Cancer patients may have constant or intermittent pain. Constant pain is present continuously and usually fluctuates in intensity. Intermittent pain implies that pain is present for definite periods of time and that the patient is relatively pain-free between episodes of pain. Patients and their caregivers need to understand the concept of "breakthrough pain," as should health care providers. Breakthrough pain is discussed earlier in this chapter.

Exacerbating/Relieving Factors

Cancer patients with pain may experience a worsening of their pain over a wide range of activities. Commonly, patients with metastatic disease to weight-bearing bones experience an increase of their pain upon standing or sitting. Patients with breast cancer metastatic to the axillary nodes may have severe pain upon abduction of their upper extremity on positioning for external beam radiation therapy. Knowledge of these factors helps clinicians to design an appropriate pain treatment plan.

Responses to Previous Analgesic and Disease-Modifying Therapies

It is important to determine previous opioid use and benefits or side effects encountered during use. Previous unacceptable side effects to a particular opioid may limit successful future titration with the same opioid. Successful tumor shrinkage to chemotherapy or radiation therapy may indicate the need for further evaluation on tumor recurrence.

Impact of Pain

The initial pain assessment should elicit information about changes in activities of daily living, such as work and recreational activities, sleep patterns, mobility, appetite, sexual functioning, and mood. Numerous instruments, including symptom checklists and quality of life measures, may prove useful in this evaluation and are detailed in Chapter 22.

The **Memorial Pain Assessment Card** is a brief, validated measure that uses visual analog scale scores to characterize pain intensity, pain relief, and mood, and an 8-point verbal rating scale to further characterize pain intensity. The mood scale, which is correlated with measures of global psychologic distress, depression, and anxiety, is considered to be a brief measure of global symptom distress. Although this instrument does not provide detailed descriptors of pain, its brevity and simplicity may facilitate the collection of useful information while minimizing patient burden and encouraging compliance.

The **Brief Pain Inventory** measures both the intensity of pain (sensory dimension) and interference of pain in the patient's life (reactive dimension). It also queries the patient about pain relief, pain quality, and patient perception of the cause of pain. Numeric scales indicate the intensity of pain in general, at its worst, at its least, and right now. An average scale quantifies relief from current therapies. The patient marks a figure representing the body by shading the area corresponding to his or her pain. Seven items determine the degree to which pain interferes with function, mood, and enjoyment of life. Advantages of this questionnaire include that it is self-administered, easy to understand, and available in many languages.

Effects of the Pain on Activities of Daily Living

Many patients function quite effectively with a background level of mild pain that does not seriously impair or distract them.[57] As pain severity increases, the pain passes a threshold beyond which it is hard to ignore. At this point, it becomes disruptive to many aspects of the patient's life. Constant daily pain can significantly impact on a patient's daily activities. Williamson and Schulz[177] showed that as pain increased over time, restriction in activity occurred, which in turn predicted increases in depressed affect. General measures of functioning should include indicators of physical, psychological, and social functional status. Some impact factors may include interference on general activity, mood, walking, ability to work, relations with others, and sleep. The Pain Disability Index was developed as a self-report measure of general and domain-specific, pain-related disability and is considered to be reliable and valid as a brief measure of pain-related disability (Table 42.14).[178]

Maltoni et al.[179] confirmed the importance of certain clinical parameters as prognostic indicators for patients with terminal cancer (clinical experience, physical activity level, clinical symptoms relating to and unrelated to nutritional state). Performance Status Tables can help the physician assess physical activity levels (Tables 42.15 and 42.16). However, the palliative treatment of advanced cancer and the terminally ill requires a broad concept of well-being that goes beyond one based only on physical functioning.[180]

Psychological State

Psychological assessment of the cancer patient with pain is imperative and should reflect an understanding of the many factors that modulate distress, such as personality, coping, and both past and present psychiatric disorders. Knowing that the patient has received outpatient or inpatient psychiatric care helps to clarify the psychological risk. Information on how the patient handled previous painful events may provide insight into whether the patient has demonstrated chronic illness behavior.

Familial and Professional Function

The clinician must learn about the patient's familial and social resources, financial situation, and the physical environment in which he or she lives. Knowledge of the patient's and family's previous experience with cancer or other progressive medical disease may provide useful insights into the response to physical illness or the genesis of psychological symptoms. Although the influence of social factors on treatment preferences and desire for aggressive cancer therapy is still poorly defined, Yellen and Cella[181] demonstrated that positive social well-being, as well as having children living at home, predicted patient willingness to accept aggressive treatment.

Quality of Life Assessment

Prolongation of survival and maintenance or improvement of health-related quality of life (QOL) are the two important goals within the treatment of individual patients. Due to the severity of symptoms and the toxicity of treatment, QOL is a major area of concern when treating cancer patients in general and elderly patients in particular. QOL is defined as the person's evaluation of his or her well-being and functioning in different life domains.

TABLE 42.14

PAIN DISABILITY INDEX

The rating scales below are to measure the degree to which several aspects of your life are presently disrupted due to chronic pain. In other words, we would like to know how much your pain is preventing you from doing what you would normally do, or from doing it as well as you normally would. Respond to each category by indicating the overall impact of pain in your life, not just when the pain is at its worst. For each of the 7 categories of life activity listed, please circle the number on the scale which describes the level of disability you typically experience. A score of 0 means no disability at all, and a score of 10 signifies that all of the activities in which you would normally be involved have been totally disrupted or prevented by your pain.

(1) *Family/Home Responsibilities*
This category refers to activities related to the home or family. It includes chores or duties performed around the house (e.g., yard work) and errands or favors for other family members (e.g., driving the children to school).

0 1 2 3 4 5 6 7 8 9 10

no disability — total disability

(2) *Recreation*
This category includes hobbies, sports, and other similar leisure time activities.

0 1 2 3 4 5 6 7 8 9 10

no disability — total disability

(3) *Social Activity*
This category refers to activities which involve participation with friends and acquaintances other than family members. It includes parties, theater, concerts, dining out, and other social functions.

0 1 2 3 4 5 6 7 8 9 10

no disability — total disability

(4) Occupation
This category refers to activities that are a part of or directly related to one's job. This includes nonpaying jobs as well, such as that of a housewife or volunteer worker.

0 1 2 3 4 5 6 7 8 9 10

no disability — total disability

(5) *Sexual Behavior*
This category refers to the frequency and quality of one's sex life.

0 1 2 3 4 5 6 7 8 9 10

no disability — total disability

(6) *Self-care*
This category includes activities which involve personal maintenance and independent daily living (e.g., taking a shower, driving, getting dressed, etc.).

0 1 2 3 4 5 6 7 8 9 10

no disability — total disability

(7) *Life-support Activity*
This category refers to basic life-supporting behaviors such as eating, sleeping, and breathing.

0 1 2 3 4 5 6 7 8 9 10

no disability — total disability

TABLE 42.15

KARNOFSKY PERFORMANCE STATUS

Grade	Performance level
100	Normal, no complaints, no evidence of disease
90	Able to carry on normal activity; minor signs or symptoms of disease
80	Normal activity with effort; some signs or symptoms of disease
70	Cares for self; unable to carry on normal activity or to do active work
60	Requires occasional assistance, but is able to care for most of his or her needs
50	Requires considerable assistance and frequent medical care
40	Disabled, requires special care and assistance
30	Severely disabled, hospitalization indicated; death not imminent
20	Very sick, hospitalization necessary, active supportive treatment necessary
10	Moribund, fatal processes, progressing rapidly
0	Dead

TABLE 42.16

ECOG PERFORMANCE STATUS

Grade	Performance level
0	Fully active, able to carry on all predisease performance without restriction
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature (e.g., light housework, office work)
2	Ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
4	Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair
5	Dead

It is a subjective, phenomenological, multidimensional, dynamic, evaluative, and yet quantifiable, construct. The routine assessment of QOL may have clinical uses at the individual patient level. These uses include fostering patient-provider communication, identifying frequently overlooked problems, prioritizing problems, and evaluating the impact of palliative and rehabilitative efforts. QOL is sensitive to the treatment of pain and treatment modalities, although pain is not synonymous with poor QOL and constitutes only one important factor determining QOL. In addition, pain reduction is not always attended by the expected improvement in QOL. Two of the most widely used assessment tools in oncology are the European Organization for Research and Treatment of Cancer, Quality of Life Questionnaire Core 30 Items scale, and the Functional Assessment of Cancer Therapy—General (FACT-G).[182] FACT-G is self-reported and consists of questions on physical, functional, emotional, and social/family well-being. Patient responses are recorded on a five-point Likert-type scale (Table 42.17).

TABLE 42.17

FUNCTIONAL ASSESSMENT CANCER THERAPY—GENERAL (FACT-G)

Below is a list of statements that other people with your illness have said are important. By circling one (1) number per line, please indicate how true each statement has been for you during the past 7 days.

PHYSICAL WELL-BEING _____	Not at all	A little bit	Somewhat	Quite a bit	Very Much
I have a lack of energy	**0**	**1**	**2**	**3**	**4**
I have nausea	**0**	**1**	**2**	**3**	**4**
Because of my physical condition, I have trouble meeting the needs of my family	**0**	**1**	**2**	**3**	**4**
I have pain	**0**	**1**	**2**	**3**	**4**
I am bothered by side effects of treatment	**0**	**1**	**2**	**3**	**4**
I feel ill	**0**	**1**	**2**	**3**	**4**
I am forced to spend time in bed	**0**	**1**	**2**	**3**	**4**
				SCORE =	**(MAX = 28)**
SOCIAL/FAMILY WELL-BEING _____	Not at all	A little bit	Somewhat	Quite a bit	Very Much
I feel close to my friends	**0**	**1**	**2**	**3**	**4**
I get emotional support from my family	**0**	**1**	**2**	**3**	**4**
I get emotional support from my friends	**0**	**1**	**2**	**3**	**4**
My family has accepted my illness	**0**	**1**	**2**	**3**	**4**
I am satisfied with family communication about my illness	**0**	**1**	**2**	**3**	**4**
I feel close to my partner (or the person who is my main support)	**0**	**1**	**2**	**3**	**4**
Regardless of your current level of sexual activity, please answer the following question. If you prefer not to, please check this box ☐ and go to the next section.					
I am satisfied with my sex life	**0**	**1**	**2**	**3**	**4**
				SCORE =	**(MAX = 28)**
EMOTIONAL WELL-BEING _____	Not at all	A little bit	Somewhat	Quite a bit	Very Much
I feel sad	**0**	**1**	**2**	**3**	**4**
I am satisfied with how I am coping with my illness	**0**	**1**	**2**	**3**	**4**
I am losing hope in the fight against my illness	**0**	**1**	**2**	**3**	**4**
I feel nervous	**0**	**1**	**2**	**3**	**4**
I worry about dying	**0**	**1**	**2**	**3**	**4**
I worry that my condition will get worse	**0**	**1**	**2**	**3**	**4**
				SCORE =	**(MAX = 24)**
FUNCTIONAL WELL-BEING _____	Not at all	A little bit	Somewhat	Quite a bit	Very Much
I am able to work (include work at home)	**0**	**1**	**2**	**3**	**4**
My work (include work at home) is fulfilling	**0**	**1**	**2**	**3**	**4**
I am able to enjoy life	**0**	**1**	**2**	**3**	**4**
I have accepted my illness	**0**	**1**	**2**	**3**	**4**
I am sleeping well	**0**	**1**	**2**	**3**	**4**
I am enjoying the things I usually do for fun	**0**	**1**	**2**	**3**	**4**
I am content with the quality of my life right now	**0**	**1**	**2**	**3**	**4**
				SCORE =	**(MAX = 28)**
RELATIONSHIP WITH DOCTOR _____	Not at all	A little bit	Somewhat	Quite a bit	Very Much
I have confidence in my doctor(s)	**0**	**1**	**2**	**3**	**4**
My doctor is available to answer my questions	**0**	**1**	**2**	**3**	**4**
How much does your relationship with your doctor affect the quality of your life?	**0**	**1**	**2**	**3**	**4**
				SCORE =	**(MAX = 12)**

TABLE 42.18

COMPONENTS OF MEDICAL HISTORY: CANCER HISTORY, MEDICATIONS, PAST MEDICAL HISTORY, AND PSYCHOSOCIAL FACTORS

Cancer history	Current medications and past medical history	Psychosocial issues
Diagnosis	Previous medical and surgical illness	Family history
Chronology	Concurrent medical conditions	Social resources
Therapeutic interventions including operations and treatments	Drug reactions	Impact of disease and symptoms on patient and family
Patient's knowledge of extent of disease		Patient's and family's goals of care
Current clinical status		

General Assessment

The initial step in the general assessment of the symptomatic cancer patient is a complete medical history that reviews the cancer diagnosis, the chronology of significant cancer-related events, previous therapies, and all relevant medical, surgical, and psychiatric problems (Table 42.18). A detailed history of drug therapy should include current and prior use of prescription and nonprescription drugs, drug allergies, and previous adverse drug reactions including side effects. The patient should provide information about prior treatment modalities for each symptom. In the course of this assessment, the interviewer should document the patient's understanding of his or her current disease status. Discussion with other providers involved with the patient's care will also help determine disease status. Table 42.19 lists the different possible categories for a patient's clinical status.

A physical examination, including a neurologic evaluation, is a necessary part of the initial pain assessment (see below). A careful review of previous laboratory and imaging studies can provide information about the cause of pain and the extent of the underlying disease (see below). Evaluation of concurrent concerns includes other symptoms and related psychosocial problems. Additional investigations are often needed to clarify uncertainties in the provisional assessment. The extent of these investigations must be appropriate to the patient's general status and the overall goals of care (Table 42.20).

TABLE 42.19

CLINICAL STATUS OF PATIENTS DEFINED BY DISEASE STATE AND TREATMENT STRATEGY

Category	Status
I	Active disease; care—palliative and supportive only
II	Active disease; treatment (e.g., chemotherapy, radiation therapy) in progress
III	Active disease, no current treatment, surveillance of tumor status
IV	No active disease; treatment of tumor in progress
V	No active disease; no current treatment, surveillance of tumor status
VI	No active disease; no current treatment, specialized care (e.g., medical oncology) not required

Associated Symptoms

Symptoms interact and therefore it is important to clarify the degree to which each symptom induces or exacerbates other physical or psychological symptoms. The evaluation should determine whether symptoms are concurrent but unrelated in etiology, concurrent and related to the same pathologic process, concurrent with the one symptom directly or indirectly a consequence of a pathologic process initiated by another symptom, or concurrent with one symptom a consequence or side effect of therapy directed against the other. Fatigue may be the most prevalent symptom reported by cancer patients.[183] Disease progression increases the number of factors diminishing QOL, as well as the prevalence and severity of physical and psychological symptoms. In addition to pain, patients with advanced cancer have fatigue, generalized weakness, dyspnea, delirium, nausea, and vomiting. These symptoms may have a major impact on both pain reporting and quality of life.

The **Memorial Symptom Assessment Scale** (MSAS) is a patient-rated instrument that was developed to provide multidimensional information about a diverse group of common symptoms. The MSAS is a reliable and valid instrument for the assessment of symptom prevalence, characteristics, and distress. This approach to comprehensive symptom assessment is helpful for clinical trials that incorporate QOL measures or studies of symptom epidemiology.[184] Portenoy et al.[185] evaluated patients with prostate, colon, breast, or ovarian cancer using the MSAS and other measures of psychological condition, performance status, symptom distress, and overall QOL. The Karnofsky Performance

TABLE 42.20

COMPONENTS OF MEDICAL HISTORY: PHYSICAL EXAMINATION, INVESTIGATIONS, AND FURTHER EVALUATION

Physical examination		
Review of available laboratory and imaging data		
Further diagnostic investigations and specific assessments	Diagnostic Investigations Symptom-specific Extent of disease	Other Assessments Psychosocial Functional

Status score was less than or equal to 80 in 49.8%. Across tumor types, 40% to 80% experienced lack of energy, pain, feeling drowsy, dry mouth, insomnia, or symptoms indicative of psychologic distress. Although symptom characteristics were variable, the proportion of patients who described a symptom as relatively intense or frequent always exceeded the proportion who reported it as highly distressing. The mean (+/− SD range) number of symptoms per patient was 11.5 +/−6.0 (0–25).

Laboratory and Imaging Data

Careful review of previous laboratory and imaging studies can provide important additional information. Specific radiologic or laboratory tests may help the clinician understand the pathophysiology of symptoms and their relationships to the disease. This information provides the basis for a provisional pain diagnosis that clarifies both the status of the disease and the nature of other concurrent concerns that may require therapeutic focus.

Some patients require multiple studies to evaluate the pain problem, clarify extent of disease, or to assess other symptoms. Assistance from physicians in other disciplines, nurses, social workers, psychologists, or others may prove necessary to evaluate related physical or psychosocial problems identified during the initial assessment. It is appropriate and useful to review the findings of this evaluation with the patient, family, and other appropriate persons, so that they can prioritize problems according to their importance for the patient. It is also useful to identify potential outcomes that would benefit from contingency planning, including the need for advanced medical directives, the evaluation of home care resources, and prebereavement interventions with the family.

Physical Examination

A physical examination, including a neurologic and musculoskeletal examination, is a necessary part of the initial pain assessment. The need for a thorough neurologic assessment is justified by the high prevalence of painful neurologic conditions in the cancer population.[186] The physical examination should clarify the underlying causes of the pain problem, detail the extent of the underlying disease, and discern the relation of the pain complaint to the disease.

Diagnosis

The provisional pain diagnosis includes inferences about the pathophysiology of the pain and an assessment of the pain syndrome. Evaluation of concurrent concerns includes other symptoms and related psychosocial problems. Additional investigations can often clarify uncertainties in the provisional assessment.

SUMMARY

Cancer is one of the medical conditions patients fear most. In addition to anxiety about cancer as a potentially lethal disease, patient and family expectancies that pain is an inevitable and untreatable consequence are major sources of distress. Controlling pain associated with cancer is a major health care problem. Lack of expertise by clinicians in assessing pain is an important cause of poor pain control. A stepwise approach to cancer pain assessment begins with a systemic clinical interview and ends with a clinically relevant diagnosis that outlines the mechanisms and contributing factors to the pain complaint. It involves determining the etiology of the pain and forecasting its future trajectory. It also involves determining the number of sites from which pain originates and the probable mechanisms involved. Assessment must include evaluation of the impact of pain on sleep, functional capability, activity level, and psychological well-being. In addition, the clinician must determine the nature, course, and impact of the cancer on the patient. A thorough evaluation will allow the clinician to obtain a basis for evaluating therapeutic intervention and determining the long-term goals of the patient and/or the patient's family.

Many health care professionals may become involved with the cancer pain patient at any one time. Successful pain management requires that the person or persons responsible for pain management adopt, or at least become familiar with, an interdisciplinary approach to care.

CHAPTER 43 ■ CANCER PAIN: PRINCIPLES OF MANAGEMENT AND PHARMACOTHERAPY

DERMOT R. FITZGIBBON

INTRODUCTION

Inadequate treatment of chronic cancer pain persists despite decades of efforts to provide clinicians with information about analgesics and pain-relieving techniques. The problems associated with undertreatment of cancer pain are outlined in Table 43.1. While the reasons for inadequate treatment of cancer pain are complex, certain barriers to adequate pain relief can be identified. These barriers may be summarized as related to health care professionals; patients, families, and the public; health care implementation and reimbursement; and drug regulatory systems.

In the United States and other western nations, physicians' concerns about regulatory scrutiny and the possibility of unwarranted investigation by regulatory agencies negatively affect their prescribing of opioid analgesics to treat pain.[1] Although most U.S. state medical boards have adopted regulations, guidelines, or policy statements relating to controlled substances and pain management, some state medical boards have rejected prescribing practices that are considered acceptable by today's standards.[1]

Internationally, there are many reasons why patients receive inadequate cancer pain control.[2] Table 43.2 lists some of these reasons. To respond to these issues, the World Health Organization (WHO) advocates a strategy which includes the development of national or state policies that support cancer pain relief through government endorsement of education and drug availability; educational programs for the public, health care personnel, and regulators; and modification of laws and regulations to improve the availability of pain relieving drugs, especially opioid analgesics.

Potential solutions for inadequate control of cancer pain include the following:

1. **Education of patient and health care providers:** Many cancer patients worry that their pain will not be controlled during the course of their disease. Moreover, they report fears of drug addiction, side effects, and tolerance. Educating patients about common barriers to cancer pain treatment can be an effective pain management strategy.[3] In addition, each patient should receive a "bill of rights" indicating that the provider is committed to achieving optimal pain control. Health care providers should learn pain assessment techniques and routinely question all patients with cancer for pain prevalence and severity.
2. **Establishment of Pain Management Practice Plan:** Several guidelines address cancer pain management, including those proffered by the WHO,[4] the American Pain Society (APS),[5] the Agency for Health Care Policy and Research,[6] and the American Society of Anesthesiologists.[7] In addition, every cancer care setting should establish and follow a pain management practice plan in order to anticipate and deal with pain in the cancer patient. Physicians caring for cancer patients should maintain a list of advanced pain management referral sources and protocols and seek expert consultation when routine management strategies fail.
3. **State Cancer Pain Initiatives:** These initiatives are grass roots, multidisciplinary organizations in the United States committed to making optimal cancer pain control a reality. The first initiative began in Wisconsin,[8] and they now exist in all states

TABLE 43.1

FACTORS CONTRIBUTING TO UNDERTREATMENT OF CANCER PAIN IN UNITED STATES

Factor	Reason
Patient-related	• Pain under-reporting: —fear of disease progression —perceived lack of time or inadequate amount of time spent in physician's office discussing pain problems Poor compliance with prescribed medications
Physician-related	• Legal issues regarding overprescription or perceived overprescription of opioids. Physician reluctance to prescribe opioid analgesics has multiple causes.[49] • Difficulty assessing pain complaints • Lack of information or lack of expertise on contemporary strategies for cancer pain management • Desire to provide the patient with the latest and greatest pain management strategies may pose difficulties with untried or unproven techniques or methods.

in the United States. A Role Model Education Program has evolved from the Wisconsin Cancer Pain Initiative.[9] The key concept in the initiative movement is the provider triad: physician, nurse, and pharmacist. In most states, this program involves attendance of the triad at a day-long course covering all aspects of cancer pain management.

A clinician may achieve pain relief in the cancer patient by several means (Table 43.3). Success requires tailoring treatment to the individual patient: matching drug treatment, anesthetic, neurosurgical, psychological, and behavioral approaches to the patient's needs. Successful management requires that the person or persons responsible for pain management be familiar with all these aspects of care.

Pain Management Improvement Strategies

Many pain clinician–educators now believe that traditional medical educational approaches require complementary interventions

TABLE 43.2

INTERNATIONAL REASONS FOR INADEQUATE CANCER PAIN CONTROL

Absence of national policies on cancer pain relief and palliative care
Lack of awareness on the part of health care workers, policy makers, administrators, and the public that most cancer pain can be relieved
Shortage of financial resources and limitations of health care delivery systems and personnel
Concern that medical use of opioids will produce psychological dependence and drug abuse
Legal restrictions on the use and availability of opioid analgesics

in health care systems that directly influence the routine behaviors of clinicians and patients.[9–14] This perspective echoes that advocated by the quality improvement (QI) movement.[15,16] The QI approach to pain treatment is based on the assumption that, although clinicians are concerned with patient comfort, their habits and procedures of practice do not support the achievement of effective pain relief. Although pain has received the most study, some experts believe that many symptoms of medical illness are neglected because patterns of medical practice and accountability have evolved with focus on structural disease rather than on burdens of illness, functional impairments, quality of life measures, and symptom-related distress.[17,18] QI programs designed to enhance treatment of cancer pain should include the following key elements[5]:

1. Routine assessment of pain using patient-appropriate validated tools.
2. Assure that a report of unrelieved pain raises a "red flag" that attracts clinicians' attention.
3. Make information about analgesics available in settings where physicians write orders.
4. Promise patients responsive analgesic care and urge them to communicate their pain.
5. Implement policies and safeguards for the use of modern analgesic technologies.
6. Coordinate and assess implementation of these measures.

The APS Quality of Care Committee issued guidelines for the treatment of acute and cancer pain.[5] These guidelines attempted to embody key elements for favorably influencing behaviors of both patients and clinicians. The guidelines addressed settings that used conventional pain relief methods (e.g., intermittent parenteral or oral analgesics) exclusively and those using current technology for pain management. While the guidelines focused on the assessment of pain and its treatment with analgesic drugs, they also identified that nonpharmacologic measures were an effective therapy.

Bookbinder et al.[14] studied the impact of implementing APS guidelines in a focused program at an academic cancer hospital. The program included routine monitoring of pain, staff education, and focus groups to identify organizational obstacles to effective pain management. During the first year of the program, patient satisfaction increased significantly but the "worst pain levels over the past 24 hours" remained unchanged. Results from the second and third years suggested further reduction of pain intensity on targeted hospital units. Major change did not occur until pain assessment became routine and the resulting data had convinced physicians to participate in the programs.

Pain education programs at a community level have shown mixed results. Elliott et al.[19] failed to show a significant reduction in pain prevalence, pain management index, pain intensity scores, patient and family attitude scores, and physicians' and nurses' knowledge and attitude scores. In contrast, de Wit et al.[20] reported that patients significantly increased their knowledge of pain and its mechanisms, with a decrease in pain intensity of approximately 20% to 30%.

CANCER PAIN MANAGEMENT OVERVIEW

Successful management of the cancer patient with pain ultimately depends on the ability of the clinician to accurately assess problems, identify and evaluate the components that contribute to the pain complaint, and formulate a plan for continuing care that is responsible for the evolving goals and needs of the patient and the patient's family (see Chapter 42). The formulation of an effective therapeutic strategy for the management of cancer pain requires a comprehensive assessment of the patient and the pain complaint. In general, the goals of patient care in oncology are often complex, but they broadly comprise prolonged survival and optimizing comfort and function. Adoption of these goals logically leads to a multimodality treatment approach targeted to specific problems (Fig. 43.1).

Comprehensive cancer care encompasses a continuum that progresses from disease-oriented, curative, life-prolonging treatment through symptom-oriented, supportive, and palliative care extending to terminal-phase hospice care. Pain management is, and should be, an integral component of comprehensive cancer care.[21] Designing an effective pain control strategy for the individual patient requires knowledge of the ways in which a patient's cancer, cancer therapy, and pain therapy can interact. Collaboration with different health care providers (such as medical oncologists and radiation oncologists) is essential to successful pain management.

Two important aspects of cancer affect management and include the oncologist's ability to treat the cancer and the ability to assess the components of the tumor pathophysiology that of themselves do not cause pain (the cancer's "nonpain" pathophysiology).[22] The ability to treat cancer modifies the need for pain management (successful treatment reduces the likelihood of pain) and the appropriateness of invasive pain procedures. Cancer nonpain pathophysiology can interfere with the oral administration of medications, narrow the patient's therapeutic window for analgesic drugs, limit the effectiveness of psychological pain therapies, and complicate or preclude invasive pain-reducing procedures. In addition, cancer therapy can interfere with, or enhance, pain therapy and vice versa. Antineoplastic treatment can interfere with pain therapy by causing additional pain or by producing other adverse effects such as fatigue and gastrointestinal (GI) disturbances. Cancer treatment can enhance pain therapy by reducing the extent of cancer, by acting as an adjuvant analgesic, and, oftentimes, providing intravenous access for parenteral drug administration to patients who require it. Pain therapy can sometimes interfere with cancer therapy by increasing or complicating the adverse effects of cancer therapy (e.g., opioid-related bowel dysfunction). It can enhance cancer therapy by improving patient function or sense of well-being, and certain palliative surgical procedures may have the ancillary effect of improving organ function.

The basic principles of tumor-directed pain control include:

1. Modifying the source of pain by treating the cancer and the inflammatory effects of cancer.
2. Altering the central perception of pain, for example, by the use of analgesics, antidepressants, anxiolytics, and psychotherapy.
3. Interfering with nociceptive transmission outside of and within the central nervous system, for example, with anesthetic techniques (e.g., neurolytic celiac plexus block, neuraxial analgesia, and spinal neurolysis), or neurosurgical procedures (e.g., cordotomy and myelotomy).

The pain experienced by most cancer patients responds to direct and indirect modification of the source of the pain combined with pharmacologic and nonpharmacologic alteration of the central perception of pain.[23–25]

The guiding principle in developing pain management goals is to individualize the approach to the patient's needs. Part of the process of developing treatment goals is to take into consideration the burdens (adverse effects; opportunity costs) and benefits of different treatment options. Clinicians may find that patient treatment goals differ from their own, either because patients feel that pain is inevitable, or because patients expect pain to be relieved with minimal effort on their part. Issues that physicians should discuss with patients include expected lifestyle, cost and reimbursement issues, and concerns about opioid tolerance, addiction, and side effects. Discussing these issues in advance may uncover and address potential barriers to treatment. Moreover, treatment goals may change during the course of the patient's illness, and all health care providers interacting with the patient during the course of the illness need to keep abreast of such changes.

Patient life expectancy should influence treatment decisions. For example, if life expectancy exceeds several weeks to months, then treatment may focus on how to enable the patient to function

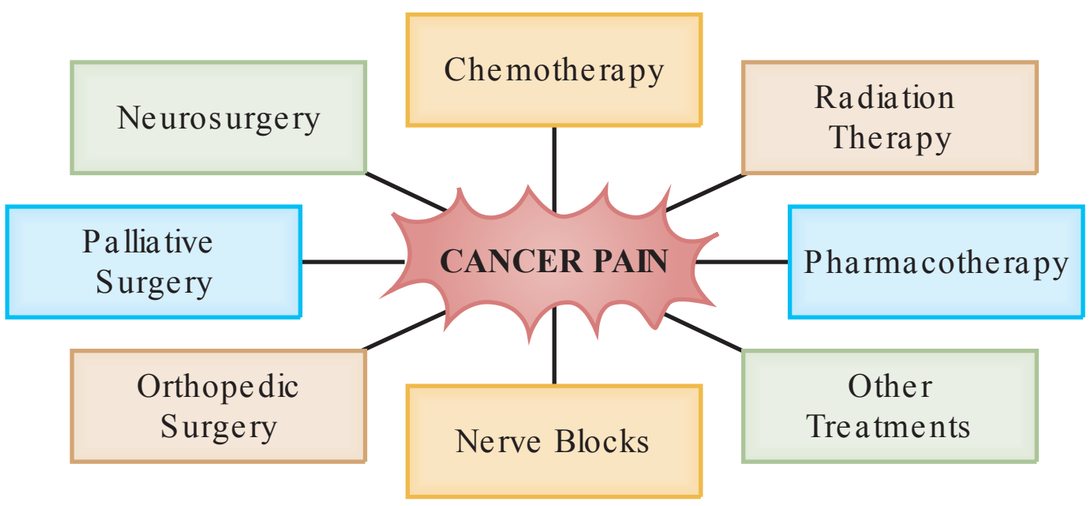

FIGURE 43.1 Multimodality therapeutic management of cancer pain. Others include psychosocial interventions, nursing care, alternative pain management strategies, and end-of-life issues.

at the highest possible level. One goal should be to relieve pain and prevent therapy from interfering with normal activities. On the other hand, those likely to die within a few days or weeks require less emphasis on maintaining an active lifestyle and more on comfort and tolerance of the side effects associated with pain therapies, allowing due attention to life closure issues. The emphasis for these patients should be on treatments that provide immediate relief, rather than those that require a long period of time to become effective. Because maintenance of mental clarity and alertness is valued by most patients, even in the last days or hours of life, patients may be willing to undergo more interventional methods of pain management to achieve better pain control.

