinely downplay adverse consequences of their opioid use. If they do acknowledge adverse consequences, they express the view that they would suffer even more if they did not have opioids to control their pain. Treating physicians generally do not have reliable methods to determine the validity of patients' attributions.

Criteria reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed, text revision. Arlington, VA: American Psychiatric Publishing Incorporated; 2000.

If the patient has alcohol dependence and is willing to try for abstinence, the brief intervention could be combined with prescription of an appropriate alcohol treatment medication as described below. If the patient has developed opioid dependence, the brief intervention could be combined with a recommendation to try buprenorphine, also described below. If the pain physician treating the patient has a federal waiver to prescribe buprenorphine, arrangements could be made to stop the opioid analgesic the patient is currently taking and make a switch to buprenorphine.

Specialty Substance Use Disorders Treatment

If a referral to a specialized substance dependence treatment provider is needed, the referral could be made to an individual practitioner, another physician, psychologist, social worker, or chemical dependency counselor who specializes in substance dependence treatment and could work with the patient in a private office setting using one or more of the psychotherapeutic or behavioral interventions detailed below. Frequently, the referral will be made to an addiction treatment or chemical dependency program or agency. The American Society of Addiction Medicine publishes Patient Placement Criteria that can aid in determining what level of addiction treatment is appropriate for a given patient. These criteria have not, however, been fully scientifically validated and are based largely on expert opinion.[24,25]

Medically Supervised Withdrawal

Some patients who manifest withdrawal when stopping their substance use may need medically supervised withdrawal (also known as detoxification) to stop the substance safely and engage in treatment. The most common substances which require supervised withdrawal are alcohol, sedative-hypnotics, and opioids, although occasionally patients may have very unpleasant withdrawal symptoms from cocaine or amphetamines and need some support and monitoring. Medically supervised withdrawal can be accomplished on an outpatient or inpatient basis depending upon the severity of the withdrawal. Alcohol or sedative-hypnotic withdrawal can be so severe as to be life-threatening. Usually, benzodiazepines are prescribed over several days in tapering doses.[26] Supervised opioid withdrawal for opioid dependence can be accomplished using methadone in a licensed treatment program[27] (see below) or with buprenorphine[28] by appropriately qualified physicians. Alternatively, the α_2 adrenergic agonist, clonidine, can be prescribed to attenuate opioid withdrawal signs and symptoms and tapered over several days.[29] Some paradigms, known as ultrarapid opioid withdrawal, have been developed whereby opioid withdrawal is precipitated with an opioid antagonist such as naloxone or naltrexone under sedation or general anesthesia to complete the withdrawal in a brief period of time. These rapid procedures have no better outcomes than more gradual withdrawal but do have more adverse events such as pulmonary problems and psychiatric instability so they are not recommended.[30] It is very important to understand that medically supervised withdrawal (detoxification) alone does not constitute treatment. If medically supervised withdrawal is not immediately followed by more definitive chemical dependency treatment, relapse is almost universal.

Opioid Agonist Treatment

Many patients with primary opioid dependence do not want to undergo withdrawal or have tried it previously with subsequent relapse. These patients might be referred to a federally licensed opioid treatment program.[31] These programs provide opioid agonist therapy with either methadone or buprenorphine. Because these medications have long half-lives, they can prevent the emergence of opioid withdrawal when taken on a once a day basis. (More detail on the clinical use of these medications for the treatment of opioid dependence is provided below.) The structure of the program is largely dictated by federal and state regulations. Patients must have a minimum of a 1 year history of opioid dependence. In the early stages of treatment, patients must come to the clinic daily for observed doses of medication with take home doses of medication for weekend days when the clinic is closed. The maximum allowed first dose of methadone is 30 mg with subsequent gradual dose escalation to an optimally therapeutic dosage. A physical examination and basic laboratory tests are required, as is periodic urine toxicology testing. Regular counseling visits are also mandated. As patients stabilize in treatment, as evidenced by regular attendance at dosing visits and other appointments, remaining on a stable dose of medication, and ceasing illicit substance use as demonstrated by drug free toxicology specimens, take home doses of medication become available so that patients do not have to attend clinic every day. After 2 years of continuous treatment, stable patients may receive up to a maximum of 1 month's take home doses. Opioid agonist treatment has exceptionally good outcomes not only in terms of reducing illicit opioid use but also in terms of reducing other substance use, in reducing mortality and morbidity, reducing criminal justice involvement, and improving employment.[32,33] It is considered to be as cost effective as other potential life-saving treatments such as coronary bypass surgery or renal dialysis.[34] All physicians are permitted to prescribe methadone for pain management, but only specially licensed facilities can prescribe methadone for opioid dependence. Prescription of methadone for pain in patients with signs of opioid dependence has obvious inherent risks and should be undertaken with careful monitoring precautions in place.

Intensive Outpatient Treatment

For patients who do not have opioid dependence or who have opioid dependence but do not want agonist therapy and have completed withdrawal, intensive outpatient treatment is often employed. This type of treatment is generally abstinence based; that is, it emphasizes the goal of total abstinence from alcohol and all illicit substances. Some programs would accept pain patients on prescribed opioid therapy if the patient has a goal of abstinence from other substance use. Intensive outpatient treatment involves behavioral interventions usually via a group format with several meetings per week over a 4 to 12 week period so that patients receive up to 72 or more hours of total treatment.[35] Frequent urine toxicology testing is also typically performed. The therapeutic content of the group sessions varies but often includes one or more of the types of behavioral interventions described below. Attendance at mutual help groups such as Alcoholics Anonymous is strongly encouraged. Not surprisingly, patients who complete these programs have better outcomes than those who drop out. Depending upon the setting and patient characteristics, the dropout rate can be substantial.

Inpatient Treatment

For patients who fail outpatient treatment or for those who can obtain funding for it, inpatient treatment is an option. Inpatient treatment could be as brief as a few days[36] but frequently lasts 28 days, and can be extended for many months in a model known as a therapeutic community[37] for patients who have severe, intractable substance use disorders that do not respond to any other interventions. Ongoing outpatient treatment subsequent to completion of inpatient treatment is often recommended. Inpatient treatment, like intensive outpatient treatment, is almost always abstinence based. Many short-term inpatient programs would accept pain patients on opioid therapy if the patients committed to abstinence from other substances. Most therapeutic communities would not accept patients receiving opioid therapy even for pain. The content of the care in inpatient treatment does not differ substantially from the content delivered in intensive outpatient

treatment, but inpatient treatment provides a controlled environment that minimizes the risk of relapse and can compress more hours of actual treatment into a shorter overall time frame.[38] In the aggregate, it appears that the quantity or "dose" of behavioral treatment received, rather than the setting in which it occurs, serves as the key mediator of outcome.

Specific Behavioral Treatments

Numerous types of behavioral interventions are used to treat substance dependence and many have been empirically validated. Mastery of specific techniques often requires considerable training and practice. Most studies comparing various behavioral intervention techniques find, as with setting, that the specific technique is less important than the total amount of behavioral intervention received. Many practitioners do not deliver the specific interventions in their pure form. In addition to the amount of intervention received, other important mediators of success are the skill of the specific therapist and the therapeutic alliance achieved between the therapist and patient regardless of what technique is used.[39] To impart at least passing knowledge of the names and basic philosophies of the more common techniques, brief descriptions are provided.

Motivational Interviewing. Motivational interviewing is a directive, patient-centered counseling style for eliciting behavior change by helping patients to explore and resolve ambivalence. Compared with nondirective counseling, it is more focused and goal-directed. The examination and resolution of ambivalence is its central purpose, and the counselor is intentionally directive in pursuing this goal using the following techniques[40]:

- Seeking to understand the person's frame of reference, particularly via reflective listening
- Expressing acceptance and affirmation
- Eliciting and selectively reinforcing the client's own self-motivational statements, expressions of problem recognition, concern, desire, and intention to change, and ability to change
- Monitoring the client's degree of readiness to change, and ensuring that resistance is not generated by jumping ahead of the client
- Affirming the client's freedom of choice and self-direction

Relapse Prevention Therapy. Relapse prevention is a cognitive-behavioral intervention based upon the notion that learning processes play an important role in the development of maladaptive behavior patterns. As applied to substance dependence, relapse prevention explores the positive and negative consequences of continued substance use, encourages self-monitoring to recognize substance cravings early on and identify high-risk situations for use, and develops strategies for coping with and avoiding high-risk situations and the desire to use.[41] A central element of this treatment is anticipating the problems that patients are likely to meet and helping them develop effective coping strategies. The skills that patients learn through relapse prevention therapy remain after the completion of treatment, and many maintain the gains they made in treatment throughout the year following treatment.

Drug Counseling. Drug counseling focuses directly on reducing or stopping the patient's substance use. It also addresses related areas of impaired functioning such as employment status, illegal activity, family/social relationships, as well as the content and structure of the patient's recovery program. Through its emphasis on short-term behavioral goals, drug counseling helps the patient develop coping strategies and tools for abstaining from substance use and then maintaining abstinence. The addiction counselor encourages 12-step participation and makes referrals for needed supplemental medical, psychiatric, employment, and other services. Individuals are encouraged to attend sessions 1 or 2 times per week.[42]

Twelve-Step Facilitation Therapy. Twelve-step facilitation consists of a structured and manual-driven approach to facilitating early recovery from substance dependence. It is intended to be implemented on an individual basis in 12 to 15 sessions and is based on behavioral, spiritual, and cognitive principles that form the core of 12-step fellowships such as Alcoholics Anonymous and Narcotics Anonymous. Twelve-step facilitation seeks to achieve two general goals in patients with substance dependence: acceptance of the need for abstinence from substances and surrender, or the willingness to participate actively in 12-step fellowships as a means of sustaining sobriety. These goals are in turn broken down into a series of cognitive, emotional, relationship, behavioral, social, and spiritual objectives.[43] Twelve-step facilitation has shown excellent results for patients with alcohol dependence but has not yet been thoroughly tested for patients with drug dependence.

Contingency Management. Contingency management treatments are based upon operant conditioning principles as elucidated by B. F. Skinner: if a behavior is reinforced or rewarded, it is more likely to occur in the future.[44] In many contingency management treatments, patients leave urine specimens multiple times each week and receive explicit reward for each specimen that tests negative for drugs. These rewards often consist of vouchers that have a monetary value and can be exchanged for retail goods. However, contingencies that lack monetary value can also be used. For example, in opioid treatment programs or office-based buprenorphine treatment, the frequency of attendance can be contingent on drug free urine specimens. Patients who provide drug-negative urine specimens get more take home medication or larger prescriptions, and those who provide drug-positive specimens have their take home privileges reduced or have to pick up a prescription more frequently. Contingency management has been demonstrated to reduce substance use significantly in numerous studies, but its implementation in clinical practice has lagged.[45]

Pharmacotherapies

Currently there are four U.S. Food and Drug Administration (FDA)-approved medications for the treatment of alcohol dependence (disulfiram, acamprosate, oral naltrexone, and injectable naltrexone) and 3 available FDA-approved medications for the treatment of opioid dependence (methadone, buprenorphine, and naltrexone). All of the alcohol treatment medications can be used by all physicians, including pain specialists if desired, within the scope of their own practice. Although methadone can be prescribed for the treatment of opioid dependence only within licensed clinics, buprenorphine can be prescribed by appropriately qualified physicians (as described below) outside of licensed clinics. Naltrexone for either alcohol or opioid dependence is not likely to have much utility in pain patients because of its antagonism of μ-opioid receptors and its tendency either to precipitate opioid withdrawal in patients on opioids or block the effects of opioid analgesics. Nevertheless, it may rarely have potential benefit in selected pain patients not currently on opioids. There are currently no FDA approved pharmacotherapies for dependence on other substances such as cocaine, methamphetamine, sedative-hypnotics, or cannabis, so these disorders must be treated with behavioral interventions alone.

Disulfiram. By inhibiting aldehyde dehydrogenase, a key enzyme in the major metabolic pathway for ethanol, disulfiram causes accumulation of acetaldehyde after alcohol ingestion. The buildup of acetaldehyde usually causes an "alcohol-disulfiram reaction" that typically ensues within minutes of alcohol ingestion.[46] Different individuals exhibit varying degrees of the reaction which may last for several hours. Signs and symptoms of

the alcohol-disulfiram reaction include diaphoresis, flushing, tachycardia, hypotension, nausea, vomiting, and headache. The concept behind the idea of disulfiram is that patients taking disulfiram will fear getting an uncomfortable reaction and thus will be deterred from drinking alcohol. To some extent, change occurs during the informed consent discussion between physician and patient at the time the patient agrees to take disulfiram. During that discussion, the patient may, by agreeing to try disulfiram, be arriving at a decisive interest in achieving abstinence from alcohol.

Patients must have achieved some time of abstinence before starting disulfiram to avoid provoking the alcohol-disulfiram reaction. Typically, 48 hours of abstinence proves sufficient. The usual starting dose of disulfiram is 250 mg/day. Genetic variability may determine sensitivity to the medication, and patients with high levels of aldehyde dehydrogenase may be less sensitive to the effects of disulfiram and require higher doses of medication up to 500 mg/day. Some patients may not tolerate 250 mg/day and should have the dose reduced to 125 mg/day.

Disulfiram is associated with a number of mild side effects such as headache, metallic aftertaste, erectile dysfunction, mild fatigue or sedation, and rash. Such side effects frequently dissipate spontaneously or with a dosage decrease. Much more serious adverse events such as optic neuritis, peripheral neuropathy, hepatic injury, or psychotic symptoms or delirium, though rare, necessitate immediate disulfiram discontinuation. Disulfiram-induced hepatic injury can occur idiosyncratically at an estimated rate of 1/25,000 to 1/30,000 patient treatment years.[47] Disulfiram-induced hepatic injury can rapidly proceed to total liver failure. It most usually occurs within the first 6 months of treatment. Symptoms include extreme fatigue, malaise, anorexia, fever, jaundice, scleral icterus, nausea, vomiting, and bilirubinuria. Baseline liver function tests should be obtained prior to initiation of disulfiram treatment and then at 1–2 month intervals during the first 6 months of treatment. With the decreased risk of disulfiram-induced hepatic injury after the first 6 months of treatment, liver monitoring can subsequently be done every 3–6 months if treatment continues. Many patients who might be considered for disulfiram therapy present with moderately elevated transaminases related to alcohol use (particularly in the context of hepatitis C). These modest transaminase elevations do not represent a total contraindication to disulfiram therapy. Very rapid rises in bilirubin and transaminases occur in disulfiram-induced hepatic injury and indicate the need to stop disulfiram at once. If the medication is discontinued promptly, the signs and symptoms of liver injury typically fully resolve. If the medication is not stopped, total hepatic failure and death can supervene unless a liver transplant is performed.

Patients with pre-existing cirrhosis or other serious liver disease generally are not good candidates for disulfiram. Other contraindications include pregnancy or lactation, history of prior hypersensitivity to disulfiram, or significant coronary artery disease. The latter group could experience myocardial ischemia during a severe alcohol-disulfiram reaction.

Disulfiram has greater benefit with monitoring of medication administration. Although the largest study to date demonstrated that disulfiram dosed at 250 mg per day over 1 year did not lead to increased abstinence rates or longer time to first drink compared to placebo, it did lead to significantly fewer drinking days over the study year.[48]

Acamprosate. Acamprosate, which has seen widespread use in Europe for many years, received FDA approval for the treatment of alcohol dependence in 2004. Acamprosate is believed to modulate both the major excitatory system in the brain, the glutamate system, and the major inhibitory system, the gamma amino butyric acid (GABA) system. Alcohol interacts with these systems as well, but when alcohol is stopped after chronic exposure, glutamatergic hyperactivity and GABA hypoactivity contribute substantially to the alcohol withdrawal syndrome. Acamprosate theoretically acts to counteract these imbalances and so may attenuate symptoms associated with subsyndromal, prolonged alcohol withdrawal such as insomnia, anxiety, and restlessness which could provoke alcohol cravings and relapse.[49,50] Acamprosate also may diminish reinforcement derived from alcohol ingestion[49] and the amount of alcohol consumed by patients in treatment who do experience relapse.[51] Numerous controlled studies of acamprosate demonstrated higher total abstinence rates and longer time to relapse for acamprosate compared to placebo.[52] For reasons that remain incompletely understood, acamprosate failed to show efficacy in two large clinical trials conducted in the United States.[53,54] It has been proposed that subjects in the U.S. studies may not have experienced sufficient prolonged subsyndromal withdrawal to benefit from acamprosate.[55]

Acamprosate has very limited oral bioavailability. It achieves steady state after 5 days and is not metabolized by the liver but is excreted unchanged in the urine. The usual dose is 666 mg (two 333 mg tablets) three times daily. The labeling indicates that acamprosate should be started after a modicum of abstinence has been achieved, but there are no safety issues if acamprosate is taken concomitantly with alcohol and abstinence is not essential. In fact, acamprosate should be continued if a patient relapses to alcohol use.

It is recommended that a serum creatinine level to evaluate kidney function be obtained prior to initiation of therapy since the dose should be lowered in patients with impaired kidney function. Acamprosate is FDA category C, so women of childbearing age must use an effective method of birth control when on acamprosate. All patients should be monitored for suicidal thoughts since such thoughts occurred more frequently among acamprosate-treated patients than among placebo-treated patients in clinical trials. Diarrhea is the only common side effect noted with acamprosate.

It is recommended that acamprosate treatment be continued for 12 months, and follow-up studies show increased abstinence rates that persist 1 year after cessation of treatment.[56] Advantages of acamprosate include its lack of drug-drug interactions and the fact that it is not contraindicated in patients with serious liver disease.

Naltrexone. The μ-opioid antagonist, naltrexone, originally developed to treat opioid dependence (see below), was subsequently approved to treat alcohol dependence in 1994 and is now available in generic form. An involvement of the endogenous opioid systems in the reinforcing effects of alcohol seems likely based on the fact that opioid antagonists block the alcohol-induced release of dopamine into the nucleus accumbens.[57] The ability of alcohol to promote the release of endogenous opioids[58,59] or to affect opioid receptor binding[60] may account for dopamine release engendered by alcohol and for the blockade of this event by opioid antagonists. Naltrexone changes the subjective experience of alcohol consumption in humans, rendering it less reinforcing and more sedating.[61] Naltrexone has demonstrated efficacy in delaying and preventing relapse to heavy drinking and reducing the percentage of drinking days, but not in promoting total abstinence in numerous (but not all) clinical trials.[62]

Naltrexone is rapidly and almost fully absorbed after oral administration, achieves its peak effect after 1 hour, and has a half-life of approximately 4 hours (metabolite half-life = 12 hours). The usual dose is 50 mg per day, which is sufficient to occupy the majority of μ-opioid receptors.[63] Many clinicians begin naltrexone at 25 mg per day for a few days to minimize side effects and then titrate up to 50 mg per day. Though data are sparse, some clinicians will also increase naltrexone to 100 mg per day if a suboptimal response occurs at 50 mg per day,

and the 100 mg per day dose demonstrated modest efficacy in the COMBINE Study.[53]

Common side effects of naltrexone include nausea, headache, dizziness, fatigue, sedation, and anxiety and typically resolve with continued treatment. Naltrexone does have a black box label warning for acute hepatitis, although most of these events occurred at doses of 300 mg per day in clinical trials for obesity, and there is little evidence of hepatotoxicity at currently recommended doses for alcohol dependence. Nevertheless, given the black box warning, it is judicious to obtain liver function tests prior to initiation and then at 1, 3, 6 and 12 months during therapy.

Because naltrexone blocks μ-opioid receptors, opioid medications will be much less effective in the situation in which an injury or serious medical condition calls for acute pain control. If given in adequate doses (usually higher than would otherwise be required), opioids can generally overcome the blockade, but close monitoring of the patient in an inpatient setting to observe for and manage respiratory depression is advised.

Long-Acting Injectable Naltrexone. Although oral naltrexone generally appears efficacious compared to placebo in reducing relapse to heavy drinking, it has not performed well in some studies. However, when patients found to be nonadherent for oral naltrexone are factored out in several other studies, naltrexone demonstrates efficacy for treatment of alcohol dependence compared to placebo.[64,65] Consequently, long-acting intramuscular naltrexone, FDA approved in 2006 for treatment of alcohol dependence, may eliminate concerns about adherence and has been shown to be effective compared to placebo in reducing heavy drinking.[66] An additional advantage of long-acting intramuscular naltrexone includes lower rates of first-pass hepatic metabolism, exposing the liver to significantly lower peak dosages than daily oral dosing. The reduced first-pass metabolism of intramuscular naltrexone leads to lower levels of the active metabolite 6β-naltrexol, which has been correlated with side effects such as nausea. Lower levels of this metabolite may lead to better tolerability of the intramuscular form of naltrexone. Long-acting injectable naltrexone is indicated for patients who have achieved some period of abstinence which could be as brief as several hours. The dosage is one 360 mg gluteal injection every 4 weeks. Patients can be started directly on the injection without a trial on oral medication.

Naltrexone for Opioid Dependence. For opioid dependent patients who have withdrawn from opioids and who do not wish to continue opioid therapy, oral naltrexone offers, from a theoretical standpoint, an ideal pharmacotherapy. Once a state of full withdrawal is achieved as verified by a naloxone challenge test, naltrexone can be started. With naltrexone on board, the effect of exogenously administered opioids will be blocked so that no euphoria is experienced and physiologic dependence cannot be reestablished. Unfortunately, very few opioid dependent patients remain on naltrexone for an extended period, so it performs only slightly better than placebo.[67] Some populations such as individuals with legal mandates or impaired professionals may do better on naltrexone. As noted above, naltrexone represents a poor choice of pharmacotherapy for most pain patients since it prevents the use of opioid analgesics. If it is prescribed, the typical dose is 50 mg per day.

Methadone. As noted above, methadone can only be prescribed for the treatment of opioid dependence through federally licensed and regulated clinics. Thus, in most cases, pain patients who need methadone treatment must be referred to one of these clinics. Such clinics are not available in many geographic regions and at times also have waiting lists.

Methadone is prescribed quite differently when used to treat opioid dependence than when prescribed for pain. Typically, for treatment of opioid dependence, a single daily dose is provided in liquid form. The maximum initial dose is 30 mg. The lowest effective dose of methadone for treatment of opioid dependence is approximately 50 mg, with an optimum average dose for most patients of approximately 80 mg (±20 mg), although some patients require a dose higher than this range. The daily dose should be sufficient to prevent emergence of withdrawal symptoms at least through the 24-hour dosing period. The dose should be sufficient to greatly diminish or eliminate opioid cravings and opioid use (as determined by both self-report and urine toxicology testing). The dose should create sufficient tolerance such that illicit opioid use does not cause euphoria. The dose should not be so high that side effects such as sedation, constipation, or loss of libido occur.[31]

Patients who do not stabilize within a few weeks should be evaluated both at the end of the 24-hour dosing cycle just prior to the next scheduled dose to assess the presence of withdrawal signs and symptoms and at 4 hours postdose to observe the patient for any evidence of intoxication or excessive opioid effect at the time of peak plasma levels.[31] If the patient does have withdrawal signs prior to the dose and no intoxication postdose, an upward adjustment in dose is probably warranted. When patients fail to stabilize after successive dose increases, consideration could be given to obtaining a trough (predose) serum methadone level. Levels below 100 ng/mL are associated with withdrawal symptoms and inadequate dosage.[68] There are rare ultra rapid metabolizers of methadone who will not become stable on a single daily dose and will exhibit low trough serum levels of methadone. For this small group of patients, splitting the dose by giving them half of the dose observed and the other half as a take-home for the evening generally promotes stabilization.

For patients on methadone maintenance, their daily dose of methadone will rarely be fully, if at all, efficacious in managing acute or chronic pain. These patients will typically need opioid analgesics, either methadone tablets or another opioid of choice, given throughout the day in appropriately divided doses given in addition to the daily dose of methadone. For acute pain, these additional opioids can be discontinued when the pain subsides. For chronic pain, the additional opioids will need to be ongoing in most cases.

Buprenorphine. Although buprenorphine can be prescribed through licensed clinics, its pharmacologic characteristics make it a very attractive medication for office-based therapy. Its partial agonist action means that it has a ceiling effect for central nervous system and respiratory depressive effects, making it far safer in overdose than methadone and other full μ-opioid agonists.[69] This partial agonist property also makes it easier to withdraw from this medication than from methadone. Withdrawing from methadone can take months or years and be difficult for patients.

In addition, buprenorphine has slow onset when administered sublingually (1.5 to 3 hours to peak plasma levels), a long half-life, and high affinity plus slow dissociation from the receptor.[70,71] Thus, it prevents the emergence of withdrawal symptoms for 24 hours or longer, and, by occupying the majority of receptors, it makes very few receptors available for binding of full agonists. Buprenorphine's long half-life allows for once daily or even thrice weekly dosing. Buprenorphine is poorly absorbed by the oral route and undergoes extensive first pass hepatic metabolism, so for treatment of opioid dependence, it is administered sublingually.

Buprenorphine prescription in the office setting was made possible in the United States by the Drug Addiction Treatment Act of 2000 (DATA).[72] DATA allows for office-based opioid maintenance therapy for opioid dependence using schedule III, IV, or V medications approved for this use by the FDA. In 2002, the FDA approved buprenorphine and buprenorphine/naloxone for this purpose, and they are the only medications at this time with this indication. In order to prescribe buprenorphine, physicians

must obtain a waiver from the Drug Enforcement Agency which requires specialty training in addictions or completion of 8 hours of training in management of opioid dependence provided by an approved association, and physicians must be able to refer patients to appropriate counseling and ancillary services. The waiver allows physicians to prescribe buprenorphine to up to 100 patients at a given time.

Buprenorphine is available for sublingual administration as a single agent or as a combination buprenorphine-naloxone preparation with a ratio of 4 mg buprenorphine to 1 mg of naloxone. The advantage of the combination buprenorphine-naloxone preparation is the prevention of abuse. Buprenorphine has adequate bioavailability sublingually, while naloxone is minimally bioavailable sublingually, so the naloxone has no effect on patients when administered as intended. If the combination medication is dissolved in an attempt to inject buprenorphine, however, naloxone, which also has a high affinity for the μ receptor, will exert its antagonist properties resulting in withdrawal instead of euphoria. The single agent should be reserved for use only in situations where there is no concern for potential abuse, such as in an inpatient setting or in individuals who are at greater risk to potential withdrawal symptoms if exposed to naloxone, such as pregnant women or those transitioning from methadone. Due to the partial agonist properties of buprenorphine, patients need to be clearly educated that they should not take this medication soon after taking other opioid drugs because buprenorphine in that situation may precipitate withdrawal.

An important component of the clinical skill in using buprenorphine involves the induction procedures. Patients who have been taking full agonist opioids must abstain from their full agonist opioids long enough to evidence signs of mild opioid withdrawal. If patients take the first dose of buprenorphine when not in active opioid withdrawal, there is a risk that buprenorphine as a partial agonist will precipitate more severe opioid withdrawal. Patients often require a fair amount of empathic emotional support to assure them that they can handle a period of several hours without opioids and can tolerate a brief episode of mild withdrawal prior to starting buprenorphine. Usually, it is not the mild withdrawal symptoms themselves that are troublesome, so much as the anxiety about more severe withdrawal. If patients are in mild to moderate withdrawal at the time of starting buprenorphine, the first dose usually alleviates much of the withdrawal within 30–60 minutes.

Induction of buprenorphine should thus begin approximately 12–24 hours after last use of a short-acting opioid drug or 24–48 hours after last use of a long-acting opioid drug, and patients should be showing objective signs of withdrawal at the time of initiation of therapy. On the first day of induction, the maximum dose should not exceed 8 mg to 12 mg. Because the transition from methadone to buprenorphine is more difficult than the transition from short-acting opioids, patients who are receiving methadone for pain and wish to transition can be first switched from methadone to a short-acting opioid, then inducted onto buprenorphine. For patients receiving methadone in a licensed clinic for the treatment of opioid dependence, this switch to a short-acting opioid is not legally permissible, and such patients must be inducted directly from methadone to buprenorphine.

If, after beginning buprenorphine, patients still have withdrawal symptoms after receiving the maximum first day dose, they should be treated symptomatically with adjunctive agents such as clonidine, antiemetics, antidiarrheals, and benzodiazepines for specific withdrawal symptoms. Over the course of the next 2 to 6 days, patients should be assessed for signs and symptoms of withdrawal with increases in buprenorphine given for persistent symptoms up to a total of 16 mg on the second day and a maximum of 32 mg per day by the end of the first week. Withdrawal symptoms beyond this time typically indicate persisting illicit opioid abuse.

Following induction, patients will stabilize on a dose over the following 1 to 2 months, and the dose should be adjusted to the lowest effective dose to prevent withdrawal symptoms, prevent craving of opioids, and suppress illicit opioid abuse. Once this dose is established, patients can be maintained on this medication indefinitely or may choose to taper off.[73]

Numerous studies have found buprenorphine to be effective in retaining patients in treatment and reducing illicit opioid abuse. A systematic review of studies, which compared 13 studies involving 2544 subjects in trials of buprenorphine versus either placebo or methadone, found buprenorphine to be effective as a maintenance therapy for opioid dependence when compared to placebo.[74] Compared with methadone, however, especially at higher doses of methadone, buprenorphine may not be quite as effective at maintaining patients in treatment or reducing illicit opioid use. Nevertheless, since buprenorphine is a safer medication than methadone, it often makes clinical sense to use buprenorphine as a first line agent. If a patient fails buprenorphine treatment, the patient can be transitioned to methadone maintenance in a licensed clinic.[75] Transition from methadone to buprenorphine is clinically more difficult than transition from buprenorphine to methadone.

As a partial agonist, buprenorphine has analgesic properties, but its analgesic effects may not always be as powerful as those of a full agonist. However, recent evidence suggests that buprenorphine produces less hyperalgesia than full agonist opioids[76] and so may have some benefit for pain control in patients not responding well to full agonists. Also, while buprenorphine has a ceiling on its respiratory depressant action, it does not appear to have a ceiling on its analgesic activity, so higher doses should continue to elicit greater analgesia.[77] Thus, buprenorphine has tremendous potential for management of patients who have combined chronic pain and opioid dependence. It allows the physician treating such a patient to continue to manage the patient in his or her own office for both disorders along with referral for ancillary counseling if needed rather than terminating such a patient or sending the patient to an addiction treatment provider or facility with the risk of a failure to follow through. As noted, some clinical skill is required to support the patient in abstaining from full agonist opioids long enough to evidence signs of opioid withdrawal such that buprenorphine induction can take place. Patients being treated with buprenorphine for combined pain and opioid dependence may get better analgesia by taking the buprenorphine in divided doses throughout the day rather than as a single daily dose. Although more data on the treatment of combined pain and opioid dependence are needed, preliminary reports indicate a positive response for many patients.[78]

THE PAIN MEDICINE PERSPECTIVE ON ADDICTION IN CHRONIC PAIN PATIENTS

For specialists in pain medicine, addiction to opioids looms over addiction to any other kind of substance as an issue of concern. Since pain specialists frequently prescribe opioids for patients with CNMP, they must be concerned about whether their opioid prescriptions are being misused by patients with pre-existing opioid addiction, and whether the prescriptions are creating addiction to opioids.

Historic and Regulatory Issues

Challenges associated with opioid therapy in CNMP occur against the backdrop of an uneasy relationship between physicians who prescribe opioids and the regulatory and law enforcement agencies that are charged with the prevention and prosecution of illegal uses of opioids. Interactions with these agencies

have almost certainly affected the opinions that physicians have expressed in publications about opioid therapy.

Historically, attitudes about prescribing opioids to patients with CNMP have gone through a succession of well-known shifts. When pain medicine emerged as a specialty in the mid-1970s, there was a reasonable consensus, based only on expert opinion and not on data, that long-term opioid therapy was problematic because of the risks of tolerance, physical dependence, and addiction.[79] Starting in the 1970s, researchers began to report that cancer patients treated with long-term opioid therapy did not show progressive tolerance, and, more generally, that opioid therapy for these patients was a reasonable therapeutic option.[80,81] During the 1980s, insights gleaned during the 1970s about cancer patients began to be applied to CNMP patients. For example, an influential paper by Portenoy and Foley[82] on a case series of 38 patients showed that it was possible to achieve long-term effective pain control for CNMP patients with opioids.

Several factors converged to lead to significant changes in the regulatory climate during the 1990s. With accumulating data demonstrating that opioids can be effective in the treatment of CNMP,[83] both physician pain specialists and patients insisted that long-term opioid therapy can benefit CNMP patients and that regulatory and legislative barriers to treatment that might relieve their suffering should be removed. Regulators and legislators responded by making opioid therapy for CNMP more accessible and acceptable.[84,85]

Pain physicians were not unanimously enthusiastic about opioid therapy during the 1990s. For example, physicians associated with multidisciplinary pain rehabilitation programs generally maintained a less sanguine view toward opioids.[86] However, pain physicians who favored opioid therapy combined forces with patient advocate groups to promote five assertions:

1. Long-term opioid therapy is an effective tool in the management of CNMP.
2. The concept of addiction as used by psychiatrists and addiction medicine specialists may not universally or easily apply to patients receiving opioid therapy for CNMP.
3. The likelihood that CNMP patients will develop addiction to prescription opioids is low.
4. There is no inherent ceiling to opioid therapy, so that it is appropriate for physicians to titrate doses upward until a patient either experiences satisfactory analgesia or develops side effects that preclude further dose escalations.
5. Patients have a right to pain relief and to receive opioids for that purpose in the absence of specific contraindications.

There is ample evidence that consumption of prescription opioids has increased markedly during the past 15 years.[87,88] Along with this increase in availability, large scale data have emerged indicating that misuse of prescription opioids has become more frequent over time and represents a significant public health problem.[84,89] Also, there has been a rise in opioid-related deaths.[90] On a smaller scale, several researchers have reported data on small cohorts of pain patients indicating that inappropriate/aberrant use of prescription opioids is far more common than physicians during the 1980s and 1990s supposed.[91–93] Finally, accumulating evidence from randomized controlled trials suggests that opioids are only modestly beneficial for patients with CNMP and appear to have limited efficacy at best for some common conditions such as chronic low back pain.[94,95] In the face of these new data, at least some pain specialists have recently urged greater restraint in the use of opioids for CNMP.[96]

Conceptions of Opioid Dependence and Opioid Abuse—The Pain Medicine Perspective

The *DSM-IV TR* criteria for identifying opioid dependence provide an appropriate starting point for the identification of such dependence among CNMP patients. However, when these criteria are applied to CNMP patients, important ambiguities arise.[97,98] One key issue is whether patients have a legitimate need for opioids. *DSM-IV TR* states, "Opioid Dependence includes signs and symptoms that reflect compulsive, prolonged self-administration of opioid substances that are used for no legitimate medical purpose."[4] But many CNMP patients report that they **do** have a legitimate medical purpose for consuming opioids, and most pain specialists would agree (at least in principle) with such an assertion. In fact, if one accepts the premises (1) that pain has such strong motivational consequences that it "forces" people to engage in whatever activities are needed to obtain pain relief and (2) that relief of pain represents a legitimate goal for patients, many of the behaviors of CNMP patients in relation to opioids would be construed as understandable and legitimate, even though comparable behaviors by individuals who are not in pain would be construed as strong evidence for opioid dependence. Thus, acceptance of these premises challenges the relevance of several of the *DSM-IV TR* criteria to CNMP patients.

Another problem in applying *DSM-IV TR* criteria for opioid dependence to pain patients is that withdrawal and tolerance are two of the criteria. An individual who demonstrates both physical dependence and tolerance to an opioid would meet *DSM-IV TR* criteria for the diagnosis of opioid dependence if he/she met any one of the other five criteria. Pain specialists assume that patients who receive long-term opioid therapy will develop opioid tolerance and physical dependence but maintain that such predictable changes should not be accepted as indicators of addiction in these patients. For example, Portenoy[99] states: "Although physical dependence, like tolerance, has been suggested to be a component of addiction. . ., the clinical experience gained in the population with chronic pain strongly affirms that addiction should be defined in a manner that fully distinguishes it from physical dependence. . . . The fundamental distinction between addiction and physical dependence implies that clinicians should never label patients who are presumed to be at risk for an abstinence syndrome (that is, physically dependent) as *addicted*."[99] Because of the conviction among pain specialists that physical dependence is not an indicator of abnormal behavior on the part of a patient, most prefer the term "addiction" to the term "dependence" when discussing opioid-related behavior that is abnormal. Trescot et al.[100] describe addiction as follows: "Addiction is a dysfunctional use behavior that includes one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving." This definition emphasizes inappropriate behavior in relation to opioids and omits any reference to physical dependence or tolerance.

A third issue that complicates the application of the *DSM-IV TR* definition of opioid dependence to patients with CNMP is that pain specialists[101,102] have often accepted the premise from cancer pain management[103] that there is no inherent ceiling to opioid dosing. Also, it is not unusual for patients to receive opioids for several years. Consequently, it is difficult to apply the *DSM-IV TR* criterion "Substance taken in larger amounts or over a longer period of time that was intended."[4]

Finally, the social context within which opioid therapy for CNMP occurs also complicates any discussion of opioid addiction in CNMP patients. In contrast to heroin or methamphetamine, prescription opioids are substances that can be obtained and used legally. But in contrast to alcohol, prescription opioids are not freely available to pain patients. Physicians act as gate keepers who control the access of patients to the medications. Since decisions about opioid use emerge out of a dialog between patients and physicians, patients' opioid usage patterns are influenced by some combination of their perceptions of their opioid needs, their ability to communicate their preferences to treating physicians, and the beliefs and preferences of treating physicians regarding opioid therapy. As one example of the complexities introduced by these social factors, a patient who is in fact ad-

dicted to opioids but has a very accommodating physician might not display behaviors indicative of addiction because his or her habit is routinely "fed" by the prescribing physician. At the opposite extreme, a patient under the care of a physician who refuses to prescribe any opioids might engage in drug seeking behaviors and seem preoccupied with getting opioids.[104]

Given the above complications, it is difficult to say exactly what *DSM-IV TR* opioid dependence means when the term is applied to a patient with CNMP. The fact that the patient takes an opioid on a regular basis does not prove addiction, even if his or her daily dose is high. The patient may appear preoccupied with obtaining opioids, but this phenomenon could be construed as evidence of the "irresistible force" of persistent uncontrolled pain. In principle, a physician could conclude that a patient was addicted if the patient took opioids when he or she was not experiencing pain, or took them in order to get "high" rather than to get relief from pain. But physicians essentially never have this kind of detailed information about the experiences of patients just before or just after they take opioids. The problems of applying *DSM-IV TR* criteria to pain patients are summarized in Table 90.4.

In practice, pain physicians typically rely on indirect indicators when they make inferences about opioid dependence in CNMP patients.[93,98] For example, they are likely to suspect such dependence when patients engage in aberrant behaviors (Table 90.5), demonstrate poor judgment in relation to opioids (e.g., drive while heavily sedated), or insist on increasing doses of opioids despite demonstrating behaviors that suggest drug toxicity.

The term "pseudoaddiction," introduced by Weissman and Haddox[104] in 1989, pulls together many of the concepts which have been developed by pain specialists and which distinguish their perspective on opioid use and abuse from that of addiction medicine physicians. Weissman and Haddox[104] said: "We have termed this syndrome pseudoaddiction because of the strikingly similar behavioral pattern seen in patients such as the one reported here to patients with idiopathic opioid psychologic dependence, namely, an overwhelming and compulsive interest in the acquisition and use of opioid analgesics. However, unlike true opioid psychologic dependence where the underlying cause is unknown, pseudoaddiction is an iatrogenic syndrome caused by the undermedication of pain."[104] They indicate that the appropriate treatment for pseudoaddiction is an increase in the opioid dose prescribed for a patient.

The concept of pseudoaddiction implies that patients may be driven to seek opioids compulsively because of the severity of their pain. Thus, as the term pseudoaddiction reveals, behaviors that are normally taken as indicators of addiction are now construed as indicators of the overwhelming "force" of untreated pain. Also, the concept is at least compatible with the idea that true opioid abuse is uncommon among CNMP patients being treated with opioids. In essence, it implies that even when a patient behaves in a manner that suggests drug addiction, the problem rests with the treatment program rather than with the patient. Finally, the recommended physician response to pseudoaddiction—to increase a patient's opioid dose—is at least compatible with the idea that there is no inherent limit to opioid dosing.

TABLE 90.5

EXAMPLES OF ABERRANT BEHAVIORS RELATED TO OPIOID USE

1. Used additional opioids than those prescribed
2. Used additional opioids than those prescribed more than once
3. Forged prescription
4. Sold prescription
5. Admitted to seeking euphoria from opioids
6. Admitted to wanting opioids for anxiety
7. Overdose
8. Injected drug
9. Abnormal urine/blood screen
10. Abnormal urine/blood screen positive for two or more substances
11. Solicited opioids from other providers
12. Unauthorized emergency room visits
13. Concurrent abuse of alcohol
14. Unauthorized dose escalation
15. Resisted therapy changes/alternative therapy
16. Reported lost or stolen prescriptions
17. Canceled clinic visit
18. Requested early refills
19. Requested refills instead of clinic visit
20. Abused prescribed drug
21. Was discharged from practice (because of aberrant behavior)
22. No show or no follow-up
23. Third party required to manage patient's medications

Modified from Webster LR, Webster RM. Predicting aberrant behaviors in opioid-treated patients: preliminary validation of the Opioid Risk Tool. *Pain Med* 2005;6(6):432–442.

Clinical Management of Opioid Addiction Within Specialty Pain Clinics

Pain specialists who prescribe opioids regularly for CNMP have to develop strategies for managing opioid addiction. However, there is no simple or uniform set of management procedures. Several factors contribute to difficulties in describing the behavior of pain specialists in relation to opioid addiction. First, a pain specialist's decisions about opioids for a patient depend on his or her assessment about whether opioids will benefit the patient, as well as his or her judgments about whether the patient is engaging in aberrant behaviors in relation to opioids. Second, there is significant variation across pain specialists with regard to use of opioids and management of opioid addiction. Finally, the procedures used by pain physicians to manage opioid addiction are generally not evidence-based. Fortunately, there are now consensus-based guidelines for managing opioid therapy[100]; the present discussion relies on these guidelines.

The management of issues related to opioid addiction can be divided into six areas: (1) initial screening and decision to use opioids; (2) establishing ground rules; (3) monitoring opioid therapy; (4) taking other steps to reduce the likelihood of aberrant behavior; (5) tapering opioids; and (6) referrals to other specialists.

1. Initial Screening: There is widespread agreement among experts that pain specialists should inquire about whether patients have present or past drug abuse problems and should be attentive to signs that patients might be prone to flout rules established by physicians. For example, if a patient reports being "fired" by other physicians because of disagreements regarding opioid therapy, this should be a red flag. In addition to interviewing CNMP patients about their past histories regarding drugs and alcohol, pain specialists can ask them to fill out a questionnaire designed to determine the risk that they will engage in aberrant behavior if they are treated with opioids. Several such questionnaires have been developed during the past several years.[9,93,105] These instruments are backed by some empirical data that support their validity. At this point, there is no instrument that is clearly superior to the others.[106] Finally, it is prudent for pain physicians to insist on an initial screening urine toxicology specimen before deciding whether to treat a CNMP patient with opioids.[6]
2. Establishing Ground Rules: There is agreement among experts that patients should sign a treatment agreement before opioid

therapy is instituted.[100,107] A pain specialist can choose from several prototypes that are in the medical literature[108] or can create his or her own. The treatment agreement should delineate behaviors that are considered appropriate or inappropriate by the prescribing physician. Agreed upon treatment goals and criteria for treatment success are crucial.

3. Monitoring Opioid Therapy: Pain physicians should monitor the therapeutic responses of patients who have been started on opioids and should determine whether they are experiencing side effects such as constipation. As far as monitoring for aberrant use is concerned, physicians should certainly keep careful track of their opioid prescriptions, so they know whether patients are exceeding their allotments. In some instances, information sharing among pharmacies alerts prescribing physicians to situations in which a patient obtains opioids from more than one physician. Also, physicians may insist on random urine toxicology screens and pill counts. There is no consensus among pain specialists about how to orchestrate these management tools.
4. Other Steps to Reduce the Likelihood of Aberrant Behavior: Traditionally, pain specialists have advocated for the use of long-acting opioids taken on a time contingent basis, rather than short-acting opioids that patients take on an as needed basis. One rationale for this recommendation is that experience with cancer pain suggests that a continuous background level of an opioid reduces the likelihood that a patient will experience severe spikes in pain that are very hard to control pharmacologically. Another rationale is behavioral. Some experts[109,110] have argued that if opioids are taken on an as needed basis, they end up reinforcing a patient's experience of pain and set the stage for excessive drug consumption by the patient. The strategy of having CNMP patients use long-acting opioids on a time contingent basis was originally promulgated by physicians working in multidisciplinary pain rehabilitation programs (see below). Although the appropriateness of this strategy is supported by animal research demonstrating a reduced risk of opioid-induced hyperalgesia when rats are maintained on steady levels of an opioid than when they are repeatedly subjected to opioid withdrawal,[111,112] the empirical evidence to support the efficacy of the strategy among CNMP patients is at best modest.[113] In the absence of definitive data, we believe it is prudent for a physician to consider the use of long-acting, time contingent opioid therapy, especially when he or she is treating a patient who has demonstrated poor judgment with respect to opioid consumption in the past. Another strategy is to use a "pain cocktail" in order to keep a patient blinded to his or her opioid regimen.[114] Thirdly, the treating physician might reduce the likelihood of aberrant behavior by prescribing opioids thought to have a relatively low abuse potential (e.g., methadone), rather than ones that historically have been associated with high abuse potential (e.g., oxycodone).[115] Fourth, the physician should give careful consideration to the issue of dose escalations. One of us (James P. Robinson) has found it useful to titrate a patient's dose until there appears to be reasonable pain control but to also make it clear to the patient that once a stable dose has been reached, it will not be increased. Finally, the physician should consider a range of adjuvant therapies that might help patients maintain control over their opioid consumption by contributing to pain relief and functional improvement. These include antidepressant or anticonvulsant medication, exercise therapy, and psychologic counseling.
5. Tapering Opioids: A pain physician might decide to taper a patient's opioids either because opioid therapy was judged to be ineffective or because the patient engaged in aberrant behavior in relation to opioids. However, if the aberrant behavior is an indicator of opioid dependence, a taper might well be ineffective, even if the patient stops receiving opioids from the pain physician. The problem in this setting is that the patient might resume opioid consumption either by getting prescriptions from another physician or by obtaining opioids illicitly. In this regard, anecdotal reports from outpatient clinics and numerous case series from pain rehabilitation programs indicate that CNMP patients can usually go through opioid tapers uneventfully.[110,116] However, follow-up of patients who go through such tapers is woefully deficient and informal observation by one of us (James P. Robinson) suggests that after patients complete treatment at a pain rehabilitation program, it is not at all uncommon for them to be restarted on opioid medications by their community physicians. It is also sobering to note that data from addiction medicine research indicate a high probability of relapse when opioid-dependent individuals undergo medically supervised withdrawal in the absence of further treatment.[27,30] Thus, it is entirely possible that pain specialists have generally been lulled into a false sense that opioid tapers are relatively easy to perform. If the aberrant behaviors actually do represent opioid dependence, in most cases it makes more sense to begin office-based buprenorphine treatment or to refer the patient for opioid agonist therapy elsewhere to reduce risk of relapse to problematic opioid use.
6. Referrals to Other Specialists: There is no consensus among pain specialists about the circumstances under which CNMP patients should be referred for specialty services regarding the opioids. The decision is easy in extreme situations (e.g., when a patient who is receiving opioids for CNMP shows up with new needle tracks and admits to using heroin). But pain specialists routinely encounter patients who insist on receiving high doses of opioids and ones who engage in at least low level aberrant behaviors, such as "losing" opioid prescriptions or requesting early refills. Most pain specialists treat at least some of these patients without assistance. As noted above, they typically cannot assess the effectiveness of their treatments, since they rarely get follow-up data on the patients. If a pain specialist does decide that he or she needs help, there are at least three choices. One is to refer the patient to an addiction medicine specialist, especially one who works closely with facilities that can provide supervised detoxification and rehabilitative services for people with drug dependence as described earlier in the chapter. A second option is to refer the patient to a pain rehabilitation program. This type of referral has the advantage of potentially managing the patient's opioid problem in the context of an overall pain management program. However, the down side of such a referral is that most pain rehabilitation programs are not well suited to addressing the needs of patients with significant addiction problems. The deficiencies of pain programs in this regard are so magnified now that virtually all such programs are carried out on an outpatient basis, in contrast to the inpatient treatment that was the norm when multidisciplinary pain rehabilitation was first introduced.[117]

Practitioners at pain programs have only one option for more specialized care for patients with drug dependence: referral to an addiction medicine specialist. We are not aware of any detailed published data on the frequency with which such referrals are made. Informal observation indicates that when staff at pain centers identify potential drug problems among patients undergoing screening for possible program admission, they triage them into three groups: (1) patients who are taking modest opioid doses and have no red flags for aberrant behaviors are typically admitted to the pain rehabilitation program, with the expectation that they can be tapered while going through the program; (2) ones who have no red flags for aberrant behaviors but are on high opioid doses are often started on opioid tapers prior to program admission, with the expectation that the taper could be completed as they go through their program; (3) ones with red flags for

substance abuse are typically referred to addiction medicine specialists.

With the advent of buprenorphine, a third choice has emerged for a pain specialist who has a patient exhibiting aberrant behaviors which ultimately lead to a diagnosis of opioid dependence. Pain specialists can now attempt to treat combined CNMP and opioid dependence in their offices using buprenorphine and referral to counseling or other ancillary services as needed.

CONCLUSION: AREAS WHERE IMPROVED COMMUNICATION BETWEEN PAIN SPECIALISTS AND ADDICTION MEDICINE SPECIALISTS IS NEEDED

From the foregoing discussion, it is apparent that addiction specialists and pain specialists have considerable overlap in their patient populations, but that their work with these patients has developed in two separate parallel tracks largely devoid of mutual interaction. The schism between the two fields is highlighted by the fact that attorneys have pitted addiction specialists and pain specialists against each other in legal proceedings involving alleged inappropriate prescribing of opioids.[118] Pain specialists, like most physicians, do not believe they have the knowledge or skill to treat addiction. Increasing evidence shows that in mild to moderate cases of addiction to nonopioid substances, particularly alcohol, physician intervention can control or ameliorate the problem. In cases of opioid dependence, physicians, including pain specialists, can manage these patients in their offices using buprenorphine. In fact, many pain specialists are in a unique position to do so because they already have a therapeutic relationship with the patient, and they have extensive expertise in opioid pharmacology. Addiction specialists should work to educate and empower pain specialists to manage cases of addiction when possible.

From the opposite perspective, pain problems are highly prevalent among patients seeing addiction specialists for acknowledged substance dependence.[3,119,120] Oftentimes, the pain problem goes untreated, exacerbating the addiction problem and creating a situation analogous but not identical to the pseudoaddiction described above. Pain specialists could help addiction specialists by educating them about prescribing opioids for pain when appropriate and monitoring functional outcomes to determine if the opioids are effective as well as by training addiction specialists in nonpharmacologic interventions for pain.

Of the many possible issues on which pain specialists and addiction medicine specialists might fruitfully collaborate, we note the following:

1. The conceptualization of drug dependence/addiction. Addiction specialists are accustomed to applying *DSM-IV TR* criteria, but pain specialists understandably lack confidence in these criteria, at least for the diagnosis of opioid dependence, in the context of a CNMP patient being treated with opioids. Although it would be difficult to accomplish, rigorous study of the application of *DSM-IV TR* criteria to this population might help to eliminate some of this uncertainty.
2. Identification of outcome variables. Whether treatment is directed at pain, addiction, or the combination of the two, it is important for physicians to identify criteria for determining when treatment has been successful. Pain specialists certainly consider pain reduction as an important outcome of treatment but also focus on patients' ability to function and the overall quality of their lives. Informal observation suggests that addiction medicine specialists have a perspective on criteria for successful treatment that is similar to that of pain specialists, but we are not aware of any collaborative efforts between the two specialties to identify these criteria.
3. Follow-up data on CNMP patients who receive opioid therapy, with attention to long-term opioid dependence. As noted above, it is possible that pain specialists have grossly underestimated the difficulties of tapering opioids in CNMP patients because they have not systematically followed the patients. The experiences and research methods of addiction medicine might help pain specialists fill this important gap.
4. Rules of thumb regarding when pain specialists should refer CNMP patients to addiction medicine specialists.
5. Strategies for optimal management of dual diagnosis patients (i.e., ones with CNMP and addiction).
6. Consideration of what is actually being treated when CNMP patients receive opioid therapy—especially at high doses. This chapter has focused on the possibility that when pain specialists try to alleviate patients' pain by prescribing opioids, they might inadvertently maintain opioid addiction or cause opioid addiction. Another possibility is that the opioids prescribed by pain physicians may function as psychotropic drugs rather than analgesics. This reflects the fact that CNMP patients may seek opioids in large part because the opioids blunt emotional distress associated with anxiety or depressive disorders.[121] These possibilities highlight the complexities of opioid therapy and of the patients who seek such therapy. Dialog among pain specialists, addiction medicine specialists, and other specialists (such as psychiatrists) might lead to more rational methods for evaluating and treating these challenging patients.

CHAPTER 91 ■ PHYSICAL THERAPY AGENTS

ROGER J. ALLEN AND ANN M. WILSON

INTRODUCTION

In the management of pain, physical therapists are available to aid in facilitating the patient's functional restoration via the prescription and pacing of therapeutic exercise and activities.[1–4] In concert with the functional physical restoration focus, physical therapy may also utilize therapeutic physical agents (frequently referred to as physical "modalities") for pain attenuation.[5–7] The philosophies and approaches to pain management may vary by clinical facility, yet the use of physical agents is widespread. While the application of physical agents may facilitate tissue repair, inflammation control, or temporary palliative relief, the use of a passive modality as a sole treatment approach is unlikely to lead

to long-term improvement in a patient's functional status. In treatment planning for pain management, thoughtful use of physical agents coordinates their application with physical restoration activities.

The physical agents used for pain management typically involve application of some form of heat, cold, light, electromagnetic, or acoustic energy to the body tissue involved in generating pain.[5,6,8] In the context of pain management, delivery of such energy to the tissues may assist in modifying the underlying process generating the pain or altering the transmission or perception of the pain message.[6] Physical agents may influence pain by a number of mechanisms such as causing temporary analgesia,[4,8] resolving inflammation and facilitating tissue repair,[5,6] modifying axonal conduction,[6] generating a counterirritant,[6] or altering muscle activation or increasing extensibility.[6] In addition, physical agents may also curb the development of maladaptive central neuropathic changes that could precipitate secondary chronic pain generators[9–11] or provide other means of palliative relief from pain perception.[7]

The utilization and selection of specific physical agents for pain management should be done on a case-by-case basis predicated on clinical impressions regarding the loci and underlying pathophysiologic processes of pain generation.[12] For a particular agent to be therapeutically useful, its effects must either address the pathophysiologic changes occurring at the tissue level or alter neural pain transmission or central processing.[12] If the origin of nociceptive pain is due to damaged and/or inflamed tissue, then locally operating agents are indicated. However, if pain is being generated by peripheral neuropathic factors or a central neuroplastic remodeling component, then potentially effective agents should be chosen from those capable of influencing neural transmission or central processing.

While pathophysiology is the primary consideration in the selection of physical agents for acute or subacute pain, additional factors must be addressed when considering physical agents for use in treating patients with chronic pain. For example, as distal subacute lesions evolve into chronic pain syndromes, the loci of pain generation may migrate.[10,12–17] Central pain generators may develop from neuroplastic remodeling of the dorsal horn, thalamus, or cerebral cortex.[10,15] Restrictions in activity and mobility in response to initial pain from the inciting lesion may lead to connective tissue changes and alterations in vascular physiology that develop into secondary pain generation sites.[13,14,16,17] Following resolution of the original lesion, secondary structural and pathophysiologic changes associated with lack of active motion may be perpetuating the pain from multiple and elusive locations.[14,18] The application of physical agents to the original lesion site may prove ineffective if the sources of the chronic pain are secondary generation sites or neural remodeling.

Another consideration related to the use of physical agents for the treatment of chronic pain is that while physical agents may influence pain processes in a number of ways, they are frequently used to provide temporary analgesia.[9,12,19] Thoughtful case-by-case consideration should be given to providing patients with chronic pain an external source of passive palliative relief.[2,12] Temporary pain relief via the use of physical agents may create a therapeutic window for the therapist to mobilize tissue or address movement impairments.[2] For some patients, however, a maladaptive cycle of pain behavior may develop from psychologic dependence on passive external palliative agents. Ultimately, this may reduce progress toward functional restoration by hindering the motivation to also actively engage in therapeutic physical activity.[2,12] Passive application of an agent that temporarily reduces pain may not only provide disincentives for the patient to approach pain management from an active or functional perspective but may also reinforce an external locus of control, whereby the patient attributes pain relief to procedures unrelated to his or her own activity or pacing.[2]

The various agents used by physical therapists in the management of pain include superficial heat and cold, light (such as low-level laser or monochromatic infrared energy), therapeutic ultrasound, shortwave diathermy, electrical currents (such as transcutaneous electrical nerve stimulation [TENS] and interferential current), and materials used to facilitate multimodal somatosensory desensitization.[12]

SUPERFICIAL THERMAL AGENTS

Thermotherapy

Thermotherapy, or the application of superficial heat, is used to increase circulation, enhance healing, increase soft tissue extensibility, and/or control pain. Heat may be delivered to superficial tissues via conduction with agents such as hot packs, paraffin wax dips, microwavable rice-filled cloth bags, electric heating pads, or air-activated wearable heat wraps. Superficial heat can also be delivered via convection using agents such as hydrotherapy or fluidotherapy. In the twentieth century, heat from infrared lamps was another popular way to deliver superficial heat. These lamps have largely been replaced by other agents due to safety concerns and are no longer in use in clinical practice.[20] In the context of pain management, potential therapeutic benefits of superficial heat are due to its effects on various metabolic, neuromuscular, and hemodynamic processes.

While the physiologic effects of superficial heat primarily influence tissue healing and acute nociceptive pain generation, thoughtfully applied thermotherapy may have utility in the comprehensive management of chronic pain. The oxygen-hemoglobin dissociation curve shifts to the right with mild increases in tissue temperature, making more oxygen available for tissue repair. Increases in enzymatic activity increase oxygen uptake by the cell, thus enhancing healing.[6] Increased skeletal muscle temperature (to 42° C) has been reported to decrease firing rates of gamma and type II muscle spindle efferents, while increasing Golgi tendon organ type Ib fiber firing rates.[21–23] This may reflexively reduce skeletal muscle tone and spasm by lowering alpha motor neuron firing rates.[24] Superficial thermal agents will not likely elevate muscle temperatures to the levels required to alter type II or type Ib activity due to their limited depth of penetration. Instead, heating the skin may lead to a decrease in gamma efferent activity, which in turn may lead to a decrease in muscle spindle activity and a reduction in muscle spasm.[6] Reducing skeletal muscle activity may also assist in breaking the pain-spasm-pain exacerbation cycle.[6,25]

Elevations in nociceptive threshold have been reported due to superficial heat.[26] By increasing activity of afferent thermoreceptive fibers, superficial heat may produce inhibitory modulation of dorsal horn pain gates.[6] Indirectly, pain may be influenced via local vasomotor effects and increased blood flow. Skin surface thermoreception directly releases bradykinins, leading to local vasodilation of the heated area.[27] Dorsal horn synapses from first order thermal receptor afferents inhibit sympathetic vasomotor efferents in the intermediolateral grey area, thus decreasing vasoconstriction neurogenically.[6] While sympathetic vasomotor outflow is decreased, local vasodilation and increased vascular perfusion may influence pain further by decreasing tissue ischemia,[28] returning nociceptors to normal firing thresholds by helping to resolve hyperalgesia, and clearing exacerbating metabolites such as prostaglandins from the region. Blood flow increases of as much as 30 mL per 100 g of tissue have been reported.[21] However, these effects influence superficial blood vessels and the tissues they supply. There is less evident vasodilation in deep muscle vasculature because of the limited ability of superficial agents to increase temperature in deeper structures.[6]

When applied in forms such as hot packs, paraffin, hydrotherapy, and fluidotherapy, superficial heat has been broadly evalu-

ated for effectiveness in the treatment of rheumatoid arthritis. Five well controlled studies have found it a beneficial adjunct,[29–33] while two found it ineffective[34,35] and possibly harmful by increasing collagenase activity which may have damaged compromised articular cartilage.[35] Uncontrolled, comparative studies report beneficial effects of superficial heat for trigger point pain in the neck and back,[36] neck and shoulder pain,[37] and chronic low back pain.[38–42]

Thermotherapy is contraindicated for the following conditions: applying heat over hemorrhagic areas; regions of acute injury, inflammation, malignancy, impaired sensation, or thrombophlebitis; the abdomens of pregnant women; or with patients with relevant cognitive impairments.[5,6,43] Caution should be used when applying heat over areas of impaired circulation, edema, superficial metal implants or open wounds, with patients manifesting poor thermal regulation, cardiac insufficiency, or acute inflammatory disorders, or with hypotensive patients or anyone prone to syncope when heating large body surface areas.[5,6,12,35,43]

Cryotherapy

Cryotherapy, or the therapeutic use of cold, can be used to control pain, minimize edema, reduce inflammation, enhance movement, and attenuate spasticity.[6] Cryotherapy can be administered with conductive agents such as ice bags or cold compression units. Cryotherapy can also be administered with convective agents such as cold whirlpool immersion, contrast baths, in which alternating heat and cold are used, or by evaporation using vapocoolant sprays. The therapeutic effects of cold result from its actions on metabolic, neuromuscular, and hemodynamic processes.[6]

A primary indication for cryotherapy is to minimize secondary hypoxic injury to adjacent tissue areas immediately following acute trauma.[5] By lowering metabolism of damaged and surrounding cells, they become more resistant to hypoxia resulting from disrupted blood supply to the region, making this the primary reason that cold is the agent of choice for the first 24–48 hours after injury.[44] This mechanism of minimizing the extent of tissue damage is dependent on immediate application of cold following trauma and is not a mechanism likely to be utilized in the management of chronic pain states.

Decreases in nociceptive input and pain perception via application of cold may occur because of influences in both local and central nervous system mechanisms. Vasoconstrictive response to cold decreases local release of vasodilating substances and chemical mediators, which in turn decreases nociceptor sensitization.[6,25] For every 1° C drop in interstitial temperature, nerve conduction velocity of somatosensory afferent fibers drops approximately 2 m/sec due to metabolic changes in the axon. A-delta fibers display the most sensitivity to cold mediated velocity attenuation.[21] The effects of application of a cryotherapy agent for 10–15 minutes may transcend immediate changes and produce pain reductions for more than an hour.[6] Prolonged analgesia may be the result of A-delta nociceptive fiber conduction block and the maintenance of subnormal deep tissue temperature for 1–2 hours following cold exposure.[6,45] Extended cold application has been shown to produce reversible neurapraxia.[46] Theoretically, by interrupting the pain-spasm-pain cycle, cold application may reduce muscle spasm, thus continuing pain relief after tissue temperature has recovered to precryotherapy levels.[6] Finally, by applying vapocoolant sprays over skeletal muscle and combining it with stretch, evaporative cooling may reduce muscle spasm and allow muscle with excess neurogenic tone to be stretched for increased range of motion.[6,47,48] The vapocoolant spray has been hypothesized to be effective in this capacity by providing a counterirritation to cutaneous afferents, which in turn leads to a reflex decrease in motor neuron activity and resistance to stretch.[6]

Existing literature is clear in support of the efficacy of cryotherapy in acute trauma management. It may also play a role in treating chronic pain. Uncontrolled comparative studies[47,49] and case studies[50,51] have reported that in the treatment of muscle spasms and myofascial pain, cryotherapy may be a beneficial adjunct. Additional comparative studies have reported it to be a useful clinical tool in managing chronic headache,[52,53] trigeminal neuralgia,[54] chronic osteoarthritis,[55] and low back pain.[42,56]

Cryotherapy is contraindicated for patients with Raynaud's disease or phenomenon; cryoglobulinemia or paroxysmal cold hemoglobinuria; those prone to cold urticaria, cold intolerance, or hypersensitivity; or over skin areas of impaired somatosensory discrimination, deep open wounds, areas of circulatory compromise or peripheral vascular disease, and regenerating peripheral nerves.[5,6,43] Cryotherapy should be used with caution over the main branch of a superficial nerve, on individuals with unstable hypertension, in patients with poor sensation, or those with poor thermoregulation.[5,6,43]

LIGHT THERAPY: LASER AND MONOCHROMATIC INFRARED ENERGY

Laser therapy utilizes light energy that has the unique properties of monochromaticity, coherence, and collimation.[6,57] These properties allow laser light to deliver electromagnetic light energy to tissue depths slightly below the dermis. Indirect physiologic effects occur at deeper levels due to the promotion of chemical reactions that mediate processes at greater tissue depths.[6,57–59]

Low level laser therapy (LLLT) used in rehabilitation settings to promote healing and manage pain utilizes lasers with power outputs less than 500 mW at a power density of 50mW/cm^2, and wavelengths ranging from 600–1300 nm.[5] This affords a depth of tissue penetration between 1–4 mm.[6,59]

The type of laser most frequently utilized for LLLT are semiconductor diode lasers that produce light in the red and near infrared portions of the electromagnetic spectrum. Diode lasers are usually hand-held probes that allow for treatment of small, localized areas. Superluminous diodes (SLDs) also produce light in the red and near infrared portions of the electromagnetic spectrum. They are brighter but less powerful than diode lasers. The advantage of SLDs is to allow hands-free operation and the ability to treat larger surface areas.[59,60]

While the mechanisms by which low-level lasers may modulate pain are not well established, there is consensus in the literature that LLLT can induce photomodulation effects of chromophores within affected tissue.[5,6,59,61,62] Cellular chromophores (light absorbing molecules) absorb photons from laser light as it penetrates the skin. Via influence over respiratory chain enzymes, chromophores may then undergo photobiomodulation in the form of either photobiostimulation or photobioinhibition.[5,63] A dose-response interaction effect occurs based on the Arndt-Schultz law of photobiologic activation.[5,63] Low doses of laser light activate photobiostimulation responses that are potentially efficacious for wound healing, whereas higher doses of laser light initiate a photobioinhibition response that may be beneficial for pain management.[5,63]

With possible application to temporary pain relief, LLLT has been hypothesized to influence nerve conduction velocity. There are reports in the literature indicating both slight increases and decreases in peripheral nerve conduction velocity due to low-level laser application with resulting changes in distal latencies.[64–67] Other studies report no effect on nerve conduction velocity following LLLT.[68,69] The influence of LLLT on clinically significant changes in nerve conduction velocity appears uncertain at this time. Other mechanisms by which LLLT may influence perceived pain remain to be explored.

Numerous studies have addressed the effects of LLLT with

respect to treating a wide array of pain generating conditions. Findings and applications cited here were derived only from controlled studies on human volunteers. For most disorders, the literature is split between studies showing some clinically significant beneficial effect over controls and those that do not. Trigger point stimulation with LLLT has been reported to relieve pain in two studies.[70,71] However, findings regarding myofascial pain treatment via laser have largely shown no significant effect over controls.[72–74] One of five controlled studies found a positive therapeutic response for epicondylitis.[75–79] The use of laser for rheumatoid arthritis pain has been found beneficial in four studies[80–83] and to have no clinical effect over controls in three.[84–86] Five studies found LLLT useful in the treatment of osteoarthritic pain, while two found no benefit.[87–93]

Controlled human studies reporting benefits from LLLT have been published that address pain conditions originating from specific loci including postherpetic pain,[94] perioral herpes pain,[95] postsurgical abdominal pain,[96] and trigeminal pain.[97,98] Laser therapy did not demonstrate significant benefits in controlled human studies reviewed regarding effects on muscle soreness,[99,100] plantar fasciitis,[101] chondromalacia,[102] orofacial pain,[103] temporomandibular joint disorder,[104] ankle pain,[105] or tendinopathies.[106–108]

Contraindications to LLLT include exposing any of the following to laser light: photosensitive skin areas; hemorrhagic areas; any area within 4–6 months after radiation therapy[6]; neoplastic lesions; unclosed fontanelles in children; the abdomens of pregnant women; over the heart, vagus nerve, or sympathetic innervation routes to the heart of cardiac patients; or locally to endocrine glands.[5,6,43,57] In addition, exposure of the cornea of the eye is also contraindicated. Therefore, both patient and therapist must utilize protective eye wear. LLLT should be used with caution over areas with compromised somatosensation, epiphyseal regions of long bones in children, gonads, infected areas, and with patients displaying fever, epilepsy, or mental confusion.[5,6,43]

Infrared radiation, once widely used as a superficial heating agent, has recently emerged as another form of light therapy that may have effects on processes leading to pain relief, tissue repair, and restoration of protective sensation. The new infrared devices produce monochromatic infrared energy (MIRE) from the near-infrared portion of the electromagnetic spectrum at a wavelength of 890 nm through a series of 60 gallium aluminum arsenide diodes in a flexible pad.[20]

The physiologic effects of MIRE on biologic tissues are thought to be due to photochemical reactions in the skin similar to LLLT rather than thermal reactions. Light energy from MIRE devices causes an increase in plasma nitric oxide (NO) from red blood cells, leading to vasodilation and increased circulation. NO is thought to facilitate vascular perfusion, resulting in improved tissue oxygenation, delivery of nutrients, and removal of waste products of metabolism.[109] The vascular effects and increased oxygenation to the tissues may facilitate wound healing and may explain the promotion of nerve growth and resultant improvement in sensation that has been observed in individuals with peripheral neuropathy.[20,110,111]

The precautions and contraindications to MIRE include avoiding placement over the low back or pelvic regions of pregnant women or over cancerous lesions. Goggles are not required during treatment because the diode arrays block the infrared radiation from the eyes. However, the pads should not be placed over the eyes.[20]

The small volume of literature available on MIRE suggests that it has potential for the treatment of pain and spasm associated with temporomandibular joint dysfunction, healing of chronic wounds, and restoration of sensation in individuals with peripheral neuropathy.[20]

THERAPEUTIC ULTRASOUND

Ultrasound is one of the most commonly used thermal agents in rehabilitation medicine[5,112,113] and is widely used as an adjunct to the management of pain and inflammation by physical therapists.[4,114–116] It is capable of producing elevations in temperature at tissue depths of up to 5 cm through the conversion of acoustic energy into heat within body tissue.[6,117] Therapeutic ultrasound can be used as a thermal agent to increase deep tissue temperature or increase pain threshold or as a nonthermal agent to facilitate tissue repair.[6] Ultrasound can also be used to facilitate the passage of medication, such as hydrocortisone preparations, into the tissues.[6]

Therapeutic ultrasound utilizes a reverse piezoelectric effect. Acoustic waves are generated by a crystal sound head at frequencies of either 1 or 3 MHz.[12] Amplitude densities are typically between 0.1 and 3 watts/cm^2.[12] Frequency and depth of penetration of the therapeutic ultrasound beam are inversely related. That is, 3 MHz ultrasound is capable of producing heat in tissues up to 2 cm from the skin surface, while ultrasound delivered at 1 MHz can reach depths of up to 5 cm.[6,118] These parameters are in contrast to ultrasound sources used for diagnostic imaging whose purpose is not to generate heat. Diagnostic ultrasound beams carry higher frequencies and lower wattage.[12]

Molecules within soft tissue vibrate due to rarefaction and compression as acoustic waves pass through them. Heat is generated, and thus increased tissue temperature, from the microfriction caused by this increased vibratory movement of molecules.[5] Sonic impedance variations within body tissue also facilitate heat generation in the presence of acoustic waves. In general, tissues with high absorption coefficients (i.e., those with low water content or collagen-rich structures such as tendon, cartilage, and bone) will attenuate more ultrasound energy than tissues with low absorption coefficients such as fat or muscle.[6,118] The thermal effects of ultrasound, which include acceleration of metabolic rate, increased circulation, reduction of pain and muscle spasm, changes in nerve conduction velocity, and increases in collagen tissue extensibility, are essentially the same as those of superficial thermal agents except that the structures heated are different.

The nonthermal effects of ultrasound are thought to be caused by the processes of cavitation, microstreaming, and acoustic streaming.[6,118] As oscillating acoustic waves pass through soft tissue, microscopic bubbles, or cavities, are formed from the effect of cyclic drops in pressure on normally present minute gas pockets. Ultrasound produces a state of stable cavitation such that the microscopic bubbles formed pulsate without imploding. A flow of fluid is then established around the pulsating microbubbles, which is referred to as microstreaming, along with acoustic streaming which is the circular flow of cellular fluids.[5,6,117] These processes have been reported to alter vascular wall permeability, cell membrane activity, and facilitate soft tissue healing.[5,117–119] In order to produce the beneficial nonthermal effects of ultrasound without causing an appreciable rise in tissue temperature, a pulsed mode with a duty cycle of 20% or less is used.[6]

The primary clinical indications for continuous (thermal) ultrasound are soft tissue shortening due to decreased collagen tissue extensibility in structures within 5 cm of the skin surface or pain. Via alterations in tertiary molecular bonding, heating collagen increases its extensibility. This property allows therapists to utilize ultrasound in treating structural contributors to chronic pain[13,14] such as maladaptive shortening of connective tissue, joint contractures, scar tissue, and tissue adhesions.[5,6,117]

Increased nociceptive thresholds may occur with exposure to continuous thermal ultrasound, thus giving the agent the potential to reduce perceived pain by influencing peripheral nociceptive activation and transmission.[5,6,12,21,117] Hypothesized mechanisms for increased nociceptive threshold include heat activation

of large diameter afferent fibers, alteration of nociceptor receptor sensitivity, and counterirritation.[117]

Ultrasound has been reported in the literature to be effective in helping manage pain originating from a variety of sources and sites. Some examples of these include myofascial trigger points,[117] muscle spasms,[120] epicondylitis,[121] carpal tunnel syndrome,[122] tendonitis,[123] back pain,[124] complex regional pain syndrome (CRPS),[125] phantom limb pain,[126] and soft tissue lesions.[127]

Nonthermal (pulsed) ultrasound is used to stimulate cellular activity during acute inflammation and repair.[6] This phenomenon has been studied extensively in vitro and with animal models.[5] The majority of human trials have been limited to individuals with chronic wounds that may not, however, respond to the ultrasonic energy in the same way.[118]

Another application of nonthermal ultrasound is for treating pain and inflammation via phonophoresis. Steroid preparations such as dexamethasone or hydrocortisone or an analgesic such as lidocaine is used between the sound head and the skin surface as a coupling medium.[6,117] Ultrasound alters the permeability of the stratum corneum which facilitates the passage of the medication transdermally into the tissues.[6,128] While the purpose of this mode of medication delivery is to facilitate local tissue effects, drugs administered via phonophoresis do enter general circulation and systemic contraindications must be taken into account.[6]

In controlled human studies, ultrasound has been reported to be an effective clinical tool in the management of shoulder pain,[129] adhesive capsulitis,[130] pain associated with prolapsed intervertebral discs,[124] and soft tissue lesions.[127] Mixed results have been reported in controlled studies for its effectiveness in the management of carpal tunnel syndrome,[122,131] elbow epicondylitis, shoulder calcific tendonitis,[123,132] and osteoarthritis.[133,134] No significant benefit over controls has been reported in controlled studies reviewed assessing the effectiveness of ultrasound for treating subacromial bursitis,[135] shoulder peritendonitis,[136] postextraction dental pain,[137,138] and perineal postlabor pain.[139,140]

The potential influences of therapeutic ultrasound on pain mechanisms primarily occur at the tissue level. It is therefore of little potential value for treating central pain states or chronic pain conditions perpetuated by neuroplastic remodeling.[12] Consideration of utilizing this physical agent with patients experiencing chronic pain should be based on individual evidence that the patient's pain generation has a nociceptive component due to an active peripheral lesion or inflammation.[12]

Contraindications include the direction of ultrasonic acoustic energy over gonads; pregnant abdomens; orbits of the eyes; epiphyseal growth plates in skeletally immature patients; fractures; malignant lesions; hemorrhagic, ischemic, thrombotic, insensate, or infected regions; plastic implants or cemented areas of prosthetic joints; areas exposed to radiotherapy within 6 months; spinal cord region postlaminectomy; and electronic implants and neurostimulators.[5,6,12]

DIATHERMY

Diathermy is the therapeutic application of short wave (10–100 MHz) or microwave (300 MHz–300 GHz) electromagnetic radiation that is converted to heat within body tissue.[5,12] The only type of diathermy in clinical use today is shortwave diathermy (SWD). SWD devices use high frequency alternating currents that oscillate as specified radio frequencies between 10 and 50 MHz. The radio frequency most commonly used for the shortwave devices used in therapy is 27.12 MHz.[6] Diathermy can be delivered continuously (continuous SWD [CSWD]) or pulsed, in which the electromagnetic radiation is interrupted at intervals (pulsed SWD [PSWD]). Thermal effects are present with CSWD, while PSWD can be delivered in such a way that the thermal effects are either minimized or negligible. (For the purposes of this chapter, the term PSWD will be used to describe only nonthermal pulsed SWD.)

SWD has potential advantages over other agents. It is capable of delivering heat to deeper tissue levels than superficial agents such as hot packs.[6] Larger areas can be heated than with other penetrating agents such as ultrasound.[6] Finally, a transmission impedance change does not occur with shortwave radiation while passing from soft tissue to bone. As a result, unlike ultrasound, shortwave energy is not reflected by bone and does not produce differential heating at tissue interfaces or present risk of burning at the periosteum.[6]

Heating of soft tissue may be accomplished by CSWD, whereas PSWD may be used to induce nonthermal physiologic effects.[5,6] When shortwave radiation is delivered to the tissue via CSWD, molecular kinetic energy increases physiologically lead to thermal effects such as increased rate of nerve conduction, increased collagen extensibility, vasodilation, increased nociceptive threshold, and acceleration of enzymatic activity.[6] Superficial heating produces physiologic heating effects within a few millimeters of the dermis, whereas CSWD may be used to produce these effects in tissues up to 3 cm from the surface.[6]

Short duration, low amplitude pulses of electromagnetic energy at a low duty cycle does not generate sustained increases in tissue temperature because of vascular perfusion and resultant dissipation of transient heat.[6] However, the application of pulsed energy produces a number of subthermal physiologic changes.[141] While nonthermal physiologic mechanisms are not fully understood, the result may be modification of cellular protein synthesis and adenosine triphosphate production via modified ion binding.[5,142–144] Electromagnetic field influences on ion binding produce a cascade of physiologic responses, including alterations in myosin phosphorylation, growth factor activation in fibroblasts and neurons, and macrophage activation.[6,145]

Most of the recent literature on the clinical efficacy of SWD is focused on the promotion of healing. Application of PSWD for 40–45 minutes is reported to increase microvascular perfusion of local tissue in normal subjects and at sites adjacent to ulcers in patients with diabetes.[6,146,147] By increasing local perfusion, PSWD has the capability to enhance nutrient availability, increase oxygenation of deep tissue, decrease anaerobic metabolism, and assist phagocytosis.[6] While CSWD and PSWD produce different ratios of thermal to nonthermal effects, both modes of application appear to result in increased cellular metabolism and functioning.[5]

The potential indications for clinical application of CSWD include decreased joint and stiffness of large muscular areas. When combined with stretching, CSWD increases joint range of motion.[6] Clinical indications for nonthermal PSWD may include pain control secondary to edema reduction and enhanced healing of soft tissue injuries, peripheral nerve lesions, and fractures.[6]

Recent studies on the clinical efficacy of SWD have addressed its nonthermal effects and evaluated its potential to augment tissue healing, with a few studies addressing SWD application in the management of chronic pain. Pulsed electromagnetic fields, which is another term used in the literature for PSWD, have been reported useful for nonunion fractures,[148,149] failed arthrodeses,[150] and osteonecrosis.[151] Significant reductions in neck pain and increase in range of motion in patients with cervical spine injuries after using PSWD have been reported in two controlled studies.[152,153] Early controlled investigations reported beneficial results from SWD treatment of osteoarthritis, while more recent studies have not found diathermy to produce reductions in osteoarthritic pain intensity over controls.[133,154,155] In reviewed studies, diathermy has failed to manifest significant benefits over controls in treating ankle sprains.[156–158] Single uncontrolled studies are available with positive outcomes using PSWD in the treatment of posttraumatic algoneurodystrophy[159] and low back pain.[160]

The manner in which electromagnetic energy from SWD increases tissue temperature gives rise to noteworthy contraindica-

tions and precautions. Materials such as metals, fat, and tissues with high free water concentrations tend to absorb disproportionate amounts of electromagnetic energy.[6] Therefore, CSWD is contraindicated in the presence of metal implants, pacemakers, neurostimulators, malignancy, pregnancy, or over the eyes, testes, or open growth plates.[5,6,12] PSWD is contraindicated in the presence of pacemakers, neurostimulators, or copper-bearing intrauterine contraceptive devices.[6,43] SWD selectively heats liquid and adipose tissue, so precautions must be taken with obese patients, when a patient begins perspiring,[6] and over moist wound dressings.[5]

In addition to the contraindications listed for other thermal agents previously mentioned in this chapter, further contraindications to SWD include malignancy, pregnancy, and over insensate skin regions. CSWD should also not be applied over the eyes or epiphyseal growth plates in skeletally immature patients due to potential damage from heat generation.[5,12]

SWD has good tissue penetration properties and the ability to heat deep structures, yet its use in the treatment of pain is now very rare. This is primarily due to the potential hazards associated with its use. Its therapeutic index is uncomfortably low. The shortwave devices in use today have the capability of delivering PSWD at either a thermal or nonthermal level in order to help address and minimize some of the hazards listed above. In general, therapists typically use superficial agents or ultrasound rather than SWD for pain management. Nonthermal PSWD is most often used to facilitate wound healing.

ELECTRICAL CURRENT

The use of electrical stimulation for pain modulation has traditionally been referred to as TENS or electroanalgesia.[161] While the tissue level is the primary site of action for managing pain for most physical agents, TENS is thought to operate by interrupting the neural propagation of pain.[162] TENS can be delivered in different ways to modulate various types of pain. For example, sensory or motor-level stimulation is used to modulate peripheral nociceptive pain or peripheral neurogenic pain while noxious level stimulation may be used if the pain is centrally mediated or in the management of CRPS.[6,163]

There are four different modes of TENS currently in clinical use that may produce electroanalgesia: sensory level stimulation, motor level stimulation, brief-intense stimulation, and noxious level stimulation.[6,161] Sensory level stimulation is used for immediate temporary relief of acute, chronic, or postoperative pain. This type of stimulation, which is also known as high frequency or "conventional" TENS, delivers high frequency (30–150 pps), short duration (50–150 μseconds) pulses at an amplitude just below the motor threshold that causes comfortable paresthesia in the area of the electrodes.[161] Conventional TENS affects primarily large diameter afferent fibers and is thought to work via the "gate control" theory proposed by Melzack and Wall.[6,161,164] This type of TENS is appropriate for use during exercise, work, or functional activities. It should be noted that for a given patient, determination of an effective TENS electrode placement site typically requires some time and experimentation.[12]

Motor level stimulation is used for the management of chronic pain or in instances where longer duration pain relief is desired. This type of TENS, which is also known as "acupuncture-like" TENS, delivers low frequency (2–4 pps), long duration (100–200 μseconds) pulses at an amplitude that causes muscle twitches. This type of TENS is proposed to control pain by stimulating the production and release of endogenous opiates such as enkephalins and endorphins.[6,161] Acupuncture-like TENS is usually applied over a trigger point, motor point, or acupuncture point related to the painful region. It is not recommended for use during activities of daily living or exercise because of interference from muscle twitching.[161]

Brief-intense TENS combines the stimulus parameters that cause both sensory level and motor level stimulation, which is then delivered at the highest tolerable intensity. It is most often recommended for use during painful procedures such as wound débridement or joint mobilization.[161] Brief-intense TENS is high frequency (60–200 pps), long duration (150–500 μseconds) pulses at an amplitude that will cause strong paresthesia and a motor response under or between the electrodes.[161]

Noxious, or painful, level stimulation, which is sometimes called "hyperstimulation," is thought to lead to analgesia via activation of the descending pain suppression system mediated by the release of endogenous opiates.[161] This type of TENS is usually only attempted if other types of stimulation have not been effective. Noxious level stimulation requires low or high frequency, long duration (250 μseconds–1 second) pulses at an amplitude that causes a painful stimulus that is maintained for 30–60 seconds. This type of TENS is typically applied over acupuncture, motor, or trigger points. It is generally quite uncomfortable and should only be used with patients who are fully aware of the expected discomfort and who agree to its application.[161]

Although TENS is usually delivered via small battery-operated monophasic or biphasic pulsed current devices, two other types of current can also have similar effects on pain modulation. The parameters that are available on interferential current (IFC) units and high voltage pulsed current (HVPC) devices can be manipulated to create sensory level conventional TENS parameters. IFC is a waveform produced by the intersection of two circuits of medium frequency alternating current of slightly different frequencies. When the two circuits intersect, there is a summation or amplitude modulation that is equal to the difference in frequency between the two circuits.[6] This amplitude modulation is called a "beat frequency" and can be adjusted to coincide with conventional TENS parameters. It has been suggested that IFC may be more comfortable than other waveforms because it offers less skin impedance and penetrates more deeply than other types of current.[6] These claims are controversial, and there is not clinical data at this time to suggest that IFC is superior to conventional TENS parameters delivered by low voltage devices.[165]

HVPC is a type of current in which monophasic pulses of short duration (usually <100 μseconds) are used. The combination of the short pulse duration and high peak current generated by HVPS devices allows for comfortable stimulation.[165] HVPC can be easily adjusted to mimic conventional TENS. Its comfort makes it an ideal alternative to conventional TENS delivered by a low voltage device.[165]

While the primary indication for TENS is attenuation of acute and subacute pain, it has theoretical utility for chronic pain conditions where peripheral nociception is not the primary mechanism of pain generation. Foley[10] has suggested TENS as a treatment option used to reduce painful input to the spine as early as possible in order to fight central pain generation via dorsal horn remodeling of *N*-methyl-D-aspartate. It has also been hypothesized to use early sensory-level TENS to body regions other than the painful locus, thus providing a competing attentional stimulus to decrease the probability of long-term cortical remodeling.[12]

Significant clinical effectiveness has been reported in controlled human studies for TENS in the management of pain associated with osteoarthritis,[166–171] neck pain,[172] trigeminal neuralgia,[173] migraine headache,[174] postamputation and phantom limb pain,[175,176] peripheral neuropathy pain,[177,178] and shoulder pain secondary to stroke.[179] There is less consistency in the clinical efficacy literature for the use of TENS to help manage low back pain,[180–186] myofascial pain,[187,188] and pain associated with rheumatoid arthritis.[189–191]

In addition to the use of TENS for direct pain attenuation, electrical currents can also be utilized to resolve inflammation, enhance healing, and facilitate delivery of topical medication transdermally.[6,192,193]

Iontophoresis is the utilization of direct current to facilitate

transdermal delivery of local ionizable anesthetics and anti-inflammatories.[192,193] Ionic medications carrying a positive electrical charge are drawn to cathode electrodes and repelled by anode electrodes, while negatively charged medication compounds display the reverse behavior.[194] Iontophoresis was originally thought to drive the ions through the skin and into deeper tissues. Recent work suggests that iontophoresis may promote transdermal penetration by increasing the permeability of the stratum corneum.[6]

For managing chronic pain conditions via iontophoresis, several ionic compounds are in use. Negatively charged medications include dexamethasone for inflammation and salicylates for both acute and chronic muscle and joint pain.[192,194] Positively charged medications include hydrocortisone for inflammation, lidocaine for soft tissue pain and inflammation, and magnesium sulfate for skeletal muscle spasms.[192,194] Physical therapy clinics are typically equipped to administer medication via iontophoresis. However, the patient must bring the ionic medication preparation prescribed by the referring physician to the clinic.[12]

Given its reliance on direct current, sustained application of iontophoresis will produce a hydrochloric acid concentration beneath the anode and a hydroxide alkaline reaction beneath the cathode.[193] When used to excess, the accumulated pH changes may result in electrochemical skin burns. These subdermal pH changes also have the potential to affect drug ionization and stability.[12] However, iontophoresis has been demonstrated to effectively deliver select medications to the site of interest.[195–197] The actual depth of penetration of drug delivery with iontophoresis is uncertain. Several studies have found diffusion of various drugs at tissue depths ranging from 3–20 mm.[6]

Although there are few controlled studies in the literature addressing the use of iontophoresis for managing chronic pain, there are reports of significant clinical effectiveness for dexamethasone delivered using this method in treating postherpetic neuralgia,[195] plantar fasciitis,[196] and myofascial pain of the shoulder (applied in combination with lidocaine).[197]

Contraindications to the use of electrical current include its use in individuals with either a demand-type pacemaker or known cardiac arrhythmias; over the anterior cervical region or carotid sinuses; over the abdomen, pelvis, or low back during pregnancy; in the presence of an implanted defibrillator, or any other implanted electrical device; and for individuals with venous or arterial thrombosis or thrombophlebitis.[6,43] The use of iontophoresis is contraindicated for patients with sensitivity to ionic medications and over open skin lesions.[5]

Precautions should be exercised when using electrical stimulation in the presence of skin irritation or open wounds, malignancies, osteoporosis (with motor-level TENS), or cardiomyopathies; over tissues susceptible to hemorrhage or hematoma, on patients with movement control disorders or impaired cognition, on craniofacial regions for patients with a history of stroke or seizures, and on patients who are driving or operating heavy machinery.[6,43] With the use of adhesive electrodes, precautions should be taken to prevent skin damage due to adhesive irritants and pH changes under electrodes when using direct current for iontophoresis or for prolonged applications such at TENS.[6,12]

SOMATOSENSORY DESENSITIZATION

Desensitization therapy involves exposing a patient's painful skin region to direct physical contact with a progression of materials that have the potential to trigger somatosensory irritation.[12,198–200] The indication for this therapeutic tool is treatment of allodynia associated with chronic pain conditions such as CRPS.[2,199–201]

Allodynia is a painful response to non-noxious somatosensory stimulation.[2,202] One of the hallmarks of CRPS, allodynia is not the same phenomenon as the normal hyperalgesia that follows tissue damage.[2,203,204] Patients experiencing allodynia may avoid the most seemingly innocuous tactile contact, sometimes refraining from wearing even delicate clothing over the affected area.[202,205,206] Allodynia treatment via desensitization aims at attenuating this abnormal chronic pain response and helping the patient return the affected area (frequently a limb) to normal somatosensory exposure and functional usage.[2,199–201,207,208] Somatosensory desensitization is also used in the treatment and prevention of postamputation phantom limb pain.[200,209,210]

Typical desensitization protocols involve having the patient rub the painful skin field with a progressive series of coarse or irritating materials.[200,201] Early desensitization therapy for CRPS used the chemical irritant capsaicin as the desensitizing agent.[211] In current practice, materials may progress from soft fabrics to items such as small pebbles or dry pasta.[201,205] Twice daily, the patient rubs the material over the affected area for approximately 2 minutes, then rests for 2–3 minutes, and finally rubs again for 2 more minutes.[12,201,205] Each week, the patient advances to a coarser or potentially more irritating material. Treatment course may span 2 to 4 months and includes home application and in-clinic checks at least weekly.[12,206,212]

Attenuation of allodynia via desensitization may be due to multifaceted mechanisms. These have been hypothesized to involve somatosensory habituation,[203] reintroduction of large fiber diameter afferent pain inhibition,[12,201] altered central processing of somatosensory input either at the dorsal horn or parietal lobe,[201,203] prevention of the development of new permanent neuroplastic pain pathways in the neuromatrix,[213] and normalization of exposure to the distal environment.[210] During the course of desensitization, the patient is encouraged to begin reintroduction of the limb or body area into normalized functional usage. With direction from the therapist, this reintroduced usage may facilitate a positive spiral of ascending exogenous analgesia and activity. Normal activities of daily living then become a continuation of the desensitization therapy and its ongoing effectiveness.[12,201,205]

Light touch somatosensory input is not the only tactile allodynia trigger. Some patients who have undergone successful desensitization to light touch or who never manifested light touch allodynia may still find non-noxious levels of pressure, vibration, or thermal variation to be painfully intolerable.[201,205,206,212,214,215] Desensitization therapy may therefore be specific to a given somatosensory modality. Therapeutic desensitizing agents must be matched to the type of somatosensory stimulation triggering the allodynia.[201,206,215] Therapeutic somatosensory desensitization may be performed using light touch,[199,200,205] thermal,[215] pressure,[206,212] or vibratory[213,216] stimuli.

While efficacy evidence from controlled studies is lacking, case studies have reported success in managing tactile,[205] thermal,[215] vibratory,[214] and pressure-related allodynia.[206,212] In one case study on the effects of pressure desensitization, the patient increased usage of analgesic medication during the desensitization trial.[206] Significant reductions in subsequent pain medication usage and pain intensity, combined with improved functional usage, suggested that use of analgesics to tolerate the desensitization therapy may not interfere with the treatment's effectiveness.[206]

Somatosensory desensitization is contraindicated over an active lesion that may be harmed by contact with physically irritating materials or mechanical pressure.[12]

CONCLUSION

There is a broad spectrum of therapeutic physical agents available to aid in the management of both acute and chronic pain conditions (Table 91.1). Determination of the suitability of physical agents and selection of the appropriate modality should be made

TABLE 91.1

CLINICAL APPLICATIONS AND EVIDENCE LEVELS FOR PHYSICAL THERAPY AGENTS

Agent	Uses	Clinical evidence level* and references
Thermotherapy Hot packs Paraffin wax Fluidotherapy Electric heating pads Air-activated wraps Rice-filled cloth bags	• increase circulation • increase soft tissue extensibility (up to 0.5 cm from surface) • reduce pain-spasm-pain cycle • decrease stiffness • pain control	Grade I[26,29–35]
Cryotherapy Ice bags Ice massage Cold compression units Vapocoolant sprays	• minimize inflammation • minimize edema • attenuate spasticity • pain control	Grade II[42,45–56]
Light Therapy Laser Monochromatic infrared	• increase microvessel circulation • tissue repair • pain control	Grade I[61,64–108]
Ultrasound Continuous (thermal) Pulsed (nonthermal) Phonophoresis	• increase circulation • increase soft tissue extensibility (up to 5 cm from surface) • facilitate tissue repair (nonthermal) • pain control	Grade I[119–140]
SWD CSWD (thermal) PSWD (nonthermal)	• increase circulation • increase soft tissue extensibility (up to 3 cm from surface) • facilitate tissue repair (pulsed nonthermal SWD) • pain control	Grade I[146–160]
TENS Interferential current Iontophoresis	• minimize inflammation • pain control	Grade I[166–193,195–197]
Somatosensory Desensitization	• allodynia attenuation	Grade III[206,212,215,216]

*The rating of clinical evidence level for pain management appearing in this table utilizes a hierarchy of three grades (I–III) describing the strength and quality of evidence that was developed by Canadian task force groups.[5,12] All three grades refer only to peer-reviewed studies published in refereed journals.
Grade I—Controlled studies conducted on human volunteers, regardless of blindness or level of randomization.
Grade II—Noncontrolled studies conducted on human volunteers.
Grade III—Human case studies.
Clinical evidence level should not be equated with a rating of clinical efficacy. For several indications of specific agents, separate Grade I studies may have yielded contradictory results.

with careful consideration of the mechanism of pain generation and pursued with careful treatment response monitoring.[12] It should be re-emphasized that while the use of physical agents for treating pain is common in physical therapy settings, their use should be viewed as adjunctive.[19,217] Effective pain management involves not just the attenuation of pain perception, but also restoration of compromised or lost function. Appropriate, comprehensive treatment integrates the application of physical agents with other indicated therapeutic activities to address the mechanisms of pain generation and facilitate functional restoration.

CHAPTER 92 ■ EXERCISE THERAPY FOR LOW BACK PAIN

ELLEN MCGOUGH AND JOYCE M. ENGEL

Exercise is the most frequently administered intervention used by physical therapists to treat low back pain (LBP) and prevent its recurrence.[1] Exercise for therapeutic purposes is defined as the systematic, planned performance of bodily movements, postures, or physical activities.[1] Regular exercise improves general fitness, results in a sense of well-being, and is associated with lower incidence and severity of comorbid conditions such as depression, fatigue, and insomnia, which are often associated with persistent pain.[2] There is support for the efficacy of exercise interventions for LBP; however, there is not yet a clear understanding concerning which components of exercise account for its benefits. There is also support for individualized exercise programs for patients with LBP across the spectrum of acute to persistent LBP.[3,4] The purpose of this chapter is (1) to describe the physical therapy (PT) evaluation and decision-making process for the development of individualized exercise programs for LBP, (2) to discuss physical and psychosocial aspects of exercise programs that may affect patient outcomes, and (3) to present available evidence for exercise approaches used for LBP.

LBP of musculoskeletal origin is a common problem and a major cause of disability. In 2006, an estimated one in four adult Americans reported that they have had a day-long pain episode in the past month with 10% stating the pain lasted a year or more.[5] Eighty percent of the population report LBP at some time during their lives,[6] and LBP is the most common cause of work-related disability in people under 45 years of age.[7] Despite the common use of pain medications, two thirds experiencing chronic or persistent pain cannot perform routine activities.[8] The annual financial cost (direct medical expenses, lost income, lost productivity) of all persistent pain syndromes is at least $100 billion.[8] Over and above the financial cost of LBP, the human cost, in terms of suffering and impact upon quality of life, cannot be estimated.

According to the American Chronic Pain Association, ''persistent'' pain is a more accurate description than ''chronic'' pain, as the former includes information on how pain can interrupt functioning, well-being, and quality of life.[9] The term persistent pain therefore will be used throughout this chapter. LBP is considered a condition, rather than a disease,[6] with multiple physical and psychosocial factors that impact the prognosis for recovery across the continuum of acute to persistent LBP conditions.[10] LBP not originating from serious spinal pathology or nerve root pain is often classified as ''nonspecific LBP'' due to our current inability to identify pathologic changes.[11] However, several classification systems have been developed to provide a framework for selecting PT interventions for the treatment of musculoskeletal LBP, including approaches to exercise.[12–15] Despite the fact that the majority of patients with isolated LBP cannot be given a precise pathoanatomic diagnosis, exercise interventions hold promise for reduction of pain and disability.[3,16,17]

Exercise for musculoskeletal LBP is just one component of a multimodal PT treatment program which often includes education of anatomy and pathomechanics, postural modification, body mechanics training, manual therapy, functional training, and physical modalities (e.g., thermotherapy, cryotherapy, electrical stimulation). Due to the complex nature of persistent pain, multidisciplinary interventions are often indicated which typically include exercise, relaxation training, cognitive restructuring, vocational counseling, and medication management.[18–20]

Designing an individualized exercise program is a dynamic process initially based on the patient's impairments and exercise tolerance and then adapted to address the patient's goals of restoring function and returning to activity and participation. Specific exercises are used for the purpose of reducing LBP symptoms and addressing physical impairments, such as muscle weakness, loss of range of motion (ROM), or decreased motor control. Specific exercise approaches are often selected based on different theories of underlying pathophysiology (e.g., disc pathology,[21] lack of segmental motor control,[22–25] or dysfunction in joint mechanics caused by factors such as hypermobility or hypomobility[26,27]). Exercise interventions designed to address body region impairments are often based on theories of movement dysfunction and muscle imbalance. This type of exercise program focuses on the correction of postural alignment, modification of faulty movement patterns, and improvement of neuromuscular control imbalances between agonist and antagonist muscle groups.[15,28]

Over the course of LBP management, patients should transition from specific exercises to a more global exercise program focused on conditioning and prevention of relapse. Global exercise programs encompass exercises for general conditioning, including aerobic, flexibility, strengthening, and endurance exercises, and should be incorporated as soon as the patient demonstrates adequate tolerance and movement control. The purposes of global exercises are to enhance fitness, promote well-being, prevent injury, and improve activity and social participation. The ultimate goal is to integrate this type of exercise program into the patient's daily routine.

The overall goal of rehabilitation programs for individuals with LBP is to restore function, assist patients in returning to activity and social participation, and prevent relapse or recurrence. Functional restoration involves not only improving perfor-

mance of physical skills, but it comprises the integration of skills into the individual's social and physical environments. When designing an individualized exercise program, there are multiple dimensions of physical function to consider including balance, cardiopulmonary fitness, flexibility, mobility, muscle performance, neuromuscular control, postural control, postural stability, and equilibrium.[1,29] In addition to physical factors, psychosocial, environmental, and personal factors should be taken into consideration when designing an individualized exercise program.[30,31]

There is broad agreement that LBP and disability should be managed according to a biopsychosocial model which includes health-related, personal, psychologic, and social dimensions and the interactions between them.[10,19,31] While the origin of LBP and disability may be caused by a biologic condition, the development of persistent LBP and incapacity are subject to dominant psychosocial influences.[10] The International Classification of Functioning Disability and Health Model is a biopsychosocial model designed to measure health and disability at the individual and population levels.[31]

Disability is an umbrella term for impairments, activity limitations, and participation restrictions.[31] Three dimensions related to functioning and disability include (1) body functions and structures, (2) activities at the individual level, and (3) participation in society. Impairments of body functions and structures are defined as problems with physiologic functions and/or anatomic parts, such as loss of joint ROM or reduced muscle strength. Activity restrictions are problems with executing a task or action and reduced participation includes lessened involvement in lived situations such as work, recreation, or social activities. Contextual factors include aspects of the human-built, social, and attitudinal environments that create the lived experience of functioning and disability as well as personal factors such as sex, age, coping styles, social background, education, and overall behavior patterns that may influence how disablement is experienced by the individual.[32] Environmental factors may include physical or social barriers or facilitators to activity and participation.[31,33]

Changes in attitudes and beliefs may have as much impact as physiologic changes, resulting from exercise, on the activity and participation of individuals.[10,34–36] This indicates that physical, psychosocial, environmental, and personal factors should all be considered when designing individualized exercise programs. The physical therapy examination and decision-making process is described in Figure 92.1.