Primary Anticancer Treatment

Pain produced by tumor infiltration may respond to antineoplastic treatment with radiation treatment and chemotherapy. These approaches to pain control are elaborated in Chapter 48.

Surgery

The surgeon treating a patient with newly diagnosed cancer must meet several responsibilities: biopsy for tissue diagnosis, adequate staging, consultation with medical and radiation oncologists for adjuvant therapy, and surgical resection. Surgery may also play a role in the relief of symptoms caused by specific problems, such as obstruction of a hollow viscus, unstable bone structures, and compression of neural tissues. A variety of surgical disciplines (e.g., general surgery, orthopedic, neurosurgical, plastic, and reconstructive) may participate in the care of the cancer patient. Beginning in the 1960s and 1970s, surgery for certain tumors such as breast, colon, and lung cancer became more conservative.

Although the development of metastatic cancer usually indicates incurable disease, curative surgical resection is possible in rare instances. These instances must meet several criteria before the surgeon can operate: the primary lesion must be controlled; there must be the potential for complete resection of the metastases; there must be no other equally effective or better antitumor therapy available; metastases should involve only one organ; one should anticipate reasonable postoperative function; expected survival should be better than if left untreated; and the patient must be able to tolerate the surgical procedure. Sometimes, excision of the primary tumor is indicated in the presence of unresectable metastatic disease. Locally advanced tumor can be very painful and unsightly, can interfere with vital functions such as breathing and swallowing, and can produce complications such as bleeding and local infection.

Stenting, Drainage Procedures, and Antibiotics

Common complications of advanced cancer include GI, hepatobiliary, and ureteric obstructions. Stents and laser treatment have a place in both upper GI and rectal obstruction due to advanced malignancy.[26–28] Endoscopic retrograde placement of ureteric stents under cystoscopic control is the most common urologic approach for the management of malignant ureteric obstruction. Difficult clinical situations may require alternative procedures such as palliative cutaneous ureterostomy, percutaneous anterograde ureteric stent placement, and a combined anterograde and retrograde technique. The insertion of internal biliary stents by endoscopic or percutaneous methods is common practice for the palliative management of obstructive jaundice caused by malignancy and most surgeons prefer this to the use of external biliary drains.[29]

The goals of antibiotic use in terminally ill patients are sometimes to prolong life and always to relieve symptoms. Treatment for cystitis, for instance, does not usually prolong life, but may relieve the patient from painful dysuria and troublesome polyuria. Antibiotics may also have pain-relieving effects when the source of pain involves infection, as illustrated by the treatment of pyonephrosis and osteitis pubis.

SYMPTOMATIC CANCER PAIN MANAGEMENT

Successful management strategies usually require a team approach focusing not only on the nociceptive processes but also on other factors that influence the final perception of pain. Figure 43.2 outlines an approach to cancer-related nociceptive and neuropathic pain.

Increasing severe pain and/or increasing and intractable side effects determine the appropriate treatment strategy. Most patients will respond satisfactorily to relatively simple oral pharmacotherapeutic strategies. When the patient requires drug treatment, therapy should comply with two basic principles: use oral analgesics and other noninvasive routes of administrations (e.g., transdermal and transmucosal) whenever possible and administer them in accordance with the principles in the WHO analgesic ladder (see below). Titrate opioid and adjuvant analgesics to maximally effective doses or to the appearance of dose-limiting side effects before considering alternative medications (e.g., opioid rotation) or more specialized (and usually) invasive approaches. As an adjunct—and occasionally as an alternative—to medication management, patients with certain pain syndromes will benefit from relatively simple anesthetic blocks, such as celiac and superior hypogastric plexus blocks, neurolytic subarachnoid and

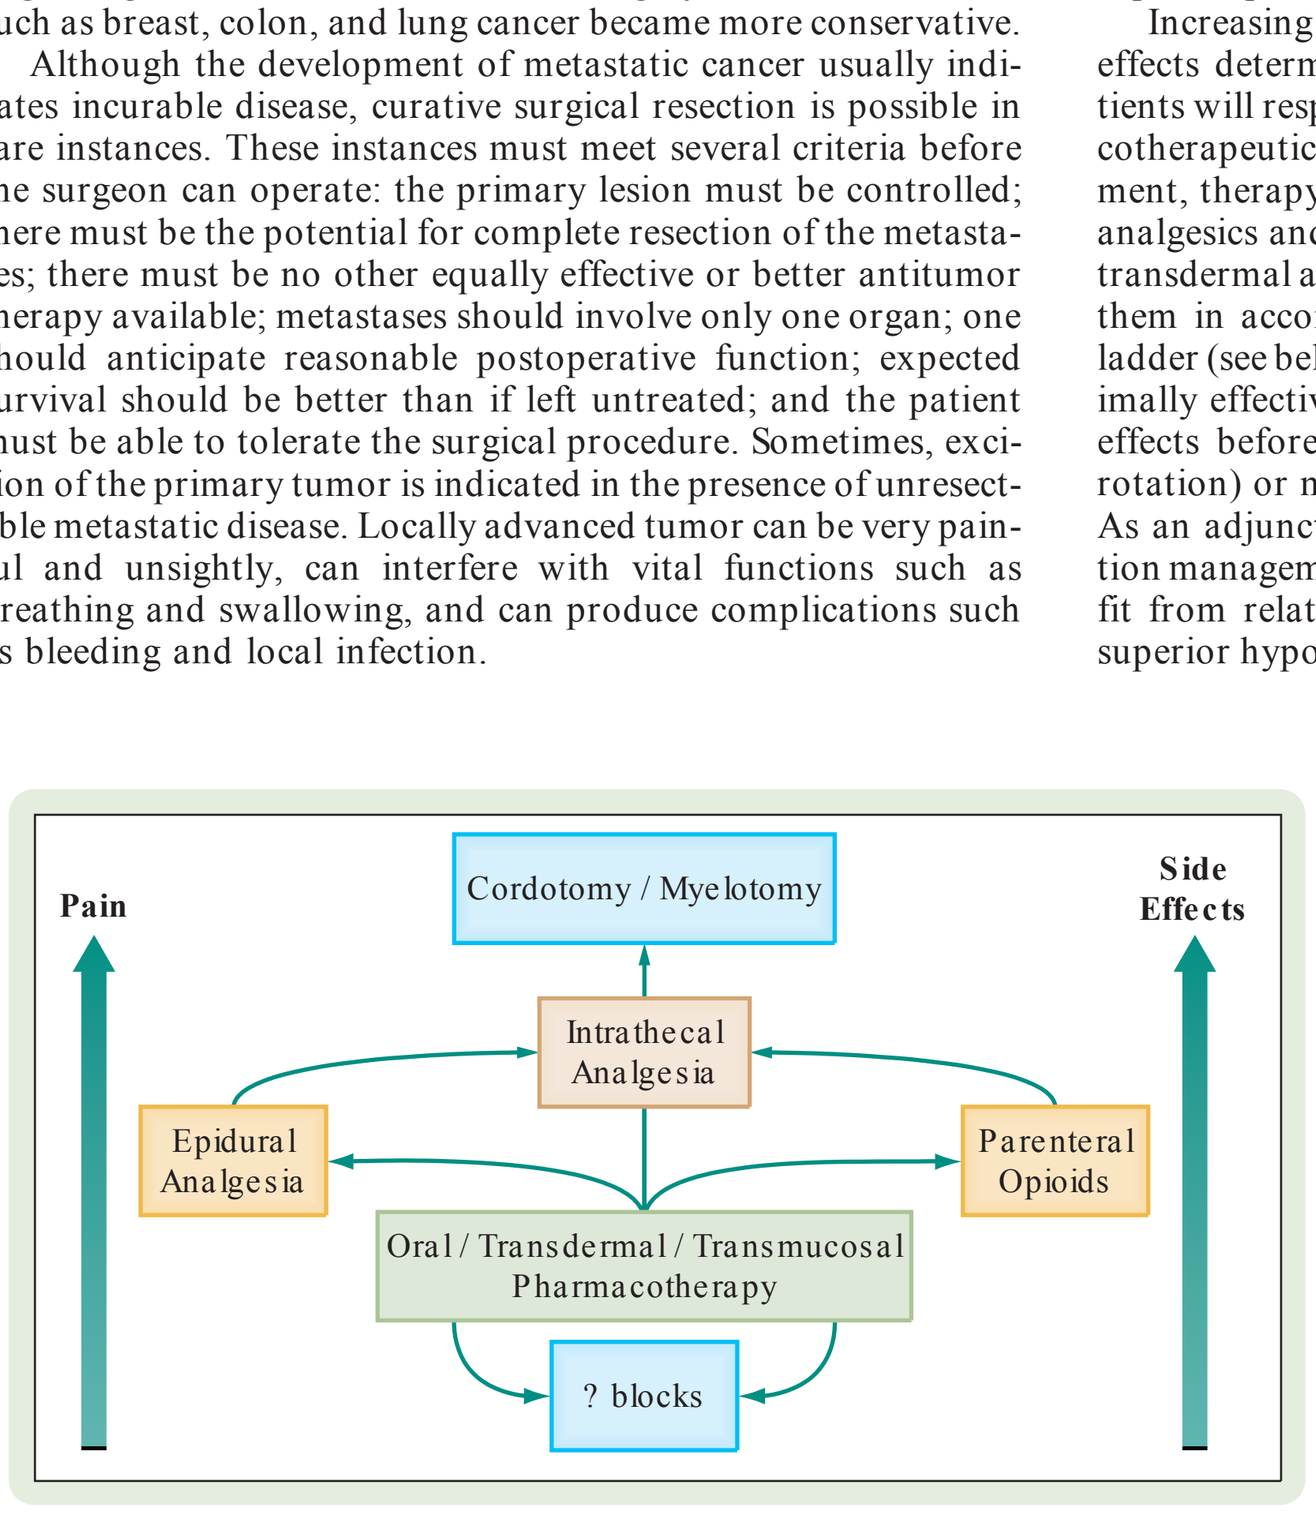

FIGURE 43.2 Tumor pain management algorithm.

intercostal blocks, and selected peripheral nerve blocks (see Chapter 44).

Severe, uncontrolled pain and/or intractable side effects require interventional pain management to achieve rapid pain control. Such interventions may include epidural analgesia and/or parenteral opioid therapy (usually intravenous or subcutaneous administration). As many of these patients have large systemic opioid requirements, it is not unusual to combine epidural and parenteral therapies. A small percentage of patients may fail these therapies and should then be treated with intrathecal drugs and/or cordotomy or myelotomy (see Chapter 44).

Occasionally, patients will have pain refractory to all interventional measures outlined. For these patients, adequate relief may only be achieved through the use of techniques such as intravenous lidocaine infusion or subanesthetic doses of ketamine. Failing these approaches, palliative sedation is an option.

World Health Organization Analgesic Ladder

In 1986, WHO proposed a method for relief of cancer pain based on a small number of relatively inexpensive drugs, including morphine.[30] This guideline has been translated into 22 languages and a total of over half a million copies have been distributed. A second edition[4] takes into account many of the advances in understanding and practice that have occurred since the mid-1980s. The groundwork for this revision was started in 1989, in the context of the meeting of a WHO Expert Committee on Cancer Pain Relief and Active Supportive Care.[2]

The WHO "analgesic ladder" is a simple and effective method for controlling cancer pain, and the proportion of cancer patients who report effective pain relief varies from 75% to 90%.[6,25,31–33] Some authors have expressed concern about the effectiveness of the WHO analgesic ladder approach and the validity of published data. Jadad et al.[34] conducted a systematic review of studies (MEDLINE from 1982 to 1995, a hand search of textbooks and meeting proceedings, reference lists, and direct contact with authors) evaluating the effectiveness of the WHO ladder as an intervention for cancer pain management. While the studies available provide useful insights into cancer pain and its treatment, they fail to predict the effectiveness of the WHO analgesic ladder in any given patient, underscoring the importance of individualized assessment and treatment plans, including mechanism-based approaches to therapy. Treatment for cancer pain should begin with a straightforward explanation to the patient of the causes of the pain or pains. Many pains respond best to a combination of drug and nondrug measures. Nevertheless, opioids, nonopioid analgesics, and adjuvant agents, alone or in combination, are the mainstay of cancer pain management (see Table 43.4).

Pharmacologic strategies for the control of tumor pain appear in Table 43.5. Table 43.6 lists the principles of pharmacotherapy endorsed by WHO.

These principles are as follows:

By Mouth

When possible, patients should take analgesic medications by mouth. However, alternative routes such as rectal, transdermal, sublingual, and parenteral (subcutaneous and intravenous) administration may better serve patients with dysphagia, uncontrolled vomiting, or GI obstruction.

By the Clock

After titration to optimal effect, patients with continuous pain should take analgesic medications on an around-the-clock (ATC) schedule. Once baseline pain is controlled, many patients will require breakthrough pain (BTP) therapy with immediate or rapid-onset opioids, since BTP is a common occurrence in cancer patients.

TABLE 43.4

A BASIC DRUG LIST FOR CANCER PAIN RELIEF

Category	Basic drugs	Alternatives
Nonopioids	acetylsalicylic acid (ASA) acetaminophen ibuprofen indomethacin	choline magnesium trisalicylate diflunisal naproxen diclofenac
Opioids for mild to moderate pain	codeine	dihydrocodeine dextropropoxyphene standardized opium tramadol
Opioids for moderate to severe pain	morphine	methadone hydromorphone oxycodone levorphanol meperidine buprenorphine
Opioid antagonist	naloxone	
Antidepressants	amitriptyline	imipramine
Anticonvulsants	carbamazepine	valproic acid
Corticosteroids	prednisolone dexamethasone	prednisone betamethasone

For the individual
With attention to detail

(From World Health Organization. Cancer Pain Relief With a Guide to Opioid Availability. Geneva, Switzerland: World Health Organization; 1996.)

By the Ladder

The WHO analgesic ladder is based on the premise that most patients throughout the world will gain adequate pain relief if health care professionals learn how to use a few effective and relatively inexpensive drugs well (Fig. 43.3). Step 1 of the ladder involves the use of nonopioids. If this step does not relieve pain, add an opioid for mild to moderate pain (Step 2). When the opioid for mild to moderate pain in combination with a nonopioid fails to relieve the pain, substitute an opioid for moderate to severe pain (Step 3). Use only one drug from each of the groups at the same time. Give adjuvant drugs for specific indications (see below).

For the Individual

There are no standard doses for opioids. *The "right" dose is the dose that relieves the patient's pain with the minimum of side effects*. Combination opioid formulations (i.e., those with the nonopioid analgesic acetaminophen or a nonsteroidal anti-inflammatory drug [NSAID]) are commonly used for mild-to-moderate pain. These have a dose limit due to toxic effects of the coanalgesic.

With Attention to Detail

Carefully determine and monitor the patient's analgesic regimen. Follow-up regularly with the patient by monitoring adherence, drug efficacy, functional outcomes (activity, sleep, mood, appetite), side effects, and aberrant drug-related behaviors. Anticipate adverse effects, such as opioid-induced bowel dysfunction, and treat them prophylactically or as soon as they become problematic.

The WHO ladder advocates the use of three classes of analgesics—nonopioid, adjuvant, and opioid. Each of these classes will be considered separately.

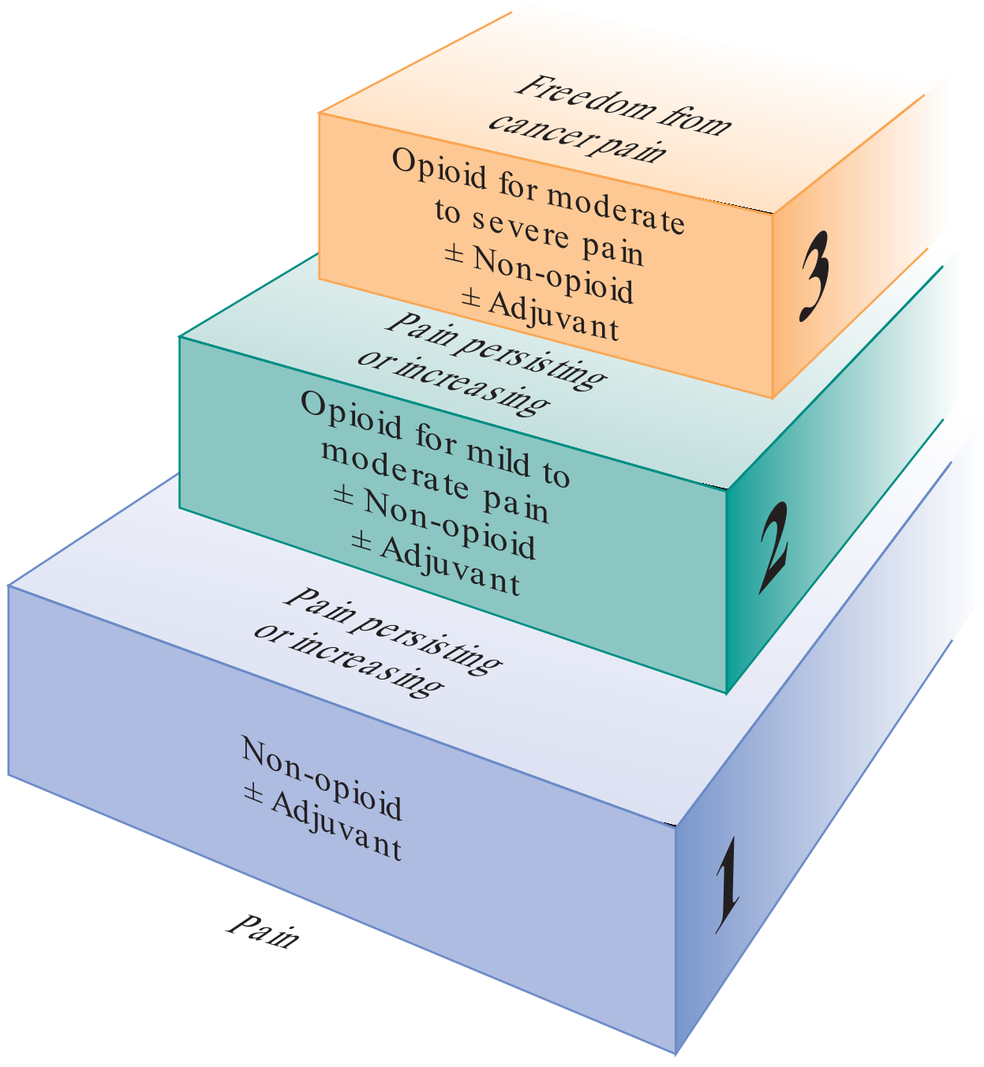

FIGURE 43.3 WHO analgesic ladder. (From World Health Organization. *Cancer pain relief with a guide to opioid availability*. Geneva, Switzerland: World Health Organization; 1996.)

NONOPIOID ANALGESICS

Nonopioid analgesic agents (also called coanalgesics) and antipyretics are essential drugs for the management of a wide variety of acute and chronic pain conditions. Clinicians should be familiar with the use, efficacy, and adverse effects of these agents. Nonopioid analgesics are important to the successful use of oral pharmacotherapy in the cancer patient with pain. These drugs may function to control pain independently (e.g., in the management of bone pain) or may help reduce the dose of opioid required for pain control (opioid-sparing effect). A wide range of drugs with varying effects and side effects are available. These medications are discussed extensively in other chapters.

Cyclooxygenase-2 (COX-2) is highly expressed during tumorigenesis and actively contributes to tumor progression,[35] and this effect involves, at least in part, induction of tumor angiogenesis.[36] Several cytokines such as reactive oxygen species and mediators of inflammatory pathway such as activation of nuclear factor-kappaB and COX-2 leads to an increase in cell proliferation, survival, and inhibition of proapoptotic pathway, ultimately resulting in tumor angiogenesis, invasion, and metastasis.[37] Increased COX-2 activity and synthesis of prostaglandins stimulates proliferation, angiogenesis, and invasiveness and inhibits apoptosis.[38] In preclinical models, selective COX-2 inhibitors possess therapeutic efficacy against established tumors, raising the possibility that COX-2 inhibitors may be used in human cancer treatment.[39] Preliminary human data suggests a potential chemoprevention role in certain cancers (breast, prostate, colon, and lung).[40] Clinical studies are currently underway to determine the benefit of this drug class taken as a sole agent or in combination with various chemotherapeutic regimens in reducing cancer risk.

Efficacy in Cancer Pain

NSAIDs are accepted as an important tool in treating cancer pain and may be combined with opioids for this purpose.[34] Although many NSAIDs are available to treat various painful conditions, it is unclear which agent is most clinically efficacious for relieving cancer-related pain and if there are clinical differences between these agents that justify their cost differences.

Eisenberg et al.[41] examined the scientific evidence on efficacy and safety of NSAIDs in the treatment of cancer-related pain. They conducted a meta-analysis of data from 25 randomized controlled trials. The studies provided data on 1545 cancer patients. Although all 25 trials reported analgesic efficacy, only the single-dose studies were comparable for analgesic efficacy analysis. Single doses of placebo produced a 15% to 36% rate of analgesia, whereas the use of NSAIDs resulted in roughly twice as much pain relief (31% versus 60%). These results support the WHO position that NSAIDs provide analgesic efficacy in patients with cancer pain.[4] The authors concluded that the meta-analysis precluded testing the hypothesis that NSAIDs are particularly effective for malignant bone pain because of a lack of comparable studies. Well-designed analgesic trials in which bone pain or pain due to other specific cancer-related syndromes assessed separately from nonbone pain are required.

Additionally, it is uncertain which opioid and NSAID combinations are the most efficacious for cancer pain or even what may be the additional benefit of combining an NSAID with an opioid in this setting. McNicol et al.[42] assessed and compared the efficacy of various NSAID and NSAID plus opioid combinations in the treatment of cancer pain. They concluded that most studies were of insufficient duration to demonstrate that the long-term use of NSAIDs is safe and effective in patients with cancer. They advised that clinicians should be as cautious in using NSAIDs in this population as they would any other population,

especially given additional bleeding risks in cancer patients and the probability that a patient with cancer may be on a broad regimen of medications, some of which may increase NSAID-related toxicity.

ADJUVANT DRUGS

Adjuvant drugs may become necessary in the care of the cancer patient for one of three reasons:

- To treat the adverse effects of analgesic medications (e.g., antiemetics and laxatives)
- To enhance pain relief
- To treat concomitant psychological disturbances such as insomnia, anxiety, depression, and psychosis

Antiemetics

Much of our experience in managing opioid associated nausea and vomiting comes from the postoperative nausea and vomiting (PONV) literature. The knowledge base of PONV physiology has significantly expanded over the past decade. The mechanisms of action of pharmacologic agents (including antagonists of 5-HT3, dopaminergic, histamine H1, muscarinic cholinergic, and opioid and NK-1 receptors) for the prevention and treatment of PONV as well as chemotherapy-induced nausea and vomiting have been elucidated. Various antiemetic agents are listed in Table 43.7.

Laxatives and Opioid-Induced Bowel Dysfunction

Opioid-induced bowel dysfunction (OBD) is a distressing condition that may persist indefinitely in the clinical setting. Hard dry stool, gas distention, incomplete evacuation, and straining are common sequelae. In cancer patients, up to 90% of patients on chronic opioid therapy develop OBD.[43] Human studies have revealed that mu receptors were more consistently distributed between the myenteric and submucosal plexuses, and between the small and large intestines.[44] Exogenous mu agonists affect the GI tract in several ways. These effects appear to be central, peripheral, and local. In response to exogenous opioids, decreased motility occurs at multiple levels in the GI tract including the stomach, small intestine, and large intestine.[45] The predominant opioid effect appears to be at the local GI level. This effect appears to occur as a result of inhibition of secretions and peristalsis.[46] The goals of therapy typically are three-fold: keep stool volume maximized to trigger enterochromaffin cell serotonin release via mucosal stretch, keep stool softer and mechanically make it easier to move, and enhance peristalsis.

Fiber bulking agents are organic polymers that retain water in stool. It is important that adequate water be taken concomitantly with fiber. Without sufficient water, fiber may worsen constipation. Many practitioners recommend a combination of a stool softener with a stimulant laxative for patients on chronic opioid therapy. Stool softeners, such as docusate sodium, are detergents that allow better water penetration into stool, making

TABLE 43.7

ANTIEMETICS

Agent	Presumed primary receptor site of action	Dosage/route	Major adverse effects
Metoclopramide	D2 (primarily in GI tract) or 5HT3 (only at high doses)	5–20 mg orally or subcutaneously or iv	Dystonia, akathisia, esophageal spasm, and colic (in GI obstruction)
Haloperidol	D2 (primarily in CTZ)	0.5–4 mg orally or subcutaneously or intravenously q6hr	Dystonia and akathisia
Prochlorperazine	D2 (primarily in CTZ)	5–10 mg orally or intravenously q 6h or 25 mg rectally q6h	Dystonia, akathisia, and sedation
Chlorpromazine	D2 (primarily in CTZ)	10–250 mg orally q4h, 25–50 mg intravenously or im q4h, or 50–100 mg rectally q6h	Dystonia, akathisia, sedation, postural hypotension
Promethazine	H1, muscarinic acetylcholine receptor or D2 (primarily in CTZ)	12.5–25 mg orally or intravenously q6h or 25 mg rectally q6h	Dystonia, akathisia, and sedation
Diphenhydramine	H1	25–50 mg orally or intravenously or SQ q6h	Sedation, dry mouth, urinary retention
Scopolamine	Muscarinic acetylcholine receptor	1.5 mg transdermal patch q72h	Dry mouth, blurred vision, urinary retention, confusion
Hyoscyamine	Muscarinic acetylcholine receptor	0.125–0.25 mg SL or orally q4h or 0.25–0.5 mg SQ or iv q4h	Dry mouth, blurred vision, ileus, urinary retention, confusion
Ondansetron	5HT3	4–8 mg orally by pill or dissolvable tablet (ODT) or intravenously q4–8h	Headache, fatigue, constipation
Aprepitant	NK1	40 mg orally qd	

(Modified from Wood GJ, Shega JW, Lynch B, et al. Management of intractable nausea and vomiting in patients at the end of life: "I was feeling nauseous all of the time . . . nothing was working." *JAMA* 2007;298(10):1196–1207.)

it softer and more voluminous. Stimulant laxatives, such as senna and bisacodyl, induce peristalsis via mechanisms that are not well understood. In vitro, applying senna to intestinal mucosa leads to immediate contraction. After optimal titration of these agents, oral osmotics are commonly added to enhance laxation by pulling along water due to osmotic forces. Osmotics include sugars, such as lactulose or sorbitol, magnesium salts, such as magnesium citrate, or inert substances, such as polyethylene glycol. When unsuccessful, rescue oral and rectal interventions are also often needed. Rectal interventions include such agents as bisacodyl suppositories and phosphosoda enemas to soften, lubricate, and mobilize hard, dry, distal stool. Often synergism of multiple categories of agents is required for successful laxation.

Opioid antagonists have also been studied in the treatment of OBD. Oral naloxone given in doses between 2 mg to 4 mg three times per day was effective in improving bowel movement frequency but some patients also experienced reversal of pain relief and this reversal occurred in spite of using very low doses of naloxone relative to the total dose of opioid taken.[47] The authors suggested that patients using higher doses of opioids appear to be the most vulnerable to the analgesic effect of oral naloxone. Two peripheral opioid antagonists (alvimopan, methylnaltrexone) have been studied for opioid-induced constipation in palliative patients with advanced illnesses with insufficient response to laxative therapy (methylnaltrexone) and postoperative ileus (alvimopan) and approved for these indications by the U.S. Food and Drug Administration (FDA). Alvimopan is only approved for short-term use in hospitalized patients.

Adjuvant Analgesics

An adjuvant analgesic is a medication with primary indication other than pain relief, but it may provide or enhance analgesia in certain circumstances. In the area of cancer pain, the common adjunctive analgesics are corticosteroids, anticonvulsants, and antidepressants. These drugs play an important role for some patients who cannot otherwise attain an acceptable balance between relief and opioid side effects. Adjuvant analgesics divide broadly into general-purpose analgesics, adjuvants used for musculoskeletal pain, and those with specific use for neuropathic, bone, or visceral pain.

General Purpose Adjuvants

Corticosteroids are the most widely used general-purpose adjuvant analgesics and are available in a wide variety of formulations.[48] The painful conditions that commonly respond to steroids include increased intracranial pressure, acute spinal cord compression, superior vena cava syndrome, metastatic bone pain, neuropathic pain due to infiltration or compression, symptomatic lymphedema, and hepatic capsular distension. Patients with advanced cancer who experience pain and other symptoms that may respond to steroids usually receive relatively small doses (e.g., dexamethasone 1–2 mg bid). Using a very short course of relatively high doses (e.g., dexamethasone 100 mg intravenously followed initially by 96 mg per day in divided doses) can help manage an acute episode of very severe pain related to a neuropathic lesion (e.g., plexopathy or epidural spinal cord compression) or bony metastasis that does not respond to opioids.[49] In all cases, gradually lower the dose following pain reduction to the minimum needed to sustain relief. Topical agents (see Chapter 79) may also be useful as an adjunctive form of pharmacotherapy without increasing systemic toxicity.

Musculoskeletal Pain Adjuvants

Pain that originates from injury to muscle or connective tissue is not unusual in patients with cancer. Pharmacological and nonpharmacological approaches do not differ significantly from patients with musculoskeletal pain who do not have cancer (see Chapter 34), other than disease- or treatment-specific issues relevant to the cancer patient. Drug–drug and drug–disease interactions must always be considered and be an ongoing component of reassessment.

Neuropathic Pain Adjuvants

Neuropathic pain is a common and oftentimes very debilitating source of distress in patients with cancer because of disease and treatment (see Chapters 24–28 and 42). Most treatment strategies for cancer-related neuropathic pain are extrapolated from noncancer-related neuropathic pain (see Chapter 80). Table 43.8 summarizes those agents that are commonly used to treat neuropathic pain in cancer patients, alone or in combination with opioids. There is a wide spectrum of drug–drug and drug–disease interactions with the various adjuvant analgesics, so appropriate patient counseling and ongoing reassessment are important to optimize therapeutic outcomes and minimize adverse effects.

Xiao et al.[50] tested gabapentin as a potential analgesic for paclitaxel- and vincristine-evoked pain in an animal model. Paclitaxel- and vincristine-evoked mechano-allodynia and mechano-hyperalgesia were significantly reduced by gabapentin, but only with repeated dosing. Paclitaxel-evoked painful peripheral neuropathy was associated with an increased expression of the alpha(2)delta-1 subunit in the spinal dorsal horn, but not in the dorsal root ganglia suggesting that gabapentin's mechanisms of action for this type of neuropathy may include normalization of the nerve injury-evoked increase in calcium channel alpha(2) delta-1 subunit expression. Dunteman[51] reported on the use of oral levetiracetam titrated over days to 2 weeks in 7 patients with neoplasms involving neural structures (four invading the brachial plexus and three the lumbosacral plexus). The maximum levetiracetam dose ranged from 500 to 1500 mg bid. All patients experienced pain control improvement after the addition of levetiracetam and opioid use decreased by at least an estimated 70%, without drug-related adverse events. Like gabapentin and pregabalin, levetiracetam lacks any significant drug–drug interactions. Table 43.9 lists antiepileptic drugs currently used for neuropathic pain.

Bone Pain Adjuvants

NSAIDs, corticosteroids, calcitonin, radiopharmaceuticals, and bisphosphonates all have a potential place in the treatment of cancer-related bone pain. Chapters 46 and 48 discuss the causes and treatment of bony disease.

Visceral Pain Adjuvants

The literature offers little support for the potential efficacy of adjuvant agents for the management of bladder spasm, tenesmic pain, and colicky intestinal pain. A trial of NSAIDs may help patients with painful bladder spasms.[52] Although there is no well-established pharmacotherapy for painful rectal spasms, diltiazem can help in the management of proctalgia fugax.[53] The treatment of pain due to inoperable bowel obstruction has been described above.

Psychotropic Drugs

Many cancer patients will require a psychotropic drug. Some need it for pain relief (e.g., tricyclic antidepressants for nerve injury pain), while others need an antiemetic (e.g., haloperidol for opioid-induced nausea). Still others require an anxiolytic, such as clonazepam or alprazolam. Some require a night sedative and others an antidepressant for identifiable depression. The concurrent use of two centrally acting drugs (e.g., opioid with psychotropic drug or two psychotropic drugs together) is more likely

TABLE 43.8

NUMBERS NEEDED TO TREAT WITH VARIOUS ANALGESICS FOR DIFFERENT NEUROPATHIC PAIN STATES

Drug	Number of trials	Central pain	Peripheral pain	Painful polyneuropathy	Postherpetic neuralgia	Peripheral nerve injury	Trigeminal neuralgia	HIV neuropathy	Mixed neuropathic pain
TCA	16	4.0 (2.6–8.5)	2.3 (2.1–2.7)	2.1 (1.9–2.6)	2.8 (2.2–3.8)	2.5 (1.4–11)	ND		NA
SNRI	2	ND	5.1 (3.9–7.4)	5.1 (3.9–7.4)	ND	NA	ND	ND	ND
Gabapentin/ pregabalin	4	MA	4.0 (3.6–5.4)	3.9 (3–4.7)	4.6 (4.3–5.4)	NA	ND	ND	8.0 (5.9–32)
Opioids	6	ND	2.7 (2.1–3.6)	2.6 (1.7–6.0)	2.6 (2.0–3.8)	3.0 (1.5–7.4)	ND	ND	2.1 (1.5–3.3)
Tramadol	1	ND	3.9 (2.7–6.7)	3.5 (2.4–6.4)	4.8 (2.6–27)	ND	ND	NS	ND
NMDA antagonists	5	ND	5.5 (3.4–14)	2.9 (1.8–6.6)	NS	NS	ND	ND	NS
Topical lidocaine	4	ND	4.4 (2.5–17)	ND	NA	ND	ND	NA	4.4 (2.5–17)
Cannabinoids	2	6.0 (3.0–718)	ND	ND	ND	ND	ND	ND	NS
Capsaicin	11	ND	6.7 (4.6–12)	11 (5.5–317)	3.2 (2.2–5.9)	6.5 (3.4–69)	ND	NA	NA

ND, no studies done; NA, dichotomized data not available; NS, relative risk not significant.

TABLE 43.9

ANTIEPILEPTIC DRUGS

Drug	Brand	Mechanism of action	Dose titration and range	Remarks
Gabapentin	Neurontin	Ca^{++} channel	100–4800 mg/d	May stop suddenly; sedation, nausea, ataxia (mostly transient by 2–4 weeks)
Pregabalin	Lyrica	Ca^{++} channel	50 mg tid; ↑ × 7 days to 100 mg tid. Max dose = 600 mg/day.	Sedation, ataxia, edema. Cognitive dysfunction.
Carbamazepine	Tegretol	Na^{+} channel	400–1800 mg/d. Start low (100 mg bid).	Taper off. Check platelet count. Nausea common. Sedation, ataxia.
Oxcarbazepine	Trileptal	Na^{+} channel	600–2400 mg/d. Start low (150 mg bid)	Taper off. Sedation, ataxia, nausea. Hyponatremia.
Lamotrigine	Lamictal	Na^{+} channel, ↓glutamate release	25–600 mg/d. Start low 25 mg/d. Follow package insert titration.	Taper off. Skin rash (rarely Stevens-Johnson–dose dependent); sedation, ataxia
Topiramate	Topamax	Mixed Na^{+} and Ca^{++}	15–800 mg/d. Start low (15 mg bid), titrate slowly (weekly)	Taper off. Cognitive dysfunction, weight loss, fatigue.
Levetiracetam	Keppra	?	1000–4000 mg/d. Start low (250 mg bid), titrate slowly (weekly)	Somnolence, cognitive dysfunction, mood changes.

to produce sedation in ill and malnourished cancer patients than in others.

Cannabinoids

Cannabinoids, the active components of Cannabis sativa L., act in the body by mimicking endogenous substances (endocannabinoids) that activate specific cell surface receptors. The isolation of its main constituent, Delta9-tetrahydrocannabinol, and the discovery of the endocannabinoid system (cannabinoid receptors CB1 and CB2 and their endogenous ligands) resulted in studies concerning the pharmacologic activity of cannabinoids. Cannabinoids exert various palliative effects in cancer patients. In addition, cannabinoids inhibit the growth of different types of tumor cells, including glioma cells[54] and pancreatic ductal adenocarcinoma.[55] Two oral formulations of cannabinoids, dronabinol (Marinol) and nabilone (Cesamet) are approved by the FDA for use in chemotherapy-induced nausea and vomiting refractory to conventional antiemetic therapy. Cannabinoids also stimulate appetite and food intake and may have a role in the management of cancer-induced cachexia.[56] Studies of the endogenous cannabinoids (endocannabinoids) have demonstrated that they are present in most tissues and that in some pain states, such as neuropathic pain, levels of endocannabinoids are elevated at key sites involved in pain processing.[57] Abrams et al.[58] demonstrated that smoked cannabis was well tolerated and effectively relieved chronic neuropathic pain from human immunodeficiency virus (HIV)-associated sensory neuropathy. In some states, medical use of marijuana is allowed for certain conditions including HIV, cancer, multiple sclerosis, and epilepsy.

OPIOID ANALGESICS

Opioids are the mainstay of pharmacotherapy for patients with moderate or more intense pain resulting from virtually any cancer-related etiology. A detailed discussion of opioid pharmacology and principles of prescribing is found in Chapter 78.

Selection of Opioid Therapy in Cancer Pain Management

As in all patients who may have pain-related indications for opioid therapy, the effective clinical use of opioid drugs requires familiarity with drug selection, routes of administration, dosage guidelines, and potential adverse effects. Several factors must be considered if opioids are to be used effectively. These include:

- Previous opioid exposure and preference
- Severity and nature of disease
- Age of patient
- Extent of cancer, particularly hepatic and renal involvement altering normal opioid pharmacokinetics. See Table 43.10.
- Concurrent disease
- Available formulations

TABLE 43.10

EFFECTS OF RENAL FAILURE ON OPIOID PHARMACOKINETICS

Opioid	Effect
Dihydrocodeine	Decreased clearance
Dextropropoxyphene	Increased norpropoxyphene (toxic metabolite)
Morphine	Increased morphine-6-glucuronide (active metabolite)
Meperidine	Increased normeperidine (toxic metabolite)

The specific pathogenic mechanism that underlies a patient's cancer pain should not be a factor in deciding which opioid to use because the mechanism of pain does not reliably predict the response to opioid therapy.[59] This particularly applies to situations in which neuropathic mechanisms dominate the pain complaint. Opioids should be used as first-line therapy in such situations, particularly if the pain is considered moderate to severe in intensity.

Short-acting agents (e.g., morphine immediate-release [IR], hydrocodone IR, hydromorphone IR, oxycodone IR, oxymorphone IR, transmucosal fentanyl) may be favored initially because they are easier to titrate than long-acting agents (e.g., morphine controlled release [CR], oxycodone CR, oxymorphone extended release [ER], and transdermal fentanyl). Short-acting opioids are characterized by a rapid rise and fall in serum opioid levels, whereas serum levels of long-acting opioids increase slowly to therapeutic levels, remain there for an extended period, and then slowly decline.[60] In general, the clinical circumstance dictates the choice of a short- or long-acting opioid. For example, the treatment of acute or postoperative pain usually requires frequent titration, and short-acting opioids, with duration of action of 2 to 4 hours, are preferred. Conversely, the treatment of cancer pain or chronic, moderate to severe nonmalignant pain usually can be treated with a long-acting oral agent, with a duration of action of 12 to 24 hours, with less need for titration. In patients being treated with long-acting agents, short-acting opioids are usually provided as rescue medication for BTP, which is very common in patients with cancer pain. An ongoing opioid regimen should include provisions for rescue doses for the treatment of BTP. The rationale for providing rescue medication instead of increasing the dose of the ATC opioid is to prevent overmedication and associated adverse events. Often, there is a narrow therapeutic window between an opioid dosage sufficient to achieve pain relief and one that is associated with unacceptable adverse events.[61] For patients treated with a long-acting opioid, an IR or short-acting opioid formulation (often the same drug) may be used as the rescue medication. In general, the rescue drug should be started at a dose equivalent to approximately 10% of the 24-hour baseline dose and titrated upward to achieve adequate pain relief.[62] The dosing frequency of the rescue drug depends on the time to peak effect and the route of administration; in general, oral rescue doses can be administered as frequently as every 2 hours if needed, but typically tend to be given every 3 to 4 hours as needed.[63] Generally, three types of BTP should be considered—spontaneous, incident, or end-of-dose failure.[64] A key principle in treating BTP is to optimize the background pain control by appropriately adjusting the ATC opioid regimen. With end-of-dose failure, the clinician can increase the dose or shorten the dosing interval of ATC opioid or increase the dose of the rescue opioid. Similar strategies may be employed for spontaneous pain but successful management of spontaneous or incident pain may require the use of short-acting, rapid onset opioids (see oral transmucosal fentanyl).

Because of the substantial interpatient variability in opioid responsiveness, clinicians who prescribe opioids for the treatment of cancer pain should be familiar with at least three different agents appropriate for the management of moderate to severe pain.[65] The opioids used most commonly in the treatment of cancer pain are listed in Table 43.11. The pharmacology of these agents can be reviewed in Chapter 78.

The regimen for opioid medications should generally provide ATC analgesia with provision for rescue doses for the management of exacerbations of the pain not covered by the regular dosage. At all times, causes of new or uncontrolled pain should be determined and addressed by disease-modifying treatments and a gradual increase in the opioid dose until either pain control

TABLE 43.11

LONG-ACTING ORAL AND TRANSDERMAL OPIOIDS USED IN THE TREATMENT OF CANCER PAIN

Opioid	Dosing and administration	Pharmacokinetics	Most common adverse events	Comments
Hydrocodone IR	5–10 mg q4–6h	T_{max} = 1.3 h; $t_{½}$ = 3.8 h	Light-headedness, dizziness, sedation, nausea	When combined with aspirin or acetaminophen, impose a dosage ceiling
Meperidine IR	50–150 mg q3–4h	Duration of action shorter than morphine	Light-headedness, dizziness, sedation, nausea	Infrequently prescribed for long-term use
Morphine IR	5–30 mg q4h	T_{max} = 1.3 h	Constipation, light-headedness, dizziness	Useful for initial dose titration and for BTP
Morphine ER	Based on dose of morphine IR; administered q12h	$t_{½}$ = 2–4 h	Constipation, light-headedness, dizziness	Available in different preparations (Ms Contin, Oramorph, Kadian, Avinza)
Oxycodone IR	5–10 mg q6h	T_{max} = 1.6 h; $t_{½}$ = 3.5 h	Drowsiness, light-headedness, nausea	Useful for initial dose titration and for BTP; if compounded with aspirin or acetaminophen, may impose a dosage ceiling
Oxycodone CR	Based on dose of oxycodone IR or previous opioid; administered q12h	$t_{½}$ = 4.5 h	Constipation, nausea, somnolence	Immediate release component (approx. 30% of total dose); equianalgesic dose ratio to oxymorphone ER is 2:1
Oxymorphone IR	5–10 mg q4–6h	T_{max} = 0.5 h	Nausea, dizziness	Useful for initial dose titration and for BTP
Oxymorphone ER	Based on dose of oxymorphone IR or previous opioid; administered q12h	T_{max} = 5 h; $t_{½}$ = 9–10 h	Nausea, dizziness	Dose and dose interval should be adjusted according to patient needs; little need for rescue medication in clinical trials
Transdermal fentanyl	One patch applied to skin q72h	T_{max} = 34–38 h	Nausea, vomiting	Useful for patients with GI dysfunction; poor adhesion to skin may limit use in some patients

is achieved or intolerable and unmanageable adverse effects supervene. The management of pain with opioid analgesics demands frequent patient assessment and a readiness to re-evaluate the therapeutic plan in the setting of either inadequate relief or adverse effects.

There is no single optimal or maximal dose of an opioid analgesic drug. In general, for progressive, tumor-related pain, the appropriate dose of an opioid is one that relieves a patient's pain throughout the dosing interval without causing unmanageable or intolerable adverse events.[66] The initial dose may be based on the severity of pain and known response to prior analgesic therapy, if any.[67] Aggressive upward titration to a stable dose (i.e., one that provides adequate pain relief throughout the dosing interval) is predicated on continuing assessment of the effectiveness of therapy. Patients rarely benefit from combinations of opioids given in suboptimal doses; ideally, clinicians should prescribe a single opioid analgesic and titrate to a stable dose.[67] However, it is important to recognize that there is significant interpatient variability with regard to responsiveness to different opioid drugs, and patients who respond poorly to one opioid may respond favorably to another.[68] In situations in which pain is not related to the tumor or its treatment, a dose limit should be considered.[69]

Hanks et al.[67] reported on the recommendations of the European Association for Palliative Care (EAPC) on the use of morphine and alternative opioids in cancer pain. These recommendations provide practical strategies for dealing with difficult situations (Table 43.12).

Tolerance and Hyperalgesia

Opioid tolerance is a phenomenon in which repeated exposure to an opioid results in decreased therapeutic effect of the drug or need for a higher dose to maintain the same effect. Prolonged use of opioids is known to result in antinociceptive tolerance, in which higher doses of the opioid are required to elicit the same amount of pain relief or antinociception.[70,71] In practice, physical dependence and tolerance do not prevent the effective use of these drugs in patients with cancer pain. The evidence for the development of tolerance to the analgesic effects of opioids with chronic administration has been mixed. Many of the studies were in cancer patients with severe pain and showed that they maintained a stable opioid dose (for weeks to years) even with different routes of administration.[72,73] Patients with stable disease often remain on a stable dose for weeks or months.[74] Collin et al.[75] demonstrated a relationship between tumor progression and escalation of opioid doses over time such that the development of opioid tolerance as a result of chronic opioid use was unlikely in cancer patients with pain. Although it is generally agreed that tolerance to the analgesic properties of opioids occurs in patients with malignant pain, dose escalation is thought to be mostly a result of disease progression rather than the development of pharmacodynamic tolerance.

Animal studies and anecdotal reports in humans suggest that high-dose opioid exposure can paradoxically induce hyperalgesic

TABLE 43.12

MORPHINE AND ALTERNATIVE OPIOIDS IN CANCER PAIN

1. The opioid of first choice for moderate to severe cancer pain is morphine. **C**
2. The optimal route of administration of morphine is by mouth. Ideally, two types of formulation are required: normal release (for dose titration) and modified release (for maintenance treatment). **C**
3. The simplest method of dose titration is with a dose of normal-release morphine given every 4 hours and the same dose for BTP. This ‘‘rescue’’ dose may be given as often as required (up to hourly) and the total daily dose of morphine should be reviewed daily. The regular dose can then be adjusted to take into account the total amount of rescue morphine. **C**
4. If pain returns consistently before the next regular dose is due the regular dose should be increased. In general, normal release morphine does not need to be given more often than every 4 hours and modified release morphine more often than 12 or 24 hours (according to the intended duration of the formulation). Patients stabilized on regular oral morphine require continued access to a rescue dose to treat BTP. **A**
5. Several countries do not have a normal release formulation of morphine, though such a formulation is necessary for optimal pain management. A different strategy is needed if treatment is started with modified release morphine. Changes to the regular dose should not be made more frequently than every 48 hours, which means that the dose titration phase will be prolonged. **C**
6. For patients receiving normal release morphine every 4 hours, a double dose at bedtime is a simple and effective way of avoiding being woken by pain. **C**
7. Several modified-release formulations are available. There is no evidence that the 12-hourly formulations (tablets, capsules, or liquids) are substantially different in their duration of effect and relative analgesic potency. The same is true for the 24-hour formulations though there is less evidence to draw on. **A**
8. If patients are unable to take morphine orally, the preferred alternative route is subcutaneous. There is generally no indication for giving morphine intramuscularly for chronic cancer pain because subcutaneous administration is simpler and less painful. **C**
9. The average relative potency ratio of oral morphine to subcutaneous morphine is between 1:2 and 1:3 (i.e., 20–30 mg of morphine by mouth is equianalgesic to 10 mg by subcutaneous injection). **C**
10. In patients requiring continuous parenteral morphine, the preferred method of administration is by subcutaneous infusion. **C**
11. Intravenous infusion of morphine may be preferred in patients:
    1. who already have an in dwelling intravenous line;
    2. with generalized edema;
    3. who develop erythema, soreness, or sterile abscesses with subcutaneous administration;
    4. with coagulation disorders;
    5. with poor peripheral circulation. **C**
12. The average relative potency ratio of oral to intravenous morphine is between 1:2 and 1:3. **A**
13. The buccal, sublingual, and nebulized routes of administration of morphine are not recommended because at the present time there is no evidence of clinical advantage over the conventional routes. **B**
14. OTFC is an effective treatment for BTP in patients stabilized on regular oral morphine or an alternative step 3 opioid. **A**
15. Successful pain management with opioids requires that adequate analgesia be achieved without excessive adverse effects. By these criteria, the application of the WHO and the EAPC guidelines (using morphine as the preferred step 3 opioid) permit effective control of chronic cancer pain in the majority of patients. In a small minority of patients, adequate relief without excessive adverse effects may depend on the use of alternative opioids, spinal administration of analgesics, or nondrug methods of pain control. **B**
16. A small proportion of patients develop intolerable adverse effects with oral morphine (in conjunction with a nonopioid and adjuvant analgesic as appropriate) before achieving adequate pain relief. In such patients, a change to an alternative opioid or a change in the route of administration should be considered. **B**
17. Hydromorphone or oxycodone, if available in both normal-release and modified-release formulations for oral administration, are effective alternatives to oral morphine. **A**
18. Methadone is an effective alternative but may be more complicated to use compared with other opioids because of pronounced interindividual differences in its plasma half-life, relative analgesic potency, and duration of action. Its use by nonspecialist practitioners is not recommended. **C**
19. Transdermal fentanyl is an effective alternative to oral morphine but is best reserved for patients whose opioid requirements are stable. It may have particular advantages for such patients if they are unable to take oral morphine, as an alternative to subcutaneous infusion. **B**
20. Spinal (epidural or intrathecal) administration of opioid analgesics in combination with local anesthetics or clonidine should be considered in patients who derive inadequate analgesia or suffer intolerable adverse effects despite the optimal use of systemic opioids and nonopioids. **B**

Level **A** evidence requires at least one randomized controlled trial as part of a body of literature of overall good quality and consistency addressing the specific recommendation (evidence levels Ia and Ib). Level **B** requires the availability of well-conducted clinical studies but no randomized clinical trials on the topic of recommendation (evidence levels IIa, IIb and III). Level **C** requires evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities. Indicates an absence of directly applicable clinical studies of good quality (evidence level IV). Categories Ia evidence from meta-analysis of randomized controlled trials; Ib evidence from at least one randomized controlled trial; IIa evidence from at least one controlled study without randomization; IIb evidence from at least one other type of quasi-experimental study; III evidence from nonexperimental descriptive studies, such as comparative studies, correlation studies, and case-control studies; IV evidence from expert committee reports or opinions or clinical experience of respected authorities, or both.
(From Hanks GW, Conno F, Cherny N et al. Morphine and alternative opioids in cancer pain: the EAPC recommendations. *Br J Cancer* 2001;84(5):587–593.)

states. Opioids such as morphine have been reported to induce hyperalgesia in humans and animals.[70] In preclinical studies, sustained opiate exposure across multiple days has been shown to reduce sensory thresholds, resulting in hypersensitivity to tactile stimulation (i.e., allodynia) and to noxious thermal stimulation (i.e., hyperalgesia).[76] Opioid-induced hyperalgesia has mostly been observed in cancer patients who receive very high and escalating opioid doses.[77] Morphine has been implicated in virtually all reported cases. Recognition of this phenomenon can be difficult in a clinical setting of cancer pain where multiple factors can confound the picture. Opioid-induced hyperalgesia should be recognized as a syndrome of neuroexcitatory effects, which includes hyperalgesia, allodynia, myoclonus, and seizures, in a setting where patients are administered large doses of systemic morphine or its structural analogues. The predominant symptom of opioid-induced hyperalgesia is severe allodynia (touch-evoked pain) and is often accompanied by myoclonus. Putting a blanket on or gently turning a bedridden patient can evoke excruciating pain. Further dose escalation will exacerbate pain complaints or symptoms. Management strategies for hyperalgesia usually require a reduction in opioid dosage and switching to a different agent, especially one that does not have known toxic metabolites.

Morphine

In a Cochrane review, Wiffen and McQuay[78] reported that oral morphine is an effective analgesic in patients who suffer pain associated with cancer and remains the criterion standard for moderate to severe pain. Oral morphine was shown to be effective over a wide dose range. In this review, it was not possible to demonstrate the superiority of one modified release product over another, either by brand or by length of time release. Some preparations have the practical advantage of a formulation as micro capsules for those who cannot readily swallow tablets. The main disadvantage of morphine in cancer patients who require high opioid doses or who have reduced renal clearance is the accumulation of active (morphine-6-glucuronide) and toxic (morphine-3-glucuronide), which may complicate the clinical picture with excessive sedation or neurotoxic adverse effects. Early signs of these effects should trigger consideration for switching to a different opioid (i.e., opioid rotation).

Oxycodone

Kalso and Vainio[79] administered morphine and oxycodone hydrochloride in a double-blind crossover study to 20 patients who were experiencing severe cancer pain. Morphine caused more nausea than oxycodone and hallucinations occurred only during morphine treatment. Otherwise, no major differences in the side effects between the two opioids were observed. Maddocks et al.[80] reported an attenuation of morphine-induced delirium in cancer patients when changed to oxycodone.

Heiskanen and Kalso[81] compared the steady-state pharmacodynamic profiles of oxycodone and morphine sulfate controlled-release in 27 patients with chronic cancer pain in a double blind, randomized, crossover design. The total opioid consumption ratio of oxycodone to morphine was 2:3 when oxycodone was administered first and 3:4 when oxycodone was administered after morphine. The total incidence of adverse experiences reported by patients was similar, but significantly more vomiting occurred with morphine, whereas constipation was more common with oxycodone. The mean daily dose of oxycodone at the end of titration was 123 mg and that of morphine 180 mg. In this study, the two opioids provided comparable pain relief. Reid et al.[82] evaluated the efficacy and tolerability of oxycodone in cancer-related pain in a systematic review of randomized controlled trials. The authors found no clinically important differences between the analgesic efficacy and the adverse effect profile of oxycodone compared with morphine. In essence, the efficacy and tolerability of oxycodone was similar to morphine, supporting its use as an opioid for cancer-related pain.

Oxymorphone

Sloan et al.[83] compared oxymorphone ER and oxycodone CR in patients ($n = 86$) with moderate to severe cancer pain. Patients were first stabilized for 3 days or longer on morphine CR or oxycodone CR. Those who attained stable pain relief for at least 3 days (three or fewer rescue doses of opioid per day) entered the first 7-day treatment period (period 1) at the stabilized dose of the titrated medication with no dosage adjustments. All patients who were treated for 7 days at their stabilized dose of either morphine CR or oxycodone CR were then crossed over to oxymorphone ER at an estimated equianalgesic dosage and treated for an additional 7 days (period 2). During periods 1 and 2, the oral IR formulation of the study medication was available as rescue medication. Each dose of rescue medication was approximately 10% of the total daily dose of scheduled medication. Similar daily pain intensity scores during the last 2 days of the initial treatment phase (morphine CR or oxycodone CR) compared with those during the last 2 days of the oxymorphone ER treatment phase indicate that equivalent analgesia was achieved after patients had been rotated to oxymorphone ER. This also suggests that the long-acting formulation can maintain drug levels in a stable fashion. Patients taking oxymorphone ER needed less breakthrough medication than patients taking morphine CR. The tolerability/safety profiles (e.g., nausea, drowsiness, and somnolence) were similar between the two drugs. There were no significant differences in daily pain intensity scores between oxymorphone ER and either morphine or oxycodone.

Hydromorphone

Hydromorphone is only available in an unmodified (i.e., IR) form. The short elimination half-life of hydromorphone necessitates at least 4-hourly administration of the drug to maintain adequate plasma levels for patients with chronic cancer pain. Therefore, its utility in cancer patients with continuous (baseline) pain is mostly in the treatment of BTP.

Methadone

Methadone is well absorbed by all routes, making it a versatile agent for cancer pain control. It has no known active metabolites and it is relatively inexpensive compared with other modified release opioid formulations. Other advantages include possibly enhanced pain relief from incomplete cross-tolerance with the potential to control pain no longer responsive to other mu-opioid receptor agonist drugs.[84–87] However, this property, along with its highly variable elimination half-life, make it a more complicated drug to use, with great potential for accidental overdose if not titrated appropriately. Prescribers must know the pharmacology of methadone very well, and patients need to be carefully counseled and cautioned to use methadone only as directed in order to prevent unintended dose accumulation.

Concomitant administration of CYP3A4 inducers will increase methadone metabolism, potentially causing a reduction in methadone plasma concentrations. This may result in the need for larger doses of methadone during the period of interaction. In addition, doses of methadone may need to be reduced when a CYP3A4 inducer is discontinued. Known inducers of CYP3A4 include rifampin, rifabutin, carbamazepine, phenytoin, phenobarbital, and abacavir. The commonly used dietary supplement

for depression, St. John's Wort, has also been shown to lower the plasma concentrations of methadone.[88] Many methadone-related deaths may be due to drug interactions rather than administration of methadone alone.[89] Drugs that potentially interact with methadone include inhibitors of CYP3A4 and CYP2D6. Drugs that inhibit CYP3A4 include fluconazole, fluvoxamine, fluoxetine, paroxetine, HIV-1 protease inhibitors, and likely erythromycin and ketoconazole. In addition to CYP3A4 inhibitors affecting methadone's clearance, methadone itself acts as a CYP3A4 inhibitor and therefore has the potential to interact with other CYP3A4 substrates.[90]

Bruera et al.[91] compared the effectiveness and side effects of methadone and morphine as first-line treatment with opioids for cancer pain. Over a 4-week period, patients were randomly assigned to receive methadone (7.5 mg orally every 12 hours and 5 mg every 4 hours as needed) or morphine (15 mg sustained release every 12 hours and 5 mg every 4 hours as needed). A total of 103 patients were randomly assigned to treatment (49 in the methadone group and 54 in the morphine group). The groups had similar baseline scores for pain, sedation, nausea, confusion, and constipation. Patients receiving methadone had more opioid-related dropouts (11 of 49; 22%) than those receiving morphine (3 of 54; 6%; $p = 0.019$). The opioid escalation index at days 14 and 28 was similar between the two groups. More than three fourths of patients in each group reported a 20% or more reduction in pain intensity by day 8. The proportion of patients with a 20% or more improvement in pain at 4 weeks in the methadone group was 0.49 (95% CI, 0.34 to 0.64) and was similar in the morphine group (0.56; 95% CI, 0.41 to 0.70). The rates of patient-reported global benefit were nearly identical to the pain response rates and did not differ between the treatment groups. The authors concluded that methadone did not produce superior analgesic efficiency or overall tolerability at 4 weeks compared with morphine as a first-line strong opioid for the treatment of cancer pain.

In a Cochrane review, Nicholson[92] concluded that methadone was no more effective than morphine for cancer-related neuropathic pain and that methadone had a similar side effect profile, but these side effects may be more apparent with repeated dosing. For all these reasons, methadone is not recommended as a first-line opioid for cancer pain treatment.

Levorphanol

Like methadone, drug accumulation may follow initiation of therapy or dose escalation. Guidelines similar to those suggested for methadone may prove helpful for managing the patient requiring high doses of levorphanol.

Fentanyl

Transdermal Fentanyl

Transdermal therapeutic system fentanyl (TTS-fentanyl) patches are rectangular transparent units each comprising a protective liner and four functional layers. These layers consist of a backing layer of polyester film, a drug reservoir of fentanyl and alcohol USP gelled with hydroxyethyl cellulose, an ethylene-vinyl acetate copolymer membrane that controls the rate of fentanyl delivery to the skin surface, and a fentanyl containing silicone adhesive. The amount of fentanyl released from each system per hour is proportional to the surface area (25 mcg/hour per 10 cm^2).

The transdermal system releases fentanyl from the reservoir at a nearly constant amount per unit time. The concentration gradient existing between the saturated solution of drug in the reservoir and the lower concentration in the skin drives drug release. Fentanyl moves in the direction of the lower concentration at a rate determined by the copolymer release membrane and the diffusion of fentanyl through the skin layers. While the actual rate of fentanyl delivery to the skin varies over the application period, each system is labeled with a nominal flux, which represents the average amount of drug delivered to the systemic circulation per hour across average skin. While there is variation in dose delivered among patients, the nominal flux of the systems is sufficiently accurate to allow individual titration of dosage for a given patient.

Following patch application, the skin under the system absorbs fentanyl, and a depot of fentanyl concentrates in the upper skin layers. Fentanyl then becomes available to the systemic circulation. There is a lag time of approximately 2 hours before clinically useful systemic levels of drug are achieved after applying the patch.[93] Serum fentanyl concentrations increase gradually following application, generally leveling off between 12 and 24 hours. The system delivers fentanyl continuously for up to 72 hours. After sequential 48- or 72-hour applications, patients reach and maintain steady state serum concentrations that are determined by individual variation in skin permeability and body clearance of fentanyl. A number of studies demonstrate that constant serum levels are maintained with the second transdermal system and that fluctuations of serum levels are small after the first 72 hours.[94,95]

After system removal, serum fentanyl concentrations decline gradually, falling about 50% in approximately 17 hours (range 13–22). Because of the possibility of temperature-dependent increases in fentanyl release from the system, it is important to advise patients to avoid exposing the application site to direct external heat sources, such as heating pads, heat lamps, and heated waterbeds. Prolonged exposure to heat or use in patients who are febrile can cause a toxic overdose.[96] Inter- and intraindividual variability in TTS-fentanyl absorption was reported in cancer pain patients over a 6-month period.[97] The intraindividual variability ranged from 2.8% to 75.1%. The bioavailability of fentanyl was statistically different according to patient age with patients >75 years of age absorbing 50% of the fentanyl during the selected 72-hour period and patients <65 years absorbing 66%. In spite of this variability, pain relief was reported as good to excellent in the majority of patients.

TTS-fentanyl offers the advantage of providing continuous administration of a potent opioid in the absence of needles and expensive drug-infusion pumps for the treatment of cancer pain. Several studies have investigated the management of cancer pain with TTS-fentanyl.[98–106] Pharmacokinetic studies indicate a relative steady state ("pseudo steady state") 15 hours[107] and 16–20 hours after application of the patch,[108] suggesting the possibility of early titration with TTS-fentanyl at 24-hour intervals. The long-term efficacy of TTS-fentanyl was evaluated in 51 cancer patients by Donner et al.[99] Seventy-five percent of patients had metastases. Patients used TTS-fentanyl for an average of 158 days (range, 15–855 days). Seventy-three percent of patients received treatment for a period of 3 to 12 months. The investigators discontinued TTS-fentanyl in 16% of patients because of insufficient pain relief. In these patients, the last TTS-fentanyl dosage was a mean of 233.3 mcg/hour (range, 25–700 mcg/hour). In addition, 4 patients returned to oral morphine therapy. At the start of therapy, patients needed 69.5 mcg/hour TTS-fentanyl (25–250 mcg/hour). At the end of therapy, the dosage was 167.7 mcg/hour (25–1000 mcg/hour). Most patients changed patches every 3 days, but 24% of patients required more frequent changing (varying from 48–60 hours). Pain relief was good throughout the study. Only 15% of patients did not require additional oral opioid (liquid morphine). Constipation decreased during the transdermal therapy. At the end of the study, 70% of therapy days were free of constipation. In addition, the need for laxatives decreased during therapy.