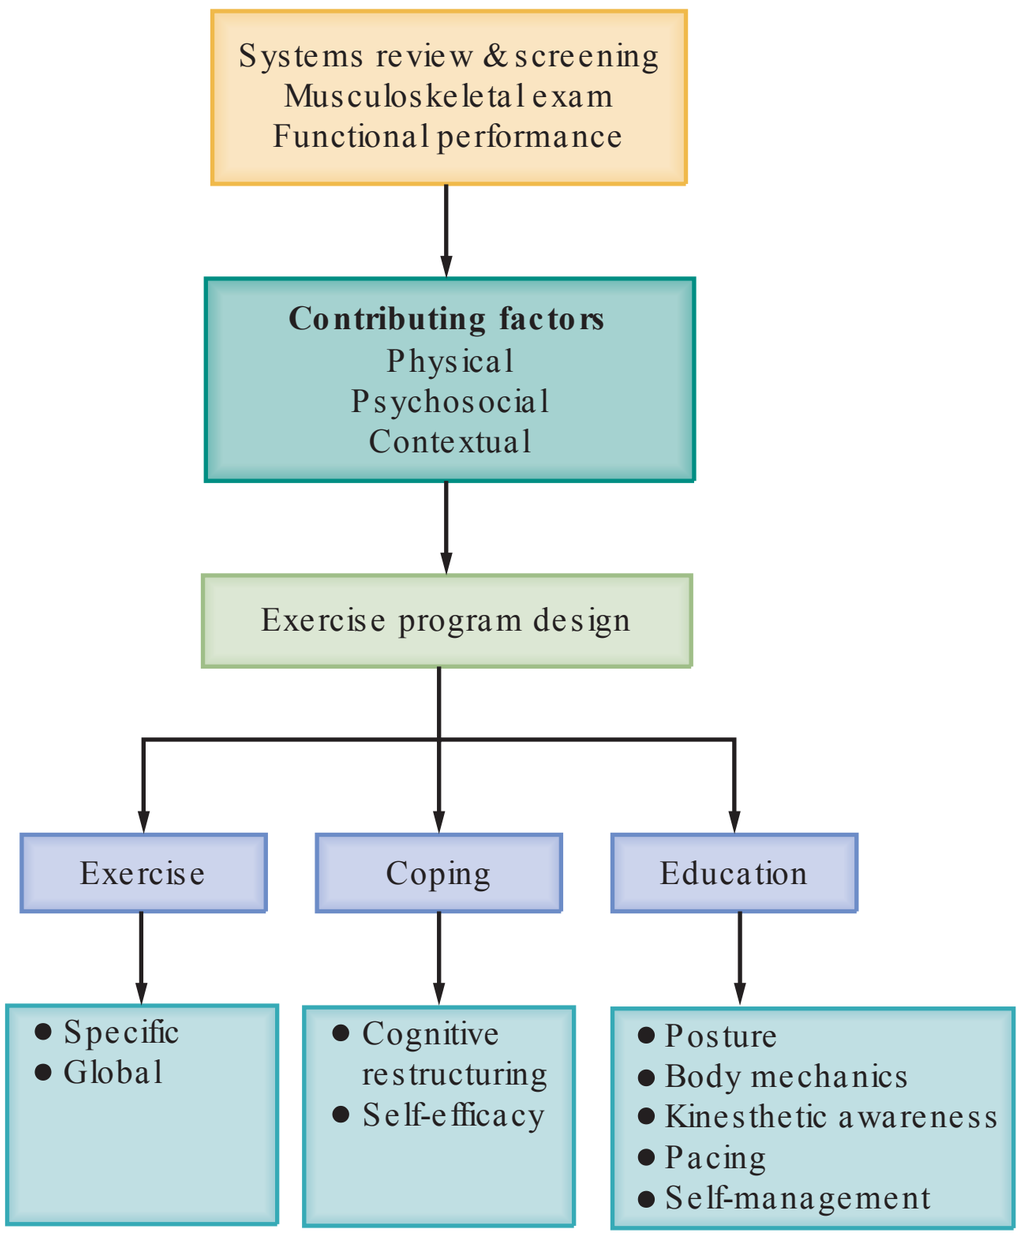

FIGURE 92.1 Physical therapy evaluation.

INDIVIDUALIZED EXERCISE PROGRAMS

Physical Therapy Musculoskeletal Examination

Individualizing the exercise program by mutual goal setting to meet both physical and psychosocial needs is essential in maximizing exercise adherence and achieving patient satisfaction.[37] Individually designed exercise programs with higher dosage and regular practitioner follow-up are associated with improvement in pain and function, especially in patients with persistent pain.[3] Supervision and adequate compliance are common aspects of randomized clinical trials that have demonstrated positive outcomes for exercise interventions for persistent LBP.[4]

Exercise programs designed by physical therapists should be individualized to the unique needs and abilities of the patient,[1] many of which can be identified in a comprehensive musculoskeletal examination. The goals of a PT musculoskeletal examination for patients with LBP include (1) to identify impairments contributing to LBP, (2) to screen for potential contraindications and precautions to exercise, (3) to screen for coexisting conditions (e.g., cardiopulmonary), (4) to record baseline measurements of impairments and activity restriction, (5) to identify barriers to activity and participation, (6) to establish baseline exercise tolerance, and (7) to understand the patient's goals, preferences, and resources for carrying out an exercise program. A PT evaluation also involves learning about the patient's understanding and beliefs about his or her back problem. In addition, the obligation to manage pain and relieve one's suffering is now recognized by governing bodies as fundamental to health care.[38]

A systematic musculoskeletal examination involves the patient's history, a systems review, special tests, and measurements.[39] In addition to questions regarding pain patterns and the nature of the back problems, the examination should include inquiry related to medical history (including previous musculoskeletal problems and interventions used), psychosocial issues, and environmental barriers to activities and participation. A systems review is conducted to screen for red flags and to identify potential problem areas. Screening of the neurologic system through testing of key muscles, sensation, and reflexes is an essential component of a LBP evaluation. Current guidelines also emphasize attention to psychosocial factors, such as the patient's attitudes, beliefs, concerns, and expectations about their back pain.[11] Screening of psychosocial factors is recommended to provide indicators for chronic conditions, referred to as yellow flags,[40] which may identify patients at risk for developing persistent pain.

Anatomical structures that may contribute to pain should be tested with a systematic approach to the examination including tests of active and passive movement, tissue palpation, end range testing, repeated movements, and sustained postures.[21,39,41] Examination of a patient's postural alignment, willingness to move, body mechanics, and movement patterns should also be incorporated to gain an understanding of problems related to posture and general mobility.[39] Functional performance tests and task analysis provide information related to the ability to perform activities needed to return to activity and participation, including employment.[1,39,41]

TABLE 92.1

The results of a comprehensive musculoskeletal examination will be used to identify physical impairments and psychosocial factors for which purposeful exercise interventions can be aimed. A comprehensive approach for an individualized program, including elements of exercise, coping, and education, can be developed based on the examination (Table 92.1). The patient's response and ability to perform specific exercises serve as an additional source of feedback for both the patient and physical therapist. During the acute stage of management, the selection of specific exercises is based on the patient's responses to the exercise direction and intensity and is modified according to the patient's symptoms and movement patterns. Advancing the exercises and functional activities is facilitated when the physical therapist re-evaluates and modifies the exercise program to maximize patient progress and fit the appropriate stage of management.

Designing Individualized Exercise Programs

When considering exercises for LBP, it is important to consider the purpose of the exercises and the stage of management. The purpose refers to the patient's and clinician's goals for the exercise intervention: (1) specific exercises designed for symptom reduction or addressing physical impairment (e.g., impaired muscle performance, joint mobility, flexibility, or kinesthetic awareness) and (2) global exercises for improving overall strength, flexibility, and endurance. The stage of management refers to a time frame or the physiologic status of the tissue.[42] Acute pain is often defined on the basis of the duration of an episode of LBP (i.e., one that persists less than 4–6 weeks[11,43]), as well as the suspicion of inflammation, since signs and symptoms including pain, muscle guarding, and tissue irritability are typically present. Subacute pain is defined as LBP persisting 4–12 weeks[11,43] and/or reduced tissue irritability and increased tolerance for movement. Depending on the stage of management, an exercise program for LBP may comprise specific exercises alone, specific and global exercises, or primarily global exercises. At any stage of management, matching the patient's baseline exercise and pain tolerance is essential to facilitate program adherence.[37]

Exercise Interventions for the Acute and Subacute Stages of Management

Acute Lower Back Pain

Designing an exercise program for a patient with acute or subacute LBP includes recommendations about body position, movement direction, exercise intensity, and activity level.[1,14,23] Common impairments and functional limitations associated with acute LBP include constant pain and muscle guarding, increased pain upon muscle contraction and stretching, and interference with activities of daily living (ADLs).[1] Although the timeline for recovery from an acute episode of LBP is generally considered to be within 4–6 weeks, relapse or recurrence is common.

During acute episodes of LBP, advice to stay active is recommended over bedrest since inactivity does not promote recovery and may even be detrimental to recovery.[10,11,44] Early advice to stay active has been associated with faster recovery, slightly less pain, greater functional recovery, less chronic disability, and less time off work.[11,43–45] Advice to continue typical activities and participation including work (when reasonable) is also recommended for the management of acute LBP.[11] Job modifications might need to be considered to facilitate continued participation in work activities.

Low intensity and specific exercises are recommended for patients with acute LBP[11,43] including direction specific and submaximal isometric muscle contractions performed in a neutral spine position or within the pain-free ROM.[24,25,46] Moderate-to-strong intensity muscle contractions are poorly tolerated during the acute phase of management.[11,43] Gentle active or passive exercises specific for symptom reduction are beneficial in reducing acute LBP,[47,48] but stretching is not recommended for acute injuries.[49] Additional treatments, such as manual therapy, cryotherapy, and transcutaneous electrical nerve stimulation (TENS), may assist with pain modulation and tolerance for movement during the acute stage of management.[25,42,43] Thermotherapy is generally contraindicated during the acute stage of management.[50]

Subacute Lower Back Pain

Pain intensity and tolerance for movement differ during the acute versus subacute stages of management indicating that exercises should be adjusted specifically for the stage of management.[51] As acute pain and muscle guarding subside, impairment may persist in muscle function, motor control, postural awareness, and functional activities during the subacute and persistent stages of management. The subacute stage of management involves a focus on postural and kinesthetic awareness, with the incorporation of submaximal strengthening and gentle stretching. Exercises should be completed in the pain-free ROM with emphasis to avoid further tissue irritation. Education in body mechanics, ergonomics, and relaxation are incorporated into the exercise pro-

gram at this stage of management.[1] In addition, education on relapse prevention and self-management of acute pain episodes is important.[1] The application of treatments such as manual therapy, electrotherapy, cryotherapy, and thermotherapy may be indicated to address soft tissue impairments and facilitate improved exercise tolerance.[50]

Persistent Lower Back Pain Stage of Management

The international guidelines for persistent LBP place less emphasis on advice for positioning, posture, and biomechanics than the guidelines for acute and subacute LBP. Instead, emphasis is placed on promoting activity and participation, improving coping strategies, and assisting patients in changing beliefs and attitudes about their pain.[11] Persistent pain and disability are associated with physical deactivation and deconditioning, influenced by both physical and psychosocial factors.[52]

In patients with persistent LBP, individualized exercise programs with regular clinician follow-up and a higher exercise dosage are associated with clinically significant improvement in pain and function.[3] Some experts have recommended that exercise programs be guided not by the patient's pain complaints, but instead by a predetermined step-wise system for exercise and activity progression. Fordyce[53] outlined such an approach when he applied operant conditioning principles to a graded exercise program for persons with persistent pain. An individual's tolerance to activity is achieved through the use of a quota system.

Quota Programs for Exercise Dosage

A quota system is a practical approach to making baseline exercise recommendations and progressively increasing the patient's tolerance for activity. Intervention should begin with a series of baseline trials in which the patient is asked to perform a demonstrated exercise to their tolerance. Tolerance is defined as the point at which a patient stops exercising due to pain or fatigue. The physical therapist then establishes a quota for each prescribed exercise or activity to be performed daily. Typically, initial quotas are slightly lower than baseline trials (e.g., approximately 75% of baseline mean) and are increased by predetermined small increments (e.g., about 10% every few days). The patient is praised for meeting his or her goal. Unlike traditional exercise programs in which the patient exercises to his or her perceived tolerance, the patient instead achieves a quota. The quota system eliminates the linking of pain with function that might result in overdoing on ''good days'' and avoiding exercise or activity on ''bad days.'' Rest breaks are scheduled instead of according to the patient's perceived need. Resting at the time of the individual's reported pain onset or exacerbation is avoided as it reinforces pain behaviors.[53,54] A gradual increase in activity also lessens the likelihood of an exacerbation of pain. Quota programs have been effective in increasing functional performance in persons with LBP.[55–57] Modalities (heat or cold) may be applied to prepare the patient for therapeutic exercise or to initiate activities.[58]

Relapse Management

Frequently, patients with persistent pain experience an acute pain episode or a significant exacerbation of their pain resulting from increased activity. Until the patient has recovered from the acute incident, the intensity of strength, flexibility, and aerobic conditioning exercises should be reduced, but the patient should be encouraged to maintain a tolerable level of exercise to avoid dehabilitation from inactivity. The patient may return to specific exercises to manage symptoms and regain mobility. An incremental, gradual increase in conditioning exercises can then be implemented.[58]

The Application of Common Exercise Approaches for Lower Back Pain

Specific Exercise

Through one-on-one evaluation and specific exercise instruction, the patient will ideally develop an understanding of principles for movement control and activity progression that will lay the foundation for progressing to a global exercise program and facilitate return to activity and participation. Specific exercise such as spinal stabilization or direction specific exercise may play a mediating role in reactivation through mechanisms involving early symptom management, improved kinesthetic awareness, and spinal region motor control.[25,59]

Spinal Stabilization Exercise Application. Spinal region motor control during functional activities can be enhanced through specific exercises, such as spinal stabilization exercises.[22,59] Submaximal training of deep lumbar musculature for the purpose of spinal segmental stabilization and movement control has also been referred to as motor control exercises for the lumbar region.[25] Research suggests that local impairments in the muscle system may be a problem of motor control rather than a problem of strength.[22,59] Spinal stabilization is a specific exercise approach designed to enhance the control of spinal orientation and intervertebral movement via training of deep trunk muscles, specifically the lumbar multifidus and transversus abdominis,[23] and sometimes also the rectus abdominis, quadratus lumborum, internal oblique abdominals, and erector spinae.[60] Spinal stabilization training is aimed at controlling pain and protecting the spinal segment from reinjury by reestablishing and enhancing motor control.[22] Restoring controlled segmental movement during static and dynamic functional activities is the ultimate goal of spinal stabilization exercises.[22]

Spinal stabilization (or motor control) exercises should be administered with direct one-on-one supervision, sometimes using ultrasound imaging, surface electromyography, or pressure monitoring devices to provide feedback to the physical therapist and patient about desired muscle recruitment.[24,25] Spinal stabilization exercises are low intensity and designed to be completed frequently throughout the day and integrated into daily activities.[23] Usually starting in the supine position with the hips and knees flexed, the therapist assists the patient in finding a neutral lumbopelvic position defined by anatomic landmarks and patient comfort. The patient is then asked to perform submaximal muscle contractions of the deep abdominal or multifidi muscles. Exercise progression proceeds from static (isometric) exercise in a supported position (supine or prone) to static exercise in less supported positions (e.g., 4-point, kneeling, or standing). Dynamic exercises through a controlled ROM are integrated into functional activities. The application of spinal stabilization during functional activities is emphasized across all stages of management, such as transitions from supine to sitting, sitting to standing, and ultimately to activities addressing the patient's participation goals. To facilitate improved functional mobility, the patient is instructed to perform submaximal muscle contractions during functional activities, especially when anticipating positions of potential mechanical stress.[60] The rate of a patient's progress toward performing higher functioning activities is dependent on their ability to develop controlled movement of the lumbo-pelvic region. The ultimate goal of spinal stabilization exercises is to integrate local motor control into functional movement, especially to prevent potential mechanical stress or pain.[60]

Directional Preference Exercise. Another form of specific exercise is the McKenzie approach to LBP. Exercises based on directional preference (DP) are at the foundation of the McKenzie approach.[14] DP is identified as a posture or repeated end-range movement in a single direction (flexion, extension, or side-glide/rotation) that immediately decreases lumbar midline pain or re-

duces the extent of referred symptoms to the extremities.[14] Exercises effective for symptom reduction are selected following a systematic examination in which the patient performs a series of repeated and sustained movements.[21] The position and direction of spinal movement that produces an immediate improvement in symptoms is selected for the patient to perform at home.[14] Patients are instructed to perform specific exercises that reduce peripheralization of symptoms and minimize LBP.[14] Peripheralization of symptoms occurs when movements or positions cause symptoms to radiate away from the midline of the back, into the buttock, or into the lower extremity. This applies to axial LBP as well as symptoms associated with sciatica. Centralization of symptoms occurs when symptoms move toward the midline of the spine, away from the periphery.[14,61] The patient is instructed that if centralization occurs during exercise, they are performing the exercise correctly. Conversely, exercises that cause symptoms to radiate away from the midline of the back, and perhaps into the buttock or low extremity, involve the wrong movement direction and/or incorrect position.[61]

In conjunction with DP exercises, postural correction and body mechanics instruction are a major component of an intervention using the McKenzie approach. For example, a common condition of mechanical LBP presents when pain increases during flexed postures and movements.[14,61] In this case, the patient would be assisted in an exercise progression that facilitates lumbar extension. Education to maintain posture with a bias toward lumbar extension with the use of lumbar rolls or back supports would be emphasized. Instruction would also be provided to maintain lumbar lordosis during all functional movements.

In summary, specific exercises such as DP and spinal stabilization are typically used for symptom relief, early mobility, and local motor control. Specific exercises are not only beneficial during the acute phase of management, but also in addressing specific impairments at any stage of recovery. For example, a patient with persistent pain may benefit from spinal stabilization exercises along with a general strengthening and conditioning for impaired spinal region motor control.[25,62] Similarly, a patient with persistent pain may address a local impairment, through symptom reduction and improving mobility, with the use of DP exercise.[47,48] While maintaining a focus on increasing activity and participation, an individual with persistent LBP may be able to manage local impairments through the use of specific exercises.

Global Exercise

The purpose of a global exercise program is to improve overall strength, endurance, mobility, and aerobic capacity. With the resolution of acute symptoms, a gradual progression of global exercise is indicated to improve strength and endurance of large muscle groups, optimize general flexibility, and increase aerobic capacity. Muscle strength and endurance training of the upper and lower extremities, with an emphasis on neutral spine mechanics and motor control, is important for promoting general muscle strength and endurance while avoiding excessive end-range forces of joints in the lumbar region.[63] The emphasis on neutral spine mechanics and motor control is also recommended when performing exercises for flexibility and aerobic conditioning.[63] During supervised exercise sessions, the physical therapist is able to provide feedback about motor control and body mechanics during functional activities. In addition, the patient is encouraged to integrate principles of motor control and body mechanics into the performance of daily functional activities.[63]

The overall goal of a global exercise program is to develop a regular exercise routine that is integrated into one's daily life and promotes well-being, prevention of injury, and enhanced activity and social participation. Matching the patient's goals and personal preferences for exercise is essential for maximizing exercise program adherence. In addition, considering physical and psychosocial barriers and facilitators to exercise is critical.[30] Through recommendations for the type of exercise, progression, and individual modifications (e.g., postural alignment, exercise tolerance), satisfaction and adherence are likely to be enhanced.

Types of aerobic exercises may include brisk walking, running, swimming, or biking. Exercise that allows partial unloading of joints such as aquatic exercises, use of an elliptical trainer, or biking are often better tolerated by those with arthritic changes or difficulty with high-impact weight-bearing exercise (especially spinal stenosis or lower extremity osteoarthritis). Postural alignment as well as impact forces should be considered for all patients with LBP including education about shock absorbing footwear and exercise surfaces. Walking typically results in extension movements of the spine[15]; therefore, patients who have no change in symptoms or reduced symptoms with extension may benefit from walking, if impact force is controlled (footwear, angle of the treadmill platform, quality of the platform used). In contrast, patients demonstrating increased pain with extension movements of the spine may do better with aerobic exercises in which the spine is neutral or slightly flexed (e.g., stationary bike).[64]

For the average healthy adult to maintain health and reduce the risk of chronic disease, aerobic exercise 30 minutes/day, 5 days/week at moderate intensity (or 20 minutes/day, 3 days/week at vigorous intensity) is recommended by the American College of Sports Medicine (ACSM) and the American Heart Association (AHA). Moderate intensity is defined as physical activity that involves exercising with enough intensity to raise one's heart rate and break a sweat, but still be able to carry on a conversation.[65] Muscle strengthening activities may include resistance exercises to strengthen major muscle groups, such as upper and lower extremity progressive weight training, or weight-bearing exercises such as squats and lunges. A minimal strength training intensity of 8–12 repetitions, 2 days/weeks is recommended by the ACSM and AHA.[65]

Recommendations regarding exercise dosage are similar for adults of all age groups, but older adults will need more attention to balance and safety issues for exercise.[65] As patients become more active, their general health improves, but the risk of musculoskeletal injury increases.[65] Therefore, guidance in pacing of activity, self-management of symptoms, postural alignment, and safe body mechanics are critical in facilitating continued activity and participation. It is essential that guidelines for exercise performance and progression be provided to each patient (Table 92.2).

Educational and Psychosocial Approaches

Positive outcomes of exercise interventions for persistent LBP may occur as a result of modified pain perception, improved mood, improved physical fitness, and a sense of well-being.[34] Cognitive-behavioral strategies are most often considered in cases of persistent pain, but may also be beneficial in preventing disability if initiated during the acute or subacute stages of management.[66] In conjunction with exercise interventions, cognitive-behavioral strategies to minimize fears and misconceptions around activity and LBP may contribute to improved function and reduced disability.[11,36,66] Persons experiencing acute pain may learn to avoid activities and participation due to a fear of continued pain and (re)injury. This cycle of fear of pain resulting in reduced activity and participation becomes well established and may result in decreased strength, mobility, endurance, and suffering.[36] Psychosocial factors associated with LBP outcomes include coping strategies, emotional reactions, attitudes, and belief systems.[35,67]

Cognitive-behavioral strategies focus on changing patients' self-perceived efficacy to cope with pain (e.g., reduction of catastrophizing or exaggerated negative thoughts) and pain interference (decreased activity and participation) in persons with chronic LBP.[68,69] Vlaeyen and Linton[70] proposed that a gradual modification and introduction of activities and participation, despite pain, would ultimately lead to fear reduction and increased

function. Results demonstrate improvements in self-reports of pain-related fear, catastrophizing, and disability.[71] Self-efficacy is defined as the sense of control that comes from patients' own beliefs in their ability to perform specific behaviors and coping skills.[72] Even brief educational interventions using an educational booklet have positive effects on patients' beliefs about LBP and have shown improved physical outcomes.[73]

EVIDENCE FOR THE EFFICACY OF EXERCISE FOR LOWER BACK PAIN

There is support for the efficacy of exercise interventions for LBP; however, there is not yet a clear understanding concerning which components of exercise account for its benefits. Several possible reasons exist for the lack of clarity around the efficacy of various exercise interventions, including (1) research study design and methodology problems,[3,74] (2) unclear definitions for acute, subacute, and persistent (or chronic) LBP,[51] (3) the inclusion of heterogeneous study populations in many studies,[75,76] (4) multimodal treatment interventions in addition to exercise,[3,17] and (5) the main effect of exercise programs may be a result of factors other than physiologic changes (i.e., psychosocial factors).[34]

Evidence for the Efficacy of Specific Exercise Approaches

Efficacy of Spinal Stabilization Exercises

In a study by Hides et al.,[24] fewer recurrences of LBP occurred following spinal stabilization exercises for first-episode LBP patients when compared to no exercise intervention. In patients with persistent LBP, supervised trunk strengthening or stabilization exercise programs incorporating flexibility and body mechanics instruction have been shown to be more effective than a waiting list, TENS, advice to take regular walks, or to independently complete a home program.[4] The greatest benefits of spinal stabilization occur during the initial phases of the rehabilitation process,[62] whether the stage of management is considered acute, subacute, or persistent.[19]

Recent studies have shown immediate or short-term benefits of incorporating spinal stabilization exercises, but limited long-term benefits beyond those of a general exercise program. In a randomized clinical trial involving patients with LBP, patients who participated in a spinal stabilization exercise program or manipulation treatment reported higher function and global perceived effects at 8 weeks versus patients participating in general exercise groups (aerobic, strengthening, and stretching). The stabilization and manipulation groups, however, were no different in their pain and disability from the general exercise group at 6- and 12-months follow-up.[25] Therefore, spinal stabilization exercises may be more beneficial than general exercises alone during the initial phases of the rehabilitation process.

Spinal stabilization exercises have not demonstrated long-term efficacy beyond that of general exercise programs. Two randomized clinical trials compared general exercise alone versus general exercises plus spinal stabilization exercises.[77,78] The groups performing spinal stabilization exercises in addition to more global exercises had similar long-term outcomes to those performing group exercises or participating in a conventional PT program (i.e., exercise, manual therapy, education, modalities).[77,78] In addition, general (or global) exercises reduced disability in the short-term to a greater extent than a stabilization-enhanced exercise approach in patients with recurrent LBP.[77] Another randomized controlled trial demonstrated no additional benefit, in terms of pain, function, or disability, of adding specific stabilization exercises to conventional PT treatment.[79]

Improved trunk ROM, muscle endurance, and decreased pain were reported in women with persistent LBP after completing a 4-week program of proprioceptive neuromuscular facilitation (PNF) exercises.[80] PNF exercises applied to the lumbar region would be considered a form of specific exercise for local motor control and strengthening. Improvement was reported after 4 weeks of training with dynamic resistance exercises, demonstrating better outcomes than the static (isometric) exercises.[80]

Efficacy of Directional Preference Exercises

The application of specific exercises based on DP shows potential benefit for patients early in the rehabilitation process during the acute, subacute, or persistent stages of management.[47,48] Pooled results of four trials comparing passive therapy with McKenzie exercises for acute LBP showed a statistically significant decrease in pain and disability favoring the McKenzie approach at 1-week follow-up. At 4 weeks, however, no difference in disability levels was noted between treatments.[46] At 12-weeks follow-up, patients advised to stay active produced superior results over the McKenzie exercises. One of the few studies including patients with persistent LBP (85% had symptoms >12 weeks), to evaluate the effect of 8 weeks of the McKenzie exercise approach versus intensive dynamic strengthening, showed a greater reduction in pain at 2 weeks in the McKenzie exercise group. At the 8-week and 8-month follow-up, however, there were no significant differences between groups in self-reported disability, global change of back-related quality of life, over-the-counter pain medications, or the number of visits to a general practitioner.[48]

Evidence for the Efficacy of Using Classification Systems for Exercise Selection

Matching the Exercise Program to the Patient

Treatment-based classification systems for LBP that match exercise approaches to patient baseline characteristics and impairments have recently been studied.[12,26,76] Long et al.[47] reported significantly greater short-term (2 weeks) improvement in pain

and function when patients were matched to a specific exercise direction based on symptom relief, compared to those matched with the opposite direction or multidirectional exercises. Since 46% of patients were considered to have chronic complaints, it appears that exercises based on DP have the potential to produce at least short-term improvement during all stages of LBP (acute, subacute, or persistent stages of management).[19,47]

A preliminary clinical prediction rule for identifying patients likely to respond to spinal stabilization exercises was developed by Hicks et al.[26] For patients completing a spinal stabilization program, a higher likelihood for improvement at 8 weeks (>50%) on the Oswestry Disability Questionnaire[81] was associated with 4 characteristics: (1) age of no more than 40 years, (2) straight leg raise greater than 91 degrees, (3) positive prone instability test, and (4) aberrant movement patterns. Fritz et al.[27] reported lower disability scores among patients receiving stabilization exercises who were classified with segmental hypermobility versus those classified with segmental hypomobility. A history of recurrent episodes of LBP is also an important indicator supporting the implementation of a spinal stabilization approach.[26]

In an attempt to study the impact of identifying LBP subgroups within acute and subacute LBP, Brennan et al.[62] compared the outcomes of patients with LBP receiving treatment (manipulation, spinal stabilization exercises, or DP exercises) matched and unmatched to their baseline subgrouping. Patients who received specific exercise interventions matched to their baseline impairments showed a significantly greater improvement on the Oswestry Disability Scale[81] after 4 weeks of treatment than those randomly assigned to a treatment group. This study provides support for individualized exercise programs based on LBP subgroups during the acute and subacute stages of management; however, these subgroups do not appear to hold up for persistent LBP.[62]

Selecting specific exercises based on baseline physical impairments may be most beneficial during the acute and subacute stages of management, but persistent pain appears to be more closely associated with psychosocial factors.[62] Elevated baseline scores on the Fear-Avoidance Beliefs Questionnaire[82] (indicating fear of movement) during the acute stage of LBP have been associated with altered movement patterns, activity limitations, and reduced participation at later stages of management.[36,83] A psychosocial approach to fear-avoidance beliefs involves a deemphasis on anatomic findings, encourages the patient to take an active role in his or her rehabilitation, and educates the patient to view back pain as a condition, not a serious disease and that pain does not equal harm.[66] George et al.[66] randomly assigned patients (<8 weeks of symptoms) to receive fear-avoidance-based PT (psychosocial approach + standard care PT) or standard care PT for a 4-week intervention period. Scores on the Oswestry Disability Questionnaire[81] at 4 weeks and 6 months were found to be dependent on an interaction between the type of PT (PT + fear avoidance approach versus standard PT) and the initial level on the Fear-Avoidance Beliefs Questionnaire.[82] Therefore, baseline fear-avoidance beliefs remained a significant predictor of disability at 4-weeks and 6-months follow-up.

Investigating the extent to which patients' adjustment to persistent LBP was influenced by their fear-avoidance beliefs, their tendency to catastrophize (excessive negative thoughts), and their appraisals of control, Woby et al.[36] explored the relative predictive utility of these factors. Fear-avoidance beliefs about activity were the only significant predictor of patients' disability, even after adjusting for age, sex, and pain intensity. It follows that patients with elevated levels of fear-avoidance beliefs related to their back pain may be more successful when cognitive restructuring interventions are incorporated into the delivery of the exercise programs.

TABLE 92.3

THE BENEFITS OF EXERCISE FOR LOWER BACK PAIN

- Reduce risk for musculoskeletal injury
- Reduce risk of comorbidity
- Improve mood
- Increase sense of well-being
- Improve activity and participation
- Reduce the risk of reoccurrence or relapse of LBP

TABLE 92.4

THE PURPOSE OF SPECIFIC VERSUS GLOBAL EXERCISES

- Specific exercises are used for the purpose of reducing symptoms, improving mobility, and enhancing motor control. This creates the foundation for the performance of global exercises and functional activities.
- Global exercise programs encompass exercises for general conditioning including aerobic, flexibility, strengthening, and endurance exercises for the purpose of promoting well-being, preventing injury, and enhancing activity and social participation. The ultimate goal is to integrate a global exercise program into one's daily routine.

Evidence for the Efficacy of Global Exercise

Aerobic conditioning, muscle strengthening, stretching, and skill-training exercises (e.g., work tasks, sport specific activities) are associated with decreased pain, improved function, and reduced disability in patients with LBP.[16,17] Improved aerobic fitness and decreased trigger point tenderness following a program of moderate-to-high intensity aerobic exercise have been demonstrated in patients with fibromyalgia.[84] Moderate-to-low intensity exercise is effective for more sedentary individuals. In addition, adequate loads during strength training appear to improve strength and may decrease symptom severity in patients with fibromyalgia.[84] It is likely that these benefits of exercise also apply to patients with persistent LBP.

In general, there is strong evidence that global exercise is effective for improving pain, function, and disability levels when compared to no treatment in patients with subacute and chronic low back pain.[3,16,17,34] In individuals with persistent LBP, exercise

TABLE 92.5

INDIVIDUALIZED EXERCISE PROGRAMS

- Individually designed exercise programs with a higher dose (intensity, frequency, duration) and regular follow-up are associated with improved pain, function, and disability in patients with persistent pain.
- Individualizing the exercise program by mutual goal setting to meet both physical and psychosocial needs is essential in maximizing exercise adherence and achieving patient satisfaction.
- Exercise program delivery should be adjusted to meet the patient's psychosocial needs and goals.
- Adherence and satisfaction are likely to be enhanced by considering the patient's goals, environmental barriers, interests, and preferences.
- Cognitive-behavioral strategies integrated into an exercise program may improve mood, enhance participation, and reduce disability.

TABLE 92.6

EFFICACY OF EXERCISE INTERVENTIONS FOR LBP

Classification systems

- Developing subgroups or classification systems may aid in specific exercise selection.
- Physical impairments may be most important when designing exercise programs for patients during the acute and subacute stages of management.
- Psychosocial factors become more important than physical impairments in the management of chronic or persistent pain. For example, fear-avoidance beliefs need to be addressed.

Specific exercises

- Specific exercises demonstrate efficacy for short-term improvement in pain and function during the acute, subacute, and persistent stages of management.
- Spinal stabilization exercises have not demonstrated long-term efficacy beyond that of global or general exercise programs. However, there may be clinical value at all stages of management that is not easily measured.
- Spinal stabilization exercises have demonstrated short-term benefits in all stages of management and in preventing recurrence of LBP.
- Exercises based on directional preference (e.g., McKenzie approach) show potential benefit for symptom reduction during the first few weeks of the acute, subacute, or persistent stages of management.

Global exercises

- There is strong evidence that global exercise programs are effective for improving pain, function, and disability in patients with musculoskeletal LBP, especially persistent LBP.
- Aerobic conditioning, muscle strengthening, stretching, and skill-training exercises are associated with decreased pain, improved function, and reduced disability.
- Attention to program progression, self-management of symptoms, postural alignment, and body mechanics are important for enhancing long-term activity and participation in global exercise programs.

alone is as effective for improving pain, function, and disability as a multimodal PT program that includes manual therapy and modalities in addition to exercise.[34] Global exercise programs are generally accepted as an effective intervention for subacute and chronic LBP, particularly when patients have been advised in program progression, self-management of symptoms, postural alignment, and safe body mechanics. Program design, exercise intensity, delivery type, and individualization of exercise interventions have been identified as elements that impact pain levels and function in adults with persistent LBP.[3]

CONCLUSION

The four core topics of the chapter are summarized in Tables 92.3 through 92.6.

CHAPTER 93 ■ COMPLEMENTARY AND ALTERNATIVE MEDICINE

CHARLES A. SIMPSON

INTRODUCTION

This chapter will look at therapies that are often classified as being ‘‘complementary’’ and/or ‘‘alternative’’ to conventional medical interventions for pain. A contemporary definition of complementary and alternative medicine (CAM) will be considered in the context of the complex and clinically challenging field of evidence-based pain medicine. A rationale for studying unorthodox treatments of pain is presented. The challenges of an evidence-based approach to incorporating complementary therapies into integrated pain management are explored. And finally, a brief survey of several commonly available complementary medicine therapies and the evidence regarding their utility are provided.

WHAT IS COMPLEMENTARY AND ALTERNATIVE MEDICINE?

Identifying and defining alternative approaches to health and healing have been problematic for decades. How these various professions, therapies, and approaches to healing have been characterized by the dominant, conventional medical mainstream is emblematic of the history, antagonisms, and misunderstandings between the two camps. How the alternative medicine disciplines have defined themselves is also instructive of the differences. Drawing meaningful distinctions between conventional biomedicine and the array of alternative methods may be useful to illuminate how each can contribute to better care for patients in pain.

THE DIVIDE

The emergence of organized medicine early in the last century marginalized a large number of existing healing disciplines, some of which enjoyed long and successful traditions treating the public. As Cohen points out,

> Although American colonies began with pluralistic notions of health care, the poor state of science, paltry qualifications of many would-be physicians, general lack of medical standards, and a cornucopia of charlatans eventually led to state regulation of healers—largely through the mechanism of licensure—and thereby to the triumph of biomedicine over competing communities of healers such as naturopathic and homeopathic physicians. Legally, state statutes made unlawful practice of medicine a crime and defined medicine in broad terms, encompassing any activity that potentially could be construed as diagnosis and treatment.[1]

As a result, Western, scientific, reductionistic biomedicine became the ‘‘real’’ medicine in legal terms. The resulting cultural authority of conventional medicine (CM) discounted traditional healers. The hegemony of this dominant paradigm was not seriously challenged until the last few decades of the twentieth century.

Fringe Medicine and Quackery

In the early 1960s British author Brian Inglis developed a model in his book titled *Fringe Medicine*.[2] This title consigned nonstandard approaches to healing to the periphery of science and the health care system.[2] Inglis considered such professions as homeopathy, bone setting, herbalists, and psychotherapy as fringe medicine. Being on the fringe implied that healers of this stripe were so far removed from the mainstream so as to pose no threat to the public or to the dominance of biomedicine.

In the succeeding 30 years, many of these fringe approaches to healing persisted and grew despite persistent opposition from the dominant medical establishment. In the 1950s, the American Medical Association (AMA), for example, developed ethics policies that forbade physicians from interacting with ‘‘unscientific, cult practitioners’’ such as chiropractors. The AMA Committee on Quackery was formed in 1963 targeting vitamins, homeopathy, chiropractic, naturopathy, all alternative cancer treatments, and other practices which compete with the drug sales of pharmaceutical companies.[3] In the case of *Wilk v. American Medical Association*, the AMA was found to have engaged in an unlawful restraint of trade under the Sherman Antitrust Act. And while the AMA’s Committee on Quackery was disbanded, other groups have taken up the charge (see http://www.quackwatch.com).

Unorthodox Medicine

This unhappy stand-off persisted until Eisenberg’s seminal study in 1993[4] revealed the depth and breadth to which these fringe practices have penetrated health care delivery. This paper reported a survey of respondents’ use of a variety of unorthodox medical practices. These were defined by Eisenberg in exclusionary terms, that is, in terms of what these therapies are *not*. Unorthodox medicine in Eisenberg’s view was *not* taught in medical schools, *not* available in hospitals, and *not* generally considered real medicine.[4]

Today, neither of these perspectives, fringe or unorthodox, provides meaningful distinctions between mainstream conventional biomedicine and those forms of healing that are different. Neither perspective bears up to careful scrutiny of the current state of complementary and alternative medicine. Eisenberg et al.[4] amply demonstrated that the volume of visits for health care delivered outside of the orthodox mainstream exceeds that of conventional care provided in physician offices—hardly an image of a fringe factor in the overall picture of the health care delivery system.

The popularity of complementary medicine with the public has not gone unnoticed by conventional medical institutions either. Health insurance plans, hospitals, and academic medical centers have integrated, to one extent or another, nontraditional health care providers and therapies into their programs. A survey of regional health plans in the northeast United States[5] found nearly universal coverage for chiropractic, with just under half of insurers covering acupuncture (usually for chronic pain) and

massage therapy.[5] A 2005 American Hospital Association survey revealed that 370 of 1394 respondent institutions (26.5%) offer some form of complementary health care.[6] Complementary medicine topics are being integrated into the curricula of up to 64% of U.S. medical schools.[7] The American Medical Student Association has developed the Educational Development for Complementary and Alternative Medicine program to promote medical school education on alternative medicine topics. The Consortium of Academic Health Centers for Integrative Medicine includes 38 highly esteemed academic medical centers including Harvard, Duke, Thomas Jefferson, and Yale. The stated mission of this consortium is "to help transform medicine and health care through rigorous scientific studies, new models of clinical care, and innovative educational programs that integrate biomedicine, the complexity of human beings, the intrinsic nature of healing, and the rich diversity of therapeutic systems."[8]

Complementary and Alternative Medicine

The fringe and unorthodox labels are a carry-over from more contentious times. Other labels have included nontraditional medicine as opposed to traditional medical care. Considering that most of these nontraditional therapies pre-date most conventional interventions, for example, in the case of acupuncture, by 3000 years, traditional versus nontraditional seems irrational. Integrative and integrated medicine have some currency as well. Integrative medicine often refers to alternative medicine therapies delivered by CM practitioners or at least in conventional medical settings. Integrated medicine implies the thoughtful collaboration of conventional and alternative medicine providers in the treatment of patients. Alternative medicine suggests that the therapies are used in place of conventional medicine. Complementary medicine is supported by evidence showing that most patients use both conventional and complementary interventions, seeking to integrate their own care. The favored terminology by the National Institutes of Health has been "complementary and alternative medicine (CAM)." This chapter will use the distinction of CM to refer to Western biomedicine and CAM to cover those professions, practitioners, and therapies that lie outside of conventional medicine. These definitions too will likely lose currency over time.

Complementary medicine practitioners tend to consider their approaches as holistic and in contrast to a reductionistic approach that is ascribed to modern, specialty-driven biomedicine. Holistic practitioners use,

> [r]ather than focusing on illness or specific parts of the body, this ancient approach to health considers the whole person and how he or she interacts with his or her environment. It emphasizes the connection of mind, body, and spirit. The goal is to achieve maximum well-being, where everything is functioning the very best that is possible. With Holistic Health people accept responsibility for their own level of well-being, and everyday choices are used to take charge of one's own health.[9]

In contrast, the reductionistic approach of CM adheres to the theory that every complex phenomenon in medicine can be explained by analyzing simple, basic, physical mechanisms.

Bridging the Divide: One Kind of Medicine

The current trend toward evidence-based medicine (EBM) may eventually point the way to a reconception and resolution of the distinction between CM and CAM. CAM is frequently dismissed by critics as being unscientific and without evidence of its safety, efficacy, and effectiveness. However, over the last decade the emergence of complementary medicine on the national research agenda through the National Institutes of Health National Center for Complementary and Alternative Medicine (NCCAM) promises to develop the academic and intellectual infrastructure that can explore the evidence that demonstrates the utility of complementary therapies. Originally formed as the Office of Complementary Medicine, the Federal budget for NCCAM grew from $2 million in fiscal year 1992 to $121.4 million in fiscal year 2007. The body of research is growing. There are currently more than 1200 randomized controlled trials (RCTs) and 150 Cochrane Collaboration reviews of alternative therapies.

Angell and Kassirer noted several years ago in a *New England Journal of Medicine* editorial[10] that in the future, medicine will be divided into those approaches to health and healing that are backed by scientific evidence and those that are not. "There cannot be two kinds of medicine—conventional and alternative. There is only medicine that has been adequately tested and medicine that has not, medicine that works and medicine that may or may not work. Once a treatment has been tested rigorously, it no longer matters whether it was considered alternative at the outset."[10] This perspective may well put to rest the arbitrary and, at times antagonistic, differentiation between CAM and conventional medicine.

A recent Institute of Medicine report on complementary medicine emphasizes, "The committee recommends that the same principles and standards of evidence of treatment effectiveness apply to all treatments, whether currently labeled as CM or CAM."[11] This evidence-based perspective will erode the barriers between health care that is provided in the tradition of Western scientific medicine and the healing disciplines that, in some instances, predate modern medicine by 3000 years.

Yet, there clearly are differences between health care available in physician offices, clinics, and hospitals and that provided by CAM practitioners. There are three features of CAM that tend to distinguish it from CM. CAM therapies are individualized to each patient. CAM almost universally incorporates a philosophy of health that emphasizes and leverages the innate capacity for healing in every individual. And finally, CAM tends to acknowledge the existence of properties of living systems that are resistant to understanding by contemporary reductionistic scientific methods of inquiry.

What Is Different About Complementary and Alternative Medicine?

These distinguishing features present significant challenges to research and assembling meaningful evidence. They also create opportunities to develop more effective, efficient, and humanizing care for a very difficult population of patients—those with pain. A recent observation by Cicerone on evidence-based practice and the limits of rational rehabilitation points out that, "we need to acknowledge the subjective meanings of illness and disability to the patients we serve. Any efforts to build our practice based on the best available systematic evidence are unlikely to succeed unless we include patients' values and beliefs and incorporate this perspective into our rehabilitation research. This aspect of evidence-based rehabilitation raises important questions about our fundamental roles and how we will choose to practice and define our field in the future."[12]

Individualized treatment is a hallmark of most CAM therapies. For example, an acupuncture practitioner may evaluate 2 patients, both with the same CM diagnosis, but develop two radically different treatment plans based on the Oriental Medicine (OM) examination findings and assessment. This approach seems to work well for patients. Studies of patients who obtain care from CAM practitioners reveal high levels of satisfaction with the practitioners and the outcome of the therapies. CAM providers spend time with their patients, and they are successful in explaining to patients the nature of their health problems. Treatment planning tends to be collaboration between therapist and patient. Interventions are developed that are consistent with each patient's own needs and preferences.

Philosophy of care is not something that most CM practitioners ponder extensively. However, philosophical discourse underlies many CAM therapies. Chiropractic, for example, contains an extensive literature that can only be described as philosophy. Beginning with the founder, D. D. Palmer, chiropractic thinkers have historically focused on not so much the rational scientific underpinnings of this healing art, but on the art itself. Innate intelligence is posited by Palmer and his successors as a fundamental life force that, when fully expressed without interference, the ultimate expression of health occurs, naturally and without need of intrusion from outside agents. In this chiropractic philosophical world view, the aim of the chiropractor is to locate and correct interferences with this natural expression of the life force. Identified as "qi" in OM, "prana" in yoga, "doshas" in Ayurvedic medicine, and "vix medica naturae" in naturopathic medicine, each discipline has elaborated some measure of a conceptual life force that guides and propels healing and health.

CM, with its intellectual traditions anchored in Western scientific thought, is understandably skeptical of notions of innate intelligence, qi, or other conceptualization of a putative life force. Finding no testable hypotheses to investigate a possible life force, CM has largely dismissed such philosophical musing. Oschman[13] provides a comprehensive review of this seeming impenetrable intellectual barrier between CAM and CM world views.

Who Uses Complementary and Alternative Medicine?

The research on CAM utilization is often confusing and contradictory. Research is complicated by a number of factors, including a lack of consensus on what therapies, interventions, and practitioner types constitute CAM, varying methodologies for collecting data, the variety of populations and settings in which data are gathered, and the different countries being studied in which the availability of CAM may vary considerably due to tradition, licensure, and cultural acceptance.

However, despite the inconsistent nature of the research efforts, it is certain that CAM use is widespread across populations, clinical conditions, settings, and sociodemographic groups. In 1993, Eisenberg and colleagues' paper[4] alerted the CM community to the magnitude of CAM utilization. This discovery revealed an ongoing phenomenon in the general population that has been verified and replicated in many subpopulations. A search of CAM on PubMed[14] with search terms "CAM utilization" returned over 500 citations. These include abstracts referring to various clinical populations (cancer, inflammatory bowel disease, autoimmune deficiency syndrome, diabetes, hypertension, allergies, rheumatic conditions, chronic fatigue, fibromyalgia, emergency department patients) and sociodemographic populations (veterans, racial and ethnic groups, geriatrics, women, children, athletes). In short, no matter what population is examined, CAM use is prevalent.

CAM use is particularly widespread among patients with chronic pain conditions. Nayak et al.[15] reported on a small sample of spinal cord injury patients with chronic pain. About 40% of respondents had used some form of CAM during the preceding year. Forty-four percent of chronic pain patients being treated with opioids reported concomitant CAM use.[16] Twenty-seven percent of veterans with cancer or chronic pain reported CAM use.[17] More veterans would have used CAM had it been covered by insurance. Tsao et al.[18] found that, given a choice of several CAM interventions, over 60% of pediatric patients (and their parents) opted to try at least one CAM approach in addition to CM treatments.

Categorizing Complementary and Alternative Medicine Therapies

There is considerable diversity in CAM practices and deciding which discipline to include under the rubric CAM and which to exclude can be problematic and markedly affects the study results of CAM utilization. Eisenberg,[4] for example, limited his survey inquiries to 16 commonly used interventions but included "relaxation therapy . . . lifestyle diets, spiritual or religious healing by others." Eisenberg does note a categorical difference, however, between CAM therapies that are delivered by a professional, such as massage and acupuncture, and those that are largely self-administered without the involvement of a trained and licensed provider, such as lifestyle diets and intercessory prayer. Hospitals reporting the integration of CAM most frequently identify massage, body movement therapies (qi-gong, yoga, tai chi), relaxation, acupuncture, guided imagery, and therapeutic touch as the CAM modalities of choice.[6] Conspicuous by their absence from the hospitals are some of the most frequently encountered CAM modalities, such as chiropractic, nutraceutical, and herbal therapies. NCCAM has categorized CAM in 5 domains: alternative medical systems, mind–body interventions, biologically-based treatments, manipulative and body-based methods, and energy therapies.[19]

For purposes of the discussion in this chapter, CAM therapies will be limited to those commonly accessible in the community to chronic pain patients and, for the most part, administered under the guidance of licensed health care professionals. While this approach may exclude some valuable and frequently used therapies, it does encompass CAM therapies that are in regular use by chronic pain patients, are at least somewhat institutionalized, have been used or referred to by conventional medicine providers, and are capable of being integrated clinically and administratively into the CM care of chronic pain patients.

The array of CAM therapies are categorized further here by their intellectual and philosophical nature as being either essentially biologically-based or energy-based. Biologically-based therapies are explained and practiced fundamentally in ways that are familiar to practitioners trained in the CM model of Western scientific inquiry. Clinical conditions are mostly described in terms of disturbed anatomy and physiology. Treatment interventions are categorized by their physiologic effects. Outcomes are measured in objective clinical terms. These disciplines, such as chiropractic and natural medicine, often view themselves as being within the context of orthodox scientific thought. Many of these therapies have been rigorously scrutinized through the lens of Western medical scientific investigation. The disciplines themselves are developing intellectual, administrative, and physical infrastructure to conduct research as part of a commitment to evidence-based practices.

In contrast, energy-based therapies are most often founded on putative notions of natural systems of "invisible energetic relations and connections that govern living form and function."[13] While some of these energy-based therapies have undergone scientific inquiry, most notably acupuncture, the fundamental world view of energy-based healers has not been altered to conform to the understandings offered by rational reductionistic methods. For example, science has attempted to understand the physiologic basis of acupuncture in terms of its neuroendocrine effects. However, few acupuncture practitioners endorse or, more importantly, practice within this intellectual context. Most acupuncture practitioners prefer instead to explain what they do in the language of OM, such as the flow of chi.

WHY CONSIDER COMPLEMENTARY AND ALTERNATIVE MEDICINE THERAPIES IN PAIN MANAGEMENT?

There is a compelling case for why CM physicians, especially in the challenging field of pain medicine, should better understand

CAM therapies. Based on the study results of CAM utilization, it is quite likely that a pain patient is using at least one CAM therapy concurrently with CM treatments. There are potential complications that arise with the combination of CAM and CM therapies, and awareness of these enhances safety and quality of care. Users often fail to reveal their use of CAM therapies to their CM providers. Understanding the rationale for and evidence that supports CAM use in pain conditions places the clinician in a helpful role of providing objective information to pain patients. And, perhaps most significantly, CAM therapies can be effective and improve the quality of care for chronic pain patients.

Over 60 million Americans suffer from chronic pain. It is estimated that 40% of them fail to achieve adequate relief.[20] Surveys of CAM users note a high prevalence of chronic conditions, including chronic pain. Observers of the CAM scene note that "consumers will continue to use CAM, particularly in chronic conditions, in which patients struggle to find any treatment that may cure their condition or improve their quality of life."[21]

Most CAM interventions are "low-tech, high-touch" in nature. They are often perceived as inherently safe and natural by patients and practitioners. However, there is a growing body of evidence that illuminates adverse reactions to commonly used CAM therapies either by themselves or when combined with CM. Drug–herb interactions, for example, present potential challenges to patient safety and compromises of therapeutic intent. Eisenberg[4] noted that patients use CAM and CM concurrently for the same condition upward of 83% of the time. What is potentially more troublesome is that CAM users failed to disclose CAM use to CM physicians.[4] Subsequent investigation indicates that this failure to disclose has not improved over time.[7] Better understanding by both CM and CAM practitioners of risks can modify the potential for adverse outcomes.

Avoiding adverse CM–CAM interactions can obviously improve patient care. Asking patients about their use of CAM, especially from an objective and evidence-based perspective, can enhance patient communication. The cultural competency of being able to provide nonjudgmental acknowledgment of CAM use, particularly when supported by objective evidence of safety and effectiveness, can reinforce a productive therapeutic relationship between patient and CM physician.

It is well recognized that effective physician–patient communication is a critical element in predicting better patient satisfaction and compliance.[22] Moreover, as reliable evidence of CAM effectiveness emerges, CM physicians may be in a position to integrate evidence-based CAM approaches in an active manner rather than passively accepting what chronic pain patients may already be attempting to integrate on their own.

Challenges of Evidence-Based Complementary and Alternative Medicine Therapies

Assessing the evidence about CAM therapies for chronic pain is problematic from a number of perspectives. CAM therapies are often inherently resistant to analysis by commonly used clinical research methods. For example, in the hierarchy of evidence, the RCT is considered to be the criterion standard. Yet many argue that this methodology, while well suited to the study of drugs, may not be the best research design to study complex, individualized treatments routinely offered by CAM practitioners.[23,24]

For instance, trials of manipulative therapy have been plagued by the difficulty in developing a "sham" manipulation and concurrently controlling for the nonspecific effects of the hands-on practitioner–patient interaction with the theoretically inert sham treatment. Similarly, acupuncture research using sham acupuncture points irritate acupuncture practitioners who note that any needling at any point on the body affects the flow of chi, and therefore cannot be considered an inert intervention in the same way that a placebo pill is used in a clinical trial of drug therapy. Functional magnetic resonance imagine and positron emission tomography imaging studies have demonstrated changes when sham acupuncture procedures are delivered.[25]

Further, evidence about treatment interventions for chronic pain is confounded by the complex nature of the condition itself. Patient selection is often a significant challenge to study validity. Aggregating patients with low back pain, for example, into a conceptually uniform study group ignores the wide variety of conditions that may fall into this pain population. It is no wonder that trials with this fundamental design flaw frequently come up with equivocal results for almost any intervention, whether conventional or complementary, and fail to reveal significant differences in effectiveness between treatments.

The challenges of applying evidence of this nature to the practical realities of treating patients have been increasingly recognized.[12] Fortunately, the research community, particularly in the CAM fields, is actively developing research strategies that are more appropriate both for the individualized nature of CAM interventions and the complex, multifactorial nature of chronic conditions such as chronic pain.

Finally, publication and indexing biases are obstacles to assembling reliable evidence about CAM therapies.[26] As in CM, studies with positive results are more likely to be submitted for publication. Many studies of CAM are in foreign language journals, thus limiting their exposure to English-speaking audiences. A more subtle bias also is observed in CM-published research on CAM. As one CAM researcher put it, "A negative study of acupuncture concludes that 'acupuncture doesn't work.' The analogue would be a negative drug trial that concluded 'medicine does not work.' "[27]

Despite these challenges in developing an evidence-based approach to the use of CAM therapies in chronic pain conditions, clinical evidence is accumulating. Many formerly unproven and unscientific therapies have, in fact, been shown to be safe and effective. Achieving the goal of Angell and Kassirer's[10] "one kind of medicine" is becoming a reality in health care and in the treatment of chronic pain.

THE COMPLEMENTARY AND ALTERNATIVE MEDICINE THERAPIES

Biophysiologic Therapies

These therapies are based mainly on concepts of biology and physiology commonly accepted in conventional biomedicine. These therapies rely on clinical theories, therapeutic approaches, and rationales that are couched in terms consistent with current scientific understanding of biology and physiology familiar to conventional medicine.

Manipulation

Manipulation is the most widely used CAM therapy.[4] It is widely practiced by a variety of specialties including Doctors of Chiropractic (DC), Osteopathic Physicians (DO), Medical Doctors (MD), physical therapists, and some lay practitioners. It is estimated that DCs deliver over 90% of all manipulative therapy.[28] Chiropractic training in manipulative techniques is arguably the most extensive among manipulation practitioners.

Manipulation is thought to improve pain by locating and treating disturbed joint and muscle function described as dysfunction, subluxation, fixation, and other terminology that may vary by discipline, training, and technique. Of the CAM therapies, manipulation has been studied the most extensively. NCCAM has identified 537 clinical trials of manipulative and other body work therapies such as massage. While the results are often and

predictably inconclusive, there is clear evidence that manipulation is superior to sham treatment and equivalent to other conservative interventions for acute spinal pain.[29] More recent investigations show long-term benefit for neck pain,[30] headaches,[31] and chronic mechanical spine pain.[32] A recent clinical practice guideline from the American Pain Society and the American College of Physicians recommends manipulation, among other CAM treatments, for both acute and chronic low back pain.[33]

Natural Medicine Therapies

A number of CAM practices use nutritional supplements and herbs (known collectively as nutraceuticals) in the treatment of chronic pain. While these natural medicine approaches are most commonly identified with Naturopathic Physicians (ND), herbs and supplements are frequently used by acupuncture/OM and chiropractic providers as well.

Natural medicine can be used directly for analgesia (white willow bark, for example), anti-inflammatories (Omega-3 fatty acids), and antispasmodics (valerian and passiflora are examples). Nutritional and herbal interventions are most commonly applied to modify perceived underlying physiologic disturbances such as fibromyalgia, depression, osteoarthritis, and rheumatoid arthritis. Of commonly used nutritional approaches, glucosamine and chondroitin sulfate have been most extensively studied. Glucosamine has been shown to slow cartilage deterioration and relieve pain in knee osteoarthritis.[34,35]

Many nutraceutical interventions are thought to modify disturbed metabolism that underlie chronic pain conditions such as fibromyalgia.[36] While much nutraceutical information on the Internet is proprietary and commercial in nature, there are evidence-based sources of information for a number of painful conditions.[36]

Body Awareness Therapy

A number of approaches to chronic pain treatment involve the idea of improving postural coordination by using conscious processes to alter automatic postural coordination and ongoing muscular activity. These body awareness therapies (BAT) may be practiced by physical and occupational therapists, massage therapists, as well as nonlicensed body-work professionals. Two common BAT have been described: Alexander technique (AT) and Feldenkrais.

AT is described as "a method that works to change (movement) habits in our everyday activities. It is a simple and practical method for improving ease and freedom of movement, balance, support, and coordination. The technique teaches the use of the appropriate amount of effort for a particular activity, giving you more energy for all your activities. It is not a series of treatments or exercises, but rather a reeducation of the mind and body."[37]

A systematic review of AT[38] revealed few high-quality RCTs but noted promising results with Parkinson's disease and back pain.

Feldenkrais is a technique said to improve function by "expanding the self-image through movement sequences that bring attention to the parts of the self that are out of awareness and uninvolved in functional actions. Better function is evoked by establishing an improved dynamic relationship between the individual, gravity, and society."[39] Jain and colleagues[40] provide a recent review of the method, its use and the relevant research, and research gaps concerning this BAT.

Therapeutic Massage

Massage therapy encompasses more than 150 named body work systems and perhaps thousands of variations and individual techniques. Therapeutic, clinical, or medical massage is engaged to treat specific clinical conditions. The physiologic effects of massage are well documented, including muscular relaxation, improved blood and lymph circulation, and neurohormonalimmunologic effects. There are more than 20 clinical trials of massage for pain. Physical Medicine and Rehabilitation Clinics of North America reviewed therapeutic massage in 1999.[41] A recent Cochrane review of massage for low back pain concluded that, "Massage might be beneficial for patients with subacute and chronic nonspecific low-back pain, especially when combined with exercises and education."[42] A more recent review concluded that there is robust evidence in favor of massage therapy for chronic low back pain and more modest support for massage in the treatment of chronic headache, shoulder pain, mixed pain conditions, fibromyalgia, and carpal tunnel syndrome.[43]

Breath Pattern Retraining

In 1975, Lum[44] introduced the concept of disordered breathing patterns as the underlying cause of "a collection of bizarre and unrelated symptoms" including cardiovascular, neurologic, respiratory, gastrointestinal, musculoskeletal, psychologic, and other syndromes. More recently, Chaitow[45] has emphasized disturbed breathing patterns as the cause of chronic pain. Proposed mechanisms are summarized as "respiratory alkalosis, leading to reduced oxygenation of tissues (including the brain), smooth muscle constriction, heightened pain perception, speeding up of spinal reflexes, increased excitability of the corticospinal system, hyperirritability of motor and sensory axons, changes in serum calcium and magnesium levels, and encouragement of myofascial trigger points." Breath pattern retraining therapists note that the respiratory mechanism is the only physiologic function that is under both autonomic and voluntary control.

A recent RCT involving chronic low back pain patients revealed equivalent improvement from 12 sessions of breath therapy as measured on a visual analogue scale (*VAS*), Roland-Morris Scale, and short form 36 health questionnaire (SF-36) when compared to high-quality, extended physical therapy.[46] Breath therapy was found to be safe.

Prolotherapy

The use of proliferation therapy (prolotherapy) has waxed and waned for nearly a century. Often provided by CM practitioners, prolotherapy is also frequently in the therapeutic armamentarium of ND. Following an injury, failure of adequate tendon or ligament healing is thought to result in instability, connective tissue insufficiency, or lack of tensile strength. Normal use of these compromised structures causes pain. Prolotherapy consists of injections of an array of substances intended to trigger growth factors in local connective tissue and restart the repair sequence that results in more normal and functional tissue.

A recent critical review of prolotherapy[47] retrieved over 30 studies of prolotherapy for spinal pain. These reflected wide variation in treatment protocols and concluded that, "clinical studies published to date indicate that it may be effective at reducing spinal pain." A Cochrane review concluded that, "If used alone, prolotherapy injections do not have a role in the treatment of chronic low-back pain. When combined with other treatments, they may give prolonged partial relief of pain and disability."[48]

Trigger Point Manipulation

Travell and Simons offered an early treatise on myofascial trigger points (TrP) which were defined originally as "a hyperirritable spot in skeletal muscle that is associated with a hypersensitive palpable nodule in a taut band. The spot is tender when pressed and can give rise to characteristic referred pain, motor dysfunction, and autonomic phenomena."[49]

The understanding of the etiology of TrPs has evolved. Current thinking has been summarized as, "TrPs are evoked by the abnormal depolarization of motor end plates . . . presynaptic, synaptic, and postsynaptic mechanisms of abnormal depolarization (i.e., excessive release of acetylcholine [ACh], defects of acetylcholinesterase, and upregulation of nicotinic ACh-receptor activity, respectively)."[50]

No objective diagnostic tests for TrPs are available. TrPs are diagnosed by manual palpation to identify a tender nodule, often at characteristic locations in muscle that, when stimulated, produce characteristic radiating pain as reported by the patient. Despite this low-tech diagnostic method, TrP detection has good test-retest reliability.[51] Various approaches to treating TrPs have been elaborated including manual compression, "spray and stretch," injection, dry needling, and modalities (ultrasound, electric stimulation, low-level laser). TrP treatment is often rendered by certain CM physical medicine practitioners, but most frequently by chiropractors, acupuncturists, massage practitioners, and other CAM providers.

The Tensegrity Model

Tensegrity (or biotensegrity) is not a therapy in itself, but rather a concept of how biologic systems function, from the ultrastructure of the cell to the organism. The concept is attributed to sculptor Kenneth Snelson and the term was coined by Buckminster Fuller to represent "tensional integrity."[52] Snelson noted, "Tensegrity describes a closed structural system composed of a set of three or more elongate compression struts within a network of tension tendons, the combined parts mutually supportive in such a way that the struts do not touch one another, but press outwardly against nodal points in the tension network to form a firm, triangulated, prestressed, tension and compression unit."[52] Donald E. Ingber of Harvard Medical School and Stephen M. Levin,[53] an orthopedic surgeon, have applied tensegrity concepts to biology and medicine. Ingber has postulated that cell function is regulated mechanically via tensegrity. Levin contends that the integrity of the musculoskeletal system "is a function of continuous tension, discontinuous compression, so that the skeleton, rather than being a frame of support to which the muscles and ligaments and tendons attach, has to be considered as compression components suspended within a continuous tension network."[53] Many body work practitioners including physical therapists, chiropractors, massage therapists, martial artists, and others have incorporated the tensegrity model into evaluation and treatment approaches.

Energy-Based Therapies

Energy medicine is a domain in CAM that deals with energy fields of two types: veritable, which can be measured, and putative, which have yet to be measured.

The veritable energies include mechanical vibrations (such as sound) and electromagnetic forces, including visible light, magnetism, monochromatic radiation (such as laser beams), and rays from other parts of the electromagnetic spectrum. These veritable energy-based therapies involve the use of specific, measurable wavelengths and frequencies to treat patients.

In contrast, putative energy fields are based on the concept that human beings are infused with a subtle form of energy. This vital energy or life force is known under different names in different cultures and traditions, such as "qi" in traditional Chinese medicine (TCM), "ki" in the Japanese Kampo system, "doshas" in Ayurvedic medicine, and elsewhere as "prana," "etheric energy," "fohat," "orgone," "odic force," "mana," and "homeopathic resonance." Vital energy is believed to flow throughout the material human body, but it has not been unequivocally measured by means of conventional instrumentation. Nonetheless, therapists claim that they can work with this subtle energy, see it with their own eyes, and otherwise sense its presence and quality and then use it to effect changes in another's physical body to influence health.

Veritable Energy Therapies

Magnetic Therapy

Magnetic therapy has a long and controversial history in medicine. It has recently regained popularity in the marketplace. Application is by way of electromagnetic coils in connection with acupuncture treatment and by way of static magnets. Magnetic therapy is typically applied to the skin overlying the affected area. The popular press indicates the use of magnets for treating a wide variety of chronic pain problems such as migraine, osteoarthritis, and injury to muscles, ligaments, and tendons. Contraindications are few but do include pregnancy, pediatric age, and presence of implantable electronic devices.

Contemporary clinical trials of magnet therapy have produced conflicting results. A study of carpal tunnel syndrome in 2002 found no statistically significant difference between magnets and placebo.[54] But the authors did note, "Although this study did not show magnets to be more effective than the placebo, the reduction in pain with this simple intervention was remarkable."[54] In a double blind, placebo-controlled trial, static magnets produced statistically significant ($p < 0.05$) short term pain relief in osteoarthritis of the knee.[55] Systematic reviews of magnet therapy are scarce and EBM reviews are lacking.

Microcurrent Stimulation

Microcurrent has been used in CM for the treatment of nonunion fracture and delayed healing. The exact mechanism of action is unknown but may involve intracellular regulation of calcium. Microcurrent has found application in the treatment of soft tissue disorders as well.

McMakin[56–58] has published three studies of this modality, which is termed frequency-specific microcurrent (FSM), in chronic pain patients. The studies are case series reports involving head, neck, and facial pain,[56] chronic low back pain,[57] and fibromyalgia associated with cervical spine trauma.[58] In the most recent study, McMakin and colleagues[58] began to explore the mechanisms of FSM. Their subjects revealed reductions in inflammatory cytokines, increase in beta-endorphins as well as subjective reports of pain relief in fibromyalgia.

Low-Level Laser Therapy

Low-level laser therapy (LLLT) is a form of phototherapy that involves the application of low power laser light to areas of the body in order to stimulate healing. It is also known as cold laser, soft laser, or low-intensity laser. It is hypothesized that photons are absorbed in the mitochondria. The light energy is converted to chemical energy within the cell affecting the permeability of the cell membrane, which in turn produces various physiologic effects. These physiologic changes affect a variety of cell types including macrophages, fibroblasts, endothelial cells, and mast cells.

LLLT is widely used in physical therapy, chiropractic, and other physical medicine practice. While reportedly safe, the modality is relatively new and is still controversial with respect to its effectiveness. A MEDLINE search retrieved over 500 citations. A recent systematic review of LLLT for acute and chronic neck pain concluded, "Significant positive effects were reported in four of five trials."[59] Cochrane reviews of LLLT used in osteoarthritis and rheumatoid arthritis revealed "conflicting evidence of benefit . . . for the treatment of osteoarthritis."[60] LLLT for rheumatoid arthritis is somewhat more positive about the therapy, "provides short-term pain relief for patients with rheumatoid arthritis."[61] Significantly, both reviews noted positive therapeutic results and called for more high quality research on LLLT.

Putative Energy Therapies

Acupuncture and Oriental Medicine

Among the putative energy therapies, none has received more notice and scrutiny than acupuncture. Acupuncture, the use of fine wire needles inserted into various points along meridians, is but one therapy within OM. The practice of OM itself includes a range of systems, interventions, schools of thought, and techniques. One such system, TCM, is widely taught and practiced in the United States. TCM encompasses herbs, massage, qigong, and acupuncture.

In the TCM view, the body is a delicate balance of two opposing and inseparable forces: yin and yang. Yin represents the cold, slow, or passive principle, while yang represents the hot, excited, or active principle. Among the major assumptions in TCM are that health is achieved by maintaining the body in a "balanced state" and that disease is due to an internal imbalance of yin and yang. This imbalance leads to blockage in the flow of qi (or vital energy) and of blood along pathways known as meridians. TCM practitioners typically use herbs, acupuncture, and massage to help unblock qi and blood in patients in an attempt to bring the body back into harmony and wellness.[62] These therapies are intended to balance the flow of qi rather than to produce a specific physiologic effect.

While not synonymous with TCM, needle acupuncture has received the most attention in the research and clinical communities. It is the most common OM therapy received by patients. Acupuncture describes a family of procedures involving stimulation of anatomic locations on the skin by a variety of techniques. There are a number of approaches to diagnosis and treatment in American acupuncture that incorporate medical traditions from China, Japan, Korea, and other countries. The most studied mechanism of stimulation of acupuncture points employs penetration of the skin by thin, solid, metallic needles, which are manipulated manually or by electrical stimulation.[63]

The body of research literature on acupuncture is robust. A search on PubMed for "acupuncture" returned more than 9000 citations. Limiting the search terms to "acupuncture and chronic pain" returned 500 articles. The Cochrane Collaboration lists 123 reviews for "acupuncture" and 18 EBM reviews specifically for "acupuncture and chronic pain." A comprehensive review of this literature base is well beyond the scope of this chapter, but it is apparent that there is conclusive evidence of the effectiveness and safety of this therapy for pain and other clinical conditions.

It is clear that acupuncture is widely used by chronic pain patients. A telephone survey reported by Breivik et al.[64] found 13% of chronic pain patients in Europe to be using acupuncture. Research methodology challenges in the investigation of acupuncture stubbornly persist. Meta-analyses frequently conclude that while acupuncture can be shown to be effective for pain relief, the therapy itself has not been shown to be superior to other therapies.[65]

Craniosacral Therapy

Craniosacral therapy (CST) developed from the work of an American osteopath, William Sutherland, in the early 1900s. It is founded on the notion of the primary respiratory mechanism that involves intrinsic motions of the cranial bones, the dura, and the flow of cerebrospinal fluid. Rhythmic motions are said to be measurable with instruments, but in clinical practice, it is by palpation that a CST practitioner identifies disturbed cranial rhythms and applies corrective gentle manipulations. Restricted motion of the cranial bones at the sutures is thought to impede CSF flow and lead to disordered function and disease.

CST is known in the osteopathic profession preferentially as cranial osteopathy. The chiropractic profession has a technique that encompasses much of CST and others as well, known as sacro-occipital technique. CST is also practiced by a variety of other hands-on practitioners including physical therapists, massage therapists, dentists, and lay practitioners.

CST is included under the putative energy category in that the motions of the primary respiratory mechanism have not been irrefutably demonstrated. Skeptics and critics have challenged the existence of these subtle rhythms.[66] Reliability studies of the manual diagnosis of disturbed cranial rhythms have been disappointing.[67] The Cochrane Collaboration contains no EBM reviews of CST. A systematic review of CST "found insufficient evidence to support craniosacral therapy."[68]

Homeopathy

Homeopathy is a system of diagnosis and treatment founded by Samuel C. Hahnemann in Germany in the late eighteenth century. Homeopathy is currently practiced widely in Europe and Great Britain and by many practitioner types in the United States including MD, DO, DC, ND, and lay providers. Clinical evaluations include detailed history interviews that lead to individualized treatment regimens depending on a host of physical, emotional, and psychologic factors. The therapies include the use of homeopathic remedies which are derived from plant, mineral, and other extracts that have been serially diluted, often to the point where, statistically at least, no physical molecules of the original substance remain.

This fact challenges fundamentally the notions of science and the physical universe that underlie CM. Most CM practitioners simply cannot accept the idea that a substance that has nothing physically "there" can have any real effect beyond that attributable to placebo. Nonetheless, a number of studies in reliable scientific journals report the apparent effectiveness of the medicine.

There is an extensive literature on homeopathy. A MEDLINE search covering 1996–2005 for "homeopathy" returned over 1300 citations. Many of these are foreign-language publications. A strictly nonscientific sampling of these abstracts indicates that pain and chronic pain conditions have not typically been studied. A search of the British journal *Homeopathy* for "pain" retrieved only 14 abstracts. As with natural medicine approaches to pain treatment, a homeopathic practitioner is more likely to be evaluating and treating underlying causes of pain rather than treating pain itself.

Ayurvedic Medicine

Ayurveda, which literally means "the science of life," is a natural healing system developed in India. Ayurvedic texts claim that the sages who developed India's original systems of meditation and yoga developed the foundations of this medical system. It is a comprehensive system of medicine that places equal emphasis on the body, mind, and spirit, and strives to restore the innate harmony of the individual. Some of the primary Ayurvedic treatments include diet, exercise, meditation, herbs, massage, exposure to sunlight, and controlled breathing. In India, Ayurvedic treatments have been developed for various diseases (e.g., diabetes, cardiovascular conditions, and neurological disorders). However, a survey of the Indian medical literature indicates that the quality of the published clinical trials generally falls short of contemporary methodological standards with regard to criteria for randomization, sample size, and adequate controls.[69]

> In the pre-biblical Ayurvedic origins, every creation, inclusive of a human being, is a model of the universe. In this model, the basic matter and the dynamic forces (Dosha) of nature determine health and disease, and the medicinal value of any substance (plant and mineral). The Ayurvedic practices (chiefly that of diet, life style, and the Panchkarama) aim to maintain the Dosha equilibrium. Despite a holistic approach aimed to cure disease, therapy is customized to the individual's constitution (Prakruti). Numerous Ayurvedic medicines

(plant-derived in particular) have been tested for their biological (especially immunomodulation) and clinical potential using modern ethnovalidation, and thereby setting an interface with modern medicine.[69]

A MEDLINE search for "Ayurvedic medicine" returned 66 results. A systematic review of Ayurvedic medicine for treatment of rheumatoid arthritis concluded that, "There is a paucity of RCTs of Ayurvedic medicines for rheumatoid arthritis. The existing RCTs fail to show convincingly that such treatments are effective therapeutic options for rheumatoid arthritis."[70] However, as with many other CAM therapies, especially the energy-based modalities, the issues raised by double-blind methodologies and placebo effects have not been thoroughly accounted for. The spiritual strength of the Ayurvedic healer and the utility of the placebo effect are both acknowledged and considered significant in many non-Western healing traditions.[71]

Touch Therapies

Touch is a fundamental human sense. The skin is arguably the largest sensory organ of the body. The power of human touch has been recognized throughout the history of medicine. Therapeutic touch (TT) and its derivatives are energy-based therapies that have become common in some hospitals and other clinical settings.

From the TT web site:

> Therapeutic Touch is a contemporary healing modality drawn from ancient practices and developed by Dora Kunz and Dolores Krieger. The practice is based on the assumptions that human beings are complex fields of energy, and that the ability to enhance healing in another is a natural potential.
> Therapeutic Touch (TT) is used to balance and promote the flow of human energy. It is taught in colleges around the world and has a substantial base of formal and clinical research. This research has shown that TT is useful in reducing pain, improving wound healing, aiding relaxation, and easing the dying process. It can be learned by anyone with a sincere interest and motivation toward helping others.[72]

A MEDLINE search for "therapeutic touch and pain" returned three citations. A Cochrane Review found insufficient evidence that TT enhances wound healing.[73] However, a pilot trial of TT in a cognitive–behavioral therapy (CBT) program found chronic pain patients who received TT in addition to relaxation and CBT fared better in terms of enhanced self-efficacy and unitary power, as well as having lower attrition rates than patients who only received relaxation training and CBT.

A study at the University of Wisconsin-Eau Claire studied another touch therapy (Tellington touch) in patients about to undergo venipuncture.[74] The intervention is described as "gentle physical touch and consisting of four components: a mental attitude of openness, use of the hands and fingers, breath awareness, and moderate finger/hand pressure." Analysis of qualitative descriptions by patients and the phlebotomist-nurse demonstrated that this massage-like, caring touch promoted relaxation and produced a helpful distraction in patients about to undergo a potentially painful procedure. While further study is warranted, the implications for physicians and others who have hands-on contact with patients of any sort, and chronic pain patients in particular, seem obvious. Human-to-human contact can have powerful effects in relieving anxiety and pain. The development of these skills by physicians and other caregivers may be of significant benefit to patients.

Reiki and Energy Healing Therapies

Reiki (pronounced RAY-kee) is Japanese for universal life energy. It is derived from rei, meaning "free passage" or "transcendental spirit" and ki, meaning "vital life force energy" or "universal life energy." Reiki is based on the belief that when spiritual energy is channeled through a reiki practitioner, the patient's spirit is healed, which in turn heals the physical body.[75] Reiki practice usually involves no direct physical contact between practitioner and recipient. By the practitioner holding his or her hands over the patient's body, the recipient is said to draw energy from the universal life force through the practitioner.

In the late 1800s, Mikao Usui developed modern Reiki from ancient Asian healing traditions said to be thousands of years old. Introduced to the West in the 1970s, Reiki has become a popular CAM therapy in the United States.[76] Reiki and other energy healing (EH) therapies have also attracted the attention of conventional medicine practitioners and researchers. A recent review noted,

> The National Institutes of Health is funding numerous EH studies that are examining its effects on a variety of conditions, including temporomandibular joint disorders, wrist fractures, cardiovascular health, cancer, wound healing, neonatal stress, pain, fibromyalgia, and AIDS. Several well-designed studies to date show significant outcomes for such conditions as wound healing and advanced AIDS, and positive results for pain and anxiety, among others. It is also suggested that EH may have positive effects on various orthopaedic conditions, including fracture healing, arthritis, and muscle and connective tissue. Because negative outcomes risk is at or near zero throughout the literature, EH is a candidate for use on many medical conditions.[77]

Reiki is practiced by a variety of licensed health care practitioners including CM and CAM physicians, allied health care providers, psychotherapists, massage practitioners, as well as nonlicensed Reiki masters. Although Reiki and other EH therapies are not without their critics[78] these high-touch, low-tech interventions are being adopted by hospitals, clinics, and physician offices as useful adjuncts to patient care.[79,80] Higher patient satisfaction, improved clinical outcomes, and lower costs are ascribed to implementing Reiki and other EH therapies.

CONCLUSION

Far from being on the fringes of modern health care, many CAM therapies have been in regular and frequent use by many chronic pain patients. Patients may seek out these therapies on their own from CAM practitioners, but they are increasingly provided in conventional health care settings as well.

Many of these unconventional therapies are being subjected to the same rigorous investigation that is expected of all contemporary evidence-based medical practices. Arguably, many CAM therapies hold up very well to this scrutiny and do so certainly as well as many commonly prescribed CM treatments.

The fact that CAM therapies are in common use by chronic pain patients suggests the need to better understand them. The emerging evidence that they are safe, clinically effective, and cost-effective when appropriately rendered further recommends them. That CAM therapies explicitly incorporate the power of intention, awareness, and healing in the human interaction of the therapeutic encounter may well be the key to achieving a more individualized, sensitive, and humanized approach to the treatment of a most difficult and challenging patient population—those with chronic pain.

CHAPTER 94 ■ PERIPHERAL NERVE STIMULATION

MICHAEL J. DORSI AND ALLAN J. BELZBERG

INTRODUCTION

Over the past 40 years peripheral nerve stimulation (PNS) has been established as a treatment option for refractory neuropathic pain. Since the first reports of pain relief following implantation of PNS in the 1960s, several authors have published their results with PNS for intractable painful mononeuropathy, complex regional pain syndrome, postherpetic neuralgia, trigeminal neuralgia, occipital neuralgia, and supraorbital neuralgia. This chapter will focus on PNS for painful mononeuropathy and occipital neuralgia.

MECHANISMS OF PAIN RELIEF

The exact mechanism of pain relief following PNS is not clearly understood. The original scientific basis for the use of electrical stimulation for the treatment of pain was provided in 1965 by Melzack and Wall's "gate control theory of pain."[1] They proposed that the transmission of pain from the periphery to the brain is regulated by a "gate" in the dorsal horn of the spinal cord. The gate may be opened by input from c- and Aδ-fiber nociceptive neurons and closed by nonnocieptive large fiber input. According to this theory, electrical stimulation increases large fiber input enough to "close" the gate and override the input from nociceptors. Wall and Sweet were the first to report a clinical correlation to this theory by placing temporary electrodes on sensory peripheral nerves or spinal roots in eight patients with intense chronic cutaneous pain, providing symptomatic relief.[2]

Several lines of evidence question the validity of the gate control theory: (1) normal pain thresholds are not affected by coactivation of large fibers, (2) in neuropathic pain conditions, low frequency stimulation of large-diameter afferents evokes pain, (3) large fiber neuropathies are rarely associated with increased pain, and (4) stimulation is inefficacious for chronic and acute nociceptive pain.

Alternative explanations for the effects of PNS on pain have been brought forward. Following peripheral nerve injury, mechanical allodynia can be mediated by Aβ-fibers[3] and maintained by central sensitization of dorsal horn neurons.[4] It has been shown that repetitive electrical stimulation of a peripheral nerve may produce excitation failure in c-fiber nociceptors and suppress activity in the dorsal horn of the spinal cord.[5,6] The peripheral effects may be due to stimulation-induced blockade of cell membrane depolarization which prevents axonal conduction.[7] Additional insights have been derived from animal studies in which spinal cord stimulation has been shown to ameliorate mechanical allodynia. In nerve injury animal models, spinal cord stimulation (SCS) has been shown to decrease hyperexcitability and long-term potentiation of dorsal horn neurons and ameliorate mechanical allodynia.[8–10] In addition, stimulation may affect dorsal horn excitability by decreasing the release of excitatory amino acids (glutamate and aspartate) and increasing the release of inhibitory neurotransmitters (GABA).[11]

INDICATIONS FOR PERIPHERAL NERVE STIMULATION

The initial flurry in PNS occurred in the 1970s and was championed by Long, Nashold, Picaza, and others. PNS was tested as a novel therapy for diverse intractable pain conditions including mononeuropathy, sciatica, metastatic disease, reflex sympathetic dystrophy, causalgia, amputation stump pain, and occipital neuralgia. Despite promising results in selected patients, the procedure never gained widespread popularity. Through the 1980s and 1990s there was a lull in the use of PNS for pain and a dearth of research publications on the topic. A second flurry in PNS occurred when one of the most challenging neuropathic pain syndromes to treat, occipital neuralgia, was taken on by Weiner and Reed. They first reported their results in treating this disorder with PNS in 1999.[12] They employed a percutaneous technique of electrode insertion in the vicinity of the occipital nerves, rather than direct electrode contact with the nerve, to treat occipital neuralgia. The following year saw publication by Slavin and Burchiel of their technique of stimulation for both occipital and trigeminal pain problems.[13] There are now a variety of both open and percutaneous methods for PNS in addition to targeting numerous regions of the body. For example, percutaneously inserted PNS electrodes have been used for control on inguinal pain,[14] abdominal pain, and low back pain.[16]

Electrical stimulation of peripheral nerves is used in a variety of medical applications in addition to pain control. The most common application is testing neuromuscular conduction during anesthesia. Other applications include pacing of a paralyzed phrenic nerve and vagal nerve stimulation for treatment of epilepsy or depression.

Careful patient selection increases the success rate of utilizing PNS for neuropathic pain. PNS is often reserved for chronic, severe pain that has proven refractory to conventional medical and surgical interventions including medications, physical therapy, nerve blocks, transcutaneous electrical nerve stimulation, or surgical neurolysis. Patient selection criteria should include: (1) pain localized predominantly to one nerve, (2) relief of symptoms after peripheral nerve block with local anesthetic, (3) absence of surgically correctable lesions including entrapment syndromes and tumors, and (4) satisfactory results on psychological or psychiatric assessment (Table 94.1).

When considering the use of PNS for peripheral mononeuropathy, the pain should be concordant with the sensory distribution of a single peripheral nerve. There can be a secondary phenomenon with pain occurring outside the primary nerve distribution as seen in central sensitization with secondary hyperalgesia. Peripheral nerve block with local anesthetic of the candidate nerve should decrease both the primary pain and secondary hyperalgesia. Patients who report excellent relief of pain following blocks are considered candidates for a PNS trial.

The value of a nerve block as predictor of PNS success for occipital neuralgia is less clear. Relief of pain symptoms after

TABLE 94.1

PATIENT SELECTION CRITERIA FOR PNS

1. Pain localized to one nerve
2. Positive response to peripheral nerve block
3. Absence of surgically correctible pathology (i.e., entrapment, tumor, etc.)
4. Satisfactory mental health screening

occipital nerve block suggests that the pain is being mediated by the occipital nerve. However, relief of pain after injection may not predict therapeutic response to PNS because the method of pain relief from these two modalities differs significantly.[17]

Transcutaneous electrical nerve stimulation (TENS) has shown efficacy for pain relief in a variety of conditions including neuropathic pain. The use of TENS has not reliably predicted success or failure of PNS. TENS provides global stimulation to the painful area, but does not provide the equivalent intensity of stimulation to that of PNS. It is our experience that lack of pain relief with TENS does not predict failure of PNS, however, exacerbation of symptoms with TENS is a poor prognostic indicator.

The selection of patients becomes much broader when looking at some of the more current indications for PNS. Treatment for a posttraumatic mononeuropathy and even occipital neuralgia may give way to novel uses such as treatment for migraines[18], cluster headaches,[19] and perhaps fibromyalgia.[20] Strict patient selection criteria still need to be established for these indications. The relative ease of electrode implantation (especially using percutaneous techniques), reversibility, testability, and adjustability make PNS an enticing therapeutic option, particularly in comparison with more destructive or ablative surgical options.

Imaging plays a supplementary role in screening for PNS by helping rule out correctable pathology along the neuraxis. Plain film radiographs can identify potential sites of osseous entrapment due to fractures, callus formation, or calcified fibrous bands. Magnetic resonance imaging (MRI) plays a role in ruling out compressive masses and intrinsic lesions such as tumors. The advent of MRI neurography has been a significant improvement in the ability to image peripheral nerves. The technique is still being refined, but will undoubtedly play an increasing role in improving our understanding of peripheral nerve pathology.

Electromyography and nerve conduction studies are part of the routine evaluation of patients with nerve injury and neuropathic pain. Rarely, these studies bring to light an as yet undiagnosed nerve entrapment syndrome masquerading as complex regional pain syndrome. These studies may be intolerable for patients suffering with cutaneous hyperalgesia or allodynia. Notwithstanding, the distinct possibility of missing a potentially treatable and correctable nerve entrapment justifies pursuing complete diagnostic evaluations.

Benefit may be obtained by addressing psychosocial factors contributing to the painful condition. Patients are encouraged to undergo formal consultation with a psychiatrist or psychologist. This may alert the treating physician to factors such as mood disorders, personality disorders, drug-seeking or manipulative behaviors, or secondary gain issues that would otherwise negatively impact compliance with stimulator use and overall outcome. As with any other pain treatment modality, the presence of psychiatric illness does not preclude the use of PNS.

Our experience with PNS has been primarily for the treatment of patients with painful peripheral entrapment neuropathy or traumatic neuroma formation. The most common peripheral nerves treated with PNS include the median, radial, ulnar, posterior tibial, and common peroneal nerves. Other targeted nerves include the ilioinguinal[21] and supraorbital nerves.[22]

The initial surgical approach for most entrapment neuropathies remains neuroplasty (see Chapter 104 for more detailed discussion of surgical approaches for treatment of painful peripheral nerve disorders). Treatment of painful neuromas begins with "neuroma relocation" in which the neuroma is resected and the freshly cut end of the nerve is buried in local muscle. Inevitably, a new neuroma will form, but the new neuroma is buried deep in the extremity and is theoretically less like to be stimulated and cause pain. In many cases, revision neuroplasty or neuroma relocation successfully relieves the pain. Only after attempts with neuroplasty or neuroma relocation have failed do we consider implanting a peripheral nerve stimulator.

SCS is often an option in the same group of patients we are considering for PNS. We typically perform a trial of SCS in the majority of patients prior to considering PNS. Some advantages of SCS over PNS include ease of implantation, variety of electrode designs, avoidance of the injured nerve and scar tissue from previous surgeries, and the ability to provide broad coverage areas. Generally, SCS is more effective than PNS for chronic pain involving the lower extremities. Unlike PNS, SCS does not evoke stimulation of the motor fibers of an injured mixed motor sensory peripheral nerve. Therefore, we consider PNS for patients who have failed SCS due to coverage/electrode issues or those with injury to purely sensory nerves (no risk of motor fiber stimulation). We are quicker to go to PNS in upper extremity problems where migration of cervical SCS electrodes may be more problematic.

Contraindications for use of PNS relate mainly to surgical risk. Coagulopathy or infections at the surgical site are contraindications to an elective surgical procedure. A remote infection with the possibility of seeding an implant is considered a relative contraindication. Similar to SCS where the electrodes are in the epidural space, the presence of an electrode next to a nerve is a relative contraindication to use of MRI. Careful consideration of risk versus benefit is required in patients who are likely to require serial MRIs (e.g., presence of a malignancy). Postoperative complications may include infection, nerve ischemia or compression, scarring, electrode migration, failure to provide adequate stimulation, mechanical failure including disconnection of the stimulator hardware, tenderness at the site of the implant, and cosmetic concerns. In addition, replacement of batteries requires an additional surgical procedure approximately every 2 years.

OUTCOMES

There is limited available data regarding outcomes associated with use of PNS. In the majority of our selected patients, PNS has been successful. Although most patients do not experience complete relief of pain, they report that the stimulator reduces the pain to a tolerable level. Following PNS, most patients are able to resume activities of daily living, return to work, and reduce their use of opiate analgesics. Our experience with PNS for painful mononeuropathy is comparable with that of several published series. Despite the lack of randomized controlled trials of PNS, there is a substantial body of literature reporting favorable results with low complication rates. In a review of 23 patients, with PNS implanted for pain radiating from the lumbar spine into the lower extremities, Picaza reported 50% to 100% pain relief in 20 patients.[23] In addition most patients reported reduced drug intake and improved social performance. Campbell and Long implanted PNS on the major nerve in the painful area of 33 patients with various refractory chronic pain conditions.[24] They evaluated relief from pain produced by nerve stimulation, along with assessments of narcotic withdrawal, ability to return to work, sleep pattern, and relief from depression. They reported excellent results in eight patients and intermediate results in seven. The most impressive results occurred in patients with traumatic peripheral nerve injuries. The majority of failures were in patients with sciatica or cancer pain. Nashold placed peripheral nerve stimulators on 38 peripheral nerves in 35 patients.[25] Successful relief of pain was obtained in 52.6% of patients with upper extremity PNS and 31% of patients with stimulation of the sciatic nerve. Failures in the lower extremity were found primarily in lesions of the posterior tibial nerve at the ankle. They speculated that the stress of weight bearing may decrease the efficacy and durability of the stimulator system. In a retrospective study of 24 consecutive PNS implants in patients with chronic peripheral nerve pain, Strege reported significantly improved pain scores in 18 patients.[26] In addition, most patients reported improved sleep, reduction of narcotics analgesics, and eight were able to return to work. Of the six failures, three failed the tempo-

rary stimulator trial and never were implanted. Late equipment failure was encountered in three patients that had initial success.

Novac and Mackinnon placed peripheral nerve stimulators in the upper extremity in 12 patients and in the lower extremity in 5 patients with various peripheral nerve pathologies.[27] Eleven patients experienced good or excellent pain relief from stimulation. Unlike Strege's series, there was no difference in pain relief for those patients who received an upper extremity implant and those who received a lower extremity implant. This may reflect structural improvements in the stimulator design. In addition, of the 12 patients who were unable to work before the operation, 6 returned to work after the operation.

Eisenberg reported long-term results for PNS implanted for iatrogenic nerve injuries and entrapment neuropathies in upper and lower extremities. Forty-six patients were followed for a median of 10.8 years after PNS. Cuff or paddle electrodes were sutured directly to the affected peripheral nerves. Thirty-six patients (78%) continued to experience at least 50% pain relief without any analgesic medications. The results were similar between patients with upper extremity pain (83% good outcomes) and lower extremity pain (73% good outcomes).[28]

In the largest series to date, Mobbs et al. reviewed 38 patients with 41 nerve stimulators implanted for blunt or sharp nerve trauma, iatrogenic or injection injuries, or persistent pain after surgery for entrapment or tumor.[29] Pain relief greater than 50% was obtained for 61% of patients. Activity levels were significantly improved in 47% of patients following stimulator implant.

The earliest report of successful treatment of occipital neuralgia with a peripheral nerve stimulator was by Picaza who reported good–excellent results in three of six patients treated.[23] Waisbrod later reported in his series of PNS patients, one patient treated for occipital neuralgia with a "very good" result.[30] The use of PNS for occipital neuralgia increased following the development of a percutaneous technique for implanting cylindrical leads along the upper cervical nerve roots.[31] Using the percutaneous technique, Weiner and Reed obtained good–excellent results in 85% of 35 patients with occipital neuralgia.[12] Slavin reported that 7 of 10 patients (70%) with implanted PNS systems, followed for 5–32 months, experienced adequate pain control, continuous employment, and decreased analgesic intake.[32]

The most common reported complications of PNS for occipital stimulation have been infection and electrode migration. To decrease the rate of electrode migration, Oh et al. implemented a semi-open technique involving placement of a single subcutaneous paddle-style electrode (Resume II/Itrel III; Medtronic Inc, Minneapolis, MN.) over the distal C1-2-3 spinal nerve branches at the skull base.[33] They reported good–excellent pain relief in 7 of 10 patients followed for 6 months without electrode migration.

A recent systematic review of the literature concluded that occipital nerve stimulation was a "useful tool" in the treatment of varied types of chronic severe headaches including: occipital nerve stimulation for the treatment of chronic headache including occipital neuralgia, migraine, transformed migraine, chronic daily headache, cluster headache, hemicrania continua, and cervicogenic headache.[34] All of the articles reviewed reported positive outcomes for pain relief, severity and frequency of pain, and use of analgesics. The outcome for PNS treatment in a variety of facial pain syndromes was reported by Johnson and Burchiel.[35] They reported on 10 patients with postherpetic or traumatic neuropathic pain treated by subcutaneous stimulation in the distribution of the supraorbital or infraorbital nerves. Seven of ten (70%) reported reduction in pain of at least 50% at 24 months. Other investigators have reported similar positive results in the treatment of otherwise intractable facial pain.[36,37]

TECHNIQUE FOR IMPLANTATION OF PERIPHERAL NERVE STIMULATOR

A two-stage procedure is typically performed for placement of a peripheral nerve stimulator. The first stage consists of implantation of a temporary "trial" electrode to assess whether PNS provides pain relief. Under general anesthesia, the nerve to be stimulated is identified proximal to the area of injury. Meticulous dissection is performed proximally to distally to free the nerve of scar and adjacent tissues. Once the nerve is clearly visible, care is taken to preserve the overlying epineurium and fascia and avoid devascularization. If indicated, an internal neurolysis or neuroma relocation is performed. For mixed motor/sensory nerves, direct nerve stimulation is used to discriminate between motor and sensory fascicles. After the ideal location is identified, the stimulating electrode is placed directly on the nerve and sutured to adjacent fascia or muscle to prevent migration. (Fig. 94.1) A temporary extension cable is connected to the electrode, and tunneled subcutaneously to exit the skin several centimeters from the surgical incision. The cable is secured to the skin with a 3-0 nylon suture.

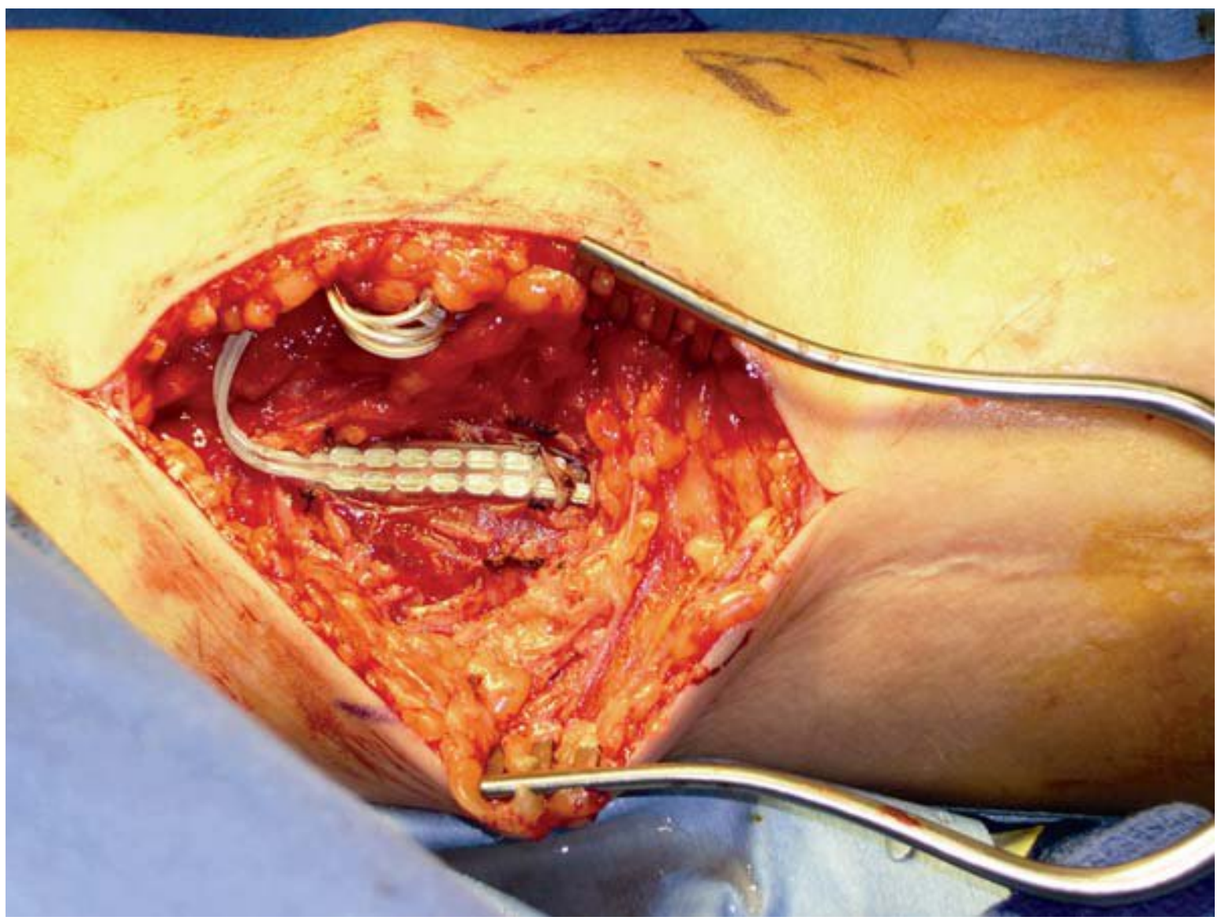

FIGURE 94.1 The stimulator electrode is placed directly on the ulnar nerve. To prevent migration, the electrode has been sutured to adjacent fascia. The wires of the electrode have been tunneled proximally via a subcutaneous track.

Over the next 2 to 7 days, a computer-based program is used to test the stimulation parameters. The patient uses the computer interface that automatically changes amplitude, rate, and pulse width of stimulation and records the patient's location and intensity of stimulation and pain relief. The goal of this trial period is to identify a set of parameters that produces a light, but not painful vibratory sensation in the distribution of the peripheral nerve. If the trial provides optimal coverage and pain relief, the patient proceeds to the second stage of surgery.

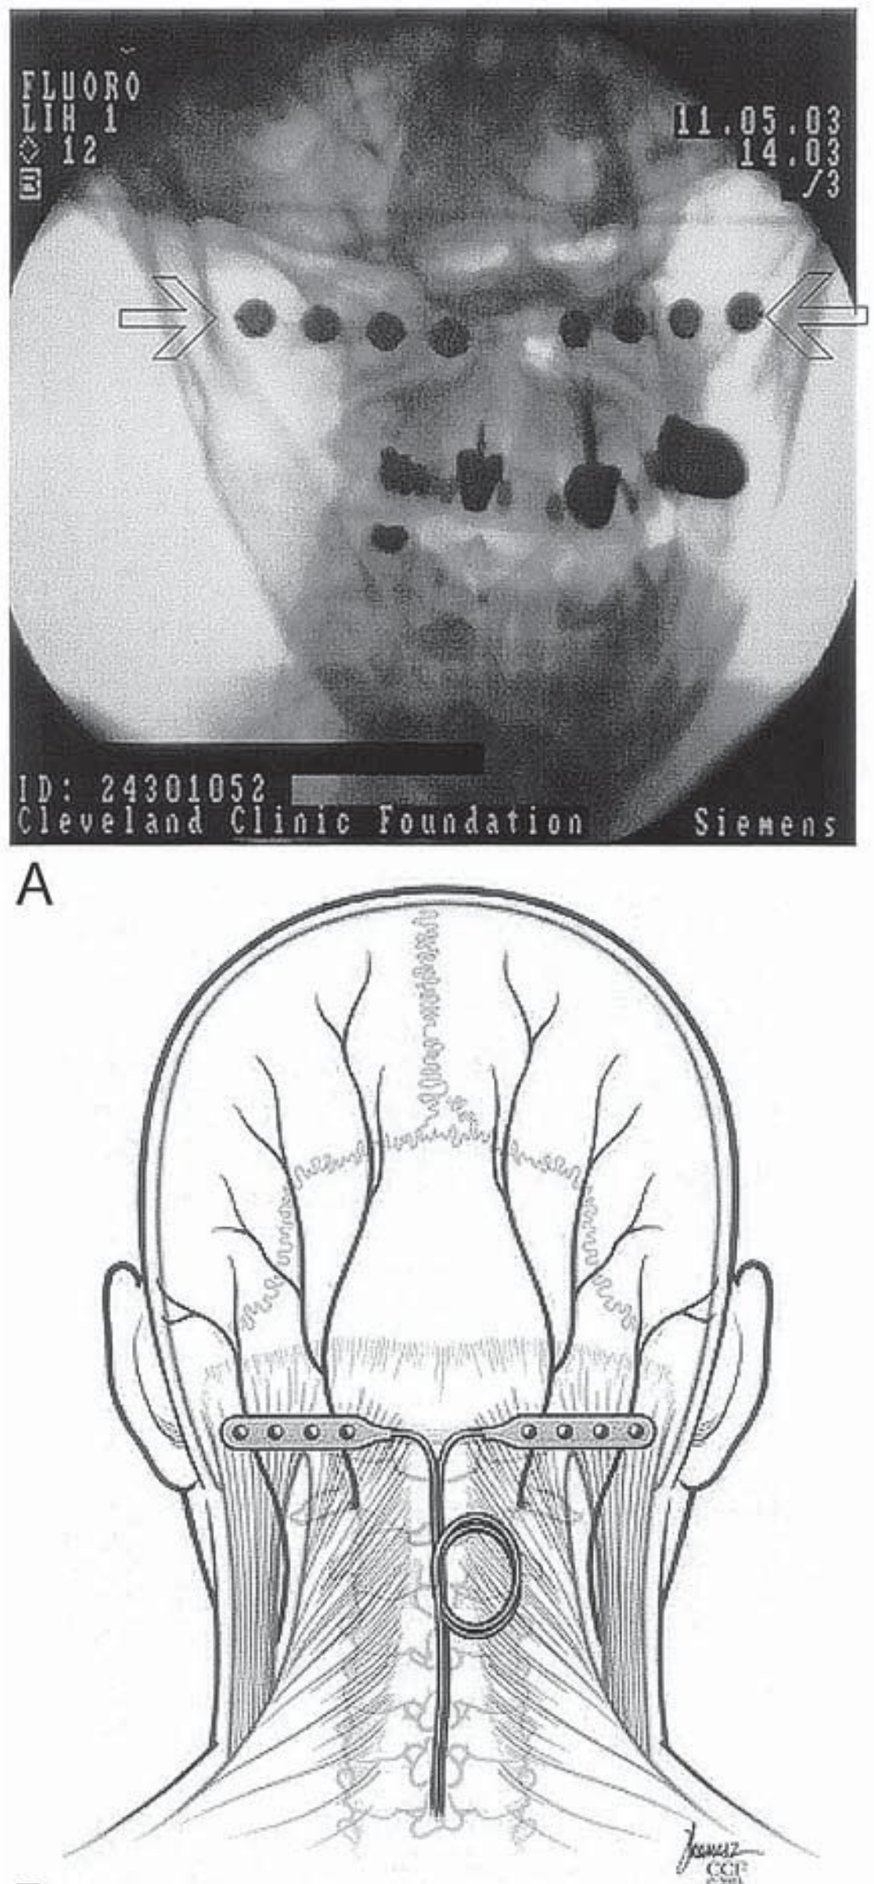

FIGURE 94.2 Radiograph **(A)** and schematics **(B)** of the midline subcutaneous approach in surgical lead positioning for electrical stimulation of the occipital nerve. **(A)** Bilateral position of subcutaneous Resume leads (*arrows*) after initial adjustment and just before intraoperative stimulation testing. Note that both leads are at the level of C1–2 dens and aimed laterally. **(B)** Schematic of the lead positioning in the subcutaneous occipital area. Note that the lead cable extensions form the loop just below the implant's position and via the same midline incision. (Reproduced with permission from Kapural L, Mekhail N, Hayek SM, et al. Occipital nerve electrical stimulation via the midline approach and subcutaneous surgical leads for treatment of severe occipital neuralgia: a pilot study. *Anesth Analg* 2005;101:171–174.)