Payne et al.[104] compared pain-related treatment satisfaction, patient-perceived side effects, functioning, and well-being in 504

patients with advanced cancer who received either TTS-fentanyl or sustained-release oral forms of morphine. The mean dose of fentanyl was 84.4 mcg/hour (range, 25–400 mcg/hour). For those who received morphine, the mean 24-hour dose was 195 mg (range, 15–3000 mg). There were no significant differences between measures of pain intensity and sleep adequacy. However, patients who received TTS-fentanyl were more satisfied with their pain medication than those who received oral morphine. Patients receiving fentanyl also experienced a significantly lower frequency and impact of pain medication side effects. However, because assessment of side effects was global in nature, the investigators could not distinguish between the frequency and/or impact of individual, particular side effects. Gourlay[109] reported that open comparative studies against sustained-release formulations of morphine (morphine sulfate controlled-release, morphine sustained-release) suggest essentially equivalent effects for analgesia, measures of QOL, physical functioning, and adverse effects, except for a lower frequency of constipation and/or use of laxatives with transdermal fentanyl.

The most common formulation-unique side effects are as a consequence of the adhesive used to attach the systems to the skin and include erythema, itching, and occasional pustule formation (>1%) with an overall frequency of cutaneous side effects of approximately 10%.[109] The TTS-fentanyl system may be considered a first-line treatment modality for moderate to severe cancer pain. Appropriately used and titrated, pain control appears satisfactory with apparent high levels of patient satisfaction. In situations where compliance may be a problem, the system may have particular advantages. In addition, the system may be considered for patients who are unable to take medications by mouth.

Oral Transmucosal Fentanyl

The FDA has approved the use of transmucosal fentanyl for the management of procedure-associated pain and for the management of BTP in cancer patients. The main clinical application for this preparation is for breakthrough and incident pain in the cancer patient.[110]

Oral transmucosal fentanyl citrate (OTFC) units consist of a lozenge with a handle and are of uniform size and shape. Product manufacture involves dissolving fentanyl in a sucrose solution, pouring it into a mold, and allowing it to harden on a handle. Fentanyl is compounded in a hardened matrix form on a stick. The lozenge is available in a variety of strengths including 200, 400, 800, 1200, and 1600 mcg. In the mouth, the unit dissolves in saliva: a portion of the fentanyl diffuses across the oral mucosa, and the patient swallows the rest, which is partially absorbed in the stomach and intestine. Patients must smear the lozenge on either the buccal mucosa or under the tongue and not swallow. Smearing avoids first-pass metabolism in the liver while swallowing does not. Ideally, the lozenge should be consumed within a 15-minute period. Onset of action is very rapid (5–15 minutes). Peak analgesic effect is 20–30 minutes and duration is approximately 2 hours. Of the total available dose, 25% is absorbed transmucosally over a 15-minute period, and an additional 25% is absorbed through the gastric mucosa during the next 90 minutes.[111] Potential advantages of this drug delivery system include rapid onset analgesia, transmucosal absorption (i.e., no need to swallow), easily titrated, and ease of use. Of note, the dose of OTFC required to control BTP is not predicted by the ATC opioid dose.[112] Consequently, each patient should be titrated to a dose that is effective for control of BTP.

Farrar et al.[113] evaluated the effect of OTFC for BTP in a double-blind, randomized trial of 130 patients. All subjects started on the lowest dose of OTFC (200 mcg) and then titrated to an effective dose for BTP up to the maximum available dose (1600 mcg) over a 2-week period. All subjects who were able to achieve adequate relief with OTFC advanced to the double-blind phase, which was designed as a 10-period crossover. In this phase, each subject received a box of 10 sequentially numbered units. Of the 10 units, seven contained fentanyl at the same dose found effective for that patient during the titration phase and three were placebo units. Instructions told patients to consume the total dose in 15 minutes and to take rescue medication after 30 minutes for inadequate pain relief. The pain types treated in the study included somatic (53%), visceral (31%), neuropathic (15%), and unknown (1%). Of the original 130 patients, 93 completed the open-label titration phase and 37 did not. Twenty patients did not complete the full 10 doses of the double-blinded phase. Eighty-six patients were included for efficacy comparisons; 6 were not because of protocol violations. In these patients, patients receiving placebo required significantly more additional rescue medication than those treated with active drug (34% vs. 15%). OTFC produced significantly larger changes in pain intensity and better pain relief than placebo at all time points (two sided $p < 0.0001$). The most frequent opioid-related adverse events reported as possibly related to OTFC were dizziness (17%), nausea (14%), somnolence (8%), constipation (5%), asthenia (5%), confusion (4%), vomiting (3%), and pruritus (3%).

OTFC was compared with morphine sulphate instant release (MSIR) for management of BTP in 134 cancer patients receiving a fixed scheduled opioid regimen in a double-blind, double-dummy, randomized, multiple crossover study.[114] OTFC was more effective than MSIR in treating BTP in terms of pain intensity, pain relief, and global performance of medication scores. In a Cochrane review, Zeppetella[115] concluded that OTFC was an effective treatment in the management of BTP.

Buccal Fentanyl

The fentanyl buccal tablet (FBT) incorporates a novel drug delivery platform, OraVescent technology (Cephalon Inc., Fraser, PA), which employs an effervescence-type reaction to enhance fentanyl absorption through the buccal mucosa and facilitate rapid systemic exposure to the analgesic. Transient pH changes accompany the effervescence reaction and increase both the rate of tablet dissolution (at a lower pH) and membrane permeation (at a higher pH) of fentanyl.[116] In a previous study of the bioavailability and pharmacokinetics of FBT compared with OTFC, a larger proportion of FBT was absorbed transmucosally (48%) compared with OTFC (22%) and T_{max} was earlier after administration of FBT (47 minutes) than OTFC (91 minutes).[117] Portenoy et al.,[118] in a randomized placebo-controlled study of FBT in patients with cancer pain, found that mean measures of the analgesic effect of buccal fentanyl separated from placebo as early as 15 minutes after administration and the extent of separation increased up to and including the 60-minute time point. A clinically significant reduction in pain intensity occurred by 15 minutes in 13% of episodes treated with fentanyl; by 30 minutes, this level of response was observed in 48% of episodes. Pain intensity decreased from a mean of 6.9 at baseline to 4.6 at 30 minutes. More recently, Slatkin et al.[119] found that most patients with cancer-related BTP experienced meaningful pain relief 10 minutes after applying FBT.

Currently, only FBT and OTFC are approved by the FDA for the management of BTP in opioid-tolerant cancer patients.

Buprenorphine

A multicenter, open-labeled, uncontrolled, prospective, observational clinical practice study involving 1223 patients with moderate to severe chronic pain demonstrated that transdermal buprenorphine was effective in alleviating cancer and noncancer pain and was overall well tolerated.[120] These patients also experienced significant improvement ($p < 0.001$) in QOL scores and reported very good to good pain relief ($p < 0.001$). The transdermal formulation of buprenorphine is not yet available in the United States.

Hydrocodone

Pure hydrocodone tablets or capsules are not available in the United States, nor is a modified release (long-acting) formulation, as of yet. It is important not to exceed toxic doses of acetaminophen or NSAID when prescribing the combination hydrocodone medications for intermittent or BTP, particularly when the patient is using other acetaminophen or NSAIDs containing drugs.

Codeine/Dihydrocodeine

The value of codeine is limited in cancer pain management by the increasing incidence of side effects at doses above 1.5 mg per kilogram of body weight.[23,121] Codeine is metabolized by CYP2D6 to morphine.[122] Patients with a deficiency of CYP2D6 enzymes or those taking inhibitors of CYP2D6, such as quinidine, cimetidine, or fluoxetine, may not be able to convert codeine into morphine and therefore may get little or no analgesic effect from codeine.[123–125]

Dihydrocodeine is an equianalgesic codeine analogue. Dihydrocodeine has active metabolites (dihydromorphine and dihydromorphine-6-glucuronide).[126] In the United States, it is available only in combination with acetaminophen or aspirin. Brands available include DHC Plus (16 and 32 mg), Panlor SS (32 mg), ZerLor (32 mg), Panlor DC (16 mg), and Synalgos DC (16 mg). Duration of effect is approximately 6 hours. When taken in higher than normal initial therapeutic doses, dihydrocodeine tends to produce euphoria.

Tramadol

Wilder-Smith et al.[127] compared the analgesic efficacy of tramadol (a dual mechanism drug with weak opioid agonist and monoamine reuptake inhibition activity) and morphine in 20 cancer patients. After 4 days, the mean daily doses were 101 +/− 58 mg of morphine and 375 +/− 135 mg of tramadol, indicating a relative potency of 4:1 with oral dosing. Side effects such as nausea and constipation were less with tramadol, but pain control was less satisfactory. Leppert and Luczak[128] reviewed the role of tramadol in cancer pain management. Overall, patients with cancer who are most likely to benefit from tramadol appear to be those with mild-to-moderate pain not relieved by acetaminophen who cannot tolerate NSAIDs and wish to avoid taking more potent opioids. In addition, tramadol also appears to have a role in reducing opioid requirements when combined with other opioids.[129]

Opioids Not Recommended for Routine Use in Cancer Pain Control

There are several opioids that should be avoided in cancer pain management, including meperidine, pentazocine, butorphanol, dezocine, and nalbuphine. Meperidine has a short half-life and its metabolite, normeperidine, is toxic.[130] Mixed agonist-antagonists such as pentazocine, butorphanol, dezocine, and nalbuphine present other problems. Although these agonist-antagonists are often classified as a kappa receptor agonist and a mu receptor antagonist, they are more accurately described as a partial agonist at both kappa and mu receptors. These agents have a low maximal efficacy and have the potential to reverse mu-receptor analgesia, and even precipitate a physical-withdrawal syndrome when taken by patients already receiving full agonists such as morphine.[131] In addition, agonist-antagonist opioids have a ceiling effect.[131,132] Propoxyphene is a poor choice for routine use because of its long half-life and the risk of accumulation of norpropoxyphene, a toxic metabolite.[133]

Long-Term Use of Opioids

Most patients with cancer are living well past 5 years after diagnosis, and many are returning to the workforce after treatment.[134] As patients live longer with cancer, concern is growing about both the health-related QOL of those diagnosed with cancer and the quality of care they receive. Cancer care progresses through stages including diagnosis, treatment, survivorship, and sometimes end-of-life care. Among the most common symptoms of cancer and treatments for cancer are pain, depression, and fatigue.[135] These symptoms may persist or appear after treatment ends.

The optimal use of opioids for long-term use in patients without active cancer should follow standard guidelines for chronic pain.[1] Posttreatment pain syndromes may evolve differently than other noncancer chronic pain syndromes, and new pain problems carry the emotional weight of possible recurrent disease. Therefore, patients in remission or putative cure who have chronic pain conditions need to be followed up with regular visits, immediate evaluation of new pain or progressive complaints, and a differential diagnosis of dose escalation that includes recurrent disease.

Opioid-Related Side Effects

Prevention or Minimizing Opioid-Related Side Effects

Appropriate dosing of opioids requires minimizing or preventing opioid-related side effects. For patients with constant pain, the early use of a long-acting opioid in preference to short-acting opioids as soon as dose titration permits may help attenuate side effects. If side effects are significant, the clinician should allow time for tolerance to develop. This may require a period of 3 to 7 days. Protecting the patient from severe side effects during this period is appropriate and will not prevent tolerance development. For example, a patient with nausea could benefit from a 1-week course of antiemetic medication at the outset of opioid therapy.

If side effects do not diminish satisfactorily over time, there are two alternatives: changing drugs and introducing supplementary medications that control the side effects. Changing from one opioid to another may enhance pain relief and reduce opioid-related side effects, particularly if incomplete cross tolerance to opioid effect is experienced.[136–140] In some cases, changing the route of administration for a particular drug, such as morphine, may eliminate certain difficult side effects.[141] It is possible to alleviate many of the most difficult side effects pharmacologically when necessary. For example, administering methylphenidate can help protect the cognitive functioning of patients using high doses of opioids.[142,143] Table 43.13 lists side effects and their treatments.

In cancer patients, certain pathophysiologic conditions commonly contribute to side effect problems or masquerade as side effect problems. For example, renal insufficiency in patients using morphine can lead to accumulation of M6G, which in turn can exacerbate side effects. Nausea is a frequent opioid toxicity, but it has other potential causes: gastric irritation, constipation or other changes in gut motility, chemotherapy, or hypercalcemia induced by bone metastases. Similarly, sedation and confusion may accompany opioid use, but other potential causes in the cancer patient, such as raised intracranial pressure, metabolic disturbances (e.g., hypercalcemia), sepsis, or concomitant drug use, merit consideration. Opioid-induced changes in mental status become less probable when the patient has been on a stable dose without recent significant dose escalation.

Opioid-induced bowel dysfunction is addressed above.

TABLE 43.13

PHARMACOLOGICAL TREATMENTS FOR OPIOID-RELATED SIDE EFFECTS

Side effect	Treatment
Constipation	Stool softener, laxative, ? opioid rotation
Sedation	Methylphenidate, modafinil
Pruritus	Diphenhydramine, hydroxyzine
Nausea	Prochlorperazine, haloperidol, metoclopramide, ondansetron, antihistamine
Dysphoria	Haloperidol, opioid rotation
Hypnagogic imagery	Haloperidol
Cognitive impairment	Methylphenidate, modafinil, opioid rotation
Respiratory depression	Naloxone
Myoclonus	Clonazepam, dose reduction, opioid rotation

Opioid Effects on Cognition, Motor Skills, and Driving Ability

A major concern that has arisen as long-term opioid therapy becomes accepted for some patients with chronic, moderate to severe pain is the effect of long-term opioid use on cognition and motor skills[144] such as driving.[145] Results have been inconsistent regarding decrements in cognitive performance. Patients with chronic pain who have been using opioids for more than 3 days exhibit relatively few differences when cognitive performance is compared with performance before taking opioids or with that of a comparable patient population not taking opioids.[146] The majority of research has revealed that the greatest potential impairment in cognitive function from opioids occurs during the first several days of use. During longer periods, impairment has been demonstrated primarily in studies that have compared patients with significant pain with healthy volunteers. The negative effects of opioids on cognition may be balanced by enhanced cognitive function with the relief of pain.[146] Questions still remain concerning the mechanisms responsible for opioid-induced cognitive impairment, interpatient variability with regard to opioid-related cognitive impairment, and the identification of predictors for cognitive impairment in patients receiving long-term opioid therapy.

The effects of opioid use specifically on driving ability has become a contentious issue, predictably because a growing number of patients are taking opioids and driving, and also because insurers may seek to assign liability in cases of motor vehicle accidents involving drivers who use opioids. Vainio et al.[147] examined the effects of continuous morphine medication on the driving ability of cancer patients. They conducted psychologic and neurologic tests, originally designed for professional motor vehicle drivers, in two groups of cancer patients who were similar apart from their experience of pain. Twenty-four patients received continuous morphine (mean 209-mg oral morphine daily) for cancer pain, and 25 were pain-free without regular analgesics. Though the results were a little worse in the patients taking morphine, there were no significant differences between the groups in intelligence, vigilance, concentration, fluency of motor reactions, or division of attention. Of the neural function tests, reaction times (auditory, visual, associative), thermal discrimination, and body sway with eyes open were similar in the two groups; only balancing ability with closed eyes was worse in the morphine group. These results indicate that, in cancer patients receiving long-term morphine treatment with stable doses, morphine has only a slight and selective effect on functions related to driving.

Galski et al.[148] published a structured, evidence-based review on the issue of opioids and driving. Overall, the majority of studies in the evidence-based review appeared to indicate that patients who use opioids are not impaired by the opioids with regard to driving ability. Byas-Smith et al.[149] reported that many patients with chronic pain, even if treated with potent analgesics such as morphine and hydromorphone at equivalent average daily morphine doses of 118 mg, showed comparable driving ability to normal subjects.

Clearly, opioids may affect cognitive function and impair driving ability in patients who are opioid-naive or in patients who are not on stable opioid regimens. Whether some degree of cognitive tolerance develops with chronic opioid use is unknown. Other unresolved questions include the effects of different types of opioids, dose effects, and interactions with other medications on driving ability. Each of these areas deserves further study, and clinicians need to counsel patients about potentially dangerous activities on a case-by-case basis.

Some helpful guidelines are provided regarding opioid medications and driving (Table 43.14).

Opioids can cause or exacerbate confusion and these effects may range from mild impairment in concentration to frank delirium with disorientation, disorganized thinking, perceptual distortions, and hallucinations. Opioid-induced hallucinations are thought to be caused by sigma receptor activation, and they can occur in the context of intact cognitive function.[150] When this problem occurs, it is important to consider other causes of altered mental status in cancer patients (e.g., other treatments, metabolic alterations, infection, and brain metastasis). When a confusional state is due to opioids, it generally follows a recent increase in dose and will usually resolve with tolerance or as the dose is reduced. Rapid discontinuation of the opioid will result in severe pain, withdrawal symptoms, and possible exacerbation of confusion; it should be avoided. Dysphoria is probably more common than euphoria following opioid administration in patients with cancer.

Use of psychostimulants (e.g., methylphenidate, modafinil) has been reported to be helpful in overcoming daytime drowsiness and mental clouding, but their use must be monitored carefully, both for adverse effects and overuse.[151]

Opioid Rotation in Cancer Pain

Opioid rotation refers to the practice of converting from one opioid to a second when the opioid analgesic response is inadequate and/or if opioid-related adverse events are intolerable or unmanageable.[152,153] Reasons for initiating opioid rotation are listed in Table 43.15. In cancer patients, the most common reasons for opioid rotation are intolerable side effects such as cognitive failure, hallucinations, myoclonus, nausea, and uncontrollable pain.[137,154]

In all cases of opioid rotation, patients must be followed up closely to assess the adequacy of pain relief and the effect on opioid-related adverse events. As with any opioid regimen, subsequent dose adjustments will probably be necessary. Use of opioid rotation requires familiarity with a range of opioids and with the use of equianalgesic dose tables (see Chapter 78). However, it is also important to consider that the evidence to support dose ratios in standard equianalgesic tables refers largely to the context of single-dose administration; they do not necessarily reflect the clinical realities of chronic opioid administration in the treatment of cancer pain with repeated dosing of opioids. Thus, the doses shown in most standard equianalgesic dose tables may not be

TABLE 43.14

DRIVING INSTRUCTIONS FOR PATIENTS TAKING OPIOIDS

Opioid medications can cause side effects that impair your ability to drive. The final decision on whether you should drive while using opioid medications is a legal issue and should be addressed with your automobile insurance carrier. Out of concern for your safety and the safety of others, please observe the following guidelines:

- Do not drive for 4–5 days after beginning opioid treatment or after a change in opioid treatment such as a dose increase.
- Do not drive if you ever feel sedated or cognitively impaired.
- Report sedation/unsteadiness/cognitive decline to our office as soon as possible.
- Under no circumstances should you use alcohol or illicit drugs such as cannabis (marijuana) and drive.
- Avoid taking over-the-counter antihistamines, as contained in numerous cold and allergy medications.
- Do not make any changes in your medication regimen without consulting our office.

Patient Signature: _____ Date: _____

Practitioner Signature: _____ Date: _____

accurate in patients who have developed tolerance or have been taking opioids for long periods of time. In addition, the phenomenon of incomplete cross-tolerance can lead to unexpected potency in the newly introduced agent.[68]

Special care is required with methadone rotations. The process of switching from a high-dose opioid agonist to methadone is complex and should only be attempted by experienced physicians.[155] Even among experienced physicians, occasional serious toxicity can occur during the administration of methadone.[156] Contrary to expectations, toxicity occurs more frequently in patients previously exposed to high doses of opioids than in patients receiving low doses. Bruera et al.[136] provide some guidelines for the conversion of patients from high-dose oral opioids to oral methadone. They recommend decreasing the previous opioid dose by one third over the first 24 hours and replacing it with methadone using an equianalgesic dose ratio. One mg of oral methadone is equal to 10 mg of oral morphine (i.e., a patient receiving 1000 mg of oral morphine per day will switch to 660 mg of oral morphine per day plus 33 mg of oral methadone during the first day). Administer methadone every 8 hours by the oral route. During the second day, if pain control is adequate, the patient requires a further one third decrease in the dose of the previous opioid. The dose of the methadone should only increase if the patient experiences moderate to severe pain. Manage transient episodes of pain with intermittent rescue doses of short-acting opioids. During day 3, discontinue the final one third of the previous opioid and maintain the patient on regular methadone every 8 hours, plus approximately 10% of the daily methadone dose as an extra dose orally for BTP. Assess pain and methadone requirements frequently until a stable methadone dose is reached. Until the equianalgesic dose ratio of parenteral and oral opioids to methadone is clearly established, patients receiving high doses of oral/parenteral opioids who require conversion to methadone should undergo this conversion only under close supervision and preferably in an inpatient environment. In general, the safe use of methadone to control cancer pain requires meticulous follow-up care and anticipatory downward dose titration.

TABLE 43.15

REASONS FOR UNDERTAKING OPIOID ROTATIONS

1. Reduced ability to control pain due to:
   a. Worsening of existing pain or underlying disease process
   b. Pharmacodynamic factors
   Development of opioid analgesic tolerance
   c. Pharmacokinetic factors
   Drug absorption (inability to swallow oral medications / poor vascular status or edema limiting transdermal delivery)
   Interaction with other drugs
   Changes in protein binding
   Biotransformation and metabolism (accumulation of metabolites)
   Reduced clearance—renal failure
2. Development of intolerable side effects /opioid toxicity
   a. GI (i.e., constipation, nausea, vomiting)
   b. Central nervous system (i.e., sedation, somnolence, dysphoria, hallucinations, myoclonus)
   c. Cardivascular (i.e., orthostatic hypotension due to histamine release)
3. Practical concerns
   a. Dose required to produce analgesia exceeds maximum daily dose (patients taking combination products, e.g., acetaminophen)
   b. Cost of drugs
   c. Drug availability
   d. Need for large volumes of drug to be delivered
   e. Changes in route of administration

Intravenous Opioid Therapy

Parenteral routes should be considered for patients who require rapid onset of analgesia, and for highly tolerant patients who require doses that cannot otherwise be conveniently administered.[157] Intravenous opioids allow for rapid control of pain. Ideally, patients with severe, uncontrolled pain who require intravenous therapy should start treatment in a monitored inpatient setting. High doses of intravenous opioids via patient-controlled analgesia (PCA) and/or by continuous infusion offers a means of rapidly controlling increasing severe pain. Intravenous therapy can employ any of several opioids: morphine, hydromorphone, fentanyl, sufentanil, and methadone.

Coda et al.[158] found differences in efficacy and side effects for morphine, hydromorphone, and sufentanil in bone marrow transplantation patients with severe oral mucositis pain. The pain relief achieved in all three opioid groups was nearly equivalent, while measures of side effects, especially for the combination of sedation, sleep, and mood disturbances, were statistically lower in the morphine group than in hydromorphone or sufentanil groups.

Subcutaneous Opioid Therapy

Continuous subcutaneous infusion of opioids is both an efficacious and safe method to control the chronic pain of the homebound and hospitalized patient.[159–162] Hypothetically, absorption of opioid from the subcutaneous compartment into the systemic circulation should be slow, but it is not, even for morphine.[163] Moulin et al.[164] reported equianalgesic responses in a comparison of intravenous versus subcutaneous infusions of hydromorphone. BTP control was equal in both groups and only occasionally did patients experience undue dermal irritation or recurrent infection. A wide variety of opioids are suitable for subcutaneous infusion: morphine, hydromorphone, methadone, fentanyl, and sufentanil.

Hydromorphone's solubility, its high bioavailability by continuous subcutaneous infusion (78%),[164] and the availability of a high-concentration preparation (10 mg/mL), make it a good choice for subcutaneous infusion. Parenteral hydromorphone is six times as soluble in aqueous solutions as morphine and five times as potent, allowing for smaller injection or infusion volumes in patients who require parenteral opioids.[165]

Continuous subcutaneous infusions offer a safe, simple, effective alternative to intravenous infusion when patients cannot take medications orally. Moulin et al.[164] compared the safety and efficacy of subcutaneous versus intravenous infusion of hydromorphone in cancer patients. Pain intensity, pain relief, mood, and sedation did not differ between the two techniques. The mean bioavailability of hydromorphone from subcutaneous infusion was 78% of that with intravenous infusion. Simplicity, technical advantages, and cost-effectiveness are clear advantages of continuous subcutaneous opioid infusion into the chest wall or trunk. Paix et al.[166] described the successful substitution of subcutaneous fentanyl and sufentanil for morphine, noting the benefits of sufentanil when the patient needs a very high dose of opioid that can be infused in a relatively small volume. Nelson et al.[167] compared continuous intravenous and subcutaneous morphine for chronic cancer pain and concluded that both routes were equianalgesic for most patients when administered as a continuous infusion.

Most patients will require a weekly change of the site of subcutaneous infusion.[161] The usual initial concentrations of morphine and hydromorphone are 5 mg/mL and 1 mg/mL respectively, calculated according to the hourly infusion rate. Ideally, the subcutaneous rate should not exceed 2 mL/hour although some have established considerably higher rates (rates of 20 to 80 mL/hour by adding hyaluronidase to the infusion to promote hypodermoclysis).[168] Due to a longer time to peak plasma levels after bolus injection with subcutaneous use than with intravenous use, the subcutaneous route requires a longer lockout interval (10–15 minute compared to 6–8 minute for the intravenous). PCA doses may equal 25% to 50% of the hourly infusion rate every 10 to 15 minutes as needed. Subcutaneous administration of opioids may prove impractical in patients with generalized edema, who develop erythema, soreness, or sterile abscesses with subcutaneous administration, in patients with coagulation disorders, and in patients with very poor peripheral circulation.

Intracerebroventricular Opioids

Intracerebroventricular (ICV) opioid delivery may be beneficial for highly selected cancer patients who are not obtaining adequate relief or experiencing intolerable side effects via other routes. With neurosurgical consultation, it is possible to deliver opioids directly into cerebral ventricles through ICV catheters from subcutaneous reservoirs. Morphine sulfate, the usual drug, gains a marked increase in potency when delivered ICV as compared to intrathecal or epidural infusion routes, and the ICV route appears to affect supraspinal pathways for analgesia.[169] Daily morphine doses for ICV delivery range from 50–700 mcg/day.[170,171] Generally, an implanted infusion pump, placed subcutaneously in the anterior abdominal wall and connected by subcutaneous tubing to an implanted ventricular catheter, delivers the drug. The duration of pain relief after ICV injections appears to be significantly longer than with intraspinal delivery, and some patients gain adequate relief via an implanted ventricular catheter connected to a subcutaneous Ommaya reservoir-type device with 1 to 2 injections per day.[172] This form of drug delivery is indicated for head and neck cancer pain, or, rarely, for patients with a good initial response to intraspinal infusions of opioids and subsequent development of apparent tolerance, but with limited (1–3 months) remaining survival time. The safety and side effects of ICV injections or infusions resemble those for intraspinal infusions, except that an increased risk of respiratory depression exists the first 3 days of therapy.[172]

Some refractory head and neck pain responds only to ICV opioids, but pain below the waist may be most amenable to spinal treatment. In a meta-analysis of 1587 cancer patients, Ballantyne et al.[173] compared ICV with the more common epidural and intrathecal opioid treatments in an attempt to establish the utility and safety of ICV therapy. All patients considered had intractable cancer pain that proved resistant to systemic treatment. Sedation and confusion occurred in 4% to 5% of patients receiving ICV therapy. Persistent nausea, urinary retention, and pruritus occurred more frequently with the two spinal treatments than with ICV therapy. Initial doses for ICV trial patients were in the range of 0.25 to 2.0 mg. Onset of effect was 2 to 30 minutes, and average duration of pain relief after a single dose was 12 to 48 hours. Tolerance proved less of a problem than with epidural or intrathecal therapy since the dose escalation was very gradual (the average increase in daily dosage was 0.375 mg/month). In a follow-up study, Ballantyne et al.[174] reported on 72 uncontrolled trials assessing ICV (13 trials, 337 patients), epidural catheters (31 trials, 1343 patients), and subarachnoid catheters (28 trials, 722 patients) in cancer patients. Data from these uncontrolled studies reported excellent pain relief among 73% of ICV patients compared with 72% epidural and 62% subarachnoid catheters. Unsatisfactory pain relief was low in all treatment groups. Persistent nausea, persistent and transient urinary retention, transient pruritus, and constipation occurred more frequently with epidural and subarachnoid catheters. Respiratory depression, sedation, and confusion were most common with ICV. The incidence of major infection when pumps were used with epidural and subarachnoid catheters was zero. There was a lower incidence of other complications with ICV therapy than with epidural or subarachnoid catheters.

HOME INFUSION THERAPY

Advances in pain management technology, such as ambulatory PCAs and the use of silicone subcutaneously tunneled neuraxial catheters, have expanded the scope and success of interventional pain management beyond the hospital to the home. Potential benefits of home infusion therapy include decreased health care costs, patient/caregiver convenience, and less time spent in hospital with the ability to extend interventional pain management strategies into the patient's home. A possible disadvantage to home infusion therapy may include the additional burden placed on the patient/caregiver in terms of role responsibilities and schedules. Home care agencies must have explicitly defined poli-

cies and procedures consistent with regulatory bodies and national and regional standards of practice.

A provider of infusion therapy must be a licensed pharmacy or work in conjunction with a licensed pharmacy. Skilled and qualified home nursing services are an essential component of home-based care; they are responsible for educating patients and their caregivers regarding administering the drug therapy, complying with the prescribed dosing schedule, understanding the drug delivery device being used (an infusion pump or other device), and other important information regarding the treatment regimen. Additional roles include monitoring for adverse effects, infection, displacement of catheters, and equipment malfunction.

Drug therapies commonly administered via infusion at home include antibiotics, chemotherapy, analgesics, parenteral nutrition, and immune globulin. Diagnoses commonly requiring infusion therapy include infections that are unresponsive to oral antibiotics, cancer and cancer-related pain, GI diseases or disorders which prevent normal functioning of the GI system, congestive heart failure, immune disorders, growth hormone deficiencies, and more.

Ambulatory infusion pumps are either designed to be therapy-specific, or are multi-purpose, enabling treatments such as chemotherapy, systemic antibiotics, total parenteral nutrition, hydration therapy, and opioid pain control. Recent developments in pump design include remote access capability by modem with the ability to change pump settings and download data.

Home-based PCA therapy provides select patients with the ability to deliver analgesia based on their own perception of need. PCA therapy may be superior to oral analgesia, especially in the treatment of severe oscillating pain. Patient selection criteria include intact cognition and proper supervision from a family member or health professional. A collaborative interdisciplinary approach is necessary for effective pain control for the cancer patient receiving interventional pain management at home. Collaboration between the patient, the patient's family, the home care nurse and home care agency, and the patient's physician is necessary. The physician remains responsible for determining the appropriate drug, bolus dose, background infusion rate, and lockout interval.