Under general anesthesia, the original incision is opened to visualize the connection of the electrode to the temporary extension cable. The cable is then disconnected and extracted through the skin. A second incision and subcutaneous pocket must be created for the receiver/battery. In the upper extremity, the pocket is created in the deltopectoral groove; in the lower extremity it is made in the anterior thigh. A hollow, metallic tunneling device is passed subcutaneously from the pocket to the electrode. A permanent extension cable (Medtronic 7496-51) is connected to the electrode and passed through to the pocket. The cable is attached to a receiver/battery (Medtronic 3470). The receiver/battery is then internalized in the subcutaneous pocket. Both incisions are closed in multiple layers. For patients who do not obtain satisfactory results with the trial stimulation, the electrode and temporary extension cable are surgically removed. Postoperatively, the patients receive 24 hours of antibiotics. Once again the computer-based program is used to confirm the ideal stimulation parameters.

For occipital nerve stimulators, subcutaneous field stimulation is achieved by use of a percutaneous electrode inserted through a needle. The needle is placed perpendicular to the course of the nerve. There are different types of electrodes that can be placed. Although easy to place, cylindrical leads have disadvantages, including a tendency for lead migration and poor directionality of stimulation. Kapural et al. described the use of a paddle-style surgical lead introduced bilaterally via a midline approach[38] (Fig. 94.2). All six patients in this study experienced 50% or greater pain relief at 3-month follow-up. The wire type electrode, compared to the plate electrode on a nerve, is much less likely to cause perineural fibrosis.

CONCLUSION

PNS is a viable option for selected patients with a diverse array of intractable pain conditions. The best results have been obtained for treatment of painful traumatic mononeuropathy of the upper extremity and occipital neuralgia. Further research is needed to elucidate the mechanisms underlying the analgesic effects of PNS. As stimulator technology advances, new surgical techniques will arise to broaden the indications for PNS.

CHAPTER 95 ■ SPINAL CORD STIMULATION

RICHARD B. NORTH AND BENGT LINDEROTH

HISTORY

In antiquity, some healers successfully treated pain by placing electrogenic fish on or near the painful area of the patient's body.[1] This crude form of electrotherapy enjoyed a measure of success but was limited in scope by the geographic and ecologic constraints associated with keeping the fish alive and available. Thus, electrotherapy was not widespread until creation of the Leyden jar in 1745 made it possible for physicians not only to deliver electrotherapy at will but also to exert a modicum of control over how much electrical current the patient received. This was an exciting medical advance, and by the nineteenth century, physicians were considered well-equipped only if they had a portable generator and could provide electrotherapy for a wide range of indications. The advent of empirical medicine in the twentieth century, however, caused most physicians to abandon the application of electrical shocks to treat pain. Fortunately, in the mid-1960s, neurosurgeon C. Norman Shealy[2] recognized that Melzack and Wall's newly published *Gate Control Theory of Pain*[3] provided a theoretical basis for a new form of electrotherapy that could be delivered with implanted electrodes. Shealy[2] called his innovation "dorsal column stimulation"; today, we know it as spinal cord stimulation (SCS).

Melzack and Wall's[3] Gate Control Theory proposes that the balance of activity between large and small nerve fibers in the peripheral nervous system determines whether or not pain signals are transmitted centrally. According to the theory, when small fiber input is dominant, a pain "gate" opens in the dorsal horn (DH) of the entrance segment of the spinal cord; this gate closes when large fibers dominate. Because electrical stimulation depolarizes large fibers before it affects small fibers, the theory suggests that it should be possible for stimulation to close the pain gate. This hypothesis inspired Shealy[2] to deliver current directly to a dying cancer patient's spinal cord with an implanted electrode and external pulse generator in a successful bid to relieve the patient's otherwise intractable pain. Paradoxically, although the electrical stimulation therapies inspired by the Gate Control Theory have succeeded, the theory itself remains controversial because it predicts that all types of pain will be inhibited. Instead, clinical experience and clinical studies have indicated that SCS exerts its beneficial impact on neuropathic pain, but acute and nociceptive pain signals remain relatively unaffected.[4,5] Furthermore, large fiber activity can itself signal pain (for example, the pain of sunburn).[6]

Despite the fact that the Gate Control Theory does not adequately explain all aspects of the therapies it inspired, it provides a useful description of the general concept of the transmission of pain signals and has stood the test of time to a remarkable degree.[7]

Today, SCS is a minimally invasive, reversible therapy implemented with sophisticated techniques and implanted equipment, including a variety of electrodes and multioutput pulse generators. Unlike most surgical procedures undertaken to relieve pain, SCS does not ablate pain pathways or result in anatomic change. SCS also offers its candidates the advantage of undergoing a screening trial with a temporary SCS system before proceeding (or not) to implantation.

Pain and its relief by SCS vary by condition and from patient to patient. When SCS is delivered to the right patient by the right (experienced) clinician in the right setting using the right equipment, pain relief is optimized and can be sustained for decades. It is important to remember, however, that SCS is expected to reduce, not eliminate, pain, particularly pathologic (neuropathic) pain which constitutes a state of disease. SCS is not expected or intended to relieve nociceptive or evolutionally useful pain.

Investigators are continually improving SCS patient care by refining techniques and equipment, and as we learn more about the mechanism of action of SCS, we will be able to potentiate the impact of SCS.

MECHANISMS OF ACTION

Introduction

The work of several investigative teams in the four decades since Shealy[2] implanted the first "dorsal column stimulation" electrode has helped us identify promising avenues of research, refine experimental techniques, and develop evidence in support of hypotheses that explain aspects of the mechanisms of action of SCS. The challenge in experimental studies is to mimic the human painful condition and deliver stimulation, for example in rats, with parameters that would be clinically relevant in humans. Even in a homogeneous population of laboratory animals, however, the yield of neuropathic pain models is uncertain, and clinical studies must grapple with even greater variability among human subjects and painful pathologies. Furthermore, the clinical application of SCS elicits a discernible tingling, known as paresthesia, which confounds experimental blinding. An additional challenge is the fact that the universally agreed upon measurement of the effectiveness of SCS (reduction in pain) is subjective and depends to an uncomfortable degree on a patient's ability to remember the intensity of past pain in order to make a valid comparison with current pain. Pain assessment also relies on rather crude measurements, such as verbal rating scales and the visual analogue scale. Thus, patient assessment is assisted by measures of medication use, physical activity, well-being, etc.

Despite these obstacles, researchers have learned enough to propose distinct mechanisms of action for the therapeutic effects of SCS in the treatment of neuropathic, ischemic, and visceral pain.

Neurophysiology

SCS affects both spinal and supraspinal circuits[8–11] but does not rely solely on antidromic activation of the dorsal columns.[12,13] Some SCS effects survive disruption of supraspinal circuits by transection of the spinal cord rostral to the electrode;[14,15] others do not.[16]

Neurochemistry

SCS modulates DH and/or supraspinal neurotransmitters; thus, the beneficial effects of SCS often outlast active stimulation (see below). SCS might[17] or might not[18] cause release of spinal opioids. Most studies indicate that endogenous opioids are not involved in the pain relieving effects of SCS; for example, the effects of SCS are not reversed by the opioid antagonist naloxone,[19] and the neuropathic pain of SCS patients is usually resistant to opioid therapy. In patients with angina, however, SCS during atrial pacing and at-rest releases the opioid peptide β-endorphin into cardiac circulation, indicating that SCS affects "local myocardial turnover of the opioid peptides leuenkephalin, β-endorphin, and calcitonin-gene-related peptide [a powerful vasodilator]."[20]

Mechanisms in Neuropathic Pain

Nerve or nervous system injury can lead to neuropathic pain, which is often radiating, generally described as "burning," and commonly involves hyperalgesia (an extreme sensitivity to pain) and allodynia (pain from normally nonpainful stimuli). In contrast, dull, aching nociceptive pain, which is mediated by receptors in skin, muscle, bone, viscera, etc., is responsive to opioids. Since SCS is not thought to cause the release of endogenous opioids,[18] the clinical expectation is that SCS will be more effective as a treatment of neuropathic, ischemic, and visceral pain than of nociceptive pain. The fact that SCS is effective in treating ischemic pain, which is considered a form of nociceptive pain, does not mean that SCS directly affects nociceptive pain. Instead, SCS exerts a beneficial effect on the underlying ischemic condition (see below).

Allodynia occurs when the activation of nerve fibers in the periphery causes hyperactivity of wide dynamic range neurons (WDRs) in the superficial laminae of corresponding DHs.[21] SCS relieves allodynia by suppressing this hyperactivity.[22] Treatment with γ-aminobutyric acid (GABA) agonists also has this effect, and SCS induces GABA release in the DH of rats[8] and activates the GABA-B receptor.[23,24] SCS also decreases DH release of the excitatory amino acids glutamate and aspartate in rats.[24]

Investigators have also proposed that electrostimulation might relieve pain by blocking conduction of primary afferents at the branch points of dorsal column fibers and collaterals.[6] This explanation is insufficient, however, because the effect of SCS extends beyond the dorsal columns, and electrical stimulation does not inhibit every type of pain.[25] Dorsal column activation, however, is more successful than ventral stimulation,[26] which might activate the spinothalamic tract fibers that evoke pain.

SCS inhibition of the pathologic response (increased firing frequency of WDRs, after-discharge in response to pressure, etc.) of DH neurons in rats exhibiting symptoms of allodynia after peripheral nerve injury continues for more than 10 minutes,[22] consistent with SCS-induced release of DH and cerebral neurotransmitters, and changes the concentration of neurotransmitters and their metabolites in cerebrospinal fluid.[26–29]

Through the use of microdialysis techniques, investigators have examined the effects of SCS on the cerebral neurotransmitter serotonin and on substance P, a polypeptide implicated in the transmission of pain impulses and in sensitizing DH neurons. In decerebrate cats, SCS invokes DH release of serotonin and substance P, but in anesthetized cats, SCS only induces a detectable DH release of substance P.[27,30]

The problem of applicability of research results from unconscious animals to conscious humans led investigators to create an experimental model using supraspinal microdialysis in conscious rats.[31,32] Application of this method revealed that a repeat 30-minute dose of SCS after a 90-minute resting period causes GABA and glutamate levels in ventrolateral periaqueductal grey matter to decrease, perhaps signaling pain inhibition (this rest/repeat scheme does not affect the concentration of serotonin or of substance P-like immunoreactivity).[8,31] Investigators also used models of painful neuropathy to explore the impact of SCS on

the pain threshold in rats and found that during and after SCS, the threshold of withdrawal from innocuous mechanical stimuli increases and that SCS affects only the component of the flexor reflex mediated by A-fibers (not the late component mediated by C-fibers).[33] Thus, current thinking holds that, to a large extent, SCS acts on a segmental spinal level,[15] although additional inhibitory influences might be transmitted by descending serotonergic and noradrenergic pathways. A related study used the partial sciatic nerve ligation model to examine how SCS affects the response to innocuous stimuli in postligation rats with and without allodynia and in controls. Only in the allodynic rats did SCS significantly depress abnormal responses and spontaneous discharge of WDR neurons.[22] The same research group introduced acetylcholine (ACH) into the list of transmitters possibly involved in the beneficial effects of SCS after a microdialysis study demonstrated that ACH is released in the DHs of rats whose pain-related symptoms after nerve injury decreased in response to stimulation.[34] These effects seem to be caused by activation of muscarinic M4 and M2 receptors in the DH.[34,35] This finding might lead to new ways to enhance an otherwise inadequate effect of SCS in certain patients.

Along these lines, based on the fact that extracellular GABA levels are lower in allodynic rats than in controls but increase in allodynic rats that respond to SCS (not all rats respond),[36] investigators have attempted to potentiate the therapeutic effect of SCS in nonresponding rats with concurrent intrathecal administration of normally subtherapeutic levels of GABA or the GABA-B agonist baclofen.[23] This strategy caused a marked increase in the rats' threshold for withdrawal from innocuous mechanical stimulation. Intrathecal administration of the selective α1-adenosine receptor agonist R-phenyl isopropyl adenosine produced similar results.[24] Administration of subtherapeutic doses of these agents as adjunct therapy with SCS causes nonresponding rats to respond to SCS.[37]

In the first clinical study based on this response, however, the addition of intrathecal baclofen and/or adenosine potentiated SCS in only 2 of 5 patients.[38] This result caused investigators to increase the dose of intrathecal gabapentin and intravenous pregabalin in non-SCS-responding rats with partial sciatic nerve lesion. In these rats, the drugs reduced tactile allodynia in a dose-dependent manner and enhanced suppression of hyperexcitability of WDR neurons.[39] A similar dose-dependent effect occurred with intrathecal administration of an otherwise subtherapeutic dose of clonidine.[40] Thus, the investigators conducted a pilot study that offered intrathecal baclofen (and, in a few cases, intrathecal adenosine) to 48 patients who did not successfully respond to technically adequate SCS.[41] Although 20 patients achieved satisfactory pain relief with baclofen plus SCS or baclofen alone, only 11 continued treatment: 7 with a combination SCS system and intrathecal baclofen pump and 4 with only a baclofen pump. At mean 67 months postimplant, 2 SCS/intrathecal patients had their pumps removed and the remaining 9 in the group (5 SCS/ intrathecal, 4 intrathecal) reported continued pain relief. The baclofen dose was increased 160% from baseline, but 5 patients reduced use of other analgesics.

Among the things rats and humans have in common are that nerve injury alone sometimes causes allodynia and that SCS is not universally therapeutic. Seeking the reason for the distinctions (information that would not only shed light on the mechanisms of action of SCS but also on patient selection for the therapy), investigators used the original spared nerve injury model and variations of the model to create lesions in rats at various points on the sciatic nerve.[42] The investigators found that the location of the lesion affects both the incidence of allodynia, which varied from 50% to 73%, and responsiveness to SCS, which was only 8% with the original spared nerve model but increased to 40% to 50% after peroneal axotomy, tibial axotomy, or partial or full tibial tight ligation. The allodynia caused by these lesions was less severe than that invoked by the original model; thus, SCS was more effective in rats with mild allodynia than in those with severe allodynia. This finding was confirmed by further study.[43] The mechanisms and neurotransmitters known or hypothesized to be involved in the effects of SCS in neuropathic pain are illustrated in Figure 95.1. We have yet to identify all of the neurotransmitters and neuromodulators affected by SCS, let alone to decipher their doubtless complicated interactions.[24,26,31]

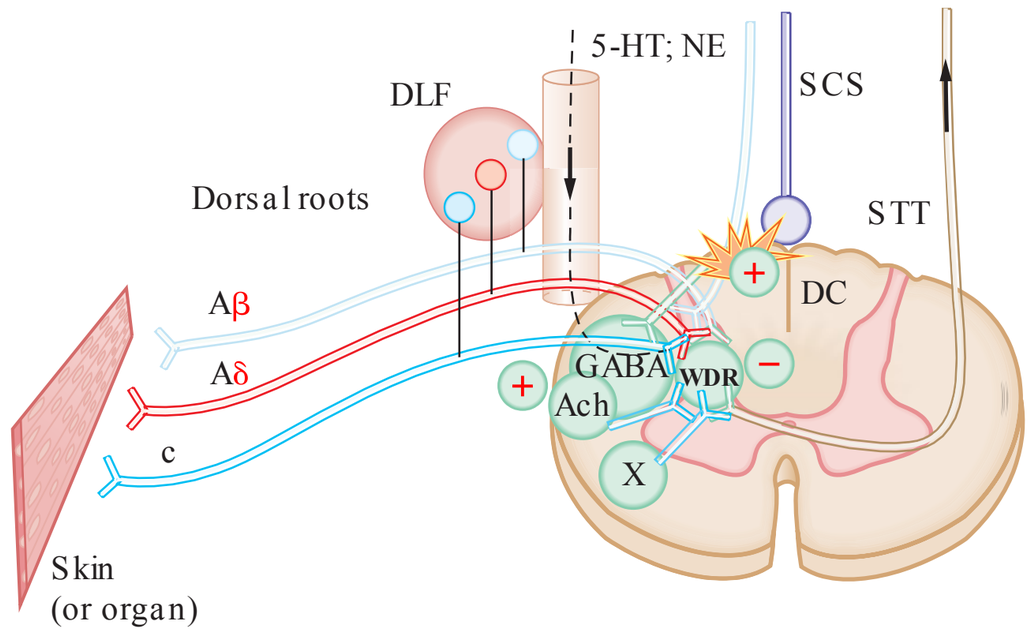

FIGURE 95.1 Schematic illustration of mechanisms and neurotransmitters possibly involved in the effects of SCS in neuropathic pain. SCS activation of dorsal column collaterals secondarily induces release of GABA from DH interneurons, activating mainly GABA-B receptors and decreasing the release of excitatory amino acids from hyperexcited second-order DH WDR neurons. SCS also causes cholinergic neurons to activate M4 and M2 muscarinic type receptors (Ach). Several other transmitters, adenosine and hitherto unknown substances are also likely involved. Furthermore, the orthodromic SCS-induced activity in the dorsal columns might—via neuronal circuitry in the brain stem (or even more rostrally)—induce descending inhibition via serotonergic (5-HT) and noradrenergic (NE) pathways in the dorsolateral funiculus (DLF), which might contribute to inhibitory influences in the DHs. DC, dorsal columns; STT, spinothalamic tract.

Putative Mechanisms in Complex Regional Pain Syndrome

Theoretically, SCS exerts its positive effect on pain in patients with complex regional pain syndrome (CRPS) by reducing central hyperexcitability, by inhibiting sympathetic efferent activity to prevent development of abnormal contacts between peripheral sympathetic and damaged somatosensory fibers,[44] or by preventing vasoconstriction, which can excite damaged sensory afferent fibers.[44,45] In the only clinical study to investigate the impact of SCS on peripheral vasodilatation in CRPS I patients who experienced pain relief, however, SCS did not induce peripheral vasodilatation.[46]

Spinal Cord Stimulation Mechanisms in Ischemic Pain

SCS is thought to induce vasodilatation and improve microperfusion in patients with ischemic pain, which is sharp, aching, heavy, and tiring[47] and a signal of restricted blood flow. Thus, SCS has a beneficial effect on the cause, not merely the symptoms, of ischemic pain. This might explain why ischemic pain is the only type of nociceptive pain known to respond to SCS and why the mechanisms seem to be fundamentally distinct from those that provide relief of neuropathic pain.[18,26,48]

Peripheral Vascular Disease

To investigate the mechanism of SCS in the treatment of peripheral vascular disease (PVD), investigators developed a new animal model that involves applying mechanical pressure to an artery in the groin of rats.[49] Using this model, SCS delivered with clinically relevant stimulation parameters recovered normal microcirculation in 100% of treated rats versus 28% of controls. In addition, administering SCS preemptively reduced the amplitude of the invoked spasm and significantly shortened the time to recovery of microcirculation.[50]

SCS also suppresses efferent sympathetic activity (maintained by nicotinic ganglionic receptors and α-1-adrenoreceptors)[49] and might activate antidromic mechanisms at intensities far below the motor threshold,[51–55] thus causing peripheral vasodilation by stimulating release of calcitonin gene-related peptide (CGRP)[50–52] from the terminals of sensory fibers that contain transient receptor potential vanilloid-1 receptors[56,57] and the release of nitric oxide from a different location (possibly endothelial cells).[57]

The balance between these two mechanisms seems to depend on the activity level of the sympathetic nervous system, the intensity of SCS, and individual patient factors (genetic differences, diet, etc.).[54]

The fact that SCS has a powerfully beneficial effect on vasospastic conditions, such as Raynaud's Syndrome, is consistent with theories that the cause of Raynaud's Syndrome is a combination of heightened sensitivity or increased density of α-adrenergic receptors[58] and CGRP-system dysfunction.[59] A stimulation-induced "normalization" of function in each system could underlie the efficacy of SCS in treating this condition.

Because administering an autonomic ganglion blocking agent attenuates SCS-induced vasodilatation, SCS is believed to exert some of its effects by inhibiting sympathetic efferents. The outcome, however, differs among different laboratories and strains of rats. This result, for instance, did not occur on administration of a ganglionic blocking agent in North American studies.[51,52,54] Instead, these studies as well as experiments by Wu et al.[56,57] favored antidromic activation as the most important mechanism of SCS-induced peripheral vasodilatation. In fact, antidromic activation dominated at low autonomic baseline activity, while the sympatholytic effects of SCS were clear with high baseline activity.[55,60] Later studies have indicated that even small diameter fibers are involved at SCS intensities much below the motor threshold[56,57] and have pointed toward additional mechanisms.[61–63] A review of the mechanisms involved in SCS-induced vasodilation is included in a report by Wu et al.[64]

The mechanisms and neurotransmitters known or hypothesized to be involved in the effects of SCS in ischemic pain are depicted in Figure 95.2.

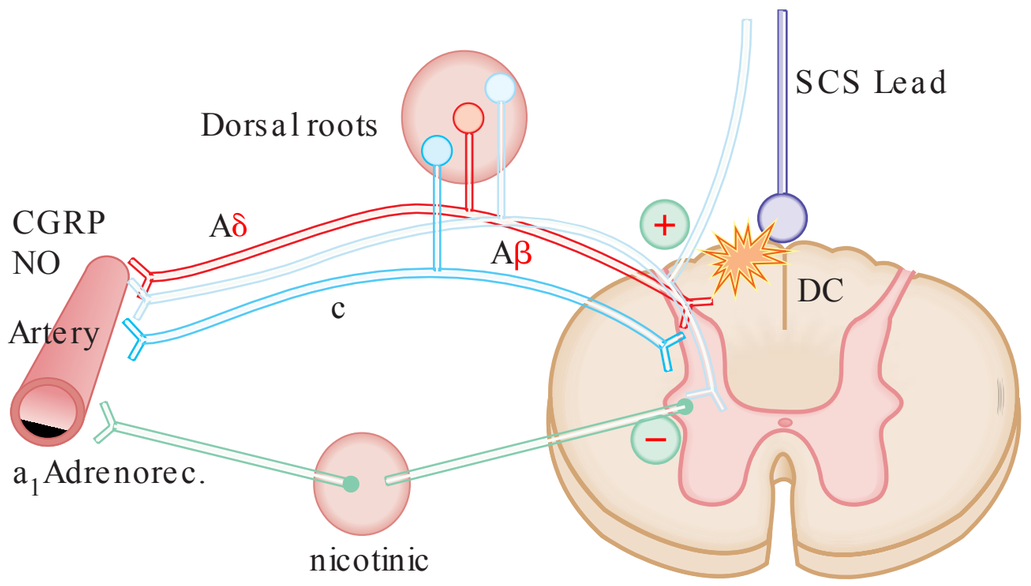

FIGURE 95.2 Schematic illustration of mechanisms and neurotransmitters possibly involved in effects of SCS in ischemic pain. SCS probably indirectly exerts inhibition onto medullary neurons, thus perpetuating sympathetic efferent vasoconstriction via nicotinic ganglionic receptors, mainly α1 (α1 adrenorec = adrenoreceptors) peripheral receptors. In parallel, SCS activates an antidromic loop inducing peripheral release of CGRP, probably also involving small diameter fibers. An inhibition of nociceptive transmission has also been indicated in experimental studies but is clinically unlikely. DC, dorsal columns; NO, nitric oxide; SCS Lead, spinal cord stimulation lead.

Angina

Investigators studying the mechanism of action of SCS in patients with otherwise refractory angina agree that SCS reduces ischemia[65] but disagree about how this occurs. Positron emission tomography has indicated that SCS causes a redistribution of coronary blood flow in patients with refractory angina[66,67] (even though experimental studies have failed to demonstrate this effect[68]). On the other hand, the decrease in the depression extending from the end of the S wave to the beginning of the T wave (ST-segment depression) that appears on electrocardiograms during SCS treatment and the observed SCS-induced reversal of lactate production to extraction might indicate an accompanying decrease in cardiac myocyte oxygen demand.[69]

The SCS-induced protective changes that increase myocardial resistance to critical ischemia[70] are manifest by the improved tolerance of patients to a deliberately paced increase in heart rate,[71] and by increased time-to-angina in exercise tests.[18] This effect might signal an SCS-induced inhibition of the excitatory effect of ischemia on the intrinsic cardiac nervous system (such an excitatory effect might lead to dysrhythmia and increased ischemia).[70–72] The possibility that SCS modulates cardiac neurons is supported by the finding that transcutaneous electrical nerve stimulation increases blood flow in intact human hearts but not in transplanted, denervated hearts.[54]

Because SCS reduces total body, but not cardiac-specific, norepinephrine spillover during pacing to moderate angina,[73] part of the anti-ischemic effect of SCS might owe its potency to an overall reduction in sympathetic activity. An experimental study using induced cardiac infarcts in a rabbit model, however, indicates that the decrease in infarct size with SCS therapy shares some mechanisms with "ischemic preconditioning" but, notably, does not cause cardiac ischemia.[74] Further studies of these phenomena are on-going.

Figure 95.3 illustrates the mechanisms and neurotransmitters known or hypothesized to be involved in the effects of SCS in angina.

Mechanisms in Visceral Pain

The treatment of visceral pain is a relatively new application for SCS, and investigators have proposed that SCS might exert its positive effect on visceral pain (and dysfunction) by moderating the so-called "brain-gut" axis (the neural circuitry thought to control the interface among visceral afferent sensation, intestinal motor function, and the brain).[61,75–77]

In fact, moving an active SCS electrode along the neuroaxis demonstrates that electric activation occurs at various levels; thus, in addition to the its beneficial effects on pain and ischemia, SCS inhibits the viscero-somatic reflexes involved with the particular spinal segmental level being stimulated (Fig. 95.4).

Computer Modeling Studies

Finite element computer models of SCS electrical fields in the spinal cord[78–80] have confirmed the current and voltage distribu-

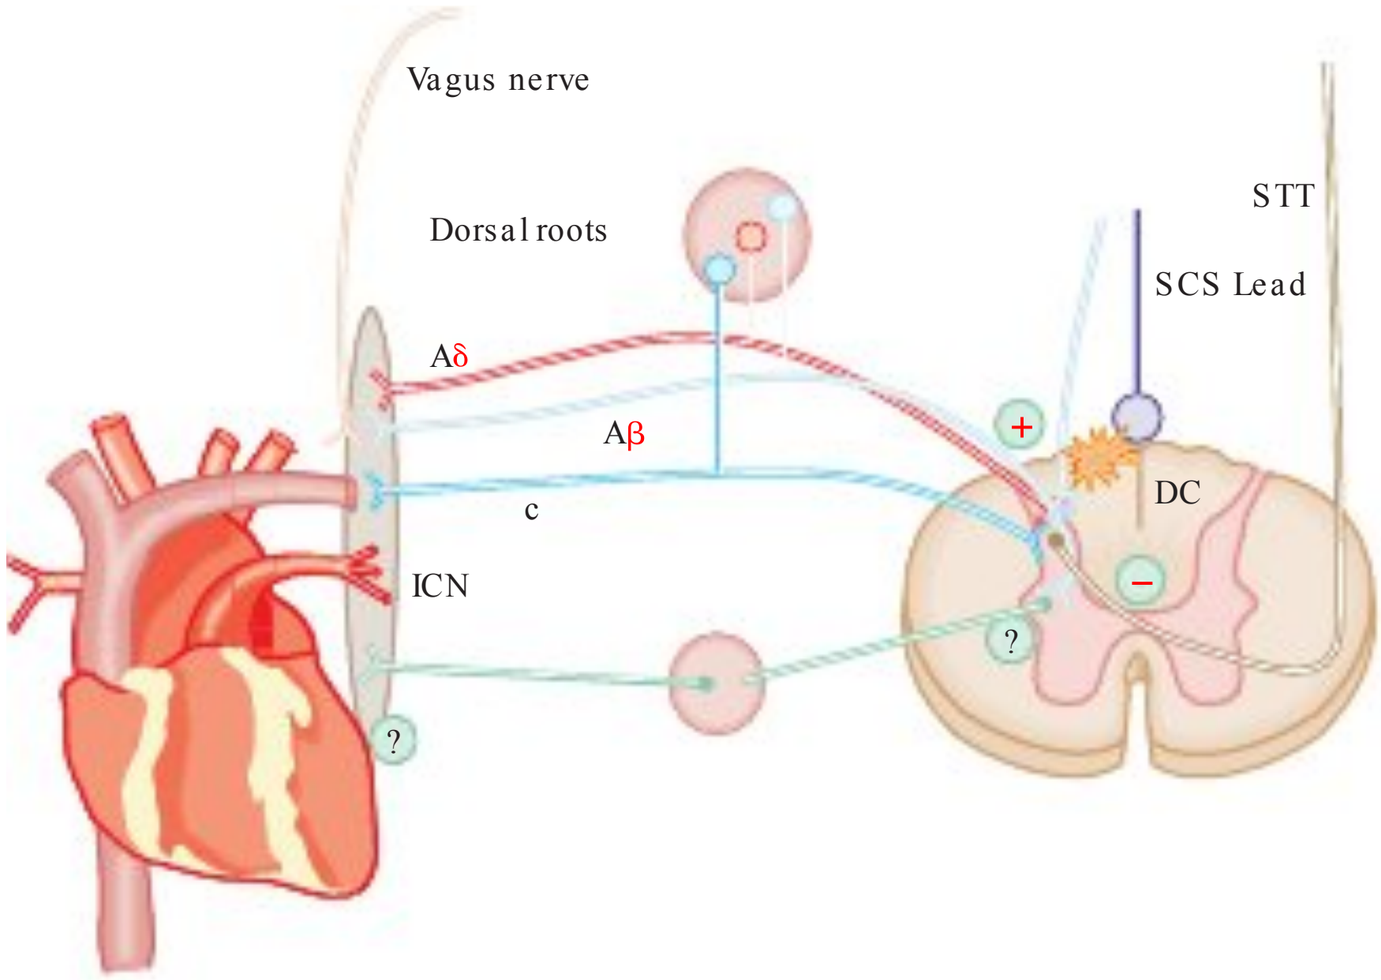

FIGURE 95.3 Schematic illustration of some mechanisms possibly involved in the effects of SCS on coronary ischemic pain. SCS might exert indirect inhibitory effects on nociceptive transmission to higher centers and on the level of sympathetic activity; SCS might also have antidromically transmitted effects. Intrinsic cardiac neurons (ICN) are deeply involved in monitoring ischemic events in the heart, and this function is drastically influenced by SCS. The interplay between somatosensory and autonomic influences and the effects of SCS is presently largely unknown but is the subject of intense investigation. DC, dorsal columns; SCS Lead, spinal cord stimulation lead; STT, spinothalamic tract.

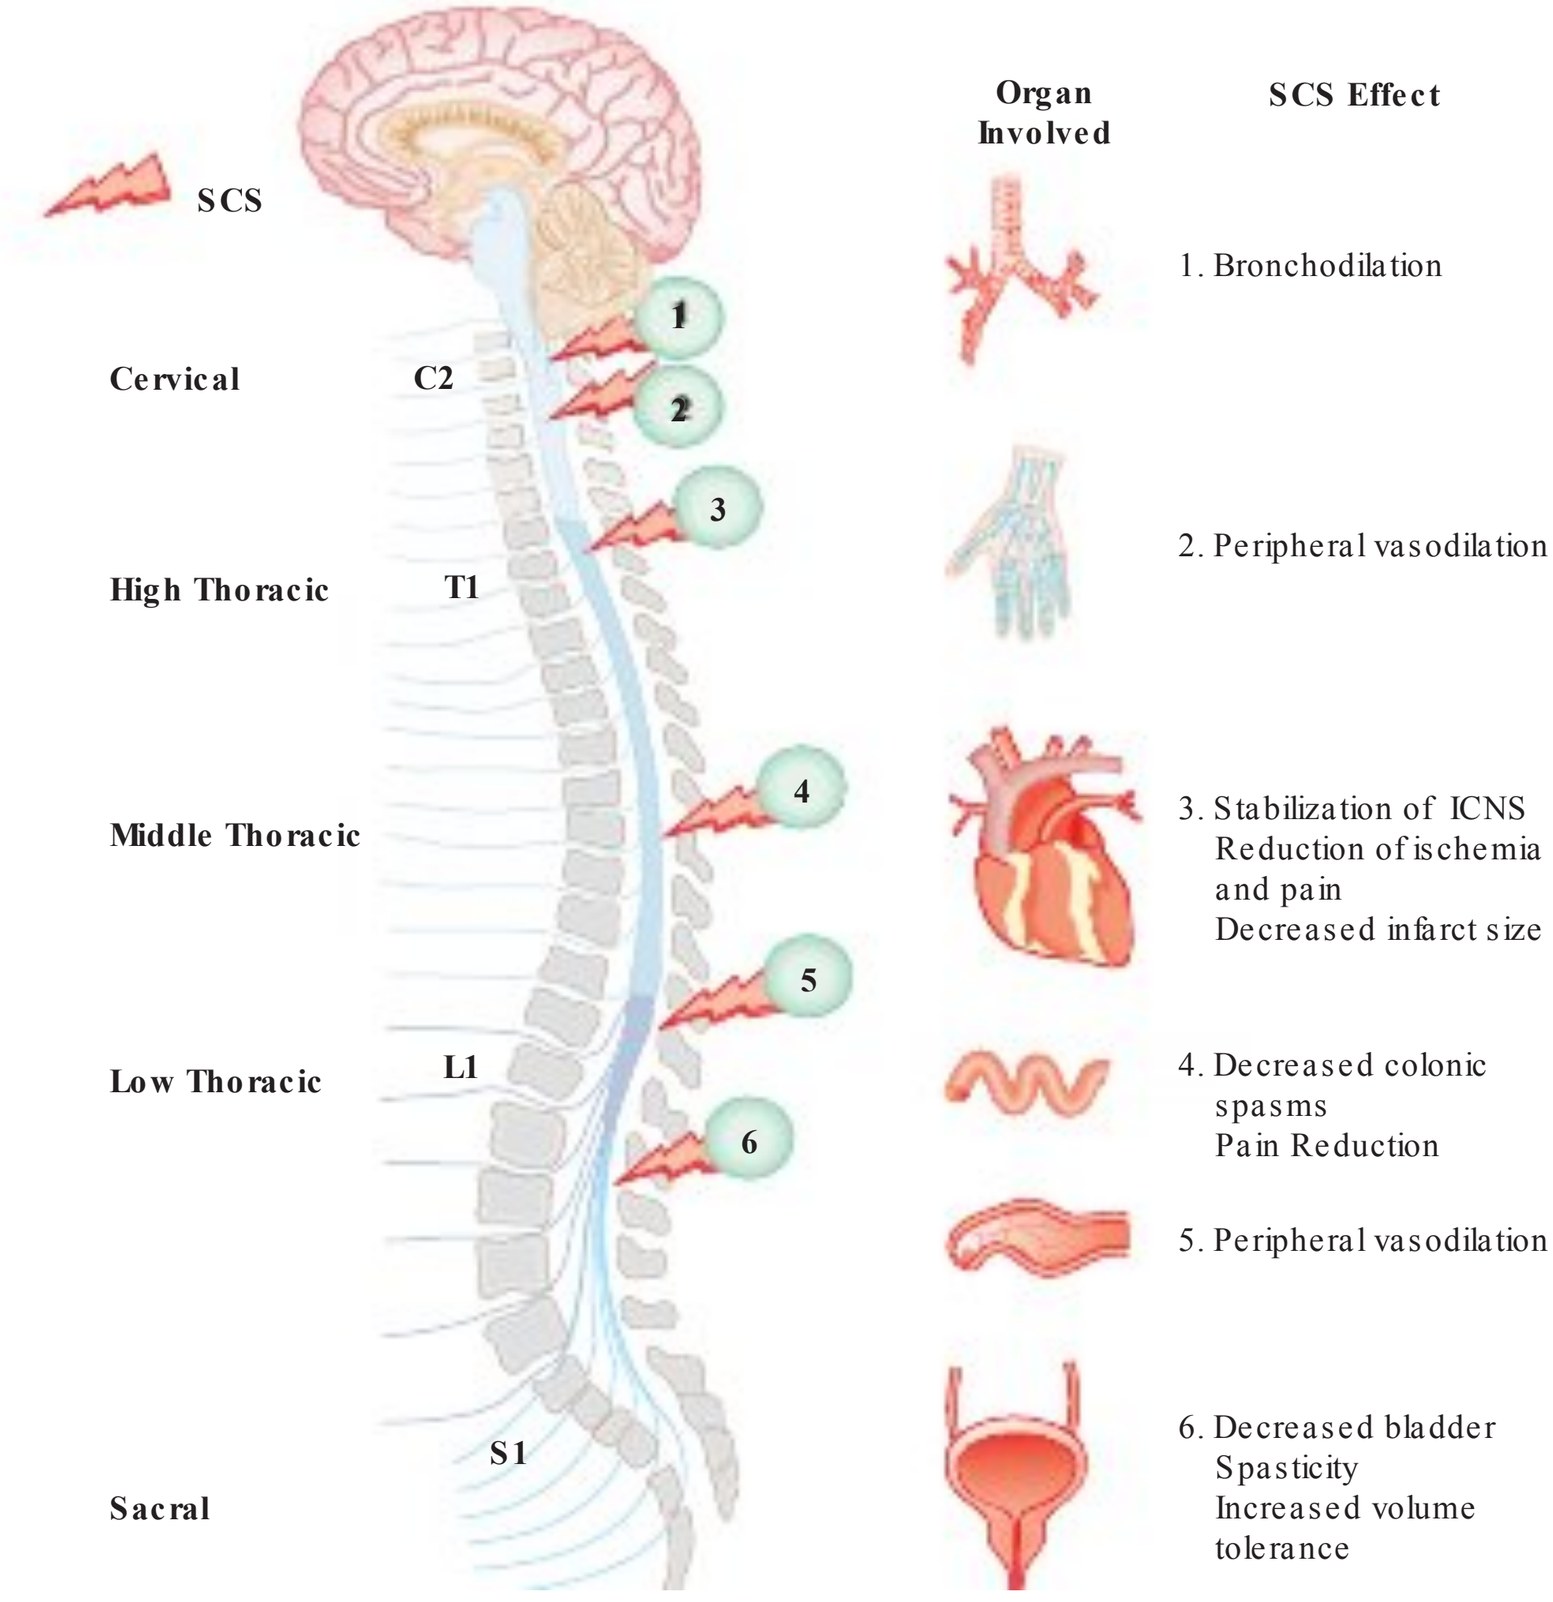

FIGURE 95.4 SCS applied at different levels of the neuroaxis might, in addition to affecting pain and peripheral blood flow, induce changes in different target organs mediated via stimulation induced changes in local autonomic activity, dorsal root reflexes, or viscero-somatic reflexes. Some of these changes in target organ function might be beneficial (redrawn after Linderoth B, Foreman RD. Mechanisms of spinal cord stimulation in painful syndromes: role of animal models. *Pain Med* 2006;7:514–526).

tion measurements previously obtained from cadavers and primates.[81] Application of these models has also led to the prediction that (1) an electrode's longitudinal position governs its segmental effect; (2) bipolar stimulation with contacts separated by 6 to 8 mm optimizes selection of midline, longitudinally-oriented fibers (a longer distance reduces therapeutic effect by favoring dorsal root stimulation); and (3) the electrical field between two cathodes placed on either side of the physiologic midline does not sum constructively in the midline. Clinical experience confirms that the correct position and spacing of SCS electrodes is essential for therapeutic success and that, instead of expanding the area of paresthesia, positioning electrodes cephalad to the involved spinal levels commonly elicits unwanted, excessive, local segmental effects.[82]

The first computerized models developed to study the spinal canal approximated the meninges, cerebrospinal fluid, fiber tracts, and grey matter with geometric shapes.[83,84] The equally simplistic, two-dimensional initial computer models of dorsal epidural stimulation[85–87] were soon replaced by a three-dimensional model that took into account fiber tracts, their branch points, and dorsal roots.[78,88]

In 1991, Holsheimer and Struijk developed a new model[89] that merged this three-dimensional construct with a McNeal-type[90] cable model of the electrical behavior of myelinated nerve fibers and data derived from mammalian myelinated fibers.[91] The resulting "University of Twente SCS Computer Model" allowed investigators to determine the impact of the location and configuration (anode/cathode, on/off) of SCS electrodes (e.g., to maximize recruitment of deep, midline, longitudinal axons rather than of the lateral, or dorsal root, fibers that can cause discomfort and motor responses) and to suggest ways to optimize SCS equipment design.

The University of Twente model was further refined when the investigators were able to apply data from human sensory fibers.[92] This improved the accuracy of predictions about the impact of various SCS threshold voltages.[93] An additional improvement streamlined the mathematical techniques used to predict stimulation effects when computing the three-dimensional action potential field.[94] Model predictions for "transverse tripole" electrode performance have been validated in part by clinical studies.[95]

INDICATIONS

Neuropathic Pain

In the United States, the major indication for SCS is the treatment of neuropathic pain arising from failed back surgery syndrome (FBSS). Two randomized controlled trials have demonstrated the superiority of treating FBSS with SCS versus reoperation[96] or optimized conventional medical management.[97] Of course, an FBSS patient with gross instability or a neurologic deficit caused by neural compression that is evident on an imaging study would undergo a corrective surgical procedure before or instead of SCS.

It is easier to achieve pain relief in the limbs than in the low back because low back pain is more likely than leg pain to have a nociceptive component, which is not expected to respond to SCS, and because pain/paresthesia overlap in the low back is generally more difficult to achieve, even with complex electrode arrays and detailed psychophysical tests. At one time, achieving low back pain relief with SCS was considered rare; however, Law's[98] research on techniques to guide paresthesia coverage kept the low back available as an SCS therapeutic target, and clinicians have built on his work to define the best electrodes[99] and contact combinations[79] for achieving pain relief in the low back.

The use of SCS to treat pain in the limbs arising from CRPS I (reflex sympathetic dystrophy) is also supported by data from a randomized controlled trial.[100,101] In that study, 5 years post-treatment, the 20 patients remaining in the group that actually received SCS reported better pain relief and superior global perceived effect than did those patients remaining in the alternate group who did not receive SCS.[102]

Other neuropathic pain indications for SCS include phantom limb/postamputation syndrome, postherpetic neuralgia, root injury pain, and pain/spasm arising from spinal cord injury or lesion.

Ischemic Pain

In Europe, clinicians have gathered evidence on the efficacy of SCS in the treatment of ischemic pain caused by refractory angina (including syndrome X),[103–106] PVD,[107,108] Raynaud's Syndrome, and diabetic neuropathy. As noted above, in patients with ischemia, SCS not only treats the pain, it also has a positive effect on the underlying ischemia. Thus, the outcome criteria used to document the impact of SCS on critical limb ischemia arising from PVD include survival, limb salvage, and measures of microcirculation,[109] as well as pain relief.

In Raynaud's Syndrome, the few published studies (all of which involve small numbers of patients) demonstrate the positive effect of SCS therapy.[110–114] This is not surprising because, compared with PVD patients, patients with vasospastic conditions are relatively young, present with relatively few obliterative vessel wall processes, and have symptoms that are often temporarily relieved by destroying or blocking the corresponding sympathetic ganglia.

Some clinicians are using cervical SCS in exploratory trials to improve cerebral blood flow in patients recovering from stroke,[115] coma,[116] or brain tumors.[117]

Visceral Pain and Dysfunction

SCS and other forms of neurostimulation are also being used to treat visceral dysfunction and pain associated with such diseases as interstitial cystitis,[118] pancreatitis,[119] motility disorders, urinary urgency and frequency,[120] pelvic pain,[121] vulvodynia,[122] and pelvic floor dysfunction.[123]

POTENTIAL BENEFICIAL OUTCOMES

Technical Goal

The technical goal of therapeutic SCS is to cover a patient's pain with a comfortable level of paresthesia. Clinicians consider this blanket of paresthesia a necessary but not sufficient condition for therapeutic success.

If an electrode migrates or if pain changes location, appropriate paresthesia coverage can be lost. Thus, contemporary SCS systems are designed to allow adjustment of stimulation parameters postimplant to steer paresthesia to a new location or to recapture coverage. Only occasionally does readjustment for these purposes require a surgical intervention.

It is possible for paresthesia to cover the painful area without providing an analgesic effect. Such clinical failure can become evident during the screening trial or can arise after a period of success. On rare occasions, a patient who experiences technical success and pain relief dislikes the sensation of paresthesia and decides not to continue the therapy.

Clinical Goal

The generally accepted clinical goal of SCS treatment for pain is a minimum of 50% pain relief, but this and other measures all have limitations.[124] Additional reported benefits of SCS include (1) reduced consumption of medication and other health care resources; (2) improved ability to engage in the activities of daily living, quality of life, neurologic function, and symptoms of emotional depression; and (3) return to work when uncontrolled chronic pain was the only impediment (and generally when the patient has been out of work for less than 2 years).[125,126]

In patients suffering from ischemic pain, SCS can improve microcirculation and tissue oxygenation. This, in turn, can promote the healing of ischemic ulcers and increase the possibility of limb salvage.

PROGNOSTIC FACTORS

Demographics provide no help in choosing the ideal SCS candidate. Age is only a factor in children, where the safety and effectiveness of SCS is not established and in the elderly, who might have difficulty dealing with the patient interface (or recharging a battery), but, as for example with driving cars, the effect of advanced age must be assessed on an individual basis.

Researchers have reported some outcome differences between men and women, but these have been minor and of little if any practical value. Thus, the only sex-related caveat is that the safety of SCS during pregnancy is not established (although pregnant women have continued to use SCS rather than suffer known and suspected adverse effects of alternative pain treatments). Even a very short life expectancy does not rule out SCS, which can be cost effective even for short-term use if an external stimulator is used.

Also, we can not reliably predict SCS outcome based on worker's compensation or litigation status, but some clinicians err on the side of caution and consider the unresolved possibility of secondary gain a relative contraindication to allowing a patient to undergo a screening trial.

For FBSS patients, it seems that the chance of success with SCS decreases as the number of relevant prior surgical procedures and the time since the last surgical procedure increases. The type of surgical procedure the patient has experienced is also important; some ablative procedures, such as rhizotomy, dorsal root ganglionectomy, or dorsal root entry zone lesioning might obliterate the neural substrate upon which SCS is thought to depend.[127]

For patients with PVD, investigators have reported that 1-year limb salvage is more likely to occur if the baseline supine $TcPO_2$ is $>$10 mm Hg, the baseline sitting-supine score is $>$17 mm Hg, and the treatment difference is $>$4 mm Hg.[128] Some investigators believe that a 50% improved $TcPO_2$ score during a 2-week screening period predicts limb salvage,[129] regardless of baseline score or disease stage.[130] In the case of diabetic neuropathy, however, these investigators found the stage of neuropathy to be inversely related to SCS treatment success,[131] independent of the stage of the disease.[132]

PATIENT SELECTION

One of the first things we learned about SCS was that achieving a successful outcome required the right patient. In any group of patients, the presence of seemingly identical pain syndromes was not enough to predict identical (or even any) SCS success in each individual. A major advantage of SCS, however, is that it is possible to perform a screening trial, which involves temporary (7–10 days) placement of an electrode to determine the extent of pain/paresthesia overlap and the resulting therapeutic effect. In some European countries, a trial period of several weeks is required for reimbursement of hospital costs.

The screening trial offers the most meaningful prognostic sign of the outcome of SCS, but, of course, not all potential SCS patients proceed to a screening trial. Information to determine a patient's suitability for a screening trial is gathered from the patient's history and from the results of a physical examination and imaging studies.

Among the important aspects of the patient's history are the location, intensity, duration, and characteristics of the pain and the patient's psychologic status. Radiating pain that has an objective basis, is distributed in a manner consistent with information gleaned from a physical examination and imaging studies, and can be labeled with a specific diagnosis is the most straightforward to treat. Imaging studies that are useful for diagnostic purposes can also provide anatomic information that can be helpful or even vital during SCS implantation.

In the United States, Medicare and many health insurance companies require SCS candidates to undergo a routine psychologic evaluation. Although no psychologic test predicts the result of SCS treatment (and physicians routinely expect new patients to meet reasonable psychologic/behavioral standards), patients who have been living with chronic pain often benefit from psychologic screening with the attendant possibility of therapy. Any major psychiatric comorbidity must be addressed before a patient undergoes a SCS screening trial.

Relative contraindications include:

- Unresolved major psychiatric comorbidity
- Unresolved possibility of secondary gain
- Inappropriate dependency on pharmaceuticals
- Inconsistency among the history, pain ratings and description, physical examination, and diagnostic studies
- Abnormal pain ratings
- A predominance of nonorganic signs (e.g., Waddell's signs)
- Alternative therapies with a risk/benefit ratio comparable to that of SCS remain to be tried
- Pregnancy
- Occupational risk (e.g., of falling)
- Local or systemic infection
- Presence of a demand pacemaker or cardioverter defibrillator
- Foreseeable need for magnetic resonance imaging (MRI)
- Presence of a major comorbid chronic pain syndrome
- Anticoagulant or antiplatelet therapy

Absolute contraindications include:

- Inability to control the device
- Gross spinal instability at risk for progression or nerve compression amenable to surgery causing a serious neurologic deficit that requires immediate attention
- Coagulopathy, immunosuppression, or other condition associated with an unacceptable surgical risk
- Need for therapeutic diathermy

TECHNIQUE

A discussion of techniques used for the various types of SCS screening trials and for SCS implantations is beyond the scope of this chapter. Instead, we refer the reader to previous publications.[133–135]

SCREENING TRIAL

Before the introduction of percutaneous catheter electrodes in the 1970s, physicians used a variety of methods to screen potential SCS candidates, including transcutaneous electrical stimulation,

which were found to lack prognostic value. The percutaneous electrodes developed to facilitate a screening trial were immediately adopted for chronic use as well. Today, SCS systems in the United States are generally only implanted in patients who pass a screening trial. In Europe, the screening trial is commonly bypassed in patients with typical angina pectoris, a short-cut that reflects the fact that more than 80% of these patients enjoy significant pain relief with SCS.

Beyond indicating that SCS therapy might be successful, the benefits of a screening trial include allowing a patient to experience the sensation of paresthesia before undergoing implantation of the expensive pulse generator. The trial also provides important information that will dictate the choice of a permanent electrode and pulse generator and the optimum stimulating configuration. A successful screening trial commonly is defined by at least 50% patient-reported pain relief despite appropriate (provocative) physical activity and stable or reduced analgesic consumption. Patient satisfaction is another vital outcome. Medicare and many third-party payers require a successful screening trial before implantation.

Screening Electrode Choice

A percutaneous catheter electrode placed under fluoroscopy provides easy access to multiple target spinal levels and facilitates mapping of pain/paresthesia overlap to determine the optimal longitudinal level for the electrode.

An insulated surgical plate/paddle electrode inserted by laminectomy limits access to spinal levels and mapping but is required if a percutaneous catheter electrode does not access the epidural space satisfactorily. Screening with a surgical plate/paddle electrode is also necessary in some patients to eliminate uncomfortable extraneous stimulation or provide sufficient pain/paresthesia overlap.

Electrode Positioning

Patients remain conscious during trial electrode placement in order to describe paresthesia coverage and have the opportunity to react to changes in stimulation parameters or unanticipated intraoperative events.

Parameter Adjustment

Trained professionals work with patients to adjust simulator parameters during the screening trial and after implantation to find the settings that maximize comfortable pain/paresthesia overlap, reduce or eliminate extraneous stimulation, and minimize power requirements. Patients are instructed at each stage so as to operate the device appropriately.

Procedural Risk Reduction

Implanting an electrode for a screening trial or chronic stimulation is associated with certain risks, including spinal cord or nerve injury, dural puncture, epidural hematoma, and infection. Risk can be reduced by ordering a preimplant MRI of the target spinal levels, performing the procedure under fluoroscopy with the patient conscious, maintaining a meticulously sterile environment, administering prophylactic antibiotics, and observing the patient for a reasonable of time postprocedure (e.g., overnight). Discharge instructions must indicate when and how patients should contact their physicians, the device manufacturer, and emergency care providers.

Trial Duration

A typical screening trial with a temporary percutaneous electrode lasts a week. In some circumstances, a shorter trial will be adequate, while in others, a longer trial might be beneficial.

Removal of Trial Electrode

Using the same percutaneous catheter electrode for screening and permanent stimulation would reduce the cost of the hardware, but this savings would be offset by the increased cost of anchoring the electrode, which must take place in an operating room. Anchoring a trial electrode for potential permanent stimulation also increases incisional pain, which might confound interpretation of the trial; anchoring also requires use of a percutaneous extension cable, which increases the risk of infection. On the other hand, a percutaneous catheter electrode designed solely for screening is relatively inexpensive can be inserted under sterile conditions with fluoroscopy and can be removed easily.

Using the same electrode for the screening trial and permanent stimulation might eliminate the possibility that the replacement electrode will not reproduce the pain/paresthesia overlap, but this strategy also eliminates the opportunity to improve upon the results of the screening trial—which can inform the patient as well as the physician.

Also, unless the trial electrode is routinely removed, a patient and/or clinician's expectation that the screening trial electrode will become permanent might bias the results of the screening trial.

DEVICE OPTIONS

In alphabetical order, the major manufacturers of SCS equipment are Boston Scientific (previously Advanced Bionics, Inc., Natick, MA), Medtronic, Inc. (Minneapolis, MN), and St. Jude's Medical (Previously Advanced Neuromodulation Systems, St. Paul, MN).

Choice of Electrode

Percutaneous catheter electrodes are available with up to eight contacts and can be implanted singly, creating a one-dimensional array or multiply, creating a two-dimensional array. Multiple percutaneous electrodes can be introduced one by one through a Tuohy needle to rest side by side. Use of three or more such electrodes in parallel permits programming of lateral anodes "guarding" a central cathode, which might mitigate dorsal root recruitment causing uncomfortable side effects; however, it can be difficult to achieve and maintain appropriate spacing between electrodes. Figures 95.5 and 95.6 illustrate a selection of available electrodes.

An important role, therefore, remains for plate/paddle electrodes, which cannot be introduced through a needle and thus require surgical exposure via laminectomy. These electrodes have as many as 16 contacts in one-, two-, or three-column configurations and are insulated to prevent excess stimulation of dorsal structures.[136] The spacing of the columns is fixed, precluding adjustment as well as postoperative migration of one column with respect to another.

Factors that dictate choice of electrode include the location of the pain, the amount of extraneous stimulation that must be managed, and the physician's qualifications and experience (anesthesiologists, for example, might be expected to use only percutaneous electrodes).

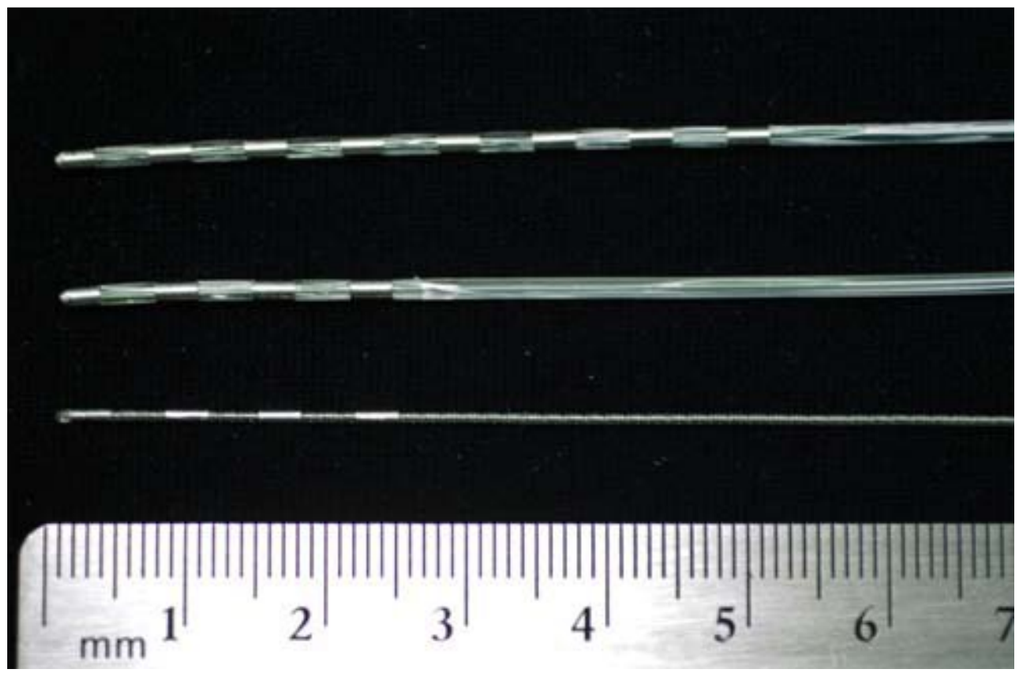

FIGURE 95.5 Percutaneous catheter electrodes have as many as eight cylindrical contacts designed for introduction through a needle.

Choice of Pulse Generator

Pulse generators are distinguished by their power sources and output configurations. The oldest style that remains in use incorporates a radiofrequency receiver and has no battery. Patients using this generator must wear an external antenna and transmitter during stimulation. In contrast, the so-called ''totally implanted pulse generator'' (IPG) has an implanted battery and is operated via an external remote control device. The earliest IPGs depended upon a primary cell that required surgical replacement when the battery was exhausted, but the newest generators, introduced in 2004, have rechargeable batteries. Since the 1980s, all generators have allowed noninvasive postoperative reassignment of each electrode contact (to anode, cathode, or off), and generators now support up to 16 independent contacts. The newest ''multichannel'' generators are capable of simultaneously or sequentially delivering pulses with different amplitudes and widths to different combinations of contacts, which of course consumes more energy compared with the simpler generators and thus motivates use of the rechargeable devices.

Factors that dictate the choice of stimulator/power generator include the patient's ability to control the device, the amount of power required, and patient convenience. Figure 95.7 presents a sample of generators.

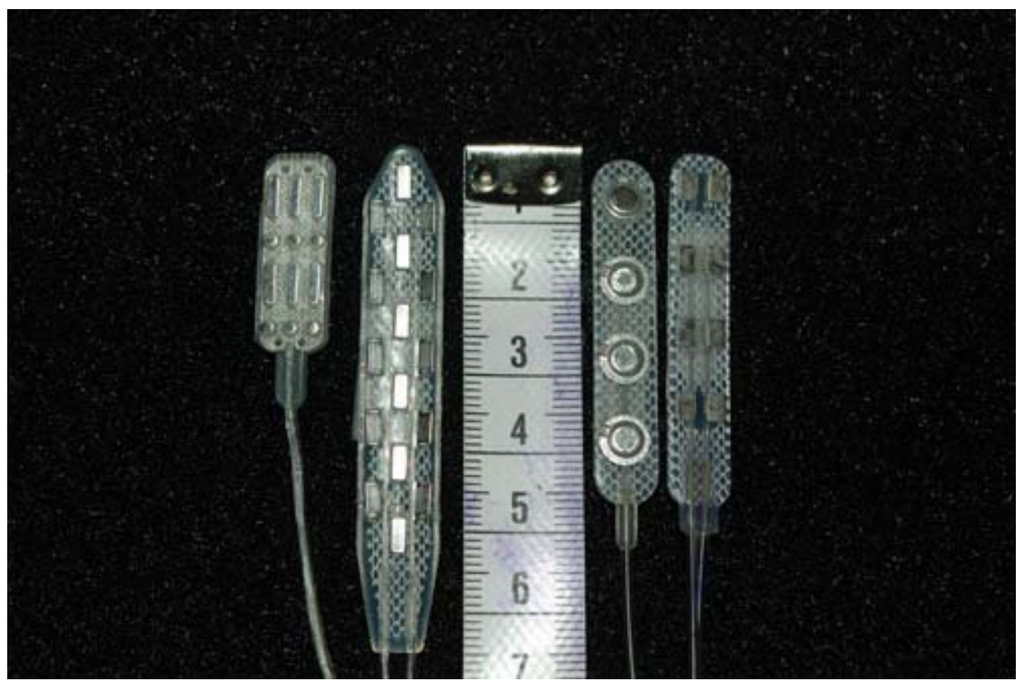

FIGURE 95.6 These laminectomy electrodes include two (on the left) with three columns of contacts; the smaller of these has a grooved dorsal surface (visible at top through the silicone elastomer) to stabilize it against lateral movement while allowing transverse flexibility. Older designs (on the right) have only one or two columns of contacts.

FIGURE 95.7 Contemporary implanted pulse generators support up to 16 contacts and have radiofrequency (RF) antennae for telemetry, which are visible only in generators powered by RF.

Programming a Spinal Cord Stimulation System

The number of contact combinations possible with either a surgical plate/paddle or percutaneous catheter electrode has grown markedly as the number of contacts has increased. In fact, more programming options exist than can be tested (for example, whereas a four-contact electrode offers 50 functional bipolar combinations of anodes and cathodes, an eight-contact electrode increases the choices to 6050, etc.). Thus, all three SCS manufacturers employ computerized equipment to find the best options for an individual patient and save these settings for subsequent use. Not only is initial programming important, skillful reprogramming can compensate for changes in impedance (e.g., due to postural changes or fibrosis), electrode migration, and changes in pain location or intensity.

Although each manufacturer's adjustment system is unique, each asks the patient to describe the area of pain and paresthesia and rate pain overlap and intensity at various settings (Fig. 95.8).

PATIENT MANAGEMENT

The patient should have a postoperative surgical check and SCS adjustment, and on postoperative day 7 to 14, return for suture or staple removal and any needed additional adjustment. From that point on, monthly visits should gradually taper to yearly visits.

Patients should understand that SCS is expected to reduce, not eliminate, pain. It is, therefore, important for clinicians to remember that other pain treatments remain available, especially those designed to treat nociceptive pain, which SCS is not expected to affect.

On/off time has a direct effect on battery longevity, but there are no studies of the impact of an imposed duty cycle on pain relief. In some patients, pain relief persists for a week or more after the device is turned off; others must operate the stimulator continuously. It is possible but rare for an SCS patient to achieve complete resolution of pain and request removal of the system.

Stimulation induces a subtle loss of normal sensation in SCS

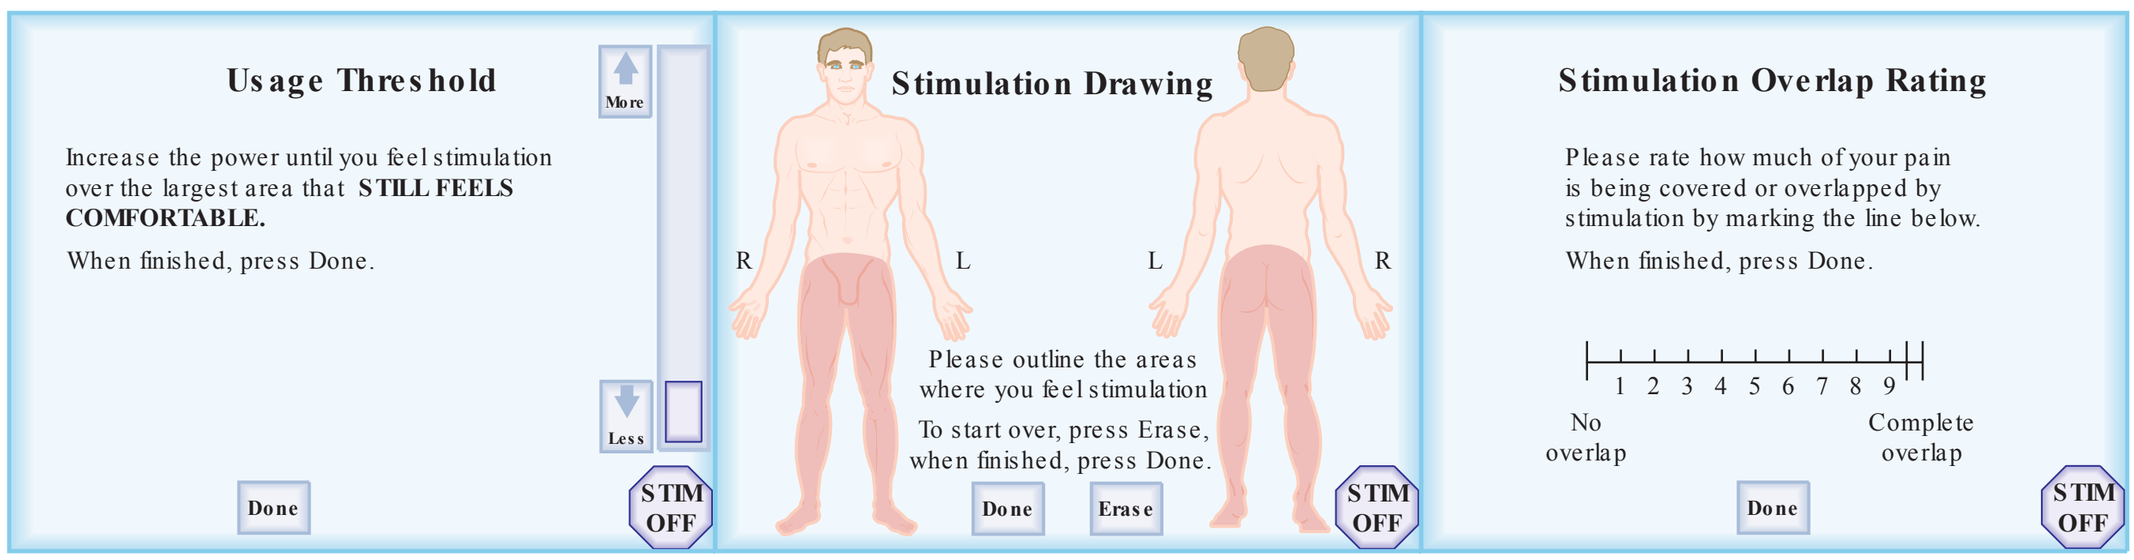

FIGURE 95.8 This computerized patient-interactive system allows the patient to (1) adjust amplitude to a specified level, (2) draw the area of paresthesia to be compared with a pain drawing and (3) rate pain/paresthesia overlap.

patients, but this loss is not sufficient to cause undesirable side effects, such as Charcot joints.[4,137] A change in paresthesia intensity corresponding to a change in posture is a normal, generally benign, side effect of SCS related to normal movement of the spinal cord with respect to the electrode(s).[138]

These side effects might, however, make certain activities hazardous; thus, we instruct patients to turn off SCS before driving a car or climbing a ladder, etc. The incidence of SCS side effects increases as stimulation amplitude and recruitment increase.[139]

As is standard practice, except in emergency cases that require immediate attention, a physician has the discretion to accept or reject any new patient who was implanted elsewhere. The device manufacturers provide all SCS patients with identification cards with the necessary contact information to facilitate appropriate emergency treatment.

Spinal Cord Stimulation Patient Precautions

SCS systems mighty affect or be affected by electromagnetic fields, and this necessitates certain precautions. MRI is generally contraindicated in SCS patients. Manufacturers generally recommend that implants be disabled before a patient enters an electromagnetic field produced by antitheft devices, a metal detector, or any other security scanning device. A patient must also refrain from scuba diving more than (typically) 10 meters deep or entering hyperbaric chambers with an absolute pressure above (typically) 2.0 atmospheres. Everyday precautions include avoiding placing excessive mechanical stress on the system.

Special steps must be taken before an SCS patient undergoes certain routine medical tests (such as cardiac monitoring) or radiation therapy with the pulse generator in the active field. Radiofrequency ablation, electrocautery, and lithotripsy also require caution. Ultrasound over the device and diathermy in any location are contraindicated in SCS patients.

SPINAL CORD STIMULATION TREATMENT CHALLENGES

Clinical Failure

The loss of pain relief despite pain/paresthesia overlap in a functioning system occurs in a minority of patients. This clinical failure might have a neurochemical basis, and it might respond to adjuvant medical therapy with baclofen or gabapentin. Clinical failure can also occur if the patient develops (1) pain in a new location that can not be covered by paresthesia unless the equipment is revised surgically, (2) troublesome postural changes in paresthesia coverage, or (3) excessive pain/irritation at the implant site that is not caused by infection and cannot be treated locally.

Biological Failure

Infection, the most common biological failure, is almost always treated successfully (treatment, however, is expensive because it generally requires removal and replacement of the SCS system). The risk of infection is small, however, and is reduced by maintaining sterility and administering prophylactic intravenous antibiotics. Should an infection occur, specimen culture will guide antibiotic therapy. Unless the infection is limited to the skin over the implant, the entire SCS system should be removed until the infection resolves, when a new system can be implanted. Clinicians have reported patients with an ‘‘allergic reaction’’ to the implant, but this is rare and might be undiagnosed infection. A second biological failure, the development of fibrosis around implanted electrodes, can impede treatment, but this problem generally can be overcome through reprogramming.

Psychologic Failure

Psychologic problems, such as conversion disorder,[140] can require system removal.

Technical Failure

Technical failure, the inability to achieve or loss of clinically useful pain/paresthesia overlap, can result from suboptimal electrode choice or placement, from electrode migration, or from equipment malfunction. Technical failure can be mitigated by increasing clinician skill and experience, which includes adoption of the best implantation techniques; for example, the risk of percutaneous electrode migration can be nearly eliminated by applying an adhesive to the anchor/strain relief during implantation,[135] and the risk of fatigue fracture can be lessened by implanting the pulse generator in the lateral abdomen instead of the buttock and by creating strain relief coils in appropriate places.

In patients with suspected spinal stenosis or another anatomic anomaly that increases the risk of spinal cord or nerve injury, it is prudent to obtain an MRI of the target spinal areas before implantation of a surgical plate/paddle electrode. With the SCS system in place, computed tomography myelography is an alternative.

The risk of dural puncture is reduced by using an anesthetic technique that permits patient feedback during implantation of an electrode and avoiding placement in scarred areas, and the risk of epidural hematoma is reduced by preoperative review of the patient's coagulation history, medications, and blood chemistry and by monitoring the patient for a reasonable amount of time. Uncomfortable extraneous paresthesia or motor responses can be avoided by careful electrode implantation and postoperative adjustment or by use of an insulated surgical plate/paddle electrode.

Equipment Failure

Every part of an SCS system can fail. The electrode/lead/extension conductors can develop an open circuit through fatigue, fracture, or corrosion, insulation might fail, the generator battery can be depleted prematurely, or the generator itself can fail (e.g., by supplying excessive or unacceptable stimulation).[141,142]

COST EFFECTIVENESS

Although the initial expense of implanted SCS equipment creates a potential barrier to patient access, investigators have established that SCS is cost effective in the treatment of FBSS,[143–146] CRPS,[147] PVD, and angina.[104,148] Cost recovery occurs in approximately 3 years in patients with FBSS or CRPS, after 1 year in patients with angina who are not candidates for coronary artery bypass surgery, and immediately in patients with angina who would otherwise receive coronary artery bypass surgery only for symptom relief.

The cost effectiveness of SCS will be improved by the development of new equipment and techniques and can be enhanced by minimizing the incidence of complications (especially those, such as infection, that require surgical intervention and system replacement) and by careful patient selection.

The incidence of complications can be reduced if the specialist is meticulous, technically proficient, and knowledgeable (e.g., a simple technique nearly eliminates percutaneous electrode migration).[135] One improvement that has had a direct impact on cost effectiveness is the development of equipment designed to facilitate noninvasive reprogramming to optimize pain/paresthesia overlap. Another improvement, the introduction of rechargeable batteries, is intended to extend the life of expensive implanted pulse generators.[149]

SPINAL CORD STIMULATION CHALLENGES

In common with most medical therapies, we can improve patient outcomes with SCS by improving patient selection criteria, equipment design, implantation techniques, and clinician training. Continued investigation of the mechanisms of action of SCS will allow us to potentiate the benefits of the therapy, and developing refined outcome measures and appropriate research techniques will help us to optimize clinical application.

The increasing presence of magnetic fields in our environment and in the use of higher field strengths in MRI investigations motivates the development of nonmagnetic electrodes and pulse generators that will tolerate the magnetic fields.

SCS remains an underused therapy that should be considered early in the treatment continuum for a large group of patients.

CHAPTER 96 ■ MOTOR CORTEX AND DEEP BRAIN STIMULATION

MING L.CHENG AND EMAD N. ESKANDAR

INTRODUCTION

Deep brain stimulation (DBS) has been used for the last three decades for the treatment of pain. Worldwide, but particularly in the United States, the number of patients treated by DBS and the number of practitioners offering this treatment has progressively decreased. This is in part because of the development of spinal therapies that are less invasive, but also the perception of variability in its efficacy after an initial wave of optimism in the 1970s.[1] This skepticism, especially for neuropathic pain,[2,3] resulted in the reversion of DBS for pain in the United States to what is essentially experimental status, with few published reports[4] in recent years regarding its use and advancement. Yet, a review of the literature supports a clear role for DBS for specific indications, such as patients with low back pain[5] who are not helped by other forms of therapy. The use of DBS for treatment of pain continues sporadically in the United States and more frequently in Europe and Japan.

The use of DBS as a treatment for pain has evolved along two separate tracks that correspond to the effect of stimulation upon the two main targets of stimulation: the periaqueductal gray region (PAG), and the sensory thalamus, known also as the ventral posterior lateral (VPL) nucleus of the thalamus. Although there are exceptions, in general, stimulation of the former affects nociceptive pain, while stimulation of the latter is more selective for neuropathic, deafferentation pain and the allodynia and dysesthesia related to neuropathic pain of peripheral origin. Stimulation of either the VPL thalamus, PAG, or periventricular gray (PVG) is achieved by stereotactic implantation of a quadripolar DBS electrode, which is then connected to an implanted pulse generator placed just inferior to the clavicle over the chest wall.

Motor cortex stimulation (MCS) is a newer therapy that was initially performed by Tsubokawa in 1990.[6] Unlike DBS, MCS is only effective for neuropathic pain with no data to suggest efficacy for chronic nociceptive conditions such as back pain. MCS is used primarily for the treatment of two pain syndromes: central pain after stroke and painful trigeminal neuropathy. Patients may also present with evoked pain in the form of allodynia or dysesthesia that can be markedly relieved by MCS. MCS may be useful for pain from peripheral nerve injury.[7,8] MCS is achieved by placing an electrode in the epidural space directly overlying the primary motor cortex, which is then similarly connected to an implanted pulse generator.

Both forms of brain stimulation have in common the use of electrical stimulation to effect a change in the patient's perception of pain that does not depend upon destruction of neural tissue. Nonablative therapies, including electrical stimulation and intrathecal drug delivery, have become the mainstays of neurosurgical intervention for pain. Brain stimulation, while clearly in this category, is not a substantial part of the armamentarium of neurosurgeons in the United States. Greater investigation in the form of well-controlled, well-structured prospective trials is necessary to establish guidelines and clearly define the efficacy of cranial stimulation therapies. With better scientific evidence, practitioners who are currently not offering cranial stimulation are likely to more readily offer them to patients who have no other options in the treatment of their pain syndromes.

DEEP BRAIN STIMULATION

Basic Considerations

Sensory Thalamic Deep Brain Stimulation

Early attempts to relieve pain through stimulation in deep brain structures began in the late 1960s and stimulated targets in the striatum[9] and in the septal region.[10] After the introduction of dorsal column spinal cord stimulation, the intracranial target for pain moved to the sensory thalamus in the 1970s.[11–13] This move to the next higher relay in the dorsal column/medial lemniscus system was logical, and the approach produced clinical results in patients that were in many ways similar to dorsal column stimulation. This included the time course of pain relief, a preferential effect upon neuropathic pain, and the effect of paresthesias over the painful treatment area. The rationale for sensory thalamic DBS was initially quite similar to the gate control theory for spinal cord stimulation, with the earliest known trials in the 1960s[14] predicated on a 1911 theory[15] suggesting that pain results from an imbalance between nociceptive and non-nociceptive portions of the sensory pathway, with stimulation of the sensory thalamus restoring this balance.

There are multiple modern theories and experimental studies that posit mechanisms for pain relief via sensory thalamic stimulation.[16–19] Most of these appear to lack clinical relevance since they were generally performed with acute nociceptive stimuli in intact animals under general anesthesia, whereas the conditions clinicians treat are much more chronic in nature and there are

well-established differences between the two mechanistically. In one such study, stimulation of sensory thalamus in the rat did not attenuate acute pain. This correlates with what we know today regarding poor efficacy with nociceptive stimuli using the sensory thalamus as the target for stimulation.[20,21] More relevant studies include one with cats that utilized a trigeminal ganglionectomy model of neuropathic pain.[22] This resulted in deafferentation hyperactivity that was inhibited in 40% of neurons with stimulation of the sensory thalamus and the internal capsule of the cats, with a long poststimulatory effect observed. In a partial sciatic injury model in rats, hind paw hypersensitivity was markedly suppressed with sensory thalamus stimulation with the effect lasting well beyond the duration of the stimulation.[23]

In humans, there is evidence that neuropathic and especially central pain leads to significant somatotopic alterations in the sensory thalamus.[24–26] As in animal studies, human microelectrode recordings taken within neuronal cells in the sensory thalamus have demonstrated substantial hyperexcitability and altered neuronal responses with spontaneous activity in patients with neuropathic pain states. In humans with deafferentation pain syndromes (e.g., phantom limb pain), an altered somatotopy as a consequence of deafferentation has been identified with areas in which receptive fields appear empty, displaced, and reorganized.[27,28] Patients report burning pain with thalamic stimulation that is referred to the painful regions of the body that is similar to the pain they experience clinically, and this elicited effect is more pronounced in patients that report allodynia and dysesthesia as part of their pain syndrome. In contrast, with stimulation in the same location in the sensory thalamus of patients without chronic pain states who are undergoing DBS for movement disorder, this group reports only sensations of nonpainful paresthesias overlaid with warmth and cold.

Stimulation of sensory fibers in the posterior limb of the internal capsule produces paresthesias that are essentially indistinguishable from sensory thalamus stimulation.[29] This suggests that similar underlying neurophysiologic mechanisms are at work. However, motor effects are common with stimulation of the internal capsule and are avoided by empirically adjusting stimulation parameters. In nonstroke patients where the thalamus is intact, there are no known benefits of using the internal capsule as the DBS target; when pain originates from a central lesion in the thalamus, however, internal capsule DBS is a clear option.[13]

Periaqueductal Gray/Periventricular Gray Deep Brain Stimulation

Stimulation of the PAG affects the experience of pain in a completely different fashion than that seen with stimulation of the thalamus. In 1969,[30] a report of powerful analgesia obtained with stimulation of the PAG in rats was followed by a series of confirmatory studies.[20,31] These studies marked a watershed in pain research by demonstrating the existence of an endogenous pain-relief mechanism in the body. Later studies demonstrated that analgesia can be produced with stimulation in an anatomically related area in the posterior wall of the third ventricle, the PVG.[32,33]

Since that time, it has been shown that rather than altering sensory pathways, the PAG is a critical player in the endogenous opioid system that extends from the arcuate to the raphe nuclei in the brain.[34] Stimulation anywhere along this system has been shown to produce analgesic effects that are reversible with naloxone.[35] Stimulation of the PAG itself has been shown to activate the endogenous opioid system[36,37] with release of met-enkephalin that coincides with pain relief[38] and to similarly increase β-endorphin levels in the cerebrospinal fluid.[39] If the opioid system is activated with PAG stimulation, then it stands to reason that tolerance to stimulation, or cross tolerance between stimulation and the analgesic effect of exogenous opioids would occur. Both of these phenomena have indeed been described,[40] with tolerance maximizing during the first 2 years after initiation of electrical stimulation of the PAG and decreases thereafter.[41]

Much of the literature regarding PAG stimulation is not relevant to its clinical application in the setting of chronic nociceptive pain. Almost all PAG stimulation experiments have been performed using acute pain stimuli, and it is the mechanisms underlying chronic pain that appear to differ from those mediating acute pain. Nonetheless, one study in an adjuvant-induced arthritic rat model of chronic nociceptive pain demonstrated abatement of scratching and biting behaviors felt to be signs of pain through the application of periventricular stimulation.[33,42]

Indications and Target Choice

Sensory thalamic and PAG DBS are therapies that are reserved for those patients whose pain remains poorly controlled despite more conservative treatment. The low utilization of DBS for pain is in some measure due to advances in modern pain therapy and the success of spinal cord stimulators and implantable intrathecal drug delivery systems in treating chronic pain. However, even more limiting to the use of DBS is the lack of scientific evidence demonstrating safety and efficacy.

Sensory Thalamic Deep Brain Stimulation

Certain neuropathic pain conditions have been successfully treated with DBS. Among these are conditions that have a supraspinal etiology, such as refractory trigeminal pain or peripheral neuropathic conditions that are associated with extensive degeneration of dorsal column primary afferent fibers. Examples include peripheral nerve injury, postherpetic neuralgia, and phantom limb pain.[43] All of these conditions may respond to sensory thalamic stimulation. In cases where central neuropathic pain is referable to damage to the thalamus itself, the sensory limb of the internal capsule has been stimulated successfully.[12,44]

Periaqueductal Gray and Periventricular Gray Deep Brain Stimulation

There are multiple reports of PAG and PVG stimulation in patients with somatogenic or nociceptive pain. Many of these patients suffered from chronic low back pain, and relief with opiates predicted responsiveness to PAG/PVG DBS.[45–47] There have also been reports of using PAG/PVG stimulation to treat intractable pain associated with cancer and in patients with other diagnoses similarly characterized by chronic nociceptive pain, including pancreatitis, ostitis, and osteoporosis. The outcome of such studies has been variable[1,3,5,21,48] with good long-term reduction of pain ranging from 19% to 79% and treatment of nociceptive pain superior to neurogenic pain.[3] There have been more recent reports that have targeted both sensory thalamus and the PAG/PVG locations, with reportedly good results.[4]

Surgical Technique

Targeting

Ideally, the location of chronic electrodes to be implanted for DBS is determined before surgery through a combination of known coordinates relative to the anterior commissure-posterior commissure (AC-PC) line for a particular DBS target, and the use of anatomic atlases and preoperative imaging including computed tomography and magnetic resonance imaging (MRI) to directly target the structure if it can be visualized. The target for the sensory thalamus[43] is approximately 2 to 3 mm anterior to PC (y coordinate) and 12 to 13 mm from midline (x coordinate) for

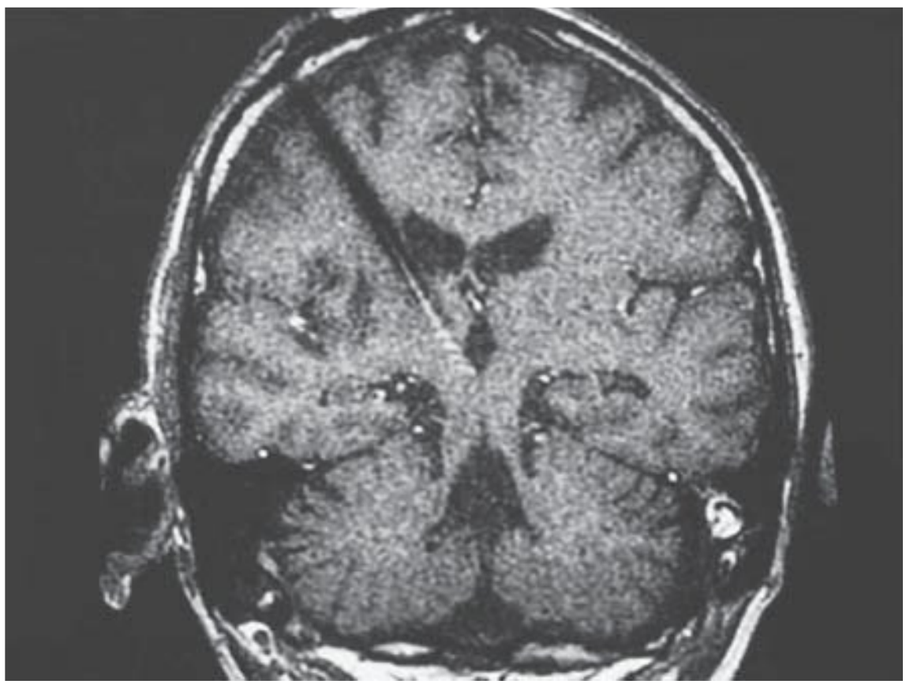

FIGURE 96.1 T1 coronal image with implanted PVG electrode. (Reproduced with permission from Owen SL, Green AL, Stein JF, et al. Deep brain stimulation for the alleviation of post-stroke neuropathic pain. *Pain* 2006;120[1–2]:202–206.)

facial pain, 14 to 15 mm for upper extremity pain, and 16 to 17 mm for lower extremity pain (Fig. 96.1). The z coordinate is approximately at the level of the AC-PC plane. The target for PVG (see Figure 96.1) is approximately 2 to 5 mm anterior to PC (y coordinate), 2 mm lateral to the medial wall of the third ventricle (x coordinate), at the level of the AC-PC plane (z coordinate).

In practice, most centers perform microelectrode recordings (MER) to confirm the trajectory and depth chosen to reach the particular target. The target is thus corroborated by the physiology of the neurons encountered during the recording pass. Some practitioners believe that MER is an absolute necessity and most practice it, but there are centers that place DBS electrodes guided solely by imaging. Such variation in practices probably reflects the fact that there is an absence of evidence that establishes the clinical superiority of microelectrode recording for the most common targets for DBS, as opposed to those used movement disorder surgery.

Potential indications and targets in DBS for pain are as indicated above: sensory VPL thalamus (or ventralis caudalis [VC] in the Hassler system), PAG, and PVG. There are many different approaches to physiologic mapping based upon MER. Single and multiunit neuronal recordings are performed at different depths along the predetermined trajectory by different surgeons with anywhere from one to five microelectrodes, and the results are typically plotted to determine the optimal trajectory and depth for chronic electrode implantation. Most practitioners use microstimulation with the microelectrode and/or macrostimulation with the chronic electrode to test for desired paresthesias in the anatomic region affected by pain and to ensure that there are no complications such as motor stimulation prior to permanent implantation. The extensiveness of the application of MER is often inversely correlated with the degree of confidence of the surgeon in the targeting accuracy, which in turn depends upon multiple factors that may include image quality and field distortion on MRI, intracranial content shift from cerebrospinal fluid loss and pneumocephalus, and change in patient position.

Microelectrode Recording

The first known report of single unit physiology was from the preparation of a muscle fiber connected to a neuron, performed over 80 years ago by a British physiologist, Lord Edgar Adrian Douglas.[49] The recording was made with an intracellular microelectrode that was created 5 years prior by a female scientist, Ida Henrietta Hyde. During the 1930s, 1940s, and 1950s, a veritable explosion in neurophysiology included such investigations as the use of the giant squid axon in elucidating the action potential, the recording of light response in the retina, and eventually to the MER mapping of the brain that is performed commonly with DBS procedures today.

The sensory thalamus is known as the VC nucleus of the thalamus in the Hassler nomenclature. Commonly used in movement disorder surgery, neurosurgeons are generally quite familiar with the ventralis intermedius (Vim) nucleus of the thalamus as a target, and VC thalamus is immediately posterior to Vim. During a typical approach, the microelectrode track starts 15 to 20 mm above the target. While the angle of approach may vary somewhat, typically the caudate is avoided by an approach just lateral to the structure. Thalamic neurons typically have large amplitude discharges without significant background spiking from more distant cells. Single unit activity is either tonic or in bursts with lower firing rates of 10–30 Hz. Recordings in VC reveal very noisy spontaneous activity and many high voltage cells. These cells generally respond to superficial light tough such as light brushing of the skin or a puff of air.[50,51] These cells respond faithfully without fatigue. The largest volume of VC is occupied by tactile cells representing the face and digits. In contrast, more anterior recordings in Vim reveal moderately active high voltage neurons that respond to contralateral passive joint movement, squeezing of muscle bellies, or pressure on deep structures such as tendons. In patients with tremor, kinesthetic cells fire rhythmically at tremor frequency.

The floor of the thalamus can be identified by the sudden loss of spontaneous neuronal activity as the microelectrode leaves the gray matter. A careful analysis of the neuronal activity of these various cell types can confirm that the appropriate target in the VC thalamus is selected. Further confirmation can be obtained with stimulation. Since Vim is thought to be the relay nucleus for kinesthetic sensation and VC the relay nucleus for superficial tactile sensation, high frequency stimulation can generally reflect this difference. The threshold (0.25–0.5 volts) for inducing paresthesias in the VC nucleus is usually much lower than that of the Vim nucleus, and in the pathologic state, the thresholds are even lower.[50] Consequently, low threshold paresthesias in the distribution of the patient's pain indicate that the electrode is correctly positioned. Neurons in the VC nucleus representing the face are found most medial, those representing the lower limbs more lateral near the internal capsule, and those representing the upper extremity and hand intermediate.

Compared to the sensory thalamus, the PVG/PAG targets are much smaller. The PVG is comprised of the nucleus endymalis and part of the nucleus parafascicularis. As a target, although it is smaller than the sensory thalamus, discrimination is easier since unlike the nuclei of the thalamus, the PVG is a discrete structure that is not surrounded by physiologically similar neurons. The trajectory of the electrode pass brings the electrode through white matter within millimeters of entry of the PVG, and due to its discrete nature the neuronal firing serves as a good confirmation marker. Intraoperative stimulation within the target produces subjective warmth that washes over the face or the torso symmetrically, even though the stimulation is unilateral. Stimulation at higher intensities may produce ocular oscillation and feelings of unease or fear.

Stimulation Regimen

For the sensory thalamus, a period of trial stimulation is performed to ensure that stimulation-induced paresthesias are present and distributed in the correct area, that they are not unpleasant or painful,[52] and that adequate pain relief is delivered. A frequency of 40 to 70 Hz is generally used, and the stimulation required to achieve this effect is typically just higher than that required to evoke paresthesias in the area of interest, and must be continued for 15 to 30 minutes. If the effect is not placebo,

there is typically a poststimulation effect in patients that lasts for several hours or longer. Over the course of the first year, the pain-relief obtained may fade. In contrast to sensory thalamic stimulation, PVG stimulation is generally performed at a subthreshold intensity.

Complications

Intracranial placement of leads is associated with a small but known risk of hemorrhage that occurs in a few percent of patients. Dysesthesias and motor disturbances may occur, which can often be remedied with adjustment of stimulation parameters. Infection is a risk with any surgery, and the risk increases with the length of the surgery and the length of the trial period with externalized extension leads. Proper risk management, such as the routine use of prophylactic antibiotics and attention to sterile technique and good surgical principles, will reduce the possibility of an adverse event.

MOTOR CORTEX STIMULATION

Basic Considerations

The first motor cortex intervention for the treatment of central pain syndromes began with the observation by Penfield that stimulation of the primary motor cortex elicited sensory responses in surgical epilepsy patients. Based upon this finding, Sweet and White[53] performed pre- and postcentral gyrectomies on 3 patients with neuropathic trigeminal pain. This, while providing long-lasting pain relief, was an aggressive technique with obvious consequences, and has not been reported in the literature since.

It is not immediately obvious why stimulation of the motor cortex would relieve pain, and to date, there are conflicting theories and supporting evidence regarding the possible mechanism of MCS. Animal studies in the 1950s established that electrical stimulation of the sensorimotor cortex reduced spinal cord afferent activity.[54] Activity of spinothalamic neurons was subsequently shown to be reduced in monkeys with such stimulation.[55] The initial report of MCS was in 1990, when Tsubokawa[6] described its application in central thalamic pain with 7 patients, obtaining "excellent or good" pain relief. MCS was shown to increase cerebral blood flow, improve pain and limb movement, and decrease hemiparesis. Simultaneously, the group reported that the stimulation decreased neuronal hyperactivity in cats that were subjected to spinothalamic tractotomy; this effect occurred with motor, but not sensory, cortex stimulation. These results were in marked contrast to those of another study of cat trigeminal deafferentation pain,[22] in which stimulation of both sensory and motor cortices inhibited hyperactivity. Interestingly, activated corticofugal pathways were found to pass by both the sensory limb of the internal capsule and the sensory thalamus, both previously known stimulation targets for neuropathic pain, suggesting a similar mechanism of action. Neuronal labeling studies further demonstrated that motor cortex fibers possessed reciprocal connectivity with the sensory thalamus.[56] Recently, it was reported that the response to high intensity stimulation is selectively inhibited by MCS in rats.[57] Positron emission tomography (PET) cerebral blood flow studies performed with MCS[8,58–60] resulted in a relative decrement in thalamic blood flow with chronic pain that is ameliorated after MCS.[61–63] In a recent report, regional cerebral blood flow is increased in the thalamus, cingulate, insula, and orbitofrontal cortex following MCS (Fig. 96.2).[63] This study also suggested that decreases in subjective pain levels may be due in part to changes in mood.[63]

Indications

In clinical practice, MCS has proven useful only for neuropathic pain. Given the availability and efficacy of spinal cord stimulation and intrathecal drug therapy, the main indications for MCS are supraspinal pain after hemorrhage and infarction,[8] postsurgical trigeminal deafferentation pain such as anesthesia dolorosa, and other forms of neuropathic facial pain such as postherpetic neuralgia. Further reports have extended the indications for surgery to include nonthalamic intracranial poststroke syndromes, including lateral brainstem infarcts,[64] phantom limb pain, multiple sclerosis, spinal cord injury, and even other neuropathic pains of the extremities.[65] In many cases, in addition to the deep, aching, and burning of central pain, these patients have shooting pain or the evoked pain of allodynia, dysesthesia, or hyperalgesia, all of which can improve markedly with MCS. For the indications described here, MCS has a better chance of success than either sensory thalamic or internal capsule stimulation.[66] For extremity neurogenic pain, it would be reasonable to perform trials for less invasive spinal cord stimulation prior to a decision regarding intracranial therapy.

Treatment efficacy for poststroke pain is variable, ranging from 45% to 75% in the overall proportion of patients reporting significant pain relief. The integrity of the corticospinal system is an important predictor of MCS efficacy; if the patient has pronounced weakness after stroke or there is difficulty in inducing motor activation with cortical stimulation during the procedure, the likelihood for a poor outcome increases dramatically.[67] There is no clear relationship between outcome and the location of the lesion that is causing central pain. Some relatively weak nonpredictive associations have been noted between MCS responsiveness and thiamylal and ketamine sensitivity and morphine resistance.[68] Success with repetitive transcranial magnetic stimulation (rTMS) may predict treatment success with MCS.[69,70] Even when the initial response is positive, however, over the course of the first year, pain relief may fade.

In contrast, outstanding results have been documented for the use of MCS in neuropathic trigeminal pain, with 75% to 100% of patients obtaining good or excellent pain relief.[7,71–73] These patients have often undergone treatment for trigeminal neuralgia and failed with one of the surgical techniques, such as glycerol, radiofrequency or balloon rhizotomy, gamma knife surgery, and even in some cases microvascular decompression. Of all brain stimulation techniques and indications, MCS for neuropathic trigeminal pain appears to be the most promising.

Surgical Technique

Anatomic identification of the motor cortex and its associated somatotopy has been a subject of multiple reports[6,8,74] going back to the classic neurophysiologic findings of Penfield in motor and sensory cortex. With modern frameless navigation equipment, image-guided intraoperative localization is becoming part of standard surgical practice. Some centers have even integrated functional MRI imaging into their localization procedure.[75] Nevertheless, localization still depends on visual identification of appropriate landmarks and therefore should be confirmed with intraoperative mapping using somatosensory evoked potentials, phase inversion, and low-frequency, high-intensity stimulation to produce peripheral muscle activity (Figs. 96.3 and 96.4). Since many patients with central pain present with severe discomfort in the distal extremities, proper somatotopic coverage may be extensive, potentially requiring wide exposure. In cases involving the distal lower extremities, exposure for electrode placement of the interhemispheric portion of the motor cortex may be necessary. In such cases, craniotomy for epidural lead placement is clearly preferable over the burr hole technique introduced by the initial practitioners of MCS.[7,72,76] In some such cases, subdural electrode placement has been used to treat distal leg pain, and it may also be performed when relief with epidural stimulation loses efficacy.[77,78]

A standard craniotomy is required for this procedure. The

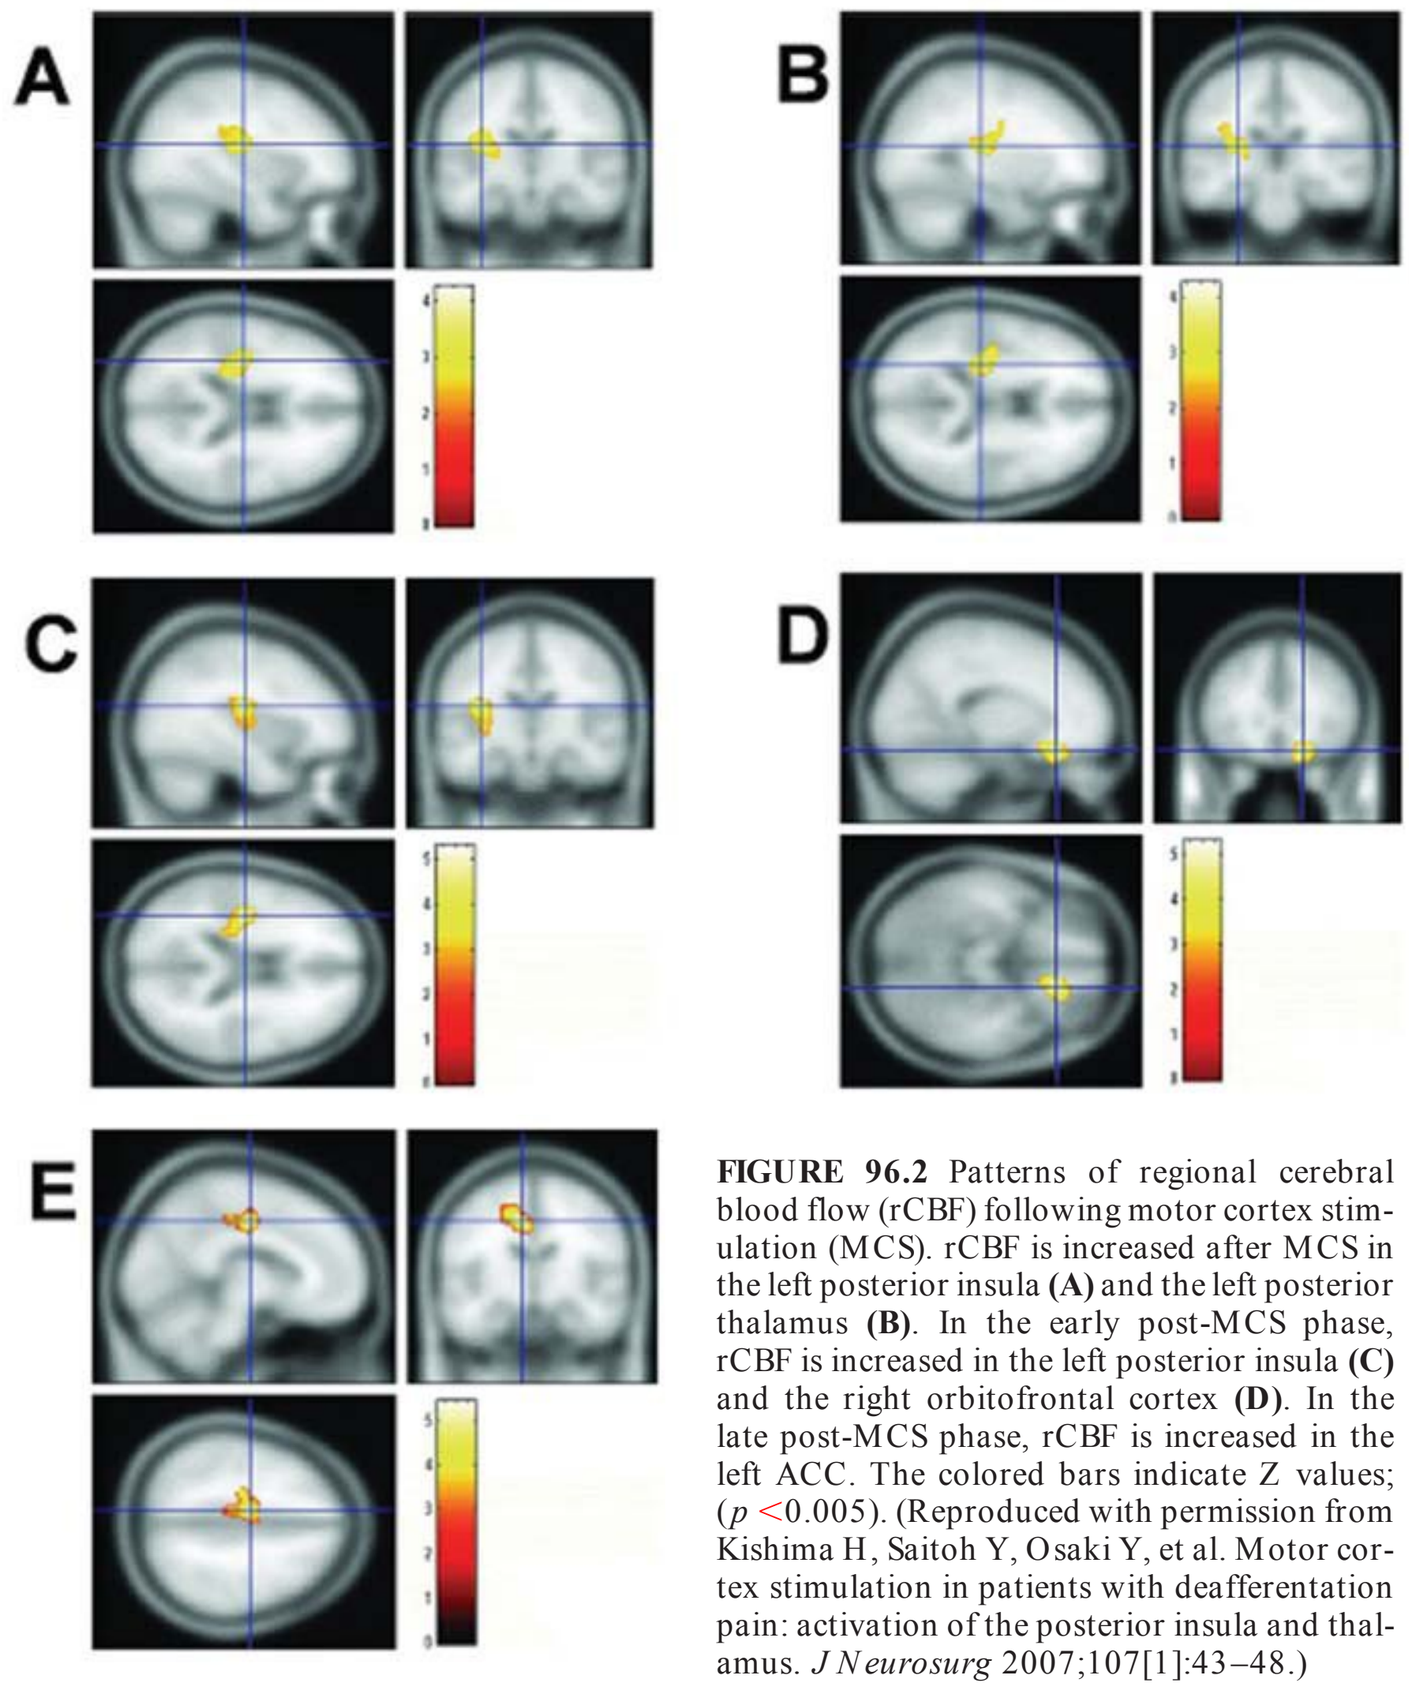

FIGURE 96.2 Patterns of regional cerebral blood flow (rCBF) following motor cortex stimulation (MCS). rCBF is increased after MCS in the left posterior insula **(A)** and the left posterior thalamus **(B)**. In the early post-MCS phase, rCBF is increased in the left posterior insula **(C)** and the right orbitofrontal cortex **(D)**. In the late post-MCS phase, rCBF is increased in the left ACC. electrode is placed in the epidural position (Fig. 96.5). More than one electrode may be necessary to provide coverage of the required area for stimulation in patients with central pain. The procedure has been performed with induction of either local[7,64,66,67,71–73,76,79,80] or general anesthesia.[77,81–85] Like all surgical procedures where hardware is implanted, careful technique and strict antibiotic prophylaxis is required.

Stimulation Regimen

As in sensory thalamic DBS and spinal cord stimulation, a period of trial stimulation of 2 or more weeks is typical. Stimulation-induced paresthesias are not usually present with MCS,[7,8] but pain relief generally occurs after a few minutes of stimulation and improves over the ensuing 10 to 15 minutes. There is typically a poststimulation effect in patients that lasts for several hours or longer. Usually, a cycle mode of 5 to 30 minutes of stimulation is followed by minutes to hours with the stimulation off. A wide range of frequencies from 5 to 130 Hz and pulse durations from 60 to 450 μsec have been used with success. Intensity is often set in a range from 0.5 to 10 volts to at an appropriate subthreshold level, for example, 80% of the voltage required for muscle contraction.[86,87] Pain relief is most common at voltages around 5 volts, and amplitudes greater than 6 volts have been associated with seizures during programming, especially as the amplitude approaches 9 volts.[88] A customized empiric approach is usually utilized for each patient to adjust each of the parameters to increase pain relief while limiting side effects for each patient.

Complications

Surgical complications, including infection and epidural hematoma, have been reported with MCS. Local pain at the site of the electrode has in a few cases required dural denervation.[8] Like all previously discussed surgical procedures, the risk of infection is always present, heightened by the necessity of hardware implantation. Hardware breakage is also possible, requiring surgery for repair.

Complications due to stimulation include seizures that have been reported during the trial phase of MCS when multiple stimulation parameters are tested, but no reports have noted the progression of seizures beyond the trial phase. Other side effects from stimulation include dysesthesias[67,72,89], dysarthria, and fatigue.[82]

TRANSCRANIAL MAGNETIC STIMULATION

Basic Considerations

Repetitive TMS is a therapy was applied to psychiatric and neurodegenerative diseases prior to consideration for pain. It is reasonable that with the advent of this new technology, trials using primary motor cortex as the rTMS target would occur for pain syndromes that have benefited from MCS. The underlying rationale for the use of rTMS comes from MCS studies, with the implicit assumption that rTMS might have similar or related effects on the motor cortex as electrical stimulation. PET blood flow studies suggest that there are several brain areas that are affected by MCS (see discussion in previous MCS section). Some reports suggest that rTMS of motor cortex creates a physiologic effect that is similar, but not identical to electrical stimulation.[90] A 2006 study with rTMS showed improvement with stimulation of primary motor cortex, but not with sensory, supplementary motor, or premotor cortex stimulation.[91] This finding does correlate with what we know about the anatomic target of MCS, and indeed suggests that rTMS may have a similar physiologic basis of action.[92] In addition, as with MCS, pain relief can last beyond stimulation, but the poststimulation duration is shorter, lasting minutes to hours for rTMS compared to hours to days with MCS.

Targeting

Determination of the target area for rTMS can be performed with frameless navigation systems that are similar to the ones neurosurgeons use in the operating theater.[91] Repetitve TMS is applied through a coil that is held and positioned with an articulated coil holder, and the motor threshold is then determined with stimulation (Fig. 96.6). Single pulse TMS can be used to elicit

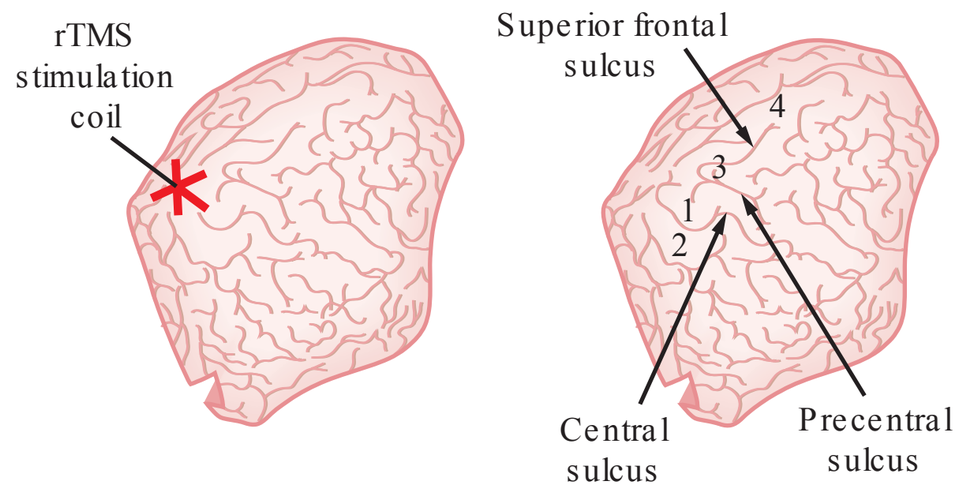

FIGURE 96.6 The use of a navigation system for rTMS. The stimulation coil (left) is centered over the motor cortex; the numbers on the right show motor cortex (1), relative to the sensory cortex (2), the premotor area (3), and the supplementary motor area (4). (Reproduced with permission from Hirayama A, Saitoh Y, Kishima H, et al. Reduction of intractable deafferentation pain by navigation-guided repetitive transcranial magnetic stimulation of the primary motor cortex. *Pain* 2006;122[1–2]: 22–27.)

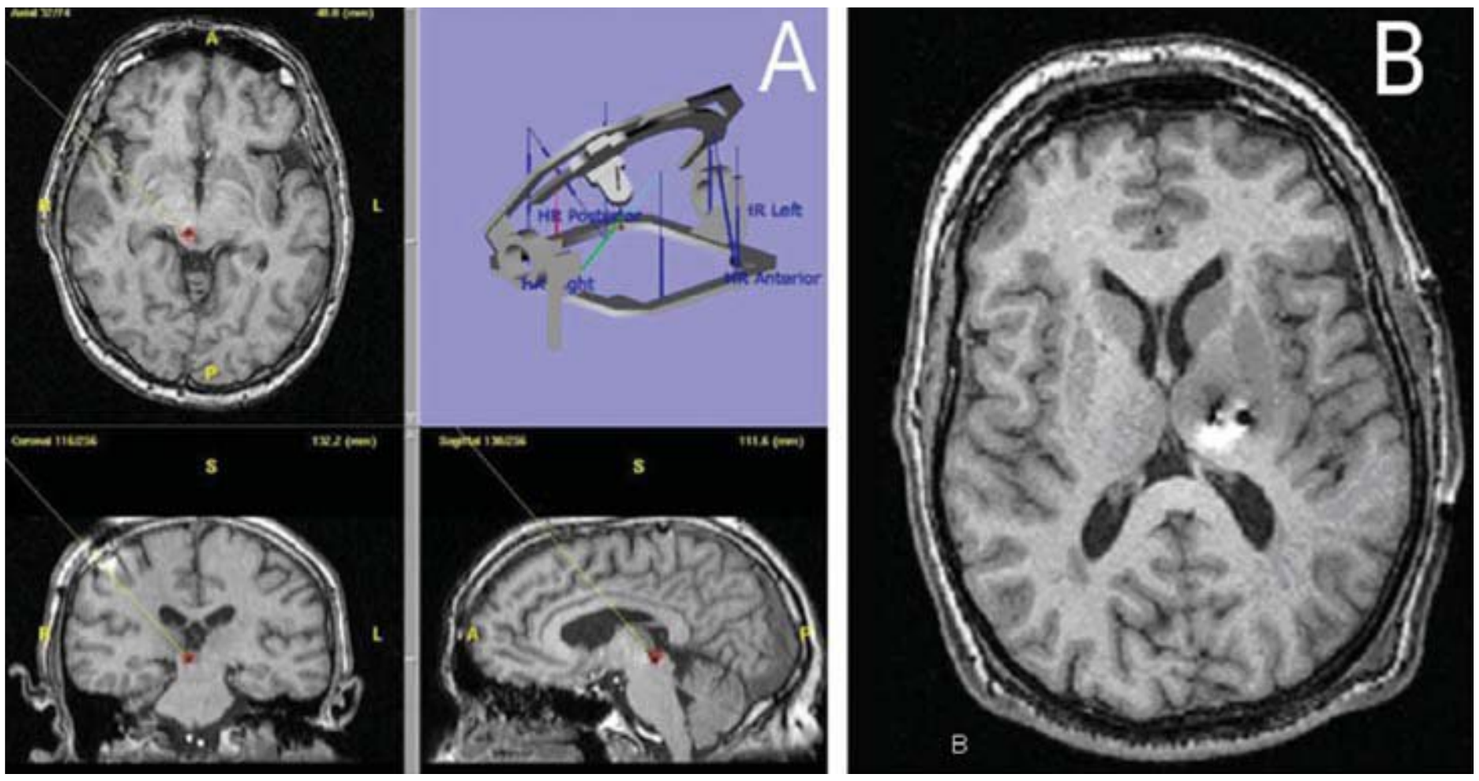

FIGURE 96.7 A. T1-weighted MRI showing planned trajectory ad target for placement of a PAG/PVG in the axial, frontal, and sagittal planes. **B.** Postoperative MRI showing VPL electrode (lateral) and the wire to the PVG electrode (medial and inferior). muscle twitching on electromyography (EMG), so it is possible to map the area corresponding to each extremity, including the painful areas.[93–95] In areas with substantial damage to motor fibers, stimulation of up to 100 A/μs can be used, with higher stimulation intensities resulting in scalp pain.[91] In some studies, electroencephalography recordings and craniometric principles were used for target localization, but there is substantial difficulty and a lack of repeatability in freehand performance of stimulation. Thus it is recommended to utilize a frameless navigation system for localization of the primary motor cortex. The principle of combining an accurate targeting technology with neurophysiologic confirmation is utilized in the stereotactic placement of DBS electrodes with MER. Analogously, the best option for rTMS is the use of a frameless navigation system with single pulse TMS for neurophysiologic confirmation.[91]

Stimulation Parameters

After determination of the motor threshold, typically the stimulation intensity is set at 80% or 90% below the threshold level. Stimulation is then performed in trains of pulses with intervals between the trains. For example, a routine rTMS session of 500 stimulations may consist of 10 trains of 10 second TMS pulses of 5 Hz, allowing 50 second intervals between trains. High frequency rTMS enhances and low frequency inhibits neuronal firing in the cortex.[96,97] Repetitive TMS at high frequencies of 10 to 20 Hz has been reported to result in good pain control,[95,98] while rTMS at a low frequency of 1 Hz was effective only in one report in normal patients with acute nociceptive pain from capsaicin.[99] It is possible that the choice of stimulation frequency may depend upon the type of pain that is being treated. For example, poststroke central pain seems to respond better to low frequency rTMS, while trigeminal neuropathy responds to high frequencies.

CONCLUSION

Neuropathic pain is a difficult to treat effectively. It is often not responsive to drug therapy, and the only recourse becomes surgical intervention with the implantation of some form of stimulation device. While stimulation therapies may not offer complete relief, good outcomes are far from rare and offer possibilities for patients who have exhausted typical avenues of treatment. Chronic nociceptive pain, most commonly represented by patients with back pain, is similarly a problem that can be difficult to treat with pharmacologic intervention alone. The neurosurgeon's armamentarium should include the full range of implanted intrathecal drug delivery devices and stimulation technologies for these difficult to treat pain conditions. Deep brain and cortical stimulation are tools that should be part of this armamentarium and should be among the options available to patients, especially those with supraspinal pain where spinal pain therapies are irrelevant. In extremity and back pain, these therapies should be considered when spinal therapies fail to provide pain relief.

Unfortunately, DBS for pain has suffered from a lack of high quality studies, despite anecdotal and limited observational evidence that suggest its use would appropriate in certain conditions where other therapies are not available. Prospective, well-designed studies with uniform, structured protocols for patient selection, implantation, and stimulation should be performed with MCS to ensure that this promising therapy does not suffer the same fate. Since paresthesias are not a hallmark of MCS, it is possible to prospectively study this therapy by providing stimulation to patients in a blinded fashion. Such studies are critical since, when properly applied, MCS can offer carefully selected patients the possibility of pain relief where no other therapies or recourses are available. It is possible that patients with syndromes that do not respond to MCS may respond to DBS at either the PVG/PAG or the sensory thalamic target. It is also possible that in some intractable cases where stimulation at any one site does not provide complete relief, combination stimulation therapy with leads in multiple sites (Fig. 96.7) including combinations of spinal cord and intracranial interventions, could provide pain relief.

CHAPTER 97 ■ DIAGNOSTIC AND THERAPEUTIC NERVE BLOCKS

MICHELE CURATOLO AND NIKOLAI BOGDUK

INTRODUCTION

Local anesthetic blocks are procedures in which a local anesthetic agent is deliberately injected onto a peripheral nerve in order to temporarily stop conduction of action potentials along it. Local anesthetic agents block conduction of action potentials by acting on the sodium channels of the nerve cell membranes. Their effect is temporary because their pharmacologic action is reversible.

Nerve blocks are an attractive tool in pain medicine because they are the only means by which to stop pain completely. Analgesics may reduce pain, but only local anesthetics stop it.

Virtually any nerve in the body can be blocked in order to relieve pain. All that is required is access to the nerve and the agent with which to anesthetize it. Many textbooks and manuals have been published that describe the techniques used to do so, but it is not the intention or purpose of this chapter to duplicate these publications. Many of the available procedures have an application in anesthesia for surgical procedures, but they are not germane to the practice of pain medicine. Some procedures have a role in securing relief of pain postoperatively; for those, the distinction between the discipline of pain medicine and the practice of anaesthesia is uncertain.

This chapter focuses on the principles of local anesthetic blocks used in pain medicine. It illustrates the more commonly used and useful procedures and reviews the evidence concerning their validity and utility. Neurolytic blocks are covered in Chapters 45, 64, 71, and 103.

APPLICATIONS

The short duration of action of local anesthetic agents limits the utility of local anesthetic blocks in pain medicine. For acute pain, their premier utility lies in providing protection from incident pain. For chronic pain, their premier use is as a diagnostic test. Otherwise, they have putative roles as a prognostic test and as palliative interventions.

COMMON PRINCIPLES

Irrespective of the purpose for which local anesthetic blocks are used, certain principles apply. These pertain to the physician, the patient, the preparation for the procedure, its contraindication, the procedure itself, and its complications.

Physician

Any physician who performs nerve blocks should be suitably trained and experienced. He or she needs to understand the pain problem being addressed and how the proposed procedure relates to the patient's management. He or she needs to be familiar with the patient, the patient's complaints, and how the patient expresses him- or herself. The physician should be able to explain to the patient the nature and significance of the procedure to be undertaken and, together with the patient, be able to assess and interpret the response. These requirements require training in more than the execution of the procedure.

The physician needs a detailed knowledge of the anatomic basis of the procedure, not only to execute it accurately but also to avoid complications. Similarly, he or she needs to be able to deal with the possible side effects and complications of local anaesthetic agents. For procedures performed under radiologic guidance, the physician needs to be able to obtain the correct views and to interpret them accurately.

More difficult to define and to achieve is technical excellence to perform the procedure expeditiously yet accurately with the minimum of stress to the patient. This includes avoiding painful structures during the insertion of the needle and keeping the number of adjustments during its course to a minimum. Acquisition of these skills requires good mentoring or forethought on the part of the practitioner and may take months or years of training.

Patient

The patient should understand the purpose of the procedure to be undertaken. This requires distinguishing between diagnostic and therapeutic procedures. Unless they are properly informed, patients may mistake a diagnostic block as a treatment and be disappointed when it appears not to have worked when the effect wears off. When a therapeutic block lacks evidence of efficacy, the patient should understand that the chances of success are unknown and that any estimate might be entirely speculative. In this regard, there is a difference between a patient consenting to a procedure and being fully informed about it.

The patient should be aware of the potential side effects and complications of the procedures, what actions are to be taken to avoid them, and what will be done in the event that they occur.

Both for diagnostic blocks and therapeutic blocks, the patient will be required to assess and report their response. Therefore, before the procedure the patient should be instructed in how to use instruments such as the visual analog scale or numerical pain-rating scale. Patients who have pain in multiple sites but who undergo blocks for only one site need to understand which pain is being tested and must be able to report the effects of the block on that particular site of pain. Relief of pain will need to be corroborated by testing activities that usually are limited by pain. For this purposes, the patient must be able to specify a set of suitable activities before the block and be able to test for their restoration after the block.

Preparation

The preparation of the patient differs according to the nature of procedure to be undertaken and the region in which the target nerve lies. For most procedures, and particularly for those that involve small doses of local anesthetic agents, standard preparations are neither indicated nor required.

Orders for "nil by mouth" are indicated only for procedures in which loss of consciousness and aspiration of gastric contents

are possible complications. Examples include cervical transforaminal blocks and procedures that involve high doses of local anesthetic. In the opinion and experience of the authors, the majority of nerve blocks can be performed safely with the patient having had a light meal 2–4 hours before the procedure. Indeed, fasting may compromise the procedure if the patient is uncomfortable or distressed for not having eaten.

For most local anesthetic blocks, establishing an intravenous line is not indicated nor is continuous monitoring of respiratory and cardiovascular function required. The doses of local anesthetic typically administered do not pose hazards that require these preparations. However, appropriate precautions are indicated for procedures that are performed close to vital structures, such as the spinal cord or the vertebral artery, or when large doses of a local anesthetic agent are to be administered. In such cases, an intravenous line should be placed before the procedure in order to ensure access for the rapid administration of fluids and resuscitation drugs, should these be necessary. Vital functions should be monitored (i.e., electrocardiogram, pulse oximetry, and blood pressure). A means of ventilating the patient with 100% oxygen with a bag and mask or via endotracheal tube and suction should be available, along with drugs and equipment to manage a cardiac arrest.

Local anesthetic blocks do not require routine sedation. Proper explanation, continuous communication, and good technique will provide patient comfort without the need for systemic medication. In the case of diagnostic blocks, there is a theoretical risk that using sedation may confound the validity of response, for which reason it is best avoided. In addition, sedation may mask the onset of central nervous complications of local anesthetics and, therefore, delay early intervention.

Only occasional patients will require sedation: those who are markedly apprehensive or who have a manifest anxiety over needles or invasive procedures. In such cases, sedation can be secured by intravenous administration of modest doses of sedatives (midazolam, propofol) or short-acting opioids (fentanyl, alfentanil, remifentanil). The dose should be titrated so as to provide sufficient sedation only for the duration of the procedure; the patient should be fully awake after the procedure in order to be able to report its effects. If sedation is used, it should be complemented with monitoring of respiratory and cardiovascular function. Supplemental oxygen may be required.

Contraindications

Blocks are contraindicated in patients who are unwilling to undergo the procedure or who have attributes that compromise the safe execution of the procedure. The latter include inability to lie still, allergy to the drugs to be used, infection at the site of injection, and anatomic abnormalities.

A coagulation disorder or anticoagulation therapy is a relative contraindication. Blocks of superficial nerves in easily accessible parts of the body may be safely undertaken. Reservations apply for blocks of deep nerves in sites where hemorrhage could compromise vital structures. Patients with compromised cardiovascular function are more susceptible to either the toxic effects of local anesthetic or the effects of blockade of sympathetic nerves. Appropriate precautions should be taken with such patients if large volumes of a local anesthetic agent are to be used.

Complications

The potential complications of local anesthetic blocks can be categorized as systemic effects of the drugs injected, physiologic effects of the procedure, inadvertent damage to structures other than nerves, and damage to nerves.

Systemic Effects

Allergy to local anesthetic agents is rare. The physiologic consequences and treatment are as for any anaphylactic reaction.

Local anesthetics have direct toxic effects on the central nervous system (CNS) and cardiovascular system (CVS). These effects become increasingly pronounced as blood levels of the offending agent rise. High or rapidly rising blood levels can occur because of inadvertent intravascular injection of the local anesthetic, unusually rapid absorption from a highly vascular region, or the administration of an excessive dose of agent.

Several precautions can be taken to reduce the risk of intravascular injection. For procedures performed under fluoroscopic guidance, a test dose of contrast medium can be administered before injecting the local anesthetic agent. This will show vascular uptake. For procedures where the uptake may be to a small but vital vessel, such as a radicular artery, digital subtraction angiography serves to demonstrate the vessel more clearly. For injections undertaken without radiographic guidance, certain steps can test for intravascular injection or reduce its consequences.

The needle should be aspirated before injection and after each 2–5 mL of injectate, if such volumes are used, in order to ensure no bloody return. For blocks using large volumes, 3–4 mL of a mixture of local anaesthetic plus 1:200,000 epinephrine (15–20 μg) may be injected as an initial test dose. If injected intravascularly, such a mixture will cause, with a high degree of probability, a brief and transient (2–3 minutes) rise in the heart rate of 20–25 beats per minute, and a rise in systolic blood pressure of 20–30 points because of the beta and alpha effects of the epinephrine.[1] This precaution was originally developed to detect inadvertent intravascular injection during epidural anaesthesia, but it applies equally well for other regional techniques.

A rising, or high, blood level of local anaesthetic is typically manifest by the onset of CNS features such as anxiety, agitation, tinnitus, muscle twitching, peri-oral numbness or tingling, and dizziness. As plasma levels rise, tonic-clonic seizures can occur. At even higher plasma levels, neuronal inhibition occurs leading to respiratory arrest, coma, and cardiovascular collapse. Although most anesthetics produce signs of CNS toxicity prior to either seizure or CVS toxicity, this is not always the case. With highly lipophilic, highly protein bound agents (e.g., bupivacaine), CVS collapse may even precede CNS symptoms.[2]

If a patient manifests features of toxicity during the course of an injection, the injection should be stopped immediately and assistance should be enlisted or summoned. Oxygen (100%), via a bag and mask, should be commenced immediately. If the patient's oxygen saturation, as judged from pulse oximetry, falls below 90%, positive pressure ventilation should be instituted. A small, anticonvulsant dose of thiopental (50–100 mg) should be administered. Cardiovascular parameters should be monitored and adverse effects treated: hypotension with fluids and pressors (ephedrine 5–10 mg); hypertension with vasodilators (labetalol 5–10 mg); and tachycardia with beta blockers (esmolol 5 mg, metoprolol 2.5–5 mg).

These measures will often abort progressive local anesthetic toxicity. However, if the toxicity appears to be proceeding toward convulsions (agitation, limb jerking, loss of consciousness), further measures are necessary. Positive pressure ventilation with oxygen should be commenced in order to ensure oxygen saturation greater than 90%. If ventilation is difficult, or if the patient convulses, muscle paralysis with 50–100 mg succinylcholine should be administered to ensure adequate ventilation. Cardiovascular monitoring and treatment of adverse CVS effects should continue. Recent evidence from animal studies[3–5] and a number of case reports of successful resuscitation from cardiovascular collapse following local anesthetic toxicity suggest that intra-

venous administration of lipid emulsion may be a life-saving adjunct.[6–9]

Physiologic Effects

Although undertaken to relieve pain, nerve blocks will, or may, block other sensory functions, motor function, balance, and sympathetic function. When these are to be expected but pose no immediate hazard, the patient should be warned to expect them and to not be alarmed by their onset. Appropriate precautions should be taken to compensate against loss of function and to avoid injury. Examples of side effects pertinent to blocks used in pain medicine are numbness or weakness in the limb following spinal nerve blocks, ataxia following third occipital nerve blocks, and hypotension or Horner's syndrome following sympathetic nerve blocks.

Blocks targeting particular nerves may spill over to adjacent nerves and produce unwanted effects (e.g., intercostal nerve blocks may produce inadvertent epidural blockade; brachial plexus blocks may produce sympathalgia or phrenic nerve block). Patients undergoing such blocks should be closely monitored for adverse effects and treated early and vigorously in the event that they do occur.

Damage to Non-neural Structures

The needles used for local anesthetic blocks have the potential to pierce and damage structures along the course of the insertion or near the target point. Examples include pneumothorax following intercostal nerve block or thoracic spinal nerve block, piercing the esophagus during stellate ganglion blocks, piercing pelvic viscera during sacral spinal nerve blocks, and penetrating the aorta or inferior vena cava during celiac plexus blocks.

Piercing a blood vessel has the potential to produce bleeding or hematoma. In patients with normal clotting mechanisms, it is rare for such bleeding or hematoma to produce significant sequelae. In patients with abnormal coagulation, bleeding may produce hypovolemia, and hematoma may exert pressure effects on adjacent structures. For these reasons, coagulopathy is a relative contraindication for local anaesthetic blocks.

Damage to Nerves

Targeting a nerve with an injection carries the risk of nerve damage. The resultant symptoms range from minor paraesthesia to severe pain. The damage may be caused by piercing the nerve with the needle or by what is injected. Components of the injectate, such as preservative, may be neurotoxic, epinephrine may cause spasm of the vasa nervorum and result in ischemic damage, or the pressure of injection may damage the nerve physically. A prospective audit, at one institution, found that the incidence of neuropathy, encountered following 1065 blocks for surgery, was 0.22%.[10]

Procedure

In order to be valid or effective, nerve blocks need to be accurate. This involves placing the injection as close as possible to the target nerve. Several techniques are available to secure accurate placement. They differ for unaided (i.e., "blind") techniques and for image-guided techniques.

Blind Techniques

For blind techniques, the oldest method of correct needle placement is to probe the nerve gently with the tip of the needle. This maneuver produces a paraesthesia in the area of distribution of the nerve. Once paraesthesia is elicited, the needle is held steady and the local anaesthetic is injected. This technique, however, has now become almost obsolete. Probing some nerves (e.g., autonomic nerves) does not elicit paraesthesia but, more importantly, probing nerves risks damaging them.

Mixed nerves, containing sensory and motor fibers, can be located by using an insulated needle connected to a peripheral nerve stimulator. By passing an electric current through the needle, the motor fibers in the nerve are stimulated, producing a twitch in the muscles supplied by the nerve. This stimulation is usually not painful because motor fibers are activated at lower current intensity than sensory fibers. A typical setting is a frequency of 1–2 Hz and a current strength of 1 mA. At this setting, a twitch will be produced as the needle approaches the nerve but still lies some distance from it. Reducing the current to 0.4–0.5 mA allows the needle to be advanced further. A well-defined twitch at this intensity of current implies that the needle is close to the nerve.

Data from clinical anesthesia practice show a high success rate of blocks facilitated by a nerve stimulator.[11] However, large volumes of local anesthetic are typically administered for operative anesthesia, and it is unclear if these data can be extrapolated to blocks in pain medicine, in which small volumes of local anesthetic are used in order to maximize the selectivity of the block. Although rare, neurologic complications may occur when nerve stimulators are used.[12]

For some blocks, palpable landmarks can be used to secure the accuracy of the block. A classical example is the intercostal block, for which the rib is an adequate landmark for the target site.

Image-Guided Techniques

When nerves and landmarks are not palpable and precision is required, unaided techniques do not ensure accuracy and selectivity of the block. In such circumstances, image guidance can be used to secure safety, accuracy, and selectivity.

Fluoroscopy is the most commonly used form of image guidance in pain medicine. Its limitations are that fluoroscopy shows only bones. Therefore, it is suitable only for target nerves that bear a dependable relationship to a bony landmark. The accuracy of the block is achieved by directing the needle to the landmark. Safety is achieved both by choosing a course that does not incur intervening structure that should not be damaged and by having the needle not stray from the intended target. Selectivity is achieved by administering a test-dose of contrast medium to establish that the injectate will flow into the region of the target nerve and will not flow onto other structures where anesthetization might compromise the selectivity of the block. The advantages of fluoroscopy are that it demonstrates a wide field of view around the target region; with C-arm fluoroscopy, views of any orientation can be obtained in order to define the location of the needle during its course or at its target point; intermittent images are rapidly applied and continuous imaging is possible if required; and the apparatus is not excessively expensive, which keeps the cost of the procedure at acceptable levels. A particular advantage of fluoroscopy is that, in the event of intravascular injection, it will reveal rostral or caudal flow of contrast medium away from the target point. This facility is not available from devices that produce planar images.

Some operators use computed tomography (CT) guidance instead of fluoroscopy. They are attracted by the definition that CT provides of viscera and vessels that should be avoided by the needle. Ostensibly, this allows for a safer placement of the needle. For injections into narrow joint cavities or irregularly orientated joints such as the sacroiliac joint, CT offers the virtue of depicting the cavity and its orientation directly. Consequently, a path for the needle can be planned to coincide directly with the joint. The disadvantages of CT guidance are numerous. Each time the needle position is checked, the patient must be rescanned. This interrupts the procedure, prolongs it, and involves considerable radiation exposure. More critically,

planar image does not reveal flow of contrast medium in vessels that run out of the plane of view. Serial reconstruction does not compensate for this because by the time the images are acquired, the contrast medium will have left the field of view. Safety with respect to inadvertent intravascular injection has not been demonstrated for CT guidance. CT is far more expensive than fluoroscopy. For these reasons, fluoroscopic guidance remains the modality of choice for pain medicine procedures. Only in selected cases would CT guidance be justified.

Ultrasound guidance is being increasingly used and explored in pain medicine.[13] It demonstrates muscles, ligaments, vessels, joints, and bones. Moreover, if high-resolution transducers are used, thin nerves can be directly visualized. Ultrasound does not involve radiation exposure, either to the patient or to the operator, and continuous screening can be used. Fluid injected is easily visualized in a real-time fashion. Ultrasound is less expensive than CT and may be less expensive than fluoroscopy. For these reasons, ultrasound guidance is emerging as an attractive alternative to other modalities of image guidance. Its limitations, at present, are the poor resolution of narrow-gauge needles (although, with experience, operators can infer the location of the needle from the movements of the soft tissues) and, in anatomically complex regions, echoes from overlying structures interfere with the image of the target area. The available data are too sparse to endorse or recommend the routine use of ultrasound for procedures in which fluoroscopy has an established role.

TEST BLOCKS

Test blocks are ones that are not therapeutic injections, prognostic tests, or diagnostic tests in the strict and correct sense of those terms. They are performed simply to test if a particular nerve is involved in the patient's symptoms. A nerve is anesthetized and the response is either that the patient's pain is relieved or not. The block is not prognostic because it is not used to predict the outcomes of any subsequent treatment. Nor is it diagnostic because the block is not used to distinguish one source of pain from another. It is used only to see if the nerve anesthetized is involved in the patient's symptoms.

Virtually any nerve in the body can be blocked in this way. Examples include supraorbital blocks for headache, suprascapular nerve blocks for pain in the shoulder, blocks of the median, ulnar, or radial nerves for pain in the hand, lateral femoral cutaneous nerves blocks for meralgia paraesthetica, ilioinguinal and iliohypogastric nerve blocks for pain after herniography, tibial nerve blocks for pain in the foot, and phrenic nerve blocks for shoulder pain or hiccups.

Proponents have typically stated that such blocks can produce "useful information," but the nature of that information, and its utility, have been poorly elaborated. In some cases, the blocks are used to "confirm" the diagnosis, but the diagnosis will already be evident from other clinical information. It may be satisfying to the operator to be able to relieve the patient's pain. The patient may find it gratifying to have their pain relieved, but any effect will be temporary because of the limited duration of action of local anaesthetic agents. The pivotal question—both clinically and philosophically—is: what then?

If the patient's response is used to predicate a subsequent treatment, the test becomes a prognostic block. In that event, however, the block and the response to it need to be valid, and the treatment needs to be effective. If those requirements are not satisfied, the blocks amount to no more than an interesting exercise.

In this context, the art of performing local anesthetic blocks has not been developed into a clinical science. Although a nerve may be blocked and although pain might be relieved, the validity and utility of this information has not been developed.

Particularly egregious in this regard is the practice of paravertebral blocks. Thoracic paravertebral blocks have been advocated for pain in the chest wall, lumbar paravertebral blocks for determining specific nociceptive pathways, and transsacral blocks for back pain or pelvic pain. In the first instance, paravertebral blocks are not target-specific; they have not been shown to anesthetize particular nerves or particular nociceptive pathways specifically. In particular, they are of no diagnostic value for spinal pain, for the block is directed to ventral rami, distal to any afferents from the vertebral column. Nor have any controlled studies shown that responses to these blocks are valid. If pain pathways need to be sought, fluoroscopically-guided spinal nerve blocks have greater face validity. Individual nerves can be selectively targeted accurately, and injections can be constrained to affect only that nerve.

PROGNOSTIC BLOCKS

A prognostic block is one undertaken to test if a definitive treatment will be successful. The rationale is that if a nerve block with local anesthetic relieves the pain, then a treatment capable of interrupting conduction along the nerve should relieve the pain for a prolonged period, if not permanently.

For prognostic blocks to be valid, evidence is required to complete a table like that depicted in Table 97.1. There needs to be a strong association between a positive response to the block and a successful outcome from treatment and between a negative response to the block and failure of treatment. Such data are hard to produce and are simply not available. They would require a study in which patients undergo treatment irrespective of their response to blocks. They also require a treatment that is dependably effective. Unless that is the case, failures may be due to the failure of treatment rather than an error in the response to blocks. Few such treatments exist.

In the absence of proper evidence, practitioners who use prognostic blocks assume that a positive response to a block should be predictive of a favorable outcome to treatment. This has not always proven to be the case. In the past, prognostic blocks of peripheral somatic nerves were used to test the outcome of surgical neurectomy. This treatment proved ineffective. Neuroma formation and deafferentation pain complicated the treatment. Positive responses to sympathetic blocks have not consistently been associated with favorable or sustained outcomes from sympathectomy—either surgical or chemical. In such cases, it is not evident if the response to blocks was false or if sympathectomy is intrinsically not effective.

Spinal Nerve Blocks

In some patients with radicular pain, medical imaging is not diagnostic. CT or magnetic resonance imaging (MRI) may show more than one spinal nerve affected by a disc herniation or by foraminal

stenosis, and the clinical features do not help to determine which nerve is the source of symptoms. Spinal nerve blocks were developed to assist surgeons to determine the symptomatic level in such cases so that surgery could be directed at the correct segmental level.

Spinal nerve blocks involve placing a needle, under fluoroscopic guidance, into the intervertebral foramen that lodges the target nerve. If anesthetizing that nerve relieves the patient's pain, then that nerve is implicated as the source of pain. If anesthetizing the nerve does not relieve the pain, that nerve is excluded as the source of pain, and investigations can be redirected to another nerve.

Cervical Spinal Nerve Blocks

Because of the proximity of the vertebral artery and the spinal cord, cervical spinal nerve blocks require consummate skill in obtaining the correct view, delivering the needle, and checking its location. Comprehensive guidelines for the safe conduct of the procedure have been published by the International Spine Intervention Society.[14]

An oblique view of the cervical spine is obtained such that the target intervertebral foramen is maximally wide. A spinal needle is inserted so that it initially touches the anterior edge of the superior articular process behind the foramen. From this position, the tip of the needle is adjusted so that it enters the foramen, tangential to the anterior surface of the superior articular process, approximately opposite the equator of the foramen (Fig. 97.1A). In an anteroposterior view, the tip of the needle is adjusted so that it lies opposite the longitudinal bisector of the articular pillar (Fig. 97.1B).

Once the needle has been placed, a test dose of contrast medium is injected to check that the injection is not intravascular (Fig. 97.1C), and a further dose is injected to show that the injectate flows medially along the nerve as far as the dural sac (Fig. 97.1D). Once flow has been shown to be safe and appropriate, between 0.5 and 1.5 mL of 1% lidocaine (or an alternative local anesthetic) is then injected.

Lumbar Spinal Nerve Blocks

Various techniques for lumbar spinal nerve blocks have been described. They differ essentially in terms of the depth to which the needle is inserted. The classical technique requires placing the needle on the anterior wall of the intervertebral foramen, just below the pedicle. Other techniques involve placing the needle above the target nerve or behind it. Explicit guidelines for each of these techniques have been prepared by the International Spine Intervention Society.[15]

The subpedicular approach aims at a target point immediately below the 6 o'clock position on the pedicle that lies above the target nerve. If this target point is obstructed by the lamina, by the superior articular process, or by a flange of the transverse process, the fluoroscope is adjusted in a manner to move the obstructing structure out of the line of view (Fig. 97.2). A spinal needle is then inserted toward the target point, taking care not to touch or injure the nerve. Its final position is checked on anteroposterior and lateral views (Fig. 97.3A,B). A test dose of contrast medium is injected to check that the injection is not intravascular and that the injectate flows along the target nerve (Fig. 97.3C,D). Once correct flow has been achieved, 1–1.5 mL of local anesthetic (0.5% bupivacaine or

2% lidocaine) can be injected. In order to ensure adequate anesthetization of the nerve, some operators elect to deliver the local anesthetic in equal aliquots in front of, above, and behind the nerve. To do so requires withdrawing the needle slightly and monitoring its position in lateral views.

Sacral Spinal Nerve Blocks

Sacral spinal nerve blocks are a complement to lumbar spinal nerve blocks in that the S1 spinal nerve is commonly affected by lumbar spine pathology. In practice, they are effectively limited to S1 spinal nerve blocks. Techniques for other sacral spinal nerves have not been described nor has an application been described. However, the technique would be analogous to that for S1.

S1 spinal nerve blocks involve introducing a spinal needle through the S1 posterior sacral foramen and into the sacral canal (Fig. 97.4). This procedure requires familiarity and versatility with the radiographic anatomy of the posterior sacrum because the posterior sacral foramen may be hard to identify. Care needs to be taken not to insert the needle too far such that it passes through the anterior sacral foramen and into the pelvic cavity. Detailed guidelines for this procedure have been published.[15]

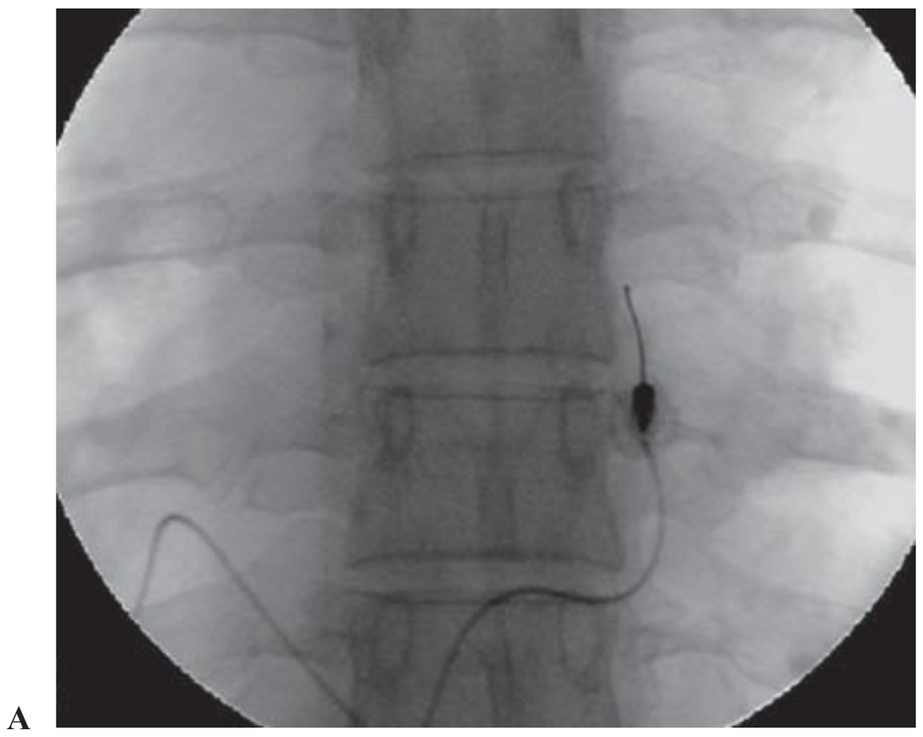
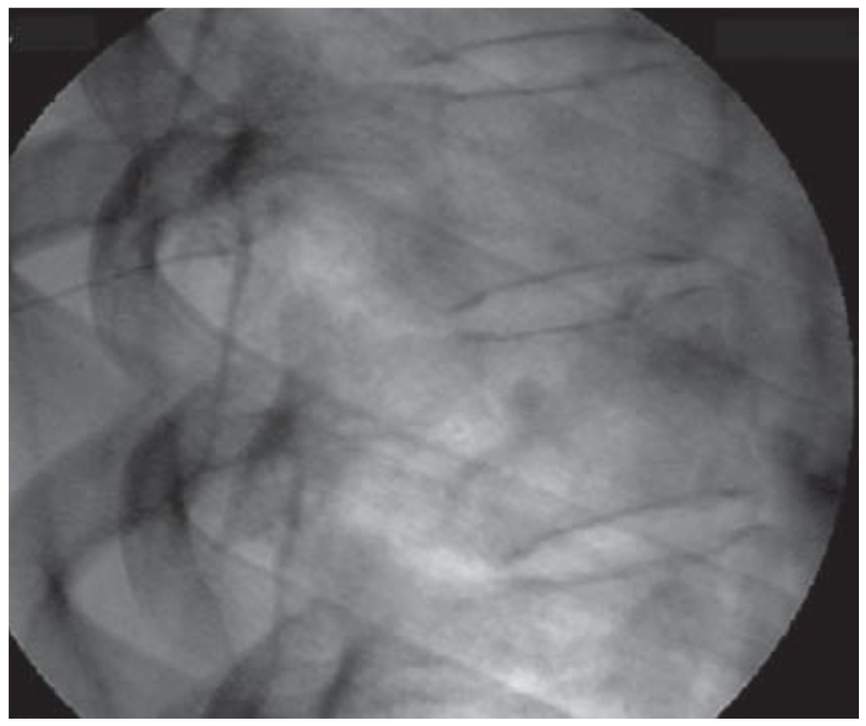
Thoracic Spinal Nerve Blocks

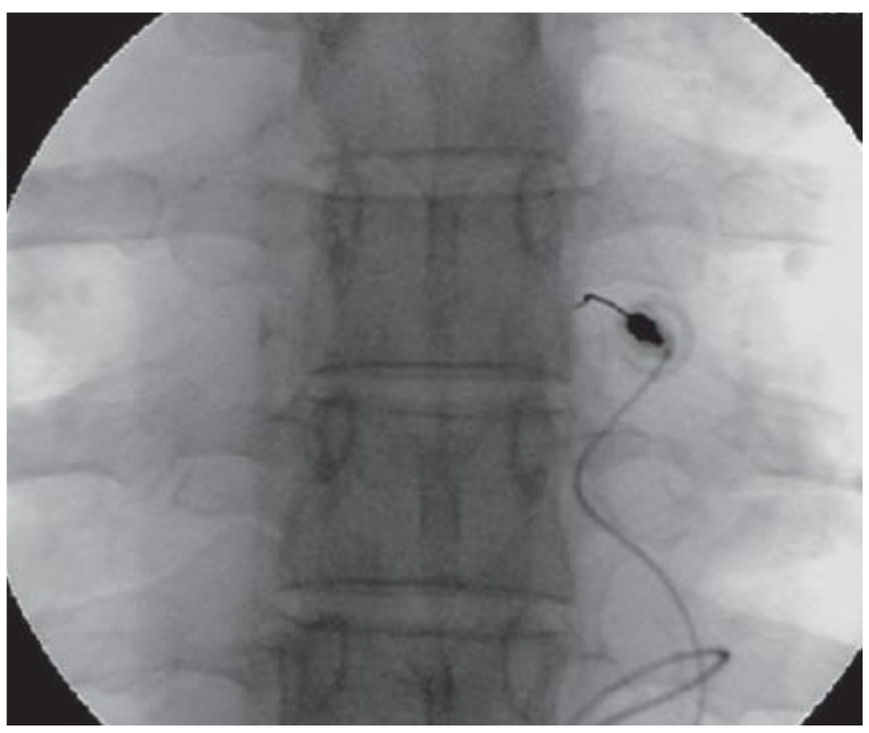
There have been no published studies of the utility of thoracic spinal nerve blocks, but guidelines for their performance have been published.[16] In practice, they are sometimes performed to select patients for radiofrequency treatment of thoracic spinal nerves[17,18] and in the diagnosis of neuropathic pain affecting the chest wall.



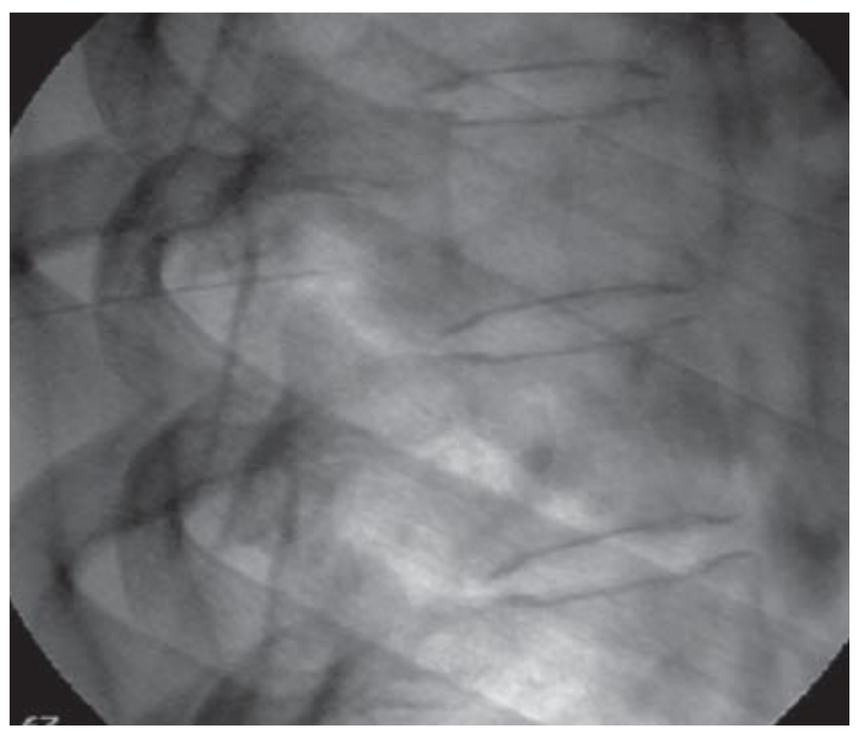
The technique recommended by the International Spine Intervention Society involves placing a needle first onto the edge of the lamina overlying the target spinal nerve and then advancing the needle beyond the edge until its tip rests just behind the nerve (Fig. 97.5).[16] This maneuver is facilitated by prebending the tip of the needle slightly so that it can be rotated laterally off the lamina and subsequently medially into the intervertebral foramen. The technique requires careful adjustment of the needle in order not to injure the nerve. Once the needle has been placed, contrast medium is used to check for appropriate flow of injectate along the nerve (see Fig. 97.5) and to avoid intravascular injection.



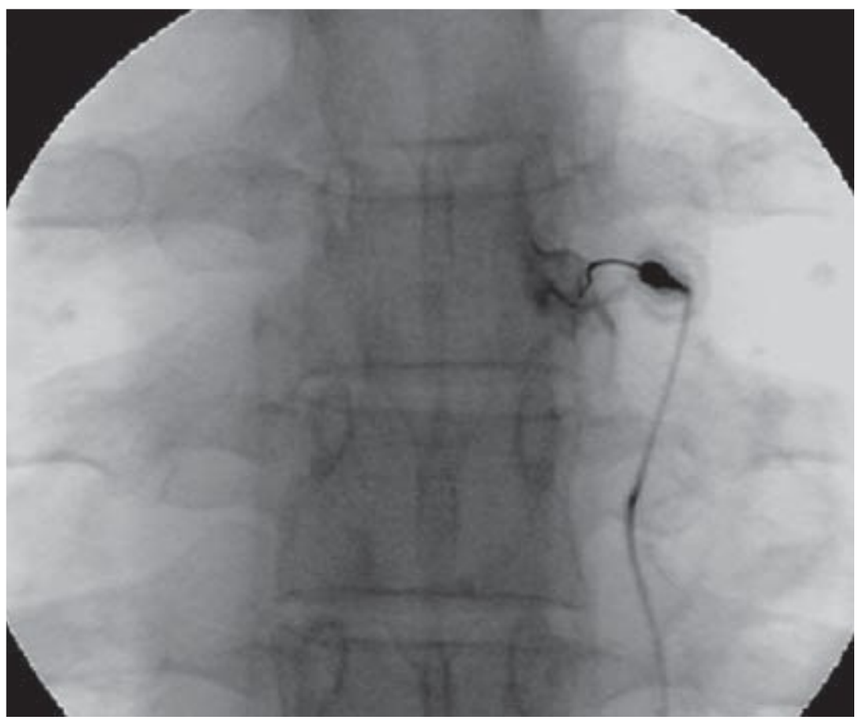
Validity



Data on the validity of spinal nerve blocks are limited because of two factors. First, nerve blocks should be performed under controlled conditions in order to guard against false-positive responses, but only one study of spinal nerve blocks has used control blocks. Secondly, the predictive validity of blocks requires a study in which patients with positive responses to blocks and patients with negative responses both be submitted to treatment. Only such a study would provide proper data on the sensitivity and specificity of the blocks. Such studies are difficult to justify ethically and have not been conducted.



Partial data are available from studies that report the proportion of patients with positive responses to blocks in whom pathology is found at surgery. This proportion is not the sensitivity of the test, but is its positive predictive value in the sample tested. Since that value is dependent on the nature of the sample studied, it is not generalizable to other samples or to practice at large.



For lumbar spinal nerve blocks, various studies have reported positive predictive values that ranged between 80% and

100%.[19–22] These high values imply that the false-positive rate of lumbar spinal nerve blocks is low and, therefore, that their specificity is likely to be high. In one study, a small number of patients with negative responses to blocks nevertheless underwent surgery.[21] Pathology was found in all cases but not at the level tested; in no case did surgery find pathology at the level tested when the block had been negative. These patients proved to have multilevel disease or anomalous nerve roots. This implies that the false-negative rate of lumbar spinal nerve blocks is low and, therefore, that their sensitivity is high.

One study measured sensitivity by performing lumbar spinal nerve blocks in 46 patients with clinical and radiologic evidence of nerve root compression, subsequently confirmed at surgery.[23] The sensitivity was 100%, with 95% confidence intervals of 88% to 100%. That same study measured specificity by performing blocks in 23 patients at levels known by radiology not to be symptomatic. No false-positive responses were encountered, and the specificity of lumbar spinal nerve blocks was estimated as "around 90%."[23]

The one study that used controlled blocks enlisted 18 patients with cervical radiculopathy and 83 with lumbar radiculopathy but did not stratify the results according to region investigated.[24] Using a criterion standard of good outcome from surgery, it found a sensitivity of 93% but a specificity of only 33%. Spinal nerve blocks were no better than MRI in predicting good outcome, but the particular advantage of spinal nerve blocks demonstrated in this study was the ability of negative responses to blocks to predict poor outcome, particularly when MRI was negative or ambiguous.

No studies have explored the predictive validity of either cervical or thoracic spinal nerve blocks. When used to select patients for procedures such as dorsal root ganglion radiofrequency, these blocks have been assumed to be valid, but that validity has not been established.

SYMPATHETIC BLOCKS

Blocks of various elements of the sympathetic nervous system have a status somewhere intermediate between diagnostic and prognostic. They are not diagnostic in the strict sense of that adjective, for the cause of pain is usually evident from clinical assessment or other investigations. Fundamentally, they are used to test if the patient's clinical features are mediated by sympathetic nerves. Knowing this does not affect management unless the response to blocks is used to prognosticate the response to neurolytic treatment of the sympathetic nerves.

Cervical Sympathetic Blocks

Cervical sympathetic blocks have been used largely in the evaluation of patients with complex regional pain syndromes of the upper limb. Other applications have been for patients with pain in the face or head.

The procedure requires delivering an aliquot of local anesthetic onto the stellate ganglion. The traditional approach has been a blind technique based on surface markings and palpation. The alternative is a fluoroscopically-guided technique.

The blind technique classically involved injecting a large volume of local anesthetic in order to ensure saturation of the ganglion. Whereas this might be acceptable for therapeutic or palliative purposes, large volumes compromise the validity of cervical sympathetic blocks because structures other than the target nerve are anesthetized. Indeed, one critic has declared that very little of the injectate reaches the area of the stellate ganglion and much spreads elsewhere.[25] In a study of eight volunteers, MRI showed that injectate was not delivered to the stellate ganglion but passed anterior to it.[26] For these reasons, a fluoroscopically-guided technique is preferred.

The lower cervical sympathetic chain runs anterolateral to the cervical vertebral column, in the trough between the scalene muscles laterally and the longus cervicis medially. The target point for blocks is the anterolateral surface of the vertebral body of C7. This can be visualized on an oblique view of the cervical spine (Fig. 97.6A). In order to avoid puncturing overlying vessels and viscera, these need to be displaced by fingers palpating above and below the target point. A needle can then be inserted toward the target point along an oblique view. Its final position should be confirmed on an anteroposterior view (Fig. 97.6B). Thereafter, an aliquot of contrast medium is injected to demonstrate flow along the gutter and not into one of the adjacent muscles (Fig. 97.6C,D).

Ultrasound guidance is an alternative to fluoroscopic guidance and offers certain advantages in this region. Ultrasound demonstrates the common carotid artery, internal jugular vein, thyroid gland, and esophagus—all of which need to be avoided during passage of the needle (Fig. 97.7). In a study that compared ultrasound guidance with the blind technique, the volume of local anesthetic required was reduced to 5 mL, the onset of block was sooner, and hematoma was avoided (but occurred in 3 out of 12 cases with the blind technique).[27] A disadvantage is that ultrasound guidance requires training and confidence in the technology and technique. The potential of ultrasound guidance to reduce complications and improve accuracy has still to be demonstrated in clinical studies.

Lumbar Sympathetic Blocks

Lumbar sympathetic blocks involve anesthetizing the lumbar sympathetic trunk, typically at the L3 level. They have traditionally been used to test if they relieve pain or other features of complex regional pain syndrome. They have also been used to test if low back pain is relieved. Although blind techniques relying on surface markings only have been used in the past, they have not shown to be valid. The preferred technique should be fluoroscopically guided in order to show that the local anesthetic is deposited accurately onto the sympathetic trunk and does not spread to other structures that might compromise the validity of the block.

The target point is the anterolateral corner of the L3 vertebral body, immediately anterior to the surface of the psoas major, which is where the lumbar sympathetic trunk runs. A target point over the lower third of the vertebral body is recommended in order to avoid the lumbar vessels which cross the middle of the vertebral body. In an oblique view of the lumbar spine, this point coincides with what appears to be the anterior margin of the vertebral body (Fig. 97.8A). In such a view, a spinal needle is directed parallel to the x-ray beam, toward the target point. Correct depth can be achieved by first directing the needle to touch the vertebral body, but then redirecting the needle so that it lies tangential to the margin of the body but at the same depth of insertion. The depth of insertion should be checked on a lateral and on an anteroposterior view (Fig. 97.8B,C). In the anteroposterior view, the tip of the needle should lie on the interpedicular line. Once the needle has been placed, an aliquot of contrast medium should be injected to check dispersal. It should flow longitudinally in the retroperitoneal space, anterior to psoas major and the lateral edge of the vertebral body (Fig. 97.8D). If the injection occurs into the psoas major, a radiate pattern of spread will appear, as the contrast medium disperses between the fascicles of the muscle. In that event, the needle needs to be relocated anterior to the muscle and outside its fascial sheath. Once appropriate flow of contrast medium has been established,

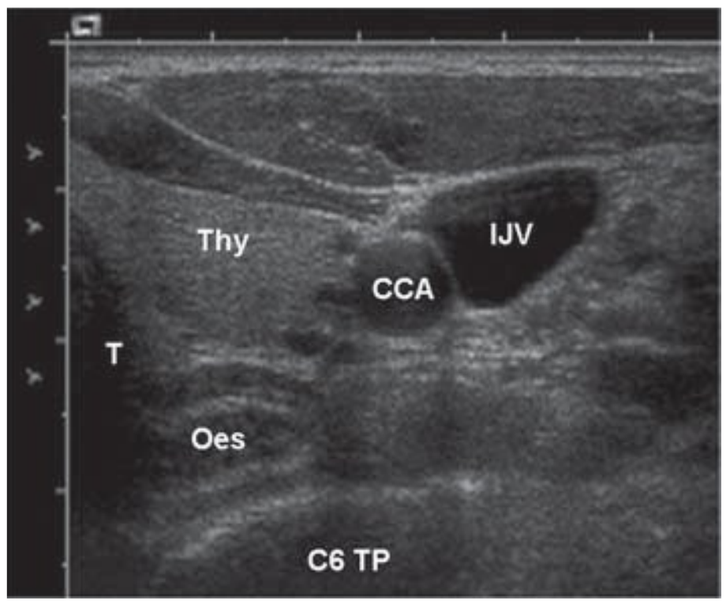

FIGURE 97.7 Ultrasound anatomy of the neck in the plane used for stellate ganglion block. Note how an anteroposterior approach, using either the traditional blind technique or fluoroscopy guidance, carries the risk of incurring the thyroid gland, common carotid artery, internal jugular vein, or esophagus. Under ultrasound guidance, an oblique approach lateral to the great vessels is possible. CCA, carotid artery; IJV, jugular vein; Oes, esophagus; T, trachea; Thy, thyroid gland; TP, transverse process of C6. (Illustration kindly provided by Dr. Urs Eichenberg, University Hospital, Berne, Switzerland.)

a similar aliquot of local anesthetic is injected to anesthetize the sympathetic trunk.

Validity

The use of fluoroscopy establishes the face validity of these blocks (i.e., the sympathetic trunk is accurately and selectively infiltrated). Face validity is confirmed physiologically by observing a rise in skin temperature in the limb of the target side, which shows that the sympathetic trunk has indeed been anesthetized.

What has not been shown is that sympathetic blocks have construct validity (i.e., that the physiologic response is due to the effects of local anesthetic and not to nonspecific factors such as placebo). This requires the execution of controlled blocks, but because of their traditional standing, sympathetic blocks have been exempt from the requirement for controls. They are assumed to be valid and, therefore, that diagnostic and prognostic inferences based on them are always correct. No research has shown this to be so. Research that has been conducted has damaged the traditional illusion.

A study showed that stellate ganglion blocks with normal saline were as effective as blocks with local anesthetic.[28] Statistically, a difference arose in that patients who received local anes-

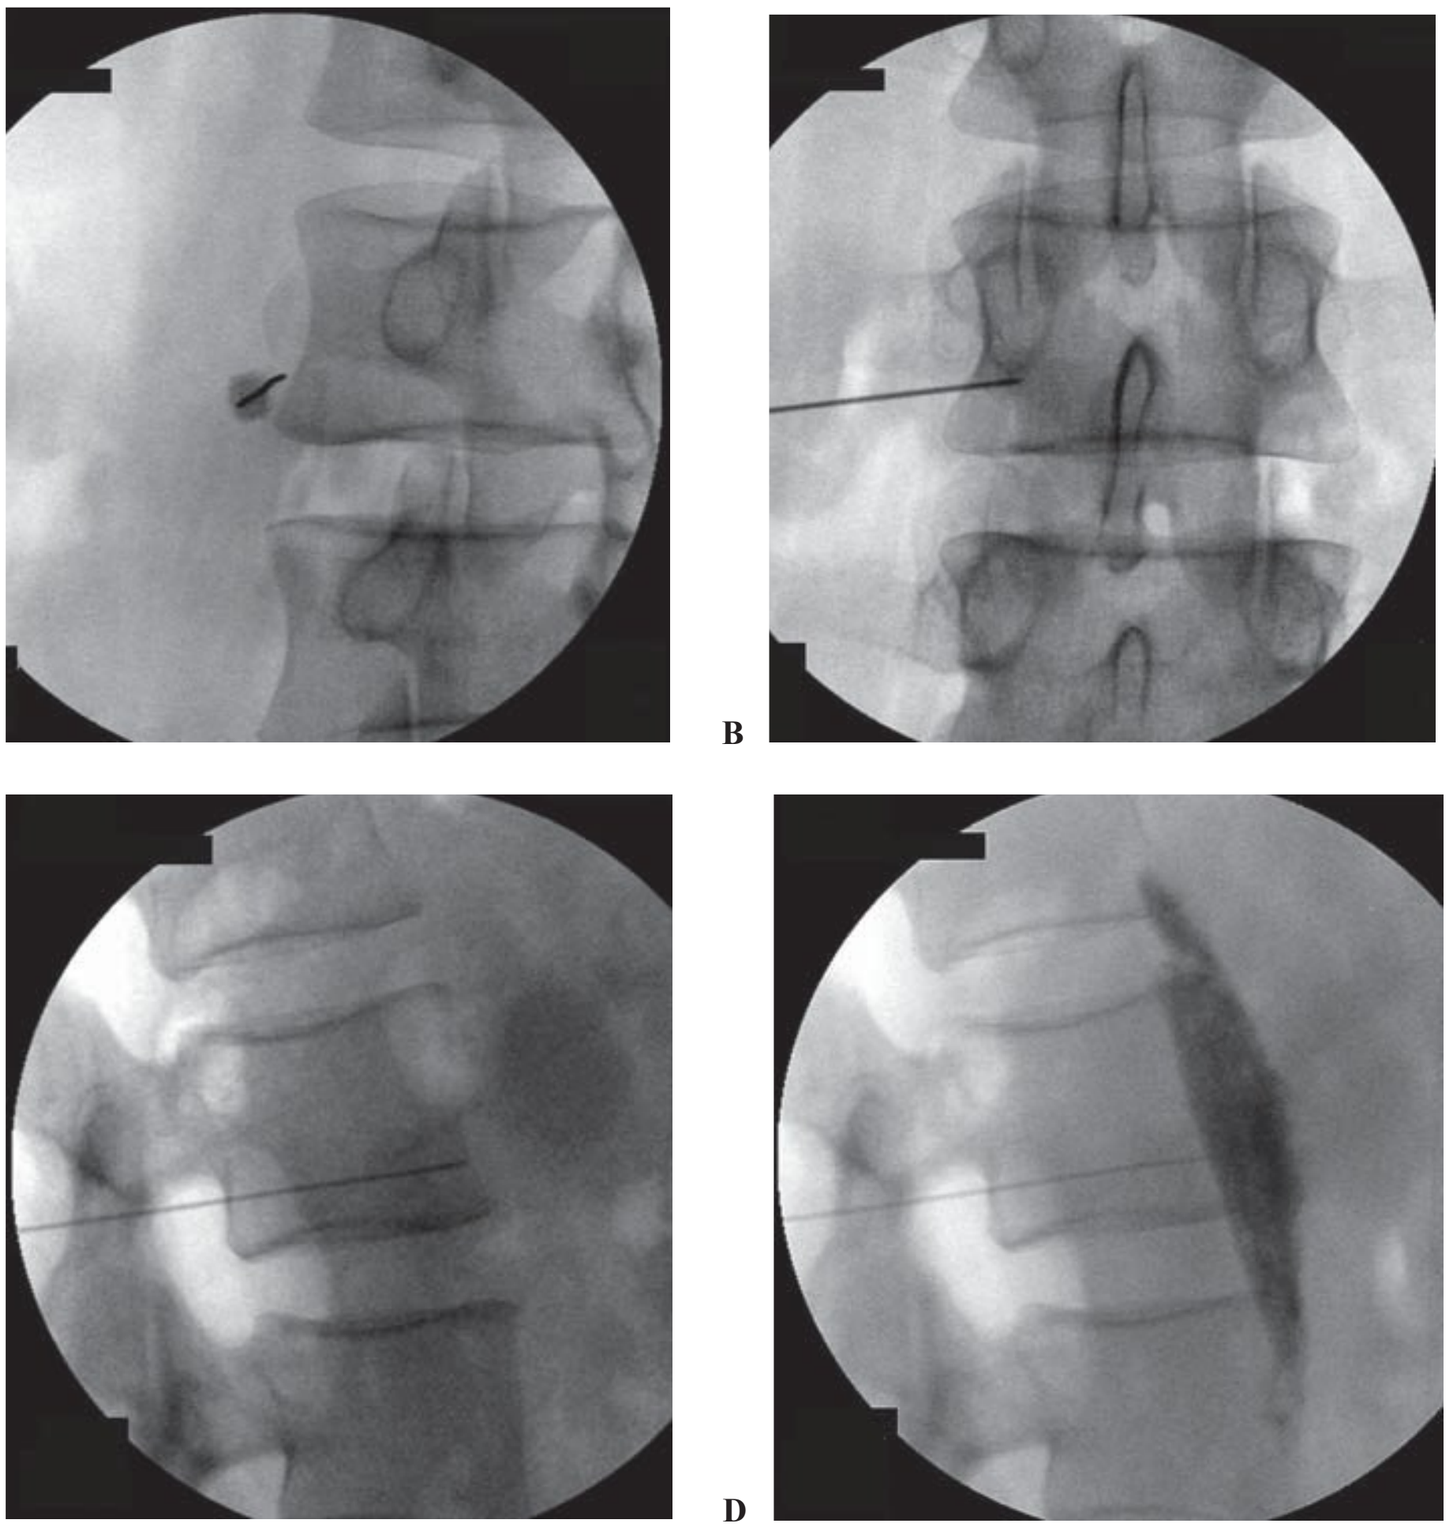

FIGURE 97.8 Stages in the conduct of a lumbar sympathetic block. **A.** An oblique view showing a needle passing tangential to the lower anterolateral surface of the L3 vertebral body. **B.** Anteroposterior view, showing the needle in place over the anterolateral aspect of the L3 vertebral body. **C.** Lateral view showing the needle in place over the anterolateral aspect of the L3 vertebral body. **D.** Lateral view showing contrast medium spreading longitudinal over the anterior surface of the psoas major muscle. thetic tended to have relief of pain lasting into the next day. Accordingly, the authors recommended that diagnostic decisions be based not on the immediate response, but on the response evident on the next day. However, this is not a secure operational criterion because some patients who received normal saline also had prolonged responses. The only way to secure the validity of stellate ganglion blocks is to perform controls in each and every patient. Unless this is done, the investigator cannot distinguish a true-positive response from a placebo response. Failing to use controlled blocks in the past may have led to overestimates of so-called sympathetic-mediated pain. Unless and until studies are conducted using controlled blocks, its true prevalence will not be known, and it remains possible that its prevalence may be zero. No studies have tested the validity of lumbar sympathetic blocks. Nor has the prognostic validity of sympathetic blocks—cervical or lumbar—been established. No one has compared response to blocks—either single or controlled—to outcomes of sympathectomy. Not using controlled blocks may be one reason why sympathectomy often proves ineffective.

Miscellaneous

Other blocks of the sympathetic nervous system are practiced, ostensibly widely. These include blocks of the celiac plexus, splanchnic nerves, and hypogastric plexuses, and blocks of the ganglion impar. However, there is no evidence on their validity as either diagnostic or prognostic procedures. The literature pertaining to these procedures focuses exclusively on their therapeutic benefits (see below).

DIAGNOSTIC BLOCKS

Many conditions associated with chronic pain have no detectable morphological correlate. The cause of pain is not evident on conventional medical imaging. For some such conditions, although the cause might not be evident, the source of pain can be established using diagnostic blocks.

The rationale for diagnostic, local anesthetic blocks is that if a structure is the source of pain, then anesthetizing it or its nerve supply should relieve the pain. If the suspected structure is not the source of pain, anesthetizing it should not relieve the pain.

Two types of blocks have been used to pinpoint sources of pain: intra-articular blocks and nerve blocks. Intra-articular blocks involve injecting local anesthetic into a joint suspected of being the source of pain. Diagnostic nerve blocks are restricted to small nerves that have a limited and specific distribution. Blocks of larger nerves are not diagnostic of a particular source because of their widespread distribution.

Principles

Controls

There are no objective tests for the presence of pain or for its relief. Investigators rely only on what the patient reports, but patients can report relief of pain for reasons other than the effect of a local anesthetic injected during a diagnostic block. They

may have an expectation that the block will relieve their pain, particularly if they have been coached or instructed to expect a positive response. Unprompted, they might want the response to be positive so that they qualify for the resultant treatment that promises to relieve their pain permanently. Patients with medico-legal claims might choose to report relief in order to vindicate their claim.

Because of these extraneous, confounding factors, a positive response to a block cannot be summarily attributed to the effect of the local anesthetic injected. Some form of control is necessary if the response is to be valid and for the interpretation of the response to be correct. The ultimate form of control is a placebo-control in which an inactive agent is injected to test for spurious responses. However, for two reasons, placebos cannot be administered in an arbitrary manner. In the first instance, administering a placebo on a single-blind basis is considered unethical in some jurisdictions. Patients would need to be informed that they might receive an inactive agent. In the second instance, for placebo blocks to be meaningful, they must be performed in the context of at least three injections.

The first injection must be an active agent, in order to provide prima facie information that anesthetising the target structure does, in fact, relieve the patient's pain. There is no point wasting resources and effort testing with a placebo a structure that is not involved in the patient's pain. The second injection cannot routinely be the placebo, for mischievous patients would know that the second injection is always the "dummy." In order to retain the effects of chance, the second injection must be randomized to be either an active or inactive adjacent. A third injection is required to administer the complimentary agent. Under those conditions, a genuine response is one in which the patient reports complete relief of pain on each occasion that a local anaesthetic was used and no relief when the placebo was used. The validity of the response is made more secure if the injections are performed under double-blind conditions, so that the operator does not subconsciously communicate cues to the patient as to what to expect.

Whereas the triple-block, placebo paradigm satisfies scientific rigor, it is not readily implemented in clinical practice. It involves multiple procedures and additional costs. Furthermore, a positive response to placebo does not necessarily rule out that the tested joint is symptomatic. An alternative paradigm is available, but it is not as widely applicable as has hitherto been thought.

In textbooks of pain medicine, eminent authorities have advocated comparative local anesthetic blocks in order to guard against placebo responses.[29–32] These involve administering a particular agent on the occasion of the first block, but using a different agent on a second occasion. The agents advocated are lignocaine and bupivacaine. The paradigm maintains that a genuine patient will report short-lasting relief when lignocaine is used and long-lasting relief when bupivacaine is used.

An important consideration for the interpretation of responses to comparative blocks is that it is not the absolute duration of relief that is important but the relative duration. In some individuals, lignocaine lasts longer than does bupivacaine in other individuals. It is not a matter that the typical duration of action of lignocaine is 2 hours and that of bupivacaine is 4 hours. Lignocaine can last as long as 7 hours in some individuals, and bupivacaine as little as 1 hour in others. However, it has been shown that in the one individual, when both agents are injected simultaneously into symmetrical sites, bupivacaine consistently outlasts lidocaine.[33,34] Therefore, the essential criterion for a positive response to comparative blocks is that the effect of bupivacaine is longer than that of lignocaine.

The comparative block paradigm was promoted on theoretical grounds, capitalizing on the known difference in duration of action of lignocaine and bupivacaine; when promoted, however, it had not been tested empirically. For more conventional diagnostic blocks, the paradigm has still not been tested, but it has been tested in two ways in the context of diagnostic blocks of the medial branches of the cervical dorsal rami.

In one study, Barnsley et al.[35] administered lidocaine and bupivacaine on separate occasions under double-blind conditions. They considered true-positive responses to be ones in which the patients reported longer-lasting relief of their pain when bupivacaine was used than when lignocaine was used. To establish the validity of the response, they used a statistical test involving the binomial distribution. They found that the chances that the patients had guessed the correct agents were less than 2 in 10,000, on which grounds they concluded that the comparative block paradigm was valid.

Another study used a more conventional strategy. Lord et al.[36] subjected patients to triple blocks under double-blind conditions, using lidocaine, bupivacaine, and normal saline in a randomized manner. They compared the diagnostic decision that would have been made on the basis of the responses to the two local anesthetics alone, with the decision based on the response to normal saline. True responses were considered to be ones in which pain was relieved on each occasion when a local anesthetic was used but not relieved when normal saline was used. False responses were ones in which pain was relieved when normal saline was injected. Contingency tables revealed that comparative blocks had a specificity of 88%. This means that among patients with a positive response to comparative blocks, there is only a 12% chance that it is due to placebo effects.

On the other hand, the sensitivity of comparative blocks was only 54%.[36] This means that, when strictly applied, the criteria for a positive response do not detect all patients with a genuine response. These criteria exclude some patients who do not respond to placebo blocks but who experience paradoxically longer-lasting relief following lignocaine than with bupivacaine. This type of response may be due to the different duration of action of lidocaine on open sodium channels in patients with ongoing pain. Consequently, failure to satisfy the comparative block criterion does not necessarily mean that the patient has reported a placebo-response. Indeed, some 65% of patients who report discordant responses to lignocaine and bupivacaine do not respond to placebo blocks.[36]

Accordingly, the strength of comparative blocks lies not in detecting placebo responders. It lies in identifying true-responses. If a patient has longer-lasting relief with bupivacaine, the investigator can be 88% certain that the response is true. If the criteria are relaxed to accept complete relief of pain irrespective of which agent lasted longer, the investigator can be 65% certain that the response is true.

Which type of control an investigator chooses to use and which criteria should be used to assess comparative blocks is a matter of preference depending on the circumstances. If an investigator wants to be or needs to be absolutely certain, placebo-controlled, triple blocks should be used. If a certainty of 88% is enough, comparative blocks with strict criteria can be used. If, on the other hand, the investigator can tolerate a false-positive rate of 35%, comparative blocks with relaxed criteria will suffice.

Criteria for Positive Response

For a response to a diagnostic block to be valid, certain criteria should be satisfied. On each occasion that the nerve is blocked, the patient should obtain complete relief of pain. That should be validated by recording the intensity of pain before and after the block, using either a visual analog scale or numerical rating scale. Moreover, for the block to be physiologically and pharmacologically meaningful, the pain should return as the effect of the local anesthetic wears off. Recording the return of pain, therefore, becomes part of the assessment. Prolonged relief of pain, lasting days, weeks, or months, does not constitute a valid response, for it is not compatible with the expected action and effect of administering a local anesthetic. Such prolonged responses are

uninterpretable. They are not consistent with a joint or other structure being the source of nociception. A painful structure should resume being painful once the local anesthetic has ceased to operate. Prolonged responses suggest either a placebo response or some sort of modulatory effect on pain perception, the nature of which has not been determined.

A positive response to blocks should be corroborated by narrative and activity. The patient should volunteer that they feel distinctly better, and they should be able to undertake and demonstrate activities that previously were prevented or restricted by their pain. If activities are not restored, the utility of the block is questionable. If activities, ostensibly restricted by the pain, are not restored when pain is relieved, some factor other than the pain must still be responsible for the restriction.

Applications

In principle, any local anesthetic block used as a diagnostic block should be subjected to controls. Unless controls are used, the response of the patient cannot be held to be valid and diagnostic decisions based on them may be incorrect. Yet, conspicuously lacking in the literature are any data on the use of controls for traditional local anesthetic blocks. It would seem that such blocks are excused the need for controls because of their traditional standing. Data on controlled, diagnostic blocks are available only for blocks of the medial branches of the dorsal rami.

Cervical Medial Branch Blocks

The medial branches of the cervical dorsal rami supply the zygapophysial joints of the cervical spine and its medial posterior muscles (multifidus, interspinales, and semispinalis). Blocks of these nerves would relieve pain from any of these structures. However, there are no known causes of chronic neck pain that lie in the posterior neck muscles.[37] Therefore, in practice, cervical medial branch blocks are a test for pain stemming from the cervical zygapophysial joints.

At typical cervical levels, the medial branch runs across the lateral surface of the ipsisegmental articular pillar (Fig. 97.9A). The target point for blocks at these levels lies at the centroid of the articular pillar or slightly higher at the C3 and C6 levels (Fig. 97.9B).[37,38] The C7 medial branch has a variable location across the C7 superior articular process, anywhere between its apex and the root of the C7 transverse process. For blocks at this level, the target point has to be adjusted accordingly.[38]

Cervical medial branch blocks are the only means available by which either to implicate or to refute the cervical zygapophysial joints as the source of neck pain. A joint is implicated if controlled diagnostic blocks completely relieve the patient's pain.

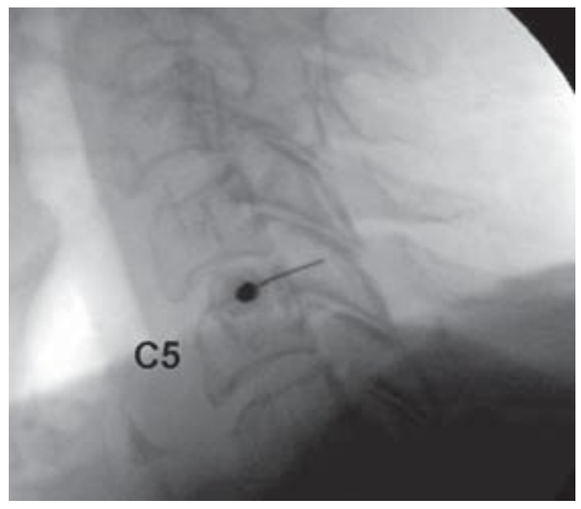

FIGURE 97.10 A lateral fluoroscopic view of the cervical spine showing a needle in place on the articular pillar of C5 for a C5 medial branch block.

In order to anesthetize a particular joint, each of the two nerves that innervate the joint must be blocked. At typical cervical levels, each joint is innervated by the medial branches that have the same segmental numbers as the joint. Thus, the C5-C6 joint is supplied by the C5 and C6 medial branches.

Cervical medial blocks require placing a needle, under fluoroscopic guidance, on to the nerve to be blocked. Explicit guidelines for the performance and evaluation of these blocks have been published by the International Spine Intervention Society.[38] For typical cervical medial branches, the needle is introduced using a lateral view. Correct depth of insertion is established once the needle reaches the articular pillar (Fig. 97.10).

For blocks of the C7 medial branch, additional measures need to be taken in order to avoid false-negative responses because of variations in the location of this nerve. Since this nerve can lie anywhere between the apex of the C7 superior articular process and the root of the transverse process, measures are required to ensure that local anesthetic covers this entire region. That might be accomplished with a single injection onto the lateral aspect of the superior articular process, provided that a test dose of contrast medium shows that the entire area is covered. Otherwise, two injections are required: one at the apex and one at the root of the transverse process (Fig. 97.11). Anteroposterior views are required to confirm the depth of insertion because, in some patients, needles that appear correctly placed in lateral views may actually be displaced laterally by a thick C7 transverse process.[38] A third placement, a few millimeters lateral to the superior articular process, is recommended in order to target C7 medial branches that sometimes are displaced off bone by a slip of the multifidus muscle.

Once the needle has been placed, some operators recommend using a test dose of contrast medium (0.1–0.2 mL) before inject-

ing local anesthetic to guard against venous uptake and, therefore, false-negative responses. For cervical medial branch blocks, the mean prevalence of vascular uptake is 3.9% (95% confidence intervals: 3.84% to 3.96%).[39] Avoiding vascular uptake avoids possible false-negative responses. Thereafter, only a tiny aliquot of local anesthetic (0.3 mL) is required to anesthetize the nerve. Greater volumes of injectate spread away from the target zone and are, therefore, superfluous and threaten the face validity of the block.

Validity

It has been shown that cervical medial branch blocks are target specific. Material injected onto the target points floods the location of the target nerve, but does not spread to adjacent nerves or the spinal nerves.[37] Nor do cervical medial branch blocks anesthetize the posterior neck muscles in a nonspecific manner. Excess injectate typically spreads across the cleavage plane between multifidus and semispinalis capitis.[38]

Single medial branch blocks are not valid. They have false-positive rates of 27%.[40] Therefore, in order to be valid, cervical medial branch blocks must be controlled in each and every case. The choice lies between placebo-controlled blocks and comparative local anesthetic blocks (see "Controls," above).

Two types of positive response to comparative blocks can occur. A concordant response is one in which pain is completely relieved for a duration concordant with the duration of action of the local anesthetic used. A discordant response is one in which pain is completely relieved but the duration of effect is longer when a short-acting agent is used. In the context of cervical medial branch blocks, both responses have been validated.

Concordant responses have a high specificity (88%) when compared with placebo-controlled blocks.[36] This means that positive responses are very unlikely to be false. However, concordant responses have a low sensitivity (54%).[36] This means that they do not detect all patients with cervical zygapophysial joint pain who do not have placebo-responses.

Discordant responses have a high sensitivity (100%). They detect all patients who have zygapophysial joint pain, but their specificity is limited (65%).[36] That means that positive responses can include some placebo responses.

For practical purposes, these different sensitivities and specificities make little difference in practice because the prevalence of cervical zygapophysial joint pain is high (60%) (see below). Given a concordant response, a practitioner can be 88% confident that the positive response is true-positive (Table 97.2). In comparison, although a discordant response has a lower specificity, its sensitivity is high, which means that the practitioner can be 81% confident that a positive response is true-positive (see Table 97.2).[41]

Multiple and independent studies have shown that cervical zygapophysial joint pain is a common basis for chronic neck pain. In patients with chronic neck pain after whiplash, the prevalence estimates have been 54% (40% to 68%)[42] and 60% (46% to 73%).[43] In drivers who sustain a whiplash injury at high impact speeds, the prevalence has been found to be 74% (65% to 83%).[44] In patients with headache after whiplash, the prevalence of C2-C3 zygapophysial joint pain was 53% (37% to 68%).[45] In patients with neck pain, not restricted to those with whiplash, the prevalence of cervical zygapophysial joint pain has been at least 36% (27% to 45%) in a rehabilitation practice[46] and 60% (50% to 70%) in a pain clinic.[47] These data render cervical zygapophysial joint pain as the single-most common cause of chronic neck pain.

Cervical medial branch blocks have established utility. They are the only means by which to diagnose the most common cause of chronic neck pain. Moreover, patients correctly diagnosed can be treated successfully with percutaneous radiofrequency neurotomy (see Chapter 103).[48–51] Those patients who obtain complete relief from cervical medial branch blocks can expect a 70% chance of achieving complete relief of pain after cervical medial branch neurotomy.[48–51]

Third Occipital Nerve Blocks

The C2-C3 zygapophysial joint is innervated by the third occipital nerve, which is the superficial medial branch of the C3 dorsal ramus. Third occipital nerve blocks, therefore, are a particular subset of cervical medial branch blocks. They are used in patients with upper cervical pain and headache, to test if that pain stems from the C2-C3 zygapophysial joint.

The third occipital nerve runs transversely across the lateral aspect of the C2-C3 zygapophysial joint (Fig. 97.12A) and may lie at a level anywhere between opposite the apex of the C3 superior articular process to opposite the bottom of the C2-C3 intervertebral foramen. Consequently, in order to cover all possible loca-

TABLE 97.2

CONTINGENCY TABLES SHOWING THE EFFECT ON DIAGNOSTIC CONFIDENCE OF DIFFERENT SPECIFICITIES AND SENSITIVITIES OF A DIAGNOSTIC TEST IN DETECTING A CONDITION WITH A PREVALENCE OF 60%

Specificity	Sensitivity	Prevalence	Blocks	Condition		Diagnostic Confidence
				Present	Absent	
0.88	0.54	60%	Positive	324	48	88%
			Negative	276	352	
				600	400	
0.65	1.00	60%	Positive	600	140	81%
			Negative		260	
				600	400	

Diagnostic confidence is the measure of how confident the practitioner can be that the condition really is present when a test is positive. It amounts to the positive predictive value that applies for a particular prevalence, and is derived from the specificity and sensitivity of the test by the equations[41]:

$$[\text{posttest odds}] = [\text{pretest odds}] \times [\text{positive likelihood ratio}]$$
$$[\text{positive likelihood ratio}] = [\text{sensitivity}] / [1 - \text{specificity}]$$
$$[\text{pretest odds}] = [\text{prevalence}] / [1 - \text{prevalence}]$$
$$[\text{diagnostic confidence}] = [(\text{posttest odds}) / (\text{posttest odds} + 1)] \times 100\%$$

tions of this nerve, blocks are recommended at each of three locations: over the middle of the C2-C3 zygapophysial joint, below this point, and above it (Fig. 97.12B).[38,45]

Third occipital nerve blocks are performed using a lateral view of the C2-C3 joint. The needle is placed at each of the three target points required for this nerve (Fig. 97.13). They are rendered valid by performing comparative blocks. A positive response is complete relief of pain on each occasion that the nerve is blocked.

The utility of third occipital blocks lies in the investigation of cervicogenic headache. In patients with posttraumatic neck pain, in whom headache is the dominant complaint, the prevalence of pain from the C2-C3 zygapophysial joint is 56%.[38] No other blocks and no other diagnostic tests have established any other source of cervicogenic headache with a prevalence that rivals this figure.[52,53] A positive response to controlled, third occipital nerve blocks is prognostic of an 88% success rate for completely relieving headache by third occipital radiofrequency neurotomy.[54]

A study using healthy volunteers has shown that the third occipital nerve can visualized by ultrasound and reliably blocked under ultrasound guidance.[55] This technology may become an alternative to fluoroscopic guidance in the future.

Lumbar Medial Branch Blocks

The medial branches of the lumbar dorsal rami supply the zygapophysial joints of the lumbar spine and its medial posterior muscles (multifidus, interspinales). At typical lumbar levels, each medial branch runs across the neck of the superior articular process of the vertebra below (Fig. 97.14). At the L5 level, it is the dorsal ramus itself that crosses the neck of the S1 superior articular process, before giving rise to its medial branch opposite the caudal edge of this process.

If defined strictly, lumbar medial branch blocks are a test for pain mediated by the particular nerves anesthetized. They would relieve pain from any of the structures innervated by these nerves. However, there is no known pathology that affects the muscles supplied by the lumbar medial branches, which can be a cause of chronic pain. Therefore, in practice, medial branch blocks are a test for pain from the zygapophysial joints, which can be a source of pain in the same way that synovial joints of the appendicular skeleton are believed to be sources of pain.

No studies have identified the pathology responsible for zygapophysial joint pain. It may be a form of osteoarthritis or a form of occult injury, but this pathology has not been demonstrated on any form of medical imaging. Age changes, as seen on plain radiographs, do not correlate with pain,[56,57] and changes as seen on CT do not correlate with the joint being painful.[58] There are preliminary findings that a form of synovitis, demonstrable by MRI, might be the underlying pathology, but this pathology has still to be correlated with relief of pain following blocks.[59]

Lumbar medial branch blocks are the only means available by which either to implicate or to refute the lumbar zygapophysial joints as the source of back pain. A joint is implicated if controlled diagnostic blocks completely relieve the patient's pain.

In order to anesthetize a particular joint, each of the two nerves that innervate the joint must be blocked. In this regard, the numbering of the nerves is one segment less than that of the joint that they supply. Thus, the L4,L5 medial branches supply

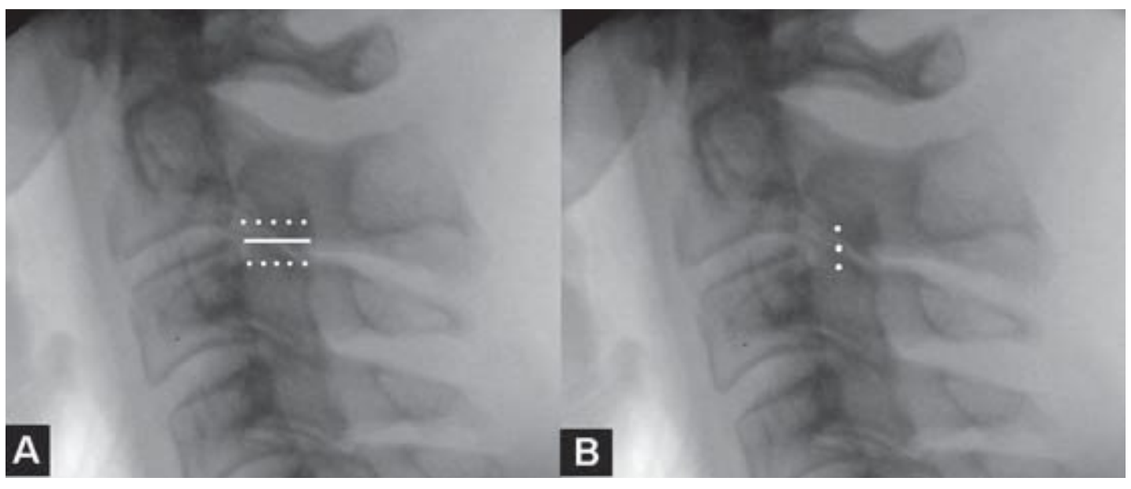

FIGURE 97.12 A lateral radiograph of the C2-C3 level of the cervical spine showing the location of the third occipital nerve and target points for blocks of this nerve. **A.** The bold line indicates the mean course of the nerve, and the dotted lines mark its upper and lower limits. **B.** The dots mark the three locations at which blocks should be undertaken in order to cover all variants of the location of the third occipital nerve.

FIGURE 97.13 A lateral fluoroscopy view of the C2-C3 level showing a needle in place for the middle of three positions for blocks of the third occipital nerve.

the L5-S1 joint, and the L2,L3 nerves supply the L3-L4 joint. Since this dissonance may lead to confusion in records or communication, a recommended annotation is that sequential nerves be recorded using a comma, because they are coupled but nevertheless separate entities, whereas joints should be recorded using a hyphen, because the two segments are connected.[60]

Lumbar medial blocks require placing a needle under fluoroscopic guidance on to the nerve to be blocked. Explicit guidelines for the performance and evaluation of these blocks have been published by the International Spine Intervention Society.[60] The target point for lumbar medial branch blocks lies at the junction of the ventral and middle third of the neck of the superior articular process at each segmental level. The recommended approach to this target is along an oblique view of the target area (Fig. 97.15A). A declined view (i.e., viewing the segment from behind and below) confirms that the needle lies on the neck of the superior articular process (Fig. 97.15B). Once the needle has been placed, a test dose of contrast medium should be injected in order to exclude venous uptake, which occurs in about 3.7% of injections (95% confidence intervals: 3.3% to 4.1%).[39] The nerve can be anesthetized with as little as 0.3 mL of local anaesthetic. More than 0.5 mL is essentially wasted, because the excess injectate spreads away from the target point, between the back muscles.

The validity of lumbar medial branch blocks has been studied more than any other block in pain medicine. The blocks are target-specific. Provided that the correct target points are used and provided that small volumes are used, the injectate remains exclusively on the target nerve.[61] Placements more proximal along the nerve risk having the injectate spread into the intervertebral foramen.[61] Construct validity has been demonstrated. Medial branch blocks protect normal volunteers from experimentally-induced zygapophysial joint pain.[62] However, in order to be valid in patients, the blocks must also be controlled.

Single blocks of the lumbar medial branches are not valid because they have false-positive rates of between 25% and 41%.[63–65] This means that if the prevalence of lumbar zygapophysial joint pain is 15% (see below), for every three blocks that appear to be positive, two will be false-positive. If the prevalence is 5%, five out of every six blocks will be false-positive. Such yields of false-positive results are unacceptable and indicate that a valid diagnosis cannot be made using a single diagnostic block. In order to reduce false-positive diagnoses, controlled blocks must be used in each and every case.

Comparative local anesthetic blocks have been advocated and used as controls for lumbar medial branch blocks on the grounds that they have been validated for the cervical spine. In the cervical spine, comparative blocks have a specificity of either 65% or 88%, depending on the stringency of the criteria for a positive response.[36] These values are acceptable for cervical medial branch blocks because cervical zygapophysial joint pain is so common. However, in the lumbar spine, where zygapophysial joint pain is far less common, comparative blocks result in inordinate numbers of false-positive results.

For a specificity of 65%, and a prevalence of 40%, the diagnostic confidence of positive comparative blocks is only 66% (Table 97.3). For a prevalence of 15%, this confidence drops to 32% and is even less for lower prevalence rates. For a specificity of 88% and a prevalence of 15%, the diagnostic confidence is only 60%, but rises to 85% if the prevalence is 40% (see Table 97.3). These calculations show that for comparative blocks to be valid in the lumbar spine, the prevalence of zygapophysial joint pain must be substantial, and the strictest criteria for a positive response must be applied (i.e., the patient must have complete relief of pain on each occasion that the nerves are blocked and must have longer-lasting relief when the long-acting agent is used). Unless these conditions apply, the false-positive rates render diagnostic confidence unacceptably low. For certainty about the response when the prevalence is low, placebo-controls are unavoidable.

The available data on the prevalence of lumbar zygapophysial joint pain is mixed and contentious and differs according to the sample studied and the criteria used to define a positive response. Using the criterion of 50% relief of pain, the prevalence has been reported as 15% (10% to 20%) among younger, injured workers.[66] Using a criterion of 75% relief of pain, the prevalence was 45% (39% to 54%) in patients attending a pain clinic,[65] and for a criterion of 90% relief, the prevalence was 40% (27% to 53%) in elderly patients with no history of trauma.[67]

The criterion of 50% relief was adopted early in the study of lumbar zygapophysial joint pain when it was believed that pain

TABLE 97.3

CONTINGENCY TABLES SHOWING THE EFFECT ON DIAGNOSTIC CONFIDENCE OF DIFFERENT SPECIFICITIES OF A DIAGNOSTIC TEST AND DECREASING PREVALENCE RATES

Specificity	Prevalence	Blocks	Condition		Diagnostic confidence
			Present	Absent	
0.88	40%	Positive	400	72	85%
		Negative		528	
			400	600	
	15%	Positive	150	102	60%
		Negative		748	
			150	850	
	5%	Positive	50	114	30%
		Negative		846	
			50	950	
0.65	40%	Positive	400	210	66%
		Negative		528	
			400	600	
	15%	Positive	150	328	32%
		Negative		748	
			150	850	
	5%	Positive	50	333	13%
		Negative		846	
			50	950	

The calculations assume a sensitivity of 100%. Diagnostic confidence is the measure of how confident the practitioner can be that the condition really is present when a test is positive. It amounts to the positive predictive value that applies for a particular prevalence and is derived from the specificity and sensitivity of the test by the equations[41]:

$$[\text{posttest odds}] = [\text{pretest odds}] \times [\text{positive likelihood ratio}]$$
$$[\text{positive likelihood ratio}] = [\text{sensitivity}] / [1 - \text{specificity}]$$
$$[\text{pretest odds}] = [\text{prevalence}] / [1 - \text{prevalence}]$$
$$[\text{diagnostic confidence}] = [(\text{posttest odds}) / (\text{posttest odds} + 1)] \times 100\%$$

from these joints could occur in patients with other sources of pain. The 50% criteria allowed for pain to persist from these other sources. However, studies subsequently showed that rarely does lumbar zygapophysial joint pain occur together with lumbar discogenic pain[68] or sacroiliac joint pain.[69] Consequently, if the zygapophysial joints are the only source of pain, patients should be completely relieved of their pain when the responsible joints are blocked. There is no provision for partial relief. However, when investigators have used a criterion of complete relief of pain, the prevalence of lumbar zygapophysial joint pain has been only 5%,[70,71] 6%,[72] or 7%.[73] But each of these studies used only single, diagnostic blocks. Therefore, the prevalence subject to controlled blocks would be expected to be even less.

These data leave the prevalence of lumbar zygapophysial joint pain in doubt. It appears to be low in injured patients, but may approach 40% in elderly patients. These data affect the utility of lumbar medial branch blocks.

Because of the low prevalence of lumbar zygapophysial joint pain, the pretest likelihood is that the patient will have a negative response to lumbar medial branch blocks. Consequently, it would be inappropriate to test each joint one at a time.[74] Doing so wastes resources. The efficient use of lumbar medial branch blocks would be initially to perform a screening block, in which the L3, L4, and L5 medial branches are blocked simultaneously. If these blocks prove negative, zygapophysial joint pain is effectively refuted. Joints are most often symptomatic at L4-L5 and L5-S1,[67] and an investigator would need good cause to test joints at higher segmental levels. If the screening blocks are positive, controlled blocks can be pursued to determine if the response is valid and to establish which particular joint is the source of pain.

Establishing a diagnosis of lumbar zygapophysial joint pain allows treatment to be offered in the form of lumbar radiofrequency medial branch neurotomy.[75] If they are selected on the basis of positive responses to controlled blocks, 60% of patients so treated can expect to obtain at least 80% relief of pain lasting 12 months, and 80% can expect at least 60% relief.[76] If pain recurs, neurotomy can be repeated in order to reinstate relief.[77]

Intra-Articular Blocks

Intra-articular injections are performed on joints of the appendicular skeleton for a variety of reasons. These include therapeutic injections and diagnostic arthrography. However, diagnostic blocks, using local anesthetic agents, are not common practice. The diagnosis of peripheral joint pain is established largely on the basis of physical examination and medical imaging, and there is no requirement for diagnostic blocks in routine practice. Some practitioners might use joint blocks in patients in whom the source of pain is ambiguous, such as hip joint blocks to distinguish hip joint pain from referred pain to the groin or buttock, but such practices are not widely used, and their validity and utility have still to be established.

Diagnostic joint blocks have a greater application in the diagnosis of spinal pain because the joints of the spine are less accessible to physical examination, and medical imaging is typically unhelpful in pinpointing a particular joint as the source of pain.

In the past, intra-articular blocks of the zygapophysial joints were used as a means of diagnosing zygapophysial joint pain. The practice still continues in some circles. However, intra-articular blocks of the spine have never been validated and have not been shown to have therapeutic utility. They have been supplanted by medial branch blocks, which have been validated and which do have therapeutic utility.

It is unclear whether joint pain is the result of intra- or periarticular pathology or both. If periarticular lesions are involved, intra-articular blocks would not be sensitive for the diagnosis of joint pain. Periarticular infiltrations are performed in clinical practice, but their validity and therapeutic utility is unknown.

There are two spinal joints for which nerve blocks are not practical and for which intra-articular blocks remain the only means of determine if that joint is the source of pain. They are the lateral atlantoaxial joint and the sacroiliac joint.

Lateral Atlantoaxial Joint Blocks

Experimental studies in normal volunteers have shown that the lateral atlantoaxial joint (C1-C2) can produce pain in the upper cervical spine and in the head.[78] In principle, therefore, this can be a source of cervicogenic headache and neck pain.

Lateral atlantoaxial joint blocks involve delivering a needle into the cavity of the joint. The recommended technique[79] involves a posterior approach, using fluoroscopic guidance. The technique for lateral atlantoaxial joint blocks does not allow for any but minimal deviations of the needle from a straight course from skin to the target point. Therefore, these blocks should be performed only by operators who can use bevel control to restrict movements to less than a few millimeters from a straight course. The needle is inserted first to reach the lateral mass of the atlas and is then adjusted to enter the joint (Fig. 97.16A). Contrast medium is injected in order to establish that the injectate enters the joint cavity and does not escape from it (Fig. 97.16B). This establishes the face validity of the injection. Once correct placement has been confirmed, about 1 mL of local anesthetic can be injected. A positive response is one in which the injection completely relieves the patient's pain. The proximity of the target area to the dural sac, spinal cord, internal carotid artery, and vertebral artery poses significant risks during lateral atlantoaxial joint injection. Misplaced injections of local anesthetic could result in a high spinal block. Intra-arterial injection of depot corticosteroids could result in embolism and stroke.

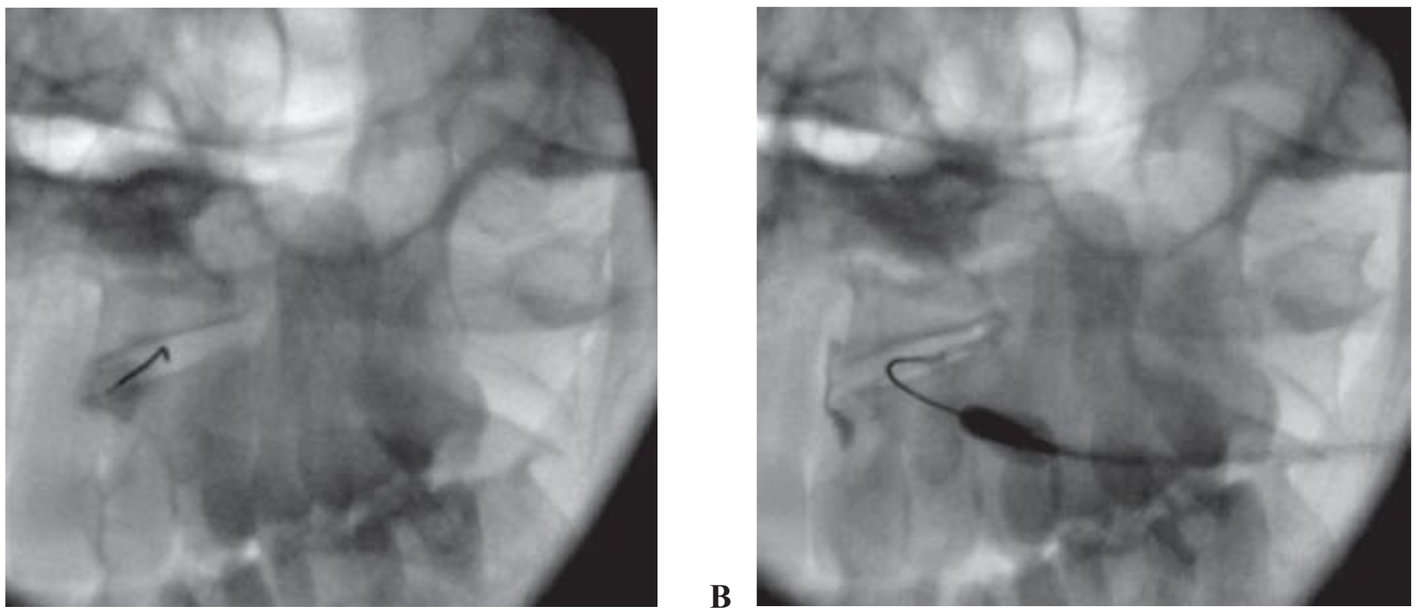

FIGURE 97.16 Anteroposterior fluoroscopy views of a lateral atlantoaxial joint injection. **A.** The needle has been advanced into the cavity of the joint. **B.** Contrast medium outlines the joint cavity and the internal surface of the lateral capsule.

The validity of lateral atlantoaxial joints has not been tested. Single diagnostic blocks may have a false-positive rate which has not yet been measured. In principle, controlled blocks are required in order to maximize validity. Controls using comparative local anesthetic blocks might be used, but the validity of comparative blocks inside joints, where blood flow is low, has not been established. Anatomic controls might be an alternative, in which the control is to block an adjacent joint (e.g., C2-C3), but the results of such controls have not yet been reported.

There are few prevalence studies of lateral atlantoaxial joint pain, but the available data indicate a nonzero prevalence. One study, using single diagnostic blocks, found that at least 16% of patients presenting with headache responded to lateral atlantoaxial joint blocks.[80] Another study found a prevalence of at least 13%.[81] Each of these may be underestimates because not all eligible patients underwent diagnostic blocks. Conversely, the figures might lower because controlled blocks were not used.

Lateral atlantoaxial joint blocks have therapeutic utility because patients can be treated by atlantoaxial arthrodesis. Follow-up studies have reported that arthrodesis succeeds in providing sustained relief of pain.[82–84] Intra-articular injections of corticosteroids are a more conservative alternative, but benefit only about 1 in 8 patients over the long-term.[81]

Sacroiliac Joint Blocks

Sacroiliac joint blocks are a test for back pain stemming from a sacroiliac joint. They involve introducing a needle under fluoroscopic control into the lower end of the cavity of the joint (Fig. 97.17).[85] A test dose of contrast medium establishes that the injectate lies within the joint cavity and does not escape from it. Subsequently, an aliquot of about 1.5 mL of local anesthetic can be injected in order to anesthetize the joint. A positive response is complete relief of the patient's pain.

Two types of controls have been used in order to maximize the validity of sacroiliac joint blocks. One study used anatomic controls by previously anesthetizing lumbar zygapophysial joints.[86] Another study used comparative local anesthetic blocks.[87] Respectively, these studies found a prevalence (95% confidence intervals) of 13% (6% to 20%) and 19% (9% to 29%). These figures indicate that the sacroiliac joint is the source of pain in a substantial proportion of patients with chronic low back pain. Sacroiliac joint blocks are the only means of identifying this subgroup of patients.

The therapeutic utility of sacroiliac joint blocks is still evolving. Various studies have explored the efficacy of percutaneous radiofrequency denervation of the joint in patients who are positive to blocks. The magnitude and duration of relief from these procedures has still to be established (see Chapter 103).