PCA is more commonly used in the home setting as an effective option in pain management. As discussed above, the subcutaneous and intravenous routes are the primary methods of administration. The availability of a central vascular access device such as a tunneled or peripherally inserted central catheter offers advantages over peripheral access to ensure safe and consistent administration of intravenous analgesia.

The safety and efficacy of home-based PCA opioid therapy has not been extensively reported as in-hospital use. One study,[175] however, reported on the use of morphine PCA in the home environment of 143 preterminally and terminally ill tumor patients suffering either from excruciating chronic pain or severe chronic/acute complex pain that could not be relieved adequately by oral analgesia. After initial dose adjustment, which lasted 2 to 3 days, the median morphine dose was 93 mg/day (range 12–464 mg/day). This median was 28% lower than the median dose administered orally prior to PCA therapy. During the course of treatment, morphine requirements increased by a median of 2.3 mg/day (range -29 +52 mg/day). Most patients were treated continuously in the home care setting until death; the median duration of treatment was 27 days (range 1–437 days). Terminal morphine demands reached a median of 188 mg/day (range 15–1008 mg/day). The authors concluded that PCA was both safe and effective in the home environment, attaining excellent results in 95 (66%) patients and satisfactory pain relief in 43 (30%). PCA was considered insufficient in five (4%) cases. Side effects, in general, were considered mild: the most common being constipation, fatigue, and nausea.

Although further study is warranted, safe provision of domiciliary interventional pain management requires selection of patients who are able to manage themselves or who have responsible caregivers, effective patient and caregiver education, well-defined policies, and use of experienced and knowledgeable home care agencies and pharmacies.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

Complementary and alternative medicine (CAM) therapies are used widely among cancer patients.[176] These therapies have been used as an alternative to conventional medicine (alternative medicine) and complementary to conventional medicine (complementary medicine). Most cancer patients use CAM with the hope of boosting the immune system, relieving pain, and controlling side effects related to disease or treatment. Only a minority of patients include CAM in the treatment plan with curative intent. Frequently, patients do not discuss CAM therapies with physicians.[177] Mansky and Wallerstedt[178] reported that the CAM domains of mind–body medicine, CAM botanicals, manipulative practices, and energy medicine were widely used as complementary approaches to palliative cancer care and cancer symptom management. In the area of cancer symptom management, auricular acupuncture, therapeutic touch, and hypnosis may help to manage cancer pain. Music therapy, massage, and hypnosis may have an effect on anxiety, and both acupuncture and massage may have a therapeutic role in cancer fatigue. Acupuncture and selected botanicals may reduce chemotherapy-induced nausea and emesis, and hypnosis and guided imagery may be beneficial in anticipatory nausea and vomiting. Transcendental meditation and mindfulness-based stress reduction can play a role in the management of depressed mood and anxiety. Black cohosh and phytoestrogen-rich foods may reduce vasomotor symptoms in postmenopausal women. Although there have been many trials of CAM therapies for cancer pain and a few expert reviews, there is a lack of rigorous systematic review.[179] Furthermore, studies have found that there is considerable variation in the search for CAM studies, making systematic reviews prone to bias.[180] Bardia et al.,[179] in a systematic review of CAM therapies for cancer-related pain, demonstrated a paucity of well-designed, multi-institutional trials. Most trials were of short duration, had small numbers without sample size justification, and did not report the adverse effects of CAM intervention. However, some data existed suggesting that mind–body medicine (hypnosis, imagery, and relaxation) may have some efficacy in decreasing cancer pain. Pan et al.[181] had similar conclusions regarding the role of CAM therapies in the management of pain, dyspnea, and nausea and vomiting in patients near the end of life. The heterogeneity of pain syndromes has made broad sweeping conclusions about the efficacy of acupuncture difficult. A National Institutes of Health consensus conference[182] on the use of acupuncture for pain concluded that while there have been many studies of its potential usefulness, many of these studies provide equivocal results because of design, sample size, and other factors. However, promising results have emerged, for example, showing efficacy of acupuncture in adult postoperative and chemotherapy nausea and vomiting and in postoperative dental pain. There are other situations such as addiction, stroke rehabilitation, headache, menstrual cramps, tennis elbow, fibromyalgia, myofascial pain, osteoarthritis, low back pain, carpal tunnel syndrome, and asthma, in which acupuncture may be useful as an adjunct treatment or an acceptable alternative or be included in a comprehensive management program.

CONCLUSION

Pain control is a high-priority goal of cancer care. As a very common and debilitating component of disease, aggressive treat-

ment of pain to maximize both quality and quantity of the patient's life is an imperative.

Detailed assessment of pain and other QOL concerns is the foundation for successful pain management in the cancer patient. Typically, the pain experience is multidimensional and treatment must address physical, psychological, social, and existential components. Failure to sufficiently understand the etiology of the pain complaint will invariably result in poor pain management. Interdisciplinary collaboration is essential for comprehensive care of the cancer patient. Disciplines and specialties involved in care commonly include pain management specialists, oncologists, surgeons, psychiatrists, psychologists, physical therapists, pharmacists, nurses, and social workers. Aggressive therapy of both cancer and pain are mutually beneficial and are best done by skilled, interdisciplinary teams.

Most patients can attain adequate symptomatic relief of cancer pain using appropriate oral pharmacotherapy. The concurrent use of adjunctive or specialized therapies is sometimes necessary, however, and referral for specialized surgical, anesthetic, or psychologic intervention benefits a significant number of patients. In addition, the growth of the home care industry and hospice has broadened the possibilities of extending basic and sophisticated pain management strategies into the home.

As more patients are cured or go into long-term remission, appropriate provisions for ongoing assessment and management of chronic pain are essential.

CHAPTER 44 ■ INTERVENTIONAL PAIN THERAPIES

SHANE E. BROGAN

INTRODUCTION

The World Health Organization (WHO) analgesic ladder, as described in the previous chapters on cancer pain management, is practical, easy to implement, and has been taught extensively to health professionals. However, even when the WHO approach is implemented appropriately and aggressively, 10% to 20% of patients do not attain acceptable pain control.[1–3] Traditionally, it has been this refractory group of patients that has been considered for interventional pain management, but the approach of reserving interventional management as a last resort has been called into question. This is particularly true in relation to intrathecal (IT) therapy, where a recent multicenter study suggests that early implementation of treatment leads to improved outcomes.[4] Another type of interventional therapy, namely neurolytic celiac plexus block, may be useful as an early intervention in controlling pancreatic cancer pain and other gastrointestinal system pain-producing malignancies.[5] Impediments to the appropriate use of interventional techniques include inaccessibility to experienced interventionalists and absence of up-to-date knowledge among cancer care providers of the various techniques available, including indications and timing, benefits, risks, and costs (Table 44.1).

The primary purpose of this chapter is to target this latter group of individuals. It is anticipated that a general understanding of interventional approaches to cancer pain control will lead to more appropriate and timely consideration of all potential therapeutic options.

INTRATHECAL DRUG THERAPY

IT drug delivery involves drug administration into the cerebrospinal fluid (CSF) through a small catheter. This route allows the medication to circulate in the CSF and adsorb directly onto central nervous system effector sites. This direct delivery to the central nervous system reduces the systemic toxicity of medication administered via enteral, parenteral, or transdermal routes. Opioids, among other pain modulating agents, have been successfully infused intrathecally in the treatment of cancer pain. Effective analgesia using IT opioids is typically obtained using a small fraction (i.e., 1/100th) of the systemic dose. The addition of adjunctive IT agents that have specific activity within the neuraxis, such as local anesthetics and alpha-2 agonists, may be used to improve overall effectiveness of IT opioid therapy in refractory cases.

Indications

IT therapy is usually indicated in the small proportion of cancer patients for whom comprehensive medical management has produced suboptimal pain control or unacceptable, dose-limiting, analgesic-related toxicity. Other factors may make IT therapy an attractive option, including inability to adhere to a more conventional analgesic regimen. Furthermore, cancer pain with a strong neuropathic component (e.g., plexopathy, complex regional pain syndrome) may respond better to IT therapy, particularly when adjunctive agents such as local anesthetics and clonidine are used.[6] In the setting of severe pain and the prospect of a very aggressive chemotherapy regimen, when the oral route will likely be an unreliable means of administering analgesics, strong consideration should be given to adopting an IT approach to pain management.

Some centers adopt an aggressive and early approach to the institution of IT therapy and have demonstrated more favorable outcomes compared to medical management alone. One study used a visual analog scale (VAS, on a 0–10 scale) pain intensity rating of ≥5 despite 200 mg/day or more of oral morphine or its equivalent per day, as their indication to proceed to IT therapy.[4] Patients on lower doses of opioids with moderate to severe pain were also permitted entry if opioid side effects refractory to conservative management prohibited further escalation of total opioid dose. Although the validity of the conclusions of this study has been questioned, the findings open the door to challenge precepts about this form of therapy as a last resort; certain patients may benefit from avoidance of long-term, and especially high-dose, systemic opioid therapy.

Intrathecal Drug Delivery Systems

Simple Percutaneous Intrathecal Catheter

This is a minimally invasive technique that can be done at the bedside for short-term use. It may be implemented as a trial method (i.e., to assess efficacy of IT opioids, with the intent of placing an implantable system if the trial is deemed a success), or it can be used as a definitive method of delivering IT drug when life expectancy is extremely short (i.e., days rather than weeks to months). In the setting of a patient with severe pain and only several days of expected life, this method will allow for rapid control of pain. Because the catheter is not tunneled, infection risk and mechanical failure is higher, markedly reducing successful longer term use.

Tunneled Intrathecal Catheter

Tunneled IT catheters are typically placed in the operating room under sterile conditions. A dorsally-placed catheter is tunneled subcutaneously for a variable distance and usually exits from the lateral abdominal wall. The most common system in use is the silastic DuPen Catheter (Bard Access Systems, Salt Lake City, UT).[7] With appropriate infection control measures, including the use of antimicrobial filters and meticulous exit site care, tunneled IT or epidural catheters can be used for months to years.[8,9] The catheter is usually not sutured internally, so it can be readily removed in the office if necessary. An advantage of the exteriorized system is that non-pain specialist palliative care clinicians, including those in home hospice settings, may become proficient

TABLE 44.1

OVERVIEW OF THE MORE COMMONLY PERFORMED INTERVENTIONAL CANCER PAIN THERAPIES

Intervention	Indications	Major adverse effects and risks	Comments
IT therapy (lumbar region catheter placement; see Chapter 41 for a discussion of intracerebroventricular therapy)	1) Nonhead and neck cancer pain refractory to usual pharmacotherapeutic approaches. 2) The presence of unacceptable medication side effects.	Infection, postdural puncture headache, and spinal cord injury are rare complications. Long-term use of IT opioids may be associated with suppression of the pituitary-gonadal axis.	Various delivery methods available depending on the prognosis. Cost of implanted programmable delivery system may be comparable to conventional medical therapy after several months of ongoing treatment, barring surgical complications.
Neurolytic celiac plexus block	Visceral abdominal (epigastric and referred) pain, originating from disease involving the distal stomach through the transverse colon; pancreatic cancer pain is the most typical indication.	Transient hypotension, diarrhea; very rarely, spinal cord injury.	Efficacy of up to 90% and good safety profile.
Neurolytic superior hypogastric plexus block	Visceral pain originating from the pelvic organs.	Serious adverse effects are rare.	
Spinal neurolysis	Pain refractory to other forms of therapy, particularly when IT therapy is contraindicated or inefficacious.	Dependent on level blocked. Cervical or lumbar neurolysis carries the risk of extremity motor weakness. Lumbosacral neurolysis risks bowel and bladder dysfunction, which is usually transient. Deafferentation pain at any level.	Alcohol or phenol are the typical agents used.
Vertebroplasty and kyphoplasty	Painful compression fracture of the vertebral body without involvement of the spinal canal.	Cement spread to the spinal canal causing neurologic injury; allergy to cement; pulmonary embolus.	Better outcomes are noted with fractures <6 months of age.
Image-guided tumor ablation	Painful bony metastases.	Bone instability and fracture.	Still not in widespread use, but preliminary studies are promising.

in its management with minimal training. Toward the end of life, when analgesic requirements may be rapidly escalating, hospice registered nurses can easily give IT boluses or increase the infusion rate as indicated and alter the drug(s) used with relative ease. With an implanted system (see below), drug changes are more complex than intravenous or oral dosing, and rapid dose titration is not as easily accomplished because of the need for pump reprogramming by trained specialists. Disadvantages of a tunneled system versus a self-contained implanted device are the need for an externalized pump apparatus, increased risk of infection, and the possibility of inadvertent catheter dislodgement or removal.

Implantable Drug Delivery Systems

The implanted drug delivery system (IDDS) uses a small, programmable, computerized electronic pump to deliver drug to the IT space through a catheter (Figs. 44.1 and 44.2). The pump is placed subcutaneously in the anterior abdominal wall and has a reservoir that can be refilled via a port accessed by a specialized needle through the skin. The pump is programmed by an external hand-held device that can alter the rate of infusion and deliver boluses and also allows for a patient-controlled analgesia function. The battery life is typically 5–7 years, so it is unlikely that a replacement would be necessary during the average lifetime of the cancer patient with advanced disease. Drug refills are office-based and minimally uncomfortable. Refills are needed every 1 to 6 months depending on the drug concentration and infusion rate.

Contraindications to an IDDS are generally related to difficulties forming a suitable subcutaneous pocket for the pump, as would be the case in severe ascites, emaciation, skin infection, or other abdominal wall pathology. Patients with systemic infection, concurrent bleeding diathesis, or clotting abnormalities are poor candidates until these abnormalities are corrected or stabilized. Advantages of this system, compared to an exteriorized system, include increased patient freedom of mobility, low maintenance, and low infection risk. Disadvantages are the need for an initially more invasive surgery, high up-front costs, and the logistical problems concerning pump refills and programming. See Table

FIGURE 44.1 Schematic of an IT drug delivery system showing the pump in the anterior abdominal wall, and the catheter tunneled to the dorsal spine and into the IT space (Courtesy of Medtronic, Inc.).

44.2 for a comparison of exteriorized versus implanted pump delivery systems.

Intrathecal versus Epidural Drug Delivery

IT drug delivery has largely replaced the epidural route as the preferred neuraxial route of administration for various reasons. With all neuraxial administration of opioids, the target sites are opioid receptors of the dorsal horn of the spinal cord, which requires either direct CSF delivery or absorption of drug from the epidural space. Compared to IT delivery, epidural infusions require a ten-fold greater volume and dose of opioid in order to diffuse passively across the dura and enter the subarachnoid (IT) space. This large difference in infusion volumes and doses has a major impact both on cost and the frequency of drug reservoir changes, which necessitates breaking the system's sterility more frequently and likely results in a higher infection rate. Furthermore, treatment failure is more frequent with the epidural route, due to inadvertent catheter dislodgement and the development of epidural fibrosis which impedes diffusion of drug to the subarachnoid space.[10] Technical complication rates have been shown to be higher with long-term epidural (55%) compared to IT (5%) infusions.[11]

FIGURE 44.2 IT pump and catheter system. The pump is refilled percutaneously with a needle through the orifice in the center of the device (Courtesy of Medtronic, Inc.).

Notwithstanding these considerations, there remain some specific indications for epidural analgesia. Pain in a pattern involving specific, consecutive dermatomes may be blocked with local anesthetics with an appropriately positioned epidural catheter. An example of this would be a thoracic epidural catheter for isolated thoracic pain caused by rib metastases, in the setting of a short life expectancy. This technique may allow for complete analgesia using local anesthetics alone without the use of epidural opioids.

Implantable or Exteriorized Intrathecal Drug Delivery: Cost Analysis

With an IDDS, the initial costs are relatively high ($15,000–$20,000 USD). Over time, the accruing and total care costs may be less in patients with an IDDS compared to those with an exteriorized system due to greater labor-related costs (including managing mechanical failures) with externalized systems. An older study suggested that, compared to an externalized system, an IDDS will be more cost effective after approximately 3 months of therapy.[12] There are no recent cost comparisons available.

Outcome Studies

A 2002 study by Smith et al.[4] randomized 202 patients with advanced cancer to comprehensive medical management (CMM) or an IDDS plus CMM. Patients were eligible if they had a visual analog scale pain intensity rating of ≥5 at two measurements within a week of randomization, despite 200 mg/day or more of oral morphine or its equivalent. Patients on lower doses of opioids were also permitted entry if opioid side effects refractory to conservative management prohibited further escalation of total opioid dose. All patients were ≥18 years of age, had life expectancy ≥3 months, and were suitable for IDDS (no active infection, obstruction of CSF flow, or mechanical barriers). The primary outcome measure was pain control (VAS improvement ≥20%)

COMPARISON OF INTRATHECAL DRUG DELIVERY SYSTEMS

	IDDS	Exteriorized IT delivery system
Cost	High initial cost but more cost effective after 3 months.	Lower cost for short-term use.
Indications	Refractory cancer pain and prognosis >3 months.	Refractory cancer pain with prognosis <3 months. Pain crisis requiring rapid control.
Infection risk	Early infection risk; low risk longer term.	Higher
Advantages	Patient freedom. Low maintenance.	Easier to change infusate. Easier to give boluses for aggressive symptom control. Can be removed in the office.
Disadvantages	More invasive. Requires more operator expertise in tertiary care setting.	Risk of dislodgement and failure.

combined with an improved toxicity profile, as measured by the National Cancer Institute Common Toxicity Criteria, 4 weeks after randomization. Clinical success was defined as a ≥20% reduction in VAS scores, or equal scores with a ≥20% reduction in toxicity.

At 4 weeks, both groups had an improvement in pain scores and toxicity. Sixty of 71 IDDS patients (84.5%) achieved clinical success compared with 51 of 72 CMM patients (70.8%, $p = 0.05$). IDDS patients more often achieved ≥20% reduction in both pain VAS and toxicity (57.7% [41 of 71] vs. 37.5% [27 of 72], $p = 0.02$). The mean CMM VAS score fell from 7.81 to 4.76 (39% reduction); for the IDDS group, the scores fell from 7.57 to 3.67 (52% reduction, $p = 0.055$). The mean CMM toxicity scores fell from 6.36 to 5.27 (17% reduction); for the IDDS group, the toxicity scores fell from 7.22 to 3.59 (50% reduction, $p = 0.004$). The IDDS group had significant reductions in fatigue and depressed level of consciousness ($p < 0.05$). IDDS patients also had improved survival, with 53.9% alive at 6 months compared with 37.2% of the CMM group ($p = 0.06$). The authors concluded that IT therapy, compared to CMM alone, improved clinical success by reducing drug toxicity, trended toward improving pain reduction, and possibly improved survival. It should be noted that the data were analyzed on an intent-to-treat basis, but that some crossover (5 patients) from CMM to the IDDS group did occur. When the data is interpreted on the basis of the actual treatment received, there was a significant difference between the VAS scores between groups, in favor of IT therapy.

In 2005, the same group of authors published a second paper examining the 6 month follow-up of the patients in the above mentioned trial.[13] The approach in this paper was to compare outcomes in terms of the actual treatment received (i.e., an IDDS versus CMM alone), rather than the intent-to-treat at randomization approach used in the 2002 study. Outcome measures were the same as in the initial study, but were also assessed in patients alive at 12 weeks after the initial randomization. At 4 weeks, 88.5% of IDDS patients achieved clinical success compared with 71.4% ($p = 0.02$) of non-IDDS patients, and more often achieved a ≥20% reduction in both pain VAS and toxicity (67.3% versus 36.3%; $p = 0.0003$). At 12 weeks, of the 56 patients remaining in the CMM group, 19 had received an IDDS. By 12 weeks, 82.5% of IDDS patients had clinical success compared with 77.8% ($p = 0.55$) of non-IDDS patients, and more often had a ≥20% reduction in both pain VAS and toxicity (57.9 versus 33.3%; $p = 0.01$). At 12 weeks, the IDDS VAS pain scores decreased from 7.81 to 3.89 (47% reduction) compared with 7.21 to 4.53 for non-IDDS patients (42% reduction; $p = 0.23$). The 12-week drug toxicity scores for IDDS patients decreased from 6.68 to 2.30 (66% reduction), and for non-IDDS patients from 6.73 to 4.13 (37% reduction; $p = 0.01$). All individual drug toxicities improved with IDDS at both 4 and 12 weeks. At 6 months, only 32% of the group randomized to CMM and who did not cross over to IDDS were alive, compared with 52% to 59% for patients in those groups who received IDDS. This study concluded that an IDDS improved clinical success, reduced pain scores, relieved most toxicity of pain control drugs, and was associated with increased survival for the duration of the 6 month trial.

Pharmacology

Over a dozen different agents have been reported to be used intrathecally in the management of cancer pain, and most of these have never been approved by the U.S. Food and Drug Administration (FDA) for IT use (Table 44.3). Morphine sulphate, one of the few agents the FDA approved for IT use, is the standard first-line drug used in IT pain therapy. Additional agents are usually then added in a stepwise fashion depending on the response to morphine alone; it is not uncommon that 1–3 adjunctive agents are added to the infused solution. A recent consensus document by Stearns et al.[14] is an attempt to standardize the therapeutic approach to IT drug selection and dosing in the cancer patient (see Table 44.3).

Opioids

IT mu opioid agonists directly activate dorsal horn and brainstem opioid receptors. Morphine sulphate is FDA-approved for IT use, and it remains the first-line agent for IT analgesia. Numerous other IT opioids have been used successfully including hydromorphone, fentanyl, sufentanil, meperidine, and methadone. The choice of agent is largely idiosyncratic. Many practitioners purport that hydromorphone causes less nausea than morphine, although there are no comparative trial data to support this view. The comparatively greater lipophilicity of fentanyl and sufentanil leads to relatively rapid absorption into proximate neural structures with less CSF recirculation and migration to the brainstem. This has some theoretical advantages when a more regional anal-

TABLE 44.3

INTRATHECAL DRUGS USED IN CANCER PAIN MANAGEMENT*

Drug	Receptor	Indication	Adverse effects	Notes
Opioids Morphine Sulphate Hydromorphone Fentanyl Sufentanil	Mu opioid receptors	Nociceptive and mixed pain, first-line therapy. Neuropathic pain second-line therapy.	Sedation, respiratory depression, urinary retention, nausea, pruritus, cognitive impairment.	The lipophilic opioids like fentanyl and sufentanil are generally added when first-line treatments have failed.
Local anesthetics Bupivacaine	Neural sodium channels	Neuropathic and mixed pain, first-line therapy; nociceptive pain, second-line.	Motor weakness, hypotension, urinary retention	The chemical sympathectomy caused by IT bupivacaine may promote gastrointestinal motility.
Clonidine	Alpha-2 adrenoreceptors	Neuropathic Pain first- or second-line therapy Nociceptive pain second-line therapy.	Orthostatic hypotension, sedation, edema.	
Baclofen	Gamma-aminobutyric acid (GABA)	Coexisting spasticity; third-line for neuropathic pain.	Ataxia, sedation, auditory disturbance.	Abrupt discontinuation may cause a serious withdrawal syndrome.
Ketamine	*N*-methyl-D-aspartate (NMDA)	Fourth-line therapy for neuropathic pain.	Anxiety, agitation, facial flushing, delusions.	Ketamine, given intravenously at subanesthetic doses, has also been used effectively for refractory pain syndromes, especially in terminal care.[61]
Droperidol	Dopaminergic	Refractory nausea; fourth-line therapy for pain.	Extrapyramidal symptoms	
Midazolam	GABA	Neuropathic pain, fourth-line therapy.	Sedation	
Ziconotide	N-type voltage-sensitive calcium channels	Fourth-line therapy.	Cognitive, psychiatric, ataxia, nausea, elevated creatine kinase, hypotension.	Still not widely accepted as a useful intrathecal agent.

*Based on the practice guidelines published by Stearns et al.[14]

gesic effect is desired, with less risk of opioid activity (respiratory depression) at the brainstem level.

Local Anesthetics

Local anesthetics, such as bupivacaine and lidocaine, are sodium channel blockers which interrupt neural action potentials along sensory and motor nerves. When given intrathecally, local anesthetics can block incoming sensory nerves and produce complete analgesia. However, this comes at the price of motor blockade resulting in weakness, and sympathetic nervous system blockade which may result in hypotension. High doses of local anesthetics may also result in neuro- or cardiotoxicity (seizure or arrhythmia). Bupivacaine, given in doses less than 30–60 mg/day, is an excellent adjunct to IT opioids and generally causes minimal motor block. In the terminally ill patient who is bed-bound and does not object to lower extremity weakness, higher doses of local anesthetics may be used to provide profound analgesia with no cognitive side effects. Supportive means to evacuate the bowels and void urine must be anticipated.

Clonidine

Clonidine is an alpha-2 adrenergic agonist which acts at the dorsal horn by modulating the transmission of noxious sensory signals. This modulation is accomplished by mimicking the activation of descending noradrenergic pathways and inhibiting neurotransmitter release.[15] Epidural and IT clonidine has been studied extensively in postoperative pain settings and in obstetric care for labor analgesia, but little data exists from cancer pain treatment studies. It is generally considered a very useful adjunct to opioids and local anesthetics when there is a predominant neuropathic pain component.[6] Dosing is limited by side effects including sedation and hypotension. The consensus guideline by Stearns et al.[14] recommends using clonidine as a third-line agent when treating refractory cancer pain, but suggests it should be used as a second-line agent when there is a neuropathic pain component.

Other Drugs

A diverse group of drugs have been reported to be useful IT adjuncts, including baclofen, ketamine, neostigmine, midazolam, ketorolac, droperidol, and ziconotide. Droperidol is indicated for refractory nausea and vomiting. Ziconotide (formally SNX-111) is a novel snail peptide that is an N-type voltage-sensitive calcium channel blocker. Ziconotide can only be given intrathecally and appears to act at the dorsal horn to decrease afferent sensory input by mechanisms different from those of other IT drugs. De-

spite its FDA approval for IT use in refractory pain, ziconotide has not gained popularity due to adverse effects including cognitive impairment and psychiatric disturbance. Clinical experience has shown that most of these adverse effects are dose related and can be avoided by slow and careful titration.[16]

Contraindications and Risk Management

Absolute contraindications to IT analgesia are rare. Skin infection over the intended catheter site, bacteremia/sepsis, and uncorrectable coagulopathy represent absolute contraindications to IT catheter placement, given the respective risks of CNS infection and spinal hematoma. Oral anticoagulants need to be held until the international normalized ratio is 1.5 or less. If indicated, a low molecular weight heparin (LMWH) may be used, provided it is held for 24 hours before the catheter placement. Oral anticoagulants may be resumed shortly after postprocedure hemostasis has been established, and LMWH dosing can resume 12 hours after the procedure.[17] Hematologic relative contraindications include a lowered white cell count $\leq 2 \times 10^9$/L, an absolute neutrophil count $\leq 1000/\mu$L, or a platelet count $\leq 20 \times 10^3/\mu$L.[14] Depending on the patient circumstances, thrombocytopenia may be treated with a platelet transfusion prior to implantation. Special consideration must be given to the feasibility of implanting available pump devices in the anterior abdominal wall, particularly in emaciated patients or children. A smaller 20 milliliter capacity pump is available and may be more practical in these instances.

Complications and Side Effects

In general, most of the commonly reported drug-related adverse effects are well tolerated or readily managed with palliative or supportive interventions. The usual IT opioid side effects are similar to those experienced with the oral or transdermal route, but usually much less pronounced and include sedation, nausea, pruritus, and urinary retention. The serious complication of respiratory depression is rare, especially in opioid-tolerant patients. Local anesthetics may cause lower extremity weakness, hypotension, and bowel or bladder dysfunction. Clonidine may cause hypotension and sedation.

Meningitis is the most feared complication of IT drug delivery but it occurs infrequently when standard infection control measures are followed. Localized skin infection is more common and can usually be managed by oral antibiotics and close observation. Occasionally, catheter or pump explantation will be necessary. Guidelines about the prevention and treatment of IT drug delivery system infection have been published.[18] Typical surgical complications may develop, including seroma formation and pump pocket hematoma. These are usually self-limiting, but ongoing assessment for infection is required, and they may add to postimplant discomfort. The best prophylaxis is an appropriately sized surgical pocket with fastidious hemostasis, and this is achieved through experience.

Catheter tip inflammatory masses (granuloma) are now a well-recognized complication of IT drug delivery. These granulomatous masses can present with new onset lower extremity neurologic symptoms and are associated with high doses and high concentrations of opioid infusate. Clinicians must have a high index of suspicion for this complication; to ignore it may result in permanent neurologic damage, whereas with early recognition and minimally invasive treatment there are seldom any long-term sequelae.[19,20]

Postdural puncture headache can result from persistent cerebrospinal fluid leak around the catheter. This uncomfortable and often distressing experience is usually self-limiting, resolving spontaneously over days to weeks. Conservative management includes rest, fluids, additional analgesia, and caffeine. A headache that persists may be treated with a fluoroscopically guided epidural blood patch, provided that there are no contraindications related to bleeding risk or leucopenia.[14]

Intrathecal Therapy and Ongoing Oncologic Care

The initiation or continuation of IT therapy need not interfere with chemotherapy or radiotherapy regimens. The superior symptom control offered by IT therapy may in fact allow patients to tolerate aggressive treatment more comfortably and increase the efficiency of the oncology suite by decreasing the amount of time spent managing complicated cancer-related symptoms. Particularly aggressive chemotherapy protocols may require that the implantation of an IT drug delivery system be strategically timed to avoid a white cell count or platelet count nadir.

Radiation therapy does affect the battery life of IDDS and may result in electrical failure. The pump may be protected by lead shielding and, if possible, radiation field avoidance. If radiation is being performed for pain control, a temporary catheter may be utilized until this therapy becomes effective, which may take up to 2 weeks (see Chapter 48).