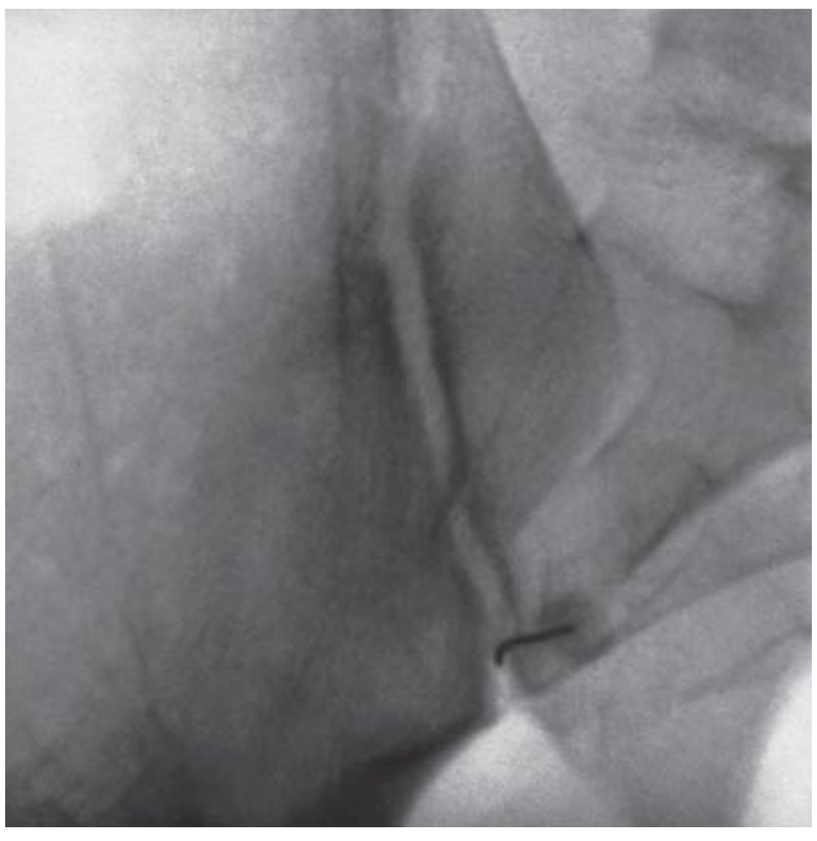

FIGURE 97.17 An anteroposterio fluoroscopy view of a needle placed for an intra-articular block of sacroiliac joint. San Francisco: International Spine Intervention Society; 2004.)

Occipital Nerve Blocks

Blocks of the greater occipital nerve have been promoted in the past as a diagnostic test for headache, but they have a curious and checkered history.[53,88] Despite their popularity, there are no data on their validity or utility.

Greater occipital nerve blocks were introduced originally for the diagnosis of a particular form of occipital neuralgia. The cause of pain was described as compression of the greater occipital nerve between the posterior arch of the atlas and the lamina of C2.[89] The diagnostic test was to anesthetize the greater occipital nerve where it emerged from the posterior neck muscles onto the scalp.

Eventually, it was shown that the greater occipital nerve could not be injured in this way.[90,91] In addition, a rarely cited publication was uncovered in which one of the original authors voiced circumspection about the validity and effectiveness of greater occipital nerve blocks.[92] However, this did not stem the enthusiasm for greater occipital nerve blocks.

A belief in entrapment neuropathy developed, according to which the greater occipital nerve could be bound in scar tissue where it emerged from the posterior neck muscles. No histologic evidence of such scar has ever been produced nor has a reason for its development been articulated, let alone demonstrated. The greater occipital nerve emerges from beneath an aponeurotic sling, between the trapezius and sternocleidomastoid.[90] This fibrous sling could easily be mistaken for so-called scar tissue.

The lack of rationale for greater occipital nerve blocks as a diagnostic test is curious. Beyond the point where it is typically blocked, this nerve supplies only the skin of the posterior scalp. There is no known disease that affects this skin in order to be a cause of chronic pain. Therefore, greater occipital nerve blocks cannot be used to determine a source of pain. The same applies to lesser occipital nerve blocks. At best, therefore, greater occipital nerve blocks can only be used to establish that afferent activity in this nerve, in some way, modulates the perception of pain. The term "mediates" cannot apply for there is no source from which nociceptive afferent traffic along the nerve might arise.

Although several studies have described the use of greater occipital nerve blocks in the diagnosis of headache, none has used controlled blocks to test for placebo responses and none has articulated what diagnosis is established if the blocks are positive. Nor can greater occipital nerve blocks be held to be selective or target specific when volumes such as 5 mL[93] or 10 mL[94,95] of local anesthetic are used.[96] Under these conditions, it is hard to determine if greater occipital nerve blocks are more than a historical curiosity based on the mistaken belief that any pain in a given area must be mediated by the most obvious nerve in that area.

There is, however, a curious mystery about greater occipital nerve blocks. It has been shown that their effect on primary headache syndromes clearly outlasts the duration of local anesthetic used.[96,97] This phenomenon implies some sort of neuromodulatory effect. It would seem that this effect has been misinterpreted in the past as a diagnostic response. The mechanism of the effect and its clinical significance have not been determined.

The use of greater occipital nerve blocks as a predicate for avulsion of the greater occipital nerve has been particularly tragic. Despite seemingly widespread use in the past, this radical surgical procedure has never been shown to be effective for occipital head-

ache. Such data as are available indicate that any beneficial effects are temporary at best,[98] yet the treatment cannot be repeated.

PROTECTIVE PROCEDURES

Protective local anesthetic blocks are ones in which a region of the body is anesthetized in order to reduce or eliminate incident pain or to facilitate function or other treatment. Examples include femoral nerve blocks during the application of traction for a fractured femur, brachial plexus blocks to allow application of physical therapy in patients with complex regional pain syndromes of the upper limb, and intercostal blocks to permit deeper breathing in patients with painful fractures of the ribs or chest pain after thoracotomy. In these examples, it is recognized that the period of relief required is temporary and that other interventions will eventually treat the pain or spontaneous healing is anticipated. If required, the blocks can be repeated to prolong the duration of effect, but the blocks are not repeated ad infinitum.

Axillary Brachial Plexus Block

Axillary blocks of the brachial plexus involve introducing a needle through the floor of the axilla, aimed toward its apex, until it is felt to penetrate the axillary sheath. The block is increasingly performed under ultrasound guidance, which has been shown to be at least equivalent or even superior to the technique involving nerve stimulation.[99,100] Some 30 to 40 mL of local anesthetic are then injected to anesthetize the major branches of the brachial plexus that innervate the upper limb. If desired, a catheter can be introduced in the same manner in order to allow for a continuous infusion of local anesthetic.

Case reports have attested to the usefulness of continuous infusions of local anesthetic as an adjunct in the management of complex regional pain syndromes of the upper limb.[101–103] Anesthetizing the limb allows physical therapy to be applied without pain. For the manipulation of forearm fractures in children, axillary blocks are as effective as deep sedation with ketamine and midazolam.[104]

Femoral Nerve Block

The target point for femoral nerve blocks lies below the inguinal ligament, lateral to the femoral artery. While palpating the pulse of the femoral artery, a needle is introduced through the skin, about 1 cm lateral to the artery. Proper placement is established either by using a nerve stimulator or ultrasound guidance. Typically between 8 mL and 10 mL of local anesthetic is administered.

Although femoral nerve blocks may be used as an intraoperative or postoperative procedure for analgesia, their particular application as a pain medicine procedure is to relieve the pain of femoral fractures while the patient is transferred or is awaiting other interventions. Controlled trials have shown that adding a femoral nerve to intravenous analgesia block increases the reduction of pain scores by an average of 3.6 points (on a 10-point scale)[105] and that femoral nerve blocks provide superior relief of pain and anxiety than does intravenous metamizol.[106]

Intercostal Nerve Blocks

Intercostal nerve blocks can be performed opposite the angle of the rib or in the midaxillary line. They require palpating the rib above the target nerve and introducing a needle first to touch the lower edge of that rib. Thereafter, the needle is allowed to slip under the rib and a further 3–5 mm deeper. Ultrasound guidance allows the visualization of the pleura and is therefore expected to be safer than the blind technique, although no controlled trials have proven this hypothesis. Typically 3–4 mL of local anesthetic (1 mL under ultrasound guidance) is used to anesthetize the nerve. In patients with rib fractures, intercostal nerve blocks reduce pain and increase oxygen saturation.[107]

PALLIATIVE BLOCKS

There is no basis for local anesthetic blocks to be therapeutic in the conventional sense. Local anesthetics have a limited duration of action, and their effects are expected to wear off. Any relief should be temporary, under normal circumstances.

However, for some conditions for which there is no other proven treatment, some physicians administer local anesthetic blocks despite their temporary effect. Although temporary, that relief may be satisfying to patients. Using blocks in this way cannot be construed as therapeutic for there is little prospect of enduring relief. A better description is that such blocks are palliative.

Nevertheless, there is anecdotal evidence that in some patients, repeating blocks can lead to prolonged periods of relief well beyond the duration of action of the agent used. Neither the proportion of patients who respond in this way or the mechanism of this effect is known. It may be a peculiar effect of local anesthetic on open sodium channels in patients with chronic pain. It may be a placebo effect. It may be due to some settling effect on CNS pathways.

Notwithstanding this lack of information, palliative blocks are an attractive option for some practitioners and for some patients when other options are not available or impractical.

Common to all palliative blocks is a lack of formal evidence of efficacy. Patients should be informed of this lest they be under the illusion that these are in fact legitimate therapeutic procedures. Those who pay for multiple repeat blocks have grounds for concern. In some countries, where insurers are responsible for income replacement, insurers would like to see that palliative blocks improve function and allow return to work.

There is little purpose in performing palliative blocks if the effects last only for the duration of action of the agent used. This achieves nothing but a temporary illusion of therapy.

If relief is prolonged, it needs to shown to be useful. In the first instance, a visual analog scale or numeric pain rating scale (NPRS) should be used to document the magnitude of relief. Also documented should be the restoration of activities, for if function does not improve, the risk–benefit or cost–benefit ratio may be considered as unfavorable.

Palliative blocks are, therefore, a very contentious intervention. Patients enjoy the relief; physicians enjoy providing it. The exercise, however, is questionable if all that is achieved is some degree of temporary relief of pain.

A Cochrane Review searched for evidence that local anesthetic blocks were effective for complex regional pain syndromes.[108] It found only two small studies whose data were statistically equivocal about whether or not blocks achieved greater than 50% relief of pain for at least hours and no valid data on longer term effects.

Sympathetic blocks are practiced, seemingly, widely for the treatment of the pain of acute herpes zoster and for postherpetic neuralgia. Despite an abundance of descriptive studies advocating sympathetic blocks for these conditions, reviews of the literature have found that sympathetic blocks might reduce the duration of acute herpes but do not affect the intensity of pain and do not reduce the incidence of postherpetic neuralgia, nor are they effective for postherpetic neuralgia.[109,110] The evidence is stronger for epidural and intrathecal blocks for these conditions.[110]

There is substantial evidence for the efficacy of neurolytic blocks of the celiac plexus for the treatment of cancer pain and

the pain of pancreatitis (see Chapters 45 and 64). Local anesthetic blocks of this plexus are substantially less effective.[111]

Blocks of the superior hypogastric plexus have been reported to be of value for intractable pain in the penis.[112] Blocks of the ganglion impar have been reported as providing at least 50% relief of pain in patients with chronic perineal pain.[112] Larger series and no controlled trials of these procedures have not been reported, possibly because of the rarity, in any one center, of the conditions for which they are used.

CONCLUSION

Anesthesiologists were prominent amongst those who founded the discipline of pain medicine. From their background and training in surgical anesthesia, they brought with them the art of local anesthetic blocks. In a new discipline, these blocks were a powerful tool: they could stop the symptom of which the patient complained. Over the last 30 years, however, the standards of science in medicine have escalated. The art of local anesthetic blocks has not kept pace with the science required of them.

Most of the publicity concerning evidence-based medicine has centered on the standards set and expected for studies of the efficacy of treatments. For such studies, rules now apply concerning randomization, blinding, controls, follow-up, outcome measures, and intention-to-treat analysis. These same rules do not apply to diagnostic tests, but others do.

The rules for operative anesthesia are straightforward and easy to apply. In operative anesthesia, the objective is to protect the patient from feeling pain once the surgery commences. Adequacy of anesthesia can be tested by a applying a noxious stimulus and asking the patient of any effect. If they are numb, the patient, the anesthetist, and the surgeon are all satisfied. At a philosophical level, it does not matter if the patient had a placebo effect. The block, nevertheless, served its purpose.

A different set of rules applies to pain medicine. The situation differs in that the objective of local anesthetic blocks is to stop ongoing pain, be that for diagnostic, prognostic, palliative, or therapeutic purposes. This is a different idiom from that of securing surgical anesthesia.

Paramount is the validity of the local anesthetic block, and placebo effects are a serious, potential, confounding influence. It does matter if the patient has a placebo response when diagnostic and therapeutic decisions are based on that response. Notwithstanding the mysteries of the placebo response and what it means, most fundamentally a placebo response is a false-positive response. It means that any decision about diagnosis may not be correct, and any decision about treatment is likely to be wrong.

Because false-positive responses can occur, sometimes commonly, practitioners cannot assume that all positive responses to blocks are true-positive. A block cannot be held to be valid unless it is subjected to some sort of control.

It is in this regard that the art of local anesthetic blocks has lagged behind the pace of contemporary science. Eminent authorities in the past have described a vast litany of the types of blocks that could be performed; some even implied that they should be done. At a scientific and clinical level, however, those recommendations pertained only to the execution of blocks. They did not address their validity and interpretation.

The assumption that single diagnostic blocks cannot be false-positive is wrong. Whenever this has been tested, substantial and sometimes prohibitive false-positive rates have been encountered. There is no reason why blocks that have not been tested for validity should be immune to false-positive response.

For prognostic blocks, the assumption has been that uncontrolled blocks will faithfully predict the outcome of treatment. This assumption may be convenient for expeditious practice, but it does not amount to evidence-based practice. Two confounding influences apply. The prediction of the blocks may be incorrect because the response to blocks is not valid, and the treatment may not work because its efficacy has not been established.

It is for these reasons that the present chapter does not resemble its forerunners or corresponding chapters in other books. Local anesthetic blocks have not been described just because they can be done. Instead, the present chapter has focused on why blocks might be done. Some degree of evidence is required to find the answer to that question. As a result, the present chapter does not describe blocks for which there is barely anecdotal evidence. Prominence has been given to those blocks for which there is evidence and in proportion to the volume and quality of evidence available. This results in an irony.

Certain blocks, held in high esteem by anesthesiologists and widely practiced, have been accorded less prominence than in previous texts. Either evidence of their validity and utility is lacking or, in some cases, the emerging evidence has challenged their assumed validity. Sympathetic blocks are the prime example. When subjected to controls, these blocks prove not to be valid, and no studies have refuted this challenge.

Other blocks, such as transforaminal blocks, have some evidence, but it is incomplete. There is room either for these blocks still to be refuted or properly validated.

Meanwhile, it transpires that the most extensive and most rigorous evidence about local anesthetic blocks pertains to those not held to be classical and, therefore, exempt from the requirements for controls. Medial branch blocks have been tested, more so than any other form of local anesthetic blocks. Variously, they have been shown to protect healthy volunteers from experimentally induced pain; they have been shown to have target-specificity; their false-positive rates are known and are large, but can be reduced by using controls; and positive responses are associated with successful outcomes of treatment. For no other local anesthetic block have these requirements been satisfied.

The foundations of pain medicine in general and interventional pain medicine in particular depend on the validity of local anesthetic blocks. The evidence, at present, would indicate that whereas medial branch blocks are sound, all other blocks are questionable. The challenge, if not duty, of experts in this discipline is to make up the difference. It is often said that no evidence of efficacy is not evidence of no efficacy, but a retort applies. Assumption is not a substitute for evidence. Perhaps future editions of this chapter can be enriched by a greater, appropriate body of evidence.

CHAPTER 98 ■ EPIDURAL STEROID INJECTIONS

NIKOLAI BOGDUK

Epidural injection of steroids is one of the oldest procedures practiced in pain medicine. Reportedly, it is the most commonly performed interventional pain procedure in the United States.[1] This history and popularity, however, stand in stark contrast to the evidence of its limited efficacy.

HISTORICAL BACKGROUND

The first recorded use of epidural steroid injections dates back to 1952, when Robecchi and Capra[2] reported the relief of lumbar and sciatic pain in a woman after a periradicular injection of hydrocortisone onto the first sacral roots through the S1 posterior sacral foramen. This route of injection was popularised in the Italian[2–9] and French literature.[10–13] However, it was soon supplanted by other routes of administration. Although developments occurred worldwide, a lumbar route was promoted particularly in the United Kingdom, and a caudal route was promoted in the United States. Implicitly, these routes were based on existing techniques for obtaining epidural anaesthesia and were developed because they were easier to perform than sacral transforami-

nal injections and because of the desire to reach nerve roots other than the first sacral.

From the late 1950s until the close of the twentieth century, a large body of literature appeared worldwide reporting the effectiveness of injections by the lumbar[14–37] and caudal epidural[38–51] routes. This literature became responsible for the reputation of epidural steroids as an effective treatment for lumbar and sacral radicular pain (i.e., sciatica).

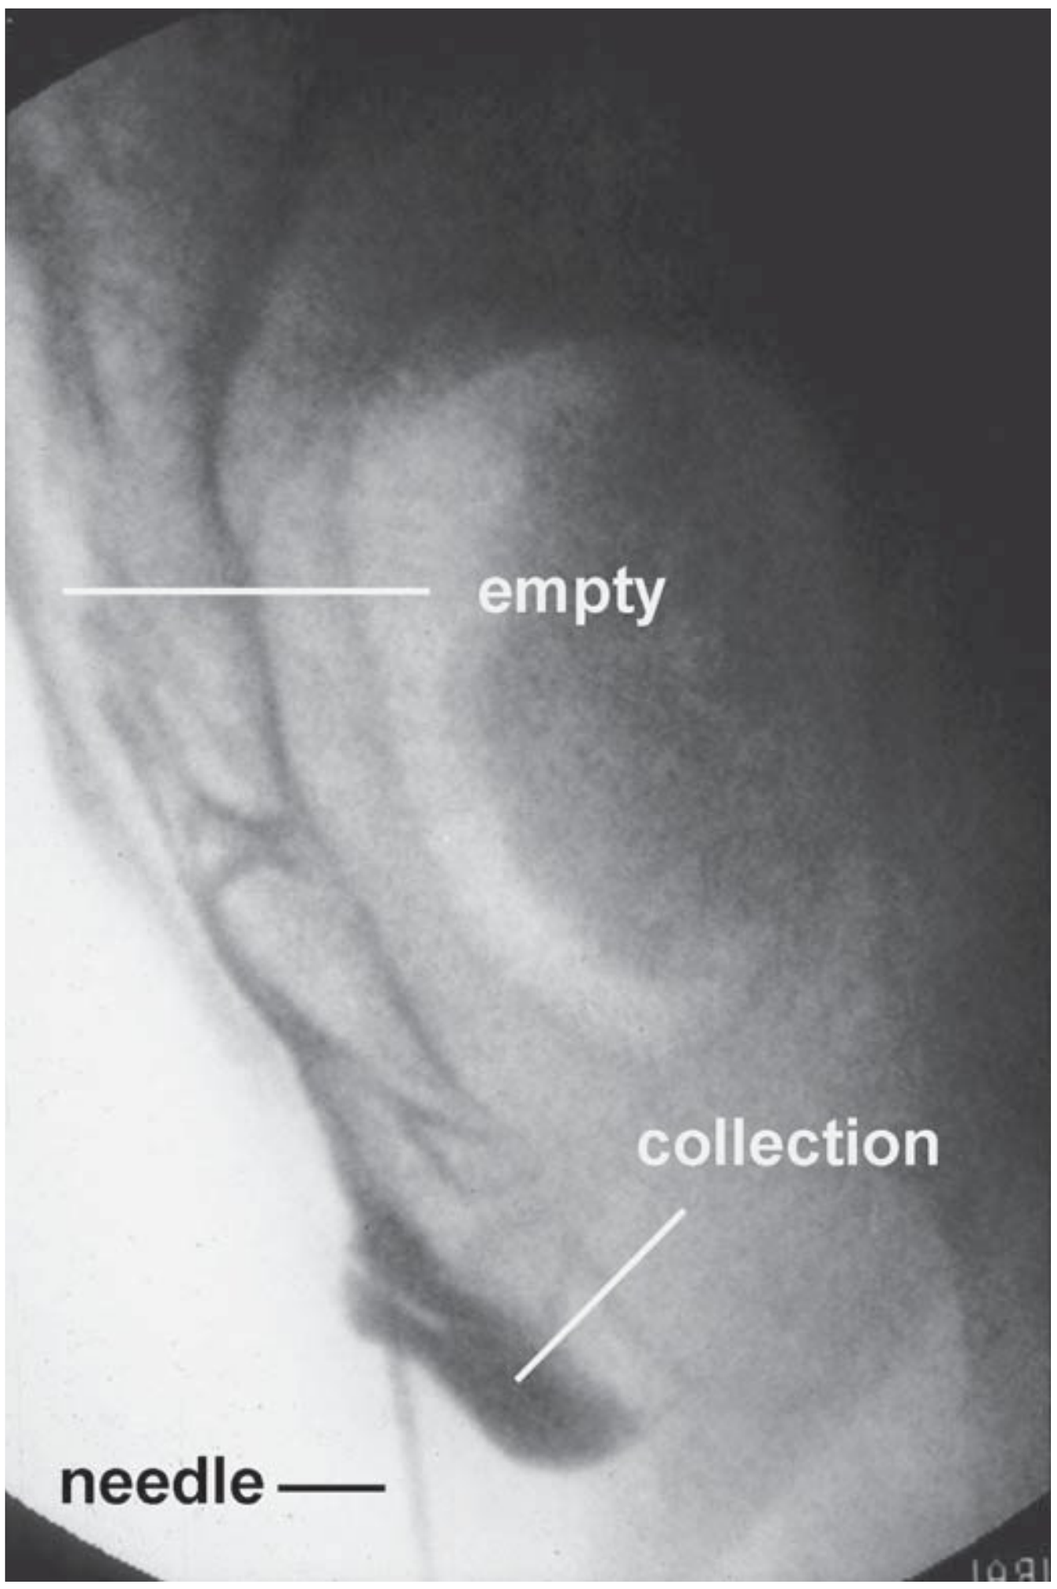
TECHNIQUES

Several techniques are available for the delivery of corticosteroids into the epidural space. They differ with respect to where the needle is placed and whether or not fluoroscopic guidance is used. A survey found that there is no uniformity of practice in the United States.[52] Different routes of administration and image-guidance are used to different extents within and between academic institutions and private practices.

Lumbar Epidural Steroids

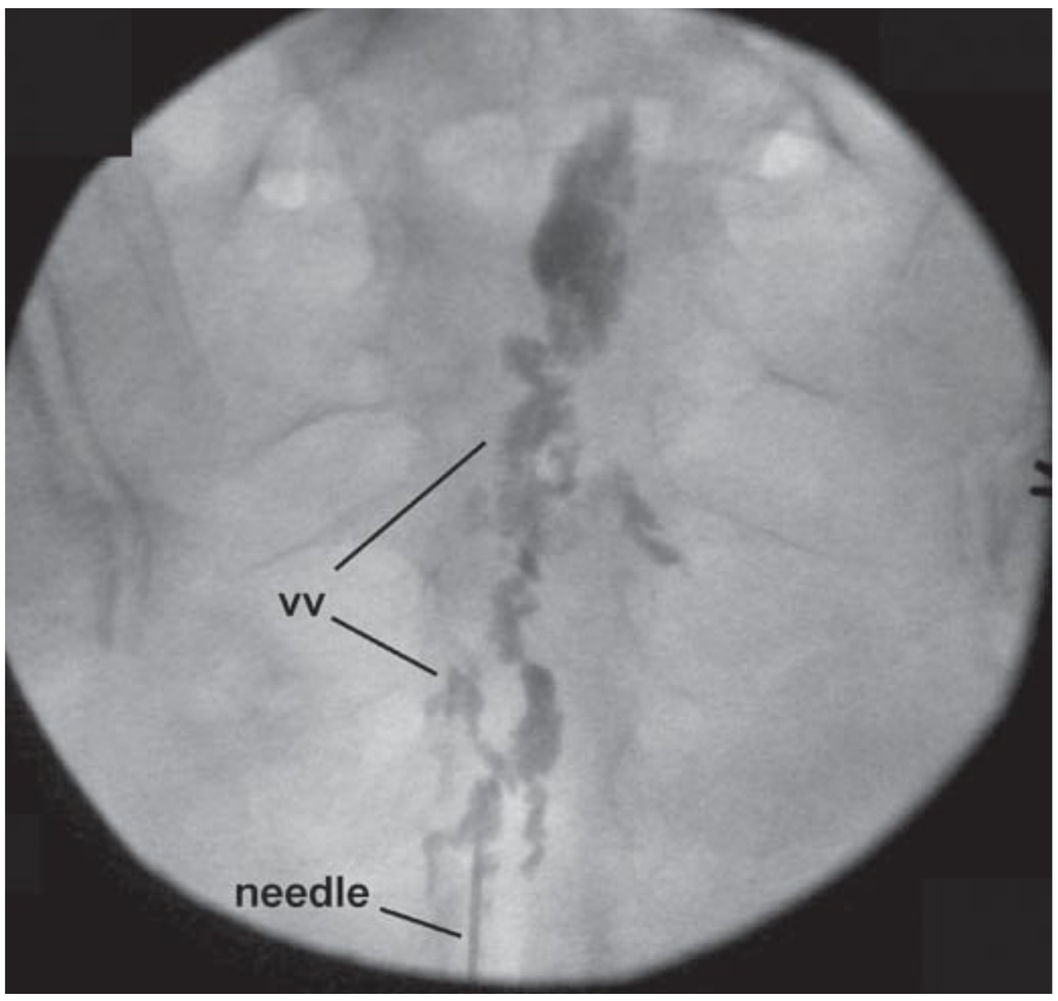
The lumbar route for administering epidural steroids involves passing a needle through an interlaminar space, usually along the midline through the interspinous ligament or slightly to the side of this ligament. The procedure requires that the needle penetrates the ligamentum flavum to enter the epidural space but to fall short of piercing the dural sac. The perceived advantage of the lumbar route is that the needle is directed close to the site of pathology. There is no agreed volume or composition of the therapeutic agent. Authors have recommended various preparations of corticosteroids, either alone or mixed with local anesthetic or normal saline, in total volumes ranging from 2 mL to 43 mL,[53–55] but volumes of 2–5 mL are typical.

Caudal Epidural Steroids



The caudal route of administration involves introducing a needle into the epidural space via the sacral hiatus. The hiatus is located by palpation, and the needle is introduced through the overlying skin until it is felt to penetrate the membrane that encloses the hiatus. The purported attraction of this approach is that it is easily performed and decreases the possible risk of inadvertent dural puncture and, therefore, of inadvertent intrathecal injection.

Caudal injections require a substantial volume of fluid to be injected in order to reach the lumbar nerve roots which lie some 10 cm or more cephalad from the site of injection. Authors have recommended various preparations of corticosteroids, mixed with various local anesthetic agents or normal saline, in volumes ranging from 10 mL to 64 mL.[53–55]



Fluoroscopic Guidance

Epidural injections have traditionally been a clinical procedure. The operator relies on palpation to identify the site of injection. For depth of insertion, they rely on dexterity and various techniques such as loss of resistance[16] or the hanging drop method.[17] Some commentators, however, have argued that such reliance on manual skills leads to errors.

It has been demonstrated that caudal injections can fail to reach the epidural space in up to 35% of cases.[50,56–59] Injections can lie dorsal to the sacrum or coccyx or be intravascular (Fig. 98.1),[60] the latter despite no blood appearing on aspiration before injection. Lumbar injections can be subdural or superficial to the ligamentum flavum in some 17% of cases[50,61]; they can be

The sacral canal contains no contrast medium. **B.** Anteroposterior radiograph of an attempted caudal epidural injection in which the contrast medium has filled veins (vv) in the epidural space. (Kindly provided by Dr. Paul Dreyfuss, Seattle, WA.)

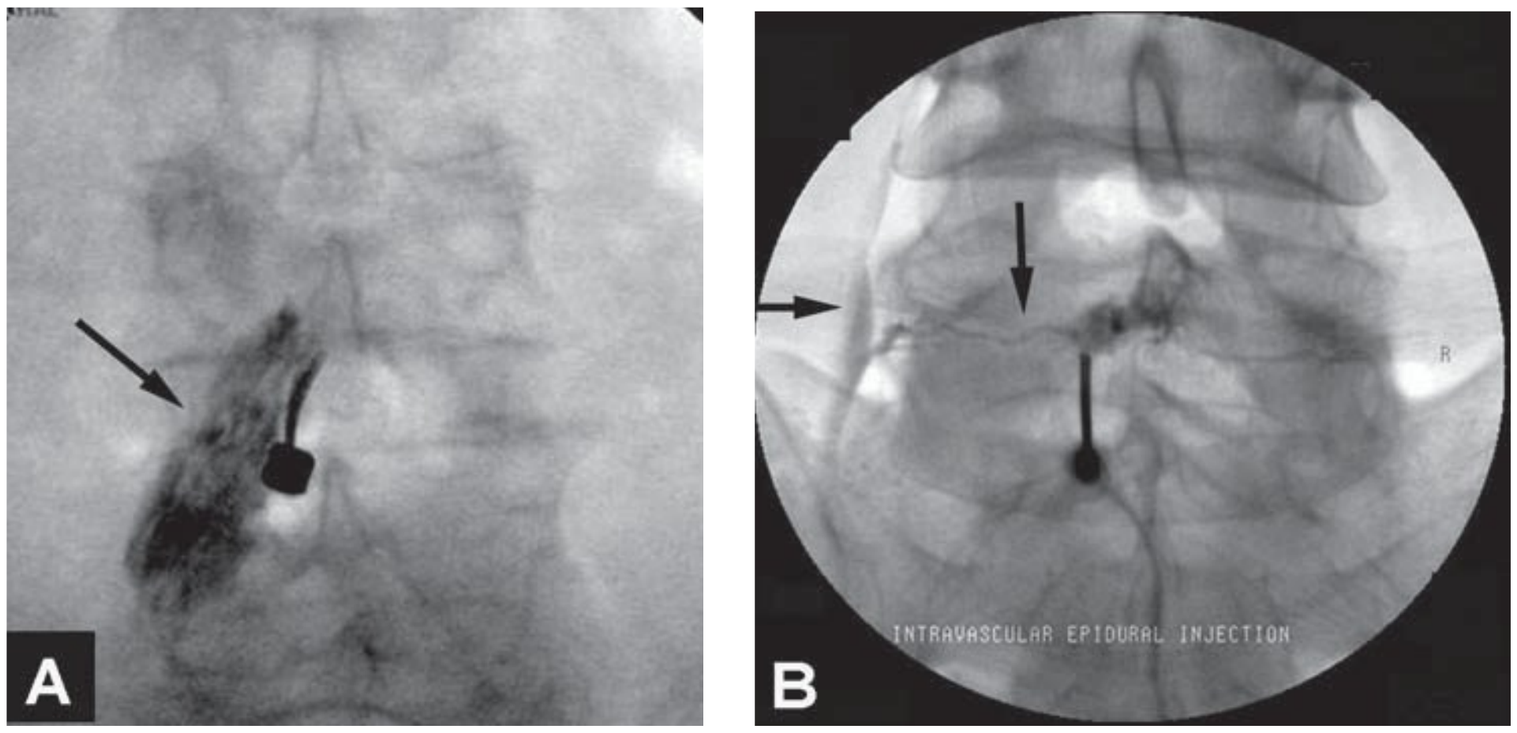

FIGURE 98.2 Aberrant lumbar interlaminar injections. **A.** Anteroposterior radiograph of an attempted interlaminar epidural injection in which the contrast medium outlined a fascicle of the lumbar multifidus muscle. **B.** Anteroposterior radiograph of an attempted interlaminar epidural injection in which the contrast medium has filled veins (*arrows*). (Kindly provided by Dr. Milton Landers, Wichita, KS.)

intravascular (Fig. 98.2). Errors are more common in patients with large body mass index,[58] when landmarks are difficult to palpate,[57] and generally in the execution of caudal injections.[58] Furthermore, even if the needle is accurately placed in the epidural space, the injectate can fail to reach the target level[62,63] or can remain in the posterior epidural space and not reach the disc-nerve root interface.[62]

Because of such errors when epidural injections are performed unaided, commentators have argued that they should be performed using fluoroscopic guidance, particularly for caudal injections.[56–58,60,64,65] Not all operators have heeded this call. Some continue to practice the procedures "blind" in a radiographic sense, but others have adopted fluoroscopic guidance.

Fluoroscopically-guided procedures differ from the classical procedures in that radiographs are used to locate the target site and to guide the needle to it (Figs. 98.3 and 98.4), and a test dose of contrast medium is injected into order to verify that the subsequent injection of therapeutic agent will be epidural and not intrathecal, subdural, or into a blood vessel. In other respects, the agents and volumes used are as for the classical procedures.

TRANSFORAMINAL INJECTIONS

Another procedure is related to epidural injections, but its taxonomic status is contentious. The procedure involves administering steroids under fluoroscopic guidance into the intervertebral foramen that lodges the affected spinal nerve. Literally and accurately, it is a transforaminal injection of steroids. Although the injectate does technically reach the epidural space, it remains around the nerve-root sleeve or on the floor of the vertebral canal. In this respect, transforaminal injections differ from classical epidural injections, in which the injectate spreads diffusely throughout the epidural space. In order to emphasise the difference, some operators use names such as "transforaminal epidural" or "selective epidural," although selectivity has never been formally established.

Transforaminal injections were developed in the belief that interlaminar or caudal injections were essentially too diffuse and that injecting directly onto the affected nerve should be more effective.[54,55] Various techniques have been described.

At lumbar levels, the variants differ only with respect to where the tip of the needle is placed.[66] In the original version,[54] the needle is directed onto the back of the vertebral body immediately opposite the lower pole of the pedicle (Fig. 98.5A,B).[66] Once the needle has been placed, a test dose of contrast medium shows that the injection is neither intrathecal nor intravascular and flows along the target nerve (Fig. 98.5C,D). The second and third variants are designed to cope with distortions of the anatomy of the nerve, such as swelling or upward displacement, or to avoid puncturing vessels on the floor of the vertebral canal.[66] They involve placing the tip of the needle above the nerve (Fig. 98.6A) or behind it (Fig. 98.6B). In all variants, once the injection of contrast medium has demonstrated correct and safe placement of the needle, an aliquot of local anesthetic is injected (typically 1–2 mL), followed by a similar aliquot of corticosteroid preparation.

At sacral levels, the needle is delivered through the posterior sacral foramen so that its tip lies above the S1 spinal nerve and below the S1 pedicle (Fig. 98.7). Once a test dose of contrast medium establishes safe and accurate placement, local anesthetic and steroid are administered as for lumbar injections.

Number of Injections

In the published literature on interlaminar and caudal injections, most authors have used only one[17,18,22–24,27–31,50] or occasionally up to three injections.[16,25,33,36] Some have used up to six injections if they appeared to be of benefit, with the proviso of not using more than three if they did not appear to be of benefit[21]; one author describes using up to 10 injections.[20] For transforaminal injections, the literature describes using up to three injections, with an average of around two required to achieve optimal outcome.[67–69]

RATIONALE

It is conspicuous in the literature that a rationale for the epidural injection of steroids was not articulated in the early studies.[53–55] Implicitly, steroids were expected to be effective because they were believed to be effective for the treatment of other pain problems such as arthritis and tenosynovitis. Only later did authors seek a rationale. The belief that emerged was that since corticosteroids were anti-inflammatory, radicular pain must be caused by inflammation of the nerve roots. Circumstantial evidence was brought to bear in support of this belief.[53–55] More recently, animal studies have reinforced the belief by demonstrating inflammatory mediators in herniated disc material, such as phospholipase A2,[70] interleukins,[71,72] tumor necrosis factor α,[73,74] and nitric oxide.[71,75] In patients, however, evidence of inflammation has not yet been produced. Nor is demonstration of inflammation a perquisite for the use of epidural injections of steroids.

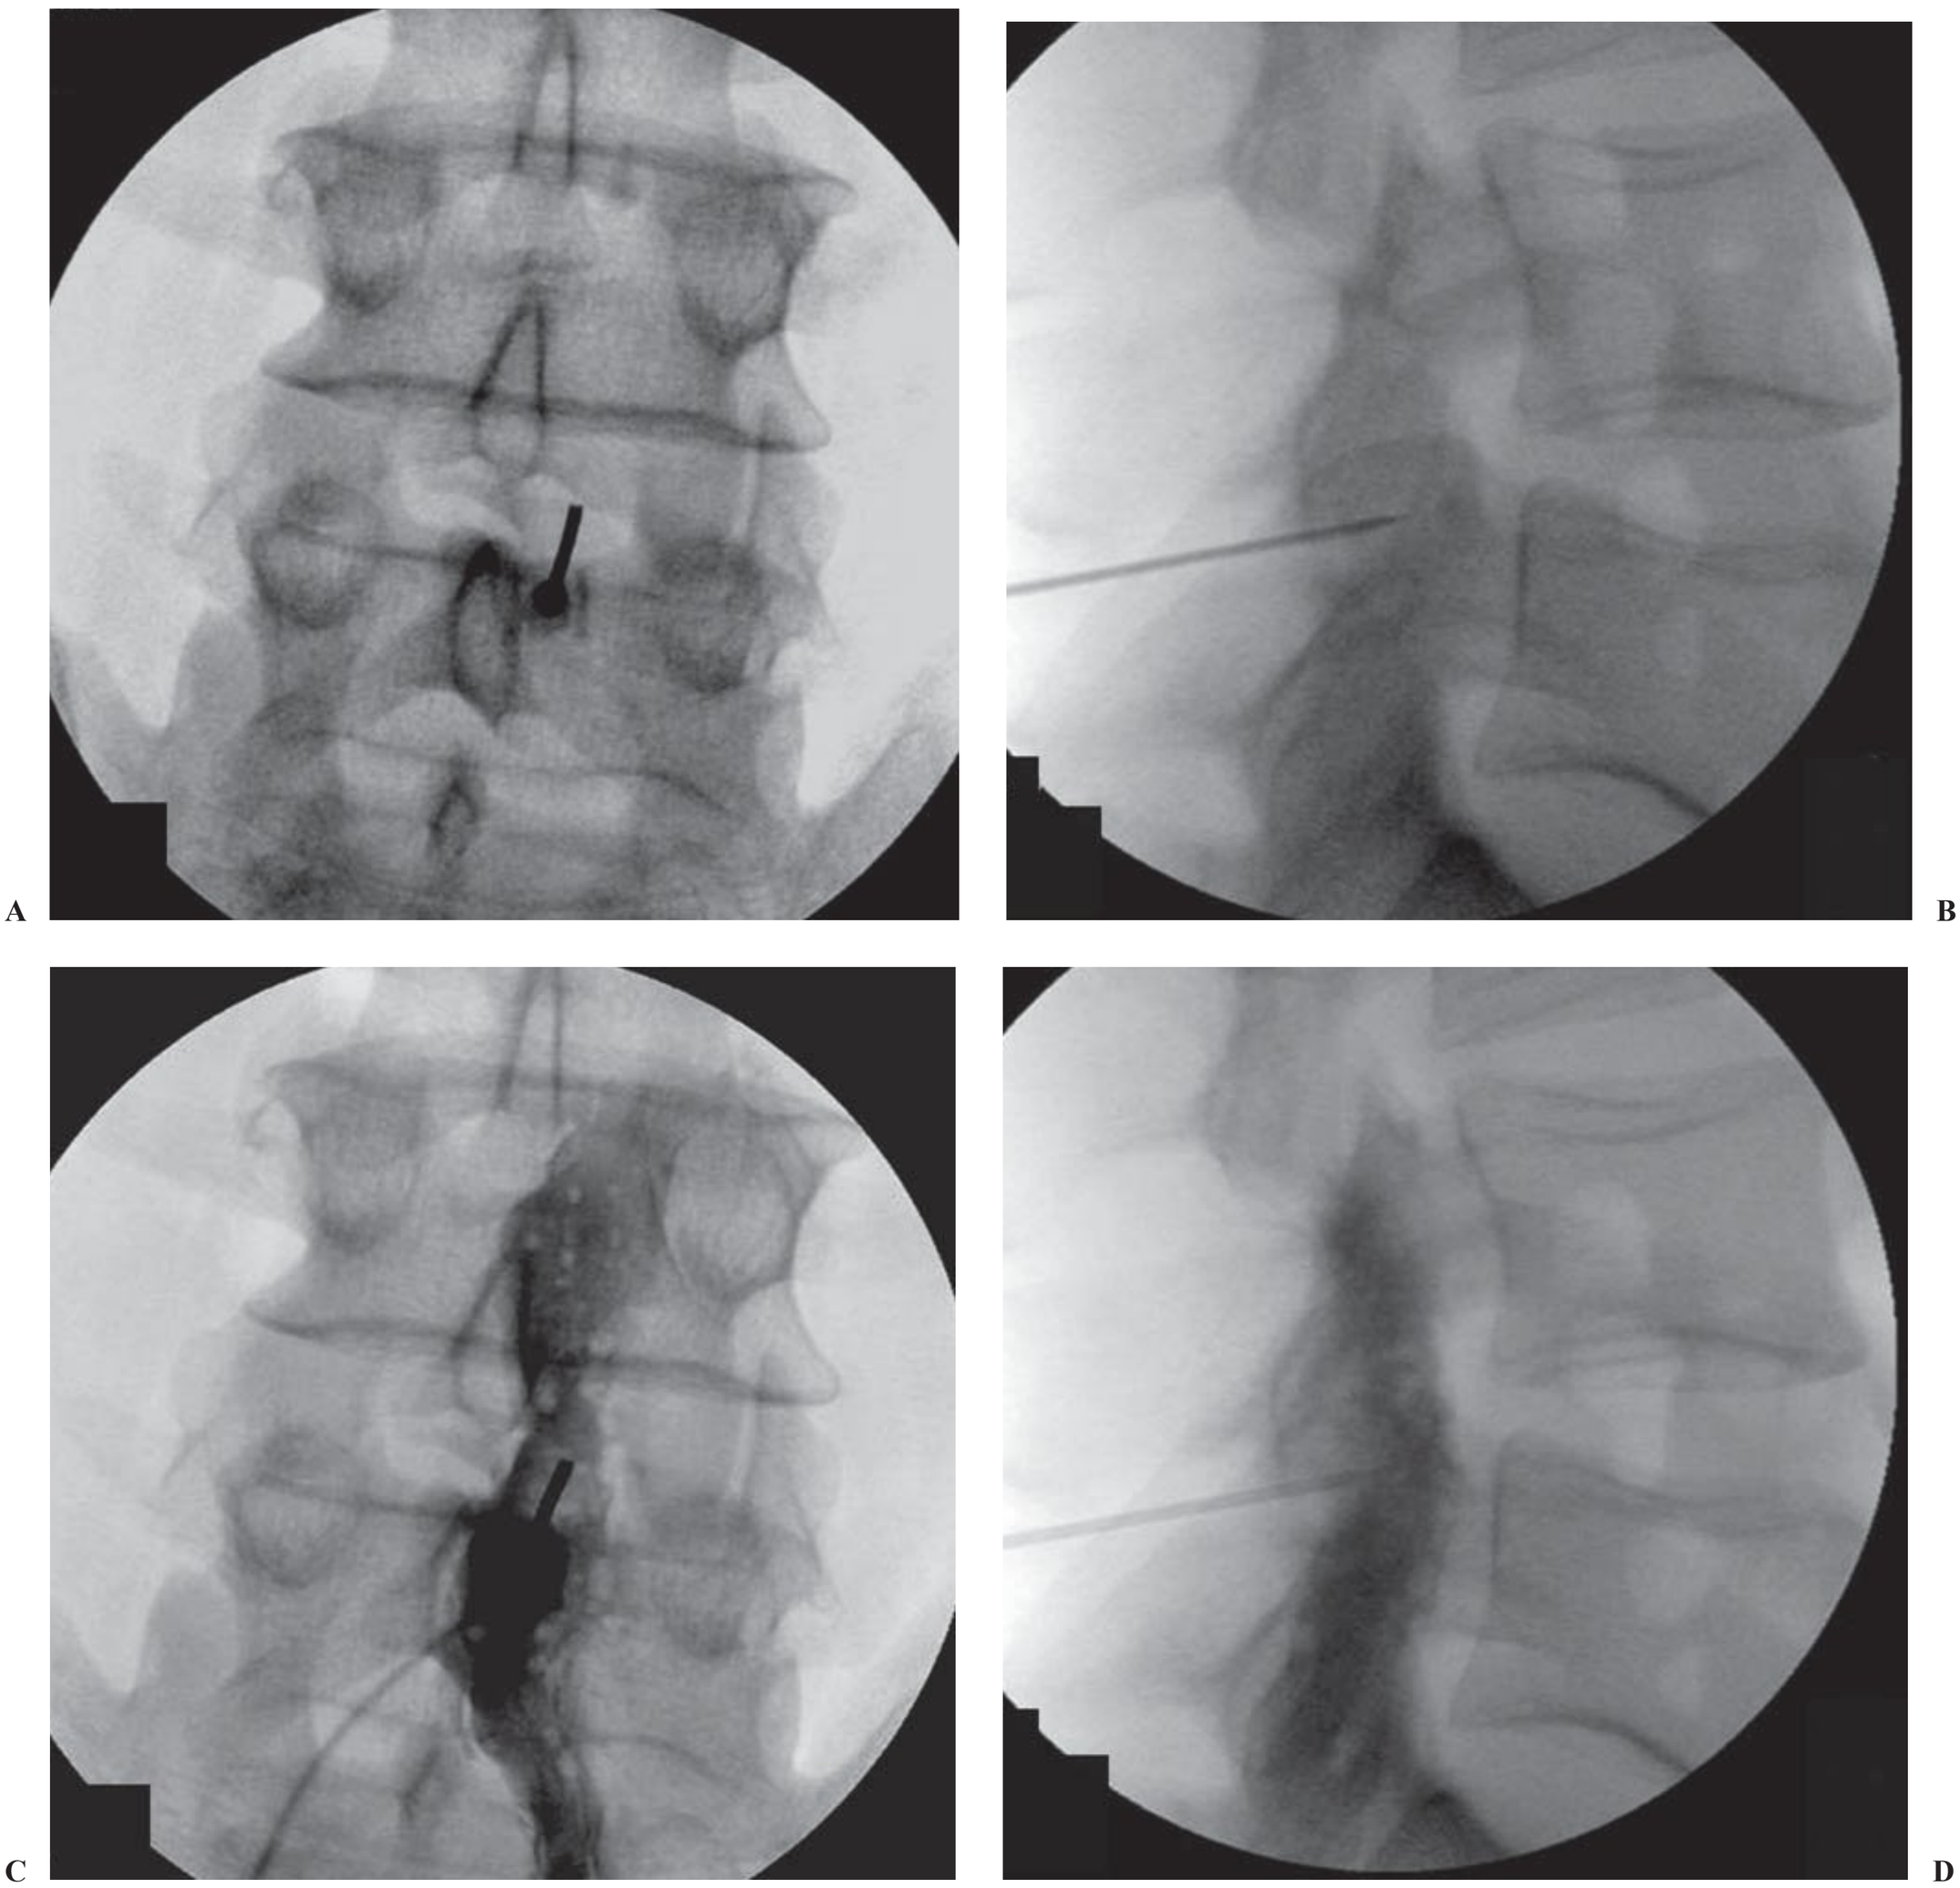

FIGURE 98.3 Images of stages of a fluoroscopically-guided, lumbar interlaminar injection of steroids. **A.** Anteroposterior view of the needle placed to the right of the midline, through the L4-L5 interlaminar space. **B.** Lateral view of needle placed. **C.** Anteroposterior view after injection of contrast medium. The contrast medium outlines the lateral epidural space and the L5 nerve root sleeves. **D.** Lateral view after injection of contrast medium. (Kindly provided by Dr. Milton Landers, Wichita, KS.)

Inflammation remains no more than a satisfying, retrospective hypothesis to rationalize the use of steroids.

INDICATIONS

For various reasons, the sole indication for epidural injection of steroids is radicular pain (i.e., sciatica). The foremost reason is that the treatment explicitly targets nerve roots, which implies a radicular origin for the pain. Secondly, whenever a rationale has been articulated, the procedure has always been cast in terms of treating inflammation of nerve roots. Thirdly, the vast majority of the literature explicitly refers to the treatment of sciatica. However, it has not always been evident that the patients actually did have radicular pain and not somatic referred pain.

Some operators have extended the indications to include back pain without radicular pain. This application, however, is not compatible with the expressed rationale for epidural steroids, for there is no evidence that back pain is an inflammatory disorder. Nor is there any evidence that disorders of the spinal nerve, dorsal

root, or dorsal root ganglion cause back pain without also causing radicular pain.

COMPLICATIONS

The possible complications of epidural injections of steroids can be classified according to the generic risks of all types of injections in general, those due the pharmacologic effects of steroids and local anesthetic agents, and those pertaining to the epidural site of injection. A unique, idiosyncratic complication pertains to transforaminal injections.

Generic Complications

Infection is a risk of any penetrating procedure. Following epidural injections of steroids, infection has only rarely been recorded and only in case reports.[76–79]

Pharmacologic Complications

Allergic reaction to local anesthetic[40] has been a rare complication of epidural injection of steroids. Hypotension because of sympathetic efferent blockade has been reported in about 2.5% of patients undergoing lumbar epidural injection of steroids,[18,31] but not after caudal injections.[53] Allergic reaction to steroids is a rare complication.[80] More commonly, epidural injection of steroids suppresses the secretion of glucocorticoids by the adrenal gland for about 2 to 3 weeks.[81,82] Overt, steroid side effects, such as hypercorticism or a Cushingoid syndrome, however, have been recorded only following the frequent administration, or the administration of large doses, of steroids (e.g., 120 mg of methylprednisolone).[83–86]

Site-Specific Complications

The site-specific risks of epidural injections are those that arise because of the proximity of the needle to the thecal sac. These hazards are shared with other spinal procedures such as lumbar puncture and epidural anesthesia.

Dural puncture has an incidence of 5% following lumbar epidural steroids but only 0.6% following caudal epidural steroids.[53–55] Inadvertent dural puncture does not constitute a complication in its own right, if it is recognized. The major risk of dural puncture is that, if it goes unrecognized, drugs will be deliv-

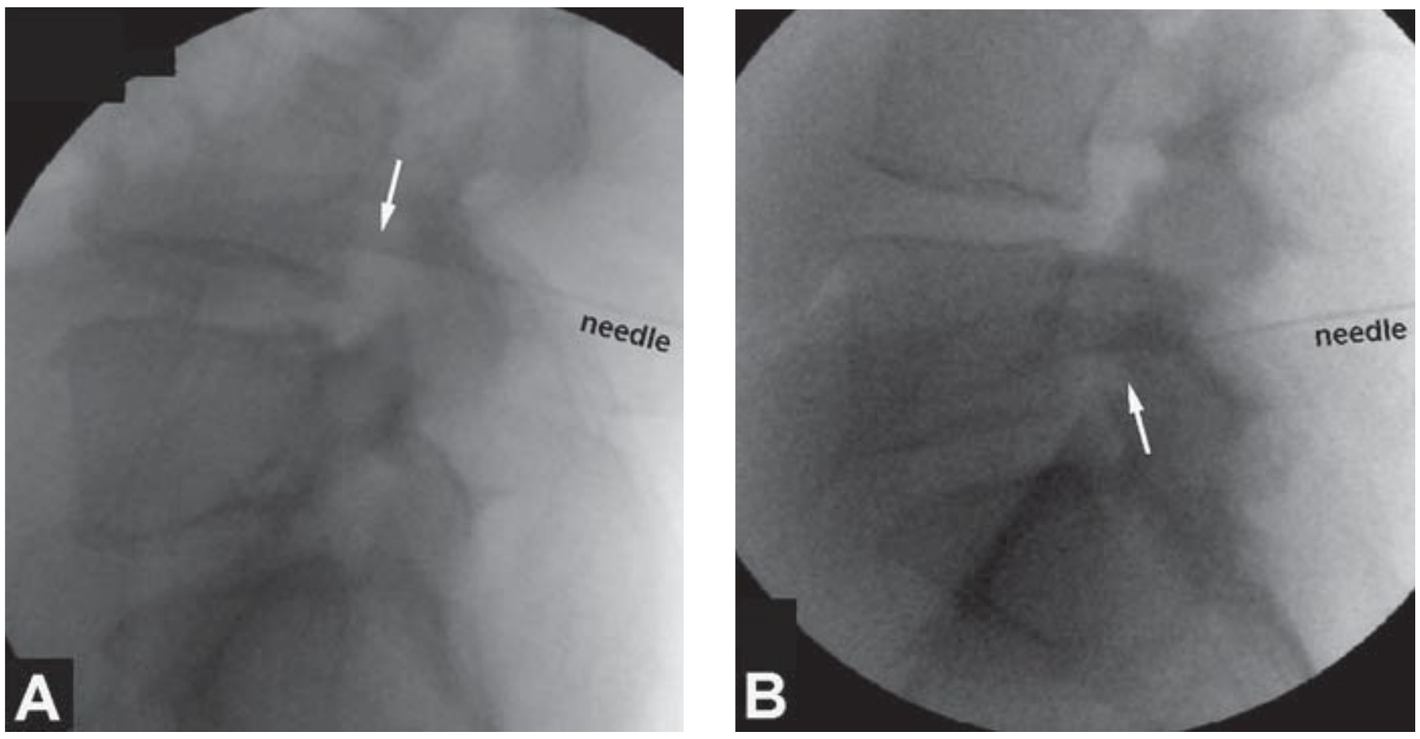

FIGURE 98.6 Lateral fluoroscopic images of alternative placements of a needle for lumbar transforaminal injections. **A.** Supraneural position, L4 nerve. **B.** Retroneural position, L5 nerve. The arrows point to the tip of the needle.

ered into the intrathecal space. If so injected, local anesthetics may cause spinal anesthesia,[40,44] and steroid preparations may have neurotoxic effects because of the additives that they contain.[53–55]

Exacerbation of pain is an enigmatic side effect of epidural steroid injection. Its mechanism is unknown but it is common with a weighted, mean incidence of 1%.[53,54] Analysis of the literature indicates that exacerbation of sciatic pain is related to the injection of large volumes of fluid into the epidural space, and it has been suggested that this symptom can be avoided by injecting slowly.[87]

Headache is a particularly troublesome side effect of epidural steroid injections. There are few reports of headache following caudal epidural steroids,[43] but many more for lumbar epidural steroids.[17,18,20,21,27,31] The incidence of headache is about 1% following lumbar injections.[53,54] Its mechanism has not been established. It may be due to unrecognized dural puncture with resultant leakage of cerebrospinal fluid or inadvertent injection of air into the subarachnoid space.[88.89] Although this complaint is generally believed to be self-limiting,[90] it can persist. Headaches persisting for more than 1 year have been recorded in 0.1% of women who underwent epidural anesthesia.[91] Options for management include abdominal binders, forced fluid intake, and autologous blood patches.[92]

Transforaminal Injections

Minor and transient side effects occur in about 9% of lumbar transforaminal injections.[93] These include transient headaches (3%), increased back pain (2%), facial flushing (1%), increased leg pain (0.6%), and vaso-vagal reaction (0.3%).

More disconcerting is the complication of spinal cord injury. This has been reported in 6 patients who underwent lumbar

transforaminal injections: 2 at L3–L4,[94] 1 at S1,[94] 1 at L2–L3,[95] 1 at L4–L5,[96] and 1 at T12–L1.[97] The mechanism of injury has not been explicitly demonstrated, but the prevailing view is that the injection penetrates a radicular artery that reinforces a medullary artery, and that when particulate steroids are injected they act as an embolus and infarct the conus medullaris.[98]

For this reason, investigators have studied the prevalence and size of particles in various steroid preparations. Results have differed with respect to average size of particles and the size of aggregates that they form, but as a general rule, preparations of methylprednisolone and triamcinolone tend to have large particles capable of embolizing a small artery, preparations of betamethasone may or may not have particles, and dexamethasone exhibits no particles.[99,100] These data have been published so that operators might make an informed choice about which steroid preparation to use with the view to minimising the risk of embolization, but it remains unclear that direct injection of any of these agents in to an artery supplying the spinal cord is safe.

EFFICACY

Classical Injections

Observational studies have reported successful outcomes in between 18% and 90% of patients treated with lumbar epidural steroids, and between 33% and 77% of patients treated with caudal injections.[53–55] These outcomes have been attributed to the use of steroids, but this inference has not been corroborated by controlled studies.

Systematic reviews have differed in their conclusions about the efficacy of blind epidural injections of steroids. The first systematic review concluded that epidural steroids are not effective.[101] A later review was more conciliatory.[102] An exhaustive, narrative review covered all publications then available in all languages and found no evidence of efficacy.[53] Three later reviews found no evidence of efficacy,[103–105] but a meta-analysis claimed a trend in favor of efficacy.[106] Two reviews concluded that epidural steroids might be effective.[107,108] A French review,[109] two from the Netherlands,[110,111] and a review conducted for the American Association of Neurologists found only modest evidence for accelerating resolution of radicular pain in the short-term (between 2 and 6 weeks after administration) and no evidence of longer-term efficacy.[112]

The reasons for this dissonance lie in how the available data are treated statistically and in differences in the definition of success and its duration. Some reviewers have considered a study to constitute evidence of efficacy if the study reported a $p < 0.05$ for any outcome measures, irrespective of duration. Others did not consider immediate relief or relief lasting less than 4 weeks to be of clinical significance, and only accepted responses at 3 months or longer to constitute evidence of efficacy.

The results of these reviews have done little to dissuade practitioners from using epidural steroids. It is pertinent, therefore, to examine in some detail both the studies held by some to constitute evidence of efficacy and those studies which deny efficacy. The latter include some studies that have appeared since the publication of several systematic reviews or not included by them.

Caudal Injections

An early study found no differences in the proportions of patients who were completely relieved, improved, unchanged, or worse at 1 to 3 months after epidural injections of procaine plus a combination of methylprednisolone and lidocaine or procaine alone.[43] Two later studies used injections of saline as the control treatment. Although the results in both studies showed a trend in favour of epidural steroids (Tables 98.1 and 98.2), neither study observed statistically significant differences between active treatment and control.

When such studies are included in a meta-analysis, they contribute toward a trend in favor of epidural steroids, but the rules of meta-analysis are that artificial pooling of studies is not a substitute for a proper study of adequate power. No such studies of caudal epidural steroids have been published.

TABLE 98.1

THE RESULTS OF BREIVIK ET AL.[113] IN A STUDY OF CAUDAL EPIDURAL INJECTIONS OF STEROIDS

Therapeutic agent	Response: Relieved	Response: Not relieved
Steroid + Bupivacaine	9	7
Saline + Bupivacaine	5	14

Outcomes were assessed at between 3 and 18 months after treatment. Although a larger proportion of patients were relieved, the difference in outcome is not statistically significant. On chi squared analysis $p = 0.072$, and on Fisher's exact test $p = 0.07$.
Data from Breivik H, Hesla PE, Molnar I, et al. Treatment of chronic low back pain and sciatica. Comparison of caudal epidural injections of bupivacaine and methylprednisolone with bupivacaine followed by saline. In: Bonica JJ, Albe-Fessard D, eds. *Advances in Pain Research and Therapy*. Vol. 1. New York: Raven Press; 1976:927–932.

Lumbar Interlaminar Injections

Although celebrated as the first controlled study to show that epidural steroids were effective, the study of Dilke et al.[87] found statistically significant differences only in certain, secondary outcome measures, such as return to work at 30 days. With respect to relief of pain, epidural injection of steroids was not demonstrably more effective than injection of normal saline into an interspinous ligament (Table 98.3). Differences in outcome approach statistical significance only if patients with unknown outcomes and those who required surgery are disregarded. If those who required

TABLE 98.2

THE RESULTS OF BUSH AND HILLIER[114] IN A CONTROLLED TRIAL OF CAUDAL INJECTIONS OF EPIDURAL STEROIDS

	Response: No pain	Better	No change	Worse	p Value
At 4 weeks					
Treated	2	5	4	1	0.66
Control	2	3	3	3	
At 1 year					
Treated	6	4	2	2	0.57
Control	6	1	1	3	

The treated group received saline, procaine, and triamcinolone. The control group received saline only. Chi squared analysis yields nonsignificant *p* values.
Data from Bush K, Hillier S. A controlled study of caudal epidural injections of triamcinolone plus procaine for the management of intractable sciatica. *Spine* 1991;16:572–575.

TABLE 98.3

THE OUTCOMES AT 3 MONTHS AFTER TREATMENT WITH EITHER A LUMBAR INTERLAMINAR INJECTION OF STEROIDS OR AN INJECTION OF SALINE INTO AN INTERSPINOUS LIGAMENT[83]

	Treatment		
Pain	Steroids	Saline	p Value
None	16	8	
Not severe	24	20	
Severe	1	6	0.05
Surgery	7	10	0.06
Unknown	3	4	0.10

On chi squared analysis, the *p* value is 0.05 if patients who had surgery or whose outcomes were unknown are disregarded. If patients who had surgery are classified as failures, the *p* value increases to 0.06. If unknown results are included, the *p* value becomes 0.10.
Data from Dilke TF, Burry HC, Grahame R. Extradural corticosteroid injection in management of lumbar nerve root compression. *BMJ* 1973;2: 635–637.

TABLE 98.5

THE RESULTS OF A CONTROLLED TRIAL AT 3 MONTHS AFTER TREATMENT WITH LUMBAR EPIDURAL INJECTIONS OF STEROIDS OR SALINE[116]

	Treatment	
Outcome measure	Steroid	Normal saline
Oswestry disability (0–100)	32	35
Pain (Visual Analog Score; 0–100)	39	40
Sickness Impact Profile (0–100)		
Overall	12	13
Physical	10	9
Restricted activity (days)	6	9

Data from Carette S, LeClaire R, Marcoux S, et al. Epidural corticosteroid injections for sciatica due to herniated nucleus pulposus. *N Eng J Med* 1997;336:1634–1640.

surgery are classified as failures, statistical significance is not achieved.

The only other study to report a positive result showed that epidural injection of steroids achieved greater improvements in pain than did an injection of saline into an interspinous ligament.[35] Baseline data and final outcomes, however, were not reported, and the effects attenuated after 12 weeks.

A Japanese study[20] reported that the efficacy of epidural steroids was not different from that of an epidural injection of local anesthetic alone. This observation was elaborated by another study.

Klenerman et al.[115] compared the effects of epidural injections of steroids, of local anesthetic alone, of saline alone, and of dry needling of an interspinous ligament. They categorized their outcomes as "failed" (less than 25% relief) or "not failed" (greater than 75% relief). The latter category included patients who were "improved" or "cured," but the numbers in these subcategories were too small to be subjected to statistical analysis separately. At 2 months after treatment, the outcomes in the several groups were not statistically different (Table 98.4). The fact that epidural injection of steroids was not demonstrably more effective than simply dry needling of an interspinous space is remarkable.

More recent studies also have found no attributable effect of steroids. Their outcomes were the same, irrespective of what was injected.

Carette et al.[116] found no differences in outcome at 3 months, whether patients were treated with lumbar epidural injections of steroids or an epidural injection of normal saline (Table 98.5). In particular, the use of steroids made no difference to disability.

Using the liberal outcome measure of "relieved or not," Valat et al.[117] found no statistically significant difference in outcome after active or sham treatment. Although a slightly larger proportion of patients were relieved by steroids at day 20 after treatment, the difference was not significant. By day 35, the proportions relieved were essentially identical (Table 98.6).

For the outcome measure—any degree of relief at 35 days—the number needed to treat (NNT)[118,119] was 100.[117] This statistic means that 100 patients would need to be treated before 1 could be claimed to have obtained any degree of relief lasting 35 days expressly because of the injection of steroids. In all other patients with successful outcomes, the success is due to the nonspecific effects of having an injection and not due to the injection of steroids. This statistic describes a very ineffective and inefficient treatment.

Another study compared the outcomes of interlaminar or intramuscular injection of steroids.[120] It reported that there was no significant difference in outcome at 35 days but provided no explicit data on pain or function. The only numerical data were that the surgery rates in the two groups (31% and 41%, respectively) were not significantly different statistically.

A large and rigorous study compared interlaminar injection of steroids with injection of normal saline into an interspinous ligament.[121] With respect to relief of pain, the outcomes at 3 weeks favored interlaminar injections, but the difference was extinguished by 6 weeks. At no time, from 3 weeks to 1 year after

NNT, number needed to treat.
Data from Valat JP, Giraudeau B, Rozenberg S, et al. Epidural corticosteroid injections for sciatica: a randomised, double-blind, controlled clinical trial. *Ann Rheum Dis* 2003;62:639–643.

treatment, were the proportions of patients who obtained at least 50% relief of pain different. There were no differences in disability scores or improvements in disability scores. At 3 weeks, the proportion of patients who obtained 75% improvement in disability was higher (12.5%) in those treated with interlaminar injections (3.7%), but this difference did not persist beyond 3 weeks. In this study, the NNT for 50% relief at 3 weeks was 11, but for lack of sustained benefit, no NNT was applicable at later times.

Utilization

A utilization review found that over 70% of the epidural injections of steroids performed in the United States are performed on patients with chronic pain (lasting more than 6 months).[122] No controlled studies have shown epidural steroids to be effective in this population. Most of the observational studies and all of the controlled studies of epidural steroids have been conducted on patients with acute or subacute pain or in mixed populations the majority of whom had pain for less than 3 months. Yet, even in those populations they have been shown not be effective. So, there is no evidence, direct or by extrapolation, to support the use of epidural injections of steroids for treating chronic pain, yet this is their most common use.

Back Pain

Proponents of the use of epidural steroids for back pain rely on a handful of observational studies that claim effectiveness.[123,124] In doing so, these proponents seem unperturbed that epidural steroids for sciatica were originally promoted on the basis of observational studies, only to have their efficacy eventually refuted by controlled trials. Without a rationale, and without evidence of efficacy, the use of epidural steroids for back pain appears more like a treatment looking for an application than a condition warranting an intervention. Others warn that the low success rates obtained for back pain are commensurate with placebo response rates.[125]

Fluoroscopically-Guided Injections

Those who decry "blind" injections yet advocate fluoroscopically-guided injections believe that fluoroscopically-guided lumbar or caudal injections should, in theory, be more effective because they are more accurate. But there is no evidence to this effect. As controlled studies have been published that refute the efficacy of blind injections, no contrary studies have been conducted and published that show that fluoroscopically-guided injections are, nonetheless, effective. In the absence of direct evidence, and in the absence of evidence that blind injections are effective, the effectiveness of fluoroscopically-guided injections makes rational sense, but remains no more than hearsay.

Transforaminal Injections

The introduction of fluoroscopically-guided, transforaminal injections of steroids was heralded by an observational study that used a novel outcome measure. That study enrolled 30 patients who were on a waiting list for surgery.[67] After being treated with transforaminal injections of steroids, 47% obtained complete relief of pain that was lasting and only 20% required surgery (Fig. 98.8). The efficacy of transforaminal injections was cast in terms of their ability to spare patients from having surgery.

A subsequent, observational study used more familiar outcome measures. It reported that 52 out of 69 patients obtained greater than 50% relief of the pain after treatment with transforaminal injections of steroids at follow-up times of between 28 and 144 weeks.[68] Other, observational studies echoed these outcomes.[126,127] Betamethasone and triamcinolone have been equally effective.[128]

Controlled trials soon followed. Two reported negative results, and three reported positive results. The first controlled trial[129] used avoidance of surgery as the outcome measure. It found that only 8 of 28 patients (29%) required surgery after treatment with transforaminal injections of betamethasone, compared with 18 out of 27 patients (67%) treated with transforaminal injections of bupivacaine. A later publication reported a 5-year follow-up of these patients, which showed that the outcome was enduring.[130] In neither publication were pain scores or disability reported. The second controlled trial[131] found no difference in effect on leg pain following transforaminal injections with betamethasone or with bupivacaine. A supplementary publication reported that betamethasone was more effective than bupivacaine in a subgroup of patients who had contained disc herniations, but only up to 4 weeks after treatment.[132] At longer-term follow-up, that superiority extinguished.

The third trial compared transforaminal injections of steroids with paraspinal injections of normal saline.[69] The outcomes favored transforaminal injections (Table 98.7). Mean pain scores were significantly lower in those patients treated with transforaminal steroids, and a significantly greater proportion of those patients obtained greater than 50% relief. Disability scores, however, were not appreciably different. What are conspicuous in these data are the magnitude of improvement in the control group and the proportion of patients who obtained greater than 50% relief of radicular pain simply following paraspinal injections of normal saline. There is no biologic link between the mechanism of radicular pain and either the pharmacologic properties of normal saline or the back muscles. These data underscore the powerful placebo effect of injections.

The fourth controlled trial compared the outcomes of transforaminal injection of methylprednisolone and bupivacaine with those of transforaminal injections of bupivacaine alone.[133] It found no differences at 1 day, 4 weeks, 6 weeks, or 3 months. In the two groups, pain scores dropped from 73 to 54, and from 77 to 55, respectively. One difference in this study was that patients received only one injection, whereas in previous studies they received at least one and up to three injections.

The fifth trial compared transforaminal injections of steroids

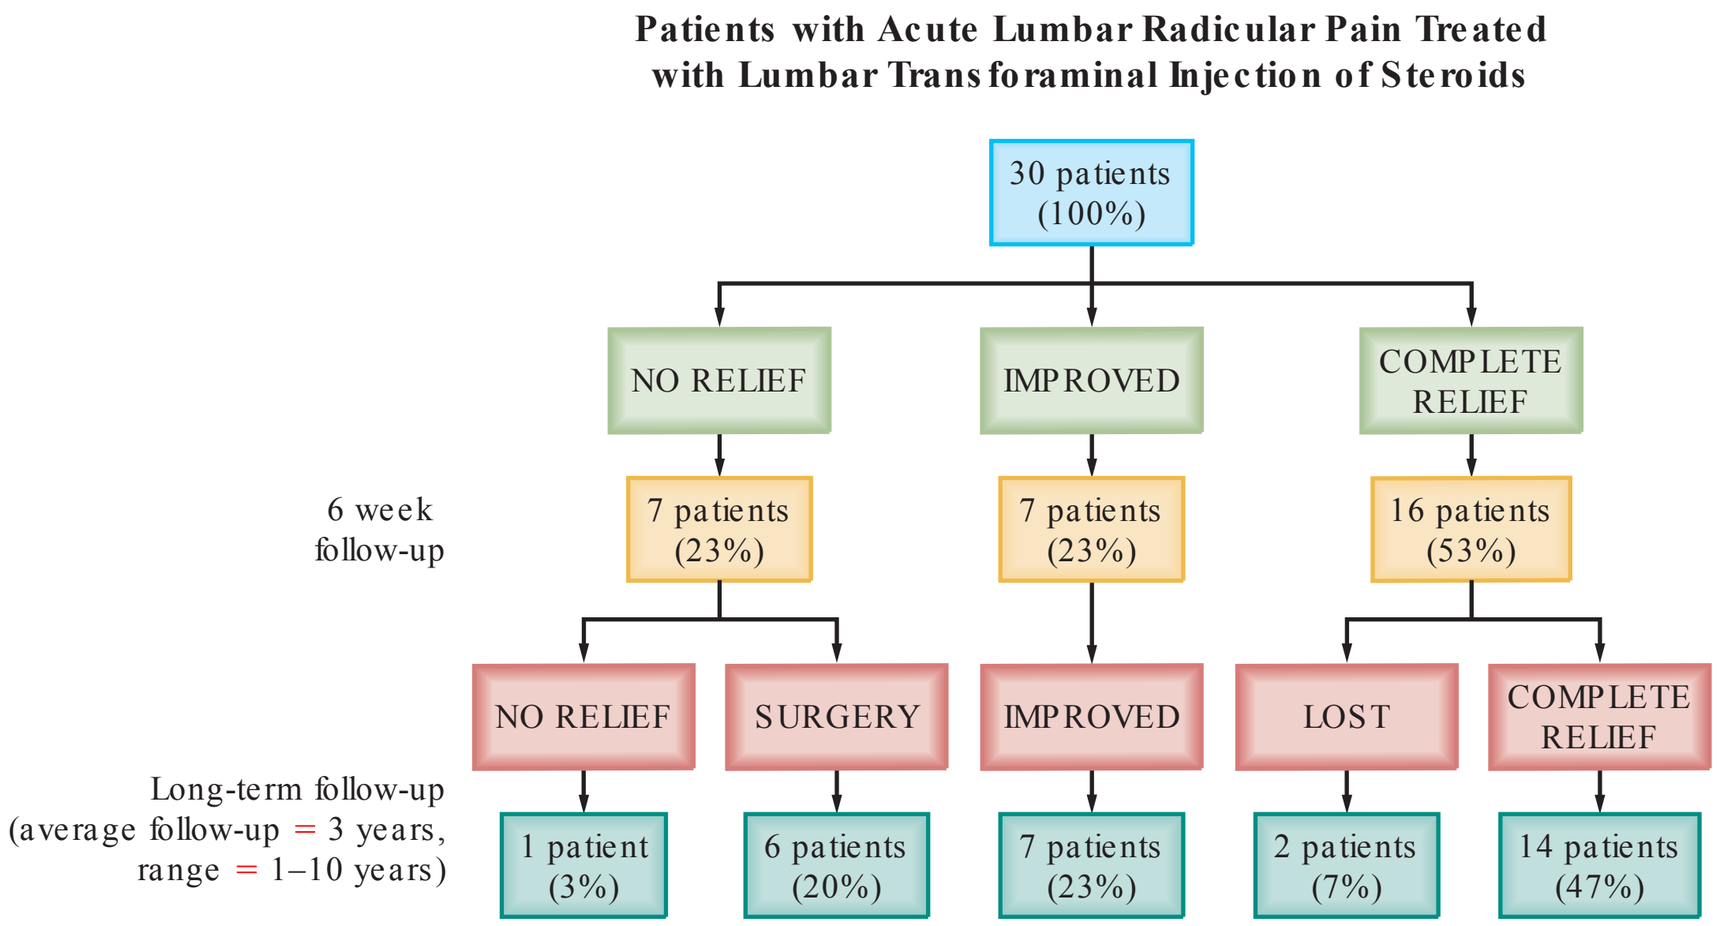

FIGURE 98.8 The results of an observational study of the efficacy of lumbar transforaminal injection of steroids. (Data from Weiner BK, Fraser RD. Foraminal injection for lateral lumbar disc herniation. *J Bone Joint Surg* 1997;79B:804–807.)

with conventional interlaminar injections.[134] No differences in outcome were evident at 6 days after treatment, but by 30 days and at 6 months after treatment, those patients treated with transforaminal injections showed statistically significant, greater improvements in pain and function relating to work and leisure.

Other studies have sought to compare the effectiveness of transforaminal injections with those of either interlaminar or caudal injections. A retrospective case-control study[135] and a practice audit[136] found in favor of transforaminal injections, as did a prospective study.[137]

Synopsis

Table 98.8 encapsulates the evidence on epidural injections of steroids. Blind caudal injections are not more effective than epidural injections of normal saline either for short-term outcomes or in the long-term.[113,114] For long-term outcomes, blind lumbar interlaminar injections are no more effective than epidural injections of normal saline or injections of normal saline into interspinous ligaments.[35,115–117,121] For short-term outcomes (i.e., less than 4 weeks), the evidence is mixed and conflicting. Whereas some have found interlaminar injections of steroids to be somewhat more effective than interlaminar injections of saline,[121] others have found no significant difference[117] or no effect greater than that from an injection of normal saline into an interspinous ligament.[87] For fluoroscopically-guided injections, there is still no evidence of efficacy. Transforaminal injections of steroids are more effective for the relief of pain than intramuscular injections of normal saline or steroids but are not more effective than transforaminal injections of local anesthetic. The only strong evidence is that transforaminal injections spare patients from surgery.

TABLE 98.7

THE RESULTS OF A CONTROLLED TRIAL THAT COMPARED THE OUTCOMES OF TREATMENT WITH TRANSFORAMINAL INJECTIONS OF STEROIDS AND PARASPINAL INJECTIONS OF NORMAL SALINE[69]

Outcome	Treatment

A SYNOPSIS OF THE EVIDENCE ON EPIDURAL INJECTIONS OF STEROIDS BY VARIOUS ROUTES

Route		Efficacy
Blind	Caudal	Short-term (<4 weeks) Epidural Steroids = Epidural Normal Saline Long-term (>4 weeks) Epidural Steroids = Epidural Normal Saline
	Lumbar	Short-term (<4 weeks) Epidural Steroids = Interspinous Normal Saline Epidural Steroids = Epidural Normal Saline Epidural Steroids > Epidural Normal Saline Long-term (>4 weeks) Epidural Steroids = Epidural Normal Saline Epidural Steroids = Interspinous Normal Saline
Fluroscopically-Guided	Caudal Lumbar	No evidence available
Transforaminal		Transforaminal Steroids>IM Normal Saline Transforaminal Steroids>IM Steroids Transforaminal Steroids > Interlaminar Steroids Transforaminal Steroids = Transforaminal LA Surgery Sparing

IM, intramuscular; LA, local anaesthetic.

CONCLUSION

The history of epidural injections of steroids constitutes a vivid example of a common medical misconception. Practitioners do not distinguish between observed effect and attributable effect. All treatments can seem to work to some extent or other. However, they may not work for the reasons that a treatment is believed to work. The attributable effect is the extent to which a treatment works for reasons other than the nonspecific effects of treatment and is revealed only by controlled trials.

Observational studies of epidural injections of steroids have reported success rates of various magnitudes. Therefore, they do appear to work. For short-term outcomes (i.e., 20–30 days), some studies have shown an attributable effect, but others have found none. Until a clearer picture emerges, the use of epidural injections of steroids might still be justified for providing more rapid relief of radicular pain in the short-term. For long-term relief, however, controlled studies have consistently found no attributable effect. Epidural injections of steroids work for reasons other than the injection of steroids. In the case of blind injections, injections of normal saline, even into interspinous ligaments, are as effective. This indicates that the act of injection, or the ceremony associated with it, may be the paramount therapeutic ingredient.

The same may still apply to transforaminal injections. For the relief of pain, transforaminal injections are more effective than intramuscular injections of saline or of steroids, but transforaminal injections of steroids are no more effective than transforaminal injections of local anesthetic alone. This raises two sets of possibilities.

Steroids and local anesthetic may have the same effect pharmacologically or physically when injected by the transforaminal route, both might be either analgesic or anti-inflammatory, or both might simply irrigate the target nerve.

On the other hand, transforaminal injections may have strong nonspecific effects. Performing injections in a special procedure room using sophisticated equipment has the attributes for a strong placebo effect. The technology and ceremony involved may produce a placebo effect greater than that produced by relatively banal intramuscular injections.

The study of Thomas et al.[134] took steps to control for this effect. The intramuscular injections were performed with the same facilities and ceremony as were the transforaminal injections. Although some, though not all, of the outcomes favored transforaminal injections, it was conspicuous that the outcomes of the intramuscular injections were not insubstantial. This leaves the question of whether the steroids have a systemic effect unresolved.

Epidural injections of steroids are the most enigmatic of treatments in pain medicine. It is not that the most commonly performed procedure in pain medicine lacks evidence of efficacy. Conventional injections have been shown to be no more effective than sham treatment. Yet they continued to be used. Since there is no scientific reason for their continued use, the reasons must be social, financial, or both.

Traditions and habits are hard to break. While so long as epidural steroids were believed to work, practitioners had something to offer their patients. If they are deemed not to work, these practitioners are disempowered. Unless they are given an

alternative, they have nothing to offer their patients and nothing for which they might be reimbursed. For these reasons, evidence of lack of efficacy becomes threatening professionally and financially. Under those conditions, it seems preferable to ignore the evidence and to maintain tradition.

At present, transforaminal injections appear to be an alternative to conventional injections. Their reputation tenuously relies on one study that has shown that they spare patients from surgery, and one study that shows that they are just more effective than intramuscular injections of steroids. Their efficacy needs to be corroborated by confirmatory studies. However, it is possible that future studies will deny any efficacy. In that event, transforaminal injections may follow the same historical evolution as conventional injections have done. Giving the patient an injection, rather than what is injected, may be the reason why the treatment appears to work.

CHAPTER 99 ■ INTRATHECAL DRUG DELIVERY IN THE MANAGEMENT OF PAIN

RICHARD K. OSENBACH

INTRODUCTION

During the past 25 to 30 years, implantable drug delivery devices designed for long-term continuous infusion of medications have become an increasingly important part of the armamentarium for physicians involved in the management of patients with chronic intractable pain syndromes. Spinal drug delivery was initially indicated for and generally limited to patients with intractable pain secondary to cancer. However, over the years, the application of intrathecal (IT) drug delivery (ITDD) has expanded to include treatment of patients with chronic benign pain conditions. Indeed, the use of ITDD for nonmalignant pain syndromes has now exceeded that for patients with cancer-related pain. In addition to opiates, alternative agents have been and are currently being studied as to their safety and efficacy for IT infusion in patients with chronic pain. In addition to chronic pain conditions, IT drug delivery is also utilized for the treatment of other neurological disorders such as spinal- and cerebral-origin spasticity, Parkinson disease, and others. The purpose of this chapter is to outline the current status of neuraxial drug infusion for the treatment of chronic pain including basic concepts of intraspinal drug delivery, the various pharmacological agents either currently in use or in development, the use of ITDD devices, as well as the outcomes associated with the use of this technology for the management of chronic pain.

HISTORICAL REVIEW

The development of ITDD devices represents one of the more substantial advances of the past several decades in the field of chronic pain management. The advent of intraspinal opioid therapy is directly linked to the discovery and isolation of opioid receptors in the early 1970s and the discovery of their existence in both the brain and spinal cord. Yaksh et al. discovered that direct application of morphine to the spinal cord in experimental animals produced measurable analgesic effects and, several years later, it was shown that the intraspinal injection of morphine (epidurally or intrathecally) produced effective analgesia in humans.[1] In 1981, the first report describing the continuous infusion of IT morphine in patients with intractable pain due to underlying malignancy was published.[2] Since this initial publication, a sizeable body of literature has appeared detailing the application, safety, and efficacy of intraspinal opiates in the management of chronic pain.[3–16]

BASIC PHARMACOLOGY OF INTRATHECAL DRUG ADMINISTRATION

The safe and effective implementation of intraspinal infusion therapy is predicated on a thorough knowledge of the pharmacology of the individual drugs and an understanding of the pharmacodynamics of intraspinal (intrathecal or epidural) drug delivery. Initial IT pharmacokinetic studies primarily focused on the use of intrathecal methotrexate (MTX); however, detailed IT pharmacodynamic profiles have now been defined for a variety of drugs, most notably the opioids, and in particular morphine.

The distribution and absorption of a drug administered intrathecally is based on multiple variables which may be divided into patient characteristics, cerebrospinal fluid (CSF) characteristics, drug characteristics, and factors associated with the injection technique[17–18] (Table 99.1). Probably the most important of these factors is the characteristic of the particular drug that is injected or infused. Following injection into the lumbar subarachnoid space, the rostral ascent of a particular drug and the ultimate cisternal concentration is determined primarily by its lipid solubility. Hydrophilic substances (e.g., morphine) do not readily cross the blood brain barrier (BBB), and infusion into the lumbar thecal space produces high lumbar CSF concentrations of the infused agent.[18] Hydrophilic drugs are distributed mainly by bulk flow of CSF such that a concentration gradient develops in a caudal-to-rostral direction. Although steady-state cisternal concentrations may not be insignificant, especially for hydrophilic compounds, lumbar drug infusion does not usually result in a significant concentration of the drug within the ventricular system. Because of the relatively small volume of CSF in the spinal canal (about 75 mL) and the relatively slow clearance of hydrophilic drugs from the CSF, infusion of even small doses of hydrophilic compounds will result in a relatively high concentration of the drug at the desired target site of action, namely the spinal cord. In contrast, drugs with significant lipid solubility will be preferentially absorbed into the substance of the spinal cord or diffuse across the subarachnoid-dural barrier into the epidural space.[18] Lipophilic drugs (e.g., fentanyl, sufentanil) usually do not reach significant cisternal concentrations. Consequently, li-

pophilic agents may be useful in producing more segmental analgesia without the supraspinal effects which occasionally occur with more hydrophilic drugs.

Continuous IT infusion of a drug using an implanted delivery system has significant theoretical and practical advantages over bolus administration through a tunneled catheter or subcutaneous reservoir. Continuous infusion assures a constant high concentration of drug in the CSF which is highly desirable since the concentration gradient represents the primary driving force for diffusion of the drug to its target site in the spinal cord. Continuous IT infusion also results in a more predictable concentration gradient and is generally associated with fewer adverse side effects than is bolus administration of the same agent.

Morphine is one of the best-studied agents in terms of IT pharmacodynamics. During the continuous IT infusion of morphine, a steady-state caudal-to-rostral concentration gradient develops with lumbar-to-cisternal ratios of morphine ranging anywhere from 4:1 to 7:1.[18] Even though cisternal levels are *relatively* low, they are not necessarily clinically insignificant, and supraspinal side effects, most notably respiratory depression, can occur. Other drugs of clinical interest for which lumbar-to-cisternal levels have been measured include baclofen (2.0–8.7:1) and the alpha-2 adrenergic agonist clonidine (3.2:1).[18]

PATIENT SELECTION FOR INTRATHECAL DRUG DELIVERY

It can be said that successes are created, not simply discovered. Indeed, this is clearly the case in selecting patients for ITDD. In many cases, treatment failure with any type of implantable device (ITDD, spinal cord stimulator, etc.) can often be attributed to suboptimal patient selection. Without question, one of the most important factors for producing a successful outcome with this type of therapy is scrupulous patient selection. It is imperative that patients with chronic pain who are considered for ITDD undergo a comprehensive multidisciplinary evaluation. It may be prudent to involve the expertise of various specialists such as neurologists, neurosurgeons, anesthesiologists, psychiatrists, psychologists, nurses, physical and occupational therapists, social workers, and vocational rehabilitation specialists.

One must remember that experience of pain is perceptual, and each patient enters into pain management with individual beliefs, experiences, and concerns. Due to the biopsychosocial nature of chronic pain, the nature and magnitude of these influences must be assessed in order to properly evaluate the potential risks and benefits of ITDD for an individual patient. Factors such as good pain coping skills, realistic expectations, strong family support, minimal influence of psychosocial stressors, and lack of cognitive disturbances are more likely to result in a successful outcome.

Each patient should undergo a detailed pain history which includes a review of all prior pain treatments and the results of such treatments. A history of lack of benefit from all prior treatment is a poor prognostic sign. All patients should have a relatively recent spinal imaging study to exclude obvious, surgically correctable conditions such as spinal stenosis or spinal instability and make certain that there is no pathology that would otherwise preclude safe placement of an IT catheter. Absolute contraindications to pump implantation include the presence of systemic infection, local cutaneous infection near the potential surgical sites, uncorrectable coagulopathy, known allergies to components of either the pump or catheter, and active intravenous (IV) drug abuse. Relative contraindications include emaciation or patients with a body habitus that may not be conducive to an implant (e.g., inadequate subcutaneous tissue to create a pocket for the implanted pump). Careful consideration must be given to patients receiving anticoagulation therapy. Although implantation is not contraindicated in these patients, all anticoagulation must be reversed prior to any type of invasive procedure. Patients with an unfavorable psychological profile should not be considered for ITDD until any psychological concerns have been addressed and resolved. Lastly, although recovering drug addiction is not an absolute contraindication, these patients need extremely careful assessment prior to proceeding with this therapy; it is important to understand that placement of an ITDD device does not lead directly or inevitably to cessation of all oral opioids.

Chronic pain conditions for which ITDD has been utilized are outlined in Table 99.2. It is important to assess the type and

TABLE 99.2

CHRONIC PAIN STATES CURRENTLY TREATED WITH CHRONIC SPINAL DRUG INFUSION

Cancer pain
Postlaminectomy syndrome

Painful peripheral neuropathy
Poststroke pain
Intractable angina
HIV-related pain

topography of pain in each patient. In general, ITDD is most effective for pain located below the upper thoracic region although ITDD can be successfully applied in patients with cervical and upper extremity pain. In general, it has traditionally been thought that nociceptive pain and mixed nociceptive/neuropathic pain responds best to IT drug infusion and that patients with pure neuropathic pain are not good candidates for this therapy. However, there is evidence to suggest that neuropathic pain can respond to opioid therapy, albeit at higher doses.[19] In order to improve analgesia in patients with predominantly neuropathic pain, many clinicians have adopted the practice of polyanalgesia or combination therapy, combining IT opioids with alternative medications such as local anesthetics and clonidine.[20] Additionally, the recent approval of ziconitide by the U.S. Food and Drug Administration (FDA) has provided another alternative for treatment of neuropathic pain.[21,22]

The ideal patient for IT opioid infusion is one who has previously demonstrated a positive analgesic response to systemic opioids. This is especially true for patients who experience therapy-limiting side effects with the use of systemic agents. However, if a patient has never shown any response to adequate doses of several different systemic opiates, there is no evidence to suggest that IT delivery of opiates will produce any better analgesic response.

ROLE OF PSYCHOLOGICAL EVALUATION

Karl Marx stated that "the only antidote for mental suffering is physical pain." Indeed, the vast majority of patients with chronic pain conditions have psychosocial issues that influence their condition. This is in keeping with the accepted theory of the biopsychosocial nature of chronic pain. Many patients with chronic pain exhibit a degree of suffering and pain behavior that is out of proportion to the underlying condition. Indeed, there are individuals who possess certain behavioral and psychological factors that may "predispose" them to the development of and enhancement of the experience of pain. Moreover, many of these patients lack the requisite psychological tools to effectively cope with their condition and, as a result, develop maladaptive psychological and behavioral issues. Consequently, given the nature of chronic pain, it is recommended that all patients undergo evaluation by an experienced pain psychologist before even proceeding with a trial of IT therapy. Although psychological evaluation has never been shown to clearly result in improved outcomes, it does provide an insight into the psychosocial effects of chronic pain on an individual patient. In addition, evaluation by an experienced pain psychologist can identify risk factors that are known to be associated with poor outcomes (Table 99.3). It should be emphasized that the purpose of the psychological evaluation is not to simply "clear" or, for that matter, exclude the patient for an implant, but rather to gain an understanding of the psychological factors that might influence the outcome in a particular patient. It is also important to realize that while a given patient might initially be noted to have an unfavorable psychological profile, this does not necessarily constitute an absolute contraindication to implantation at some time in the future. Patients who are willing to work with a psychologist and/or psychiatrist can progress to the point where they are appropriate candidate for ITDD at some point in the future. Table 99.3 outlines some of the more important questions that should be addressed with the psychological evaluation and also lists a number of risks factors that may influence outcome.

TRIALING TECHNIQUES FOR INTRATHECAL DRUG DELIVERY

Prior to implantation of a permanent ITDD device, all patients, without exception, should undergo some type of screening trial to determine effectiveness and potential drug-related side effects. Indeed, in a 2006 Canadian survey, all centers indicated that a trial injection or infusion was carried out before placement of an implanted ITDD system.[23] Even before proceeding with the trial, it is imperative that the patient and physician establish the specific goals for determining that success of the trial. Goals are not necessarily uniform across all patients, but must be individualized on a case-by-case basis, depending on the particular circumstances. Obviously, one of the goals, and probably the most important goal from the patient's point of view, is absolute pain reduction. Nearly all of the literature that has been published regarding neuromodulation procedures defines a "successful trial" as a 50% reduction in the patient's baseline pain. Although 50% pain reduction would seem to be a reasonable achievement if not arguably an excellent result in the chronic pain population, I would submit that this figure should not be used as the sole determining factor of the success or failure of an individual trial. There are certainly patients for whom a lesser reduction in pain is sufficient and results in improvement in activities, reduction in medication use, etc. On the other hand, there are clearly patients who will be disappointed with the outcome if they experience anything short of complete pain resolution, which reminds one of the philosophy that "one man's junk is another man's treasure." Indeed,

TABLE 99.3

PSYCHOLOGICAL RISK FACTORS ASSOCIATED WITH POOR OUTCOME OF IMPLANTABLE PAIN DEVICES

Risk Factors

Thought disorders

Personality disorders
- Borderline personality
- Anti-social personality

Mood disorders
- Major depression

Somatization disorders
- Undifferentiated somatoform disorder
- Conversion disorder
- Hypochondriasis
- Body dysmorphic disorder

Addiction disorder

Alcohol or drug abuse in primary caregiver

History of physical and/or sexual abuse

Emotional abuse or neglect in primary caregiver

Catastrophizing

Dementia or other cognitive disturbances

Excessive anxiety

High levels of psychosocial distress

Suggested Referral Questions for Psychological Evaluation

Identify any untreated or under treated major affective disorder

Axis II (personality/character) disorder
- Effects on the perception of pain, compliance, cooperation, etc.

Any untreated or under treated alcohol or drug problems (present or past)

Exceptions/attributions regarding pain and proposed therapy

Nonphysical factors and their contribution to patient's pain perception and behavior

Type and degree of social support

some patients are simply unable to psychologically cope with the realization that they will have some degree of pain for the duration of their life. These patients often have difficulty discontinuing systemic opioids following pump implantation, demand frequent increases in their IT drug dose, and generally do not demonstrate the kind of improvement in function commensurate with their stated degree of pain reduction. These patients often pose difficult long-term management problems, which make it imperative that the implanting physician clearly outlines the *reasonable* benefits and expectations of the therapy *before* even proceeding with the trial. By establishing reasonable goals and expectations at the outset, future problems can often be avoided. Indeed, clinicians who fail to follow this basic principle will, more often than not, be left to deal with an unhappy and frustrated patient.

Although pain reduction is obviously important, perhaps the most important and revealing outcome measure is improvement in function. The type and degree of functional improvement will vary between patients. Nonetheless, it is important to establish reasonable goals for functional improvement that can be measured and confirmed after institution IT drug delivery. Physical and occupational therapists can be quite valuable in assisting the clinician in developing achievable goals and monitoring the patient during therapy. These individuals also provide an independent evaluator other than the implanting physician for whom there is always going to be some inherent bias in evaluating the outcome of treatment. Besides improvement in physical function, other important and useful measures of outcome include improvements in vocational activity (i.e., return to work), increase in social and avocational activities, improvement in sleep patterns, improvement in mood/affect, reduction in adjuvant medication use, and reduction in health care utilization. There exist a number of valuable standardized and validated measurement tools that are can be utilized to assess outcomes. These include tools such as SF-36, the Brief Pain Inventory (BPI), various mood scales, etc. These questionnaires can be administered prior to treatment and at various intervals thereafter to provide objective measurements that can then be correlated with the patient's reported degree of pain reduction.

It can not be sufficiently emphasized that careful patient selection is the key to success of not only ITDD but also of any other invasive type of therapy. It should also be remembered that a successful trial does not guarantee long-term success. Indeed, many patients with an implantable pain device (ITDD system, SCS system, etc.) who incur failure of their pump battery or pulse generator never have their power source replaced because they felt the therapy was not sufficiently effective.

Aside from the criteria that will be used to determine the success or failure of the trial, there are a number of issues including: (1) the method that will be used for screening, (2) duration of the trial, (3) which drug to use and what starting dose, (4) the potential use of a placebo, and (5) what to do with systemic opioids during the trial. There are several accepted screening methods available for IT trials including include single IT bolus injection, multiple IT boluses, continuous epidural, or IT infusion.

There is currently no clear consensus among clinicians as to the ideal trial technique. Each has it advantages and disadvantages. The single IT bolus represents the simplest, most cost-effective method of screening for IT drug delivery. However, depending on the dose injected, bolus injection may result in sub-analgesic drug levels, thus producing a "false negative trial." Additionally, drug-related adverse side effects are generally more common following bolus injection than continuous infusion and these side effects may obscure the analgesic response. There is also a higher likelihood of a placebo response when using a single injection technique. Even though a single low-dose bolus of opioid produces a positive response, it is difficult to determine an accurate starting dose for the implanted pump. Finally, although single shot bolus trials are simple to perform, they do not provide the ability to evaluate the effect of the therapy on function as well as some of the other outcome measures that have been discussed. Although multiple IT boluses are more costly and time-consuming, they do provide the ability to titrate the dose and establish a dose-response curve. It is also possible with this technique to employ placebo injections for comparison with active drug administration. On the other hand, multiple boluses are often associated with an increased incidence of side effects, lack correlation with continuous infusion, and require multiple dural punctures unless a temporary IT catheter is used.

The continuous or functional trial is probably the one preferred by the majority of implanters. In fact, in a survey of implanters at academic teaching institutions conducted in 1999, 52% indicated they preferred continuous infusion for performing screening trials. Fifty-nine percent of implanters utilized the IT route, 17% used epidural infusion, and 22% employed both route at various times.[24] Intuitively, it would seem that continuous infusion would have clear advantages over bolus techniques. Continuous infusion can be performed using either the IT or epidural route. Although either is acceptable, it is important to understand the difference between IT and epidural drug delivery (Table 99.4). Regardless of the route chosen, continuous infusion allows for controlled dose titration and assessment of a reasonable starting dose once the pump is implanted. On balance there is a reduced risk of side effects with continuous infusion. There is also less chance of a placebo response since continuous infusion allows for the placebo response to dissipate over time as the trial is continued. Perhaps, most importantly, a continuous trial, particularly if continued for a sufficient period of time, allows for assessment of functional outcome which is perhaps the most important determining factor of success. Notwithstanding the advantages, there are some relative disadvantages to continuous

TABLE 99.4

COMPARISON OF EPIDURAL VS. INTRATHECAL DRUG INFUSION

Criterion	Intrathecal	Epidural
Onset of Action	Faster onset	Slower onset
Systemic Effects	Minimal systemic effects	Larger systemic effects
Duration of Effect	Long-lasting	Short-lasting
Dosage	Smaller dose (1/10 Epidural dose for morphine)	Larger dose required
Adverse Effects	Post-LP headache Risk of meningitis	More systemic side effects Risk of epidural abscess Respiratory depression

infusion. It is more complicated and requires greater expertise for placement of a tunneled catheter and is obviously more costly to perform than a bolus trial. Although it has been suggested that continuous trials are associated with increased morbidity, that has not been the author's experience. Again, as long as one adheres to strict surgical principles and is diligent in management of the patient during the trial, the morbidity is generally very low.

Anderson et al. randomized 40 patients to either IT bolus injection or continuous epidural infusion (CEI) and compared the outcome of the two groups in terms of pain reduction.[25] Twenty-seven patients had a successful trial and went on to implantation of a permanent device for long-term therapy (IT bolus = 17, CEI = 19). A "successful" response occurred in 64% and 60% of the CEI and IT bolus groups, respectively. Drug-related complications were more common in the IT bolus group (88%) compared with the CEI group (70%). The cost of CEI ($4,762) was considerably higher than that for the IT bolus group ($1,862). Follow-up data were available for 24 patients ((IT bolus = 10, CEI = 14). The patients who were trialed with a single IT bolus experienced a 57% reduction in pain scores (80 to 34) at 6 months compared to a 48% reduction in pain scores (82 to 43) in the CEI group. The authors concluded that the differences in pain and functional response to long-term IT opioids among patients selected by either trial method are not large.

The use and value of placebo administration has been raised previously. The rationale of the use of a placebo is to reduce the likelihood of a "false positive" trial. Unfortunately, normal individuals commonly exhibit a placebo response and the rate of placebo response may exceed 60% in patients with chronic pain. It may also be difficult to interpret the response, and a positive placebo response should not necessarily be taken as an equivalent to a negative trial. Once again, because a sufficiently long continuous trial will generally allow for dissipation of any placebo response, most implanters (including the author) do not utilize placebo infusion as a routine part of their screening trial.

Other issues that need to be addressed include the duration of the trial, the specific medication(s) and dosages administered, and the handling of baseline systemic opiates during the trial. There is currently no standard protocol in existence that addresses issues such as trial duration, trialing with specific medications, or how to handle baseline opioids during the trial. The author's current protocol includes slowly weaning the patient off all opioid medications and giving the patient an opioid-free drug holiday for 6 weeks prior to commencing the trial. An exception is made for the patient with pain related to cancer. This is clearly not the standard practice of most implanting physicians and could even be considered somewhat controversial. This practice is based on the fact that almost all patients referred to the author (and probably to most implanting physicians) for IT opioids have been on long-term systemic opioids, sometimes at exceedingly high doses. Under these circumstances it is likely that the patient has developed opioid tolerance and/or hyperalgesia. Under such circumstances, it is very difficult if not impossible to obtain significant pain reduction with relatively low doses of IT opioids. It has also been our experience that, even in cases where it is possible to obtain reasonable analgesia, many patients are then reluctant to taper off their systemic opioids. This practice requires extreme dedication by both the patient and clinician and an indelible trust on the part of the patient in his/her physician.

A tunneled externalized catheter is implanted and a continuous functional outpatient trial is conducted for anywhere between 2 and 4 weeks. By providing the patient a drug holiday, it is possible to begin the IT infusion at very low doses (usually around 0.25–0.5 mg per day of IT morphine) of medication. For patients with nociceptive pain or mixed nociceptive/neuropathic pain, we usually start with an opioid. If the pain is predominantly neuropathic, bupivacaine or clonidine is added to the infusion. The patient is evaluated at least three times per week to determine the analgesic response, degree of functional improvement, and the development of side effects. Incremental dose escalation is performed and if a significant degree of pain reduction or functional improvement is not realized by the time the patient reaches 2 to 4 mg of IT morphine (or its equivalent) per day, the trial is terminated and the catheter is removed. Again, the success or failure of the trial is based on the goals that have been agreed on by the clinician and patient prior to proceeding with the trial. If the trial is deemed a success, the patient is then returned to the operating room for revision of the catheter and implantation of the pump. Patients are provided short-acting opioids during the immediate postoperative period for management of surgical pain and these are weaned and discontinued over a 2-week period. Patients are routinely counseled that they may experience incident pain that will usually be transient depending on their daily activities and are provided with nonpharmacological coping strategies for managing these situations. During the past 2 years that we have been using this protocol, we have realized a higher degree of success compared with previous implants and have been able to maintain patients on a low stable dose of mediation. Interestingly, there have been occasional patients whose pain actually improves once they have been weaned off systemic opioids to such a degree that they never even proceed with the trial.

IMPLANTABLE PUMP TECHNOLOGY

Fully implantable infusion pumps were first used for the continuous delivery of heparin, insulin, and intraarterial chemotherapy and later applied to intraspinal drug infusion. There are two basic types of fully implantable devices for continuous delivery of IT medications: constant flow pumps and programmable pumps.[26,27]

The first generation pumps were constant flow devices preprogrammed to deliver medication at a single, fixed, constant rate. The initial prototype of the constant flow pump consists of a hollow titanium two-chambered device which consists of a drug reservoir and a chamber that contains a volatile two-phase fluorinated hydrocarbon (FHC) which functions as a propellant. Installation of medication into the drug reservoir results in compression of the propellant which transforms it to a liquid state. As the propellant is warmed by the patient's body temperature, the FHC is transformed from liquid to vapor which then exerts continuous pressure on a system of bellows which expand and force the drug out of the reservoir and into the IT catheter. The standard pump holds a volume just under 50 cc and is filled by puncturing a special inlet septum with a noncoring Huber needle. Flow rates designed to deliver 1.0 to 6.0 cc's per day are pre-set and calibrated at the factory. Although this pump is relatively simple and inexpensive compared to fully programmable devices, the major disadvantage is that dosage alterations require the pump to be drained and refilled with a different concentration of drug. Also, flow rates can be altered by certain physical and physiological factors and these fluctuations in drug delivery rate can result in parallel fluctuations in analgesia (Table 99.5).

The second type of fully implanted drug delivery device is a fully programmable pump such as the SynchroMed Infusion System (Medtronic Neurological, Minneapolis, MN). The current model (SynchroMed II) consists of a collapsible drug reservoir into which the drug is injected through a self-sealing septum. The pump is powered by a lithium-cadmium battery which drives an internal peristaltic pump. The pump contains an electronic module with a computer chip which allows one to program variable infusion rates, bolus injections, etc. A small radiofrequency antenna allows the pump to be noninvasively interrogated by telemetry and programmed with an external handheld programmer. The pump can be programmed for a variety of delivery modes which can be tailored to the individual circumstances. The pump

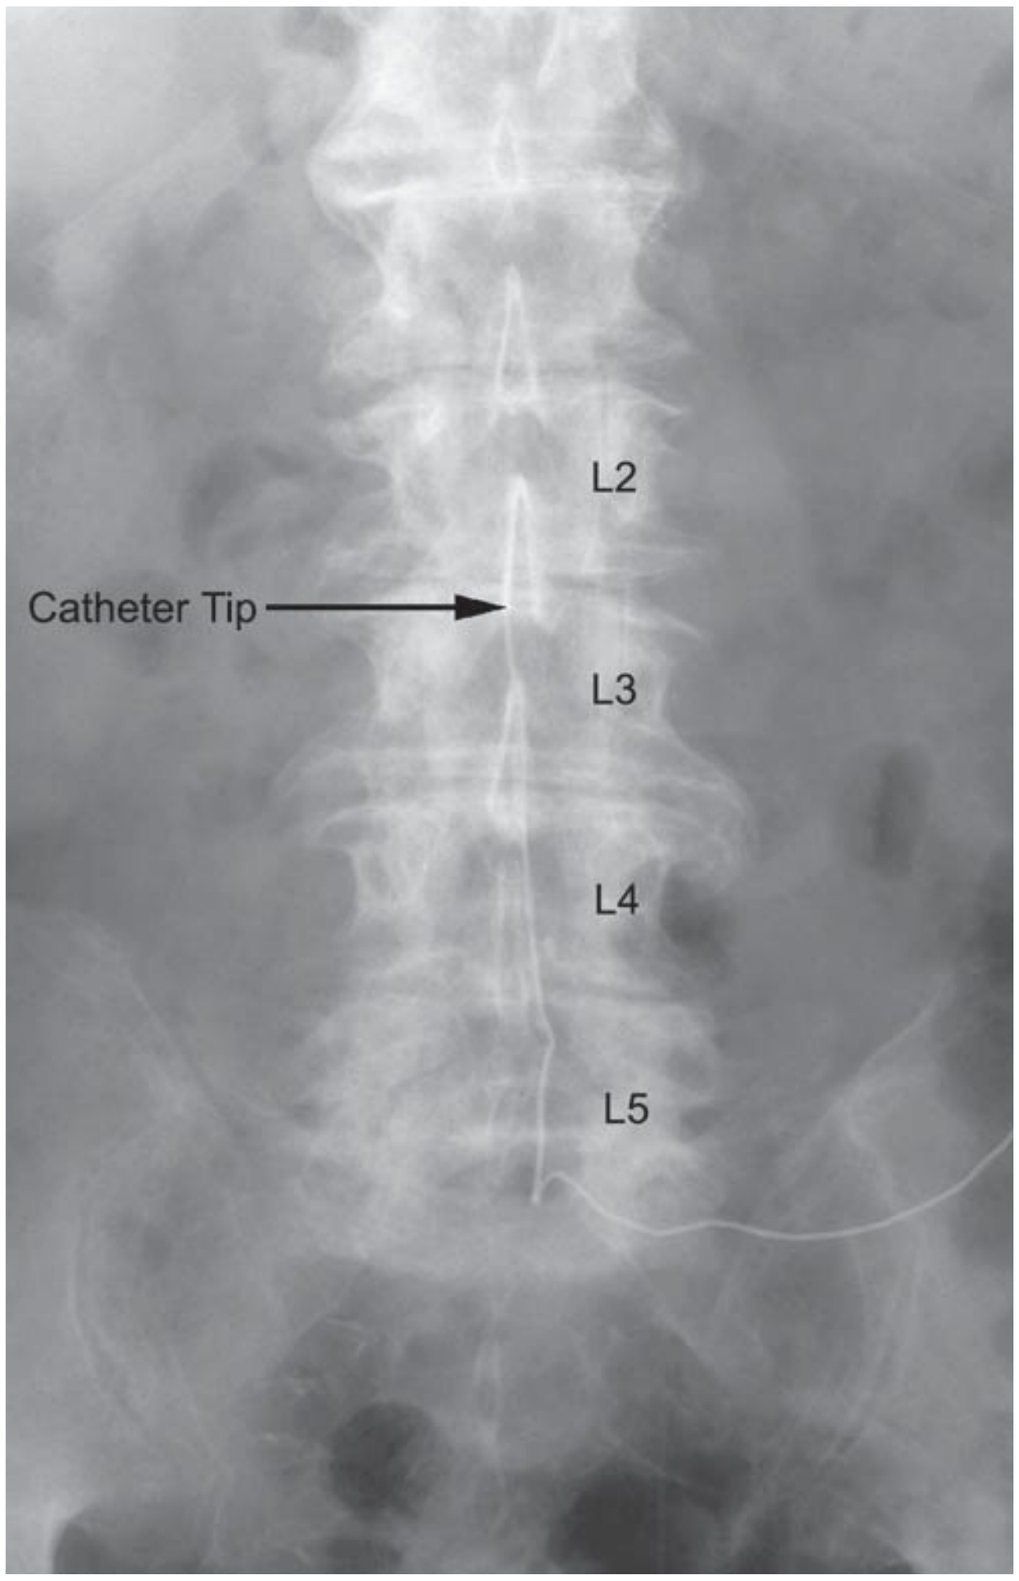
TABLE 99.5

FACTORS AFFECTING DRUG DELIVERY WITH CONSTANT FLOW INFUSION PUMPS

- Body temperature
  - — calibrated for 37°C
  - — 10% to 13% increase in flow per 1°C rise
- Geographical elevation
  - — calibrated for elevation of implanting center
  - — flow increases at higher altitudes
- Blood pressure (at site of drug discharge)
  - — inversely proportional
  - — 3% change for every 10 mm Hg MAP
- Drug viscosity
- Reservoir capacity
  - — flow rate calibrated for 50% capacity
  - — 4% variability at extremes of volume
- Pump "Dead Space"
  - — 4 mL "dead volume"
  - — correction factor for concentration

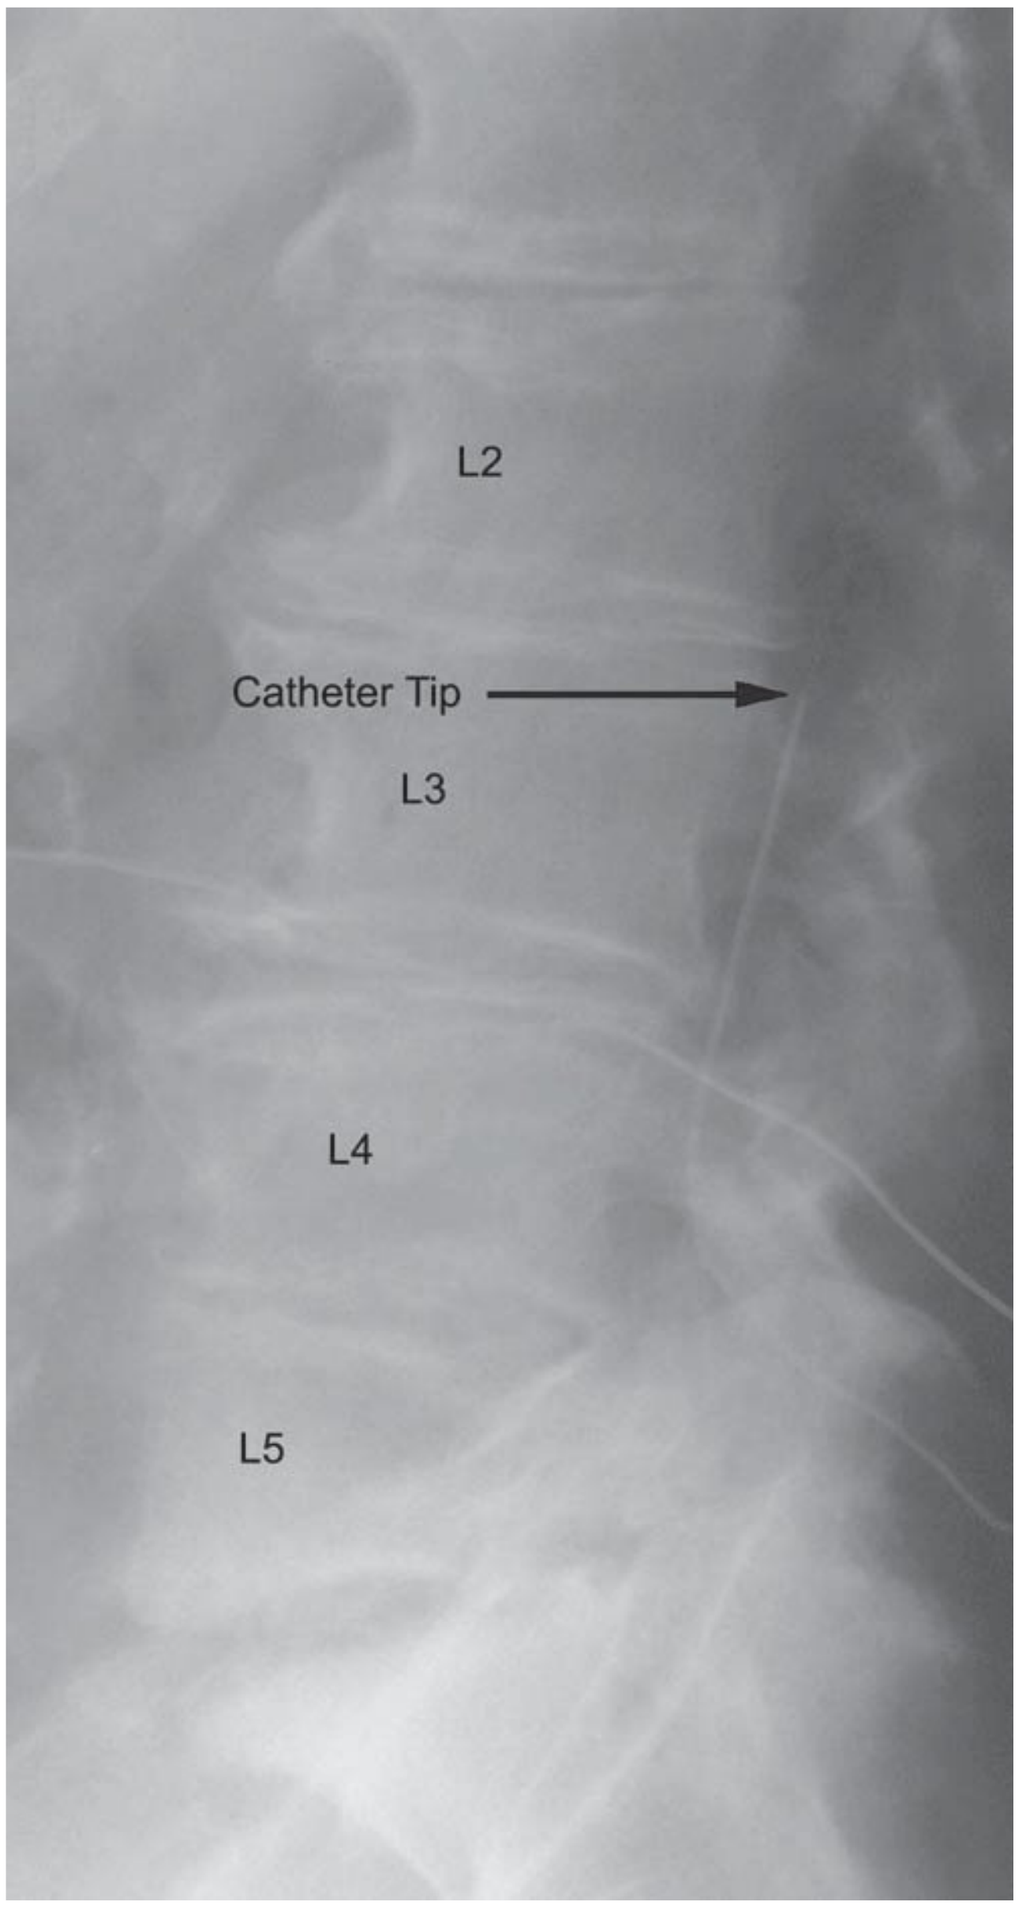
comes with a catheter access port (CAP) side port which is extremely valuable for trouble shooting catheter-related problems.

SURGICAL TECHNIQUE OF PUMP IMPLANTATION



Implantation of an ITDD system is usually a straightforward procedure for the properly trained and experienced implanter. However, despite the perceived simplicity of the implant procedure, there are numerous pitfalls that can lead to complications. It is clearly preferable to avoid rather than have to manage complications. In general, many complications can be avoided through attention to meticulous aseptic operative technique, gentle tissue handling, and adherence to certain technical points in terms of catheter insertion and pump implantation.[28] It should be clearly recognized that implantation of a permanent ITDD should only occur following a successful trial.

Implantation of an ITDD can be performed either under local anesthesia with IV sedation or general anesthesia, depending on the clinician's preference and the overall condition of the patient. All patients should receive a single dose of prophylactic antibiotics directed toward the normal skin flora within 30 minutes of incision. No postoperative antibiotics are prescribed as there is no literature to support their use in an otherwise clean surgical wound. The patient is positioned and secured in a lateral decubitus position. The pump can be placed on either side, either in the subcostal region or lower quadrant of the abdomen. It is important to position the pump such that it does not impinge on or sit directly over any bony prominence (e.g., iliac crest, rib cage) as this is likely to result in local pain and the need for revision of the pump pocket site. Other factors that occasionally need to be taken into account include the presence of either current or expected ostomies (e.g., percutaneous gastrostomy and/or suprapubic catheter) and body habitus (emaciation or morbid obesity). Although implantation of a pump is not absolutely contraindicated in these patients, there is likely a higher risk of infection and every effort should be made to implant the pump as far from these sites as possible.



Prior to pump implantation, all patients should undergo an appropriate imaging study of the spine (CT with IV contrast, CT-myelography, or MRI) to ensure there is no anatomical obstruction that might preclude safe catheter insertion. The first step is to insert and properly position the catheter in the subarachnoid space.[28] This should always be performed with the use of intraoperative C-arm fluoroscopy to verify the correct position of the catheter. A small stab incision is made in the mid-lower lumbar region based on fluoroscopic imaging. Keeping in mind that the spinal cord terminates around T12 or L1, needle entry should be caudal to this level, ideally at L2-3 or L3-4. The exact insertion site may vary depending on the spinal anatomy, the presence of spinal instrumentation, etc. A lumbar puncture is performed with a no.15 gauge Tuohy needle using a paramedian approach with a shallow insertion angle. Midline insertion should be avoided as the steep angle required makes catheter insertion more difficult. Additionally, a midline catheter will likely incur constant stress from pinching between the spinous processes and this more often than not leads to fracture of the catheter. The shallower the angle of insertion, the easier the catheter will advance and the more likely it is that the catheter will be ultimately wind up in the dorsal subarachnoid space. After obtaining good flow of CSF, the catheter is inserted through the needle and is threaded rostrally. Either a one- or two-piece catheter can be used depending on the clinical situation and the preference of the implanter. The catheter should pass easily with minimal resistance. Under no circumstances should the catheter be forced passed the point of an apparent obstruction. Doing so can lead to complications including inadvertent entry of the catheter into the substance of the spinal cord which can result in serious neurological sequelae. The tip of the catheter should generally be positioned in the upper most portion of the lumbar cistern (Fig. 99.1). For the average patient with failed back surgery syndrome and pain in the axial lumbar region and/or lower extremities, this is an ideal position given that most of these patients will be receiving a hydrophilic agent such as morphine or hydromorphone. If the pain topography is more rostral, such as the cervical spine or upper extremities, the catheter may need to be positioned more rostrally in order to get a sufficient concentration of the drug to the target area of the spinal cord. If one is using a predominantly lipophilic agent (e.g., fentanyl or sufentanil), the tip of the catheter needs to be positioned within a couple of levels of the segmental level of pain. Once the catheter has been advanced to the desired level, the guide wire is gently removed. This is best performed by straightening out the catheter and applying gentle traction to the guide wire. CSF should be observed to flow spontaneously from the end of the tubing although it is occasionally necessary and acceptable to gently aspirate the catheter to commence CSF flow. Once CSF flow is confirmed, the tubing is temporarily occluded with a smooth clamp to prevent loss of excessive amounts of CSF.

With the Tuohy needle still in place to prevent inadvertent damage to the catheter, a skin incision is made incorporating the needle and carried down to the lumbodorsal fascia. A small pocket should be fashioned to accommodate a strain relief loop of catheter and prevent kinking in the lumbar incision. The needle is then withdrawn leaving the catheter in place and the catheter is anchored at the fascial insertion site to prevent migration using one of the standard anchoring devices and permanent suture material. The author's preference is to use a butterfly-type V-wing anchor which, when sutured in placed, closes around the catheter. This technique avoids placing any suture material around the catheter itself and minimizes the risk of occlusion.

With the catheter securely in place, the next step is to create a subcutaneous pocket in the abdominal region. The pocket should be sufficiently large to easily accommodate the pump and allow closure of the wound without any significant tension. However, one should avoid making the pocket too large as this can allow the pump to rotate within the pocket in the event the anchoring sutures break. Using a tunneling rod, the catheter is then tunneled from the back to the abdominal pocket and continued

Philadelphia: Lippincott Williams & Wilkins; 2006:164–165, Figures 15-5 and 15-6.)

flow of CSF is confirmed from the catheter. If a two-piece catheter is used, the distal (i.e., intrathecal) catheter is trimmed by an appropriate amount (if so desired) and then connected to the proximal catheter using a pin connector; this connection is then covered with a strain relief sleeve to prevent kinking at the connection site. This pin connector is then used as a second anchoring site, thereby creating a gentle strain relief loop between the fascial anchor and the pin connector. The amount of the distal catheter that is trimmed should be measured and recorded in order to accurately calculate the catheter volume. Once the pump has been prepared and filled with drug (this will vary depending on the type of pump), it is brought onto the surgical field and connected to the proximal catheter. The pump is then placed into the subcutaneous pocket, ensuring that the refill side is toward the skin and secured in place with permanent sutures, utilizing either the suture loops attached to the pump or by placing the pump into a Dacron pouch and securing the pouch to the fascia. This is an important maneuver to prevent the pump from flipping, thus preventing access to the refill port. Any excess proximal catheter should be gently coiled beneath the pump. It is generally recommended that a generous amount of proximal catheter be left in the pouch since this will create an additional strain relief loop in the system. After securing the catheter and anchoring the pump, the catheter access port (if there is one) should be entered with a 24-gauge noncoring needle and CSF aspirated and reinjected to ensure patency of the system. A small amount of non-ionic preservative-free contrast can also be injected to confirm patency of the system. If contrast is used it should be flushed from the catheter using preservative-free saline. The surgical wounds are then meticulously closed in anatomical layers. The pump can then be programmed and the system primed to bring active drug to the tip of the catheter.

MEDICATIONS FOR INTRATHECAL DRUG DELIVERY

Although IT morphine often provides adequate analgesia with an acceptable side effect profile, it is ineffective or poorly tolerated in many patients. Initially, it was believed that IT delivery of opiates at fractional doses of those used systemically or even epidurally to

achieve effective analgesia would eliminate many of the problems associated with systemic opiates. In retrospect, this was a rather naive assumption. As more infusion systems are implanted (particularly for noncancer pain), it has become apparent that many of the difficulties associated with the long-term administration of systemic opiates such as physiologic tolerance, hyperalgesia, and other dose-limiting side effects (e.g., nausea, constipation, pruritus, peripheral edema, respiratory depression) also occur with IT opiates. It has become more apparent that spinal opiates are either completely or relatively ineffective in treating many neuropathic pain syndromes (e.g., spinal cord injury pain, postherpetic neuralgia, and reflex sympathetic dystrophy), albeit with some exceptions. Basic research in animal models of pain shows that multiple neurotransmitters (e.g., glutamate, gamma-aminobutyric acid [GABA], substance P [SP], acetylcholine, and opioids) are intimately involved in the neurophysiology of pain transmission.[13,29] Consequently, much of the research effort in spinal drug infusion has centered around the investigation and development of alternative pharmacologic classes of agents that have antinociceptive effects when administered intrathecally in animals. These agents are discussed later. Although not currently approved by the FDA specifically for IT therapy, the use of some of these agents (e.g., clonidine, local anesthetics) is nonetheless now well accepted, and they are routinely used ''off-label'' as reasonable alternatives to morphine or other opiates.

Opioids

Morphine

The discovery of spinal opioid receptors in the 1970s represents the initial event that spawned interest in the IT administration of morphine. Several types of opioid receptors have been identified (mu, delta, kappa). Mu receptors are the most important subtype in so far as the major clinical effects of morphine are concerned.[13] Indeed, high concentration of mu receptors have been identified in the dorsal horn of the spinal cord, the presumed spinal site of action of morphine and other opioids used for IT infusion. Intrathecal morphine is considered to be about 10 times more potent than the same dose administered epidurally and approximately 100 times as potent as the same dose given IV. The most commonly used conversion values for morphine are: 1 mg IT morphine = 10 mg epidural morphine = 100 mg IV morphine = 300 mg oral morphine. It should be clearly understood that these figures represent estimates and that the relative potency of morphine administered by different routes may not be the same in all patients or in patients who have been receiving chronic systemic therapy.

The advantages of IT drug administration include the lack of an absorption phase and essentially 100% bioavailability. Because of the small volume of distribution (spinal CSF volume is approximately 75 mL) of morphine when injected or infused into the CSF, a dose of IT morphine yields significantly higher CSF concentration than that which occurs when given epidurally where significant vascular absorption occurs. In addition, because the rate of elimination of morphine from the CSF and plasma is similar, the duration of action of IT morphine is relatively long. Following IT administration, morphine is not detectable in serum for the first 2 hours.[30] Because morphine is a hydrophilic compound, there is slow rostral spread of the drug through bulk flow of CSF, one factor responsible for clearance of morphine from the CSF. This slow rostral spread is also thought to be responsible for the delayed respiratory depression that can occur following IT administration, particularly in opioid-naïve patients. Studies have indicated that following IT infusion of morphine in the upper lumbar region, a steady-state concentration gradient develops over a period of about 72 hours, with a lumbar: cervical concentration ration of around 7–8:1. Elimination of IT morphine occurs through vascular absorption through the blood supply of the spinal cord. CSF elimination of opioids in general is bioexponential and dependent on the lipid solubility of the drug. With a single bolus injection of morphine, there is thought to be little metabolism of the drug. However, with chronic infusion morphine is metabolized to morphine-6-glucuronide (M-6-G) which has been shown in animal studies to have a potency 10 to 45 times that of morphine itself.[30] Preservative-free morphine is currently the only opioid that is approved for intrathecal use by the FDA.

Hydromorphone

Despite the paucity of clinical studies, the use of IT hydromorphone as an alternate opioid has steadily increased. Hydromorphone was initially utilized for ITDD in patients who manifested intolerable side effects to IT morphine or inadequate analgesia. Indeed, based on the large clinical experience with hydromorphone, this agent has been recommended as a ''Line 1'' agent by the most recent Polyanalgesia Consensus Conference.[31] Intrathecal hydromorphone is approximately 5 to 6 times more potent than IT morphine and is somewhat more lipophilic.[13] Perhaps its main attraction is that IT hydromorphone is generally associated with fewer side effects than is IT morphine.

Fentanyl and Sufentanil

There has been a considerable amount of both human and animal research regarding the IT use of both fentanyl and sufentanil.[13] Both fentanyl and sufentanil are highly potent mu receptor agonists which are highly lipid soluble. Both have a rapid onset (approximately 10 minutes) and relatively long duration of action (1–4 hours for fentanyl, 2–6 hours for sufentanil) following acute IT administration. Because of the lipid solubility of these agents, it is important that the tip of the delivery catheter be positioned within a few spinal segments of the segmental pain level. While this is not particularly critical for treatment of axial lumbar and/or lower extremity pain, it is important for treatment of pain at more rostral levels. In such cases, if the catheter is not located relatively close to the segmental level of pain, the drug will be absorbed into the spinal cord preventing the development of adequate concentration at the intended target site.

There have been numerous preclinical studies that have documented the analgesic efficacy of IT fentanyl or sufentanil in animals, mostly in response to acute or bolus administration. The long-term clinical use of these agents is limited to only a few studies containing small numbers of subjects.[13,32] Overall, the analgesic response to long-term infusion to either agent was favorable and relatively well-tolerated. Effective dosages have been in the microgram range: 10 to 115 μg/day for fentanyl and 12 to 77 μg/day for sufentanil.

Meperidine. There is relatively little information regarding the use of IT meperidine. There has been a single prospective study detailing the chronic IT delivery of meperidine, with or without clonidine in 10 patients with cancer-related pain.[31,33] The study showed that patients experienced a significant reduction in neuropathic pain. However, between 1 and 3 weeks into therapy, it was discovered that plasma levels of meperidine and its metabolite normeperidine rapidly increased. In fact, the concentration of normeperidine exceeded that of meperidine in one patient. These observations are important as increased levels of meperidine and/or normeperidine can lead to neurotoxicity.

Methadone. Methadone is a racemic mixture of the D- and L-isomers that produce different effects. The D-isomer has been shown to block the N-methyl-D-aspartate (NMDA) receptor in both in vitro and in vivo models. There has been a single prospective clinical trial of IT methadone for the treatment of chronic noncancer pain in patients who had failed prior IT trial with

other IT analgesics.[34] Thirteen of 24 patients (54%) reported some degree of pain reduction during the course of treatment, prompting the authors to conclude that methadone might be a potentially useful neuraxial agent for treatment of chronic pain. However, there have been no stability or toxicity studies to allow one to conclude that this medication is safe for long-term use.

Local Anesthetics

Local anesthetics have played a central role in the treatment of pain for decades, although it was not until the 1990s that continuous infusion of these agents was routinely used.[6] Currently, local anesthetics such as bupivacaine are commonly given by continuous chronic IT infusion, often combined with opiates for the treatment of both cancer and nonmalignant pain. In low concentrations, local anesthetics such as bupivacaine are nontoxic and alter neurotransmission in a predictable and reversible fashion.

Bupivacaine is the most common local anesthetic used for continuous IT infusion. It appears to be most effective in patients with a neuropathic component of pain, although it may also provide some degree of benefit for patients with nociceptive pain. The utilization and dose escalation of bupivacaine is mainly limited by its side effects, which include sensorimotor blockade at higher doses, and hemodynamic instability. Usually, clinically relevant side effects do not occur with doses less than 15 mg/d, although administration of doses, as high as 118 mg/d has been reported with apparently no adverse effects. Optimal dosing is reached with progressive titration beginning with a daily dose of 3 to 5 mg/d. There has been some interest in liposomal encapsulation for local delivery by the IT route because this tends to reduce the toxicity and cardiovascular effects while increasing the anesthetic duration.

Ropivacaine is a long-acting amide type of local anesthetic that is unique in that it blocks sensory nerve fibers to a greater extent than motor fibers. It is similar to bupivacaine in onset and duration of sensory blockade. The potential advantage of ropivacaine is that it produces less motor block and has less cardiovascular toxicity than bupivacaine. As of yet there have been no clinical studies published on the long-term use of IT ropivacaine for the management of chronic pain.[31]

Tetracaine is another local anesthetic that acts through blockade of sodium channels. Unfortunately, tetracaine has been shown to have direct neurotoxicity in animals manifested by damage to both the dorsal and ventral roots, chromatolytic deterioration of motor neurons, and vacuolation of the spinal cord. Because of the potential neurotoxicity, tetracaine should not be used for long-term IT drug delivery.[31,33]

Alpha-2 Adrenergic Agonists

Alpha-2 adrenergic receptors play an important role in spinal antinociception. Alpha-2 receptor agonists in general, and clonidine in particular, are believed to produce their antinociceptive effects through inhibitory interactions with both pre- and postsynaptic primary afferent nociceptive projections onto secondary neurons in the spinal dorsal horn. Clonidine in particular has been felt to act by postsynaptic activation of descending noradrenergic inhibitory systems. It has also been suggested that the analgesic effects of this class of drugs might also be produced through the inhibition of SP release.[35] Clonidine-induced spinal analgesia is reversed by alpha-adrenergic antagonists such as yohimbine but not by naloxone, providing further evidence of it mechanism of action.

Clonidine is one of the best studied of the nonopioid substances which have been adapted for intraspinal delivery. Clonidine has been shown to have analgesic action in both cancer and nonmalignant pain syndromes when administered intraspinally.[13] Clonidine is a highly lipid-soluble drug which is rapidly absorbed and eliminated from CSF. Bolus administration of IT clonidine results in dose-dependent analgesia at doses of 150, 300, and 450 μg and effective analgesia has also been shown with continuous intrathecal infusion. Intraspinal clonidine appears to be devoid of any local neurotoxicity. The rapid onset of antinociceptive action when given intrathecally provides a strong argument that the major pharmacologic effects occur at the segmental spinal level. However, delayed supraspinal analgesic effects can not be completely discounted since it has been shown that application of clonidine to the locus ceruleus results in analgesia. Since IT injection does not usually result in high cisternal concentrations of clonidine, these supraspinal effects might be explained by systemic absorption and central redistribution of the drug.

Although clonidine is the most common drug in this class to be used for spinal analgesia, other agents such as epinephrine, tizanidine, and dexmedetomidine continue to be studied for spinal infusion. Because the antinociceptive actions of the alpha-2 adrenergic agonists (and most of the other alternative agents discussed later) occur through a nonopioid mechanism, they are often effective in individuals who have become tolerant to morphine or other opiates. These agents (clonidine in particular) shift the opioid dose-response curve to the left and appear to be synergistic with opioids; in other words, the analgesia produced by the combination of clonidine with an opiate often results in a magnitude of analgesia greater than that produced by either agent alone. The major side effects of spinal clonidine include hypotension, bradycardia, and sedation. The hypotensive effects most commonly occur with lower and moderate doses and are generally counteracted at higher doses by a direct peripheral vasoconstrictive effect.[36] Unlike the opiates, clonidine does not cause respiratory depression. Clonidine has been studied in various animal models for possible neurotoxicity prior to its clinical use and has been found safe.[37] Currently, clonidine is approved for medium-term epidural infusion in patients with cancer pain.

Eisenach et al. examined the effects of both IV and IT clonidine on both nociceptive and neuropathic pain in human volunteers.[38] Nociceptive pain was produced using thermal heat stimulation; neuropathic pain was induced by an intradermal injection of capsaicin, which consistently produces sustained pain, hyperalgesia, and allodynia, hallmarks of neuropathic pain. Injection of 150 mg of IT but not IV clonidine resulted in a significant reduction in nociceptive pain from noxious thermal stimulation. The same dose of IT clonidine also resulted in significantly less pain and hyperalgesia following intradermal capsaicin injection, although development of allodynia was not affected. Both IV (150 micrograms) and IT (50 and 150 micrograms) clonidine reduced mean arterial blood pressure to a similar degree. Filos et al. examined the dose-response hemodynamic and analgesic effects of IT clonidine in humans in a prospective randomized double-blind study. Postoperative patients received 150, 300, or 450 micrograms (Groups I, II, and III, respectively) of IT clonidine by bolus lumbar injection 45 minutes after tracheal extubation.[39] Analgesia was assessed by Visual Analogue Scale (VAS) scores at standard time points for 24 hours following surgery, as was blood pressure, heart rate, sedation, and respiratory rate. Pain relief was defined as "the time to first request (in minutes) for supplemental analgesics." IT clonidine reduced pain scores in a dose-dependent fashion. Pain relief was as follows: Group I, 402 ± 75 minutes; Group II, 570 ± 76 minutes; and Group III, 864 ± 80 minutes, with significant differences ($p < 0.01$ to 0.001) observed among all three groups. Only the 150-microgram dose (Group I) produced a significant reduction ($p < 0.05$) in mean arterial blood pressure (21% ± 13%). Mild sedation occurred in all three groups, but respiratory rate was unaffected.

Clonidine has become a popular agent for spinal infusion in patients with reflex sympathetic dystrophy (RSD), now know as complex regional pain syndrome (CRPS) type I. Rauck et al. studied the efficacy of epidural clonidine in 26 patients with severe

pain from CRPS I using a randomized, double-blind, placebo-controlled design.[40] Cervical or lumbar catheters were placed in patients with upper or lower extremity RSD, respectively. Epidural clonidine (300 or 700 micrograms) and placebo were randomly administered on 3 consecutive days and the analgesic response assessed at specified intervals for 6 hours following injection using VAS scores and the McGill Pain Questionnaire (MPQ). Patients considered positive responders were offered entry into a trial of continuous epidural clonidine infusion. Within 20 minutes of injection, both doses of clonidine but not placebo produced significant reductions in both VAS and MPQ scores that persisted for the 6-hour study period. Blood pressure was reduced by a similar amount with both clonidine doses. Nineteen patients were subsequently treated with continuous clonidine infusion (32 ± 6 μg/h; range 14 to 50 μg/h) for 43 ± 8 days (range 7 to 225 days). Their VAS scores, which were measured at weekly intervals during infusion, were significantly reduced compared with those recorded prior to clonidine therapy. Clonidine is currently approved by the FDA for continuous epidural infusion. Clonidine is not currently approved for intrathecal infusion. However, it may receive FDA approval for this application in the near future.

Although clonidine has been the most widely studied of the alpha-2 agonists, several other agents have also received attention as potential spinal analgesic agents. Tizanidine is another alpha-2 agonist that has shown promise as a potential analgesic substance. Leiphart et al. studied the effects of tizanidine in a rat model of mononeuropathic pain that is believed to mimic the hyperalgesia and allodynia typical of many neuropathic pain syndromes in humans.[41] Tizanidine increased the intensity of the mechanical stimulus required to induce paw withdrawal and reduced the duration of limb withdrawal from both normal temperature and cooled surfaces in a dose-dependent fashion. The effects of tizanidine were limited to the hyperalgesic limb and served only to normalize reactive latencies. However, morphine affected both the experimental and unaffected hind limb and increased withdrawal latencies to supernormal values. These findings suggest that IT tizanidine may be more specific for the hyperalgesia and allodynia associated with neuropathic pain states and perhaps may be valuable in managing patients that exhibit these findings.

Dexmedetomidine, another alpha-2 agonist with a higher alpha-2 receptor affinity than clonidine, has been studied experimentally for its effects on neuropathic pain.[42] A dose of 1 μg of dexmedetomidine or 10 μg of clonidine administered intrathecally following sciatic nerve section resulted in a significant reduction in autotomy behavior (self-mutilation thought to be a sign of neuropathic pain) compared with both IT morphine and saline controls. Interestingly, morphine (but not alpha-2 agonists) caused a significant reduction in autotomy behavior when given prophylactic ally or before sciatic nerve section. This finding suggests that morphine may prevent autotomy if administered prophylactic ally, whereas alpha-2 agonists may be useful for treating established pain on a chronic basis. This observation could potentially have practical implications on the prevention or treatment of certain pain states such as pain following peripheral nerve injury or phantom pain. To date there have been no studies in humans to investigate the efficacy or toxicity of this agent when given intrathecally.

Finally, catecholaminergic analgesia has been studied in animals using adrenal medullary allografts and, more recently, in humans with chromaffin cell xenografts.[43,44] When injected into the spinal subarachnoid space, catecholamines have been shown to produce profound analgesia. Catecholamine analgesia may involve an independent mechanism as well as concurrent activation of opioid systems within the spinal dorsal horn. Implantation of adrenal medullary tissue into the subarachnoid space has been shown to produce elevated levels of catecholamines and met-enkephalin, an endogenous opioid peptide. Using a model of chronic pain in the rat, Sagen et al. have shown that adrenal medullary transplants reduce pain responses to acute noxious stimuli.[43] Furthermore, the analgesic effects are blocked by naloxone and are partially inhibited by phentolamine, providing further evidence of a strong opiate mechanism for this therapy.

Buchser et al. implanted purified bovine chromaffin cells in seven patients with terminal cancer and intractable pain.[44] Four patients suffered from neuropathic pain, and two from nociceptive pain, and the remaining patient had a mixed type of pain. The cells were introduced in a hollow fiber with a semipermeable membrane that was implanted with a minimally invasive procedure in the IT space. No pharmacologic immunosuppression was given. The implants remained in place for a mean duration of 74 days (range 41 to 172). All of the implants were retrieved and analyzed after the patients died. Opiate reduction in the four patients receiving epidural morphine at the time of the implant ranged from 30% to 100%. McGill pain ratings improved 50% to 80% in five patients. Pain reduction measured by VAS scores improved between 10% and 80% in five patients and was unchanged in two patients. Viable cells were identified after explantation in six of the seven patients. Although this study represents the first successful trial of encapsulated xenogenic cells in humans, the preliminary findings regarding analgesia probably warrant a randomized study to evaluate the efficacy of this therapy.

Calcium Channel Antagonists

Calcium is a critical element in the regulation of intracellular processes, including modulation of neuronal excitability, release of neurotransmitters, activation of second messenger systems, and gene transcription. Calcium has been found to play an important role in nociception and pain transmission. Regulation of calcium entry into cells is controlled by voltage-sensitive calcium channels (VSCCs) consisting of at least six neuronal subtypes (L, N, P, Q, R, and T). VSCCs are abundantly expressed on presynaptic nerve terminals where they regulate the calcium-dependent release of neurotransmitters that control synaptic transmission. As it turns out, N-type VSCCs are concentrated in the most superficial laminae of the dorsal horn of the spinal cord, where most primary nociceptive afferent fibers (A-delta and C fibers) terminate. Selective antagonists of N-type calcium channels such as ziconotide (also known as SNX-111), a synthetic agent derived from omega-conopeptide that selectively binds to N-type VSCC, have consistently been antinociceptive in animal models of acute, chronic, and neuropathic pain.[45,46] Based on animal studies, numerous studies of ziconotide have been conducted in humans to determine both safety and efficacy. Based on these studies ziconotide was ultimately approved by the FDA for IT use in humans.[47,48]

Staats et al. conducted a double-blind, randomized, placebo-controlled trial of the safety and efficacy of ziconotide (SNX-111) in 102 patients with chronic intractable neuropathic pain with VAS scores in excess of 50 (0 to 100 mm scale), despite the use of systemic opiate analgesics.[49] A positive response was defined as a reduction in baseline VAS score after 6 days of at least 30% without any concomitant increase in opiate requirements. Patients that received SNX-111 experienced a 37% reduction in VAS scores compared to only 3% in the placebo group ($p < 0.0002$). Adverse events included dizziness, nausea, nystagmus, abnormal gait, urinary retention, constipation, and confusion. Another study by Brose et al. reported the results of a Phase I/II open-label, dose-escalation study of IT SNX-111 in 31 patients with intractable pain that had been inadequately controlled with IT morphine.[50] Many of these patients had neuropathic or mixed neuropathic-nociceptive pain syndromes, including cancer, AIDS pain, phantom limb pain, and poststroke (thalamic) pain. SNX-111 was administered for up to 7 days with assessments performed at 4-hour intervals. Daily-dose escalation de-

pended on the patient's response. Twenty-five patients (84%) experienced what was considered to be partial or complete pain relief that was accompanied by concomitant reductions in pain medication requirements. The most common side effects (the majority of which were reported by Staats) included mental confusion, word-finding difficulties, nystagmus, gait, and balance problems. The frequent side effects associated with intrathecal ziconotide have limited the overall use of this agent.

N-methyl-D-aspartate Receptor Antagonists

The involvement of excitatory amino acids (EAAs) and the NMDA receptor system in nociceptive transmission, along with a clearer understanding of the development of central sensitization and wind-up phenomena, have generated considerable interest in developing antagonists of this receptor for the treatment of chronic pain, particularly neuropathic pain states. NMDA receptors alter opioid receptor sensitivity in a variety of pain states and have been implicated in the development of both opioid tolerance and opioid-induced hyperalgesia. Ketamine has been the most studied and has been used both epidurally and intrathecally for the treatment of postoperative and chronic pain.

Yang et al. conducted a double-blind crossover study to evaluate the effects of ketamine on spinal morphine analgesia in 20 patients with cancer pain.[51] All patients underwent placement of an IT catheter for injection of spinal analgesics. Patients were randomly assigned to initially receive twice-daily bolus injections of either morphine alone or morphine plus 1 mg of benzethonium-preserved ketamine. The initial dose of IT morphine was 0.05 mg; this dose was escalated in daily increments that did not exceed the preceding dose until acceptable analgesia was achieved. After achieving and maintaining adequate analgesia, patients were crossed over and the titration was repeated. Although overall pain reduction was comparable in both groups, patients that received a combination of morphine and ketamine required on average less than 50% (0.17 to 0.02 mg/d) of the daily morphine dose for acceptable analgesia compared to those that received morphine alone (0.38 to 0.04 mg; $p < 0.05$). Moreover, the frequency with which patients required upward titration of their morphine dose was considerably less in those that received both morphine and ketamine. Finally, the rescue dose of morphine required for breakthrough pain was more than three times greater in the group that received morphine alone.

To date, the use of NMDA receptor antagonists has been limited due to side effects. All of the NMDA receptor antagonists to some extent produce phencyclidine-like side effects such as disinhibition, hallucinations, paranoid delusions, and rises in arterial blood pressure.[52] There is also animal data suggesting that some of the NMDA antagonists may be neurotoxic when administered intrathecally. Using a sheep model for IT infusion, Hassenbusch et al. conducted a randomized, double-blind toxicity study of three NMDA antagonists: dextrorphan, dextromethorphan, and memantine.[53] Gross and histologic examination as well as neurologic measures demonstrated that all three agents produced a dose-dependent chronic inflammatory response of the spinal cord that led to necrosis. Although these agents are not currently suited for widespread use in humans, their beneficial effects, especially on wind-up pain and hyperalgesia, suggest that further efforts should be directed toward developing an agent that retains its analgesic properties while eliminating most of the side effects.

Gamma-Aminobutyric Acid Agonists

Gamma-aminobutyric acid (GABA) and glycine are inhibitory neurotransmitters that are widely distributed throughout the nervous system. The beneficial effects of GABA agonists such as baclofen in reducing both spinal- and cerebral-origin spasticity have been well chronicled. Less well known are the potential analgesic effects of these agents. GABA can be readily found within the pain transmission system, particularly in Lissauer's tract, and in laminae I, II, and III of the dorsal horn of the spinal cord. Baclofen is a GABA-B agonist and has been shown to be analgesic when administered intrathecally in animals. The antinociceptive effects of GABA agonists are not reversed by naloxone, suggesting that GABA-aminergic analgesia is not mediated through endogenous opiates. IT baclofen diminished allodynic behavioral responses following IT administration of prostaglandin F2-alpha and reduced c-*fos* gene expression in an animal model of neurogenic pain.[54]

Taira et al. studied the effects of a single-bolus injection of IT baclofen (50 to 100 μg) in 14 patients with neuropathic pain syndromes (8 with poststroke pain and 6 with spinal cord injury pain).[54] Nine of the fourteen patients experienced marked pain relief within 1 to 2 hours of the injection, which lasted 10 to 24 hours. Injection of placebo produced no effect. Both spontaneous pain and allodynia and hyperalgesia were reduced whereas discriminative pain and touch were unaffected.

Herman et al. demonstrated similar analgesic effects of IT baclofen in patients with pain and spasticity following spinal cord lesions, although the two effects appeared to be temporally distinct.[55] In other words, after a bolus of IT baclofen, suppression and reappearance of the neuropathic pain occurred separate from the spasm-related pain. Not only did spinal baclofen reduce the pain associated with spasticity, it also diminished the dysesthetic pain. In contrast to this study, Loubsher et al. assessed the effects of spinal baclofen in 12 patients with spinal cord injury.[56] Six patients were determined to have neurogenic pain, three had musculoskeletal pain related to spasms, and three had both components. After 12 months, 78% of the patients with a neurogenic component to their pain were unchanged, whereas 83% of the patients experienced improvement in the musculoskeletal pain component. These authors concluded that IT baclofen does in fact reduce pain associated with spasticity but has little effect on chronic neuropathic spinal cord injury pain.

Several studies have been conducted on the effects of midazolam, a GABA-A agonist. Serrao et al. performed a prospective, double-blind, randomized, dummy-controlled trial comparing the therapeutic effects of epidural steroid injection (ESI) with IT midazolam (2 mg) in 28 patients with chronic mechanical lower back pain.[57] Pain was assessed before and 2 months after treatment using the short-form MPQ as well as VAS and verbal rating scales. Although both treatments resulted in improvement in pain, the group treated with IT midazolam was able to reduce their intake of oral analgesics to a greater extent than those who received ESI. Based on the available data, and considering that baclofen is already approved by the FDA for IT infusion using an implanted pump, the use of IT baclofen for neuropathic pain seems to warrant further investigation with a larger scale multicenter study.

Gabapentin

The use of IT gabapentin has been evaluated in a number of rodent models.[33] Injection of an IT bolus of gabapentin resulted in reduction in mechanical allodynia and thermal hyperalgesia. There was no demonstrable effect on acute nociceptive pain assessed by the formalin or hot plate test. IT gabapentin produced no deleterious hemodynamic effects but did lead to mild neurological dysfunction when dose in excess of 300 μg were used.

Somatostatin and Somatostatin Analogues

Somatostatin is a tetradecapeptide that is widely distributed throughout the central nervous system (CNS). Somatostatin was

initially discovered by virtue of its ability to inhibit the secretion of growth hormone from the pituitary gland. However, its distribution is not limited to the pituitary axis. Indeed, somatostatinergic neurons can be found in the spinal cord, primarily in the substantia gelatinosa where they seem to exert inhibitory effects on nociceptive neurons.[58] Somatostatin is also present in other areas of the CNS concerned with pain transmission and modulation such as the periaqueductal grey (PAG) and both ascending and descending pain-modulating systems in the brainstem. The presence of somatostatin in primary afferent axons that terminate in lamina II of the dorsal horn of the spinal cord, spinal interneurons, descending inhibitory pathways, and PAG presents a strong circumstantial argument for an antinociceptive role of this substance. Single cell recordings have indicated that somatostatin inhibits the responses of dorsal horn neurons to noxious stimulation.[59] Somatostatin has been shown to elevate pain thresholds in experimental animals and has been reported to produce analgesia in humans when administered by either an epidural or intrathecal route.[60–63] The exact mechanism of action is unclear although it does not appear to be opioid-mediated since the antinociceptive effects of somatostatin are not antagonized by naloxone.

Mollenholt et al. administered somatostatin either epidurally or intrathecally in eight patients with terminal cancer.[63] At a mean daily dose of 1252 μg (range 250 to 3000 μg), somatostatin proved to be an effective analgesic agent in six of these patients. Although none of the patients exhibited any signs of neurologic dysfunction during treatment, autopsy findings demonstrated demyelination of the spinal roots in two patients and demyelination of the dorsal columns in another patient. Aside from concerns regarding neurotoxicity, another major problem is that somatostatin is an unstable peptide subject to rapid enzymatic degradation, making it unsuitable for long-term use.

Octreotide, a stable, nonenzymatically degraded, nontoxic analogue of somatostatin, has yielded promising results as a spinal analgesic for cancer pain. Penn et al. reported the efficacy and preclinical neurotoxicity of IT octreotide in six patients with terminal cancer.[60] At a concentration of 500 μg/mL, octreotide was found to be stable within the SynchroMed model 8611 programmable infusion pump (Medtronic Neurological, Minneapolis, MN) over a 4-week period. Insignificant concentration changes were measured at the catheter tip, and within the pump drug reservoir. Preclinical toxicity testing in dogs showed no evidence of histopathologic changes. Based on the stability and toxicity studies, six patients were treated with IT octreotide. Dosing was initiated at 2.5 to 5.0 μg/h and increased by increments of 2.5 to 5.0 μg/h to a maximum dose of 20 μg/h or 240 μg/d as necessary to achieve pain control. Treatment was continued for periods of 13 to 91 days (mean duration 45.5 days). Baseline mean VAS scores of 9.7 were significantly reduced to 1.7 after 1 week of treatment. Although VAS scores increased to 3.6 at 1 month, the improvements remained statistically significant. The same authors have reported long-term experience with octreotide in two patients with nonmalignant pain.[61] Although this experience is modest if not anecdotal, it nevertheless provides additional evidence for a sustained analgesic effect of IT octreotide in nonmalignant disease states.

There does appear to be some element of tolerance, necessitating upward titration of the dose over time. Although octreotide does in fact produce analgesia, many factors currently make this agent impractical for widespread clinical use. First, the commercially available preservative-free preparation comes at a concentration of 500 μg/mL, necessitating frequent refills. Additionally, in order to avoid damaging the infusion device, the pH must be adjusted. Perhaps the most important factor is the extreme cost—in excess of $20,000 per year—which makes this agent unsuitable. Notwithstanding the limitations of octreotide, these results should prompt further investigation into the development of other somatostatin analogues that might be equally effective but more practical for clinical development.

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) have long been known to participate in the modulation of pain transmission. The analgesic effects of TCAs are believed to be mediated through effects on monoaminergic and serotonergic pathways in the CNS, specifically, prevention of reuptake of these transmitters. In vitro testing has also shown that the TCAs bind with the NMDA receptor complex, possibly meaning that the antiallodynic and hyperalgesic effects of the TCAs are mediated via an NMDA receptor mechanism.[64] The effect of IT TCAs on pain behavior has been studied in several animal models. Presently, IT administration of TCAs in humans is not possible due to the lack of preclinical toxicity data, the observed development of motor impairment at high doses in rat experiments, and the unavailability of preservative-free preparations. However, the profound reduction in hyperalgesia and the synergistic effect with opiates provide ample reason to pursue and develop this class of agents as an effective mode of pain control.

Acetylcholinesterase Inhibitors

Acetylcholine (ACH) is a ubiquitous neurotransmitter in all parts of both the central and peripheral nervous systems. Choline acetyltransferase, the rate-limiting enzyme in the synthesis of ACH, is abundant in nerve terminals within the dorsal horn of the spinal cord. Moreover, the presence of acetylcholinesterase in certain descending raphe-spinal projections implies that ACH may be implicated in the modulation of nociception. ACH diminishes the response of dorsal horn interneurons to excitatory amino acids. Some neurons are depolarized by cholinergic substances, whereas others become hyperpolarized. IT administration of both muscarinic and nicotinic agents has indicated that analgesic effects are mediated only through muscarinic receptors. Animal studies have shown that spinal neostigmine produces analgesia (albeit transiently) and also enhances the analgesia provided by IT clonidine, but with fewer side effects.

Based on animal data, human applications of the use of IT neostigmine have been performed. Hood et al. studied the effects of IT neostigmine in 28 healthy volunteers.[65] Although IT administration of neostigmine was antinociceptive to a noxious cold stimulus, significant side effects occurred, including nausea, vomiting, reversible lower extremity weakness, and, at larger doses, tachycardia and hypertension. Although neostigmine alone is probably not suitable based on the side-effect profile, further studies may be warranted using this agent in patients who have become tolerant to opiates.

Adenosine

Although the results have been conflicting, some studies have demonstrated that adenosine, an endogenous nucleoside, and its analogues may participate in pain modulation. Belfrage et al. performed an open-label trial to determine the safety and efficacy of IT adenosine in 14 patients with neuropathic pain accompanied by tactile hyperalgesia or allodynia.[66] Patients were given IT injections of either 500 or 1000 μg of adenosine ($n = 9$), and areas of tactile pain were mapped. Spontaneous and evoked pain were assessed (VAS scale of 0 to 100) before and 1 hour after injection. Median VAS scores for spontaneous and evoked pain were reduced from 65 to 24 ($p < 0.01$) and 71 to 12 ($p < 0.01$), respectively. Parallel increases in tactile pain thresholds in areas of allodynia were also observed. The median reduction in the area

of tactile hyperalgesia/allodynia was 90% ($p < 0.001$). Twelve of the fourteen patients experienced pain relief for a median of 24 hours. The only noted side effect was transient lumbar pain at the site of injection.

Nitric Oxide

Nitric oxide (NO) is synthesized from L-arginine by activation of NO synthase. Because NO easily penetrates cell membranes, it has been identified as a substance that may potentially act like a neurotransmitter. Because synthesis of NO is induced through an NMDA receptor mechanism, and because NMDA receptors have been implicated in the wind-up phenomenon, NO may in fact participate in the development of this pathologic state. There is evidence of increased synthesis of NO in the dorsal root ganglion animal models of neuropathic pain. Yaksh and Malmberg have injected arginine analogues that functionally inhibit NO synthesis intrathecally and found that they induce a dose-dependent reduction in the formation of the hyperalgesic state. Although there are currently no human trials to evaluate the role of NO synthesis inhibitors, this may represent fertile ground for future research.[67]

Prostaglandin Inhibitors

Prostaglandins (PGs) are another well known group of substances that participate as neurotransmitters. PGs are synthesized at the spinal cord level in the identical way to that which occurs systemically. Activation of the NMDA receptor and subsequent calcium influx are thought to lead to activation of phospholipase A_2, and ultimately to the formation of cyclooxygenase products. PGs increase calcium conductance in dorsal root ganglion cells, thereby increasing the release of SP and other peptides. Potentially, inhibition of IT PG formation might result in a reduction in neurotransmitters such as SP, thereby decreasing nociception. The effects of nonsteroidal antiinflammatory agents are mediated through inhibition of PG synthesis. In fact, recent attention has been directed toward evaluating the analgesic effects of IT nonsteroidal agents. Malmberg and Yaksh have studied the effects of IT ketorolac on nociception.[68] IT ketorolac was found to inhibit the development of hyperalgesia in a rat model of neuropathic pain, but it had minimal affect on the acute phase of pain. When administered concomitantly with morphine, ketorolac produced a synergistic analgesic effect on both the fast and slow components of pain. Further research is obviously needed to define the exact role of the various PG substances as they relate to pain transmission, as well as to study the potential for spinal toxicity.

Calcitonin Gene-Related Peptide Antagonists

Calcitonin gene-related peptide (CGRP) is another neuropeptide found in dorsal root ganglion cells, A-delta and C fibers, Lissauer's tract, and the terminals of primary afferents in laminae I, II, and V of the dorsal horn.[64] There are two types of CGRP, and perhaps as many as four receptor subtypes. A noxious thermal stimulus has been shown to result in increased levels of CGRP in lamina II or the substantia gelatinosa. Moreover, some studies have shown that IT administration of CGRP actually increases nociceptive transmission, although the data on this are conflicting. It has been suggested that CGRP may enhance the effects of SP by either inhibition of the enzyme that degrades SP or augmentation of SP release. Yu et al. showed that, although IT administration of CGRP does not produce any apparent effect on pain transmission, IT injection of CGRP 8-37, a known CGRP receptor antagonist, does induce a dose-dependent reduction in nociception.[69] Notwithstanding the work of Yu et al., the conflicting evidence regarding CGRP indicates that the role of this substance needs to be more clearly defined before human trials of CGRP antagonists can be conducted.

Substance P Antagonists

Substance P belongs to the family of substances known as the tachykinins. It is believed to be involved in the transmission or modulation of nociceptive information. SP is stored in synaptic vesicles in primary afferents located in lamina I and II of the dorsal horn and preferentially binds to the NK-1 receptor. Based on SP's presumed role in pain transmission, studies have focused on whether antagonists of SP may be effective in producing analgesia. Again, data are conflicting regarding the effects of IT SP antagonists. Unfortunately, further studies have been hampered by the fact that these substances are neurotoxic and subject to rapid biodegradation, thus hindering application to human clinical trials.

CLINICAL STRATEGY FOR INTRATHECAL DRUG INFUSION

In order to develop a rational approach to the safe and effective use of IT medications, a panel of experts in the field of spinal drug delivery was initially convened in 2000.[70] This initial Polyanalgesic Consensus Conference provided an algorithm for the use of various agents for IT delivery. There have been two additional consensus panels convened in the past 7 years to update the information published in 2000.[31,33] The most recent update, conducted in 2007, produced a number of new recommendations regarding concentration and dosing of IT agents (Table 99.6) as well as an updated algorithm for implementation of the various agents currently in use (Table 99.7).

Line 1 contains morphine, hydromorphone, and ziconotide, all used as single agents. Morphine remains the only opioid currently approved by the FDA for chronic IT administration. Hydromorphone has been elevated to a Line 1 agent owing to it's increasing IT use and the growing body of preclinical and clinical evidence supporting it's safety and effectiveness. Ziconotide has recently been approved by the FDA and is the only nonopioid analgesic approved for long-term IT use. Both morphine and hydromorphone require close monitoring of dose and concentration

TABLE 99.6

CURRENT SUGGESTED DOSE AND CONCENTRATION LIMITATIONS FOR IT DRUG DELIVERY

Drug	Maximum concentration	Maximum daily dose
Morphine	20 mg/mL	15 mg/day
Hydromorphone	10 mg/mL	4 mg/day
Fentanyl	2 mg (2000 μg)/mL	Unknown
Sufentanil†	50 μg/mL	Unknown
Bupivicaine	40 mg/mL	30 mg/day
Clonidine	2 mg (2000 μg)/mL	1.0 mg (1000 μg)/day
Ziconitide‡	100 μg/mL	19.2 μg/day

†Sufentanil is not available for compounding
‡Maximum daily dose based on recommendations of Elan
(Adapted from Deer T, Krames EJ, Hassenbusch SJ, et al. Polyanlgesic Consensus Conference 2007: Recommendations for the Management of Pain by Intrathecal (Intraspinal) Drug Delivery: Report of an Interdisciplinary Expert Panel. *Neuromodulation* 2007;10:300–328.)

TABLE 99.7

2007 POLYANALGESIC CONSENSUS PANEL INTRATHECAL TREATMENT ALGORITHM

Line no.1	Morphine	Hydromorphone	Ziconitide
Line no.2	Fentanyl plus Ziconitide	Morphine/Hydromorphone plus Bupivicaine/Clonidine	Morphine/Hydromorphone
Line no.3	Clonidine plus Ziconitide	Morphine/Hydromorphone/Fentanyl	Bupivicaine and/or Clonidine
Line no.4	Sufentanil	Sufentanil plus Bupivicaine and/or Clonidine Plus Ziconitide	
Line no.5	Ropivicaine, Buprenorphine, Midazolam, Merperidine, Ketorolac		
Line no.6	EXPERIMENTAL AGENTS	Gabapentin, Octerotide, Conopeptide, Neostigmine, Adenosine	

(Adapted from Deer T, Krames EJ, Hassenbusch SJ, et al. Polyanlgesic Consensus Conference 2007: Recommendations for the Management of Pain by Intrathecal (Intraspinal) Drug Delivery: Report of an Interdisciplinary Expert Panel. *Neuromodulation* 2007;10:300–328.)

due to the potential of formation of a catheter tip inflammatory mass. Ziconotide has a limited use due to the relatively narrow therapeutic window associated with this medication.

Line 2 includes fentanyl which has been suggested as an alternative for patients who develop intractable supraspinal side effects to any of the Line 1 agents. It is believed that fentanyl far less likely than other opioids to result in granuloma formation so this is a reasonable alternative for patients with increased risk for this problem. Line 2 also begins to explore the use of polyanalgesic therapy when a single agent fails to provide adequate analgesia. Morphine or hydromorphone may be combined with either bupivacaine, clonidine, or ziconotide. It had previously been thought that clonidine when co-administered with opioids may provide some protective effect regarding granuloma formation; however, there have now been several reports of granuloma formation in patients receiving clonidine.

If a combination of medications on Line 2 fails to provide adequate relief, Line 3 suggests the possibility of clonidine alone or the use of opioids combined with bupivacaine and clonidine and possibly even ziconotide. This approach obviously becomes more complicated in terms of management. If Line 3 approaches are unsuccessful, one can consider switching to sufentanil, the primary Line 4 drug. Sufentanil has been safely used in humans and is thought to have granuloma-sparing effects. In Lines 2, 3, and 4, the addition of agents such as bupivacaine, clonidine, and ziconotide, may prove most beneficial for patients with pure neuropathic or mixed nociceptive/neuropathic pain. The agents listed in Line 5 of the algorithm were not considered experimental by the panel, but there is little information regarding their use in the literature. Because of the paucity of safety and efficacy data, they should only be used by highly experienced implanters and only with complete informed consent. Finally, the agents listed on Line 6 are still considered experimental and should only be used by experienced implanters with on a treatment protocol that has been approved by the local Institutional Review Board.

COMPLICATIONS OF SPINAL DRUG DELIVERY

A thorough understanding of the potential complications that might occur during the course of spinal drug infusion is essential for any clinician involved in the implantation and/or management of spinal drug delivery systems. Unfortunately complications are inevitable, even for the most seasoned clinicians. While complications are bound to occasionally occur, it is critical that they are recognized and dealt with in a timely fashion. To that end, it is imperative that anyone involved with this therapy have a fundamental knowledge of the neuroanatomy, physiology, and pharmacological effects as these factors relate to spinal drug delivery. Complications associated with ITDD can be generally divided into surgical complications related to the implant procedure, device-related complications, and pharmacological complications (Table 99.8).[71]

Surgical Complications

Wound Hematoma/Seroma and Epidural Hematoma

Bleeding is obviously a risk of any surgical procedure. Bleeding can occur either intraoperatively or postoperative, can be superfi-

TABLE 99.8

COMPLICATIONS OF INTRATHECAL DRUG DELIVERY

Surgical Complications
- Wound hematoma or seroma
- Intraspinal hematoma
- Wound infection
- Meningitis
- Epidural abscess
- Postdural puncture headache
- Persistent cerebrospinal fluid leak
- Malposition of subcutaneous pump pocket
- Neurological injury

Device-Related Complications
- Catheter-related problems
  - Migration
  - Fracture
  - Occlusion
- Mechanical pump failure

Pharmacological Complications
- Drug-related side effects
- Tolerance
- Withdrawal and abstinence syndromes
- Opioid-induced hyperalgesia
- Inflammatory catheter tip mass (granuloma)

Complications Associated with Pump Refill
- Contamination of pump reservoir
- Accidental subcutaneous administration
- Accidental intrathecal bolus during intended refill

cial or deep, and can be related to either mechanical (surgical) or systemic factors. Fortunately, severe bleeding is rarely a problem with implantation of ITDDs. The strategy for management of bleeding problems due to systemic factors such as coagulopathies, medications, etc., is obviously prevention. Prior to proceeding with insertion of a catheter for screening or implantation of the pump system, all patients should be screened for risk factors that could cause intraoperative or postoperative bleeding. A careful medical history including family history of bleeding problems is usually the most accurate method of screening for coagulation disorders. Laboratory studies such as prothrombin and partial thromboplastin times, platelet function assays, etc., may be ordered although these studies can sometimes be normal even in the presence of a coagulopathic state, further emphasizing the importance of a thorough clinical history. If the patient is being treated with anticoagulant medications such as aspirin, clopidogrel, or Coumadin, these agents must be stopped for a sufficient period of time prior to the procedure, usually 7 to 10 days. It is important to check with the patient's primary physician or specialist to ascertain that it is indeed safe to discontinue these medications.

Intraoperative bleeding is rare since these procedures do not usually require extensive surgery, and the anatomical areas that are involved are not particularly vascular. Most of the bleeding problems associated with ITDDs involve the subcutaneous tissues, particularly the pump pocket. Failure to obtain meticulous hemostasis in the subcutaneous tissues can lead to complications such as wound hematoma/seroma and/or infection. Infiltration of the surgical sites with local anesthetic containing 1:200,000 epinephrine can be helpful in reducing superficial bleeding. The judicious use of electrocautery for the majority of the dissection will also minimize bleeding. A word of caution: extensive use of electrocautery in one location can destroy and devitalize tissue making it a perfect nidus for infection. Also, electrocautery should be avoided on the skin edges as this can lead to poor wound healing and subsequent wound breakdown and/or infection.

Clinically significant intraspinal bleeding related to needle or catheter insertion is rare. The risk of intraspinal bleeding can be minimized by keeping the number of needle passes to a minimum. Tumors can occasionally be a source of bleeding so extra caution should be exercised when implanting a pump in a patient with spinal metastases. Significant bleeding from the needle may be managed by gentle irrigation through the needle which will usually be sufficient. A small amount of epidural bleeding will not be clinically significant. However, accumulation of sufficient blood in the epidural space can lead to the development of a clinically significant epidural hematoma. This is usually heralded in the immediate postoperative period by severe escalating back pain and the onset of neurological dysfunction. An epidural hematoma sufficiently large to produce neurological dysfunction is a neurosurgical emergency. Consequently, any patient who develops neurological symptoms or signs in the immediate postoperative period should undergo an immediate imaging study (CT or MRI) of the spine and neurosurgical consultation should be obtained.

Wound hematoma and/or seroma occur more commonly than clinically significant epidural bleeding. This complication is usually due to inadequate hemostasis. A wound hematoma is usually manifest by local pain, pressure, and swelling over the surgical wound and may or may not be accompanied the serous or serosanguineous drainage. Most wound hematomas or seromas can be managed conservatively and will resolve spontaneously. However, in the event of a large collection, either surgical evacuation or percutaneous aspiration may be indicated. In the event of a wound hematoma or seroma, early pump refills should be limited since puncture of the skin may increase the risk of infection. Also, a large hematoma overlying the pump will make accessing the refill port more difficult and increase the chances of accidental subcutaneous injection of the medication.

Infectious Complications

The incidence of infection following implantation of an ITDD is relatively low since one is dealing with a clean (Class I) surgical wound. Indeed, the presence of an active systemic infection or localized soft tissue infection near the site of implantation should be a contraindication for implantation until the problem has been resolved. Most wound infections present relatively early (within 1–4 weeks) after pump implantation. The usual presentation includes pain, swelling, erythema, tenderness over the surgical incision, sometimes accompanied by purulent drainage. Although fever may be present, absence of fever should not produce any false sense of security. In the absence of systemic symptoms and/or signs of infection, some authorities have advocated a period of conservative management for several weeks including percutaneous aspiration, intravenous antibiotics, and, in some cases, instillation of antibiotics directly into the pump pocket. Although there are likely anecdotal reports of success with this strategy, the author's observations are that this almost never works and only delay the inevitable. In the author's opinion, if an infection of the pump pocket occurs, the device (including the catheter) should be removed. Occasionally, if there is absolutely no evidence of extension of the infection toward the lumbar catheter insertion site, it is sometimes possible to leave the intrathecal catheter in situ and occlude it just above the fascial insertion site such that once the infection is resolved the catheter can be revised and a new pump implanted in a site remote from the previous infection. Notwithstanding this exception, the safest and most conservative approach is to remove the entire system and start from scratch once the infection has resolved. In circumstances where the device requires removal, the clinician must have a strategy for reinstitution of systemic analgesics in order to prevent the development of withdrawal syndrome.

Meningitis is another infectious complication that, although rare, can occur following pump implantation. The clinical presentation of bacterial meningitis includes fever, chills, intractable headache, malaise, nausea/vomiting, neck/back pain, and nuchal rigidity. Most patients who develop meningitis look ill and progression of the condition can be extremely rapid. The key to treatment is early recognition of the clinical signs. If meningitis is suspected, a lumbar puncture should be performed to obtain CSF and broad spectrum antibiotics should be instituted. What to do with the device is somewhat less clear. Again, the most conservative approach is to remove the hardware. If there is absolutely no indication of infection of the surgical site and the infection appear limited to the CSF, it may be reasonable to remove the IT catheter and leave the pump in situ in which case the pump should be emptied of active drug and filled with preservative-free saline and set to run at the minimum flow rate. However, the pump can not simply be stopped and then restarted after the infection is cleared.

Epidural abscess is rare following implantation of a pump although there are numerous case reports of epidural abscess following insertion of epidural catheters. The clinical presentation of epidural abscess is similar to that of an epidural hematoma although the onset is generally more delayed and the progression of symptoms may be slower. Early diagnosis requires a high degree of suspicion and any patient who develops neurological signs or symptoms should undergo an imaging study to exclude this problem. If an epidural abscess is confirmed and the patient demonstrates signs of neurological dysfunction, neurosurgical consultation should be obtained immediately and consideration given toward surgical decompression. Although epidural abscess has traditionally been considered a neurosurgical emergency, there are increasing reports of nonoperative management of this condition. If the patient has no sign of neurological dysfunction, it may be possible to manage the problem with antibiotics combined with close clinical observation. This approach is probably most applicable to abscesses that occur in the lumbar region since the

cauda equina is more resistant to compression than the spinal cord itself. Again, the most conservative approach regarding the implant is removal. Most postoperative epidural abscesses are due to *Staphylococcus aureus* and should be treated with at least 6 weeks of intravenous antibiotics.

Cerebrospinal Fluid Leak and Postdural Puncture Headache

Insertion of the IT catheter requires performing a lumbar puncture with no.15 gauge Tuohy needle. Therefore, CSF leak and postdural puncture headache (PDPH) are definite risks associated with pump implantation. This problem may occur as a result of multiple dural punctures or as a result of CSF that can leak around the catheter where it enters the dura. Some implanters try to minimize this risk by placing a purse string suture around the catheter below the fascial insertion site. If this technique is employed, one must be careful not to make the suture so tight that it occludes the catheter.

PDPH is classically described as a severe postural headache that occurs when the patient goes from the supine to upright position, although there are clearly patients who lack a significant postural component. The diagnosis is usually fairly straightforward. Initial management includes bedrest, fluids, and the use of an abdominal binder. Medications such as IV caffeine (500 mg in 1000 cc normal saline given over 1 hour) and ACTH (1.5 μg/kg in 1 liter of normal saline given over 1 hour) are sometime effective. If conservative measures fail to eliminate the problem, an epidural blood patch is indicated. This should be done using strictly aseptic conditions and fluoroscopic guidance in order to avoid damage to the IT catheter. If the leak persists after all of these measures, surgical exploration to seal the leak may be required.

Occasionally, patients will present with a CSF hygroma beneath the lumbar incision. In most cases, this will resolve spontaneously given time and patience. It is usually not necessary and generally not recommended that these collections be aspirated owing to possible introduction of infection or damage to the catheter. If the collection is large and/or the patient is symptomatic, then surgical exploration to close the leak around the catheter is required.

Neurological Injury

Neurological injury following pump implantation is most commonly associated with the development of an epidural hematoma or abscess. Although uncommon, direct neurological injury can also occur from insertion of the needle or IT catheter. Direct neurological injury should almost always be preventable providing one adheres to certain principles. First, prior to surgery, all patients should have an imaging study of the spine, preferably an MRI to ensure that the spinal canal is patent and that the catheter can be inserted safely. This is especially important in patients with cancer and spinal metastases to make certain that the tumor will not interfere with passage of the catheter. Also, an imaging study will exclude the presence of problems such as a low-lying or tethered cord. Secondly, the needle should be inserted in the lower to mid-lumbar region in order to avoid direct injury to the conus, which usually terminates around T12 or L1. The position of the conus can be seen on the MRI and therefore avoided. Once the needle has been inserted and free flow of CSF confirmed, the catheter should be inserted and positioned using fluoroscopy. The catheter should be gently advanced; under no circumstance should the catheter be forced if undue resistance is met. If this occurs, the entire catheter and needle assembly should be removed and the process repeated. The position of the catheter tip should be confirmed with fluoroscopy. Ideally, the catheter tip should be positioned in the upper portion of the lumbar cistern. By keeping the catheter caudal to the conus and spinal cord, this will minimize the risk of cord compression due to IT granuloma. If the catheter goes retrograde, it should also be removed and repositioned. If the catheter remains low in the lumbar region, it can potentially "knot" and damage the nerve roots of the cauda equina in the event it needs to be removed. It is not uncommon for the catheter to cause transient nerve root irritation that is usually manifest by radicular pain. This is usually self-limited and resolves over several days to weeks. However, in the event it persists, it may become necessary to remove the catheter.

Device-Related Complications

Catheter Problems

Complications related to the catheter system represent a considerable source of morbidity in patients with ITDDs. Catheter-related problems include fracture, migration, kinking, occlusion, and dislodgement. In three separate clinical trials conducted by Medtronic, catheter-related complications were reported in 20% to 25% of patients who received an implant. This included both one- and two-piece catheters. During a 1- to 2-year follow-up period, approximately 80% of the catheters remained complication-free. Correction of a catheter complication not only requires additional surgery, but also results in interruption of therapy and production of a potential withdrawal syndrome. Given that approximately 20,000 new implants are performed annually with a catheter complication rate of 25%, that means that 5,000 catheter revisions are required yearly. With an average cost of revision around $10,000, the annual revision cost is about $50,000,000.

A catheter problem is usually manifest by loss of analgesia in which case it will be necessary to troubleshoot the system to diagnose the specific problem. A sequential systematic approach will usually identify the problem. Following is the author's protocol for evaluating a potential catheter or pump-related problem. First, proper function of the pump itself can generally be confirmed through telemetry. We routinely interrogate the device and ensure that the expected information is accurate. The accuracy of the pump prescription is checked and new medication with the appropriate concentration is instilled. The residual drug volume is checked against that predicted by the telemetry and these volumes should agree. Plain radiographs that include the entire catheter and pump system are obtained to exclude disconnection of the catheter from the pump as well as fracture, migration, or kinking of the catheter. Although most catheter fractures can be seen with plain radiographs, some are subtle and can not be detected with plain x-rays. If a physical problem with the catheter is identified, the patient is scheduled for catheter revision as soon as possible. If the integrity of the system appears intact and the pump appears to be functioning properly, an MRI is obtained to exclude the presence of a catheter granuloma. If this evaluation fails to reveal the source of the problem, then a dye study is performed to further evaluate the catheter. The catheter access port (CAP, Fig 99.2) is accessed using either a no.24 or no.25 gauge needle provided in the CAP kit. Prior to injecting anything being injected, the catheter should be aspirated to confirm CSF flow and several milliliters of CSF should be removed. The removed CSF can be analyzed for drug levels, although this usually takes several weeks to obtain results. If CSF can not be removed, nothing should be injected as this could potentially push drug within the catheter directly into the CSF resulting in a drug overdose. Assuming one can easily aspirate CSF, a small amount of dye is slowly injected and observed under fluoroscopy. If the catheter is patent and there is no obstruction at the tip, dye should be observed to flow from the catheter and then dissipate quickly in the subarachnoid space. It is also possible to study the catheter by placing a radioisotope such as Indium in the drug reservoir and imaging the system over a period of 2 to 3 days which is the time that it usually takes for the tracer to appear in the CSF depending on the flow rate of the pump.

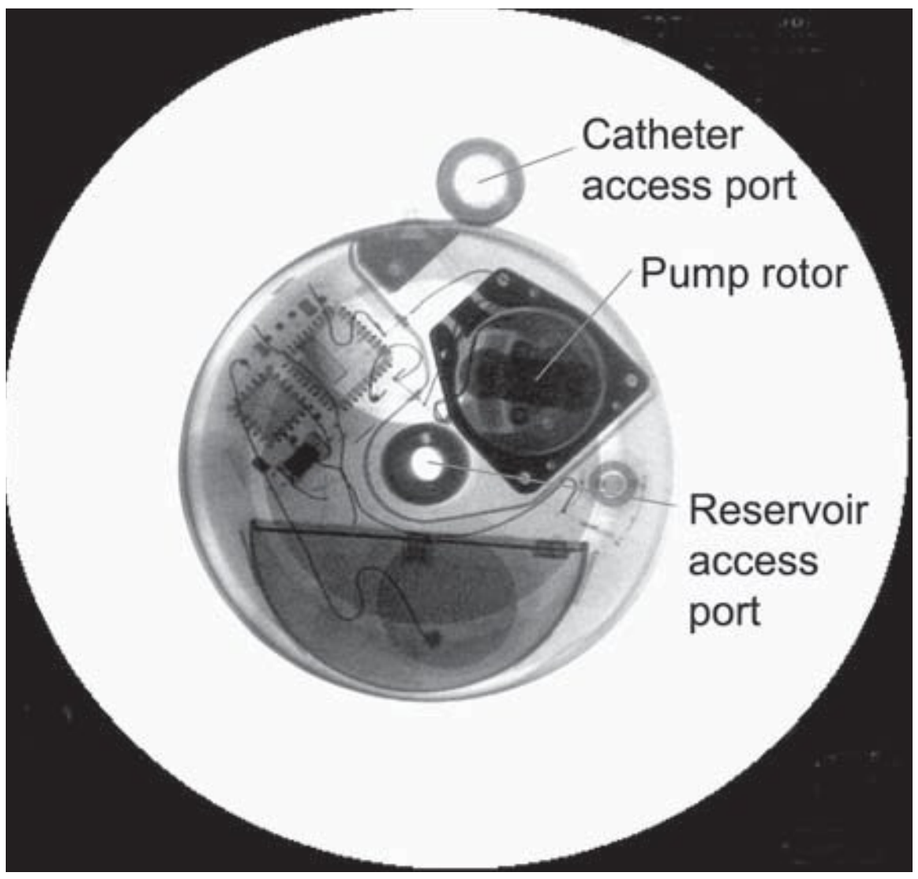

FIGURE 99.2 Plain radiograph of the Medtronic SynchroMed programmable intrathecal drug delivery pump. (Used with permission from the manufacturer. The pump shown is the most common pump in use worldwide in 2009, the SynchroMed pump manufactured by Medtronic Neurological, Minneapolis, MN.) (Reproduced with permission from Deer TR. Complications associated with intrathecal drug delivery systems. In: Neal JM, Rathmell JP, eds. *Complications in Regional Anesthesia and Pain Medicine*. Philadelphia: Saunders Elsevier; 2007:229, Figure 23-2.)

Refill Complications

Complications related to refilling a drug delivery device include inadvertent subcutaneous administration, accidental IT injection, and pump programming errors. All of these complications are avoidable by adhering to a strict protocol for pump refills. The danger during initiation of ITDD and refilling of the reservoir is apparent from a recent postmarketing study carried out by Medtronic. They reported that mortality after initiation of ITDD or device interventions (reprogramming, refilling of the drug reservoir) occurred as a result of multiple factors, including excessive intrathecal morphine dosing during initiation of ITDD, lack of close supervision of concomitant opioid or respiratory depressant drug intake, and early hospital discharge preventing monitoring for respiratory depression early after initiation of ITDD.[72] Before refilling any drug delivery device, one should check to ensure that the drug prescription matches that currently in the pump. Refills should be performed sterilely to avoid contamination of the drug reservoir. Refills should only be performed with the appropriate needles that are provided in the pump refill kit. The drug reservoir is accessed with no.22 gauge Huber needle and the catheter access port with a no.24 or no.25 gauge needle, depending on the model of the pump. The needle intended for entering the CAP should *never* be utilized for accessing the drug reservoir. In this instance, if the smaller needle is accidentally inserted into the CAP, the entire volume of medication will be directly injected into the IT space. The CAP bypasses the drug reservoir and pump and can not be accessed with a no.22 gauge needle. If there is any question that the needle is in the appropriate port, it is prudent to confirm this with fluoroscopy. The provider performing the refill should confirm that the residual volume of the reservoir matches that predicted by telemetry. Once the refill has been completed and the pump reprogrammed, the pump prescription should again be double checked for accuracy.

Inadvertent injection into the subcutaneous tissues around the pump as well as injection through the CAP directly into the IT space have both been reported. This can obviously lead to significant problems such as respiratory depression. Moreover, respiratory depression is likely to be delayed in onset and occur long after the patient has left the office. If subcutaneous injection occurs, treatment with an opioid antagonist may be warranted. This should be done under careful observation using small incremental doses to avoid severe complications such as hypertension, cardiac arrhythmias, and pulmonary edema. In the event that direct injection into the CSF does occur and it is recognized, the drug infusion should be stopped and the patient admitted to the hospital for observation and closely monitored for any signs of respiratory or hemodynamic problems. Again, judicious use of opioid antagonists as described is warranted. It is also possible to remove some of the drug through a high volume lumbar puncture although this will not remove all of the drug. If the patient develops signs of respiratory compromise in spite of these measures, the guiding principle should be "airway, breathing, and circulation" and there should be no hesitation in proceeding with endotracheal intubation of the patient and providing mechanical ventilatory support until the drug effects have dissipated.

Pharmacological Complications and Drug-Related Side Effects

Side Effects of Intrathecal Opioids

It is commonly believed that switching from systemic to IT delivery of opioids alleviates all of the clinically significant side effects. This is clearly a misconception, as IT opioid infusion is commonly associated with side effects. Often, these side effects are mild and well-tolerated and do not interfere with therapy. Indeed, just as patients develop tolerance to the analgesic effects of the drug (see later), they also tend to develop tolerance to the side effects. On the other hand, some patients develop side effects that may be so bothersome as to have a significant impact on the treatment. The most common side effects experienced by patients receiving ITDD include respiratory depression, gastrointestinal symptoms, urinary dysfunction, hormonal alterations, and itching.

Aside from true anaphylaxis, which is extremely rare with the use of opioids, respiratory depression is the most clinically concerning drug-related side effect. Respiratory depression results from the supraspinal interaction of the drug with mu-2 opioid receptors in the brainstem. It can occur from rostral spread of the drug and is probably more common when using hydrophilic agents which can attain significant concentrations in the cisternal CSF. It can also occur with systemic absorption into the blood and redistribution to the CNS. It is most likely to occur in patients who are opioids naïve. In fact there are relatively few reports of clinically significant respiratory depression in patients who have been exposed to opioids for even relatively short periods of time. It is also quite uncommon in patients being treated for cancer pain. Besides lack of prior exposure to opioids, additional risk factors for respiratory depression include advanced age, absence of severe pain, debilitated physical condition, preexisting pulmonary disease, sleep apnea, and, of course, additional opioids dosing by alternative routes. Respiratory depression can occur as early as 4 hours following IT dosing although it is often delayed in onset up to 24 hours. Treatment consists of support of respiration and the judicious use of a mu-receptor antagonist such as naloxone or kappa-agonist–mu-anatagonist such as nalbuphine using appropriate precautions as outlined previously in this chapter.[71]

Urinary retention is another common side effect of IT opioids, reported in 20% to 40% of patients. It is a direct spinal side effect that is caused by reduction in detrusor muscle tone and detrusor-urethral sphincter dyssynergia. It does occur with the intraventricular administration of morphine. It is believed to be mediated primarily through mu- and delta-receptors. It is more common in males and rare in women and individuals who are opioid tolerant. It is often self-limited and usually resolves within

24 to 48 hours. Treatment entails intermittent bladder catheterization until the problem resolves. One can also consider adjunct pharmacological treatment with opioids antagonists and/or phenoxybenzamine. If the problem persists, an alternative strategy involves switching to another opioid.[71]

Gastrointestinal side effects such as nausea, vomiting, and constipation are less common than with systemic delivery. However, they still occur in up to 25% to 30% of patients, especially those who are opioid naïve. Nausea and vomiting are mediated by the interaction of opioids with the chemoreceptor trigger zone. Treatment is usually symptomatic with antiemetic agents.

Pruritus occurs in about 25% of patients exposed to IT opioids and is perhaps even more common in opioid-naïve individuals. It is more common with morphine than other opioids and is believed to result from degranulation of mast cells. The problem is usually self-limited and can be managed with antihistamines albeit with mixed results. In the case of severe persistent itching, the best approach is to probably switch to an alternative opioid such as hydromorphone or fentanyl. It is important to differentiate opioid-induced pruritus from true allergy. Most patients and many clinicians not familiar with the actions of IT opioids will misconstrue itching as an allergic reaction. In fact, true allergic reactions to morphine or its congeners is very rare.[71]

Finally, there is compelling evidence that opioids can have a negative effect on neuroendocrine function.[73] Morphine has been shown to inhibit the release of gonadotropin- and corticotrophin-releasing hormones from the hypothalamus, resulting in reduced circulating levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), ACTH, and beta-endorphin. The end result is reduction in serum levels of cortisol and testosterone. Clinically, the end effect is reduction in libido and/or impotency. In men, reductions in testosterone can also result in decreased muscle mass and increased fat mass. In addition to the effects just noted, IT morphine administration can also produce significant fluid retention, possibly due to alterations in antidiuretic hormone function.

Opioid Tolerance

Tolerance can be defined as the requirement for progressively escalating doses of medication in order to achieve the same degree of clinical effect. In pharmacological terms, tolerance represents a pharmacodynamic effect manifested by a rightward shift in the dose-response curve. Two mechanisms for opioid tolerance have been proposed: desensitization (i.e., decreased activation) of opioid receptors following prolonged exposure to opioids, and opioid receptor down regulation.[74] Desensitization involves changes in opioid receptor physiology that are believed to result from alterations in G-protein receptor function. This change apparently results in an uncoupling of G-protein from the opioid or possibly a switch in coupling such that the receptor couples with a nonanalgesic G-protein. In any event, the end result is decrease in analgesia. Down regulation, the second mechanism believed to produce opioid tolerance occurs when opioid receptors are internalized from the cell membrane by endocytosis, due to substances termed arrestins.

Although tolerance is used mostly in terms of loss of analgesia, it should be noted that tolerance also occurs to other effects of a given drug. Tolerance is believed to be an important causal factor in the loss or complete failure of analgesia in patients with implanted drug delivery systems, particularly those patients primarily receiving opioid medications. Tolerance usually develops over the course of time, and the rate at which tolerance develops may vary between individuals. Moreover, tolerance does not usually develop equally to all effects of a given drug at the same rate. Before concluding that loss of analgesia is indeed related to tolerance, it is important for the clinician to exclude other reasons such as problems with the delivery system or progression of disease.

Management of tolerance depends to large degree on the baseline treatment protocol for a given patient.[71] In some cases, simple dose titration by 10% to 30% per day will overcome the problem. If indeed the problem is simply a tolerance issue, then increasing the dose should result in demonstrably improved pain control, at least for some period of time. Depending on the delivery system, dose escalation will be limited by the volume that can be safely infused. The maximum infusion rate generally recommended for an epidural infusion is around 10 to 15 mL/hour; for IT infusion, the rate should not exceed more than 10% of the patient's calculated CSF volume (typically 75 mL total, limiting the daily infusion to 7.5 mL/day). These limitations can sometimes make restoration of analgesia impossible by dose titration alone unless the infusion prescription can be prepared in a higher concentration, although there are also limits to this as well (Table 99.6).

It has been suggested that continuous drug delivery is less likely or will less rapidly lead to the development of tolerance although there are no studies that clearly demonstrate this to be the case. Switching to a more potent opioid may result in a slower development of tolerance by reducing the rate of receptor down regulation. One can also consider switching to a different opioid assuming there is incomplete cross tolerance between the two drugs. Another strategy is to add other agents such as clonidine that act through alternative spinal modulating systems and therefore might have some opiate-sparing effects. Finally, it has been suggested that a local anesthetic agent be substituted for the opioid to provide an opioid-free interval.

Opioid-Induced Hyperalgesia

Opioid-induced hyperalgesia is a condition that is manifest by a dramatically augmented sensitivity to stimuli that would be considered noxious and/or allodynia, defined as a pain that is produced by a normally nonnoxious stimulus. This phenomenon has been increasingly recognized in patients who have been treated with long-term opioid therapy and is yet another potential cause loss of analgesia with IT drug infusion. Opioid-induced hyperalgesia is not simply an escalation of the patient's original pain condition. Rather, the ''abnormal'' pain often originates from an area that is anatomically distinct from the original pain. In some patients, pain seems to increase and become more diffuse over time despite escalation in their opioid regimen. It has recently been shown that opioid-induced hyperalgesia may also develop in the context of short-term therapy in the absence of physical dependence or withdrawal.[74] Several mechanisms have been proposed for this phenomenon: glutamate activation of NMDA receptors as well as increases in excitatory peptide neurotransmitters such as cholecystokinin (CCK).[74]

Intrathecal Inflammatory Masses (Intrathecal Granuloma)

Inflammatory mass associated with the tip of an IT catheter is a potentially serious complication that, if not promptly recognized and managed, can result in spinal cord damage and irreversible neurological dysfunction. IT granuloma was first reported in 1991 and, over the course of time, additional case reports and small case series appeared in the literature. By 2000, 41 cases had been reported. Due to the growing concern regarding this problem, a consensus panel met and subsequently published recommendations on the management of catheter tip inflammatory masses. A similar consensus panel was reconvened in 2007 and the recommendations and guidelines of this panel were recently published.[75] The panel reviewed the pertinent literature including preclinical data, information on pathophysiology of inflammatory mass formation, and clinical data, and ultimately developed an algorithm for prevention and treatment.

An inflammatory catheter tip mass typically is comprised of both acute and chronic reactive inflammatory cells derived from

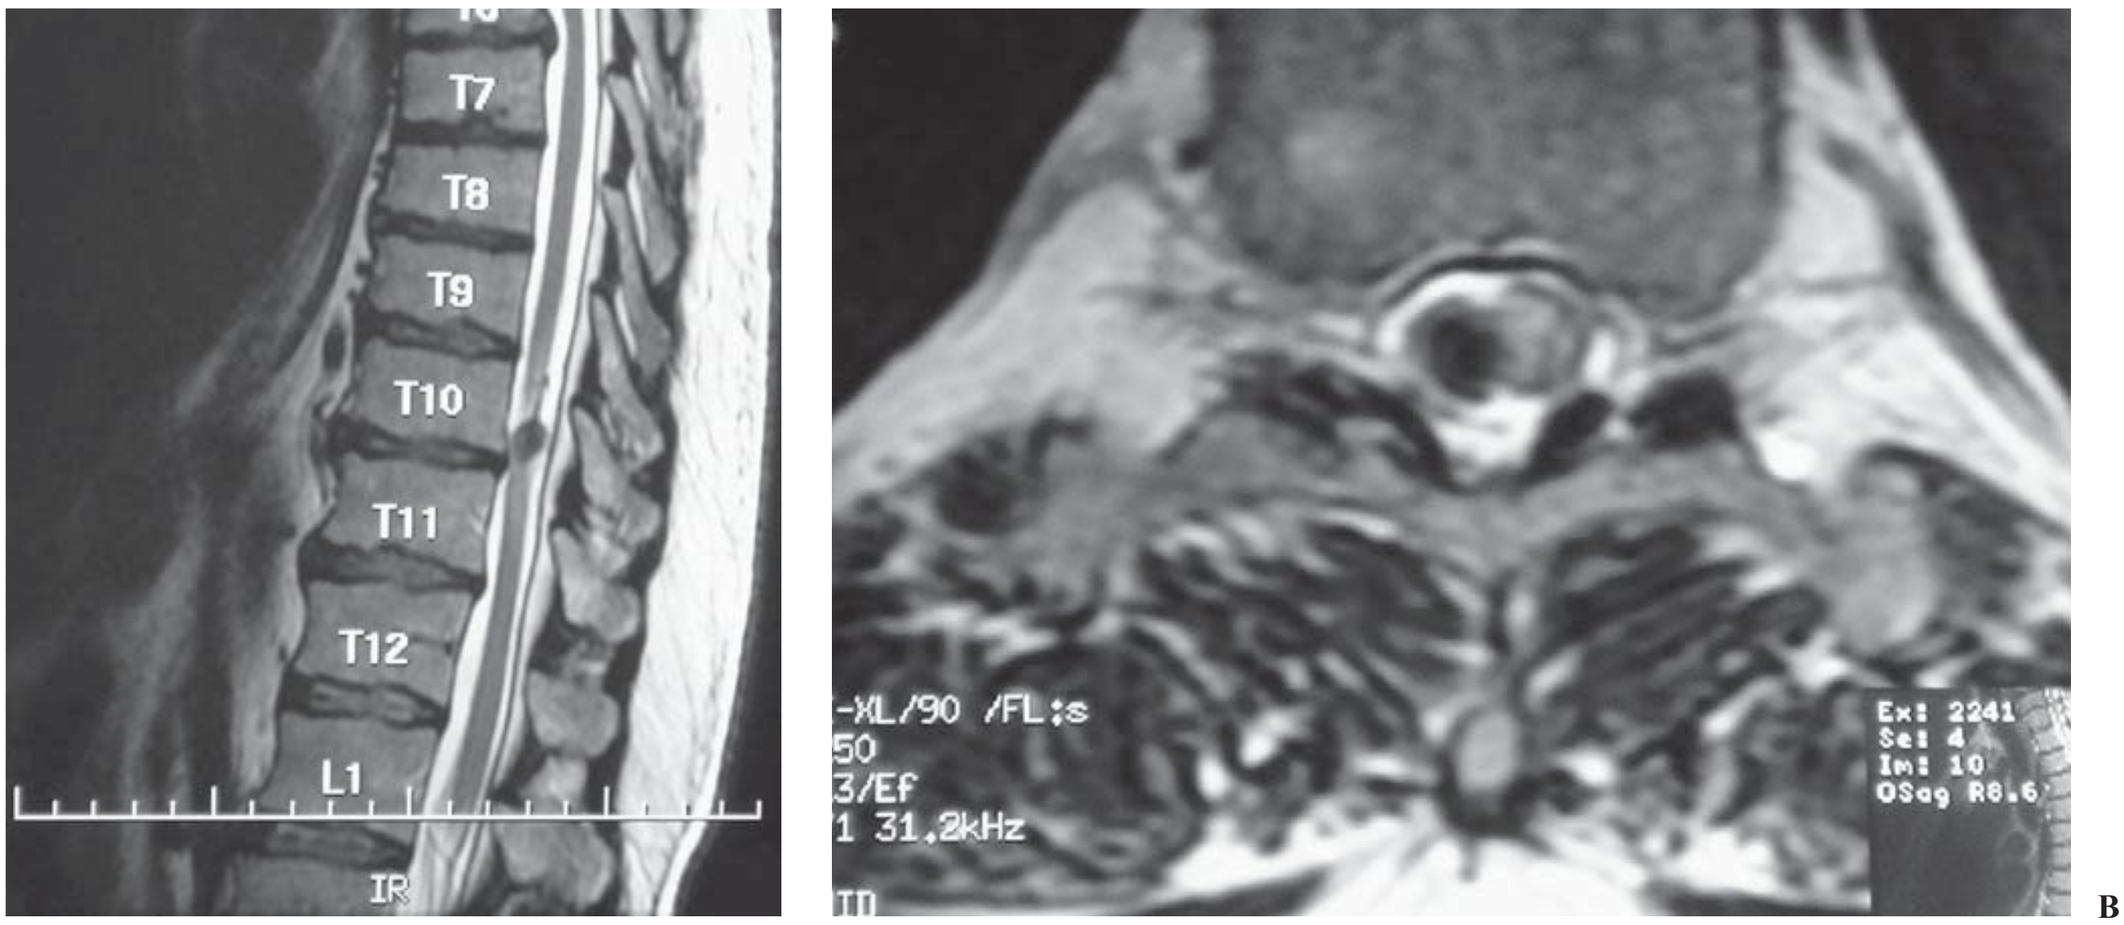

FIGURE 99.3 MRI study of a patient with an inflammatory mass surrounding the tip of an implanted intrathecal drug delivery catheter. **A.** Midline, sagittal, T2-weighted image. The inflammatory mass involves the dorsal aspect of the spinal cord at the level of the inferior end plate of T10. **B.** Axial, T2-weighted image through the inflammatory mass. The mass displaces the spinal cord toward the left. (Reproduced with permission from Deer TR. Complications associated with intrathecal drug delivery systems. In: Neal JM, Rathmell JP, eds. *Complications in Regional Anesthesia and Pain Medicine*. Philadelphia: Saunders Elsevier; 2007:229, Figure 23-1.)

the arachnoid and/or fibrosis that do not directly involve the spinal cord parenchyma. Although these masses represent a build-up of granulation tissue and have been termed "granulomas," they do not fit the classical histopathological description of a true granuloma. An infectious agent has never been associated with these inflammatory masses. There are a number of preclinical studies in both dogs and sheep that demonstrate that catheter-tip inflammatory masses occur predictably in animals receiving IT morphine infusions. Based on preclinical studies, the panel concluded that these masses likely occurred as a result of infusion of high concentrations and/or high daily doses of IT morphine.

Although most of the preclinical evidence implicated the use of morphine, more recent data indicate that other opioid infusions may be associated with inflammatory catheter tip masses. There has also been a more recent report implicating IT baclofen as a potential causative agent.

Although the occurrence of inflammatory masses in humans is less predictable than is animal models which are short-term in duration, it is believed that the incidence in humans increases with the duration of IT therapy, ranging between 0.4% after 2 years of treatment up to 1.16% after 6 years of treatment. Moreover, animal data fails to clarify whether there is even a minimal dose in humans that will not incite granuloma formation. Notwithstanding, these data do support the concept that both concentration and total dose of all opioids, with the exception of fentanyl, are important in the development of inflammatory masses. Based on the available data, the 2007 consensus panel has published recommendations for maximum dosages and concentration of the currently used IT agents (Table 99.6).

The first clinical clue to the development of an inflammatory catheter tip mass in a patient who has otherwise been doing well is often an increase in the patient's pain and the requirement for continuous dose escalation. In such cases, absent an obvious progression of disease, one should begin to consider that diagnosis of an inflammatory mass. Any patient who develops new neurological symptoms should be evaluated with spinal imaging, preferably MRI. A catheter tip inflammatory mass can usually be detected with MRI (Fig. 99.3).

Management of the patient with an inflammatory catheter tip mass depends on the clinical situation, but is primarily related to the presence or absence of neurological signs and/or symptoms. If a mass is detected and the patient does not have neurological symptoms, it is possible to retract the catheter caudally a few centimeters out of the granuloma and reduce the drug dose and/or concentration. One additional suggestion has been to switch to a "safer" medication such as fentanyl or ziconotide. If symptoms persist despite these changes, the patient should be rapidly weaned off all IT opioids, the medication should be removed from the pump, and the pump filled with saline. One needs to pay close attention to signs of withdrawal, not only from opioids but also from adjuvant medications that may also be in the pump such as clonidine and/or baclofen. If the symptoms resolve after removing the catheter from the mass, the patient should be re-imaged in 6 months to confirm resolution of the granuloma before reinstituting the therapy. If a small granuloma is still evident, one must weight the options of further retraction of the catheter versus removal of the catheter. If neurological signs and symptoms persist or in the event that a granuloma is detected that is producing significant spinal cord compression, then the system should be removed. In patients with a large granuloma compressing the spinal cord and producing neurological dysfunction, consultation with a neurosurgeon should be obtained to determine whether removal of the granuloma itself is warranted.

Drug Withdrawal

Disruption of the IT catheter, pump battery failure, and human error during refill and reprogramming can all lead to sudden cessation of drug delivery and result in drug withdrawal. Of the medications that are currently used for IT delivery, distinct abstinence syndromes are most commonly associated with opioids, baclofen, and clonidine. There are currently no reports of withdrawal associated with the use of IT ziconotide.

The clinical symptoms and signs associated with opioid withdrawal include any or all of the following: increased lacrimation and rhinorrhea, diaphoresis, mydriasis, pilomotor erection, restlessness, irritability or agitation, gastrointestinal symptoms (nausea, vomiting, diarrhea), tremor, abdominal cramping, and, of course, increased pain levels.[71] In severe cases, acute opioid withdrawal can lead to pulmonary edema or cardiovascular collapse resulting in death. The most common causes of opioid withdrawal are catheter disruption and pump refill/programming errors. Because of the risk of opioid withdrawal, antagonist medication must be used with extreme caution in patients undergoing chronic opioid therapy. Treatment should be aimed at respiratory and hemodynamic support with restoration of the drug infusion as soon as possible.

Baclofen withdrawal is a serious complication that, if unrecognized, can be life-threatening. It is usually heralded by increase in spasticity, sometimes to the point of rigidity, pruritus, hyperthermia, drowsiness progressing to obtundation, respiratory depression, rhabdomyolysis, acute renal failure, acute multiorgan failure, and even death.[71] Early recognition is the key to treatment. The treatment of baclofen withdrawal requires urgent attention, the goal being restoration of the IT baclofen infusion as soon as possible. For patients with signs of severe baclofen withdrawal, it is not sufficient to merely provide oral medication until the problem can be fixed. In such cases, it may be prudent to place a temporary lumbar drain and restart the infusion until such time as the problem can be correctly diagnosed and treated. Abrupt cessation of clonidine can also be associated with adverse effects such as rebound hypertension, particularly in patients receiving higher doses. All patients receiving clonidine should be provided a prescription for either oral or transdermal clonidine and advised to contact the implanting physician should they develop any symptoms or signs of clonidine withdrawal.

OUTCOME OF INTRATHECAL DRUG INFUSION

Cancer Pain

Continuous IT infusion of opioids was first used for the management of cancer pain in the early 1980s and, over the next decade, remained the single most common indication for ITDD. During the past several years, it seems the use of IT opioids for cancer pain has possibly diminished, due in large measure to the development of more effective long-acting oral opioids as well as the development of less expensive drug infusion reservoirs. Nevertheless, continuous IT opiate infusion remains one of the most effective and satisfying methods of controlling cancer pain and affording patients maximal independence.

Intrathecal opioids are indicated for the management of cancer pain in two circumstances: (1) in patients whose pain is refractory to reasonable doses of oral opiates, and (2) in patients who are unable to tolerate sufficient doses of oral medications needed to adequately treat their pain due to undesirable systemic side effects, mainly sedation. Although appropriate management of the patient is the paramount goal, the current climate of health care in the United States has dictated an ever increasing recognition of the cost of care. In order to justify the cost of an implanted system, potential candidates for pump implantation should have a life expectancy of at least 3 to 6 months. Cost analysis studies comparing implanted programmable pumps to external infusion systems have shown that for patients requiring treatment more than 3 months, an IDP is the more cost effective device.[76,77]

Continuous infusion of intrathecal opiates has proven to be a highly effective and safe method for controlling cancer pain.[2,4,5,9] Adequate pain control which results in significant reduction in oral narcotic intake and increase in activity can be achieved in the majority of patients. A retrospective multicenter survey regarding intraspinal opiate therapy revealed the average reduction in pain to be just over 60% (n = 382) regardless of etiology.[9] Increase in activity was noted in nearly 82% of patients (n = 399) with 59% realizing moderate to significant increases in activities of daily living (ADL). Just over 95% of patients reported either good (42.9%) or excellent (52.4%) pain relief. There were no significant differences in the level of pain relief reported between patients with cancer and those with nonmalignant pain syndromes. Complications related to the delivery system occurred in 21.6% of patients (n = 380) and were most often related to the catheter. Adverse drug effects were reported in approximately one quarter of the patients. The most common adverse effects were nausea and vomiting (25.2%) and pruritus (13.3%).

Perhaps the best evidence for the use of ITDD in patients with cancer pain comes from the study of Smith et al..[76] The authors performed a randomized controlled trial of ITDD versus conventional medical management (CMM) in a cohort of 202 patients. Entry criteria include inadequately controlled pain of 5 or greater (0–10 VAS scale). Clinical success was defined as either a 20% reduction in baseline VAS score, or equivalent VAS score accompanied by at least a 20% reduction in toxicity following 4 full weeks of treatment. Nearly 85% (60 of 71) of patients randomized to ITDD achieved clinical success compared to70% (51 of 72) of patients who received CMM ($p = 0.05$). Mean pain scores fell from 7.8 to 3.7 (52%) for the ITDD group compared to 7.8 to 4.8 in the CMM group ($p = 0.055$). Toxicity scores fell 50% for the ITDD group compared with only 17% for the CMM group ($p = 0.004$). Interestingly, the ITDD also showed improved survival, with 54% alive at 6 months compared with 37% in the CMM group.

Intrathecal Drug Delivery for Chronic Noncancer Pain

During the past two decades, there has been an increasing trend toward the use of chronic intrathecal opiates in the management of refractory nonmalignant pain syndromes.[6–12,14–16] Nonmalignant pain related to failed back surgery syndrome is now the most common indication for the use of ITDD. However, in spite of encouraging results in carefully selected patients with noncancer-related pain, the use of intraspinal opiates for nonmalignant pain has remained a controversial issue among clinicians, lay persons, and government regulators. Indeed, much of the fear regarding this issue has been born of the belief that the use of opiates in nonmalignant pain invariably leads to tolerance and drug abuse. However, numerous retrospective and prospective studies suggest that these previously held beliefs are for the most part erroneous. Nonmalignant pain syndromes for which IT opiates have been and might be used are outlined in Table 99.2. The treatment strategy in patients with nonmalignant pain syndromes should obey the principle that the least invasive and least costly interventions should be attempted first, reserving more invasive and expensive therapies for patients who fail the former. Unfortunately, patient selection for IT administered opiates is not as straightforward as in patients with cancer. Although there are ample reports of significant pain reduction using ITDD, translation of pain reduction into functional improvement has been more difficult to achieve.