SPINAL CHEMONEUROLYSIS

Spinal chemoneurolysis involves the destruction of nerve root axons or other spinal cord elements by chemical means, using alcohol or phenol. The destruction of selected nerve roots interrupts nociceptive pathways and can potentially create excellent analgesia in a relatively selective body area. Alcohol or phenol ablation of central neural structures has largely fallen out of favor in recent decades, mostly because of advances in the pharmacologic treatment of pain, including via the IT route as previously described. Nevertheless, it remains a useful and effective technique in developing countries with limited opioid access, and where a rapidly effective therapy, requiring little or no follow-up, is required. Like other interventional pain management techniques, intraspinal neurolysis does offer the advantage of localized pain control while minimizing the burden of systemic side effects. However, the potential adverse effects of the procedure are significant, including motor nerve root dysfunction, bowel or bladder dysfunction, and dysesthesias in the denervated dermatomes.[21] In experienced hands, these adverse effects may be minimized, but the potentially high morbidity of these problems has generally placed intraspinal neurolysis toward the end of the treatment spectrum in modern day practice.[21–25]

Spinal Chemoneurolysis Technique

Spinal chemoneurolysis, or simply neurolysis, notwithstanding its value in appropriately selected patients, is rapidly becoming a forgotten technique, and therefore physicians with experience with this treatment modality, and the ability to teach it to trainees, are becoming relatively scarce. Neurolysis is targeted at the sensory nerve root and dorsal root ganglion within the subarachnoid space while attempting to spare the more anteriorly located motor nerve roots. Neurolysis may be performed at the cervical, thoracic, or lumbo-sacral levels, with the last being the most common site of intervention. Neurolysis in the epidural space has also been described, but is less favored because of pain on injection and disappointing outcomes.[26] Knowledge of the chemical properties of alcohol and phenol is essential to the safe and effective use of each agent. The disposition of alcohol and phenol are distinctly different when deposited in the IT space (Figs. 44.3 and

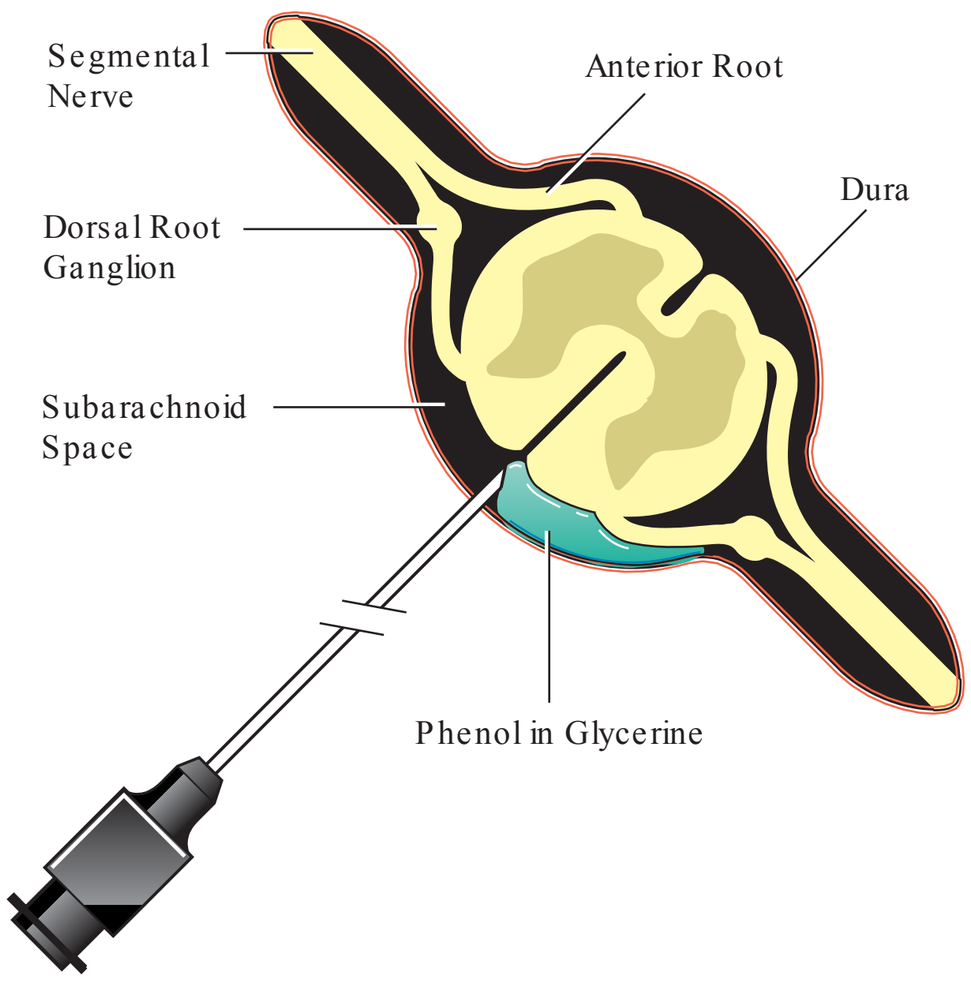

FIGURE 44.3 Lateral supine position used for injection of IT phenol, with the hyperbaric solution falling toward the sensory dorsal roots.

44.4). Alcohol is hypobaric relative to CSF, and therefore will "float" upward, whereas phenol is hyperbaric and will "sink" within the subarachnoid space relative to the position of the needle tip. These properties allow for reasonably selective targeting of nerve roots using careful patient positioning and needle placement. The patient is placed in the lateral decubitus position, with the painful side uppermost for alcohol neurolysis, and dependent for phenol neurolysis. Since it is most common for patients to be intolerant of having the painful side down (dependent), alcohol ablation is the preferred technique. For alcohol neurolysis, the patient is rolled 45 degrees away from the operator who is on the dorsal side of the patient, so that the hypobaric alcohol preferentially floats to the dorso-lateral subarachnoid space where the sensory dorsal roots reside. To treat this same anatomic location with phenol, the patient needs to be rolled toward the operator. A small bore spinal needle is advanced into the IT space at the appropriate nerve root level for the affected pain site to be treated. Recall that nerve roots and their respective dermatomal, myotomal, and sclerotomal levels do not necessarily line up anatomically. Tiny aliquots (0.1–0.2 mL) of the neurolytic agent are then injected incrementally with careful monitoring of sensory changes and dermatomal spread until the desired region is blocked. A detailed description of spinal neurolysis technique is contained within the text, *Neural Blockade*.[21]

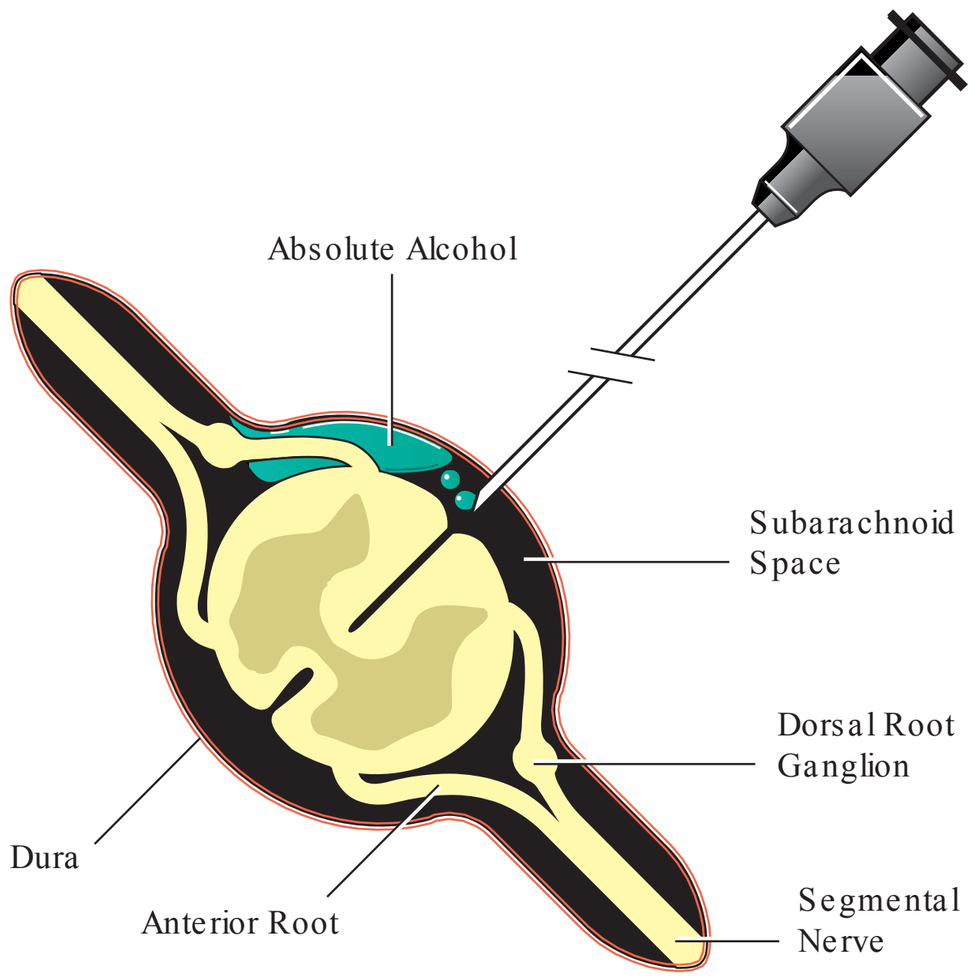

FIGURE 44.4 Lateral prone position used for injection of IT alcohol, with the hypobaric solution rising toward the sensory dorsal roots.

Lumbosacral Neurolysis

Lumbosacral spinal neurolysis can provide excellent pain relief of the pelvis, perineum, rectum, and genital area in patients who have been refractory or intolerant of aggressive conventional management. Patients, who are confined to bed due to their symptom burden, or who have already had urinary and bowel diversion procedures, can expect good pain relief with an acceptable risk of complication. Prior to proceeding with lumbosacral subarachnoid neurolysis, consideration should be given instead to performing a superior hypogastric plexus block as this procedure may be equally effective yet considerably safer.

Cervical and Thoracic Neurolysis

Cervical neurolysis is seldom performed due to the technical difficulty of subarachnoid access at this level, the compactness of anatomy in this region making selective neurolysis more difficult, as well as the inherent risk of causing injury to the cervical spinal cord with consequent neurologic deficits and adverse symptoms (including pain). Thoracic neurolysis for thoracic wall pain is also technically difficult, but the consequences of motor root dysfunction are less pronounced, in that the loss of several levels of intercostal muscle function is usually well tolerated. Thoracic neurolysis does have the advantage of not placing the innervation of the bowel, bladder, and lower extremities at risk, and consequently has less risk of significant morbidity.

Adverse Effects

Studies reporting on bladder and bowel dysfunction after lumbosacral neurolysis report that about one quarter of patients develop urinary incontinence, with most resolving within 10 days.[27–29] Bowel dysfunction and lower extremity weakness was relatively less frequent. Yet, it should be noted that some of these patients may already have had urinary and bowel diversion for surgical reasons, making the decision to proceed with neurolysis somewhat easier. Other adverse effects of IT neurolysis include deafferentation pain and headache. Rare complications include infection, spinal cord damage, and posterior spinal artery thrombosis causing paraplegia.

Contraindications

IT neurolysis is contraindicated when: (1) the patient has spinal cord tumor or tumor obliteration of the subarachnoid space at the selected level; (2) skin infection is present at the needle puncture site; (3) the patient is unable to tolerate appropriate positioning; and (4) there is a primary pain source, such as a bone metastasis or fracture, that is amenable to more definitive procedural treatment.

CELIAC PLEXUS BLOCK

Chemical neurolysis of the components of the celiac plexus can be a highly effective treatment of visceral pain of the upper abdomen, and is the most commonly performed interventional cancer pain technique.

Indications

Neurolytic celiac plexus blockade (NCPB) is typically performed for cancer related *visceral* pain originating in the upper abdomen. Pain originating from the somatic nerve fibers emanating from the upper abdominal wall will not be blocked by NCPB, and therefore it is very important to distinguish between visceral versus somatic pain before contemplating this procedure. The celiac plexus carries afferent fibers from the upper abdominal organs from the stomach to the mid transverse colon, including pancreas and gallbladder. Deep visceral pain related to pancreatic adenocarcinoma and cholangiocarcinoma are typical indications for NCPB. As will be discussed later, this is a highly efficacious and safe procedure, so it should be considered early in the treatment of upper abdominal cancer pain.[30]

Anatomy of the Celiac Plexus

Understanding the path of the needle and the position of its tip in relation to the local anatomy is crucial to the safe and effective performance of any interventional procedure. The celiac plexus is a complex grouping of 1–5 ganglia of various sizes interconnected by a dense network of neural fibers. The plexus is located in the upper abdomen typically anterolateral to the aorta at the L1 vertebral level, just caudal to the take-off of the celiac artery; however, some variability has been noted, and the plexus can be found anywhere from the level of T12–L1 disc space to the level of the L2 vertebral body.[31] Just lateral to the celiac plexus are the adrenal glands, and inferiorly are the renal arteries. The celiac plexus is formed by the convergence of sympathetic preganglionic and afferent fibers from the greater (originating from the T5–T10 spinal level), lesser (T10–T11), and least (T12) splanchnic nerves. The splanchnic nerves are composed of preganglionic autonomic efferent fibers to the upper abdominal viscera that synapse in the celiac ganglia, and ascending afferent fibers capable of carrying nociceptive signals from abdominal viscera including the distal portion of the stomach, pancreas, gallbladder, and other hepatobiliary structures, the duodenum, and small intestine, and the large intestine, as far distal as the transverse colon. The splanchnic nerves travel from the spine in the posterior mediastinum, anterolateral to the thoracic vertebral bodies, and pierce the diaphragmatic crus to enter the retroperitoneal abdominal cavity. Parasympathetic preganglionic and afferent fibers originating from the vagus nerves also contribute to the celiac plexus.

General Considerations

Preparation of patients should include counseling regarding the potential adverse effects and complications of the procedure. Anticoagulants should be discontinued long enough to allow normalization of coagulation profiles. Intravenous access is mandatory so that sedation may be administered, adverse effects can be treated, and prehydration can be accomplished. The latter point is important, as celiac plexus blockade will cause splanchnic vasodilatation potentially leading to systemic hypotension, particularly in the cancer patient who may already be dehydrated and hypovolemic. An important factor to consider is whether the patient will be able to tolerate lying in the prone position; a patient with gross ascites, even with sedation, will be unable to assume the appropriate position, and may be a better candidate for an anterior or endoscopic approach.

Tumor location within the pancreas and the degree of local tumor burden has been shown to impact NCPB outcome, with pain related to head of pancreas lesions having a more favorable outcome compared to lesions of the body and tail of the pancreas.[32]

Computed tomography (CT)-guided celiac plexus studies using a radio-opaque injectate have shown that outcome may also be affected by local anatomic distortion caused by tumor infiltration.[33,34]

Adverse Effects

NCPB is a relatively safe and well-tolerated procedure. Serious complications include transient or permanent spinal cord damage and paraplegia due to spread of the lytic injectate to the nerve roots, epidural, or IT space. Neurologic damage may also ensue after damage to an anterior spinal artery, such as the artery of Adamkiewicz, disrupting the vulnerable arterial supply of the spinal cord.[35,36] Fortunately, serious neurologic complications are very rare, with an incidence of less than 0.2% in one series of 2730 NCPBs.[37] Side effects are common and generally mild and well tolerated. NCPB will predictably cause a disruption of the sympathetic nervous supply to the proximal bowel resulting in unopposed parasympathetic (vagal) tone. This excessive parasympathetic tone will typically result in transient gastrointestinal hypermotility and diarrhea in approximately 44% of patients, a side effect that is seldom considered a problem by the patient who has been constipated due to opioid consumption and debilitation. The loss of sympathetic tone also results in splanchnic vasodilation, intravascular fluid shift to the bowel, and hypotension in approximately 38% of patients.[5] This should be anticipated and prevented with preprocedural volume enhancement and sufficient means to monitor and treat falling blood pressure (e.g., ephedrine).

Celiac Plexus Block Techniques

Numerous approaches to the celiac plexus have been described, ranging from traditional blind landmark techniques to sophisticated CT-guided methods. A 1992 study by Ischia et al.[38] compared the outcomes of the retrocrural technique, a transaortic approach, and neurolysis of the splanchnic nerves at the T12 level. No statistically significant differences ($p > 0.05$) were found among the three techniques in terms of either immediate or up-to-death results. Procedure mortality was zero with the three techniques and morbidity negligible. NCPB provided excellent pain relief in 70% to 80% of patients immediately after the block and in 60% to 75% until death.[38] Celiac plexus neurolysis may also be achieved intraoperatively at the time of diagnostic or therapeutic laparotomy, with reported good success.[39]

Posterior Approach to the Splanchnic Nerves and Celiac Plexus

The most common celiac plexus block technique is the posterior approach using a needle on either side of midline. This was first described as a blind technique, but is now performed with the help of fluoroscopy or CT. The L1 vertebral body is identified with fluoroscopy and then the c-arm is rotated obliquely so that a skin puncture site 6–8 cm (6 cm for smaller, cachectic, individuals; more toward 8 cm for obese patients) lateral to the midline will allow for coaxial needle advancement to the anterolateral aspect of the upper half of L1 vertebral body. A 15 cm or longer 20-gauge needle is then advanced toward the anterolateral

shadow of the L1 vertebral body. The intention is to just miss contact with the vertebral body, as this can be quite uncomfortable for the patient. Care should be taken not to touch the L1 transverse process, as this can be mistaken for the vertebral body, giving an incorrect, and potentially dangerous, estimate of depth. This author typically performs the left side first, so if an inadvertent aortic puncture is obtained, a transaortic approach can be completed, assuring good placement anterior to the aorta and avoiding the need for a second needle placement (the transaortic approach has been advocated by some practitioners[40] as a safe, alternative technique, and involves intentionally piercing the aorta in order to provide direct chemoneurolysis to the celiac ganglia anterior to the aorta). The second needle is placed in identical manner from the right side, aiming for the space anterolateral to the right side of the L1 vertebral body. Final needle advancements should be done under lateral fluoroscopic guidance: The left needle tip should be advanced 0.5 cm ventral to the anterior edge of the L1 vertebral body (further advancement may result in aortic puncture); the right needle tip is advanced 1 cm beyond the anterior edge of the vertebral body (Fig. 44.5). As the aorta is approached, transmitted arterial pulsations may be appreciable at the needle hub, but this is unreliable. The anatomic location of these needle tips is likely to be retrocrural, and in good position to block the splanchnic nerves as they pierce the diaphragm. Note that the celiac plexus itself is not the primary target when using the retrocrural technique, but this appears to be of little clinical significance.[38]

If an anterocrural needle position is desired, with direct lysis of the celiac plexus itself, the needles need to be further advanced through the crus of the diaphragm. The final anatomic position of the needle can only be determined by injecting several milliliters of a radio-opaque contrast agent through each needle in an anteroposterior and lateral projection. Retrocrural contrast will spread cephalad along the anterolateral aspect of the T12 and L1 vertebral bodies, while anterocrural spread will be noted in a more anterior and caudal plane. In either case, spread toward the midline should be present. While injecting the radio-opaque contrast, meticulous attention should also be given to avoiding: (1) vascular uptake which might result in neurolytic being delivered to the spinal cord or other organs; (2) posterior spread toward the neuroforamina, the nerve roots, and the epidural space; and (3) contrast uptake into the intima of the aorta (this is seen, under real-time fluoroscopy, as a pulsating ''streaking'' outlining the assumed position of the aorta). Once the needles are in a radiographically satisfactory position, 5–10 mL of lidocaine 2% is injected through each needle after attempting aspiration of blood, CSF, or urine and confirming proper needle placement. After several minutes, the patient is questioned about the presence of any unwanted lower extremity weakness or other neurologic symptoms. A reduction in abdominal pain should also be noted, though this may be unreliable if the patient has received intravenous analgesics or sedatives. Finally, neurolysis is achieved by injecting 10–12 mL of ethyl alcohol (60% or higher, concentration) or phenol (6% or higher concentration) through each needle.

Anterior Approaches

Numerous anterior approaches to the celiac plexus have been described with efficacy and safety profiles comparable to those of the posterior approaches. A single needle may be placed through the anterior abdominal wall under CT guidance, potentially traversing the bowel, stomach, and pancreas, to the preaortic region where the celiac plexus elements reside.[33,41] An increasingly popular approach to the celiac plexus is via transgastric endoscopy. A needle is advanced through the endoscope under ultrasound guidance through the posterior wall of the stomach into the preaortic area in the vicinity of the celiac plexus.[42–44] This technique requires that the patient can tolerate esophagogastroscopy.

Outcome Studies

Numerous case reports, uncontrolled case series, and several randomized controlled trials[38,39,45–47] report a preponderance of favorable outcomes with NCPB. A 1995 meta-analysis by Eisenberg et al.[5] revealed 24 papers (with 1145 patients) suitable for inclusion. Included were two randomized controlled trials, one prospective case series, and 21 uncontrolled retrospective case series. When analyzed, good to excellent pain relief was reported in 89% during the first 2 weeks after NCPB. This effect persisted after 2 weeks, with partial or complete pain relief reported in 90% of living patients at 3 months, and in 70% to 80% until death. The most frequent indication was unresectable pancreatic cancer (63%), with the balance being a variety of nonpancreatic pain sites including the stomach and esophagus. The pancreatic and nonpancreatic cases did not appear to have a significantly different outcome. The bilateral posterior approach with 15–50 mL of 50% to 100% ethyl alcohol was the most common technique used. No procedure-related mortality was reported, and adverse effects were minimal. The most common adverse effects reported were transient hypotension, diarrhea, and transient pain at the site of injection.

A recent controlled trial by Wong et al.[46] randomized 100 patients with unresectable pancreatic adenocarcinoma to either NCPB or systemic analgesia therapy (SAT) and a sham injection. A blinded observer recorded patient pain intensity, quality of

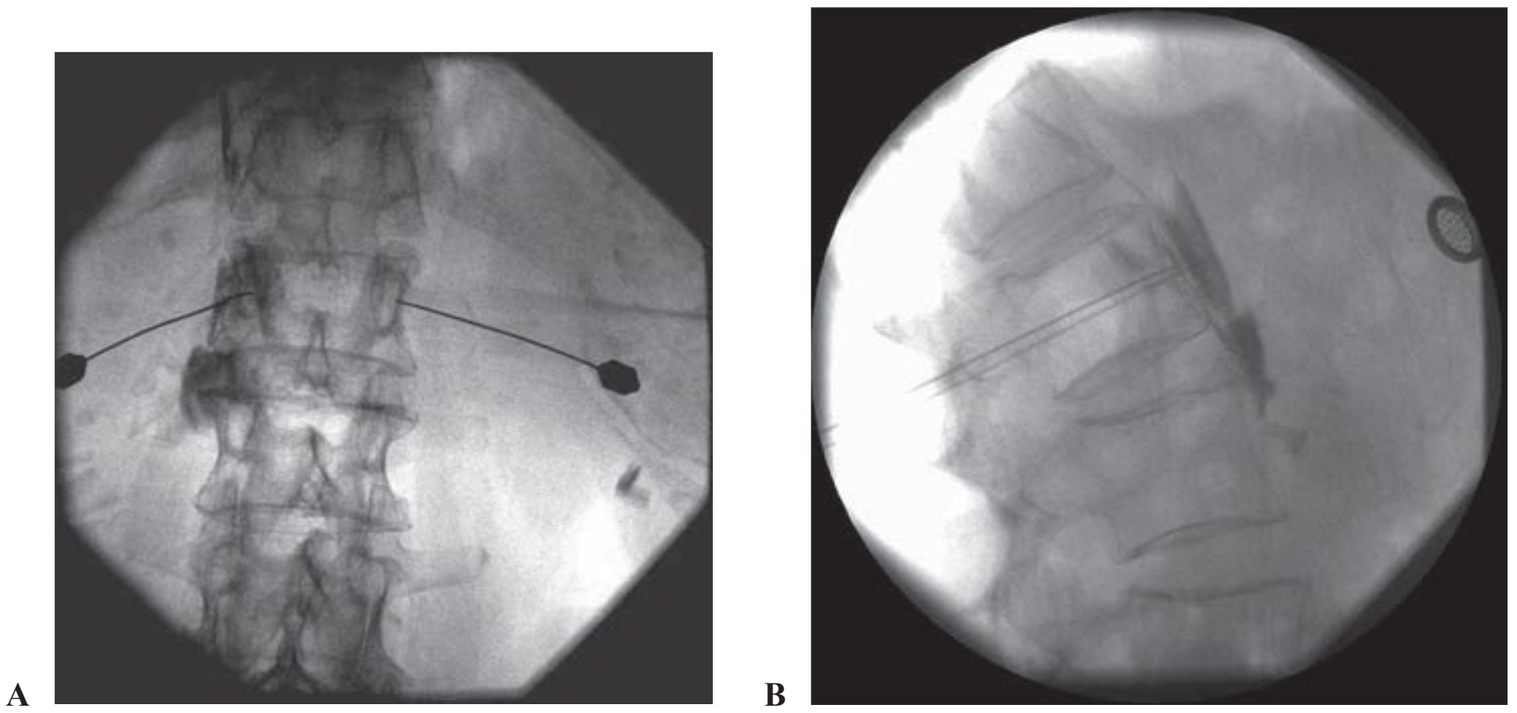

FIGURE 44.5 Fluoroscopic images of a retrocrural celiac plexus block. **A.** Anteroposterior view with the needle tips anterolateral to the L1 vertebral body. Contrast has been injected through the left needle with spread cephalad along the course of the splanchnic nerves. **B.** Lateral fluoroscopic view showing the needle tips advanced anterior to the anterior shadow of the L1 vertebral body and contrast spreading in the retrocrural fascial plane.

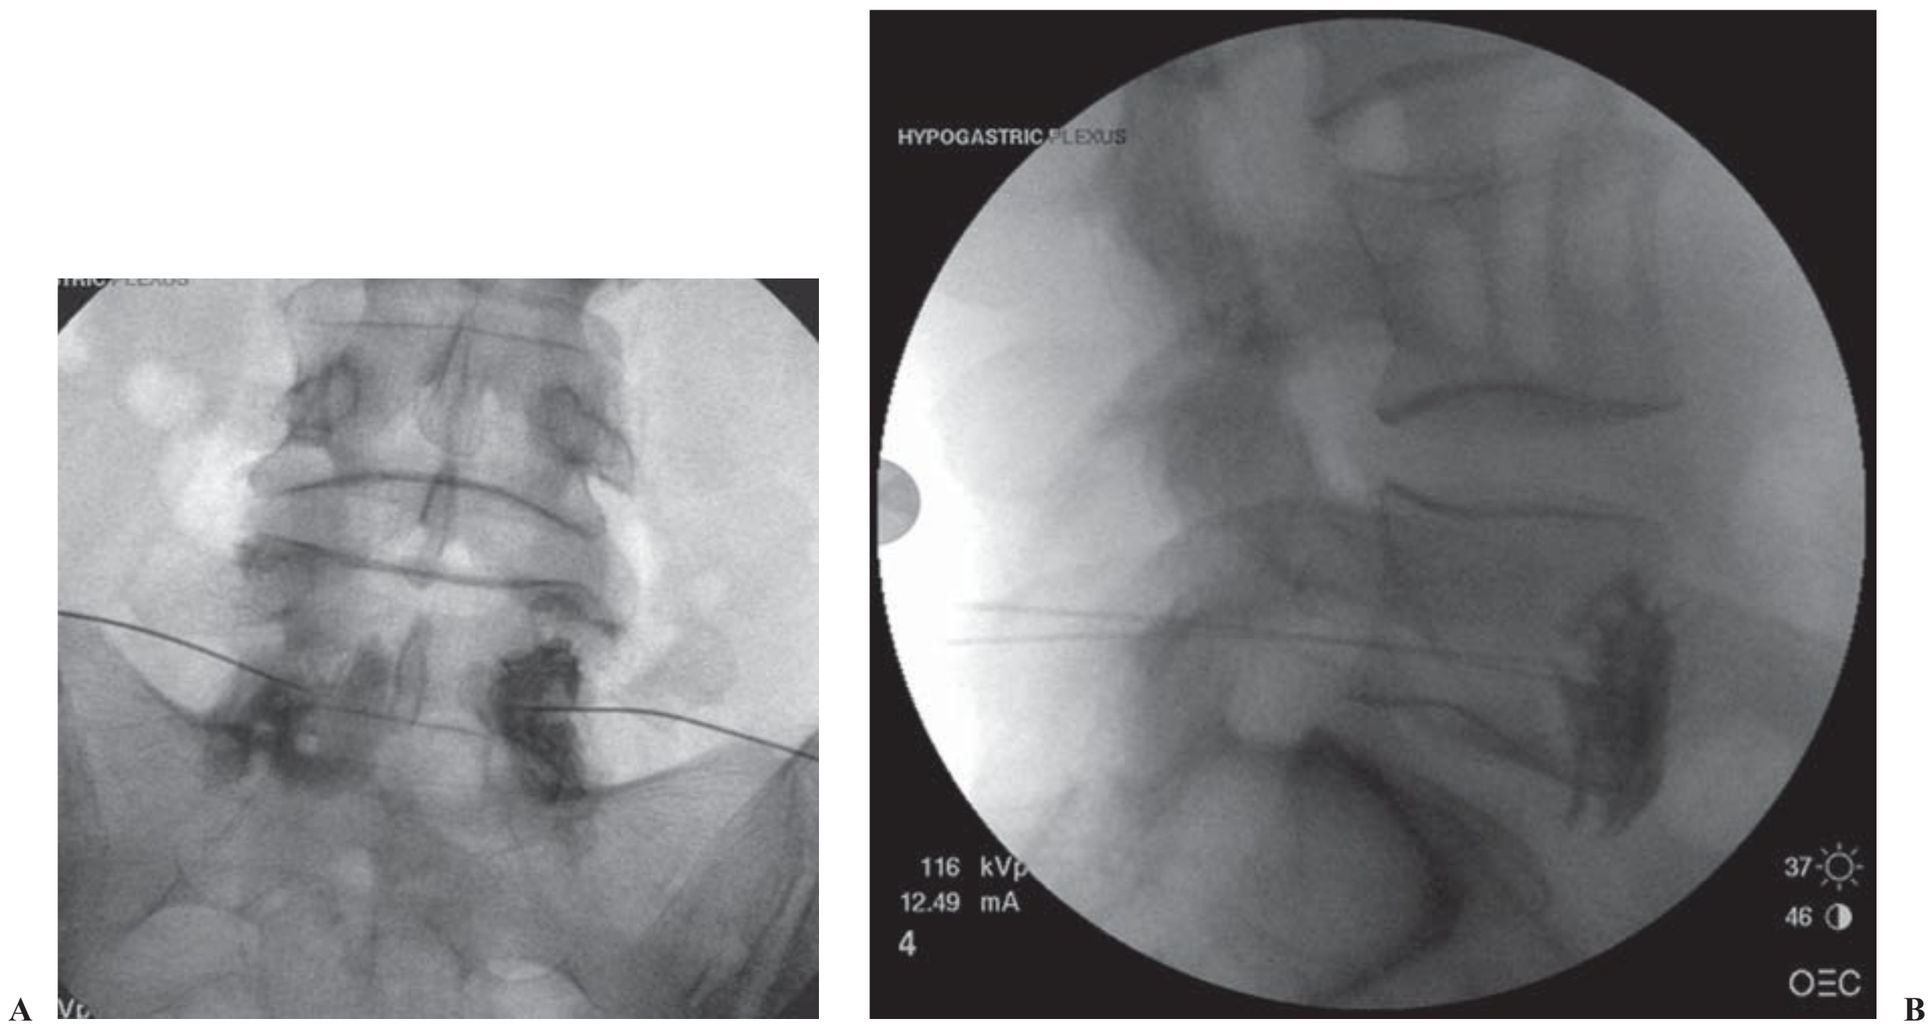
life measures, opioid consumption and related side effects, and survival time for 1 year. Baseline pain scores were relatively low, but comparable, in both groups (VAS 4.4 +/−1.7 vs. 4.1 +/−1.8, respectively). The first week after randomization, pain intensity and QOL scores were improved (pain intensity, $p <$ or $= 0.01$ for both groups; QOL, $p < 0.001$ for both groups), with a more significant decrease in pain for the NCPB group ($p = 0.005$). Using repeated measures analysis, pain was found to be lower for NCPB over time ($p = 0.01$). However, opioid consumption ($p = 0.93$), frequency of opioid adverse effects (all $p > 0.10$), and QOL ($p = 0.46$) were not significantly different between groups. In the first 6 weeks, fewer NCPB patients reported moderate or severe pain (pain intensity rating of> or = 5/10) compared to opioid-only patients (14% vs. 40%, $p = 0.005$). At 1 year, 16% of NCPB patients and 6% of opioid-only patients were alive, but this was not a statistically significant difference.



While the previous study did not show a difference in life expectancy, a randomized, placebo-controlled study by Lillemoe[39] in patients with abdominal pain and unresectable pancreatic cancer demonstrated longer survival when an intraoperative chemical splanchnicectomy was performed, compared to patients who received saline. A subsequent study by Staats[47] involved additional follow-up and analysis of this same group of patients. Data on visual analog pain scores, mood, and interference with activity were collected preoperatively and every 2 months postoperatively until death. Univariate and multivariate analyses of variance showed that neurolysis, compared to the medical management, had a significant positive effect on mood scores, pain interference with activity, and had an associated increase in life expectancy (9.15 +/−9.04 vs. 6.75 +/−4.65 months, $p < 0.05$).

SUPERIOR HYPOGASTRIC PLEXUS BLOCK

Visceral pain is common in advanced cervical, bladder, rectal, and prostate cancers. The superior hypogastric plexus is located anterior to the lower part of the L5 vertebral body and upper portion of the S1 vertebral body, posterior to the psoas fascia and peritoneum, and bounded laterally by the iliac vessels. This plexus innervates the pelvic viscera through the hypogastric nerves and inferior hypogastric plexus, and percutaneous blockade of this system (Fig. 44.6) can result in analgesia for cancer-related pelvic visceral pain. The plexus continues caudally to form the ganglion impar (this can be independently blocked to treat perineal pain) just anterior to the sacrococcygeal membrane.

The primary indication for superior hypogastric block is visceral pelvic pain that has been refractory to medical management. A local anesthetic block is typically performed first, and if good pain relief is obtained, a neurolytic block is then performed. The block is commonly performed using fluoroscopy and a bilateral posterior approach, and appropriate needle placement is confirmed with radiographic contrast. A single needle technique, traversing the L5–S1 intervertebral disc, has also been described in patients with difficult anatomy compromising the bilateral approach, with reportedly good outcomes and a favorable safety profile in a case series of eight patients.[48] No randomized studies have been published, but several prospective case series have consistently demonstrated good to excellent pain relief in over 70% of patients, reduced opioid consumption, and no significant adverse effects or complications.[49–52]

A study by Plancarte and colleagues[49] studied 227 pelvic cancer pain patients with gynecological, colorectal, or genitourinary cancer who experienced poor pain control despite the use of opioids. A bilateral percutaneous neurolytic superior hypogastric plexus block with 10% phenol was performed 1 day after a successful diagnostic block with 0.25% bupivacaine. All patients reported a VAS pain score of 7–10/10 before the diagnostic block. A positive response to a diagnostic block was obtained in 159 patients (79%). These patients then had a neurolytic block with a 72% (115/159 patients, 95% confidence interval of 65% to 79%) success rate, defined as a VAS<4/10. Sixteen (10%) of these 159 patients did require a second block if the first was suboptimal. The remaining 44 patients (28%) had moderate pain control (VAS 4–7/10) after two blocks and received supplemen-

FIGURE 44.6 Anteroposterior (**A**) and lateral (**B**) fluoroscopic images of an appropriate needle position for a superior hypogastric plexus block for visceral pelvic pain. The needle tips are anterior to the anterolateral surface L5 with contrast spread in an appropriate plane to block the fibers of the plexus.

tary oral pharmacologic therapy and epidural analgesic therapy with good results. All patients experienced significant reductions in oral opioid therapy after the neurolytic blocks. No additional blocks were required by patients who had a positive response during the 3-month follow-up period. No complications related to the block were reported. This study concluded that neurolytic superior hypogastric plexus block provided both effective pain relief and a significant reduction in opioid usage (43% decrease) in 72% of the patients treated with neurolysis.

VERTEBROPLASTY AND KYPHOPLASTY

The percutaneous treatment of painful vertebral collapse secondary to metastatic tumor has emerged as a very promising therapy over the last decade. Metastatic spread to the skeleton is common, and 30% to 80% of bony metastases involve the vertebrae (see Chapter 46).[53] Vertebroplasty is a minimally invasive outpatient procedure whereby painful vertebral compression fractures are stabilized by the injection of the bone cement polymethyl methacrylate (PMMA). Access to the vertebral body is typically achieved by passing a specialized needle under fluoroscopic guidance through the pedicles bilaterally, as illustrated in Figure 44.7. Kyphoplasty differs in that the injection of cement is preceded by the attempted restoration of vertebral height by the inflation of a percutaneously placed intravertebral balloon. Kyphoplasty, compared to vertebroplasty, is technically more difficult, more uncomfortable for the patient, and considerably more expensive. However, kyphoplasty does attempt to reduce the vertebral collapse, and some authorities believe this is a worthwhile goal. A meta-analysis comparing vertebroplasty and kyphoplasty studies showed that vertebroplasty produced more significant pain relief, but had a higher risk of cement extravasation into the spinal canal.[54]

Indications

Vertebroplasty or kyphoplasty are indicated in an acute or subacute (<6 months) painful vertebral body pathologic (secondary to osteoporosis or tumor) fracture without the involvement of the spinal canal and its elements.[54,55] Careful clinical correlation between the pain symptoms and the radiographic findings should be established, as not all radiographically evident fractures are symptomatic. If there is doubt about the significance of a fracture, or in the presence of fractures at multiple levels, clinical correlation is often best achieved by examining the spine with the aid of fluoroscopy, while palpating or percussing the spinous process of the vertebrae in question to see if concordant pain can be elicited. In the case of a fracture involving the spinal canal, actual or impending neurologic deficits are best treated by a surgical approach with decompression and probable spinal fusion.

Contraindications

Absolute contraindications to vertebroplasty and kyphoplasty include asymptomatic stable fractures, clinically effective medical therapy, osteomyelitis of target vertebra, uncorrected coagulation disorders, allergy to any required component, and local or systemic infection. Relative contraindications include radicular pain or radiculopathy caused by a compressive syndrome unrelated to vertebral body collapse, a retropulsed fragment with >20% spinal canal compromise, tumor extension into epidural space, and severe vertebral body collapse (vertebra plana). The need for subsequent radiation to the area is not a contraindication, as PMMA has been shown to be resilient to radiation at therapeutic doses.

Outcomes

Both vertebroplasty and kyphoplasty have consistently shown a significant improvement in postprocedure pain scores. In a meta-analysis by Eck et al.,[54] 168 eligible studies on vertebroplasty and kyphoplasty were assessed for their comparative analgesic efficacy and rates of complication. The mean pre- and postoperative VAS scores for vertebroplasty were 8.36 and 2.68, respectively, with a mean change of 5.68 ($p<0.001$). The mean pre- and postoperative VAS scores for kyphoplasty were 8.06 and 3.46, respectively, with a mean change of 4.60 ($p<0.001$). The pain reduction for vertebroplasty was noted to be statistically greater ($p<0.001$) compared with kyphoplasty. However, the risk of new vertebral fracture was 17.9% with vertebroplasty versus 14.1% with kyphoplasty ($p<0.01$), and the risk of cement leak was 19.7% with vertebroplasty versus 7.0% with kyphoplasty ($p<0.001$).

IMAGE-GUIDED ABLATION OF PAINFUL BONE METASTASES

Isolated bone pain secondary to metastatic tumor activity is typically treated with external beam radiation, analgesics (opioids and nonsteroidal anti-inflammatory agents), and systemic therapies including bisphosphonates, radiopharmaceuticals, corticosteroids, and chemotherapy (see Chapters 43, 46, and 48). A recent advance has been the use of radiologically-guided needle placement into selected painful metastases to provide thermal destruction using radiofrequency energy,[56] laser, and cryoablative[57,58] techniques. Another technique is percutaneous alcohol injection using selective arterial embolization[59] or direct tumor infiltration.[60]

A multicenter study by Goetz et al.[56] treated 43 patients who had failed standard therapy for painful osteolytic metastases with image-guided radiofrequency ablation. Ninety-five percent of patients had a clinically significant reduction in pain (visual analog scale decrease of ≥2, on a 10 point scale). Before treatment, the mean worst pain score was 7.9; after treatment, the average worst pain score was 4.5 ($p<0.0001$) at four weeks, 3.0 ($p<0.0001$) at 12 weeks, and 1.2 ($p<0.0005$) at 24 weeks. Pain interference scores and opioid consumption also improved during the 24 weeks of reported follow-up. Complications were seen in three patients; two were not serious, while one involved an acetabular fracture following radiofrequency ablation to this area.

OTHER TECHNIQUES

Numerous other innovative techniques have been described to control refractory cancer pain by interventional means. Neurosurgical pain control techniques are beyond the scope of this chapter, and are discussed elsewhere in this text (see Chapters 102–104). Spinal cord stimulation may be very useful in the treatment of neuropathic pain as seen in brachial plexus lesions or chemotherapy related peripheral neuropathy (see Chapters 94–96). Peripheral nerve chemical or radiofrequency neurolysis may have a role in cancer-related facial pain, extremity pain, and pain of selected dermatomes in the trunk (see Chapter 101). It is also worth mentioning that many cancer pain patients have a secondary component of myofascial pain that may be amenable

to trigger point injection and/or physical therapy before proceeding with more invasive techniques (see Chapter 35).

SUMMARY

Interventional therapies have a well-defined and beneficial role in the treatment of appropriately selected patients with various cancer pain syndromes. Optimizing outcomes depends upon timely referral with adequate assessment and patient selection; managing expectations of referring physicians, patients, and family members; assuring adequacy of postinterventional care; and an experienced, skilled interventionalist who will assume full responsibility for pre- and postintervention evaluation and follow-up care as indicated by the dictates of each patient's circumstances.

CHAPTER 45 ■ PAIN CAUSED BY CANCER OF THE HEAD AND NECK AND ORAL MUCOSITIS

JOEL B. EPSTEIN, MARK M. SCHUBERT, PRABHAT K. BHAMA, AND ERNEST A. WEYMULLER, JR.

INTRODUCTION

Head and neck pain in cancer patients may arise from a number of sources, including the cancer, therapy of the malignant disease, or it may be unrelated to the cancer or the cancer therapy (Table 45.1). One of the most common cancer-related, pain-producing conditions affecting the head and neck region is ulcerative oral mucositis that, when severe, can be a dose- and rate-limiting toxicity of cancer chemotherapy and radiotherapy and is the most debilitating patient-reported complication of many intensive cancer treatments. This chapter reviews the pathogenesis of mucositis mechanisms of pain in head and neck cancer, and current strategies for preventing and managing these painful conditions. Pain due to head and neck cancer and mucositis include multiple pathophysiological mechansims involved in other oncologic conditions that affect soft tissues, vascular, bone, and nervous system structures, including molecular mechanisms associated with reactive oxygen species, inflammatory mediators, neuropeptide release, and stimulation of receptors.[1–3] Phenotypic changes may occur, involving all levels of the sensory and autonomic nervous system, and are impacted by individual variables including genetic and psychosocial features. Understanding these mechanisms may lead to additional approaches to prevention and management.

TABLE 45.1

OROFACIAL PAIN IN CANCER PATIENTS

I. Acute
1. Caused by disease: invasion of bone, nerve, muscle, mucosal damage; tumor pressure
2. Caused by cancer therapy: surgery, radiation therapy, and chemotherapy
   a. Oral/dental pain: mucositis, infection (e.g., *Candida*, dental, HSV), neuropathy
3. Unrelated conditions causing pain (e.g., myofascial pain, trauma)

II. Chronic
1. Caused by persisting/progressive disease
2. Caused by cancer therapy: surgery, radiation therapy, and chemotherapy
   a. Mucosal atrophy/xerostomia
   b. Mucosal infection
   c. Neuropathy
   d. Temporomandibular (myofascial) disorders
   e. Dental caries
   f. Osteonecrosis/mucosal necrosis
   g. Postherpetic neuralgia
3. Unrelated conditions causing pain

HSV, herpes simplex virus.

PAIN MECHANISMS DUE TO LOCAL AND REGIONAL CANCER OF THE HEAD AND NECK

Tumor may compress and invade pain-sensitive structures and induce inflammation. Potential mechanisms of bone pain due to malignancy include periosteal pressure and stretching, compression and invasion of nerves, vascular damage, microfractures, and muscle spasm. Inflammatory mechanisms can be activated by both cancer and cancer treatments and include release of cytokines and other algogenic molecules that cause pain in the tumor environment of hypoxia and low pH. Tumors produce growth factors and cytokines that activate inflammation and nociceptive pathways. In head and neck cancer (HNC), inflammation is a major cause of pain,[2,3] initiated by reactive oxygen species (ROS), and release of mediators from tumor cells, circulating leukocytes, platelets, endothelial cells, and immune cells resident in the affected tissue and nerve fibers (sensory and sympathetic). ROS cause endothelial cell damage and increase vascular permeability, and nitric oxide (NO) induces second messenger mechanisms within neurons that may cause neuropathic pain. Further, oxidative stress activates transcription factors that cause upregulation of proinflammatory cytokines and may trigger apoptosis.

Tissue inflammation increases circulating kallikreins leading to production of bradykinin (BK) that produces pain and amplifies pain induced by serotonin (5HT). Glutamate is upregulated at sites of inflammation and affects amino-3-hydroxy-5-methyl-4-isoazolepropionic acid (AMPA), N-methyl-D-aspartate (NMDA), kainite, and metabotropic receptors. Furthermore, inflammation increases the expression and sensitivity of ion channels, such as sodium channels on nociceptors.

The low pH associated with solid tumors appears to be due to inflammation, tumor cell metabolism, and apoptosis or necrosis with release of cellular contents that may cause pain due to activation of sensory neurons through acid-sensing ion channels (ASICs). In addition, cancer-induced activation of osteoclasts results in lower pH for dissolution of bone mineral.

Tumor necrosis factor (TNF) is central in the activation of cytokines and growth factors and plays a role in inflammation, neuropathic pain, and is a key mediator in mucositis. Nerve growth factor (NGF) production is mediated by interleukin (IL)-1β and is upregulated by TNF-α. NGF activates cutaneous mast cells, leading to release of inflammatory mediators that induce pain and may also activate the sympathetic nervous system. Norepinephrine (NE) causes hyperalgesia at sites of tissue injury.

Prostaglandins (PG) synthesized by cyclo-oxygenase pathways (COX-1 and COX-2) are induced in peripheral tissues by inflammatory cytokines and growth factors. Increased levels of PGs are seen in loco-regional tumors and in metastases. PGs cause sensitization of afferents including C-polymodal nociceptors and A-δ high-threshold mechano-nociceptors and mediate hyperalgesia induced by BK and NE. COX-2 is upregulated in head and neck cancers and in mucositis.[4]

Modulation of nerve input and transmission involves presynaptic modulation of the primary signal by excitatory and inhibitory input from adjacent neurons and from descending pathways. Second order neurons and central pathways are also subject to modulation from higher centers. Modulation is mediated by interaction with receptors including AMPA, NMDA, and by neurotransmitters including substance P (SP), serotonin (5-HT), NE-A, opioid, cholecystokinin (CCK), and gamma-aminobutyric acid (GABA). Modulation is impacted by stress, learned behavior, and acute pain. Perception of pain is impacted by attention, expectation, anxiety, and depression. Mucosal changes, hyposalivation, tissue fibrosis, neurovascular changes, and recurrent cancer and secondary complications of cancer or therapy may result in chronic pain.

Neuropathic pain may result from insult to the peripheral nervous system (PNS) and/or the central nervous system (CNS), including alteration in sensory and sympathetic fibers, and may result in peripheral sensitization and central sensitization. Surgery or cytotoxic agents may lead to neuropathy due to nerve damage via crush, pressure, cut, or inflammation, resulting in ectopic firing and changes in receptive field that lead to nerve excitability and spontaneous activity (wind-up). Persistent input may also result in increased receptive fields in second order neurons and centrally. Neuronal hyperexcitability may be due to overexpression of sodium channels and activation of the NMDA receptor, which develops at voltage gated sodium channels (VGSCs).

Interactions between the sympathetic nervous system and nociceptors are thought to be associated with some of the findings in neuropathic pain. Injured C-fiber terminals may atrophy and be replaced by A-β fibers that sprout into the superficial layers of the dorsal horn and may contribute to sensory abnormalities following peripheral nerve injuries. SP in A-β fibers may be increased and lead to pain.

In addition to neuronal sensitization, TNF-α, IL-6, and IL-11 promote osteoclast formation and likely play a role in malignant bone pain. The effects of IL-1 are probably mediated by induction of NO, BK,[156] and PGs. Endothelin-1 (ET-1) may be a cause of pain in cancer involving bone. Prevention and treatment of pain based on increased understanding of pathogenesis may lead to novel approaches and improved patient outcomes.

PAIN MECHANISMS DUE TO CHEMOTHERAPY AND/OR RADIOTHERAPY

Peripheral neurotoxicity is common with a number of chemotherapeutic agents, including vinca alkaloids (vincristine, vindesine, and vinblastine). Platinum agents, including cisplatin, induce neuronal apoptosis and may lead to damage or loss of large myelinated sensory fibers; in addition, NGF and induction of lysosomal storage defects have been shown in the dorsal root ganglion (DRG). The taxanes (paclitaxel, docetaxel) cause microtubular aggregation and may increase the risk of neurotoxicity when combined with platinum agents. Other agents including noncytostatic drugs used in cancer treatment (e.g., interferon, thalidomide) or in supportive care (e.g., amphotericin-B) may also induce sensory neuropathies. Additive effects may occur from combinations of drugs.

Treatment of neuropathy generally focuses on use of centrally acting medications.[5,6] Unfortunately, strategies for prevention of neuropathy have not been documented. Amifostine and lipoic acid have been assessed in the prevention of neurotoxicity caused by platinum agents.[7,8] Melatonin was shown in one clinical trial to reduce chemotherapy induced neurotoxicity[9] and the potential role of glutamine has been examined.[10,11] Continuing study of approaches to prevent and manage neurotoxicity are needed.

Bisphosphonates are key pharmaceuticals for the treatment of malignant disease involving bone and are commonly employed for patients with multiple myeloma and metastatic breast, prostate, lung, and colon cancers. Benefits of bisphosphonate therapy include prevention of skeletally related events, hypercalcemia of cancer, and reducing bone pain associated with malignancy. Bisphosphonates inhibit osteoclast activity and thus reduce resorption of bone associated with both normal remodeling and malignancy-related bone resorption. One of the acute side effects associated with bisphosphonate administration can be bone pain, including mandible pain that may be somewhat vague, but can occasionally mimic dental pain. Since late 2002, bisphosphonates have become recognized as being associated with nonhealing bony lesions involving dentoalveolar bone. In cancer patients on bisphosphonates, the most frequent risk factor for bisphosphonate-associated osteonecrosis (BON) is dental surgery (e.g., extractions, periodontal surgery).[12–17] Pain associated with BON, when present, is usually associated with secondary infection of the soft tissues surrounding the areas of exposed bone.[154,155] Chronic BON can spread to involve nerve bundles (e.g., the inferior alveolar nerve) and produce nerve pain and numbness.

PAIN DUE TO SURGERY

Pain is a common complaint at the time of diagnosis in patients with head and neck cancer,[18] although of mild severity (visual analogue scale [VAS] ~3/10).[19] Surgical extirpation may alleviate pain, but more often, following treatment for head and neck cancer, pain increases and generally improves subsequently.[20] Furthermore, surgery on the neck is associated with shoulder and arm pain.[18]

Wittekindt et al. demonstrated that subcutaneous botulinum toxin A injections may reduce chronic neuropathic pain following neck dissection.[21] It has been theorized that the etiology of myofascial trigger points is excessive release of acetylcholine at motor end plates.[22] Botulinum toxin A achieves pain relief by preventing acetylcholine release at the neuromuscular junction. Although effective in neck dissection patients, it is unclear if this strategy has any benefit for patients who have not undergone neck dissection.

Spread of disease to regional lymph nodes is a crucial prognostic factor in head and neck cancer.[23] Treatment for cervical metastasis traditionally included radical resection of all lymph-bearing tissues in the neck, including removal of lymph nodes from levels I to V, the sternocleidomastoid (SCM) muscle, internal jugular vein (IJV), and spinal accessory nerve (SAN). This operation is known as the *radical neck dissection*, and was originally described by Crile in 1906.[24]

Based on recent studies, neck dissection has been found to have a negative impact on quality of life (QOL) and health status.[25–29] Moreover, it has been demonstrated that more extensive neck dissections are associated with higher shoulder-related disability.[27,28,30,31] Fortunately, over the latter half of the 20th century, neck dissection has evolved from solely radical neck dissection to include more conservative approaches. This has positively influenced the QOL in patients who have neoplastic disease requiring neck dissection.

The presence of shoulder and neck pain after neck dissection has been shown to be a common cause of postoperative morbidity in patients with head and neck cancer.[32] It has been postulated that mechanical overload of the shoulder secondary to change in scapular position and lack of stabilization after trapezius denervation leads to shoulder pain.[33] However, it has been demonstrated that even with preservation of the SAN, patients can have shoulder pain.[34] Moreover, pain following surgery may often be caused by tissue injury sustained during the procedure.[35]

Recently, attention has been given to the preservation of cervical sensory nerves and the effect this has on QOL. Roh and colleagues conducted a retrospective cohort study of 53 patients who underwent selective or modified radical neck dissection. The results of the study suggest that cervical sensory root branch preservation during neck dissection reduces postoperative pain and permanent sensory deficits. Additionally, the study found that dissection of level V nodal tissue (the posterior triangle of the neck) is associated with neck pain and shoulder pain.[36]

PAIN DUE TO MUCOSITIS

Oral mucositis is a frequent complication of cancer chemotherapy and radiotherapy. A five-stage model for oral mucositis has been proposed where ROS are generated during the initial phase[37–40] that results in cell damage and triggers secondary mediators, including nuclear factor-κB (NFkB) in the epithelium and connective tissue. Following upregulation of NFkB, pro-inflammatory cytokines such as TNFα, IL-1β, and IL-6 are generated, which can induce hyperalgesia. NO may also be a key factor producing pain. The ceramide pathway has been implicated in the amplification of oral mucositis and may modulate pain. Mucositis ulcerations can become secondarily colonized/infected by oral flora and further increase cytokine release and, thus, increase mucosal pain.

In addition to mucosal damage, radiation therapy damages bone by killing osteocytes, osteoclasts, and osteoblasts, and irreversibly damages endothelial cells in the vasculature throughout the radiated volume. This results in chronic hypocellular, hypovascular, and hypoxic oral soft tissue, leading to risk of soft tissue necrosis and osteonecrosis. Pain from radiation necrosis involves inflammatory and neuropathic mechanisms (see previous text) and is increased in the presence of secondary infection.

Epidemiology

Mucositis is the most common cause of oral pain during intensive treatment of cancer involving chemotherapy, radiation, or chemoradiotherapy[41–69] (Table 45.2). Oral mucositis is a common complication of myeloablative conditioning regimens used in hematopoietic cell transplant (HCT) and is virtually universal in patients treated with tumoricidal radiation therapy that includes the oropharynx. The increasing use of combined chemotherapy and radiation treatment modalities and more aggressive therapy protocols to improve cancer cure rates has increased the frequency and severity of oral complications. Changes in management include increased use of combined radiation and chemotherapy, and hyperfractionation of radiation therapy, which may result in increased toxicity.[41,43,44,46,49,52,54,57,62,69] The potential impact of targeted monoclonal antibodies and other tumor-specific targeting molecules upon mucositis is not documented, and it is not known if usage in combination with other chemotherapy may increase mucosal damage. Studies that assess mucositis as a primary or secondary outcome with targeted agents have not been conducted,[70,71] although the pattern of oral mucosal involvement and dermatologic involvement appears different than seen in traditional chemotherapy, suggesting that different mechanisms may be involved.

Advances in medical management of patients receiving intensive cancer therapies, including use of antimicrobial prophylaxis and therapy and the use of growth factors to speed hematopoietic recovery, has sharpened the focus on oral mucositis as a significant and treatment-limiting complication in cancer therapy.[72–74] Oral mucositis is also often coincident with therapy-related toxicity at other sites, including veno-occlusive disease in HCT[69] and gastrointestinal toxicity.[75] The potential for systemic infection caused by oral opportunistic and acquired flora associated with oral mucositis has been documented in several studies of leukemia and HCT patients.[76–80]

TABLE 45.2

FREQUENCIES OF ORAL PAIN ASSOCIATED WITH CANCER THERAPY

Acute pain during treatment	
Oropharyngeal mucositis	
Chemotherapy	15% to 70%
Bone marrow transplant	50% to 85%
Radiation therapy	Up to 100%
Postsurgical therapy	Up to 100%
Chronic pain following cancer therapy	
Mucosal pain	Up to 33%
Pain associated with mucosal infection	
Candidiasis	
After stem cell transplant	Up to 50%
After radiation therapy	20% to 33%
Herpes simplex in seropositive stem cell transplant patients	Up to 90%
Neuropathy	16%
TMD/myofascial (patients with head and neck squamous cell carcinoma)	25% to 30%

TMD, temporomandibular disorder.

Pathogenesis

Intensive cytotoxic chemotherapy and radiation therapy directly affect the proliferation of epithelial cells and connective tissue elements leading to damage to the epithelium and submucosal tissues and potentially to loss of the mucosal barrier (Fig. 45.1 and Table 45.3). Epidermal growth factor (EGF) secretion may increase the risk of mucositis[81] and, conversely, cytokines that reduce epithelial cell proliferation have the potential to decrease the severity of tissue damage. Interaction with cytokines produced in the connective tissue such as granulocyte-macrophage colony stimulating factor (GM-CSF), TNF, IL-6 and IL-11, and others may affect tissue damage.[72–75,82,83] The oral microflora may play a role in progression of mucosal damage, as suggested in studies of gram-negative bacterial flora in radiation-induced

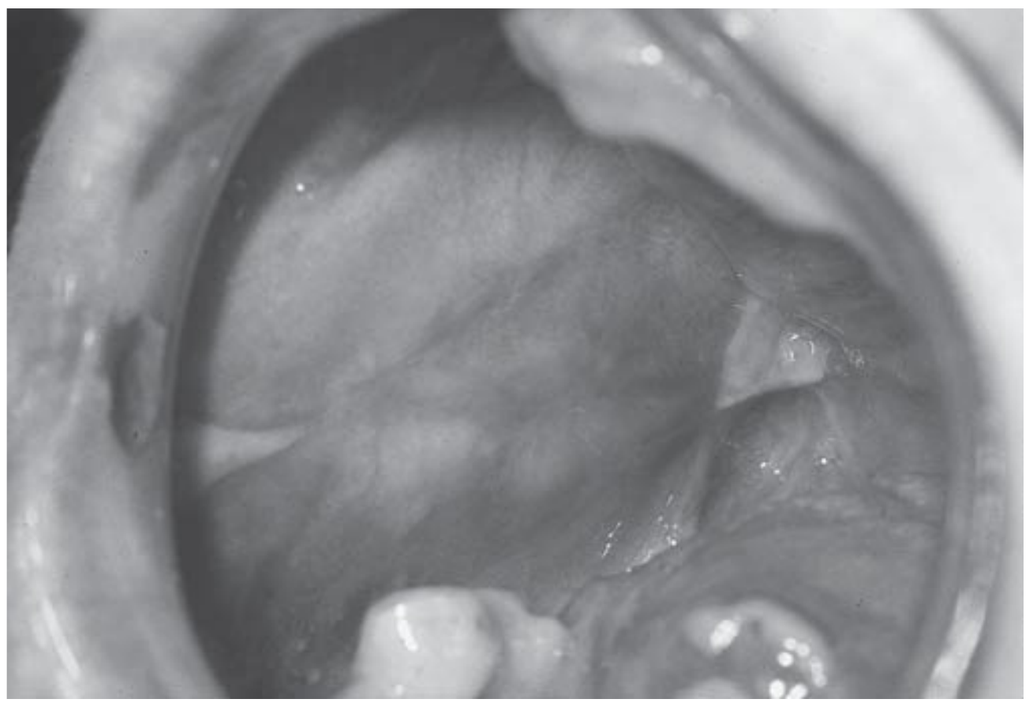

FIGURE 45.1 Mild mucositis with erythema and minor erosion of the cheek mucosa in a patient following autologous bone marrow transplant (at day +14). Mild mouth discomfort was reported.

TABLE 45.3

FACTORS CONTRIBUTING TO OROPHARYNGEAL MUCOSITIS

Direct factors	Indirect factors
Radiation therapy	Myelosuppression
Dose/fraction	Immunosuppression
Total dose/days	T-cell loss/dysfunction
Chemotherapy	B-cell loss/dysfunction
Drug/dose/schedule	Reduced secretory immunoglobulin A
Bone marrow transplant	Infections
Chemotherapy	Bacterial
Irradiation	Plaque control
Salivary gland dysfunction	Viral
Mucosal trauma	Herpes simplex
Physical	Varicella zoster
Chemical	Cytomegalovirus
Thermal	Other
Microbial flora	Fungal
Graft-versus-host disease	
Manifestations	
Prophylaxis	
Therapy	
Patient susceptibility

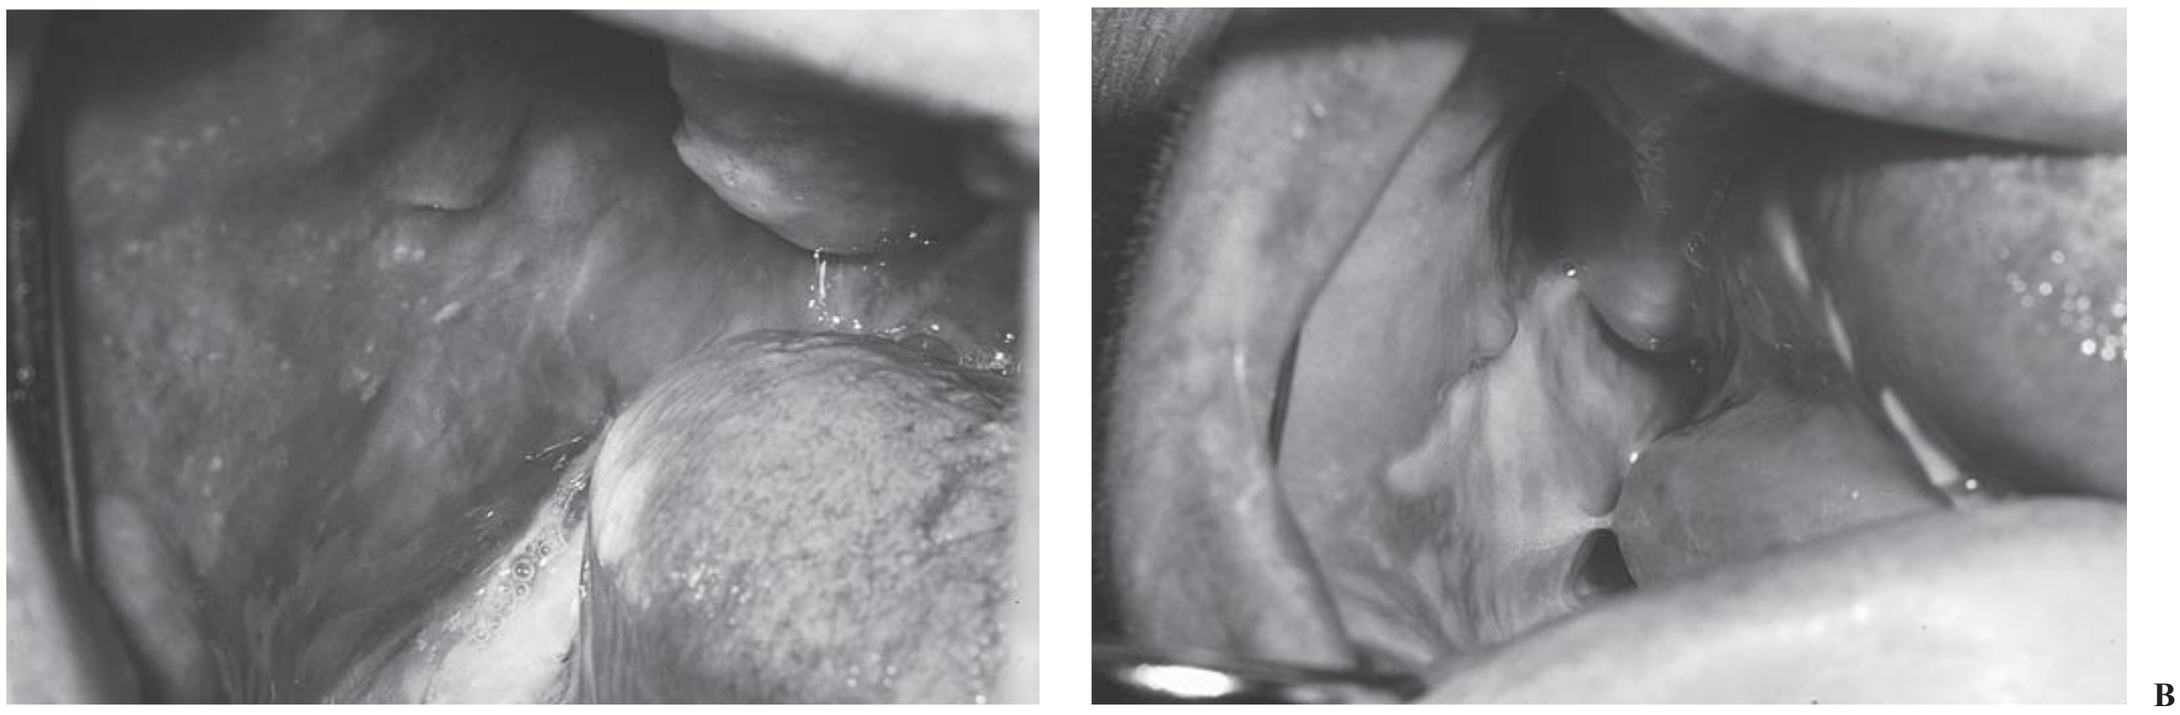
mucositis. The outcomes of microflora-induced mucosal damage are influenced by the potential effect of cancer therapies on the hematopoietic system and, ultimately, damage to local and systemic immune function. Resolution of mucositis may be dependent on production of pluripotential growth factors affecting epithelial and connective tissues.[52,72–75] During resolution, cytokines inducing epithelial cell proliferation and migration and angiogenesis play a role.[52,84–90] Pain associated with mucositis is dependent on the degree of tissue damage, sensitization of nociceptors, and elaboration of inflammatory and pain mediators.