Winkelmüller et al. reported on 120 patients with nonmalignant pain syndromes managed with long-term intrathecal opiates with an average follow-up of more than 3 years.[11] Nearly three-quarters (74.2%) of the patients derived benefit from the therapy, with a mean pain reduction of 58%. Overall, 92% of patients were satisfied with the treatment and 81% reported an improvement in their quality of life. The incidence of tolerance was low, only 5.8% (seven patients) and was successfully managed in four patients by means of ‘‘drug holidays.’’ Anderson et al. investi-

gated the long-term efficacy and safety of intrathecal morphine in 33 patients with non-malignant pain.[12] These investigators noted a significant reduction in pain which persisted up to 2 years. Although the daily intrathecal dose of morphine dose appeared to increase for the initial months of treatment, this tended to stabilize and remain constant after 1 year.

Roberts et al. reported their results of ITDD for noncancer pain in 84 patients who were followed on average for 3 years.[14] Nearly two thirds of their patients suffered from low back and/or radicular pain. Mean pain reduction was around 60% and 74% of patients self-reported increased activity levels as well as significant reduction in oral medication. Unfortunately, these gains were not accompanied by change in work status. Technical complications requiring an additional surgical procedure occurred in 40% of patients. These patients were initially receiving relatively high doses of morphine (9.95 mg/day) and by the end of 6 months, the mean daily dose had escalated to 15.3 mg/day.

Finally, Deer et al. reported the results of ITDD for the treatment of low back pain from the National Outcomes Registry for Low Back Pain.[15] Out of 166 patients enrolled to be trialed for an ITDD system, 136 (82%) received a permanent implant. Scores for back and leg pain scores fell by an average of 47% and 31% respectively at 12 months follow-up for those who received an implant. In additional more than 65% of patients demonstrated reduction in Oswestry scores by at least one level compared with baseline. At 1 year follow-up, 80% of patients indicated they were "satisfied" with the therapy, and 87% said they would undergo the procedure again for the same outcome.

CONCLUSION

IT drug delivery has clearly evolved and progressed since its inception nearly 30 years ago. This technique represents a viable option for patients with intractable pain conditions that can not be adequately managed with other means. Although the surgical procedure for pump implantation is relatively "simple," the management of patients with ITDD systems is far from simple. Indeed, ITDD, particularly for patients with nonmalignant pain conditions, represents an indefinite long-term commitment on the part of both the patient and clinician. Multiple issues tend to develop over the course of treatment including drug-related side effects and system complications that must be addressed. Consequently, this therapy should not be entered into lightly. In spite of the potential problems associated with this therapy, it can be useful and rewarding, so long as one adheres to the principles of judicious patient selection, meticulous surgical technique, and diligent patient management.

CHAPTER 100 ■ INTRADISCAL THERAPIES FOR LOW BACK PAIN

WAY YIN AND NIKOLAI BOGDUK

Intradiscal therapies are interventions in which agents—physical or chemical—are delivered into an intervertebral disc either to stop pain or to reverse or remove processes responsible for the pain. Fundamental to the use of such interventions is the belief that the lumbar intervertebral discs are a common source of chronic low back pain. This belief has a long history and is based on a variety of circumstantial and direct evidence.

DISCOGENIC PAIN

As long ago as 1940, Roofe[1] reported finding nerve fibers in lumbar discs. In 1947, authorities as eminent as Inman and Saunders[2] noted that the intervertebral discs were innervated and remarked that they might be a source of back pain. Other investiga-

tors at that time reported that probing the disc, in patients under local anesthesia, evoked back pain[3,4]; and a modern study has since reproduced these observations.[5] Also in that same era, discography was developed—initially as a diagnostic test for disc herniation—but investigators noted that stimulating the disc with injections of contrast medium reproduced the patient's low back pain.[6–9] This implied that the disc was responsible for the patient's back pain.

Resistance to the belief that lumbar intervertebral discs could be a source of pain was based initially on the assumption that discs were not innervated and, so, could not be painful, but a study in 1959 confirmed that the outer anulus fibrosus was endowed with free nerve endings and complex receptors.[10] Later studies corroborated these findings[11] and established that the innervation arose from the sinuvertebral nerves, ventral rami, and grey rami communicantes.[12,13] Using modern staining techniques, studies confirmed the presence of nociceptive nerves in the anulus fibrosus.[14–17] Furthermore, in addition to the normal innervation, damaged or degenerated discs can attract an ingrowth of new nerves, which follow blood vessels and granulation tissue.[18–20]

Once these data eliminated opposition on anatomic grounds, the opposition to belief in discogenic pain turned to the validity of how it could be diagnosed. This has remained a contentious issue.

Some practitioners rely on imaging findings of disc degeneration to implicate the disc as a source of back pain, but this lacks validity. So-called degenerative changes are as prevalent in patients with back pain as in asymptomatic subjects.[21]

Others rely on discography to detect painful discs. The validity of discography as a diagnostic test has been challenged on the grounds that disc stimulation can be painful in asymptomatic subjects,[22] but competing studies[23] and a meta-analysis[24] have shown that the false-positive rate of lumbar discography is no greater than 9% and is substantially less if strict operational criteria are followed.[25] Those criteria require that a disc be classified as symptomatic only if injecting the disc with contrast medium reproduces the patient's pain at pressures of injection less than 50 psi, preferably at less than 15 psi, and that the evoked pain is of an intensity greater than 6 out of 10 on a numerical pain rating scale.[23–25]

Magnetic resonance imaging (MRI) can help to target potentially painful discs. Discs that exhibit high-intensity zones in the posterior anulus are very likely to be painful on discography.[26–32] Similarly, discs that exhibit Modic endplate changes are also likely to be painful.[29,33,34]

PATHOLOGY

Until recent years, the pathology responsible for discogenic pain has been elusive. However, it is now evident that the lumbar disc responds to a variety of nutritional, metabolic, and mechanical insults in a similar manner.[35,36] Those responses are expressed as what, to date, have been called degenerative changes.

The disc matrix is produced by chondrocytes in the nucleus pulposus (NP), and synthesis is promoted by factors such as transforming growth factor (TGF) and insulin-like growth factor (IGF), which reside in the matrix (Fig. 100.1). Under normal conditions, the matrix is continually renewed. For this to occur, old matrix has to be degraded. The chondrocyte produces enzymes, known matrix metalloproteinases (MMPs), which degrade the matrix. These enzymes are controlled by tissue inhibitors of matrix metalloproteinases (TIMMPs).[35,36]

Injury disturbs the normal balance between synthesis and degradation toward degradation (see Fig. 100.1).[35,36] Injury results in the liberation of phospholipases, which in turn act on arachidonic acid to produce prostaglandins and leukotrienes (LTs). LTs are chemotactic and attract macrophages. Macrophages release superoxide and cytokines such as tumor necrosis factor alpha (TNFα), interleukins, and interferon. These cytokines stimulate the chondrocyte to produce more MMPs and, thereby, promote matrix degradation. The cytokines also stimulate nitric oxide synthetase to produce nitric oxide (NO). NO inhibits the chondrocyte, but also combines with superoxide to produce peroxynitrite, which inhibits the TIMMPs, thereby promoting matrix degradation. Superoxide itself inhibits the chondrocyte, and directly degrades the matrix.

As the nucleus degrades it is no longer able to retain water and loses its hydrostatic properties. Pressures within the nucleus become irregular and reduced (see Fig. 73-3),[37,38] and the nucleus is less able to sustain compression loads. Meanwhile, compression loads are increasingly borne by the posterior anulus, which

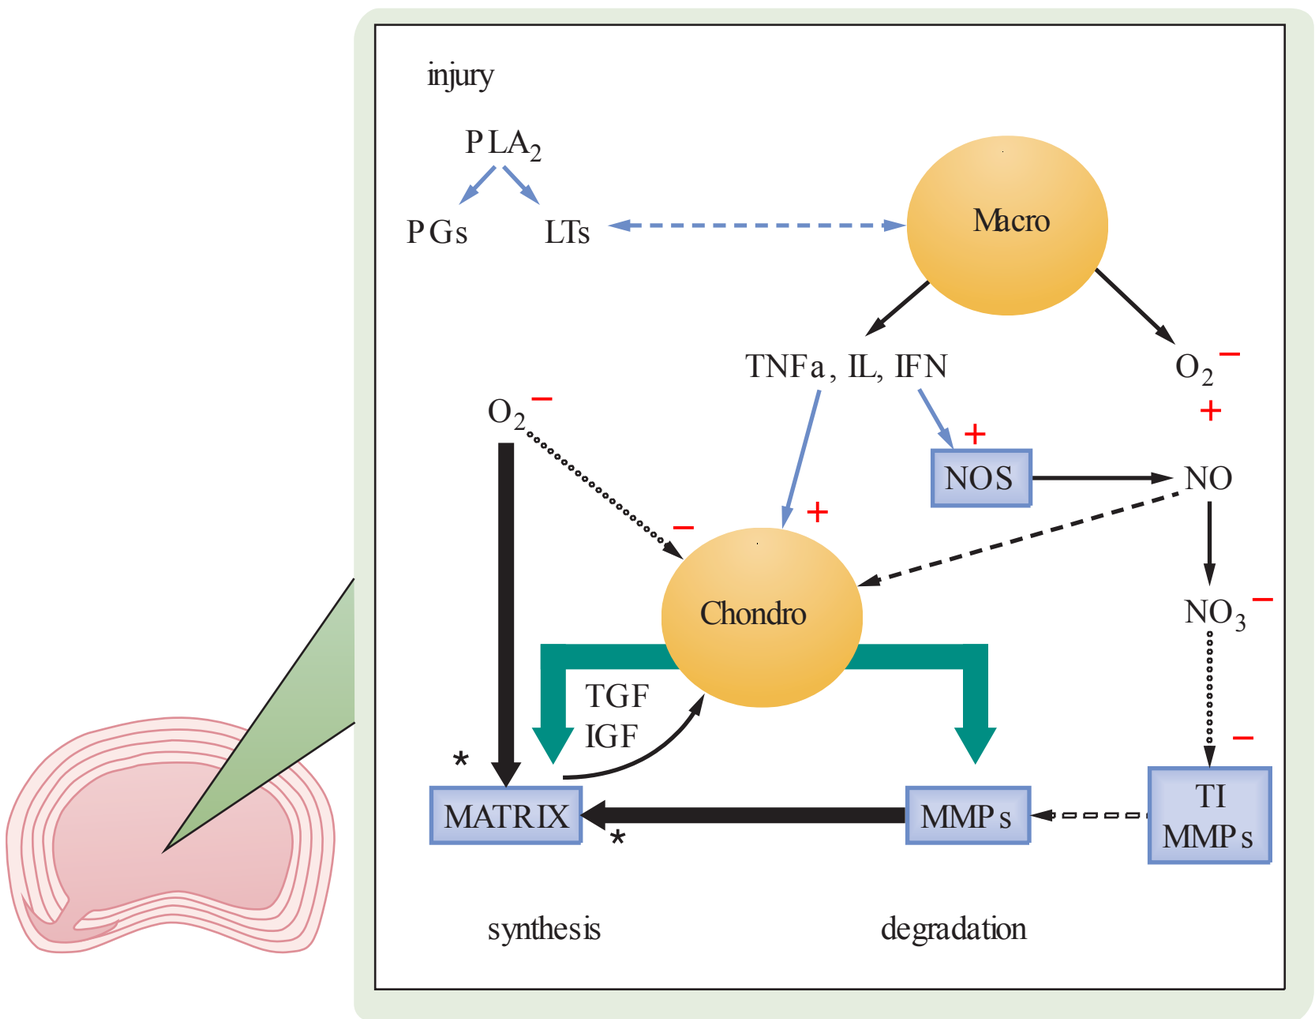

FIGURE 100.1 The molecular biology of disc degeneration and internal disc disruption. Bold arrows and plus signs (+) indicate production, promotion, or stimulation. Dashed arrows indicate attraction. Dotted arrows and minus signs (−) indicate inhibitory influences. Open arrows and asterixes (*) indicate degradative effects. Chondro, chondrocyte; IFN, interferon; IGF, insulin-like growth factor; IL, interleukins; LTs, leukotrienes; Macro, macrophage; MMPs, matrix metalloproteinases; NOS, nitric oxide synthetase; NO, nitric oxide; NO_3, peroxynitrite; O_2^-, hyperoxide; PGs, prostaglandins; PLA_2, phospholipase A2; TFG, transforming growth factor; TIMMPs, tissue inhibitors of MMPs; TNFα, tumor necrosis factor alpha.

is subjected to loads substantially above normal (see Fig. 73-3).[37,38]

The depressurized nucleus is unable to brace the anulus internally. As a result, the inner anulus buckles and delaminates. Progressive disruption of the anulus leads to the development of radial fissures, which are characteristic of the condition known as internal disc disruption.[39–41] The severity of disruption can be graded according the extent to which fissures penetrate the anulus (see Fig. 73-2). Grade III fissures reach the outer third of the anulus, and become grade IV fissures if they extend circumferentially around the outer anulus.

Classical, macroscopic, degenerative changes, such as osteophytes, loss of disc height, or simple loss of disc signal on MRI, do not correlate with pain, but other features do. Reduced pressures in the nucleus,[42] increased pressure in the posterior anulus,[42] and grade III radial fissures[43,44] each correlate strongly with the disc being painful on discography. In particular, radial fissures are the hallmark of painful discs. They do not represent age-changes[44] and are most likely features of previous injury. Some 70% of painful discs exhibit radial fissures, and some 70% of discs with radial fissures are painful.[43]

In patients with chronic low back pain, the prevalence of internal disc disruption is at least 39%.[45] The diagnostic features are a reproduction of the patient's pain by disc stimulation at low pressures of injection, provided that stimulation of adjacent discs does not reproduce pain, and demonstration of a radial fissure on postdiscography computed tomography (CT) scan.[25]

The mechanism of pain appears to be a combination of mechanical and chemical factors. The increased pressures in the posterior anulus provide a basis for mechanical pain. The inordinate pressures in the posterior anulus would stimulate the nociceptive nerve endings in the outer anulus. Inflammatory mediators from the degraded nucleus provide a basis for chemical pain. Mediators that track through the radial fissure would reach the nerve endings in the outer anulus. They could stimulate the nerve endings to produce chemical nociception, or they could sensitize the endings and lower their threshold to mechanical stimulation. Both mechanisms could be amplified if new nerve fibers are attracted into the disc by the radial fissure.[18–20]

THERAPIES

Some intradiscal therapies target the innervation of the disc (Fig. 100.2). They seek to interrupt nociception from the affected disc without seeking to alter its pathology. Other therapies seek to alter the macroscopic features of internal disc disruption by coagulating fissures or by removing degraded matrix from within radial fissures or the nucleus. At a molecular level, various therapies target agents involved in the degradative systems of the disc (see Fig. 100.1).

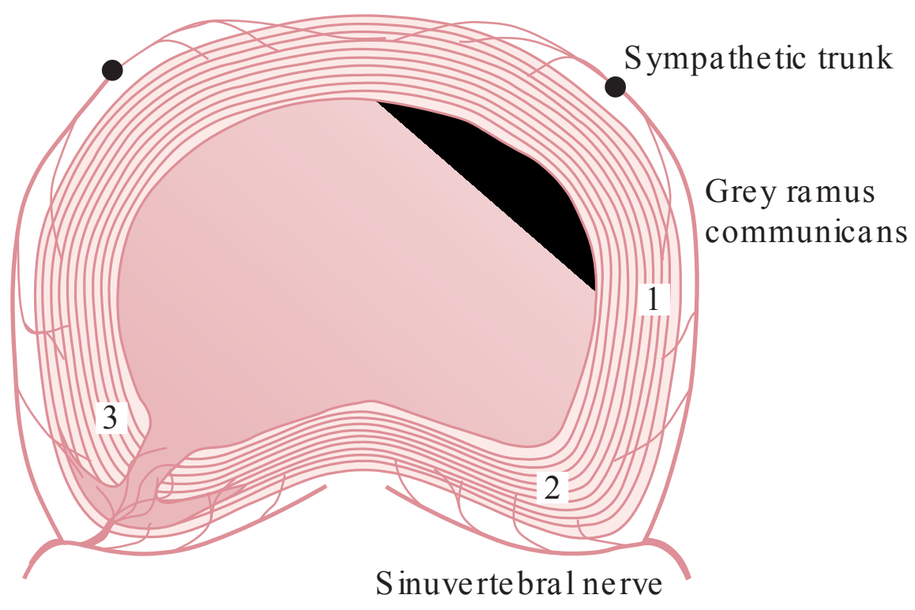

FIGURE 100.2 A sketch of a transverse section of a lumbar intervertebral disc showing the structural elements that are targets of some intradiscal therapies. The disc is innervated laterally and anteriorly by branches of the sympathetic trunk and grey rami communicantes (1), and posteriorly by the sinuvertebral nerves (2). Nerve endings are normally found within the outer third of the anulus fibrosus. Radial fissures (3) attract a neoinnervation in which nerve fibers extend deeper into the disc. Treatments can be directed at the degraded nucleus, the radial and circumferential fissures, or the nerve endings that mediate discogenic pain.

Denervation

Attempts have been made to denervate painful discs at a variety of sites using a variety of means. Most have proved unsuccessful.

Ramus Communicans Lesions

Once it was demonstrated that lumbar discs derive some of their innervation from the grey rami communicants,[12] the possibility was raised of treating discogenic pain by thermocoagulating the ramus communicans.[46] The weakness of this rationale, however, is that the grey rami constitute only one of the sources of innervation, and they innervate the anterior and lateral aspects of the disc—not the posterior anulus, which appears to be the most likely source of pain. This weakness is borne out by the only study of grey ramus communicans coagulation.

A prospective, controlled study compared the effects of thermal radiofrequency lesioning in the region of the ramus communicans with those of injections of lidocaine over the same site.[47] In terms of pain scores and SF-36 scores, significant differences arose in favor of radiofrequency treatment at 4 months following intervention. However, the degree of relief afforded by radiofrequency therapy was modest, amounting to only a 46% mean decrease in pain, and the authors did not stratify their data to demonstrate the number of patients experiencing high-grade relief (75%–100%).[47] Moreover, the study was confounded because patients who received radiofrequency therapy also received an injection of triamcinolone (40 mg) at the site treated, which the control group did not receive. It is, therefore, not evident if the modest improvements seen in the study group arose from the radiofrequency lesion created or the injection of corticosteroids.[47]

Intranuclear Radiofrequency

The NP is normally devoid of nerve endings. Therefore, placing radiofrequency lesions in the nucleus has no prospect of coagulating nerves in the immediate vicinity of the electrode. However, proponents of intranuclear radiofrequency argued that the electric field produced around the electrode would be sufficient to heat and destroy nerve fibers in the outer anulus fibrosus, and thereby provide relief of pain.[48] This belief was based on a theoretical assessment of the magnitude of the electric field and the proposition that temperatures of 45° C would be achieved in the outer anulus and would be enough to coagulate nerves.

Cadaver studies rapidly dispelled this notion.[49,50] Significant heating did not occur in the outer anulus. Nevertheless, the procedure continued to enjoy some popularity in some circles. A controlled trial eventually demonstrated that intradiscal radiofrequency achieved no greater relief of pain than sham therapy.[51] What were promoted as successful outcomes in earlier observational studies amounted to no more than placebo responses.

Sinuvertebral Nerve Lesions

Since the sinuvertebral nerves innervate the posterior anulus fibrosus, they would be a logical target for denervating a painful posterior anulus. However, because these nerves are often plexiform, they are unlikely to be selectively and completely targeted by conventional means of denervation. Although anecdotal references may be found in lectures, monographs, and texts,[52–54] no controlled or prospective studies of the efficacy of sinuvertebral

nerve lesions for the treatment of lumbar disc pain are currently available.

Intradiscal Electrothermal Therapy

The use of a resistance-coil flexible heating element deployed within the fibers of the posterior anulus or along the nuclear-anular boundary was developed in the mid-1990s. Under the trade name of IDET, the technology proposed that therapeutic benefits resulted from "several heat related effects," including "destruction of pain receptors on the outer layers of the disc . . . [thermal-induced] remodeling of the collagen fibers that make up the anulus fibrosus . . . [and] cauterization and subsequent disintegration of vascular ingrowth."[55–59] None of these conceptual mechanisms have ultimately been verified by in vitro studies.[55–57] Nevertheless, IDET has been the focus of intense study and sometimes conflicting reviews.[59–63]

Eight observational studies[64–73] have demonstrated a mean reduction in pain by at least 30 points. The proportion of patients who achieve greater than 50% has ranged from 50%[66,67,74] to 70%,[64,65] and up to 20% of patients achieve complete relief.[66,67] Outcomes are maintained for 2 years.[67,71,73]

Two randomized, placebo-controlled trials have been published with differing results.[75,76] In one study, where rigorous selection criteria were applied, and both diagnostic provocation discography and subsequent IDET (or sham) was performed by highly experienced practitioners, a clear difference was demonstrated between placebo and experimental groups.[75] By the general criteria applied to many surgical studies (≥50% relief), IDET was effective in 40% of patients. Furthermore, the degree of relief was stratified in this study—a courtesy seldom extended by studies of pain treatment. Twenty-two percent (7/32) of patients undergoing IDET for lumbar disc pain experienced 75% to 100% relief of pain. The duration of relief was not addressed in this study, for it was designed explicitly to test IDET against placebo. In that regard, it warned that patients undergoing intradiscal therapy could experience placebo effects, but it showed that the effects of IDET could not be wholly attributed to placebo effects.

The other controlled study[76] enrolled a similar number of patients (albeit with different demographics) with similar complaints to those of the former study.[75] Intriguingly, it found no effect, either from active treatment or from sham treatment. The lack of any placebo effect stands in marked contrast with the majority of other sham-controlled studies in clinical medicine. This lack of any demonstrable or measurable response remains unexplained. Since that study was not able to reproduce the responses seen in observational studies and since no placebo effects were demonstrated, that study does not provide evidence that those responses are due to placebo effects.

Although providing relief in a relatively small subset of patients with disc pain, IDET currently represents the most thoroughly investigated percutaneous intradiscal therapy for symptomatic internal disc disruption. The majority of prospective studies demonstrate that in well selected patients, 40% to 50% may experience greater than 50% reduction in pain with improvements in other functional outcome measures and that a small fraction (approximately 20%) may expect high-grade to complete relief which is durable.

Nucleoplasty

Application of frequency alternating current radio between two closely apposed electrodes separated by an insulator can result in the generation of a stable plasma field in conductive tissue. Moving such an electrode—and thereby the plasma field—through tissue results in vaporization of tissue in the path of the plasma field, leaving a void. Percutaneous application of this technology for the removal of disc tissue is a patented technology marketed as "nucleoplasty," or "percutaneous plasma disc decompression." The procedure involves creation of several tunnel-like voids in the disc nucleus following multiple passes of the plasma field generated by the electrode or "nucleotome." The vaporized disc material is subsequently vented out of the disc nucleus. Vaporization of solid disc nucleus results in a reduction of mass in the disc nucleus, theoretically decreasing intradiscal pressures and thus resulting in disc decompression.

Nucleoplasty is purported to reduce pressures in the NP.[77] Although this might be of relevance for the treatment of radicular pain due to disc herniation, it is unlikely to be relevant to the treatment of discogenic pain. The pressures within a disc are not uniform (see Fig. 73-3).[37,38] Therefore, it is not evident that reducing pressure at one site affects pressure elsewhere or throughout the disc. Moreover, in painful discs, nuclear pressures are already reduced, not raised. The offending pressures are in the posterior anulus, not in the nucleus. Therefore, nucleoplasty lacks an anatomic rationale for the treatment of discogenic pain.

In vivo animal studies have demonstrated that plasma discectomy alters cytokine expression in experimentally induced disc degeneration.[78] The relevance of these changes to the effectiveness of nucleoplasty for discogenic pain remains unknown.

Clinical applications for plasma discectomy, like those for other techniques for percutaneous discectomy, have typically focused on the treatment of radicular pain associated with disc protrusion, herniation, or bulge.[79] No prospective, randomized, controlled studies are available (at this time) regarding the use of percutaneous plasma discectomy for either radicular pain or discogenic pain.

Observational studies with follow-up longer than 1 month include retrospective case series[80,81] and limited nonrandomized prospective series with varying levels of follow-up and patient selection criteria.[82,83] Two studies are available but it is not clear whether they evaluated patients prospectively or retrospectively.[84,85] All available studies grouped patients with low back pain and radicular pain together, which precludes any determination of efficacy for either specific condition. No available studies have specifically examined the efficacy of percutaneous plasma discectomy in patients with rigorously determined primary discogenic pain.

Chemical Therapies

Chemical therapies for discogenic pain target one or other of the agents involved in disc degradation. Some have proved unsuccessful; others show promise.

Intradiscal Steroids

Because phospholipase A2 (PLA2) has been implicated in disc degeneration and disc injury, intradiscal injection of corticosteroids has a rationale. By inhibiting PLA2, steroids prevent the arachidonic acid cascade and the production of prostaglandins and leukotrienes (see Fig. 100.1). However, intradiscal steroids were first used before the molecular biology of the disc was known, ostensibly because of their reputation of efficacy in treating arthritis.

Feffer[86] published the first report in 1956. He treated 60 patients with intradiscal injections of hydrocortisone, each at two levels (L4-L5 and L5-S1), using a transdural, midline approach. Patients were selected for treatment because they were "either in extreme pain and not responding to bedrest or had rapidly recurring symptoms in spite of bedrest, plaster-of-Paris jackets, back supports, and other conservative measures."[86] Seven were injected for diagnostic purposes when the etiology was in doubt.[86] Discography was performed during the treatment, but was not used as a selection criterion. Patients were maintained at strict bedrest for 2 to 3 weeks before and after injection. Responses

were graded on the basis of pain, spasm, scoliosis, sciatic irritability, and neurologic findings. Feffer reported that 37 of 60 patients had "rapid remission of symptoms . . . usually . . . in four to six hours, and major discomfort had disappeared in twenty-four hours. Remissions have been permanent in thirty-three of these patients for a maximum follow-up period of eight months. . . ."[86] Nucleograms in 55 of the 60 patients were interpreted as abnormal. Five patients had "normal nucleograms," none of whom showed improvement. In 16 of the 18 failures reported, laminectomy and discectomy was performed and "all the discs . . . demonstrated irreversible changes."

Feffer[87] subsequently published a reappraisal of his original methodology with longer-term follow-up in 1969. This retrospective report described 244 patients with follow-up between 4 and 10 years, of whom 46.7% reported "permanent remission" of symptoms. Interestingly, Feffer[87] noted better responses in patients over the age of 50 with predominant back rather than radicular complaints.

These encouraging results later prompted a double-blind comparison between intradiscal injection of hydrocortisone and chymopapain injection in patients with "long-term back pain and/or sciatica."[88] The purpose of this study was to determine the effects of chymopapain, then considered a promising and relatively novel therapeutic alternative, against a reference. Intradiscal hydrocortisone was used as a control as it was felt to have "some therapeutic value," and the author felt ethically "disinclined to use a true placebo."[88] Twenty patients were randomized prospectively to receive either a single intradiscal injection of hydrocortisone or chymopapain based on diagnostic discography. Twelve of 20 patients (60%) undergoing chymopapain injection were reported to have demonstrated "good" (near complete to complete relief) or "fair" results, and as did 53% of patients who underwent hydrocortisone injection. Although detailed outcome measures were not reported, the author concluded that chymopapain injection was more effective than intradiscal hydrocortisone injection, but the differences did not reach statistical significance. The possibilities of placebo responses to injection (potentially approaching 60%–70%) were discussed, but dismissed.[88]

Following the withdrawal of chymopapain from the commercial medical market in the mid-1970s, Wilkinson and Schuman[89] published the results of a case series of 29 patients who had normal myelography and no focal neurologic symptoms. Unlike previous reports where a water-soluble steroid (hydrocortisone) was injected, these investigators used a suspension of methylprednisolone. No controls were used. Sequential injections were performed if an initial response was seen in the first 3 months following initial injection. Fifty-eight percent of initial injections were performed in patients with discogenic pain (defined as "back pain with little or no radiation into the lower extremities"), and 42% of injections were performed for predominant complaints of radicular pain. For patients with predominant "discogenic pain," 31% had "good results" with 37% reporting a good result in the radicular pain group. When the authors stratified their outcomes and excluded patients who had failed single injection or who had undergone prior lumbar spine surgery, the interpretation of respondents experiencing a "good result" increased to 54% in the low back pain group and 40% in the radicular pain group. The statistical significance of these findings was not reported.[89]

Due to the heterogeneous patient populations, methodologies, and outcome measurements from these initial studies, Simmons et al.[90] performed a more rigorous prospective double blind, controlled trial comparing intradiscal injections of 80 mg methylprednisolone suspension against 1.5 mL 0.5% bupivacaine injected at the time of diagnostic discography. More rigorous patient selection criteria and outcome measures were applied, and only those patients with discography-proven single level disc pain in the absence of disc extrusion were considered. Patients were excluded if their age was greater than 50 or if previous surgery had been performed. Outcome measures included visual analog pain scores (VAS), Oswestry pain questionnaire, and pain diagrams. The period of follow-up was extremely short (10–14 days). Only 21% of patients who were randomized to methylprednisolone suspension and 9% who received bupivacaine reported overall improvement. When individual outcome measures were compared, improvements in VAS were seen in 43% of patients who received steroid and in 36% of those who received bupivacaine. Oswestry Pain Questionnaire responses showed similar responses (36% improved with steroid, 27% with bupivacaine).

Another more recent randomized control trial was performed with 1-year follow-up.[91] Patients complaining of predominant back pain were randomized at the time of provocation discography to receive intradiscal methylprednisolone suspension (40 mg) or 1 mL normal saline. Selection criteria were fairly rigorous: only patients with single level disc concordant pain were enrolled, and postsurgical patients were excluded. It is unclear whether workers compensation patients were excluded. Discography was not manometrically-controlled. The severity of degeneration at the symptomatic level was not recorded. Of 120 patients enrolled (60 into each of the steroid and saline groups), 77% in the steroid group and 87% in the saline group completed follow-up. These authors noted no discernible improvements in Oswestry Disability Index (ODI) or VAS pain scores in either group.[91]

Others have used different selection criteria. A retrospective case series examined the effects of intradiscal prednisolone acetate (25 mg) injection in patients with painful discs associated with MRI evidence of Type I and Type II endplate changes on following provocation discography.[92] Prospective outcome data were recorded for all 74 patients whose charts were reviewed retrospectively, and included VAS, Quebec disability score, and other subjective measures. A change in VAS was recorded at 1 month following injection, with VAS and disability scores measured as secondary outcomes at 1, 3, and 6 months following injection. Compared to patients with Type II changes, moderate and statistically significant improvements in VAS were seen in patients with Type I or Type I and Type II changes at 1 month following injection. The mean reduction in VAS was 5.3 mm in patients with Type II lesions, but 30.2 mm for Type I, and 29.4 mm for combined Type I and II lesions. At 1 month, only 1 of 11 patients with Type II lesions reported greater than 50% relief of pain, whereas 18/33 patients with Type I lesions and 13/25 patients with combined lesions reported that degree of relief. However, the treatment effects between groups became indistinguishable at 6 months. Although the authors concluded that intradiscal injection of steroid in patients with chronic low back pain and predominant Type I endplate changes on MRI, significant limitations remained with regard to the relatively low number of patients demonstrating such findings and the retrospective nature of the study.

In essence, despite favorable reports from observational studies, two randomized placebo-controlled studies have indicated that intradiscal steroid injections are not effective in the management of discogenic, chronic low back pain. Whether more rigorously selected patients with internal disc disruption may benefit from intradiscal steroid injection remains unclear, but the size of such a subpopulation is likely to be small.

Etanerceptt

Because TNFα is involved in the degradation of lumbar discs (see Fig. 100.1), there is a rationale for using TNF-blocking agents to treat discogenic pain. One such agent is etanercept, which binds TNF receptors.

A placebo-controlled study assessed the efficacy of intradiscal injection of etanercept in doses increasing from 0.1 mg to 1.5 mg.[93] No differences were found at 1 month, either within or

between patients treated with etanercept or normal saline, with respect to relief of pain or disability. Prima facie, these results deny a role for intradiscal etanercept in the treatment of discogenic pain, although the possibility remains that higher doses might still be effective.

Methylene Blue

Methylene blue, a common histologic stain, has also been used in clinical medicine for over 100 years. As a dye, it has been used to detect mucosal defects in urology and gastroenterology and to stain cement in orthopaedics. In general medicine, it has been used to treat methemoglobinemia and hepatopulmonary syndrome and pruritus ani. It has weak neurolytic effects, but its main actions appear to be inhibition of guanylate cyclase and NO synthesis. The latter property affords it a role in the treatment of discogenic pain by blocking the degradative effects of NO (see Fig. 100.1).

Investigators from China have reported a prospective pilot study in which 24 patients underwent injection of methylene blue into one (18/24) or two (6/24) discs immediately following provocative discography.[94] Patients were followed for a minimum of 12 months, with mean duration of follow-up 18 months. Outcome measures included the ODI and VAS pain ratings. The mean improvement in VAS in the single level injection group was 5.65 and 4.40 in the two-level group, with ODI improvements of 36 and 24, respectively. These changes were statistically significant. Across the entire treatment group, VAS was reduced from 7.52 $\pm$ 1.31 to 2.18 $\pm$ 1.79 (71% reduction) at 12 months, and ODI was reduced from 48.71 $\pm$ 5.28 to 15.38 $\pm$ 13.63 (68% reduction). Three of 24 patients showed no improvement or improvement less than 2 points on VAS. Of the remaining 21 patients, 11 were reported to have rated pain at less than VAS 2 at 12 months, with 5/21 (24%) apparently experiencing complete relief.

These results are extraordinary. No other intervention for chronic back pain has ever achieved such outcomes. However, the context of the study is unclear. It is not evident if the patients expected the treatment to work or if they faced fusion if the injections did not work. It is not known if patients in China respond to research studies in a manner different that of patients in the Western world. If methylene blue is as effective as reported, it urgently needs to be tested both in different populations and under controlled conditions.

Ozone

Intradiscal injections of ozone have been promoted largely in the Italian literature,[95–100] although some English-language publications have appeared.[101–104] The professed rationale is that ozone suppresses intradiscal inflammation.[105–107]

However, although back pain is mentioned in the indications, radicular pain appears to have been the primary indication. No studies have reported the effectiveness of ozone for back pain. Furthermore, although high rates of success in large numbers of patients have been enthusiastically promoted, the available literature is composed largely of case reports and retrospective case series, in which validated outcome measures have not been used.

Although touted as "safe," several cases of serious complications and death associated with intradiscal injection of O_2/O_3 have been reported.[108–110] The injection of an oxidizing gas—in relatively large volumes—in and around the disc may be especially problematic if safeguards against intra-arterial or subarachnoid injection are not rigorously maintained.

Proliferants

Some investigators have sought to ameliorate disc pain through the injection of substances purported to enhance healing of diseased disc tissue. Typically, solutions have been used that contain chondroitin sulfate, glucosamine hydrochloride, dimethylsulfoxide (DMSO), bupivacaine, and hypertonic dextrose[111,112] or hypertonic dextrose alone.[113]

An initial prospective case series involved 30 patients receiving an average of 2.5 intradiscal injections of a compounded mixture of chondroitin sulfate, glucosamine hydrochloride, DMSO, bupivacaine, hypertonic dextrose, and nonionic contrast dye.[111] The investigators reported that 57% of patients experienced greater than 50% improvement in pain sustained over a minimum follow-up of 12 months. Some 30% of patients reported reduction of pain score to 0 or 1 on a 10-point scale.

A subsequent retrospective study compared the efficacy of intradiscal injection of the aforementioned with IDET with more modest results.[113] The study was hampered by differing group sizes between IDET (74) and intradiscal injection (35), as well as mean duration of follow-up (IDET: 15.5 months; disc injection: 8 months) and uncontrolled cross-over (17% of patients undergoing intradiscal injection had previously failed IDET). The results of this study demonstrated meager improvements in both groups (mean VAS reduction from IDET: 1.27; from intradiscal injection: 2.2). No other functional outcomes were assessed, and the durability of relief in the intradiscal injection group was not with the IDET group.

In a more recent study, single and repeated intradiscal injections of hypertonic dextrose with bupivacaine were studied in 76 patients with primary complaints of leg pain, with or without back pain.[113] An average of 3.5 injections were performed into discs that were positive on provocative discography. Approximately 50% of patients were reported to experience significant improvements in pain, although the percentage experiencing complete relief was not stratified, and a strong selection bias existed for patients who reported improvements in pain while undergoing intradiscal dextrose injections. The authors also did not explain the elicitation of "concordant pain reproduction" in patients undergoing discography without low back pain and their inclusion in the study.

Whether intradiscal injections of hypertonic dextrose, with or without other agents, such as local anesthetics, chondroitin, glucosamine, or DMSO, successfully relieves pain arising from symptomatic internal disc disruption remains unclear. Since numerous pharmacologically active agents were used in these noncontrolled studies, the specific agent (or combination) that may affect a positive clinical response is difficult to ascertain. Although authors have referred to injection of these agents as "regenerative" or "proliferative" therapies, chondroitin and glucosamine have not been shown to have any specific anabolic effect on the disc, and DMSO is neurolytic. The term "regenerative" seems more appropriate for emerging intradiscal therapies that have a known positive effect on connective tissue metabolism.

Regenerative Therapies

A variety of cytokines, growth factors, and virus-mediated gene therapies are known to promote favorably the metabolism of connective tissues. Several are being explored for the restitution of degraded discs. To date, however, these agents have largely been studied only in laboratory animals or tissue cultures. Such studies as have been conducted in humans have addressed only safety. Efficacy has not been addressed.

Thompson et al.[114] were the first to examine the effects of various growth factors on mature canine intervertebral disc cell cultures. In their model, certain growth factors, especially human platelet derived transforming growth factor-β (TGF-β_1) and epidermal growth factor (EGF), resulted in marked increases in matrix synthesis and cell proliferation (EGF) or matrix synthesis alone (TGF-β_1). Increases in matrix synthesis with TGF-β_1 were dramatic. The effect of growth factors, however, was time-limited

to several days. Other investigators have demonstrated that application of platelet-derived growth factor (PDF) and IGF-1 may reduce the rate and number of human anular cells undergoing apoptosis in vitro.[115]

In vivo injection of another human growth factor, osteogenic protein-1 (OP-1, also known as bone morphogenic protein-7), into rabbits resulted in mild increases (12%–15%) in disc height up to 8 weeks following injection.[116] Subsequent studies of intradiscal OP-1 in a rabbit, anular-puncture, degenerated disc model demonstrated reversal of loss of disc space height sustained at 24 weeks.[117] Sustained restoration of disc space height at 12 weeks in a chemically-induced (intradiscal injection of chondroitinase ABC) degenerative rabbit disc model has also been reported.[118]

Nishida et al.[119] pioneered the feasibility of adenovirus-mediated gene transfer to rabbit nuclear cells in vitro and in vivo. Subsequently, their group was able to demonstrate the in vivo feasibility of TGF-β_1 gene transfer utilizing an adenovirus vector (Ad/CMV-hTGFβ_1) in rabbit intervertebral discs.[120] In discs injected with Ad/CMV-hTGFβ_1 a 30-fold increase in active TGFβ_1 production 1 week after injection was seen with a 100% increase in proteoglycan synthesis over saline-injected controls. Proponents of gene therapies argue that although temporary increases in matrix synthesis or nuclear cell proliferation demonstrated with direct intradiscal injection of growth factors is promising, the relatively short biologic half-life of growth factors would require sustained delivery systems in vivo. Such technical challenges would be difficult to overcome with existing technologies. Thus, if existing intervertebral disc nuclear chondrocytes could be induced to produce growth factors endogenously, an intrinsically self-sustaining source of growth factors may be more attractive.

The feasibility of utilizing adenoviral vectors to induce genetic changes in disc nuclear cells or the direct injection of human growth factors has not yet been investigated in humans. Concerns remain regarding the regulation of growth factor effects or induced cellular synthetic activity in nontarget tissues.

Although disc cells account for only about 1% of the disc tissue by volume,[121] they play a crucial role in matrix synthesis. As cells are of crucial value to the metabolic health of the disc and its nuclear matrix, an alternative therapeutic strategy would focus on augmenting intradiscal cell populations through introduction of autogenic or allogenic cartilaginous chondrocytes, NP cells, or mesenchymal stem cells.

The effects of injection of an autogenously collected NP and NP cell cultures in an anular stab model of disc degeneration in rabbits have demonstrated that disc degeneration and formation of type II collagen can be delayed.[122] Subsequent investigation of the effects of allogenic NP demonstrated similar delays in the formation of degenerative changes without stimulating an immune response.[123] The determination of the degree of disc degeneration in both studies was performed semi-quantitatively, using histologic stains to examine changes in cell populations and type II collagen 24 weeks[122] or 16 weeks[123] after injection. Nuclear degeneration not reversed by the introduction of autologous or allogenic NP aspirates.

Other researchers have focused on autologous chondrocyte transplantation. Reintroduction of fresh or cryopreserved NP in a degenerative rat model suggested that degeneration could be delayed.[124] A detailed in vivo study of the effects of cultured autologous nuclear chondrocytes was performed in dogs. Plain film radiographs, disc height analysis, MRI imaging, and histologic analysis was performed at 3, 6, 9, and 12 months after autologous transplantation. The discs subjected to tissue harvest were examined to determine whether disc repair occurred. Transplanted cells retained viability and underwent expected morphological changes from tissue culture once reintroduced into the disc. The transplanted chondrocytes produced type I and II collagen and proteoglycans similar to normal tissue, and at longer time intervals following transplantation, disc height was better retained. No inflammatory reactions were seen.[121] A human safety trial has been initiated with interim results suggesting that intradiscal reintroduction of autogenous chondrocytes may better disc height after lumbar discectomy.[125,126]

More recently, the effects of intradiscal transplantation of autogenic and allogenic mesenchymal stem cells (MSCs) have been investigated. MSCs possess a theoretical advantage of mature cell transplants in their pluripotency. Proponents of intradiscal MSC transplantation argue that since the causes of disc degeneration are likely multifactorial, the use of autogenic or allogenic stem cells minimizes the likelihood of host antigenic recognition and MSCs, once differentiated, may be less susceptible to genetic senescence or apoptosis. The use of allogenic MSCs may offer "off the shelf" availability—rather than requiring labor intensive autogenic cell harvesting and culture—and potentially avoid genetic predisposition to degeneration.

Several investigations have demonstrated that MSCs can be introduced into animal discs, remain viable, and differentiate into NP-like cells, produce matrix, and retard experimental disc degeneration.[127–129] In vitro experiments with human MSCs demonstrated differentiation of MSCs into NP-like chondrocytes if cocultured with human NP cells. Differentiation required direct cell-cell contact.[130] Subsequent investigations demonstrated that MSCs differentiated into chondrocytes-like cells if implanted in a three-dimensional matrix, including several hydrophilic gels. Partial depolymerization and deacetylation of chitin from crustaceans creates a hydrogel (chitosan). Combining chitosan with glycerophosphate creates a temperature sensitive hydrogel (C/Gp) which is liquid at room temperature and gels at body temperature, which would make C/Gp an ideal delivery vehicle for MSCs clinically. Bovine MSCs have been demonstrated to differentiate toward NP-like chondrocytes (as opposed to articular chondrocytes) when placed in C/Gp gel without added differentiating media in vitro.[130] The ability of MSCs to differentiate into NP-like chondrocytes (and not osteocytes or articular chondrocytes) in a gel environment without specific differentiating media is intriguing. Stem cells cultured in a three-dimensional gel matrix in a hypoxic environment tended to differentiate into NP-like cells, the addition of TGFβ-1 resulted in concert to activate genes expressed by NP cells, including those that encode matrix proteins and cell surface receptors.[131]

The identification of technically feasible delivery vehicle for MSCs (such as temperature sensitive hydrogels), their demonstrated in vivo ability to differentiate into NP-like cells in a hypoxic disc nucleus-like environment, and their and ability to produce nuclear matrix aggrecans and proteoglycans once differentiated is extremely promising. The pace at which discreet mechanisms controlling MSC differentiation are being discovered is rapid. A complete understanding of the control pathways that regulate differentiation of implanted MSCs and their long-term in vivo viability remain as important questions to be answered before studies in humans can be considered.

Proponents of regenerative-, gene-, and cell-based therapies have predominantly focused on preventing or reversing disc degeneration associated with loss of nuclear matrix, cells, or restoring internal disc mechanical integrity. In experimental animal models of disc degeneration, usually incited by anular stab incisions, several approaches including direct intradiscal injection of growth factors or cell transplantation with or without a hydrogel lattice have been demonstrated to delay or partially reverse degenerative changes. However, a correlation between experimentally-induced animal disc degeneration and human disc pain has not been established.

Animal models of disc degeneration have mostly involved the creation of an anular injury (usually an incision) in young, otherwise healthy discs. It has not been the intent of these models to establish whether or not the induced degenerative changes are painful, but to mimic chemical, histologic, and radiographic changes that parallel degenerative changes in humans. No natu-

rally occurring model of disc degeneration in commonly used laboratory mammals has been identified that closely mimics the degenerative changes seen in bipedal primates such as humans.

An important, and possibly crucial, caveat is that tissue cultures and animals may not be valid and realistic models of the human condition. In humans, the lumbar discs are persistently subjected to large compression loads during activities of daily living. What has still to be demonstrated is that intradiscal agents can exert their effects in the face of a hostile mechanical environment.

Ultimately, a focus on preventing or treating disc degeneration per se may have limited clinical relevance in man, as loss of disc height, anular bulges, protrusions, and even herniation are found in the majority of asymptomatic adults.[132–135] Progressive degeneration over 5 years in people initially asymptomatic does not correlate with the development of pain.[136] The ubiquitous nature of lumbar disc degeneration and its high prevalence in both symptomatic and asymptomatic individuals has underscored the importance of disassociating the presence of degeneration with identification of a particular symptom complex.[137] Although regenerative approaches show promise, including the possibility of creating a fully tissue engineered disc from homologous nuclear and anular cells,[138] the ultimate role of regenerative approaches in patients with disc pain remains far from clear, but technological advancements in this field may ultimately prove clinically useful once specific clinical applications and the timing of intervention becomes clear.

CHAPTER 101 ■ NEUROLYTIC BLOCKADE FOR NONCANCER PAIN

JAYANTILAL GOVIND† AND NIKOLAI BOGDUK

INTRODUCTION

Definition

Stedman's Medical Dictionary defines neurolysis as either the selective, iatrogenic destruction of neural tissue to secure the relief of pain, or a procedure in which the nerve is electively freed surgically from inflammatory tissue.[1] This chapter deals with the former half of this definition. It covers using chemical or physical means to damage peripheral nerves focally in order to prevent the transmission of nociceptive information along the target nerve so as to provide relief of pain. Surgical interventions are described in Chapter 104.

Etymologically, the term "neurolysis" actually means teasing apart or dissolving a nerve and "neurotomy" means opening a nerve, but no superior term has been advanced and accepted to refer to producing focal damage to a nerve while leaving it intact. In this chapter, the term "neurolytic blockade" has been adopted as a general term to refer to all procedures whose intent is to prevent the conduction of nociceptive traffic along the treated nerve. Reflecting convention, rather than good etymolog-

†Dr. Govind worked assiduously to compose this chapter and he considered it a great honor to be able to contribute to the Bonica text. Sadly, he did not see the culmination of his work. He passed away on the 20th of June, 2009. In Australia he is remembered as someone who strove to have interventional pain medicine accountable to the evidence. N. Bogduk.

ical practice, "neurolysis" has been retained in the context of chemical procedures and "neurotomy" in the context of physical procedures.

PRINCIPLES

Neurolytic blockade is a therapeutic option when the actual source of pain cannot be treated. The objective is to relieve the pain by blocking the nerves that transmit nociception from its source.

The primary indication for neurolytic blockade is complete relief of pain when the target is anesthetized temporarily with controlled, local anesthetics (see Chapter 97). Longer-lasting relief can then be achieved using chemical or physical agents.

Of the chemical agents, phenol and alcohol are the most commonly used, and there are no comparative data by which to choose between the two. Glycerol has a special application in the management of trigeminal neuralgia.

Of the physical modalities, heat and cold have both been used to interrupt conduction along peripheral nerves. In both instances, an electrode is placed on the nerve and used to produce a small lesion that incorporates a segment of the nerve. Cold lesions (cryoneurotomy) are produced by passing carbon dioxide through the electrode. Thermal lesion (thermal neurotomy) are produced by passing a radiofrequency (RF) current through the electrode. Variants of RF neurotomy have been developed in which the emphasis lies in the frequency and modulation of the current applied rather than the heat that it generates.

History and Trends

The earliest form of neurolytic blockade was surgical neurectomy in which the nerves from a source of pain were simply transected. This approach has largely been abandoned for several reasons: neurectomy did not achieve long-term results, and when pain returned the procedure could not be repeated; painful neuromas could develop on the proximal stump of transected nerve; and transecting large nerves could result in deafferentation pain.

Chemical and physical neurolytic blockades were developed to overcome or circumvent these problems. Neuroma-formation could be avoided by not transecting the nerve. If the nerve recovered and pain recurred, the neurolytic procedure could be repeated. Small nerves, not readily accessed surgically, could be targeted with electrodes or injections in order to avoid having to target their larger, parent nerves.

Limitations

Classical pathology teaching describes how nerves recover after they have been transected. Wallerian degeneration occurs in the distal stump and is completed within 24 hours in small nerve fibers and in 48 hours in larger nerve fibers. In the proximal stump, regeneration of axon tubules occurs within hours of the transection. The process is driven by neurotrophic agents, such as tumour necrosis factor alpha, T cells, macrophages, leukocyte inhibitory factor, and cell adhesion molecules, which are expressed in a highly coordinated fashion.[2–4] A growth cone, containing mitochondria, vesicular elements, neurofilaments, and endoplasmic reticulum, emerges from the proximal stump, and proceeds into the distal stump, if it is accessible; Schwann Cells undergo mitotic activity and form a framework for developing fibers.[2] Regeneration occurs at a rate of approximately 1 mm per day, so that reinnervation of a structure 5 cm away would take approximately 50 days. This process requires an intact dorsal root ganglion to synthesize the regenerative proteins and other nutrients.

Neurolytic blockade involves a different pathology, much of which has not been explored and explained. The differences arise according to where in the nerve the lesion is made, the nature of the lesion, and its size.

If the dorsal root ganglion is destroyed, regeneration will not occur because the cell nucleus is not available to drive the process. Consequently, permanent relief of pain (but also permanent side effects and complications) can be expected from neurolytic procedures that target a dorsal root ganglion.

If a peripheral nerve is targeted, chemical neurolysis does not destroy it. Instead, the chemical applied denatures the components of the axons in one way or another focally. Chemicals can bind to membrane proteins or other elements, or they can exert an osmotic effect which focally desiccates the nerve. The nerve can recover from such processes. All that is required is that the damaged elements be replaced in the normal course of maintenance of the cell membrane or other constituents. The rate at which this happens, however, has not been established.

Cryoneurotomy works by freezing intracellular water; the ice expands and essentially fractures the nerve membrane, thereby preventing conduction along it. From this effect, the nerve can recover by reconstituting the damaged segment of membrane. This process appears to be relatively fast: it is measurable in weeks.

Thermal RF neurotomy denatures all the proteins in the segment of nerve incorporated in the lesion made. Nevertheless, the nerve remains macroscopically intact. Regeneration does not occur by classical processes because the nerve is sealed by the coagulated proteins, not transected and left open. Therefore, growth cones cannot emerge. Before the nerve can regenerate, the coagulated material has to be removed by endocellular repair mechanisms. The rate of this process has not been determined, but appears to be measurable in months, based on the duration of effect of thermal RF neurotomy. Critical in this regard is the length of nerve affected. It is axiomatic that if a short segment (1–2 mm) is coagulated, recovery will be faster than if a longer segment (10–15 mm) is coagulated.

CHEMICAL NEUROLYTIC BLOCKADE

Principles

Phenol, alcohol, and glycerol are locally neurotoxic in a dose-dependent manner. These dehydrating agents cause a nonselective destruction of neuronal tissues followed by necrosis, nonsegmental demyelination, Wallerian degeneration, and complete conduction block, occurring within 10 minutes of application.[5–15]

Phenol

First introduced by Lister in 1867 as an antiseptic, phenol (carbolic acid) is a neurolytic agent with local anesthetic properties. Concentrations of less than 1% produce local anesthesia without toxicity or neurolysis and may be used as a topical anesthetic. In higher doses (>8.5 g) phenol causes central nervous depression and cardiovascular collapse.[7] Phenol can be injected directly onto peripheral nerves or into the subarachnoid space in order to target

dorsal root ganglia. Nonselective neuronal destruction leading to Wallerian degeneration is its principle mode of action.

Alcohol

Alcohol (absolute alcohol, ethanol, ethyl alcohol) is a clear volatile hygroscopic liquid[9] that exerts its analgesic effect by nonselective neuronal destruction.[10–12] Because of its irritant effect, alcohol may exacerbate local pain on injection and may produce dose-dependent burning and dysesthesia. Prior injection of local anesthetic may minimize this effect. Alcohol has produced variable results and some consider the risk of complications outweighs its benefits.[10]

Applications

Alcohol or phenol have been widely used to perform neurolytic blockades of various parts of the sympathetic nervous system of the abdomen. Targets have included the lumbar sympathetic trunks and the splanchnic nerves but most commonly the celiac plexus and ganglia. Indications have included pain due to carcinoma of the pancreas or chronic pancreatitis, and pain due to various types of abdominal or pelvic cancers.

Various techniques are available by which to block the celiac plexus, ranging between anterior or posterior approaches, using fluoroscopy, computed tomography, or endoscopic ultrasound for guidance.[16] For cancer pain in general, one review found that neurolytic celiac plexus blocks provided benefit for 70% to 90% of patients until death or beyond 3 months, regardless of the technique used.[17] Others, however, have warned of a narrow risk-benefit ratio.[18] Neurolytic blocks of the celiac plexus, superior hypogastric plexus, or lumbar sympathetic chain, supplemented by drug therapy, are each more effective than drug therapy alone.[19]

For patients with unresectable carcinoma of the pancreas, a review concluded that neurolytic celiac plexus blocks reduced pain and analgesic consumption, but although improvements were significant statistically, they were of minimal clinical significance.[20] A strong, controlled study found that neurolytic celiac plexus blocks reduced pain significantly more than systemic analgesic therapy and a sham injection, but did not significantly reduce opioid consumption or improve quality of life.[21] Neurolytic plexus blocks are more effective in patients with carcinoma of the head of the pancreas than in patients with carcinoma of the tail, but are not effective in patients with advanced tumour proliferation.[22]

For the pain of chronic pancreatitis, the evidence is less robust and less heartening. Response rates are low,[16] and unequivocal data on efficacy and long-term outcomes are lacking.[23]

Descriptive studies promoted neurolytic lumbar sympathetic blocks as a worthwhile treatment for rest pain in patients with peripheral vascular disease, particularly those in whom surgery could not be performed.[24,25] A controlled trial showed that neurolytic blocks were far more effective than local anesthetic blocks.[26]

Phenol or alcohol can be injected intrathecally in order to target particular nerve roots. Mixing the neurolytic agent with glycerine produces a hyperbaric solution, which can be guided under gravity to the target nerve or nerves. Adding contrast medium to the solution allows the movement of the solution to be monitored. With skillful technique, the solution can even be guided into a single nerve-root pouch by appropriately tilting the patient. As a treatment for cancer pain, such injections have been promoted in case reports and book chapters, but there have been no controlled trials.[27] The treatment provides complete relief of pain in up to half of the patients treated.[28] The duration of effect is measurable in weeks or months, which may be sufficient for patients with short life-expectancy.

For the treatment of lumbar zygapophysial joint pain, in one trial 42% of the study sample reported more than 80% pain relief over a mean period of 6.2 years (range 1–10), and litigation made no difference to the outcomes.[29] These claims have not been corroborated by any other study.

Glycerol

Propane-1,2,3-triol, or glycerol, is a colorless, hygroscopic, syrupy liquid,[13] which has a unique application in the management of trigeminal neuralgia. Percutaneous retrogasserian glycerol rhizolysis is achieved by the instilling, under fluoroscopic guidance, no more than 0.3 mL into the Gasserian cistern. Glycerol nonselectively damages both the axons and the myelin sheath,[14] and 30% to 76% of patients suffer sensory loss.[15] Some achieve good pain relief without detectable facial numbness.[30] Onset of analgesia takes about 1 to 10 days to occur, but can be delayed for up to 6 weeks.[31] It provides excellent pain relief while largely sparing trigeminal nerve function in most patients.[31] As many as 72% of patients can be totally free of pain for 3 years, and in one series, 60% remained pain free for more than 10 years after a single injection.[30] Within the first year, 10% to 53% recur,[31] while 25% to 83% recur between 2 and 5 years.[32] These long durations of effect are concordant with the trigeminal ganglion being the target of the treatment. Damaging ganglion cells prevents or impedes regeneration of the peripheral nerve fibers that they subtend.

Glycerol is preferred when pain is localized to the first division as it rarely produces corneal anaesthesia, but the overall efficacy is less than for RF neurotomy.[33] In the elderly or where microvascular decompression is contraindicated, glycerol gangliolysis is safer, more effective than stereotactic surgery, and is more cost-effective.[34]

CRYONEUROTOMY

Cryoneurotomy relieves pain by causing a variable degree of nerve injury. Freezing is achieved by a simultaneous reduction in pressure and temperature as expanding carbon dioxide is forced through a specialized probe. An ice ball averaging 3.5 to 5.5 mm in diameter rapidly forms at temperatures as low as −50° C to −70° C. Subzero temperatures cause nonselective but reversible conduction block, and the effect is prolonged when the intracellular contents are crystallized. There is little clinical difference provided that the temperature is maintained below −20° C for 1 minute.[35,36]

Nerve injury is dose-dependent and ranges from a mild neurapraxia to changes of Wallerian degeneration, associated with very minimal inflammatory reaction. Within a few days of freezing, the lesion is seen as a dense cellular matrix of macrophages.[37] In contrast to chemical neurolysis, painful neuromas, neuritis, or dysesthesia are avoided as exact regeneration is facilitated by an intact epineurium and perineurium.[35,36] The duration of the block depends on the rate of nerve regeneration at the proximal stump, which averages 1 to 3 mm per day.[35,36] Cryolesioning is a safe, simple, and repeatable procedure: it produces a temporary block and its therapeutic effect may last for many weeks. The main disadvantage is that the relief of pain is often of short duration and is unpredictable.[38]

Cryotherapy is an effective adjunct to the pharmacologic management of trigeminal neuralgia when other more invasive treatments are contraindicated. In most patients, the relief of pain is immediate, and in one series, at least 58% remained pain free for 12 months with a mean time to recurrence of 20 months.[39]

For chronic lumbar zygapophysial joint pain, modest outcomes have been noted in two studies. One study claimed a 72% success rate 6 weeks after cryotherapy.[40] The other found that

62% of patients reported at least 50% relief of pain for 12 months, with parallel improvements in activities of daily living.[41]

Cryoneurotomy has been reported as useful for the management of postthoracotomy pain and intercostal neuralgia.[42] In these conditions, the short duration of relief obtained may be enough to render patients comfortable while natural healing occurs or other measures are implemented.

THERMAL RADIOFREQUENCY

Introduction

Thermal (continuous) percutaneous RF procedures have now evolved as one of the better and more practical neurosurgical procedures for the management of chronic disabling pain. With modern imaging and the development of sophisticated equipment, precise ablation of neural pathways is possible. When meticulously executed in correctly selected patients, the RF neurotomy with temperature monitoring has proven itself to be safer and more effective than any other procedure. The technique required principally depends on the source of nociception and the accessibility of the nerves that innervate it. Critical to its correct application is an understanding and appreciation of its limitations, the pathophysiology of the primary condition, and a valid diagnosis.

Physics

Thermal RF should not be confused with electrocautery. Tissues are not burned or oxidized. Rather, they are coagulated in situ by the application of a high-frequency, alternating electric field.[43] The objective of RF lesioning is to deliver sufficient heating power into biological tissue such that the tissue temperature is raised above the "lethal temperature" range of 45° to 50° C, since neural cells exposed to these temperatures for 20 seconds or more will be destroyed by heat.[44,45] This requires an RF generator, an insulated electrode with an exposed ("active") tip of 2 to 10 mm, and a ground or dispersive ("passive") plate with a large surface area. The electrode is placed either into (e.g., central nervous system) or onto (e.g., peripheral nerve) the target structure. The larger dispersive plate is positioned at a convenient location of the body remote from the electrode. The patient completes the electrical circuit and the generator delivers the alternating current between exposed tip of the insulated electrode and the large dispersive plate.

The passage of low-energy, high frequency alternating current (100,000–500,000 Hertz) causes intense oscillation of ions. This oscillation heats charged molecules, notably proteins.[46] The exposed, active tip of the electrode acts as an antenna around which the current concentrates into a greater density. Consequently, greater heating occurs in the tissues around the electrode, and it is the tissue about the electrode-tip, rather than the electrode itself, that becomes the source of heat. The tissues heat the electrode, and a thermocouple, built into the electrode, monitors the temperature generated. Once a certain temperature is reached, lesion formation ("coagulation") occurs.

Tissue temperature (T) is related directly to current density (I) but inversely to the fourth power of the radius (R) from the electrode (i.e., $T = IR^{-4}$). Current density is less at the distal tip of the electrode than at its sides. Therefore, the lesion extends little, if at all, in a longitudinal direction from the tip. Rather, it extends radially around the circumference of the exposed shaft and generally assumes the shape of a prolate spheroid (football).[46] However, because the tissue temperature drops rapidly with distance from the electrode, the lesion is limited in size to 2 mm or less beyond the surface of the electrode (Fig. 101.1).

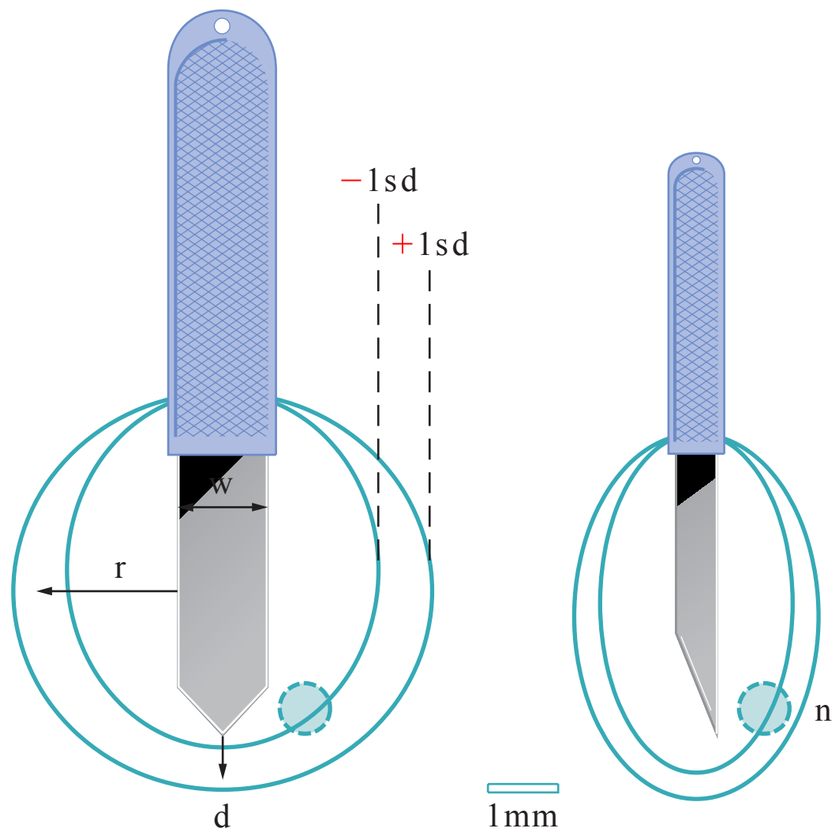

FIGURE 101.1 Longitudinal sections through thermal radiofrequency electrodes, showing the geometry of the lesions that they produce. The lesion has a transverse radius (r) that is proportional to the width (w) of the electrode. Less lesion is produced distally (d). For the same electrode on different occasions, the size of the lesion varies around a mean value in a normal distribution. Smaller electrodes generate smaller lesions. Smaller lesions may fail to incorporate a target nerve completely, even if the electrode is placed close to the nerve.

The physical variables that govern lesion size include current density, its rate of application, lesioning temperature, electrode size, the duration of heating, and impedance.[45–48] Temperature is the fundamental lesioning parameter and temperature monitoring remains central to the safety of the procedure and quantification of lesion size.[49,50] Because there is no consistent relation between temperature and voltage, temperature-controlled RF lesioning is preferred to voltage-controlled lesioning in order to create reproducible and well-defined lesion sizes.[51] The use of lower temperatures may not be acceptable in the clinical setting because it may not produce a permanent or long-term or sufficiently extensive lesion. Above 60° C,[52,53] soft tissues generally will coagulate, and if the surface temperature of the electrode is elevated to 80° to 85° C, then tissues within a short distance from the surface will be heated to 60° to 65° C or more. Once the electrode surface temperature reaches 80° C, lesion size increases with time as the temperature is maintained. Most of the increase in size occurs within 60 seconds, but an appreciable growth continues between 60 and 90 seconds.[53] After 90 seconds, further growth is prevented because the coagulated tissues present an increasing impedance (resistance) to flow of current and, therefore, the generation of any further lesion.

The lesion should be generated by increasing the temperature by about 1° C per second. This avoids cavitation, steam formation, microexplosions, and charring,[45–47] but more critically, in the event that the patient experiences adverse sensations, heating can be aborted promptly before any damage is done.

The size of the lesion is directly proportional to the diameter (width) of the electrode. Since lesions develop from the surface of the electrode, those formed by a larger electrode will reach further away from its center. Lesions made by small-diameter electrodes will extend only a short distance from their surface (see Fig. 101.1). In practice, the radius of a lesion is equal in length to between 1 and 2 times the width of the electrode used. Beyond this range, tissues may escape coagulation.[53]

Because electrodes generate lesions radially, they must be

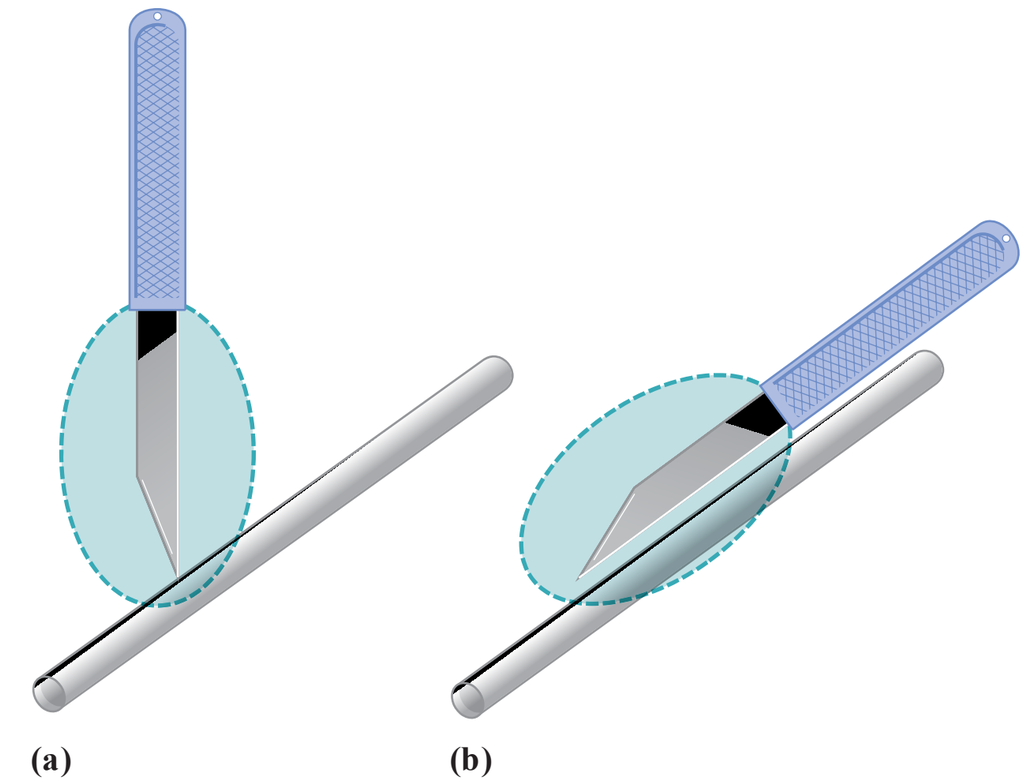

FIGURE 101.2 The influence of orientation on the effects of thermal radiofrequency neurotomy. **A.** If an electrode is placed perpendicular to the target nerve, it may coagulate the nerve only partially and for a short length because of the limited range over which the electrode generates a lesion distally. **B.** If an electrode is placed parallel to a nerve, it incorporates a large volume of the nerve along a greater length.

placed close and parallel to the target nerve in order for the lesion to be optimally effective.[52] If the electrode is placed perpendicular to the nerve, the lesion made may fail to incorporate the target nerve (Fig. 101.2). Throughout the lesioning process, the electrode must be held in place lest it dislodges, and its proper placement should be checked by periodic fluoroscopic monitoring.

Pathology

Heating by RF causes many cells to die rapidly at temperatures greater than 45° C. Similar effects are produced irrespective of whether the electrode is placed either inside the dorsal root ganglion or onto a peripheral nerve. Above 55° C, there is an indiscriminate destruction of both small and large myelinated fibers, focal necrosis, hemorrhages, extensive edema, and features of Wallerian degeneration.[54–59] Even with a low voltage of 0.1 V, an electrode placed inside a dorsal root ganglion and heated to 67° C causes a total loss of myelinated fibers with hemorrhage.[59]

Physiology

The study by Letcher and Goldring[60] is often misrepresented as showing that RF neurotomy selectively destroys small-diameter fibers, while preserving large-diameter fibers. Rather, what the study showed was that depression of C-fiber and A-δ fiber action potentials preceded depression of the potentials of A-β fibers, but within a short time, all fibers were ultimately and equally affected and the disappearance of action potentials was independent of fiber size. No class of fiber was exempt from the effects of heat.[60] These findings were confirmed in two independent, clinical studies which showed that RF neurotomy of the medial branches of the lumbar dorsal rami resulted in electromyographic abnormalities in over 80% of patients.[61,62] These abnormalities indicated that large-diameter, alpha motor neurons were not spared by RF neurotomy.

Applications

In general medicine, thermal RF is widely used for the treatment of supraventricular tachyarrhythmias.[63] Water-cooled electrodes permit the generation of larger lesions to ablate thick ventricular muscle effectively.[64] In pain medicine, thermal RF has been used to treat trigeminal neuralgia, to interrupt pain pathways in the spinal cord or brainstem, and to treat various types of spinal pain and miscellaneous other types of pain.

Trigeminal Neuralgia

For the symptomatic treatment of trigeminal neuralgia, various descriptors, such as RF trigeminal neurolysis, RF thermocoagulation of the Gasserian ganglion, or retrogasserian thermorhizotomy, each refer to the generation of thermal lesions in an area between the trigeminal ganglion and its sensory root. Under fluoroscopic guidance, the electrode is introduced via the foramen ovale until the active tip sits at the posterior end of Meckel's cave, the average depth of insertion being 5 to 6 cm. Once the electrode appears to be adequately placed, a test electric stimulus is delivered to the nerve. If the electrode has been accurately placed, test stimulation will evoke pain in the area in which the patient normally experiences pain. Lesioning temperature may range between 55° and 90° C,[32,65,66] and the current may be applied either continuously for up to 300 seconds[65] or in 45 to 90 second cycles.[66]

The evidence of efficacy for trigeminal RF neurotomy consists of several large, observational studies, some encompassing over 1000 patients.[67] In one series, 41% of patients sustained relief for 20 years.[66] However, because of methodological inconsistencies, a recent systematic review[68] found only four studies on which sound conclusions could be based.[65,66,69,70] Nevertheless, collectively, these studies reaffirmed the general, favorable impression conveyed by the literature at large. Compared with other commonly used ablative techniques, RF neurotomy provided the highest rate of complete pain relief, and some 75% of patients were free of all pain for at least 6 months. At 12 months, RF provided a higher rate of complete pain relief than stereotactic radio-surgery.[68] In a later, unrelated study,[71] 90% of patients reported complete pain relief with their first RF, and a significant proportion continued to enjoy excellent relief some 15 years later. Presumably due to neuronal regeneration, the success rate diminishes and pain returns, such that just over 50% remain completely relieved at 5 years,[68] with a 14-year recurrence rate of 25% in one series.[71]

Common side effects are sensory loss sufficient to affect quality of life in more than 30% of patients, keratitis in some 10%, and dysesthesia in 4% to 10%. Although rare, reported complications include cranial nerve palsies, brain stem injury, meningitis, and vascular fistula formations (see also Chapter 106).[72–75]

Central Ablative Procedures

In conditions where pain is intractable and refractory to most forms of nonsurgical and minimally invasive intervention, relief may be secured by interrupting pathways in the spinal cord.[76] The most common target sites are the dorsal root entry zones, the spinothalamic tract, and trigeminal pathways.

Dorsal Root Entry Zone Lesions. Dorsal root entry zone (DREZ) lesioning is performed for the relief of central (deafferentation) and peripheral (neuropathic) pain caused by disease of peripheral nerves or injuries to them.[76,77] In these conditions, deafferentation results in spontaneous activity in the apical neurons of the dorsal grey column of the segments to which the affected nerves relay.[78] DREZ lesioning involves inserting a small electrode into this region in order to ablate the spontaneously active cells.[77] Multiple lesions are usually required in order to capture all the active neurons. Better outcomes are obtained when the dorsal root and the dorsal horn are primarily affected by the injury and both the pain and the pathology are topographically well-defined. Conversely, DREZ lesioning is contraindicated where pain is poorly localized because identifying the level at which the opera-

tion should be performed is difficult.[76] The ablative process includes the central portion of the dorsal root, the tract of Lissauer, and layers I–V of the dorsal horn. In this manner, the lateral portion of the dorsal horn, where C fibers predominate, is destroyed. By sparing the medial portion of the dorsal horn, tactile and proprioception senses are preserved.

Better outcomes are obtained if test electrical stimulation is used. Stimulation not only confirms the relevant segments but also identifies additional zones of dorsal horn electrical hyperactivity which would have been missed if topographical landmarks alone are used.[79,80]

Controlled trials have not been performed, but this may be understandable given the nature of the disorder and the nature of the intervention. Advocacy is based on multiple observational studies in which significant proportions of recipients report remarkable relief. DREZ lesioning has been particularly effective for the pain of brachial plexus avulsion with 66% to 87% patients affirming more than 70% relief,[81–85] and an appreciable proportion not requiring supplementary medication.[83] For traumatic spinal cord injuries, percentage relief of pain can range from at least 50% to complete relief with no limitation of activity or the need for opioids.[86,87] With respect to postamputation pain, the outcomes are better for phantom pain than for stump pain alone.[83] DREZ lesioning has not been particularly effective for postherpetic neuralgia. Some 18% to 47% report complete pain relief but such relief is not consistently maintained.[81] The close neuroanatomical relationship between the site of DREZ lesioning, the lateral corticospinal tract, and the dorsal column can lead to severe neurologic complications such as motor weakness, bladder or sexual dysfunction, and dysesthesia (see also Chapter 106).[88]

Cordotomy. Percutaneous cordotomy can be used to treat unilateral intractable pain transmitted by the lateral spinothalamic tract.[89] A lesion made in the antero-lateral segment of the spinal cord totally abolishes pain and temperature in one-half of the body below the lesion.[89] The procedure is typically performed percutaneously at the C1-C2 level, using a lateral approach to insert the electrode. Indications for these procedures have included severe neuropathic pain arising from brachial plexus root avulsion imitating phantom pain, electric burns, postherpetic neuralgia, and cancer pain.[90] In patients with cancer pain, some 70%[91] or more[92,93] initially obtain worthwhile relief. This relief wanes with time, but persists in most for the duration of remaining life (see also Chapter 104).

Trigeminal Procedures. Pain mediated by the trigeminal nerve can be treated by ablating various sites within the central nervous system, such the descending trigeminal tract (trigeminal tractotomy), the nucleus caudalis (trigeminal nucleotomy), or all of the substantia gelatinosa of the nucleus caudalis (nucleus caudalis dorsal root entry zone [NCDREZ]). Nociceptive type pain is most sensitive to NCDREZ ablation.[81]

Indications have included severe glossopharyngeal neuralgia, craniofacial dysesthesia, posttraumatic neuropathy, and anesthesia dolorosa.[90] For intractable facial pain, such as "end-stage" trigeminal neuralgia that has failed all other means of treatment including microvascular decompression,[81] NCDREZ lesioning has been successful in 60% to 70% of cases (see also Chapter 104).[94,95]

Medial Branch Neurotomy

Some forms of spinal pain are mediated by the medial branches of the dorsal rami. These nerves innervate the zygapophysial joints and certain paramedian posterior muscles of the vertebral column. Since there are no disorders known to affect, selectively, only particular segments of the back muscles, pain mediated by the medial branches is regarded as arising from the zygapophysial joints. The actual source of pain, however, is immaterial, for the singular indication for medial branch RF neurotomy is complete relief of pain following controlled, diagnostic blocks of these nerves (see Chapter 97).[96–99]

The medial branches of the dorsal rami are small targets and can vary in location, particularly at cervical levels. Therefore, the principle of medial branch neurotomy is not so much to place the electrode on the target nerve, but to place a sufficient number of lesions in a sufficient number of locations so that the matrix of lesions produced covers all possible locations of the nerve. For this purpose, a detailed knowledge of both the surgical and radiographic anatomy of the nerves is mandatory.[100–102]

Cervical Medial Branch Neurotomy. Of the numerous techniques that have been used for cervical RF neurotomy,[103–106] only one has been validated.[103] This technique has been endorsed by the International Spine Intervention Society, and its execution has been described in detail in that society's guidelines.[107] Techniques reported by other investigators have not been tested in a similar rigorous manner, and their efficacy is not known.

Idiosyncrasies of the anatomy of the typical cervical medial branches govern the technique required to secure optimal coagulation of these nerves. The electrode must lie parallel to the target nerve. Therefore, since the nerves run obliquely across the articular pillar at the C3, C4, C5, and C6 levels, essentially parallel to the plane of the zygapophysial joints, the electrode must be inserted parallel to this plane (i.e., cephalo-ventrally). Furthermore, since the surface of the articular pillar is curved, two insertions are required in order to coagulate a maximal length of nerve. An oblique insertion is used to reach the nerve over the anterolateral sector, and a sagittal insertion is used to reach the nerve over the lateral sector of the pillar (Fig. 101.3). In both insertions, an appropriate number of lesions must be made in order to match the size of the electrode and the lesion that it produces with the possible locations of the nerve. These differ at different segments. At C5, the nerve typically crosses the central two-fourths of the articular pillar. At segments progressively further away from C5, the nerve tends to lie higher on the pillar.[53,107]

At the C7 level, the medial branch crosses the lateral aspect of the superior articular process of C7. This process is insufficiently curved to warrant an oblique insertion. The nerve can be reached with a sagittal insertion alone. Nevertheless, the nerve can lie as high as the tip of the superior articular process or as low as the base of the transverse process. Therefore, multiple lesions must be made to capture the nerve in all of its possible locations.

Once the electrode has been placed, a lesion is generated by maintaining a temperature of 80° to 85° C and maintained for 90 seconds. Throughout the lesioning process, the electrode must be held in place lest it dislodges, and its proper placement verified by periodic monitoring.

Once the first lesion has been made, the operator must judge if and how many further lesions need to be made in order to accommodate all the possible locations of the target nerve. This requires knowing the variations in location at each segmental level[53,107] and estimating the size of the lesion made by the electrode used. In general, if a large gauge electrode (16G) is used, one or two lesions may suffice, but if a small gauge electrode (22G) is used, three, four, or five lesions may be required. In both instances, patients with taller articular pillars will require a greater number of lesions than patients with short pillars.

Of all the techniques described in the literature, this is the only technique that has been tested and has consistently shown to confer sustainable and complete relief of pain.[103,108–111] Alternative techniques including the simultaneous insertion of multiple electrodes or shortening the operative time[112] have not generated comparable or better outcomes.

A placebo-controlled trial firmly demonstrated that the effects of cervical RF neurotomy, when meticulously executed in correctly selected patients, were not due to chance.[103] The treatment

was so effective that a sample of 24 had 100% power for the results obtained. Patients reporting complete relief of their index pain required no other supplementary treatment, and activities of daily living previously impeded by pain were reinstated. To achieve maximal coagulation of each of the two targeted nerves, the procedure required at least 2 to 3 hours operating time. In the control group, the median time for recurrence of pain was 8 days after surgery. The median duration of relief of pain, following active treatment, was 263 days.[103]

Long-term follow-up confirmed that at least 64% of patients so treated obtained complete relief of their pain for a median duration of 422 days.[53,109] If pain recurred, relief was reinstated by repeating the procedure. Patients, who initially obtain relief for greater than 90 days, had an 82% chance of further success by a repeat procedure. If initial relief lasted less than 90 days, the chances of successful repeat treatment reduced to 33%.[109] Successful treatment led to the complete resolution of psychologic distress,[113] and treatment was equally effective in litigants and nonlitigants.[108,111,114]

No other form of treatment for neck pain has been shown to be as effective as RF medial branch neurotomy. Three independent reviews have concluded that cervical medial branch neurotomy is an efficacious treatment for proven cervical zygapophysial joint pain.[115–117]

Unlike for trigeminal neuralgia or DREZ lesioning, the relief of pain after medial branch neurotomy is not permanent. The ganglion cells of the nerve are not targeted, and the nerve regenerates. With optimal coagulation, the average duration of relief is about 9 months but may last for up to 12 months or longer.[53,103,109] Pain may recur once the nerve has regenerated, but the return of pain is usually gradual and may not return to its former intensity. Should pain become intolerable and interfere with the activities of daily living, relief can be reinstated by repeating the procedure. Multiple repetitions are possible without compromising the outcomes.[53,103,109] Confirmatory diagnostic blocks should always precede any repetition of the procedure lest a different or new source of pain be overlooked.[53]

At typical levels (C3-C7 inclusive), side effects of cervical medial branch neurotomy are uncommon and self-limiting (Table 101.1).

Skin burns are avoided by using a firmly applied dispersive/ground plate with a large surface area rather than a spinal needle to dissipate electrical energy. Meticulous technique and strict asepsis should guard against infection and hematoma formation. Neurologic complications are avoided by ensuring that electrodes always remain external to the vertebral column and do not reach either the vertebral artery or the intervertebral foramen.

Concerns about Charcot's joints are unfounded.[119,120] There are no published reports of Charcot's arthropathy directly attributable to RF neurotomy, nor does selective denervation of the wrist joint cause Charcot's arthropathy.[121] Contemporary pathophysiology implicates a neurovascular mechanism, diabetes has replaced tertiary syphilis as the most common cause,[122] and arthropathy can occur in advance of abnormal neurology.[123,124]

Dermoid cyst	1
Köbner's phenomenon	1
Neuritis	2
Numbness in the cutaneous territory of one of the coagulated nerves	29
Dysesthesia in the cutaneous territory of one of the nerves coagulated	19

Charcot's joints classically occur in weight-bearing joints of the lower limb in which all the surrounding muscles are insensate, resulting in instability.[125] This does not occur with spinal RF neurotomy. The medial branches innervate only the deep paramedian muscles. The superficial and lateral muscles are spared. Thus, the spinal motion segment is not rendered insensate. Meanwhile, the disc and articular processes maintain stability passively.

Catastrophic spinal cord injuries have occurred only when electrodes have been egregiously misplaced.[126] They are avoided by careful placement of electrodes in the correct target zone and monitoring of their location during the generation of lesions.

Third Occipital Headache. Pain from upper cervical segments can be referred into to the head, where it is perceived as headache. This type of headache is known as cervicogenic headache. Its mechanism is convergence in the trigeminocervical nucleus between afferents of the upper three cervical spinal nerves and trigeminal afferents.[127,128] Of the possible sources of cervicogenic headache, the strongest volume of evidence implicates the C2-C3 zygapophysial joint.[127–134] Pain stemming from the C2-C3 zygapophysial joint is mediated by a single nerve: the third occipital nerve (TON).[100] Accordingly, headache stemming from this joint have, appropriately, been called third occipital headache.[130] The TON is the superficial medial branch of the C3 dorsal ramus.[100]

In accordance with the guidelines of the International Headache Society,[135] the essential criterion for the diagnosis of third occipital headache is complete relief of pain following controlled, diagnostic blocks of the TON (see Chapter 97). Once so diagnosed, third occipital headache can be treated by third occipital RF neurotomy.

The TON crosses the C2-C3 zygapophysial joint transversely and may lie anywhere along the height of the C3 superior articular process, but more often, the nerve courses along the lower half of the convexity of the C2-C3 zygapophysial joint.[100] To ensure maximal efficiency, RF lesions must be placed along the entire height of the C3 superior articular process in order to encapsulate the nerve at all possible locations. Oblique and the sagittal insertions of electrode are standard, as for medial branches at typical cervical levels (Fig. 101.4).[107] Meticulous technique is required to ensure optimal outcomes. This involves placing the electrodes accurately and holding them in place during coagulation.[108]

Placebo-controlled trials of third occipital neurotomy have not been conducted because active neurotomy causes numbness in the cutaneous territory of the TON, and this effect cannot be masked. Observational studies are, therefore, the best possible evidence of effectiveness. They have shown that at least 85% of patients with proven third occipital headaches can be rendered completely free of pain, provided that meticulous surgical technique is used.[108,111] The median duration of relief is at least 297 days, and when pain recurs, relief can be reinstated by repeat neurotomy. Outcomes have not been affected by litigation status.[108,111]

Third occipital neurotomy is associated with distinctive side effects (Table 101.2). Numbness is to be expected because the TON has a cutaneous distribution that is larger and more constant than that of typical cervical medial branches. Touch-evoked hypersensitivity and dysesthesia typically resolve spontaneously, usually within 2 weeks, but may last up to 6 weeks. The TON also innervates the semispinalis capitis and contributes substantially to cervical proprioception and tonic neck reflexes. Therefore, neurotomy is commonly associated with a mild ataxia. Generally, this ataxia is not disabling, for patients can rely on visual cues to locate horizontal objects, and thereby stabilize the orientation of their head. No long-term effects have been reported.

Because of possible problems with ataxia, presumptive bilateral neurotomy is not recommended in patients with bilateral third occipital headache. If bilateral neurotomy is indicated, it is recommended that one side be treated first and the other side be tested with a prognostic block to test that subsequent neurotomy on this side does not produce disabling ataxia.

Randomized, placebo-controlled studies have been published which purported to test the efficacy of RF neurotomy for the treatment of cervicogenic headache.[136–139] In all studies, patients were selected on clinical grounds which have not been validated. Therefore, there was no guarantee that patients actually had a cervical source of pain. In no study were patients selected on the basis of controlled diagnostic blocks. Therefore, the segmental source of pain was not established. In all studies, multiple segments were treated in every patient, but in no study was an anatomically validation surgical technique used. For these reasons, none of these studies constitutes a valid test of the treatment of cervicogenic by RF neurotomy.[134,140]

Lumbar Medial Branch Neurotomy. Confusion and inconsistencies have plagued the conduct and assessment of lumbar medial branch neurotomy. The crucial problem has been adherence to the surgical anatomy of the procedure. Other problems pertain to how electrodes are placed and how patients are selected.

At typical lumbar levels, the medial branches of the lumbar dorsal rami cross the neck of the superior articular process.[140] At the L5 level, it is the dorsal ramus itself that crosses the superior articular pillar before forming its medial branch, so the dorsal ramus becomes the target nerve rather than the medial branch.

At typical lumbar levels, the medial branch does not lie consistently at an exact location. Rather, it can lie somewhat higher or lower across the junction of the transverse process and superior articular process. Therefore, a single point does not constitute the target point for neurotomy. Rather, a target zone applies across which a matrix of lesions needs to be placed in order to accommodate possible variations in the exact location of the nerve.[140] These considerations are less of a problem for the L5 dorsal ramus, whose course over the ala of the sacrum is comparatively more constant.

Electrodes that are placed perpendicular to the target nerve may fail to incorporate the nerve in a lesion or may coagulate the nerve incompletely because little lesion is produced distal to the tip of the electrode. In order to coagulate the nerve adequately and reliably, electrodes must be placed parallel to the nerve. This requires an insertion in a ventro-cephalad direction at an angle of approximately 45 degrees to the transverse plane of the vertebra that the nerve crosses.[140,141] In addition, electrodes need to be angled about 15 degrees medially in order to avoid the mamillo-accessory ligament, especially when this ligament is ossified.[140,141]

At all levels, the target zone lies along the middle two-quarters of the neck of the superior articular process.[140,141] Lesions placed

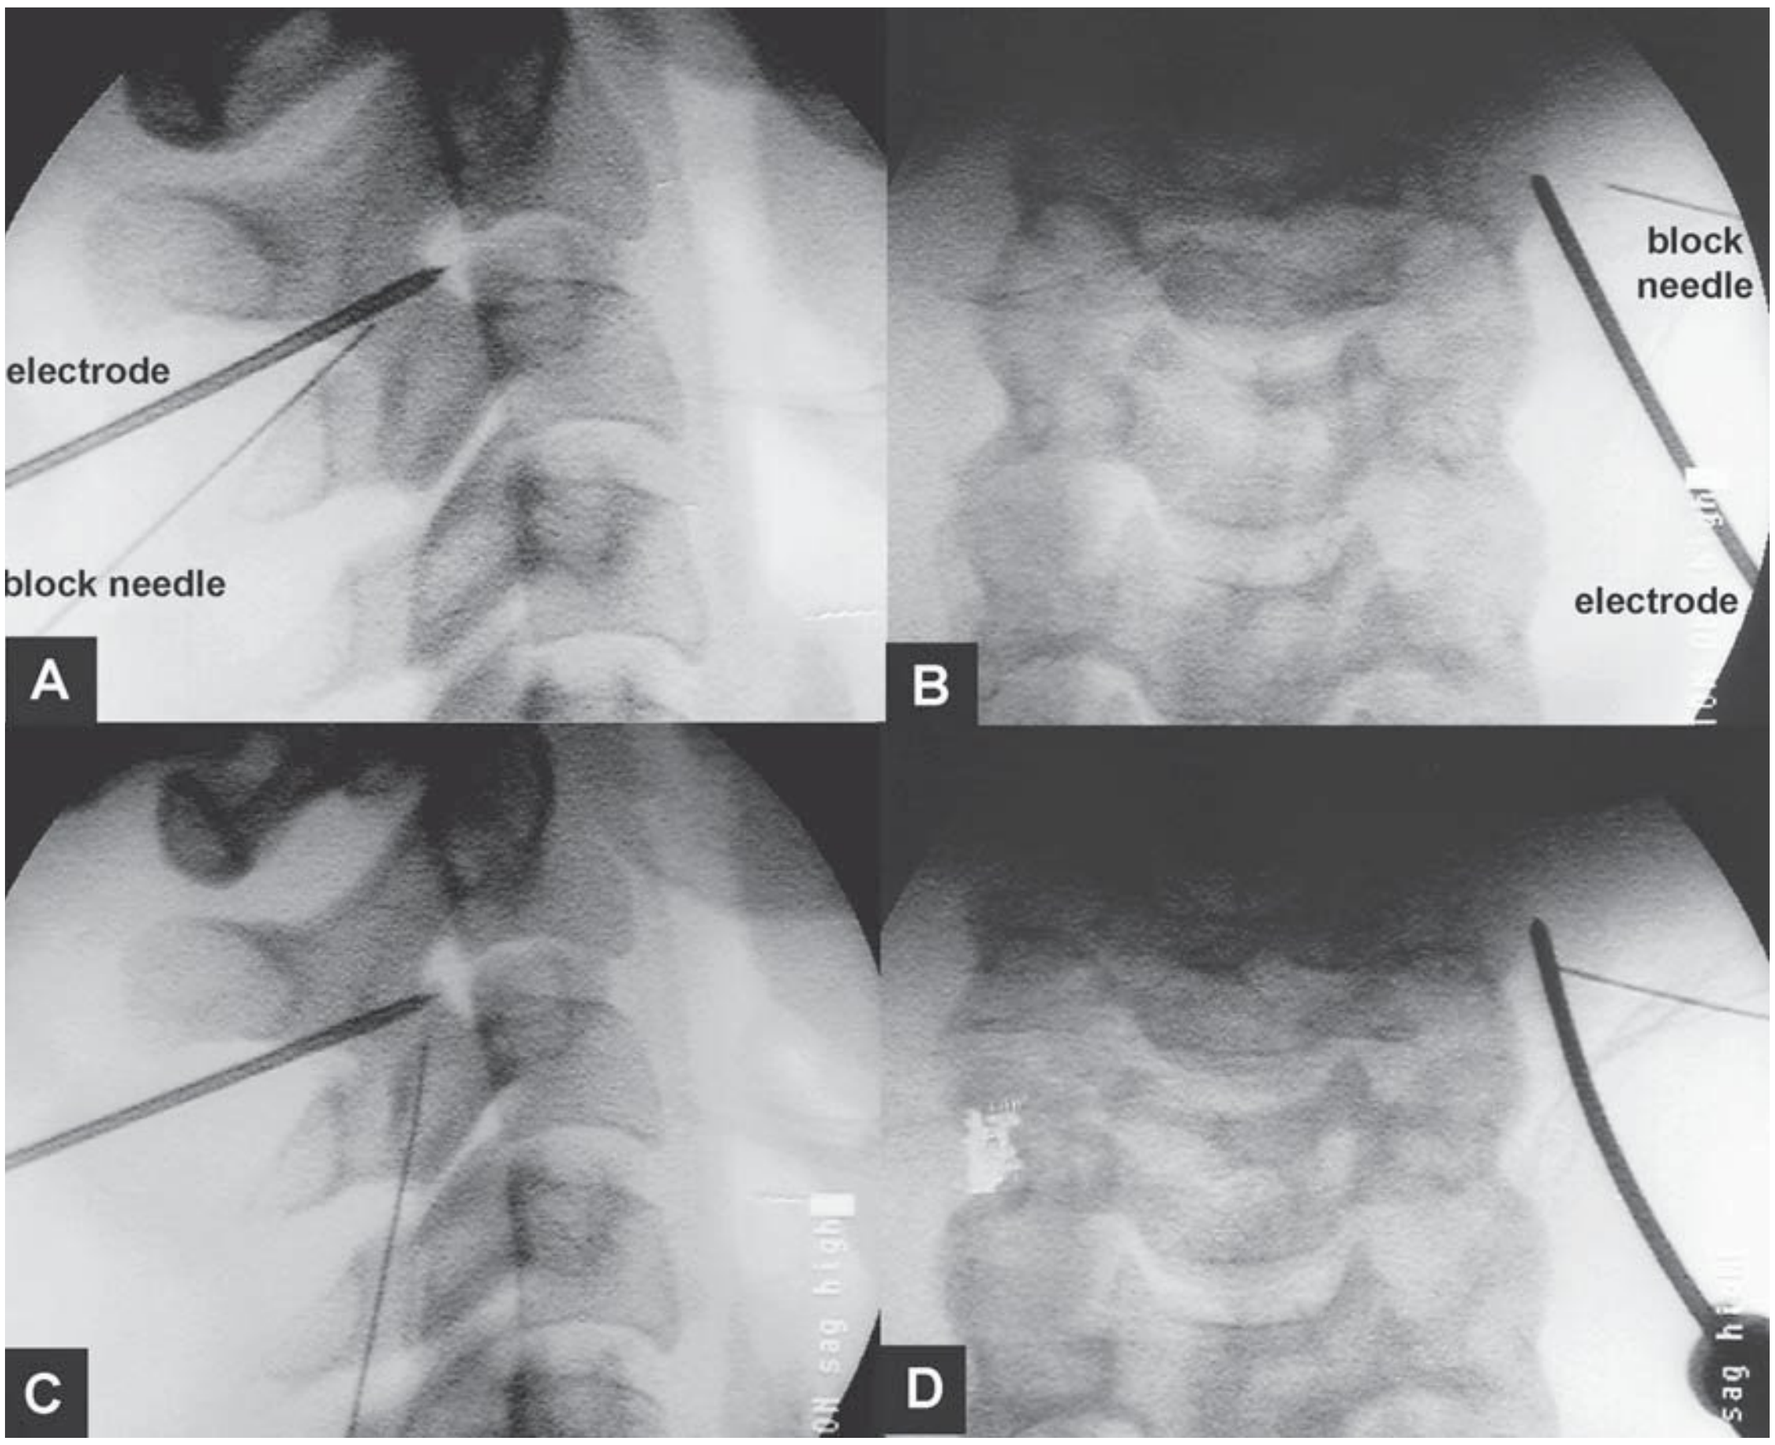

FIGURE 101.4 Fluoroscopy views of electrode placement for third occipital radiofrequency neurotomy. **A.** Lateral view of oblique insertion of electrode. The electrode tip lies over the anterolateral aspect of the C2-C3 zygapophysial joint. The electrode lies in the higher of two positions required to encompass the third occipital nerve thoroughly. (A block needle overlies the target zone in case supplementary anaesthesia is required.) **B.** Anteroposterior view of an oblique insertion. The tip of the electrode lies medial to the lateral margin of the silhouette of the C2-C3 zygapophysial joint. **C.** Lateral view of a sagittal insertion. The tip of the electrode lies over the lateral aspect of the C2-C3 zygapophysial joint. proximal to this area risk incorporating the lateral branch of the dorsal ramus. Distal to this area, lesion will not capture the medial branch because it is covered by the mamillo-accessory ligament.[140] When correctly placed over this target zone, an electrode with a 10 cm active tip should adequately incorporate an adequate length of the target nerve. Electrodes with a 5 mm tip need to be placed proximally and then distally along the target zone in order to capture the optimal length of nerve. The matrix of lesions produced should extend onto the root of the transverse process and slightly dorsally across the root of the superior process. Such a matrix encompasses all possible locations of the nerve.[140,141] The number of lesions required to produce this matrix depends on the size of the electrode used. With larger gauge electrodes, an adequate matrix can be produced with one or two lesions. If smaller electrodes are used, four, six, or more lesions will need to be placed lest the nerve escape coagulation.

As recommended by the International Spine Intervention Society,[141] the procedure requires obtaining a caudally declined view of the target area, such that the transverse process is viewed edge-on, coupled with a slight lateral obliquity. In this view, the electrode is inserted parallel to the x-ray beam so that it lodges against the neck of the superior articular process (Fig. 101.5A). Depth of insertion is established in other views. In an oblique view, the active tip of the electrode should cross the junction of the transverse process and superior articular process (Fig. 101.5B). In an anteroposterior view, the electrode should fit snugly against the lateral surface of the superior articular process (Fig. 101.5C). In a lateral view, the active tip should lie opposite the middle two-fourths of the neck of the superior articular process (Fig. 101.5D). In this location, a lesion is produced. Depending on the gauge of the electrode used and the length of its active tip, one or more

Itch	10%

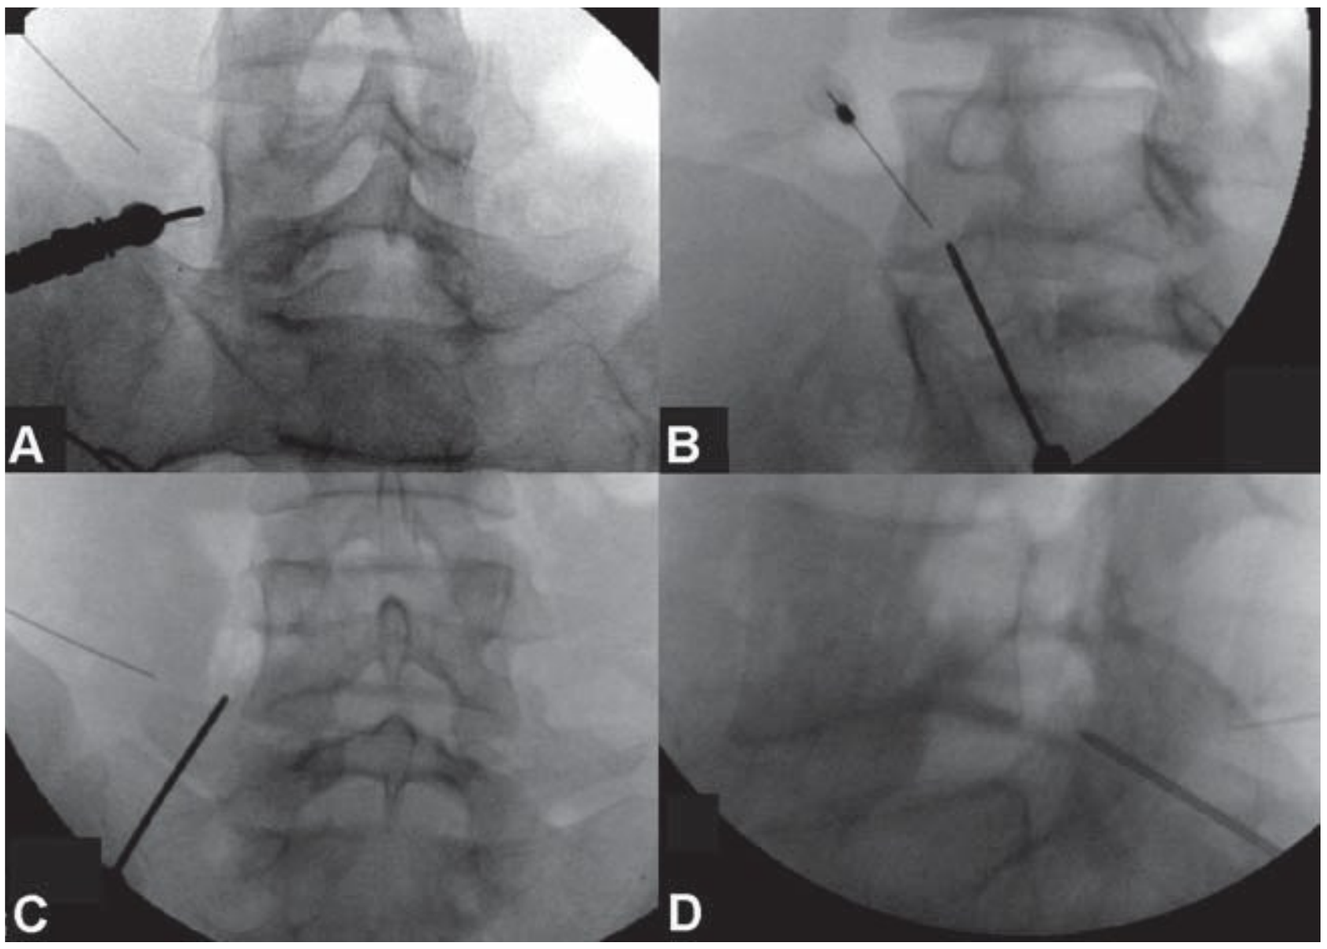

FIGURE 101.5 Fluoroscopy views of an electrode in place for an L4 medial branch radiofrequency neurotomy. **A.** Declined (pillar) view showing the tip of the electrode lodged in the notch between the superior articular process and transverse process of L5. **B.** Oblique view showing the tip of the electrode crossing the junction of the superior articular process and transverse process. **C.** Anteroposterior view showing the electrode orientated obliquely, cephalad, and medially against the lateral surface of the superior articular process. **D.** Lateral view showing the active tip of the electrode lying opposite the middle two-fourths of the neck of the superior articular process.

lesions may need to be placed in order to cover variations in the location of the nerve. If the lesion placed on the neck of the superior articular process is small, another lesion should be placed on the root of the transverse process. If a short active tip is used, a second lesion should be placed after withdrawing the electrode 5 mm from each of its deeper positions.

Techniques that do not comply with this protocol cannot be relied on to achieve adequate coagulation of the target nerve. Common flaws in this regard are placing the electrode perpendicular to the nerve, making one lesion rather than a matrix, and using small gauge electrodes which produce almost trivial lesions.[140]

Pivotal to the effectiveness of lumbar medial branch neurotomy is selection of patients. The essential indication is complete relief of pain or near complete relief following controlled diagnostic medial branch blocks (see Chapter 97). Unless this criterion is satisfied, there are no grounds for believing that the patient has pain mediated by these nerves and that neurotomy should relieve this pain.

Several controlled trials of lumbar medial branch neurotomy have been published, but none has satisfied the requirements outlined above. Patients were not selected on the basis of controlled diagnostic blocks. Electrodes were placed perpendicular to the nerve. Single lesions were made. Small gauge electrodes were used. Under those circumstances, it is not surprising that efficacy was not demonstrated in these trials. It is conspicuous, as well, that systematic reviews[142,143] of this procedure did not recognize these technical flaws of the studies, and how they affect conclusions about the efficacy of lumbar medial branch neurotomy.[144]

The benchmark for effectiveness of lumbar medial branch neurotomy was established by an observational study.[62] That study showed that, when properly executed in correctly selected patients, good outcomes can be expected. Some 80% of patients maintain at least 60% relief of their pain at 12 months, and some 60% of patients maintain at least 80% relief.

Subsequently, a larger cohort study treated 209 patients selected on the basis of positive responses to controlled diagnostic lumbar medial branch blocks.[145] Of the 174 patients who completed the audit, 68% experienced greater than 50% relief sustained for between 6 and 24 months.

Two placebo-controlled trials have established that the effects of lumbar medial branch neurotomy cannot be attributed to placebo. The first used a suboptimal technique—electrodes were placed perpendicular to the target nerves. Consequently, the duration of relief of pain was limited. Nevertheless, in that context, it was clearly evident that active treatment was superior to sham treatment.[146] The second study[147] selected patients on the basis of controlled, diagnostic blocks and placed electrodes parallel to the target nerves and in multiple locations. It showed superior outcomes from active treatment than from sham treatment.

Relief from lumbar medial branch neurotomy is not permanent. Progressively, the nerve regenerates over a period determined by the accuracy and thoroughness of coagulation. If pain recurs with sufficient intensity to warrant treatment, the procedure can be repeated and the relief of pain reinstated.[148]

If correctly and carefully executed, lumbar medial branch neurotomy should have no complications. In one large series, no complications were reported barring temporary localized pain and self-limiting neuritic pain.[149] Postsurgical neuritis with dysesthesia and hypoesthesia, including exacerbation of the primary pain, has been reported.[150,151] Injuries to the spinal nerve or ventral ramus have occurred when the electrode has been incorrectly placed or has dislodged during the procedure.[126,152,153]

Damage to spinal nerves or the spinal cord should not occur. They have occurred only when operators have misinterpreted the radiographic anatomy and have grievously placed electrodes in the wrong location or when the electrode has dislodged but its position has not been monitored during the procedure.[126,152,153] Injuries have also occurred when operators have conducted the procedure under general anesthesia.[126] Under general anesthesia, patients cannot report inappropriate sensations indicative of a lesion being generated in the wrong location.

Thoracic Medial Branch Neurotomy. Some practitioners have reported performing RF neurotomy of the medial branches of the thoracic dorsal rami.[154] A dissection study, however, revealed that the target points used in that study were remote from the medial branches and, therefore, that those nerves could not have been coagulated.[155] A technique for thoracic medial branch neurotomy based on accurate anatomy has not been developed, let alone tested.

Sacroiliac Pain

Opinion and the evidence is divided as to how the sacroiliac joint is innervated.[156] Some maintain the joint receives its innervation posteriorly from the lateral branches of the L5 and S1 and S2 dorsal rami, and anteriorly from branches of the lumbar and sacral ventral rami.[157–160] Others maintain that the innervation

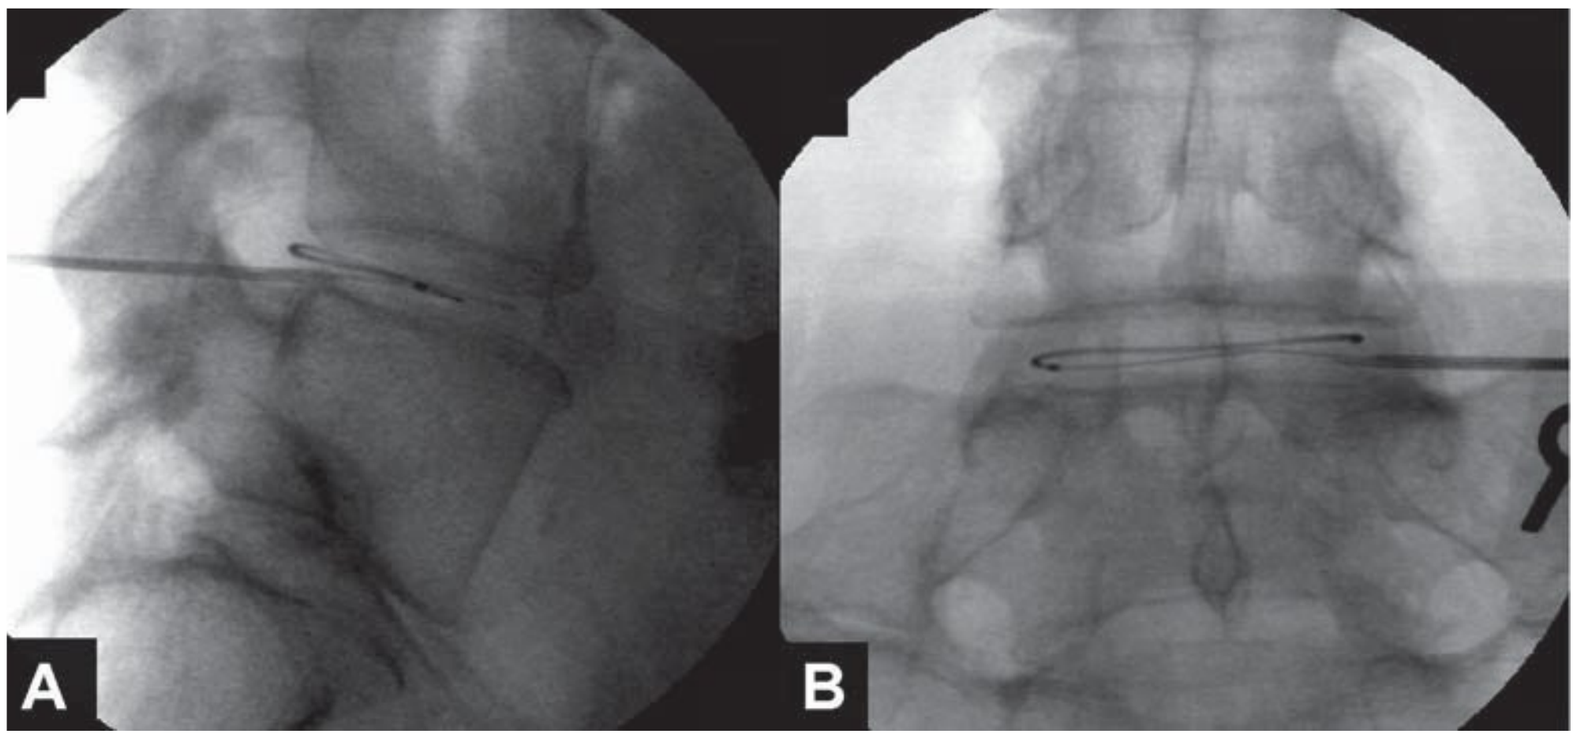

FIGURE 101.6 Electrode placement for intradiscal electrothermal anuloplasty of an L4-L5 intervertebral disc. **A.** Lateral view. **B.** Anteroposterior view. (Illustrations kindly provided by Dr. Paul Dreyfuss, Seattle, WA.)

is exclusively from the sacral dorsal rami.[161] This latter view allows for sacroiliac pain to be treated by RF neurotomy of the lateral branches of the sacral dorsal rami.

Various techniques have been developed and advocated on the basis of descriptive studies. Some placed a strip of lesions along the posterior edge of the sacroiliac joint.[162] Others have placed electrodes around the lateral perimeter of the posterior sacral foramina, using single[163,164] or multiple[165] electrodes. Some have used electrical stimulation to find the target nerves.[163]

The outcomes of sacroiliac RF treatment have been modest and short-lasting. Between 30% and 50% of patients reported at least 50% relief of their pain for 3 or 6 months. Better outcomes have been reported when nerves were targeted,[163,164] rather than when electrodes were placed in the posterior capsule and ligaments.[162] Higher success rates have been reported in studies in which patients who reported at least 70% relief of their pain following a single intra-articular block underwent stimulation-guided RF.[163]

A placebo-controlled study has shown that the outcomes of active RF neurotomy for sacroiliac pain are patently superior to sham therapy.[166] However, the duration of successful outcomes was limited, as in the observational studies. The application of RF neurotomy requires a more enduring efficacy for it to become an entertainable option for sacroiliac pain.

Discogenic Pain

Investigators have explored various applications of thermal RF or related technologies to treat back pain stemming from the lumbar intervertebral discs. Some applications have been discredited. For some, the evidence is mixed. For others, it remains encouraging. Other intradiscal therapies are covered in Chapter 100.

Intranuclear Monopolar Radiofrequency. The first application of RF treatment for discogenic pain involved placing a monopolar electrode into the center of the nucleus pulposus in order to produce a single lesion. The rationale was that such a lesion produced sufficient heat to destroy the nerve endings in the outer anulus. A clinical study reported an impressive success rate for this procedure.[167] Subsequently, a clinical study found outcomes to be short-lasting,[168] and a controlled study found no effect greater than sham treatment.[169] Laboratory studies showed that intranuclear lesions did not generate temperatures in the outer anulus capable of coagulating nerves.[170,171]

Intradiscal Electrothermal Anuloplasty. Intradiscal electrothermal anuloplasty (IDET) involves threading a flexible electrode, in a circumferential fashion, into the anulus of a painful disc (Fig. 101.6). The electrode emits radiant heat, which produces a narrow lesion around and along the length of the electrode. The originally proposed rationale was that heating the anulus stiffened it by denaturing its collagen,[172] but histologic evidence of such an effect has not been forthcoming. Electron microscopic features of extensive collagen disorganization with shrinkage and chondrocyte damage described in one study[173] could not be confirmed in a contemporary study in which normal morphology prevailed.[174] Other conjectures have been that IDET might seal radial or circumferential fissure or coagulate nerve endings.[175,176] These conjectures require that the electrode be placed very close to such fissures or into the innervated zone of the anulus. Studies have shown that temperatures recorded 10 mm away from the tip were insufficient to denature nociceptors[177] or to affect the nerve count in laboratory animals.[178] Temperatures greater than 45° C were achievable at least 9 mm away from the active tip, but not all discs responded uniformly.[179]

Some outcome studies reported very low success rates,[180–183] but many reported notable,[184–189] or substantial,[190–196] reductions in pain. Overall, the data from descriptive studies suggest that IDET achieves an average reduction of pain of about 4 on a 0 to 10 scale, and that around 50% of patients can expect at least 50% reduction of their pain (Fig. 101.7).

A case-control study found IDET to be more effective than treatment by thermal RF anuloplasty (see below).[194] A cohort study[195,196] found IDET to be more effective than rehabilitation.

A notable feature is that IDET was not universally effective. Some 50% of patients obtain no benefit at all.[195,196] Most of the remainder obtain at least 50% relief of pain, and some obtain complete relief. Outcomes are largely stable over 1 and 2 years.[195–198]

Two randomized controlled studies have provided conflicting results. In one of these trials, the success rate for IDET was zero, but it was zero as well for placebo treatment.[199] These results raise intriguing questions. A zero success rate for active treatment is incompatible with the results of most outcome studies. This implies either a different selection of patients or a different execution of the technique. The lack of any placebo effect is quite curious. If IDET works because of placebo effects, one would expect successful outcomes in at least a proportion of patients treated with sham therapy. It seems somewhat ingenuine to conclude that IDET is a placebo when no placebo effect is encountered.

The second randomized controlled trial[200] provided more realistic results. Consistent with previous outcome studies, over 50% of patients obtained no benefit, but the remainder benefited to greater or lesser degrees. In those patients, outcomes for pain and physical function were significantly better than in patients

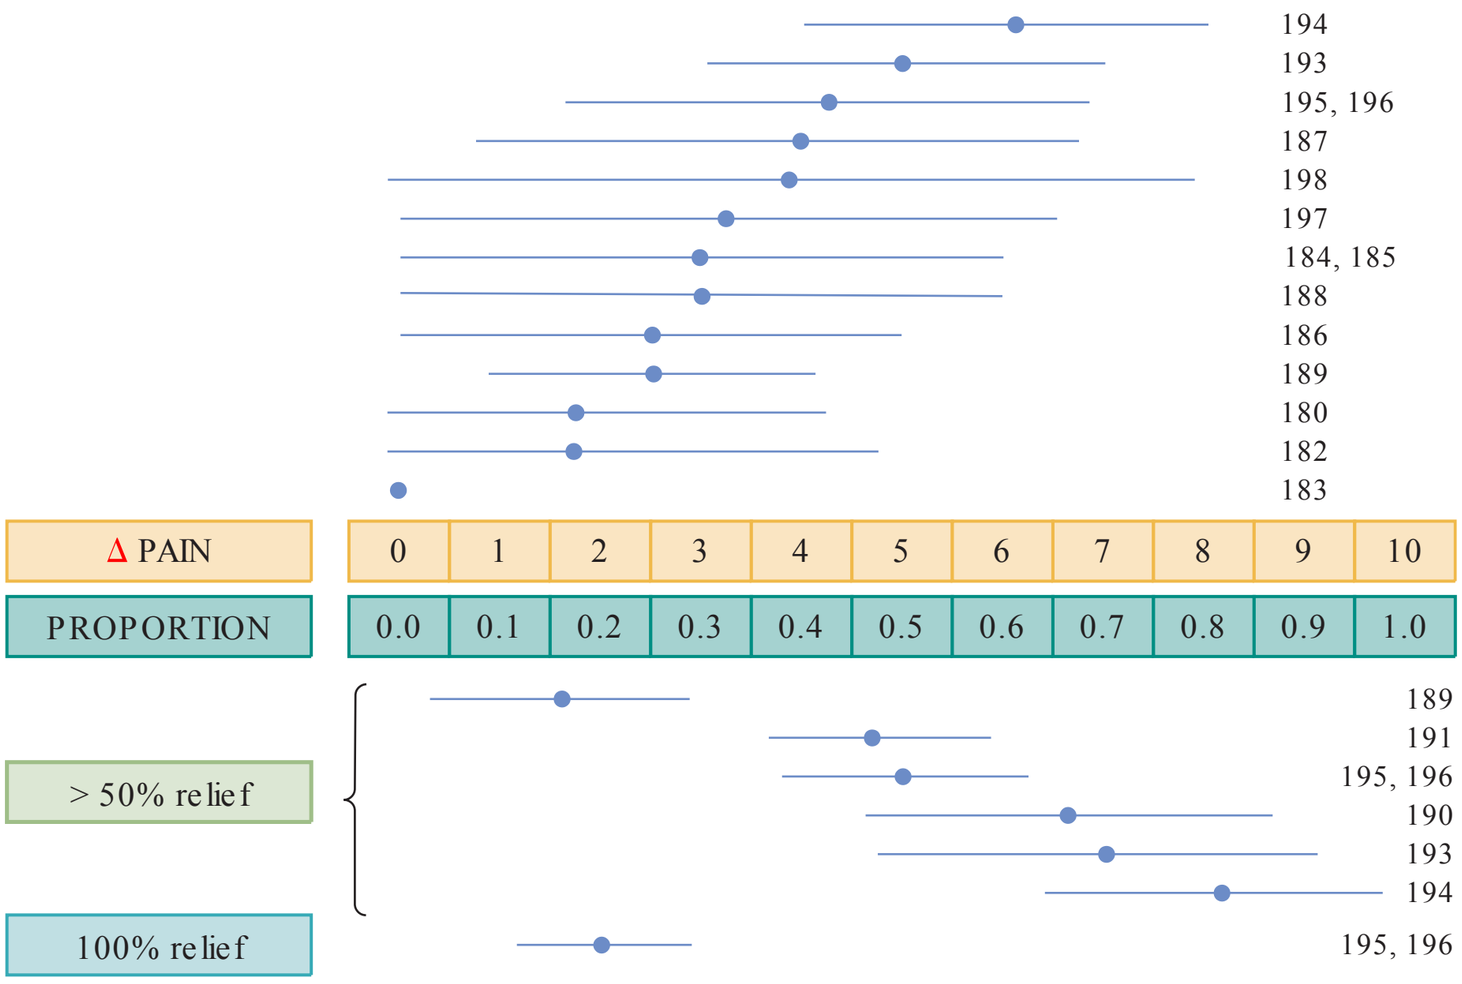

FIGURE 101.7 A graphic summary of outcomes for intradiscal electrothermal therapy reported in observational studies, a case-control study, and a cohort study. For studies that reported outcomes as reductions in pain, the mean reduction and standard deviation of each study have been depicted above the scale labeled "Δ pain" (change in pain expressed as reduction on a 0–10 analog pain scale). For studies that reported proportions of patients obtaining at least 50% relief of pain and complete relief of pain, the proportion and its 95% confidence intervals have been depicted below the scale labeled "proportion." Each datum point is accompanied by the reference number of the study.

who received sham treatment. This study provided the evidence that the effects of IDET could not be attributed wholly to placebo effects, but having encountered placebo responses, it also warned also that all intradiscal therapies should be subjected to controlled trials in order to refute placebo effects.

Despite being methodologically sound, this latter study[200] was criticized in a Cochrane Review for having a sample that representative of an "average" orthopaedic practice.[201,202] This criticism is gratuitous because it ignores the difficulties in getting patients to enroll in placebo-controlled studies of surgery and because IDET is not designed for average or all patients. It is applicable only for patients with internal disc disruption who satisfy strict indications.[175,176,203] For such patients, no form of conservative treatment, including cognitive behavioral therapy, has been shown to be as effective as IDET. Nor do these patients undergo spontaneous resolution if left untreated.[204]

Other reviews have been more charitable.[205,206] Both reaffirmed that with proper selection, IDET had the potential to reduce fusion surgery by at least 50%,[206] and hence is a valid option before undertaking spinal surgery.[205]

The reasons for the limited success rates of IDET have not been explored, but technical issues seem to apply.[176] The electrodes used have a limited field of influence. They create lesions to within only 2 mm from their surface. Fissures or nerves outside this field would escape coagulation, even if the electrode seems reasonably placed. Large fissures would not be encompassed by the small-sized lesion. For such reasons, alternative technologies have been developed and explored.

Complications associated with IDET have included injuries to the cauda equina.[207–209] This implies that electrodes were misplaced into the vertebral canal, but the techniques used in these cases were not illustrated in the reports. Neurologic complications can be avoided by careful attention to where the electrode is placed and by having the patient awake during the procedure so that they can warn of the onset of adverse symptoms. In cases where neurologic injuries have occurred, operators persisted in the procedure despite the onset of burning pain.[126] Vertebral osteonecrosis has been cited in two publications[210,211] but has not been distinguished from infection or a pre-existing intraosseous disc herniation.[126] Disc herniation,[212] discitis, infections, nerve root damage, allergic reaction, and vascular injury such as retroperitoneal bleeding have also been reported.[213]

Thermal Radiofrequency Anuloplasty. Thermal RF anuloplasty is analogous to IDET in that it requires inserting a flexible electrode into the anulus fibrosus. However, instead of applying radiant heat, the electrode operates in the manner of thermal RF to heat surrounding tissues.[214,215]

No randomized trials of this intervention have been conducted. An outcome study found reductions in pain in only a modest proportion of patients.[216,217] A case-control study found thermal RF anuloplasty to be less effective than IDET.[194]

Intradiscal Biacuplasty. Intradiscal biacuplasty is an emerging innovation for the treatment of discogenic pain. It involves placing electrodes bilaterally into the posterolateral corners of the target disc (Fig. 101.8). The innovation is that each electrode is cooled by passing water through it. For this reason, the procedure is also known as "cold RF." Cooling each electrode prevents coagulation around the active tip, which prevents the development of high impedance in the tissues.[218] As a result, current can be passed between the two electrodes over a prolonged time (15 minutes) to generate a lesion between the electrodes across the entire posterior anulus. The lesion produced is larger, both in depth and in height, than that produced by IDET. Temperatures sufficient to ablate nociceptors are confined to the anulus fibrosus.[218] In human cadaveric[219,220] and porcine discs,[218] no histopathologic changes to either osseous or neural tissues were evident following cold RF. Theoretically, these technical differences offer the promise of greater efficacy than with previous intradiscal therapies.

Transdiscal biacuplasty is still being evaluated in a multicenter trial. At one center, mean pain scores were reduced from 7.2 (1.9) to 3.4 (1.9), and 7 out of 13 patients reported at least 50% relief of pain at 6 months after treatment.[221] Improvements in pain were associated with improvements in disability and physical function, as well as decrease in use of opioids. At another center, 4 out of 8 patients had greater than 50% reduction in pain at 6 months.[222] These outcomes have still to be corroborated in larger numbers of patients. However, the procedure is easy to perform and is painless to the patients, which renders it an attractive, potential option for discogenic pain.

Radiofrequency Dorsal Root Ganglion

RF dorsal root ganglion (RF-DRG) is known by various names in which thermal RF lesions are directed at dorsal root ganglia.

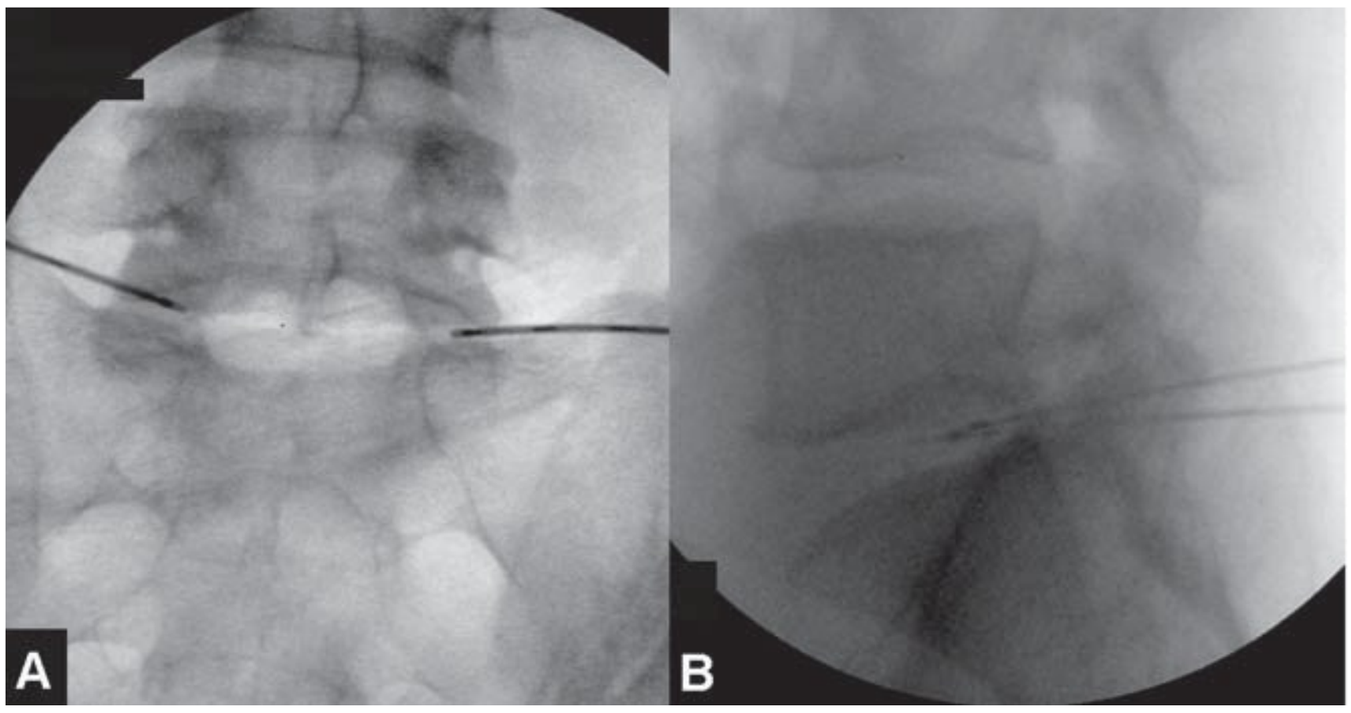

FIGURE 101.8 Fluoroscopy views of electrodes in position for intradiscal biacuplasty of an L5-S1 disc. **A.** Anteroposterior view. **B.** Lateral view.

The professed objective was not to coagulate the ganglion but to place a lesion close enough to provide relief of pain while only partially affecting the ganglion. It has been used to treat chronic pain mediated by cervical, lumbar, or thoracic dorsal root ganglia.

Descriptive studies promoted the use of RF-DRG for cervical,[223] thoracic,[224,225] and eventually lumbar,[226] pain syndromes. Outcomes were reported in terms of whether the patients were "pain-free" or had "good" (50%–100%) relief of their pain. Other outcome measures were not provided.

A descriptive study of cervical RF-DRG reported that 2/20 patients (10%) were pain free at 3 months, 4/20 were so at 6 months, and 2/17 (11%) at 12 months.[223] Eight patients had good relief at 3 months, but their numbers dropped to 2 at 6 months, and 2 at 12 months. In a controlled trial, success was defined as a reduction by 2 points or more on a 10-point VAS.[227] A significantly greater proportion of patients (8/9) had a successful outcome following active treatment than those (2/11) who underwent sham treatment. Follow-up, however, was limited to only 8 weeks. At this time the actively treated patients had reduced their mean pain scores from 6.4 to 3.3, whereas the sham-treated patients maintained the same scores (5.9, 6.0). Although this study provided data to the effect that the initial effects of cervical RF-DRG were not due to placebo, they do not attest to a successful, lasting effect. The data of the preceding observational study would predict that outcomes would attenuate substantially beyond 8 weeks.

A retrospective review of 361 patients treated by lumbar RF-DRG found 61 to be free of pain at 2 months.[226] This number became 23 at a mean follow-up of 22.9 months, but the range of that period was 2 to 70 months. A further 103 patients reported incomplete but greater than 50% relief at 2 months. This number dropped to 73 at longer-term follow-up. When tested in a placebo-controlled trial, lumbar RF-DRG was no more effective than sham treatment.[228]

The first study of thoracic RF-DRG announced that 30/45 patients (67%) were pain free and a further 11 (24%) had greater than 50% reduction in pain at 2 months.[224] At long-term follow-up, ranging from 13 to 46 months, 20 patients were pain free and 15 had greater than 50% relief of pain. The second study did not reproduce these outcomes.[225] At 8 weeks, only 8 of 43 patients (18%) had complete relief of pain, and 9 (21%) had greater than 50% relief. At follow-up beyond 36 weeks, only 5 patients (12%) were pain free, and 8 (18%) had greater than 50% relief. Patient selection may have been the reason for this dissonance. The first study had a large proportion (38%) of patients with postsurgical pain (thoracotomy, mastectomy, abdominal scar), in whom good outcomes were achieved. Such patients were absent from the second study. Conversely, the second study had a large proportion (47%) of patients with neuralgia. In the first study, patients with neuralgias had less than average outcomes. The second study did not stratify its results according to diagnosis. The efficacy of thoracic RF-DRG has not been tested in a controlled trial.

Sympathectomy

Surgical sympathectomy has a long heritage for the treatment of peripheral vascular disease and various chronic pain problems. For peripheral vascular disease, sympathectomy confers quantifiable clinical improvement. Subjectively, some 50% of patients secure complete relief of their pain with partial improvement in a further 31%.[229] Objectively, improvement in cutaneous[230,231] and muscle perfusion,[232] promote the healing of ischemic ulcers,[233] limit the spread of gangrene, and prevent amputation.[234] For chronic pain problems, the evidence is less than impressive.

Despite concerns expressed as long ago as 1942 about the efficacy of surgical sympathectomy for the management of noncancer pain,[235] the procedure was enthusiastically pursued for the management of reflex sympathetic dystrophy or complex regional pain syndrome (CRPS), migraine, dysmenorrhoea, epilepsy, chronic pancreatitis, postherpetic neuralgia of the trigeminal nerve, postdiscectomy syndrome, and phantom limb pain.[236,237] However, systematic reviews have found no tangible evidence supportive of sympathectomy for the management of neuropathic pain.[238,239] Furthermore, postsympathectomy neuralgia is a common complaint with a reported incidence between 15% to 50%.[240,241]

Despite this background, some operators have advocated thermal RF as an alternative to surgical sympathectomy.[242] Evidence, however, is limited to small case series.

For chronic abdominal pain, caused by pancreatitis or of unknown origin, one study of 10 patients reported good relief of pain lasting over 12 months following RF ablation of the splanchnic nerves.[243]

There is some evidence, from observational studies, that RF sympathetic neurotomy can improve vascular function in disorders of the upper limb, but those studies provide no data on the relief of pain.[244] For the relief of pain by RF stellate ganglion neurotomy in patients with CRPS, an attempted review found only one publication, which provided inadequate data.[245] That review offered its own outcome data, claiming that one-third of patients achieved more than 50% reduction of pain. Follow-up, however, was limited, with a drop-out rate of 69%. A later, retrospective study found that stellate ganglion neurotomy provided at least 50% relief of pain in 35 of 86 with various, unspecified pain syndromes.[242] The duration of relief was said to have an average of 52 weeks, with a range of 2 to 186 weeks, but these figures were based on a follow-up of only 27 of the patients.

TABLE 101.3

PAIN DISORDERS TREATED WITH PULSED RF[266,267]

Pain Types	Conditions Treated
Somatic	Arthritis; back, neck, shoulder, elbow, sacroiliac, temporomandibular, and hip joint pain
Visceral	Groin pain, orchialgia
Neuropathic	CRPS, trigeminal and glossopharyngeal neuralgia, radicular pain
Headaches	Posttraumatic, occipital neuralgia
Postsurgical	Tonsillectomy, postherniorrhaphy neuralgia, postlaminectomy syndrome

Miscellaneous

Thermal RF neurotomy has been used to treat miscellaneous chronic pain problems, such as cluster headache,[246,247] other oral and facial pain,[248,249] and hip pain.[250] The evidence is limited to case reports.

PULSED RADIOFREQUENCY

Pulsed RF was developed as an alternative to thermal RF. Instead of delivering a sustained current and thereby generating heat, the current is delivered in pulses, with temperature maintained at or below 42° C. Doing so avoids the production of a destructive lesion, but purportedly, the pulsed electric field exerts therapeutic effects.[251–254] Relief of pain is attributed to the electric field exerting a "central modulatory" effect ostensibly through a series of yet to be defined physiologic events.[155,252–254]

Proponents of pulsed RF attribute its antinociceptive effect to activation of transcription factors such as *c-fos*[255,256] and ATF3.[257] However, although one study reported the expression of *c-fos* in spinal neurons exposed to pulsed RF at 38° C but not to thermal RF at an equivalent temperature,[256] another study showed no difference in *c-fos* expression when exposed to either thermal RF or pulsed RF.[258] In any event, the *c-fos* is not a marker of relief of pain. Expression of *c-fos* is not associated with long-term neuronal plasticity, nor does *c-fos* exert a preferential antinociceptive effect.[259,260] It is little more than an expression of neuronal activity. Rats exposed to cat odor show greater c-*fos* expression than controls,[261] and persistent *c-fos* expression can occur in the presence of chronic social stress.[262] The data are no different for ATF3. Elevated levels occur in cardiac ischemia, liver toxicity,[263] and seizures.[264] Like *c-fos*, ATF3 is thought to be a marker of neuronal injury,[265] but its precise physiologic significance is not known.

Whether delivered percutaneously, transcutaneously,[266] or intra-articularly,[267] pulsed RF has been widely applied for all manner of pain, irrespective of pain pathophysiology (Table 101.3). The number of publications, however, is disproportionate with the quality of published evidence. A narrative review[268] and a systematic review[266] both found the descriptive literature uncompelling for lack of diagnostic criteria, small effect-sizes, lack of follow-up, incomplete follow-up, lack of controls, and the confounding effect of cointerventions. For cervical and lumbar zygapophysial joint pain and trigeminal neuralgia, pulsed RF has neither surpassed nor equaled the published benchmark set by thermal neurotomy.[53,62,103,109] The results of two controlled trials do not dispel these conclusions.

In one randomized controlled trial, thermal RF was shown unequivocally to be superior to pulsed RF in the management of trigeminal neuralgia.[269] Within the first 3 months of commencing the trial, all patients who received pulsed RF showed no signs of improvement and all required their medications. The trial was abandoned and the entire study sample was treated with thermal RF. At the end of 6 months, all patients treated with thermal RF were pain free and none required medications.

In the second controlled trial, 23 patients with suspected cervical radicular pain were randomized into a group of 11 who were treated with pulsed RF and a group of 12 who were treated with sham RF.[270] Relief of pain by at least 50% at 3 months was obtained in 9 of those treated with pulsed RF and by 4 of those who received sham treatment. Significant differences evident at 3 months were lost by 6 months. At no stage did active treatment achieve significantly greater improvements in function or quality of life than did sham treatment. No patient was rendered pain free, and all patients still required medications.

A third study[271] showed that the results of pulsed RF for lumbar medial branch neurotomy were inferior to those achieved by thermal RF.

CONCLUSION

The field of neurolytic blockade for chronic pain provides a suitable canvas upon which to illustrate the vicissitudes of evidence-

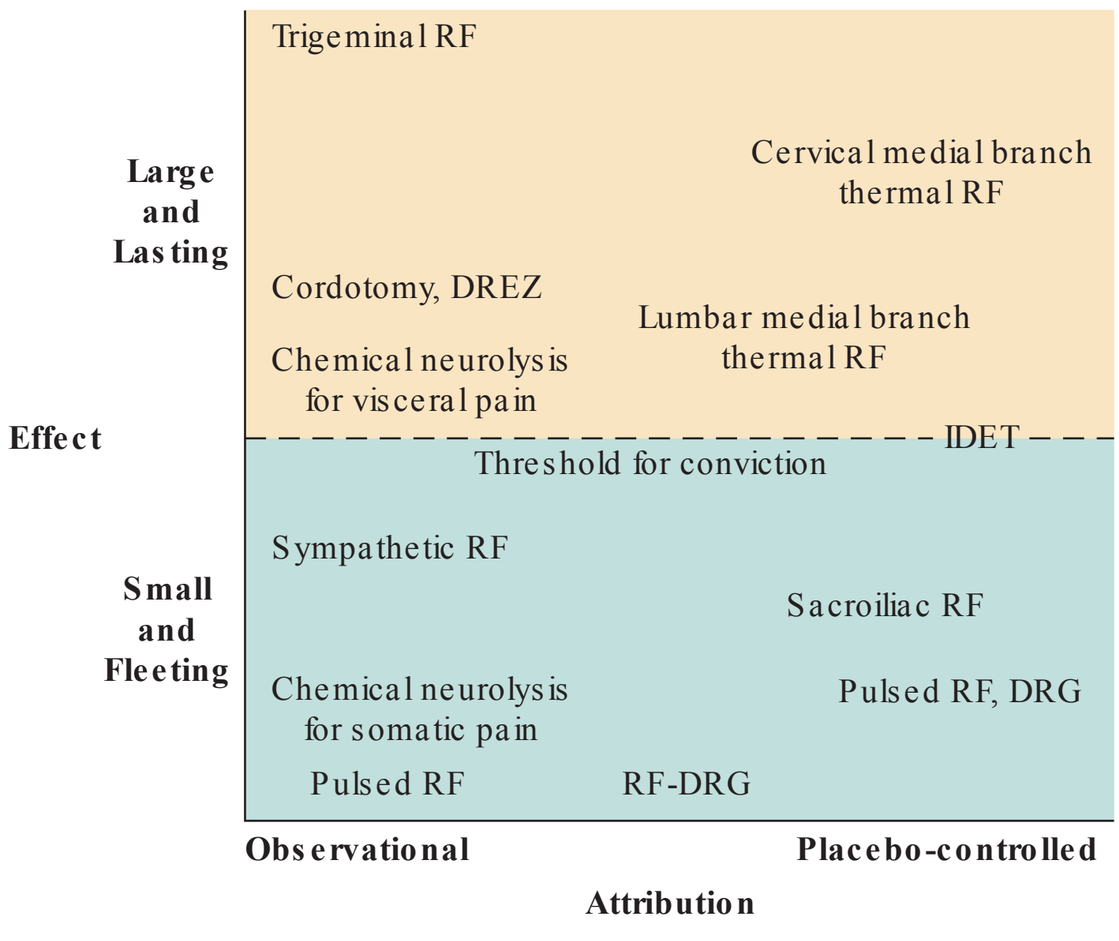

FIGURE 101.9 A graphical representation of the extent to which the evidence for various neurolytic procedures is convincing or not, according the nature of studies and the nature of the effect of treatment.

based medicine. Although it has become fashionable in some circles, to demand randomized controlled trials as the only acceptable form of evidence, this is an extreme view. Other levels of evidence can be sufficiently convincing. For neurolytic procedures, the evidence for various procedures is spread across a spectrum of credibility and conviction (Fig. 101.9).

At the heart of evidence appraisal is not whether a study is a controlled trial or not, but whether the evidence is convincing or not. In other fields of medicine, it has been shown that rarely have placebo-controlled trials overturned practices that were based on well-conducted observational studies.[272–274] This is reflected in the domain of neurolytic blockade. The issue is whether or not the evidence presented reaches some threshold of conviction (see Fig. 101.9).

There have been no placebo-controlled trials of thermal RF neurotomy for trigeminal neuralgia. Yet, no one challenges the effectiveness of this treatment for lack of controlled trials. This treatment is firmly established because of strong observational data. The effect of this treatment is strong and lasting. A large proportion of patients obtains complete or near complete relief of pain, and the duration of that relief can be measured in years, if not decades. For most practitioners, this is enough to attract conviction that thermal RF neurotomy is a worthwhile treatment for trigeminal neuralgia. Only the most ardent pundit would deny conviction, and none has done so publicly about this intervention.

In this case, the principle reflected is that conviction about effectiveness is achieved if a successful outcome can be demonstrated to occur consistently across multiple studies, consistently for a large proportion of patients, and that outcome is enduring. Moreover, the relief obtained is consistent with the known biological basis of the intervention. In the case of trigeminal thermal RF neurotomy, all these criteria have been satisfied.

Other RF interventions pale in comparison. Data to show that relief occurs in a substantial proportion of patients, that it occurs consistently across large numbers of patients, that it is enduring, or that relief means complete relief of pain are lacking. Investigators have sought recognition of their procedure on the basis of single studies with small sample sizes. What passes for success is little more than 50% relief of pain, whose duration is measured in weeks and occurs in a minor proportion of patients. No evidence is provided that this limited degree of relief reduces the burden of illness: that patients require no other form of treatment or that physical and social activities are restored by the treatment.

It is not that observational studies are an insufficient level of evidence. The issue is that most observational studies in this field provide insufficient evidence to achieve a threshold of conviction, or they provide evidence of insufficient effect to be convincing.

For sympathetic RF and for chemical neurolytic blockade for somatic pain, evidence is lacking for a substantial effect consistently across large numbers of patients that is lasting in duration. In the case of chemical neurolytic blockade for cancer pain, a worthwhile effect has been demonstrated consistently across a number of studies, although some questions still remain concerning benefits for variables other than pain. There has been no demand for controlled trials probably because of the limited life expectancy of the patients for whom these treatments are used. The same applies for treatments such as cordotomy.

For pulsed RF, outcomes are modest or poor, occur in minor proportions of patients, and are of short duration. There is not a demonstrated rationale for the procedure. When peripheral nerves have been the target of treatment, outcomes either fail to achieve the benchmarks reported for thermal RF or have been shown to be inferior to those of thermal RF.

Demands for stronger evidence are justified if there is no evident rationale or biological basis for why the treatment should work, if treatment effects are small, or if treatment effects are large but have not been shown to occur consistently across large samples. Without placebo-controlled trials, under these circumstances, consumers of information cannot determine if the reported results are no more than fortuitous but statistically accidental outcomes.

In the field of neurolytic blockade, various interventions have suffered different fates when subjected to placebo controls. Some have been vindicated but others have been shown to be no more effective than placebo, despite previous enthusiasm for them.

Despite being heralded as a successful procedure, lumbar RF-DRG proved no more effective than placebo. Pulsed RF-DRG proved more effective, statistically, than placebo in some measures, but not consistently across all measure. Nor were its effects enduring. It amounts to a procedure that produces some outcomes, in some patients, for a short time.

For thermal RF, the evidence differs for different applications. For some the evidence is convincing, or should be so, for others it has not reached the threshold of conviction.

A rigorous, placebo-controlled trial showed that cervical medial branch RF neurotomy was not a placebo. Subsequent follow-up studies showed that the effects were either enduring or can be reinstated by repeat treatment at about yearly intervals. Moreover, the validated outcomes were complete relief of pain, restoration of function, and no need for other health care.

For lumbar medial branch RF neurotomy, the evidence is also reasonable. A placebo effect has been refuted, outcome studies have shown prolonged effects, and relief can be reinstated if pain recurs. Still to be shown, however, is if treatment restores function, reduces the need for other health care, and secures return to work. A persisting problem is that not all operators perform this procedure in a manner that has been shown to be effective.

Sacroiliac RF is still in evolution. Although placebo effects have been refuted, the magnitude of relief obtained and its duration remain limited. For thoracic medial branch RF neurotomy, evidence is simply lacking.

RF cordotomy and DREZ lesioning are spared the requirement for randomized controlled trials because of the delicacy of the procedure and the target involved. Ethically, it is hard to justify placebo-controlled trials of invasive procedures on the spinal cord. Outcome studies could, perhaps, be more rigorous than they have been in order to attract greater conviction about the effectiveness of these procedures, but given the highly specialized nature of these procedures, the available evidence is probably enough.

The most curious example of evidence is IDET. Although there is an abundant literature and although placebo-controlled trials have been conducted, conviction about this procedure is marginal or contentious. The low success rate of this procedure limits its attraction. Had IDET been consistently successful in a consistently large proportion of patients, it might have attracted more widespread conviction. Proponents have gathered behind the defense that this procedure should be used only in patients who satisfy particular, stringent indications. Yet, even in such cases, the success rate remains modest. A treatment more consistently effective than IDET will readily replace it as an alternative to lumbar fusion.

CHAPTER 102 ■ SURGERY OF THE PERIPHERAL NERVOUS SYSTEM AS A TREATMENT FOR PAIN

ANTHONY C. WANG, JAMES N. CAMPBELL, AND PARAG G. PATIL

INTRODUCTION

In this chapter, we consider ablative and decompressive surgical approaches to pain that target the peripheral nervous system. Ablative procedures interrupt signal flow between pain generators in the periphery and brain. For example, cutting a peripheral nerve may prevent transmission of pain-encoding signals from an injured region to the spinal cord. By contrast, nonablative procedures may relieve pain due to compression of nerves by adjacent connective tissue.

There are four major categories of pain surgery involving the peripheral nervous system: peripheral neurectomy, nerve entrapment release, dorsal rhizotomy and ganglionectomy, and sympathectomy. The treatment of trigeminal neuralgia, one of the most prevalent diseases successfully treated with surgery, is presented in Chapter 103. Ablative procedures aimed at the spinal cord, such as the dorsal root entry zone operation for brachial plexus avulsion or cordotomy for cancer pain, are presented in Chapter 104.

There are two fundamental approaches to control intractable pain: attempts to palliate symptoms and attempts to eliminate pain definitively. Pharmacologic, psychologic, physiotherapeutic, neuro-modulatory, and neuro-interventional approaches each attempt to reduce the severity of pain symptoms. Surgical approaches have great appeal for their potential to eliminate pain altogether. In fact, nerve decompressions are among the most common peripheral nerve surgeries. By contrast, ablative procedures such as neurectomy and ganglionectomy are notorious for achieving only short-term benefits, a reputation that undermines their appeal. In support of such skepticism, animal research suggests that axotomy alone may be sufficient to induce pain.[1] However, regardless of the perception that inappropriate patient selection may lead to considerable morbidity, the experience of some clinicians remains that ablative procedures have the capacity to relieve pain enduringly and that ablative procedures are useful therapeutic ventures in properly selected patients.

PERIPHERAL NEURECTOMY

Basic Considerations

There are two reasons that a nerve may be cut to eliminate pain. One reason is to denervate a peripheral pain-producing structure to treat nociceptive pain. For example, facet rhizotomy denervates the facet joint as a treatment for axial spine pain. A second reason to cut a nerve is to remove an abnormal focus of nerve injury (e.g., excision of a neuroma). In this case, there is some irony in the use of neurectomy to treat pain, as transection of a somatic nerve may have been the original cause of the pain. To understand how neurectomy may relieve pain, we must consider some aspects of the pathophysiology of neuropathic pain.

Pathophysiology of Neuropathic Pain

When sensory nerve fibers are severed, the proximal axons remain in continuity with cell bodies in the dorsal root ganglion. These axons sprout and seek Schwann-cell guides. Schwann cells are believed to up-regulate expression of neurotrophic factors, which induce axonal growth.[2–5] If the perineurium of the injured nerve has remained intact, as in the case of crush or certain thermal injuries, the sprouts may successfully reinnervate the target tissue. Successful regeneration may also occur when the transected ends of the nerve are surgically reapproximated (neurorrhaphy). However, when Schwann-cell guides are not present, the axon sprouts are unable to reach the target tissue and randomly double-back on themselves. This disordered process of growth ultimately results in a densely packed cluster of nerve sprouts known as a neuroma.

Weir Mitchell[6] brought attention to the problem of painful nerve injury after caring for wounded soldiers during the American Civil War. A century later, Denny-Brown and Kirk[2] presented one of the first studies demonstrating that axotomy can induce behavioral signs of pain in an animal model. More recent studies have suggested that axotomy of a major nerve, by itself, may induce hyperalgesia in animals. Although nontraumatic neuropathies may induce pain in diverse ways, the single nerve lesion offers a useful model through which to understand the mechanisms of neuropathic pain.

At least four pathophysiologic mechanisms appear to play a role in nerve-injury pain:

Ectopic generation of action potentials. Though normally silent, nociceptive afferents may become spontaneously active following nerve injury, producing action-potential activity in the absence of a stimulus.[3] This activity may be experienced as spontaneous pain. In addition to abnormal signaling in the nerve itself, the activity may sensitize central neurons, such that inputs from non-nociceptive, tactile afferents produce pain (allodynia).[7]

Ectopic excitability. Uninjured nerve trunks are minimally sensitive to mechanical stimuli. Gentle percussion over a nerve is not painful. Following injury, however, regenerating fibers may abnormally respond to mild, mechanical stimuli. Such ectopic mechanical excitability gives rise to Tinel's sign, an electrical sensation in the nerve's original target distribution, elicited by mechanical stimulation at the location of regenerating axons. Furthermore, ectopic excitability to mechanical stimuli may be accompanied by chemical sensitization. For example, injured nociceptive axons may become abnormally sensitive to catecholamines. As a result, the physiologic release of norepinephrine from sympathetic terminals may induce pain (sympathetically maintained pain [SMP]).[4,5]

Nervi nervorum. Nerves themselves appear to be innervated by nociceptive fibers. These nervi nervorum fibers may be sensitized to mechanical stimuli following nerve injury. Such a mechanism may explain, for example, the local tenderness and mechanical hyperalgesia of the ulnar nerve when it is entrapped at the elbow or the local tenderness of nerves entrapped by scar tissue.[8]

Ephaptic conduction. Under normal conditions, signals in adjacent afferent nerve fibers are insulated from each other. Activity in an injured nerve fiber may cross to a nearby fiber, through a direct electrical connection between the two. During such ephaptic transmission, or cross-talk, a non-noxious sensory stimulus may evoke activity in nociceptive fibers and thereby cause pain.

Some of the mechanisms of ectopic generation of action poten-

tials and ectopic excitability have been described. When an axon is severed, the axonal transport of sodium channels and other ion channels from the neuronal cell body to the sensory terminal is interrupted. As a result, channels may be expressed ectopically in the neuroma formed at the nerve injury site. Nociceptive fibers in the neuroma thereby become sensitive to normally nonpainful stimuli, producing pain when these stimuli are present.[9,10] In addition, nerve injury may lead to profound changes in gene expression, promoting ectopic excitability.[11]

Other mechanisms may also contribute to neuropathic pain. While inflammatory and neuropathic pain syndromes are traditionally considered separately, immunologic studies have implicated several pathways through which inflammatory responses may alter nociceptive processing, resulting in neuropathic pain.[12] Evidence supports what may be termed the wallerian degeneration hypothesis.[13] According to this hypothesis, uninjured nociceptors that are adjacent to nerves undergoing wallerian degeneration may become spontaneously active and develop sensitivity to catecholamines, resulting in spontaneous pain and SMP. To the extent that neuropathic pain results from these mechanisms, peripheral neurectomy may be expected to worsen pain, since the nerve undergoes wallerian degeneration distal to the site of neurectomy.

Rationale for Neuroma Relocation Surgery

The concept of surgery to remove a neuroma as a treatment of nerve injury pain is a flawed one. Neuromas arise from nerve fibers proximal to a region of transection or severe injury which remain in continuity with their cell bodies in the dorsal root ganglia. Cutting the nerve at a location that is proximal to the site of nerve injury to remove the neuroma results in the formation of a new neuroma at the proximal location. Surgery in which neuromas are "removed" should therefore be termed neuroma relocation surgery.

Not all neuromas are painful. The tissue milieu surrounding the nerve may determine whether a neuroma becomes painful or remains painless. The use of peripheral neurectomy as a treatment for painful neuromas is therefore predicated on the hope that relocation of the neuroma may convert it from a painful one to a painless one. For example, relocating a neuroma to a nonpressure-sensitive area may alleviate pain in some patients. Relocation of neuromas into muscle was first described in 1918. Since that time, the identification of anatomic locations appropriate for nerve relocation has improved outcomes substantially.[14–22]

Thus, an important consideration in peripheral neurectomy is the role of location in the production of pain. If the location of nerve injury contributes to pain, then relocating the neuroma to a mechanically favorable area may be advantageous. However, to the extent that there is location-independent ectopic generation of action potentials in the neuroma, neuroma relocation surgery will fail. Additionally, some investigators have argued that central mechanisms may account for pain in many situations of nerve injury.[23] In this circumstance, neuroma relocation surgery may also fail. However, our observations as well as those of other experienced clinicians suggest that in patients with nerve injury pain, where anesthetic block of the injured nerve relieves pain, peripheral neurectomy may provide significant pain relief.

Clinical Considerations

Preoperative Evaluation

Clinical scenarios favoring peripheral neurectomy may be broadly divided into two circumstances: neuropathic pain resulting from nerve injury and nociceptive pain from a diseased tissue other than nerve. Nerve injury pain is characterized by numbness, burning, and allodynia. Tinel's sign may be present at the site of a painful neuroma. Candidates for neuroma relocation surgery should respond to local anesthetic blockade.

Successful anesthetic blockade is an important prerequisite for effective neuroma relocation surgery. If blockade of the putative, pain-generating neuroma fails to relieve pain nearly entirely, the rationale for neuroma relocation surgery is precarious. The decision to operate may be made with more confidence if more than one block is done. Once candidate nerves are identified, local anesthetic blocks indicate the level of benefit that can be obtained following nerve ablation. A successfully applied block should induce anesthesia in the distribution of each target nerve, but not beyond, to indicate the specificity of the blockade. Injection of saline or injections away from the nerve may enhance blockade specificity by identifying nonspecific responses (e.g., placebo responses).

Findings associated with complex regional pain syndrome, such as edema, hyperalgesia, and trophic changes, also suggest that neurectomy will not alleviate pain. Notably in such cases, peripheral nerve blockade typically produces little relief. Patients should be additionally assessed for hyperalgesia to cooling stimuli. This finding is suggestive of SMP, discussed below. Finally, local tenderness in combination with Tinel's sign suggests nerve entrapment. In this instance, nerve decompression would be indicated rather than neurectomy. It is important to note that even subtle entrapments without significant motor or sensory loss may induce severe pain.

Even after one has identified a specific nerve as the pain generator, and one has determined that there are no contraindications to neuroma relocation surgery, a wait-and-see approach may remain most appropriate. For example, where injury is relatively recent and the nerve relatively minor, one may choose to observe. The pain may resolve spontaneously. Where there is only partial nerve injury with remaining function, neurectomy may sacrifice function without any assurance that the new neuroma will be less painful than the old one. In this circumstance, nerve repair should be considered before performing neuroma relocation surgery.

Nerve repair has potential to relocate neuromas with the advantage of restoring neurologic function. The clinician sometimes faces the ironic situation that to repair an injured nerve, a normal nerve (e.g., sural nerve) may be sacrificed to provide donor grafts. In effect, nerve repair is, in a sense, still a neuroma relocation operation—the neuroma is relocated to the donor nerve. Repair of an injured nerve, when feasible, is generally preferable to permanent transection. By contrast, if a nerve has already been completely severed, the risk of relocating the neuroma is low. Thus, in a case of a well-defined neuroma, when an anesthetic block relieves pain, surgical neurectomy may be the preferred first-line of surgical therapy.

Careful analysis may lead to rewarding outcomes. The following case presents the history, preoperative evaluation, and treatment of a patient with neuropathic pain:

> A 44-year-old woman presented with a chief complaint of right vaginal pain. This problem had been present for 3 years and originated with an excisional biopsy of a right-sided vaginal ulcer near the introitus. The pain was always present, but especially disturbing were lightning attacks of pain that occurred unpredictably several times a day. Examination disclosed a subtle sensory loss in the right vulvar area. Medication trials were minimally helpful. An anesthetic block of the right pudendal nerve led to 50% pain relief. A combined ilioinguinal and genitofemoral nerve block also led to 50% pain relief. A local anesthetic block of all three nerves together led to 100% pain relief. As treatment, the right pudendal nerve was severed distal to the sacral spinous ligament through a perivulvar approach, and the patient, predictably, had 50% of her pain relieved. At a separate surgery, the right ilioinguinal and genitofemoral nerves were severed through a retroperitoneal approach. At 3-year follow-up, the patient had complete relief. There were no adverse sequelae.

In this case, both lumbosacral neural segments provided inner-

vation to the painful neuromas. Failure to appreciate this would have led to a less than satisfactory result. This case underscores the need for complete blockade of pain during the application of local anesthetic to ensure that all involved nerves are identified.

Operative Technique

Once peripheral neurectomy has been selected as the treatment of choice, the primary surgical issue is where to relocate the neuroma. Troublesome neuromas typically are in areas near joints, scars, and structures that may tether the nerve. The idea of surgery is to relocate the neuroma to a new location where tethering does not occur.[17] Nerves may be cut back to locations such that the ends can be placed in healthy, well-vascularized muscle. Some have also advocated that neuromas be placed in holes in bone.[23b] Placement of a cut nerve into these environments does not change the fact that the cut ends of the nerve will sprout and that a neuroma will form. However, with relocation of the neuroma into muscle or bone, chances are reduced that the new neuroma will be subject to the tension and shearing forces likely to play a role in pain generation.

Alternatives to neuroma relocation exist. The nerves may be cauterized, frozen, burned, or injected with toxic chemicals. These options have been reported to be successful, but their advantages over surgical neurectomy have not been demonstrated. A surgical procedure where the neurectomy is done sharply, with limited damage to the surrounding environment of the nerve, is most appealing from a mechanistic perspective. Damage to the surrounding tissues, such as necrosis due to phenol injection, may create a new focus for pain generation.[24]

Indications and Outcomes for Treatment of Neuropathic Pain

Ordinarily, neurectomy should be reserved for those situations in which nerve decompression is unlikely to provide a satisfactory result and nerve repair is not possible. Division of major nerves can cause significant motor deficits, sensory deficits, and pain. Ablation of such nerves as a treatment of pain should ordinarily be considered only if the nerve is already divided. Nerve graft repair should be considered as an alternative to repeat transection. Neurectomy of minor nerves has a role in pain treatment and the risk-reward ratio may be favorable.

Amputation Stump Pain

In cases of stump pain, it is worthwhile to examine the patient for tender neuromas. A prosthetic device, for example, may apply pressure to the neuroma, causing pain. Surgical relocation of neuromas to more proximal or protected locations may provide significant benefit in these cases.[25]

Intercostal and Intercostobrachial Pain

Chest trauma or thoracotomy may damage intercostal nerves. Shoulder trauma and axillary node dissection may damage the intercostobrachial nerve. Motor deficits associated with intercostal and intercostobrachial neurectomy are clinically insignificant. Hence, neurectomy is usually without significant drawbacks. This procedure can be safely accomplished through video-assisted thoracoscopy, as well as through an open procedure.[26]

Perineal and Inguinal Pain

Injuries to the pudendal, ilioinguinal, iliohypogastric, and genitofemoral nerves may result in severe pain. These injuries are often due to abdominal and pelvic surgery, episiotomy, hernia repair, entrapment, or blunt trauma. For example, the Pfannenstiel transverse incision may injure the ilioinguinal/iliohypogastric nerves. Groin pain from inguinal herniorrhaphy is not uncommon. Stulz and Pfeiffer[27] reported relief of pain with neurectomy in 70% (16 of 23) of patients with ilioinguinal and iliohypogastric neuralgia as a complication of prior surgery. Starling and Harms[28] reported similar rates of success: 89% (17 of 19) for ilioinguinal neuralgia and 71% (12 of 17) for genitofemoral neuralgia. In the largest series to date, Amid[29] reported 95% improvement in pain among 225 patients. Our own experience supports the use of neurectomy, but the incidence of long-term favorable outcomes is much more modest.[30]

Meralgia Paresthetica

Entrapment or injury of the lateral femoral cutaneous nerve, meralgia paresthetica, may result in pain and dysesthesia in the anterolateral thigh. In cases where the diagnosis is unclear, local anesthetic blockade may be helpful. Transection should ordinarily be considered as a back-up procedure when decompression is not feasible and nonsurgical approaches, such as weight loss, have failed.[31]

Saphenous Neuralgia

Entrapment of the saphenous nerve in the subsartorial canal[32] may occur with or without a history of trauma. Damage to the saphenous nerve may occur when the saphenous vein is harvested.[33] The condition is associated with pain (with or without numbness) along the anterior and medial leg and the dorsum of the foot. Proximal neurectomy may be used if the nerve has been directly injured. Otherwise, in our experience, the nerve should be decompressed as first-line treatment.

Morton's Neuroma

This condition involves compression of the digital nerve, typically between the third and fourth tarsal bones. The compression leads to a swelling of the nerve, which is mistakenly called a neuroma. Patients present with pain in this region worsened by wearing shoes and walking. If conservative measures (e.g., orthotics) fail, neurectomy may be offered. Indeed, this operation is a common procedure for this condition. Johnson et al.[34] reported relief of pain in 67% (22 of 33) of patients, with 6 years average follow-up, following excision of the plantar interdigital neuroma. Others have reported surgical success rates of up to 90%.[35,36]

General Results for Neurectomy for Neuropathic Pain

What are the predicted results of neurectomy for nerve injury pain? The question is difficult to answer because the patients undergoing this treatment are heterogeneous. In addition, measurement of patient outcome varies greatly among studies with regard to methodological rigor, length of follow-up, and technique. As suggested by the studies cited above, success rates vary from modest to high.

Burchiel and colleagues[37] have taken a systematic approach to the treatment of nerve injury pain, moving the field toward a definition of the indications for neuroma surgery. In their study, 42 patients with nerve injury pain were divided into four treatment groups:

1. Patients with distal sensory neuromas treated by excision of the neuroma and implantation of the proximal nerve into muscle or bone marrow.
2. Patients with suspected distal sensory neuromas in which the involved nerve was sectioned proximal to the injury site and implanted.
3. Patients with proximal neuromas-in-continuity of major sensorimotor nerves treated by neuroplasty, which frees a nerve from adjacent tissue.
4. Patients with nerve injuries at points of anatomic entrapment treated by neuroplasty and transposition.

Surgical success (rated as a greater than 50% subjective improvement in pain levels, subjectively rated pain relief as "good" or "excellent," and no postoperative narcotic usage) varied between the groups. In the 40 patients who received postoperative follow-up care over 2 to 32 months (average of 11 months), 16 (40%) met these criteria. By group, successful pain relief was accomplished in 44% (8 of 18) of group 1, 40% (4 of 10) of group 2, 0% (0 of 5) of group 3, and 57% (4 of 7) of group 4.

After obtaining these results, Burchiel et al.[37] attempted to determine retrospectively the extent to which indicators of nerve injury predicted surgical success. Such indicators included Tinel's sign, hyperalgesia, a "discrete nerve syndrome," litigation, and prior procedures. Some predictors showed promise. For example, a discrete nerve syndrome, defined as a condition in which a single nerve could account for all the neurologic findings and pain distribution, tended to predict success. However, none of the relationships between preoperative diagnostic variables and treatment success achieved statistical significance at the $p < 0.05$ level.

One can only speculate why the results of this series differ substantially from those of other series. Perhaps patient selection accounts for differences, yet Burchiel and colleagues[37] appeared to discriminate patients at high risk for failure. Surgical technique could also play a role, but there is no evidence on which to base such a statement. In some cases, neuromas are innervated by more than one nerve. For example, proximal resection of the superficial radial nerve to treat dorsoradial wrist neuromas often relieves pain only temporarily. Further inspection reveals that the lateral antebrachial cutaneous nerve may also innervate these neuromas, and thus success may require sectioning this nerve as well.[38]

Another reason for failure in neuroma relocation surgery may relate to the discovery that the distal side of a severed nerve may also form a neuroma at the site of injury. Plexus formation distal to the neurectomy may allow intact nerve fibers from other nerves to sprout in retrograde fashion to innervate this distal site. This retrograde sprouting may create a potentially painful neuroma on the "wrong" side.[39] Neuroma relocation surgery should perhaps attend to neuroma formation on both sides of a severed nerve.

Indications and Outcomes for the Treatment of Nociceptive Pain

Neurectomy may be performed to interrupt the flow of pain signals through intact nerves from a diseased, pain-generating tissue to the spinal cord. In these cases, a balance is sought between elimination of input from the pain-generating tissue and the potential formation of a painful neuroma. Following neurectomy, regrowth of the transected nerve and invasion of the diseased tissue by surrounding nerves may result in a return of pain. In addition, intact and otherwise "normal" nerve fibers may be sensitized by the release of growth factors in partially denervated tissues. Progression of the underlying disease process may also enlarge the injured tissue region, producing pain beyond the region of surgery. In spite of these considerations, in the following disease processes, neurectomy may be an effective treatment of nociceptive pain.

Axial Spine Pain

The medial branches of dorsal rami innervate the paraspinal muscles, the interspinous ligament, and the zygapophyseal (facet) joints. Pain associated with movement of the lower back, which is relieved by rest and is not attributable to other spine pathology, may be relieved through bilateral, percutaneous radiofrequency or chemical ablation of these branches in the lumbar spine.[40,41] A success rate of 85% with mean duration of relief of 10.5 months was reported by Schofferman and Kine[42] through this procedure. In addition, neck pain associated with whiplash injury may benefit from a similar procedure in the cervical spine.[43] The mechanism of pain relief is thought to relate to denervation of the facet joint. Since the dorsal ramus innervates several structures, other mechanisms are possible. Evidence is indeterminate for similar pain of thoracic origin.

Many experts suggest diagnostic anesthetic blocks of the facets prior to a facet denervation procedure. Good results are expected only in patients who get excellent benefit from the blocks. Patients who have axial pain in addition to radicular symptoms tend not to benefit from facet denervation procedures alone. Among preexisting symptoms, only paraspinal tenderness has been shown to predict treatment success, while increased pain with facet loading maneuvers predicts less favorable outcomes.[44,45]

The procedure is performed percutaneously with radiofrequency heat lesions. The advantages of this procedure are that it can be done on an outpatient basis and morbidity is low. The disadvantage is that the procedure often confers only temporary relief or often no relief at all, regardless of the temporary effects of diagnostic facet blocks. In addition to continuous, high-temperature radiofrequency medial branch ablation, pulsed radiofrequency, cryodenervation, and phenol neurolysis have also been used to provide intermediate to long-term pain relief.

In patients with no prior spine surgery, these procedures have been reported to provide initial relief for 60% to 70% of patients.[33,43,44,46] Rates are reported to be considerably lower (20% to 50%) for patients with prior spine surgery.[33,46,47] However, a history of spine surgery is associated with treatment failure not only for radiofrequency denervation, but other interventions as well, including epidural steroid injection and open surgery. Our view is that this is a low-morbidity procedure that can provide effective, albeit impermanent, pain relief for patients with axial spine pain. Recurrence of pain following denervation can be treated with repeated neurotomy with comparable efficacy. See Chapter 101 for a detailed discussion of neurolytic blocks, including radiofrequency neurolysis.

Extremity Joint Pain

Denervation procedures aim to eliminate pain arising from degenerative processes in the joint, while preserving functions that may be lost after other forms of joint surgery. Buck-Gramcko[48] reported retention of wrist mobility with substantial reduction of pain in 69% (135 of 195) of patients following wrist denervation surgery. Wilhelm[49] reported success in 90% of patients with tennis elbow treated by denervation. Dellon et al.[50] reported satisfaction in 86% (60 of 70) of patients following partial denervation surgery for persistent, postoperative knee pain. Pulsed radiofrequency denervation has also been used to provide relief, though generally with shorter effect when compared to conventional radiofrequency ablation, and limited evidence to support the efficacy of this approach.[51]

Pelvic Pain

Neurectomy of the superior hypogastric (presacral) plexus has been advocated as a treatment for medically refractory pelvic pain. In 1948, Ingersoll and Meigs[52] reported complete relief of primary dysmenorrhea in 81% (72 of 89) of women treated with neurectomy. More recently, with the development of more effective analgesics, ablative approaches to pelvic pain have been largely limited to patients with secondary dysmenorrhea associated with endometriosis. Nezhat et al.[53] reported at least 50% relief from pain in 70% to 85% of patients with various stages of endometriosis with 1-year follow-up, following presacral neurectomy combined with excision and vaporization of endometriotic lesions. Debate over the proper role of presacral neurectomy has been ongoing for well over 50 years. Introduction of the biopsychosocial model of chronic pain has potential to spare many women from surgery.

Cancer Pain

Peripheral neurectomy is infrequently used in the treatment of pain due to cancer. This is due to the availability of alternative strategies with low morbidity and higher success rates, such as spinal opiates. Transecting a peripheral nerve may fail to relieve pain because of overlapping receptive fields of adjacent nerves or central plasticity. Sectioning major peripheral nerves results not only in numbness but also in unacceptable motor loss. Peripheral neurectomies are rarely indicated in the extremities. However, localized chest or abdominal wall pain can successfully be treated with intercostal neurectomies. Alcohol injection, cryoprobe, or radiofrequency lesions provide similar success to open surgery and lowered morbidity for the treatment of cancer pain.

NERVE ENTRAPMENT RELEASE

Basic Considerations

Pathophysiology of Nerve Entrapment Pain

Nerve entrapment syndromes result from pressure applied directly to a nerve, causing pain, paresthesias, or weakness in the sensory distribution of the nerve.[38,54,55] Entrapment commonly develops where peripheral nerves traverse confined anatomic spaces, rest in superficial locations or in proximity to joints, or become tethered to adjacent tissues. Structural factors such as anomalous nerves, cervical ribs, muscles, or connective tissue bands also may contribute. Repetitive motion, nerve traction due to joint position, chronic vibration, and high force constitute physical stressors that increase the risk of symptomatic entrapment.

While the degree of compression required to cause nerve injury may vary, axonal degeneration follows pressure in a dose-dependent relationship.[56] Symptoms can arise following a few significant events or after a longer period of repetitive mild insults. The time course and force of injury are just two of the prognostic considerations. The length of the affected nerve region, as well as the presence and severity of nerve ischemia are important factors in the development of symptomatic nerve entrapment. Finally, nerves become more vulnerable to injury in the presence of concurrent systemic metabolic disease, and nerves lose their regenerative capacity with age.

Several pathophysiologic mechanisms have been proposed to explain pain associated with peripheral nerve entrapment at the cellular level. Evidence for these mechanisms arises from studies of animal models.[56–58] Following local nerve compression, internodes along myelinated fibers distort in shape. Demyelination appears earliest in the segment nearest to the point of compression.[59,60] Eventually, segmental demyelination leads to diffuse demyelination and, ultimately, axonal degradation. Compressive injury usually affects larger, more peripherally located myelinated nerves as opposed to smaller or unmyelinated fibers.

Nerve ischemia may also play an important role in nerve entrapment pain syndromes. Focal pressures of 20 to 30 mm Hg may impede venous blood flow, while higher pressures may reduce arterial supply.[61,62] Within 4 hours of extraneural compression, increasing permeability of the blood-nerve barrier leads to development of subperineurial edema.[63–66] As there is no lymphatic drainage of the endoneurial space, sustained intraneural pressure elevations persist for at least 24 hours after compressive forces are removed. Following such injury, reactive inflammation, fibrin deposition, and proliferation of endoneurial fibroblasts and capillary endothelial cells lead to intraneural fibrosis of perineurial and epineurial tissues.

Ischemia does not appear to play a role in the initial demyelination associated with acute compressive injury.[67,68] Rather, nodes of Ranvier adjacent to the point of compression are outwardly displaced and disrupt the myelin sheath. Segmental demyelination follows, stemming from these sites of myelin invagination.[69,70] Disruption of anterograde axoplasmic flow of vital nutrient proteins reduces terminal membrane excitability. Long-standing ischemia thereby results in replacement of funicular contents with fibrotic tissue, producing derangements in electrical conductivity.[71]

Nerve Entrapment and Systemic Disease

Several endocrine and rheumatologic diseases show an association with increased risk for nerve entrapment. Approximately 15% of upper extremity nerve entrapment patients have diabetes. This may result from an increased association of peripheral neuropathies with entrapment. Both hypo- and hyperthyroidism have been shown to pose an increased risk for nerve entrapment, which is thought to result from glycogen deposition in Schwann cells.[72] Up to 30% of acromegalics are diagnosed with nerve entrapment syndromes, which often resolve with treatment of the underlying acromegaly.[73,74] Obesity and pregnancy have well-documented associations with entrapment syndromes, with as many as two thirds of pregnant women experiencing temporary symptoms.[75] Rheumatoid arthritis is also thought to contribute to entrapment in anatomic locations where synovial overgrowth can produce compression of a nerve. There is an estimated 45% incidence of entrapment neuropathy in rheumatoid arthritis patients.[76,77] Amyloidosis, carcinomatosis, gout, mucopolysaccharide storage diseases, and polymyalgia rheumatica are all suspected to pose an increased risk for exacerbation of nerve entrapment.

Clinical Considerations

Preoperative Evaluation

Clinical Findings. Patients suffering from nerve entrapment syndromes present with pain, paresthesias, or motor weakness along a specific nerve distribution. Nocturnal pain, either sharp or burning, classically develops before the onset of daytime or persistent symptoms. Muscular changes, such as atrophy or fasciculation, as well as sensory alterations, such as altered two-point discrimination or temperature sensation, can occur in advanced cases. Specific symptoms result from the location and severity of compression.

On physical examination, Tinel's sign may be present. Tinel's sign is an electric radiating sensation in the distribution of the nerve, produced by percussion over the nerve. Tinel's sign represents ectopic excitability, a hallmark of nerve entrapment, and may be accompanied by local tenderness. Provocative maneuvers may reproduce or exacerbate symptoms and have significantly positive predictive value in the diagnosis of entrapment syndromes.

In many cases, diagnosis of a specific entrapment syndrome may be difficult to make. Compensation of one muscle group by another may create uncertainty in identifying etiology of the entrapment. Furthermore, entrapment syndromes may be accompanied by concurrent radiculopathy, producing synergistic pain, thereby adding to the diagnostic challenge.[78] In addition, pain associated with entrapment syndromes may not be well-localized. For example, radial nerve entrapment may present with global arm pain. Finally, results of electrodiagnostic studies may be normal in some cases, further increasing the diagnostic dilemma.

Electrodiagnostic Studies. Physical findings may be supported by electrodiagnostic studies. Nerve conduction studies (NCS) measure action potentials along axons while electromyography studies (EMG) measure muscle fiber activity. In sensory NCS, a stimulus is applied to the nerve and a sensory nerve action potential

(SNAP) is measured at various distal points along the nerve. Alterations in axon number, diameter, myelination, or temperature all affect the magnitude and temporal profile of the SNAP. In motor NCS, a stimulus is applied to the nerve and a compound motor action potential (CMAP) is measured from the innervated muscle. Changes in conduction velocity, amplitude of CMAP, and distal motor latency suggest that conduction inhibition exists between the point of initial stimulation and the site of recording. Needle EMG examines the spontaneous electrical activity of individual muscle fibers resulting from denervation, reinnervation, or acute muscle injury.

These studies aid in the differentiation of peripheral nerve entrapments from brachial plexopathy and radiculopathy by defining the nature and extent of neurologic dysfunction. For example, although NCS cannot be performed in structures like the brachial plexus due to an inability to record and stimulate across the region of compression, a plexus lesion would be expected to affect the function of multiple peripheral nerves. In entrapment neuropathy, large myelinated sensory fibers are typically affected before motor fibers. Hence, NCS are most often effective earlier in the disease than motor conduction studies (ulnar compression at the elbow is a notable exception to this rule). Entrapment is represented by abnormal recordings of evoked SNAPs along a short nerve segment. Prolonged latency or reduced motor conduction velocity are also indicative of injury, although they are less sensitive measures. Fibrillation seen on EMG occurs as a result of wallerian degeneration of distal nerve segments and suggests advanced entrapment. In general, a combination of studies and measurement points yields the best information with which to form a diagnosis.

Comparison among the nerves of interest and a nearby unaffected nerve is often more accurate than comparison of a nerve with normal reference values. Cooler temperature, increasing age, and patient size all serve to prolong sensory latencies, confounding reference values. As a result, and to avoid such confounding factors, it is common to perform sensory latency comparisons at as many as three sites (median-ulnar midpalmar, median-ulnar ring finger, and median-radial thumb) in the diagnosis of carpal tunnel syndrome (CTS).[79] While the greater number of studies increases the likelihood of false-positive results,[80] summation of the latencies of these three studies has proven to be the most sensitive and specific test for CTS.[81]

Following entrapment release, it is notable that clinical improvement may not correlate reliably with electrodiagnostic studies. However, in patients with persistent symptoms following treatment, comparison with pretreatment studies may be helpful. If earlier studies are unavailable, a series of postoperative studies over several months should be obtained.

Imaging Studies. Developments in ultrasonography and magnetic resonance imaging (MRI) have resulted in a potentially expanded role for imaging in the diagnosis of entrapment neuropathies. Ultrasonography now offers the highest available resolution for visualizing the location of entrapment (Fig. 102.1). However, ultrasound is unable to show pathologic changes within nerves. In contrast, signal and configuration characteristics seen in chronically compressed or tethered peripheral nerves have been well-characterized by MRI (Fig. 102.2). On MRI, indicators for nerve abnormality include focal enlargement, T2 hyperintensity, and an indistinguishable or nonuniform fascicular pattern. In addition, MRI simultaneously visualizes muscular alterations due to atrophy and neurogenic edema.

Specific MRI findings have been correlated with clinical findings, electrodiagnostic findings, and postoperative outcomes for several nerve entrapment syndromes.[82–85] With current technology, MRI may be a useful adjunct in the diagnosis of entrapment. Specific indications for MRI may include ulnar entrapment, entrapment in the presence of superimposed neuropathy, entrapment where other tests are equivocal, and postoperative evaluation of entrapment.[86] The value of MRI imaging in the setting of uncommon entrapments is less clear.

Operative Technique

Substantial experimental evidence supports three treatments of peripheral nerve entrapment: splinting, local corticosteroid injection, and surgical release. Splinting reduces the offending stimulus through postural correction and reduction of repetitive injury, thereby decreasing reactive inflammation. Local corticosteroid injections have been shown to be helpful in mild cases. Surgical release of anatomic compression is the mainstay of treatment in more advanced cases of peripheral nerve entrapment.[87]

In general, operative release of entrapment can be quite rewarding, as the risks of surgery are typically low and pain improvement is often dramatic. Avoidance of additional trauma to the compressed nerve is of great importance to surgical outcome. Occasionally, unexpected sources of entrapment may be found during surgical exposure, such as cysts, soft tissue masses, and bony prominences. Choices of surgical approach and operative technique are based largely upon individual surgeon preferences.[88] Rates of success and complications vary with the location of entrapment and the etiology of pain.

Specific Indications

Entrapments of the Median Nerve

Carpal Tunnel Syndrome. CTS results from compression of the median nerve between bones of the wrist and the flexor retinaculum. CTS is the most common nerve compression syndrome, with an annual incidence of 150 per 100,000 population and a 2:1 female predominance.[89,90] Patients with CTS present with pain along the radial half of the hand, particularly at night, and weakness of median innervated muscles. Phalen's sign—recreation of pain through complete wrist flexion for 30 to 60 seconds—is a sensitive and specific marker of mild to moderate CTS.[91,92] Electrodiagnostic studies typically demonstrate decreased median-nerve conduction velocity at the wrist. Imaging findings on MRI, when performed, may demonstrate increased signal intensity in the nerve, volar bowing of the flexor retinaculum, and flattening of the median nerve at the level of the hamate.[93]

Initial therapy includes splinting, activity modification, and nonsteroidal anti-inflammatory medications for mild disease. Corticosteroid injections offer nearly a 70% positive response initially, although eventual recurrence of symptoms is high.[94]

Surgical decompression of the carpal tunnel is indicated in cases that have failed conservative management or in cases with severe or rapid onset of symptoms. Some 80% of patients achieve excellent pain relief with surgery, while another 10% achieve partial relief; less than 1% of patients experience worsening of their pain symptoms. For patients with motor weakness, similar results have been reported with 84% of patients returning to baseline function and another 9% experiencing some improvement.[92,95–97] Early surgery in patients with ongoing pain has been associated with improved resolution of symptoms.

Incomplete decompression of the nerve is seen in the majority of cases in which pain relief is incomplete, absent, or transient. Another cause of recurrent pain includes postoperative fibrosis. Failure to appreciate the path of the recurrent motor (thenar) branch of the nerve can result in postoperative weakness following release. Injury to the palmar cutaneous branch can result in postoperative pain in the wrist and proximal thenar eminence.[98,99]

Anterior Interosseus Syndrome. Anterior interosseus syndrome results from isolated injury or entrapment of this largely motor branch of the median nerve.[100] The nerve arises distal to the

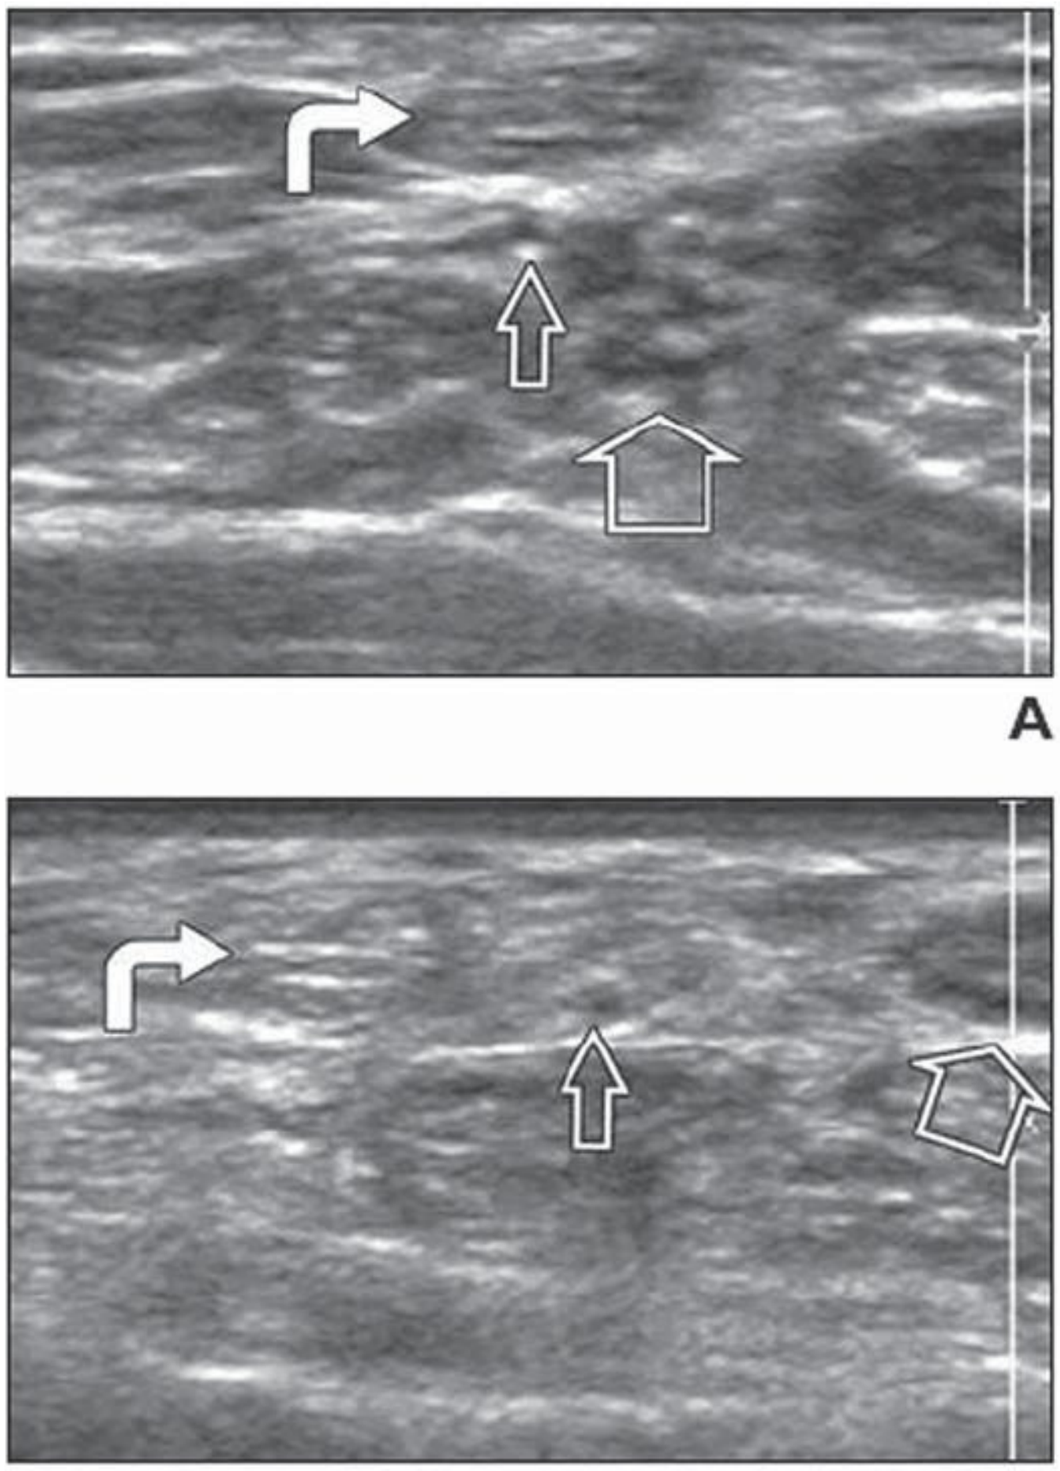

FIGURE 102.1 Series of transverse 17-5–MHz sonography images obtained from proximal to distal over palmar cutaneous branch of median nerve (MN) in 35-year-old healthy man with corresponding diagrams. Relationships of palmar cutaneous branch of MN (thin open arrows) with MN (*thick open arrows*), flexor carpi radialis tendon (*curved arrow* in **A**,**C**,**E**,**G**; *fcr* in **B**,**D**,**F**,**H**), and antebrachial fascia (*arrowheads*, **E–H**) are shown. **A,B.** Palmar cutaneous branch of MN detaches from MN as one of its most radial fascicles. **C,D.** Palmar cutaneous branch of MN gradually deflects to approach flexor carpi radialis tendon. **E,F.** Palmar cutaneous branch of MN runs slightly deep in relation to antebrachial fascia. (*continued*)

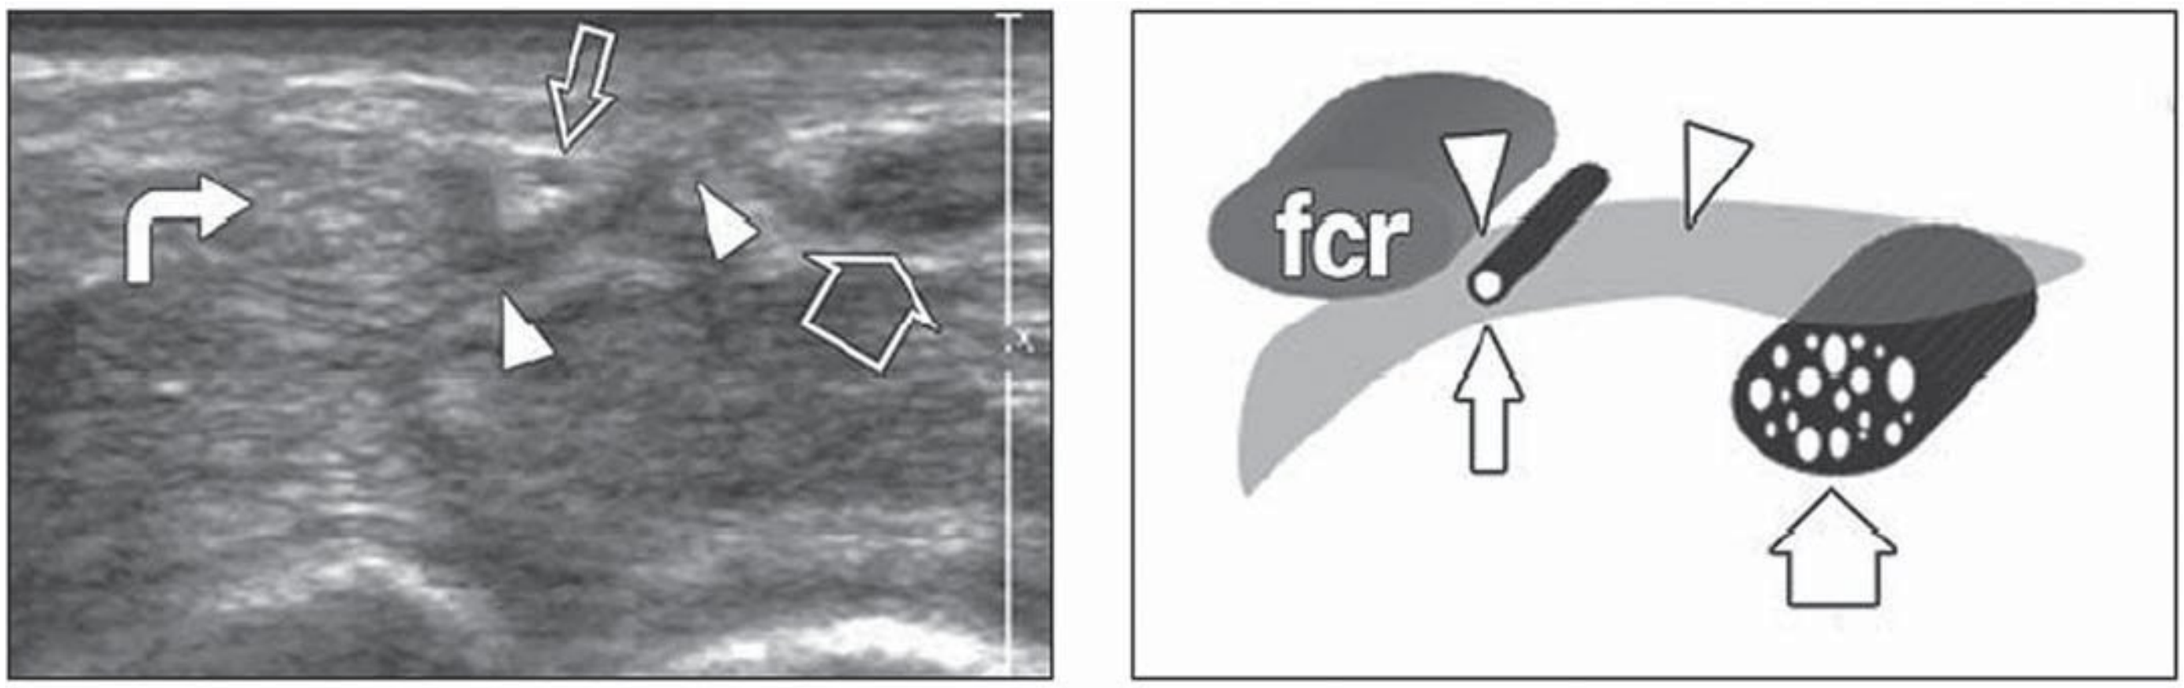

FIGURE 102.1 (*Continues*) **G,H.** Palmar cutaneous branch of MN lies adjacent to flexor carpi radialis tendon after piercing fascia. (Reproduced with permission from Tagliafico A, Pugliese F, Bianchi S, et al. High-resolution sonography of the palmar cutaneous branch of the median nerve. *Am J Roentgen* 2008;191:107–114.)

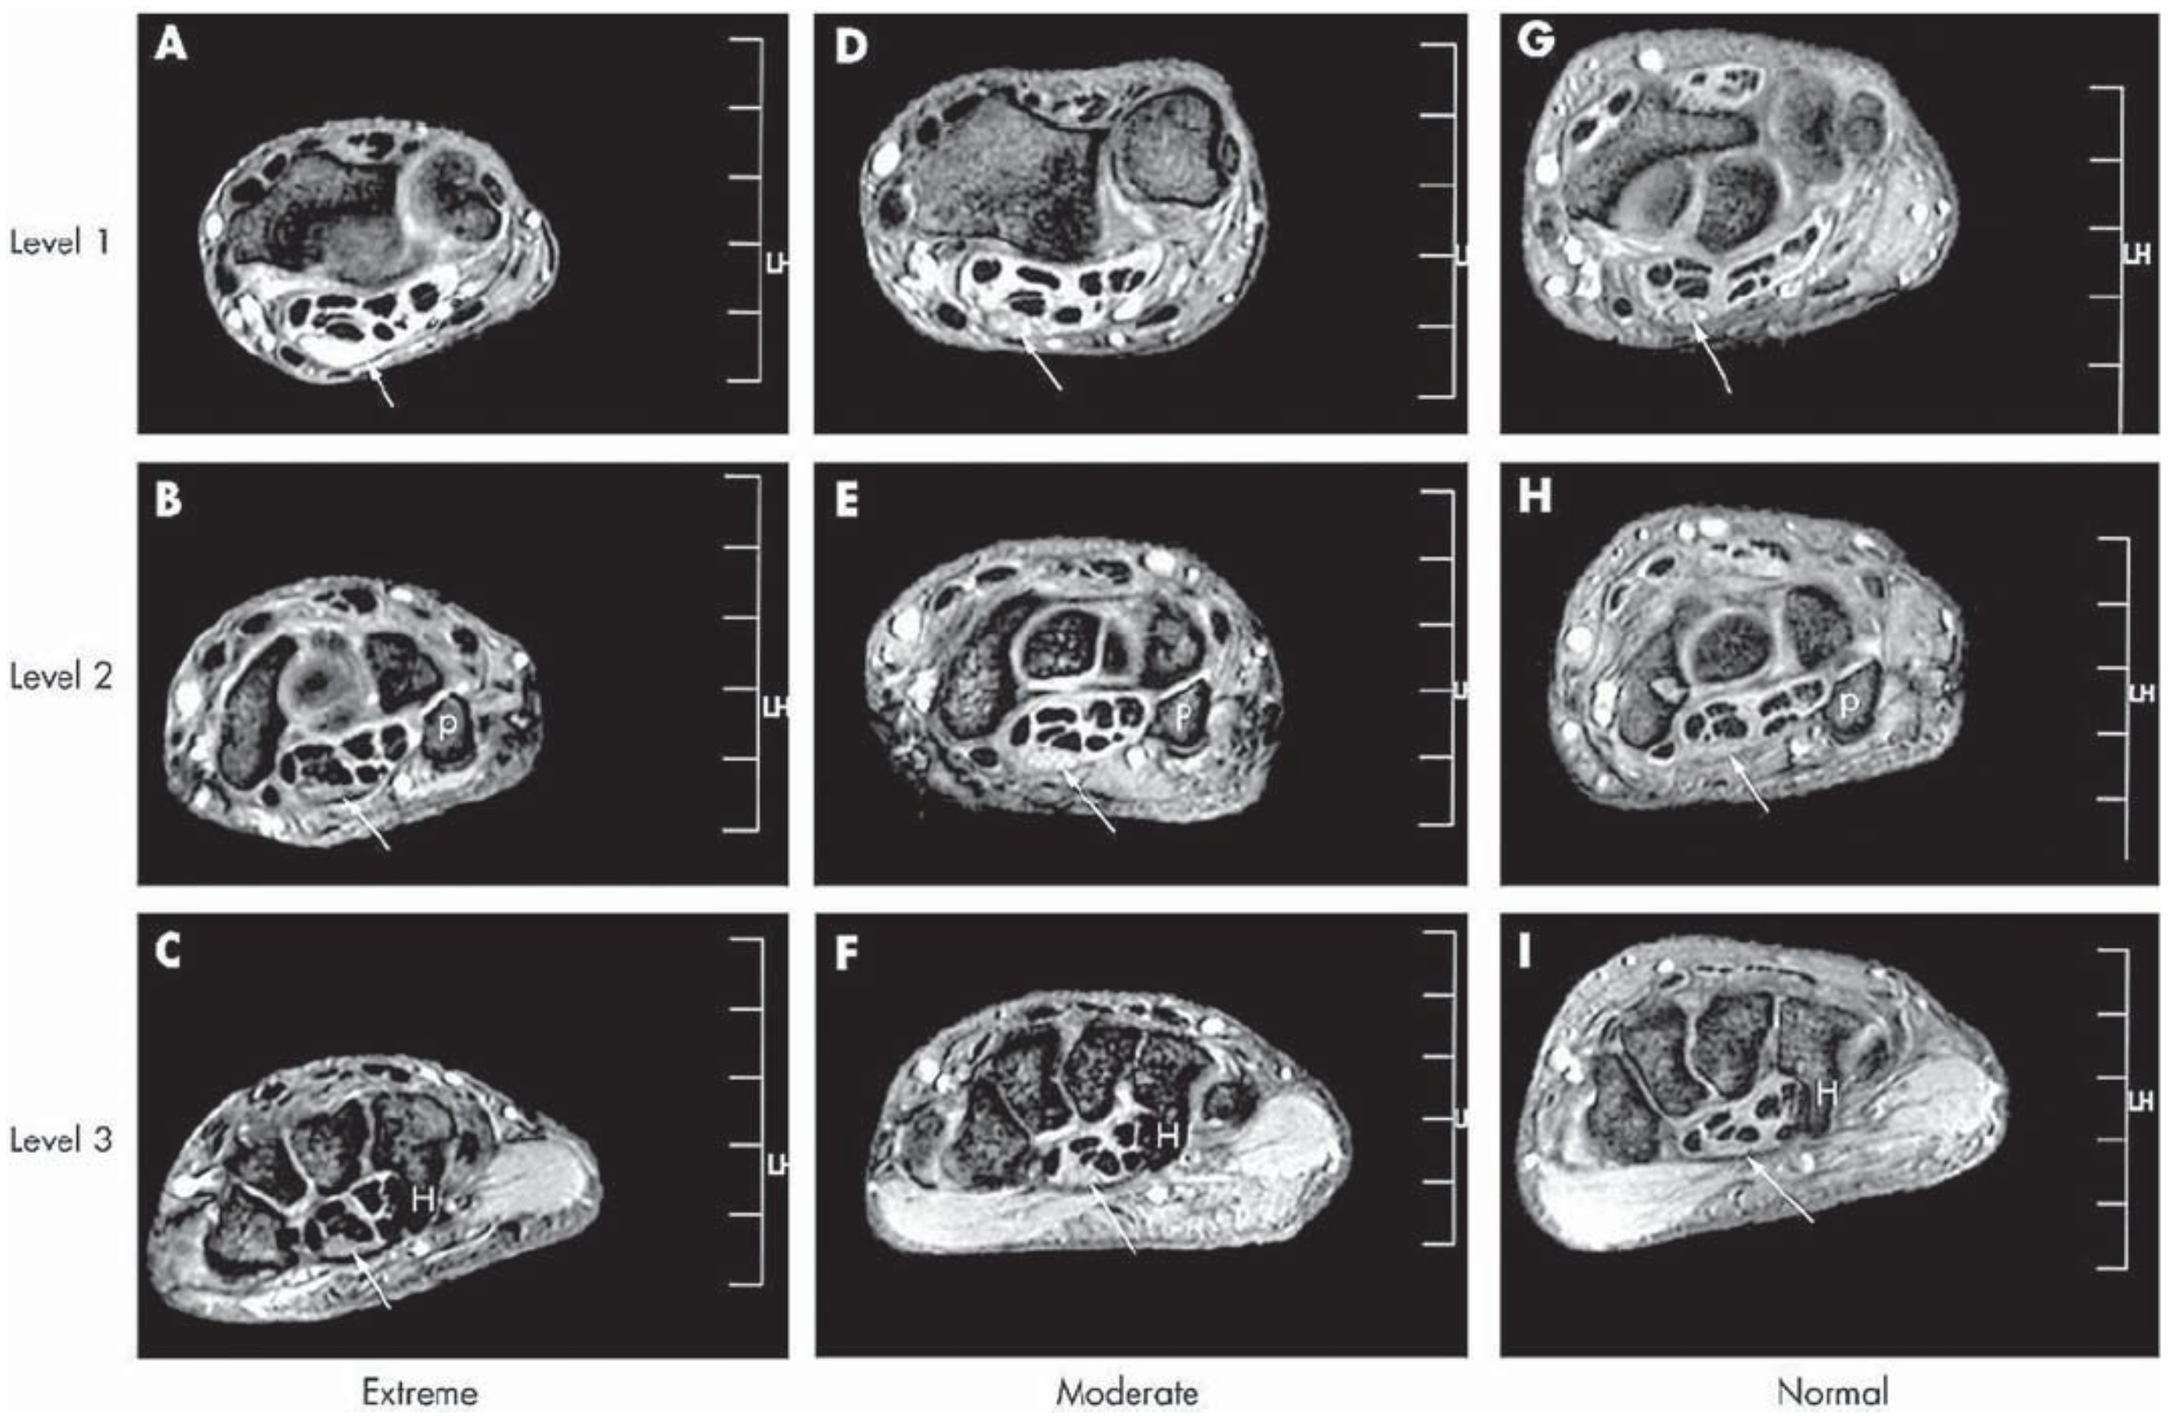

FIGURE 102.2 T2-weighted gradient echo images at the distal part of the distal radioulnar joint level (DRUJ) (1), at the level of the pisiform (2), and at the level of the hook of the hamate (3) in three different stages of idiopathic carpal tunnel syndrome. Solid arrow indicates the cross section of the median nerve. Upper part represents the dorsal side, and the righthand side represents the ulnar side. H, hook of the hamate; P, pisiform bone. **A–C.** Extreme stage. Enlargement and high signal intensity of the flattened median nerve are seen at level 1, and enlargement of the median nerve at levels 2 and 3. Palmar bowing of the TCL is evident. **D–F.** Moderate stage. Enlargement and high signal intensity of the median nerve are seen at level 2. They are slightly appreciated at level 3, and still not seen at level 1. Palmar bowing of the TCL is well appreciated. **G–I.** Normal wrist. Enlargement of the median nerve is not seen at any level. Isointensity of the nerve to the hypothenar muscle is seen throughout the cross sections. Palmar bowing of the TCL is not seen. (Reproduced with permission from Uchiyama S, Itsubo T, Yasutomi T, et al. Quantitative MRI of the wrist and nerve conduction studies in patients with idiopathic carpal tunnel syndrome. *J Neurol Neurosurg Psych* 2005;76:1103–1108.)

medial epicondyle, and is vulnerable to injury in supracondylar and forearm fractures.[101–103] In severe cases, there may be weakness of flexor pollicis longus, flexor digitorum profundus to the index finger, and pronator quadratus.

Patients with anterior interosseus syndrome may present with a characteristic pinch as compensation for weakness in the long flexors of the index finger and thumb. The condition may also present with pain in the forearm associated with tenderness in the proximal volar forearm. EMG may confirm changes associated with muscular denervation. Surgical exploration with neuroplasty is most commonly performed for patients whose pain does not respond to anti-inflammatory medications or avoidance of repetitive pronation/supination activity.[104–108]

Entrapment by the Ligament of Struthers. Struthers' ligament can cause compression of the median nerve, brachial artery, or brachial vein as they pass beneath it, proximal to the medial epicondyle. A variant bony spicule (supracondylar process) arising from the humerus at this level can place the nerve at risk for entrapment.[109] A rare disorder, this pathology can potentially be mistaken for CTS.[110] Motor weakness of the pronator teres, flexor carpi radialis, and flexor digitorum profundus (to the first two digits), while not always present, indicate a point of compression proximal to the carpal tunnel. Release of the ligament and excision of the supracondylar process typically provides pain relief.

Pronator Syndrome. Pronator syndrome presents as a vague, aching pain in the volar aspect of the elbow and forearm that is exacerbated by activities involving grasping or pronation of the forearm.[111] On physical examination, tenderness can usually be elicited by deep palpation over the pronator teres. Compression occurs at the lacertus fibrosus, within the muscle between the two heads of pronator teres, or beneath the flexor superficialis tendon at its origin. Avoiding maneuvers that exacerbate the pain and intra-muscular injection of corticosteroids may be attempted prior to surgical release.

Entrapments of the Ulnar Nerve

Ulnar Nerve Entrapment at the Elbow. Ulnar nerve entrapment at the elbow (UNEE) is the second most common peripheral nerve entrapment syndrome after CTS. At the elbow, the ulnar nerve is bounded medially and anteriorly by the medial epicondyle and laterally by the olecranon. A dense fascial layer overlies this space, forming the cubital tunnel. Entrapment may occur at the cubital tunnel, in the epicondylar groove, beneath the arcade of Struthers, or at the medial intermuscular septum.[112] Antecedent trauma, inflammatory change, and mass lesions increase the risk of UNEE. Subluxation of a hypermobile ulnar nerve over the medial epicondyle may lead to traumatic injury. An anomalous and potentially compressive anconeus epitrochlearis muscle may be found in up to 30% of patients.[113–115]

UNEE typically presents insidiously with paresthesias in the ulnar distribution of the forearm, wrist, and hand. Muscle weakness leads to impaired grip and clumsiness in the hand, and in more severe cases, atrophy of intrinsic hand muscles. Tinel's sign and the elbow flexion-pressure test, which is done with manual compression of the ulnar nerve just proximal to the cubital tunnel for 30 seconds, offer significant sensitivity and specificity for UNEE.[116,117] Electrodiagnostic studies may demonstrate reduced sensory and motor conduction velocity across the elbow.

The optimal surgical technique for entrapment release in UNEE has not been established. Options include transposition of the nerve and in situ decompression. For transposition, the ulnar nerve is displaced anterolaterally in order to shorten its course around the medial epicondyle. Transposition may be subcutaneous, intramuscular, or submuscular, with respect to the flexor-pronator muscle mass.[118–126] Among the larger case series, successful surgical results of 90% have been reported, regardless of technique.[127–131] Many surgeons favor in situ decompression as an initial surgical treatment, particularly when patients have milder symptoms and isolated compression at only one site.[132–136]

Traumatic etiology, chronic symptoms, absence of sensory potentials, and severe muscular weakness are among the indicators of poor prognosis for surgical outcome. Pain symptoms more often resolve, while motor symptoms may only partially improve, after surgery. Persistent pain following ulnar nerve decompression at the elbow may be due to injury of the medial antebrachial cutaneous nerve.