In head and neck cancer treated with radiation, pain intensity and pain interference scores directly correspond to mucositis and increase at week 3, often peak at week 5, and persist for weeks following the end of treatment. Concurrent chemoradiotherapy and intensified radiation protocols increase the severity and duration of oral mucositis.[91–93] However, marked improvement may be seen through 12 months posttreatment, with general functional and physical appearance measures returning toward baseline level. Follow-up of oropharyngeal cancer patients (up to 1 year) treated with radiation showed that pain is common (58.4%) and interfered with daily activities in approximately one-third of subjects.[94]

Hematopoietic Cell Transplant



Ulcerative mucositis is the most debilitating patient-reported toxicity of HCT and treatment for hematologic cancer.[54,55,60,62] Mucositis is compounded in patients with herpes simplex virus (HSV) reactivation and in those with poor oral hygiene.[53,60,65,66,95] HSV prophylaxis has altered the frequency and severity of mucosal ulceration due to HSV in HCT patients; however, even in patients given acyclovir prophylaxis, oral ulcerative mucositis occurs in up to 75% of patients.[55]

Mucositis symptoms can be increased in HCT patients with xerostomia[63] and the related oral microflora and dental plaque changes may influence the severity of mucositis.[95–101] Intensive oral hygiene has been documented to reduce the severity and duration of oral mucositis.[95] Studies have demonstrated that approximately 48% of bacteremia in the early period post-HCT are associated with oral bacteria. Some providers are concerned about the risk of bacteremia and gingival bleeding due to brushing and flossing during the first 3 weeks post-HCT; however, septicemia is not increased in patients who continued intensive oral care.[95] Immunoglobulins and other antimicrobial proteins in the saliva are decreased after HCT conditioning, which may be an additional factor in the increased risk of mucosal infection.[75]

Clinically, oral mucositis for autologous HCT patients becomes evident approximately 2 to 5 days after marrow infusion (day +2 to 5) with resolution in more than 90% of patients by day +15.[55] Allogeneic HCT patients will generally show a slightly slower onset and slower resolution of mucositis. Damage to the mucosa most often presents in a bilateral pattern, primarily involving the nonkeratinized mucosa of the cheeks, lateral and ventral surfaces of the tongue, floor of the mouth, soft palate, and labial mucosa. The mucosal reaction may begin shortly after exposure to the conditioning regimen and progress to erythema and ulceration (Fig. 45.2; also see Fig. 45.1). Increased mucosal toxicity is usually seen in patients additionally conditioned for HCT with total body irradiation.[62,64,72]

Head and Neck Radiation Therapy

Tumor-related pain is commonly present at the time of diagnosis of head and neck and oral cancer (85%), although the intensity is usually not severe.[58,102] The presence and severity of pain are related to tumor stage and with bone involvement.[58] Pain occurs with treatment in all patients treated for oropharyngeal cancer and increases in severity throughout the course of radiation and persists after treatment.[41,58,67,68] Radiotherapy-related mucositis is the most frequent complication in patients during irradiation for head and neck cancers (see Table 45.1). Mucositis affects the oral tissues included in the fields of irradiation (Figs. 45.3 and 45.4). Mucositis-related pain increases during radiation treatment, and typically resolves within 1 to 2 months, or longer with combined radiation and chemotherapy. However, mucosal discomfort often continues for 6 to 12 months or longer, although the severity of pain decreases over time after treatment.[58] Chronic complaints include mucosal sensitivity attributed to mucosal atrophy (33%), musculoskeletal syndromes (temporomandibular disorder) (25%), and neurologic syndromes attributed to deafferentation (16%).[58] In another study, the most common persisting complaints after radiation treatment included xerostomia (57%), jaw pain involving the muscles of the jaw or joint pain (27%), and a 10% increased rate of dental caries.[103] Chronic complica-

A B

FIGURE 45.3 **(A)** Initial tissue reaction in a patient receiving radiation therapy (dose received 1400 cGy of planned 6000 cGy) resulting in erythema and sensitivity of the right buccal mucosa. **(B)** Late tissue reaction in the same patient receiving radiation therapy (total dose received 6000 cGy) resulting in oral pain and mucosal ulceration within the radiation field.

tions of radiation therapy were assessed in 676 head and neck cancer patients treated in a multicenter study and 11% had severe complications (grade 3 or 4) involving the oral mucosa, bone, or muscle.[104] These late complications were related to total radiation dose, complications in bone were more common with large radiation fields, and complications in bone and muscle were related to radiation fraction size. The severity of chronic mucosal damage may relate to severity of acute mucosal reaction.

Combined Radiation Therapy, Surgery, and/or Chemotherapy

Treatment of locally advanced head and neck carcinoma is associated with significant treatment complications affecting oral function. Hyperfractionated radiotherapy and chemotherapy improve survival, but treatment is frequently limited by the severity of oral toxicity.[41,44,46,57,105,106] Severe oral mucositis occurs in essentially all patients treated with accelerated fractionated irradiation for supraglottic cancer[1] and in those treated with combined chemotherapy and radiation therapy.[105,106] Severe mucositis may cause considerable pain, limit or prevent oral intake, and may lead to suspension of cancer therapy.[41,106] Changes in the delivery of radiotherapy, including increasing total dose, hyperfractionation, accelerated therapy, and the combination of radiation therapy and chemotherapy, have increased the severity and duration of mucositis. Intensity modulated radiation therapy (IMRT) may not decrease ulcerated mucositis and symptoms, even though the volume of severe reaction may be reduced.[93] Mucosal reactions in patients receiving radiation treatment for head and neck cancer are currently regarded as unavoidable side effects but advances in knowledge of pathogenesis and new therapy is expected to change this view, with prophylaxis, intervention, and improved symptom management.

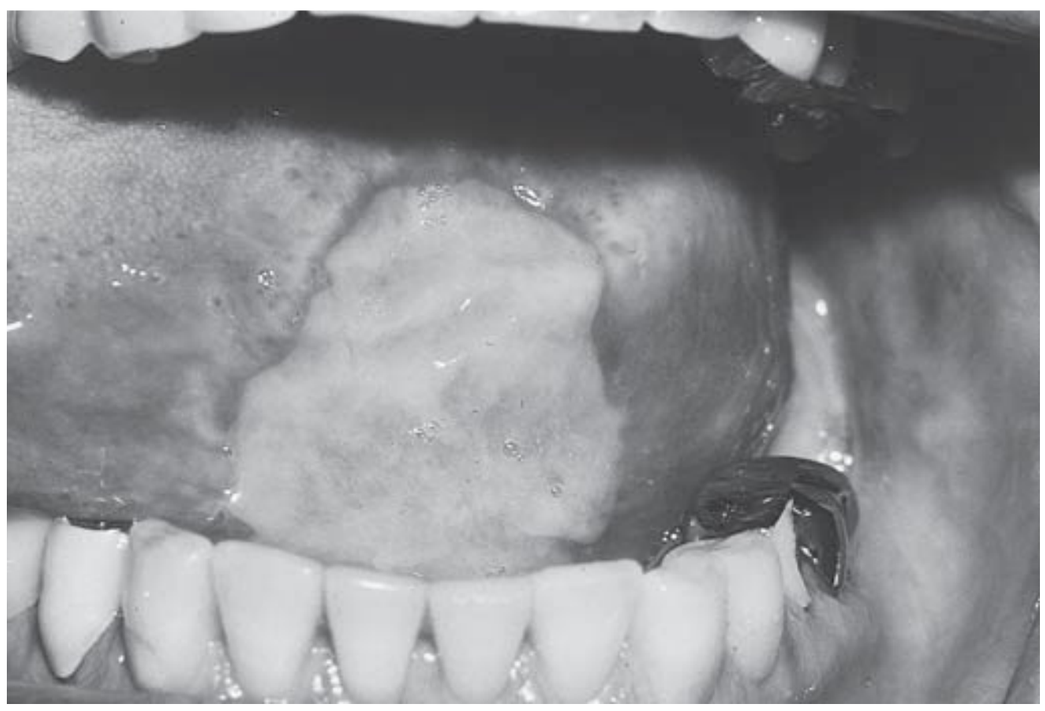


FIGURE 45.4 Localized ulcerative mucositis following brachytherapy for a squamous cell carcinoma of the middle portion of the lateral border of the tongue.

The importance of fungal colonization and infection in radiation mucositis is not clearly defined.[107–109] One study showed fewer cases of candidiasis in patients on fluconazole and half the number of breaks in radiation therapy than those not provided prophylaxis with fluconazole.[107] However, others have not found an association between candidiasis or oral colonization and mucositis during cancer therapy.[107,109]

Targeted chemotherapy with monoclonal antibodies and small molecules are becoming part of therapy. The impact on mucositis is not well defined, as mucositis has only been recorded with multiple toxicities and no studies have assessed mucositis using a validated scale as a primary or secondary endpoint. However, the available data suggest that oral mucositis is not more common than that seen with standard therapy and, in fact, it may occur less frequently and be less severe.[70,71,110–116] Approximately 90% of patients develop oral pain during HCT.[56]

PAIN ASSESSMENT

Most studies use a VAS or 5- or 10-point scales to assess oral pain or the McGill Pain Questionnaire.[56,117] The McGill Pain Questionnaire was compared with two different factor models in patients with oral mucositis pain after HCT, and it was recommended that a single pain rating may provide a better practical measurement.[117] Many patients may be unable or unwilling to complete lengthy questionnaires, particularly when their overall condition including pain is at its worst. Notwithstanding analgesic use, most of the variance in pain report is explained by the severity of the mucositis rather than psychosocial variables.[51]

MANAGEMENT OF ORAL MUCOSITIS

Wide variation exists in quality of mucositis prevention and management studies. Many enroll a small number of patients, using outcome measures that are not validated, and may lack sensitivity. This makes assessment of outcomes difficult, mandating careful review of the methods employed in every study before generalizable conclusions can be drawn. Guidelines for the use of outcome measures and more refined study design and protocols in the management of mucositis are improving the value of more recent studies. Evidence-based guidelines[118–120] have been developed to provide guidance and will continue to evolve as new approaches to prevention and management are studied.

Development of strategies for the prevention and management of oral mucositis has been enhanced by an improved understanding of the multifactorial nature of the condition (Table 45.4). Radiation shields are recommended during standard radiation therapy. The use of midline mucosa-sparing blocks for protection of the mucosa during radiation therapy, thereby reducing mucositis, resulted in less weight loss, fewer hospitalizations for nutritional support, and a trend toward fewer treatment interruptions ($p = 0.07$) than in control patients.[48] The impact of IMRT on oral mucositis pain is not well understood, with reduced area of severe tissue damage, but broader areas of low dose radiation exposure.[93]

Kepivance (palifermin; Biovitrum, Inc., Stockholm, Sweden) is the only approved agent for prevention of oral mucositis in HCT.[14,121] Further study of patients with metastatic colon cancer treated with fluorouracil-based chemotherapy showed benefit of Kepivance reducing mucositis,[122] suggesting broader potential application than currently indicated. Clinical trials to determine the prevention of mucositis in patients receiving head and neck radiation are currently under way. Benzydamine (not available in the U.S.) is recommended for use in patients receiving radiotherapy (>220 cGY/day). Oral cryotherapy is recommended for prevention of mucositis in those receiving bolus 5-FU or edatrexate treatments, or high-dose melphalan conditioning regimens for HCT. Low-energy lasers have been studied in the prevention and management of mucositis associated with HCT and head and neck radiation with consistent findings across studies.[123–125] The mechanism of action may be due to effects of cytokine release following laser exposure and enhanced epithelial cell growth, but further study is needed. Low-energy laser for prevention of mucositis has shown consistent results and further study is needed to determine the optimal delivery for clinical use.

TABLE 45.4

PREVENTION AND MANAGEMENT OF ORAL MUCOSITIS

Pretreatment oral/dental stabilization
- Eliminate sites of infection, trauma
- Dental cleaning
- Good oral hygiene
  - Saline mouth rinses

Antimicrobial approaches
- Systemic antimicrobials
  - Antibiotics
  - Antivirals acyclovir, valacyclovir, ganciclovir
  - Antifungal fluconazole
- Topical antimicrobials
  - Chlorhexidine
  - Antimicrobial lozenges (polymyxin, tobramycin, amphotericin)

Anti-inflammatory approaches
- Topical agents
  - Prostaglandins
  - Benzydamine
  - Corticosteroids

Biologic response modifiers
- Granulocyte-macrophage colony stimulating factor
- Granulocyte-colony stimulating factor
- Epidermal growth factor
- Transforming growth factor, interleukin-11

Miscellaneous approaches
- Good oral hygiene
- Saline/bicarbonate mouth rinses
- Low-energy lasers
- Mucosal coating agents
- Vitamin supplements
- Anticholinergic agents (xerogenergic agents)
- Modification in cancer treatment protocols

PAIN MANAGEMENT

With only a small number of approaches documented to prevent the incidence or shorten the duration of oral mucositis, management of oral mucositis depends on palliative approaches. The use of a *stepped protocol* for pain management is currently the most appropriate approach. The elements of this protocol include the progressive utilization of: (1) basic oral care, (2) bland rinses, (3) topical anesthetic and mucosal coating agents, and (4) systemic analgesics.

Basic Oral Care

A growing body of evidence is being accrued that supports the importance of maintaining oral care protocols to remove bacterial dental plaque from teeth and periodontal tissues during intensive cancer therapies.[118,119] Patients should maintain good oral hygiene by brushing, flossing, and possibly using antimicrobial products.

Bland Oral Rinses

Although there are no studies demonstrating the effectiveness of normal saline or bicarbonate rinses in decreasing mucositis, they have been shown to reduce mucosal pain.[126,127] Frequent use of bland rinses can provide relief for mild mucositis, help remove debris, and moisturize mucosal surfaces. In a study of 40 patients undergoing radiotherapy to more than 50% of the oral cavity, half were randomized to an oral care protocol using either saline or hydrogen peroxide rinses, and the latter was associated with increased mucosal sensitivity.[128]

Topical Anesthetics and Analgesics

Topical anesthetics represent the next step up in the strategy to manage mucositis pain. While there are no studies specifically examining efficacy of various topical anesthetic agents, any agent that can be safely applied to oral mucosa to induce topical numbness that is tolerated by the patient can be used.[61] Lidocaine viscous solution is frequently recommended, but other agents that can be used include benzocaine, dyclonine, and diphenhydramine. Topical anesthetics can cause mild initial irritation, obtund

taste, and diminish the gag reflex if gargled or swallowed. Swallowing of these agents to control pharyngeal pain is not generally recommended due to possible systemic side effects and toxicities if swallowed in large doses. Benzydamine has been shown to reduce mucositis and associated oral pain in radiation-induced mucositis by initially producing an anesthetic effect, but with an extended analgesic effect.[61,68] Local applications of topical anesthetic creams or gels may be especially useful for local painful mucosal ulcerations.

Topical analgesics have shown effect in mucositis pain. Initial studies of topical morphine show pain reduction in oral mucositis,[129] and doxepin in single and multidose studies has shown extended duration pain relief without burning sensation when applied to ulcerated tissue.[130]

Coating agents used as oral rinses in patients with mucositis, such as milk of magnesia and loperamide have been recommended frequently, but have not been subjected to controlled studies.[61,118] Sucralfate suspension has been studied in mucositis,[131–134] but results have been inconsistent and its use for radiation or chemotherapy mucositis are not supported.

A number of mucosal coating agents or rinses have been licensed by the FDA for the management of oral mucositis, including Gelclair (EKR Therapeutics, Bedminster, NJ), MuGard (Access Pharmaceuticals, Inc., Dallas, TX), and Caphosol (EUSA Pharma, Inc., Langhorne, PA). However, there is no or insufficient evidence to recommend their use for prevention of mucositis.[135,136]

Topical Antimicrobials

Early studies suggested that topical antimicrobials may have utility in preventing oral mucositis, but follow-up research has failed to provide evidence to support their use for prevention of mucositis.[118] Chlorhexidine has been assessed in HCT patients in a number of studies but conflicting results with its use in mucositis have been seen. The majority of follow-up studies do not demonstrate a prophylactic effect on mucositis.[137] It is important to note that the effectiveness of chlorhexidine rinsing on plaque levels, gingival inflammation, and caries risk have not been endpoints in these studies, and the use of chlorhexidine for bacterial plaque control during cancer therapy may still be useful.

Studies of antimicrobial lozenges combining agents such as polymyxin, tobramycin, and amphotericin B in head and neck radiation therapy was shown in a single center trial to be effective.[138] However, follow-up studies to duplicate the benefit of using either topical antimicrobials or b-defensin, while showing effectiveness in reducing oral microbial colonization, did not significantly impact on mucositis.[139–142]

Analgesics

Symptom management for oral mucositis often requires the use of systemic analgesics. Mucositis is the most common condition requiring the use of systemic opioid analgesics during cancer therapy.[45] A wide range of agents can be used including acetaminophen, nonsteroidal anti-inflammatory agents (NSAIDs), and opioids.

Systemic analgesics should be prescribed following the World Health Organization (WHO) analgesic ladder.[61] These recommendations include the use of nonopioid analgesics alone, or in combination with opioids and adjunctive medications, based on pain severity and effectiveness of therapy (see Chapter 39). In patients with oral mucositis pain, topical approaches should be used initially and should continue to be used in combination with systemic analgesics in order that the best pain management can be achieved with the least potent and lowest doses of systemic pain medications. Studies have shown that optimum pain control may be achieved by moving directly from WHO ladder level I analgesics to titrated doses of WHO ladder level III analgesics. Improvement in pain control is achieved by combining level III analgesics with adjuvants at lower total doses of analgesics, and therefore modification of the analgesic ladder has been discussed.[143]

A number of different delivery methods can be used for mucositis pain control. Oral, transmucosal, transdermal (patches), intravenous, and suppository routes can be used. Patient-controlled analgesia (PCA) is recommended in pain management for hospitalized cancer patients with severe mucositis.[144] A study of preteen children receiving HCT assessed morphine or hydromorphone PCA for mucositis or other painful conditions found that children successfully mastered PCA to control pain associated with HCT.[45] No instance of drug overdose or difficulty stopping the opioid was noted.[45] As has been previously voiced, addiction is not nearly so much a risk in these patients with severe and debilitating pain as is underuse and underdosing of analgesics.[61]

Anti-infective Approaches

Infection may result in direct mucosal damage, initiating or complicating mucosal pain. Acyclovir prophylaxis in HSV-seropositive HCT patients is strongly supported in the literature. Antiviral therapy prevents both HSV reactivation in HSV-seropositive HCT patients and viral shedding (seen in 2.9% of patients), in most cases.[145] Oral ulcerations may be caused by cytomegalovirus (CMV) in HCT[146] and shedding of CMV was detected in 13.3% of CMV-seropositive patients. No correlation between severity of mucositis and serologic status of HSV or CMV was seen in patients provided acyclovir prophylaxis.[145] Ganciclovir after stem cell transplant in HCT has been shown effective in suppressing CMV infection[147] and acyclovir prophylaxis has also been shown to prevent shedding of CMV by approximately half in HCT patients.[148]

Consecutive HCT patients at risk of streptococcal bacteremia were treated for 5 days with clindamycin and ceftazidime for the initial management of fever associated with severe oral mucositis.[79] Bacteremia caused by viridans streptococci occurred in 70% of patients with severe mucositis and culture results were positive a day prior to fever in approximately one-third of cases, showing that mucosal ulceration predisposes to systemic infection by oral flora. Approaches to reduce mucosal damage will reduce pain and infection risk and have been suggested as a better means of reducing systemic infection rather than via antimicrobial approaches.[79]

In a series of patients with leukemia receiving HCT, fluconazole prophylaxis was compared with no prophylaxis[109] and a trend toward reduction in oropharyngeal colonization by *Candida albicans* was seen ($p = 0.07$). However, the clinical implications are unclear since no relationship was seen between *Candida* species, antifungal prophylaxis, and mucositis, indicating that *Candida* was not involved in the etiology of mucosal damage in these patients.[108] In a randomized controlled trial, fluconazole prevented systemic fungal infections (7% of fluconazole versus 18% of placebo patients)[149] and the incidence of mucosal infection and oropharyngeal colonization by *C. albicans* was reduced.[150,151] Therefore, while *Candida* may complicate oral mucositis and cause mucosal sensitivity and systemic infection, it does not appear to be a cause of mucositis.[152]

XEROSTOMIA

Preventing mucosal toxicity will reduce the pain of oral mucositis. Mucosal toxicity is dose limiting for patients on etoposide and may be related to direct effects of myoablative doses of etoposide that are secreted in saliva.[59] Twelve patients received propantheline, an anticholinergic xerostomia-inducing agent, or placebo, and mucositis was less frequent and less severe ($p = 0.05$) in the propantheline arm. Another study investigated the effect of drug-induced xerostomia on mucositis during HCT by comparing

patients with historic controls.[153] Propantheline was found to significantly reduce oral mucositis due to high-dose etoposide, although no effect was seen on esophagitis and enteritis. These findings suggest that for chemotherapeutics that are secreted in saliva, pharmacologically induced hyposalivation may decrease the exposure of the chemotherapeutic to the mucosa and thereby reduce local tissue damage.

TOPICAL APPROACHES FOR MANAGEMENT OF ORAL MUCOSITIS

Biological Response Modifiers and Cytokines

EGF in saliva was assessed in patients receiving head and neck radiation therapy.[157] The quantity of EGF in the oral environment decreased because of decreased volume of saliva and decreased in concentration per milliliter of saliva as mucositis increased throughout the course of radiation therapy.[157] These findings suggested that EGF may represent a marker of mucosal damage and has the potential to promote resolution of radiation-induced mucositis.

Mixed results have been seen with GM-CSF in several human trials.[72–75,83,84] Studies assessing granulocyte colony stimulating factor (G-CSF) have also presented mixed outcomes. These results may be due to mucositis as a secondary endpoint or toxicity report only in these studies.[52,84,85] Overall, the available and conflicting results do not provide sufficient information to recommend use of white cell growth factors for the treatment of mucositis.

Cognitive and Behavioral Interventions

Relaxation, imagery, biofeedback, hypnosis, and transcutaneous electrical nerve stimulation have been employed in the management of cancer pain with varying patient acceptance and efficacy.[61,158,159] Cognitive behavioral interventions in pediatric oncology and HCT included providing information before procedures and positive reinforcement after procedures and, less commonly, behavioral interventions such as rhythmic breathing, distraction, and imagery.[160] Psychological services were primarily available on an as-needed basis and support groups were not generally offered. Increasing emphasis on psychological support and techniques for pain management may be useful for patients during HCT.

A controlled clinical trial of psychological interventions in cancer-related pain was conducted in 94 HCT patients with oral mucositis in four groups, and relaxation and imagery training was shown to reduce pain associated with oral mucositis. However, adding cognitive-behavioral skills to relaxation and imagery did not improve pain relief.[161] The reader is referred to other chapters in this section for more detail with regard to psychological approaches to pain and an in-depth review of treatment of bone pain, use of nonopioid and opioid pharmacotherapy for cancer pain, radiopharmaceuticals, and interventional approaches to pain control in cancer.

CONCLUSION

Pain in the head and neck and oropharynx of cancer patients has a significant impact upon QOL and needs to be treated aggressively to prevent comorbidities. Cancer and cancer therapy results in release of reactive oxygen species, growth factors, cytokines, and enzymes that may cause nerve irritation or damage that may result in acute and chronic pain. Anxiety and depression compound the pain experience. Mucosal damage, particularly in the presence of immunosuppression and neutropenia, may result in risk of systemic infection (Fig. 45.5). Oropharyngeal pain in cancer patients frequently requires systemic analgesics, adjunctive medications, physical therapy, and psychological therapy, in addition to oral care and topical treatments (see Table 45.4). Good

FIGURE 45.5 A model of the pathogenesis of oral mucositis.

TABLE 45.5

SYMPTOMATIC MANAGEMENT OF PAIN OF ORAL MUCOSITIS

Maintain good oral hygiene
Prevent mucosal damage (see Table 45.2)
Coating agents (e.g., milk of magnesia, aluminum hydroxide gel [Amphojel], sucralfate, loperamide [Kaopectate], Gelclair, Caphosol)
Topical analgesic/anti-inflammatory (benzydamine)
Topical anesthetics/analgesics
Systemic analgesics
Adjuvant systemic medications
Adjuvant cognitive/psychological support
Physical therapy (rinsing, ice chips)
Miscellaneous agents

oral hygiene including tooth brushing and dental flossing reduces the severity of oral mucositis and does not increase the risk of bacteremia.

Clinically apparent mucositis is the result of drug toxicities, tissue damage, and inflammation. The primary event is cell damage from chemotherapy, radiotherapy, or both. Secondary influences include indirect toxicities resulting in immunosuppression, neutropenia, reactivation of latent virus (herpes viruses), and opportunistic microbial (bacterial and fungal) infections. Salivary gland dysfunction caused by dehydration and direct effects of the cancer therapy on gland function may alter the local mucosal defenses. Because the etiology is multifactorial (see Table 45.3), approaches to prevention and treatment also have been multifactorial (see Table 45.4). Effective prevention and management of mucositis affect the pain experienced during cancer treatment and, when mucositis is present, symptomatic management is needed (Table 45.5).

Systemic analgesics remain an important mainstay in pain treatment along with topical analgesics and anesthetics. Pain management including adjunctive pain medications are often underutilized in head and neck cancer-related pain syndromes. Novel approaches of potential interest are agents that affect neurotransmitters of pain such as substance P and potentially reactive oxygen species, cytokine production, prostaglandins, and other neurotransmitters.

Biological response modifiers offer the potential for prevention and to speed healing. Oral care and continuing good oral hygiene is recommended prior to and during cancer therapy. Keratinocyte growth factor (Kepivance) is the only approved and recommended medication for prophylaxis of mucositis in HCT. Benzydamine is recommended in head and neck radiation therapy but it is not available in the United States. Oral cooling (cryotherapy) with ice chips is recommended for patients receiving short half-life systemic chemotherapy. Available local agents of questionable value include a coating agent (Gelclair) and a mineralizing oral solution (Caphosol). Meanwhile, a number of agents with different mechanisms of action are undergoing investigation. Of potential value is the use of xerostomic-inducing medications to reduce exposure of the oral mucosa to chemotherapeutic drugs that are secreted in saliva.

Whereas antimicrobial approaches have been shown to not prevent mucositis, there may be a positive effect on dental and gingival health and on candidiasis. Other approaches that require further study include low-energy lasers and anti-inflammatory medications.

CHAPTER 46 ■ CANCER-RELATED BONE PAIN

JANET ABRAHM, EDGAR ROSS, AND ROBERT J. KLICKOVICH

EPIDEMIOLOGY REVIEW

Bone pain due to cancer is caused by primary bone tumors and those malignant diseases that commonly metastasize to the bones. Metastatic bone pain most commonly results from cancers of the breast, prostate, and lung. Other malignancies involving bone are renal cell carcinoma, thyroid cancer, lymphoma, and multiple myeloma.[1] The longer these malignancies persist, the higher the probability of bone metastasis. Because current therapies are increasing survival time with most of these malignancies, there is an increasing prevalence of metastatic bone disease. Specifically, since prostate cancer is most likely to metastasize to bone rather than other organs, and patients with prostate cancer are also likely live longer than patients with other metastatic diseases, they are more likely to have more prolonged periods of pain secondary to bony invasion.[2]

Of all bony metastases, vertebral involvement is the most common. The incidence ranges from 30% to 70%.[3] Most patients with metastatic disease of the vertebrae experience back pain. Bony metastases compromise both the bone's integrity and strength. In the vertebrae, this leads to the risk of a pathologic fracture, most commonly in the elderly. Compression fractures affect between 8% and 30% of cancer patients with vertebral body involvement.[4,5] In many cases the fracture occurs without an initial traumatic event suggesting that load is an independent factor in the etiology of a pathologic fracture.[6] Other factors that can lead to pathological fractures include iatrogenic causes such as steroids, malnutrition-induced osteoporosis, bone mineral loss as a result of inactivity, and destruction of bone secondary to radiation therapy.[7]

Complications from vertebral fracture include a redistribution of load across affected vertebral bodies creating fractures at adjacent levels, an increased risk of embolic phenomena as a result of inactivity and pain, kyphosis-induced restriction in vital capacity,[8] predisposition to atelectasis, and early satiety-induced anorexia.[9] Because of this, bony metastases can contribute significantly to decreased lifespan in the patient with one or more tumor-related compression fractures.[6,10]

Pathophysiology

Over the past 10 years, animal models for bone tumor growth, bone remodeling, and bone pain have demonstrated a correlation with many features found in human bony metastatic pain. Mouse studies using murine sarcoma cells injected into the intramedullary space of the femur demonstrate mechanical as well as movement-related pain behaviors. These behaviors[11] increase with time and with tumor-induced bone destruction offering a model that appears to replicate the human experience of how metastatic bone cancer contributes to bone pain. In normal mice, a nonnoxious stimulus to the femur does not elicit the synthesis of any tissue factors, while in mice with bone cancer, a nonnoxious stimulus elicits the synthesis of substance P which binds to the neurokinin-1 receptor expressed in the spinal cord. Likewise, c-fos is not expressed at the level of the spinal cord in normal mice, but this protein is found in a population of mice with bony tumors.[12]

Both osteolytic and osteoblastic changes in bone occur in some tumor types such as lung, breast, and renal tumors. A predominance of osteolysis is found in multiple myeloma and sarcomas, leading to extreme destruction of bone. Osteoblastic lesions commonly result from metastatic prostate cancer.[13] In the prostate model, colonies of malignant prostate tissue exist along the length of the intramedullary canal divided by newly formed bone. In the sarcoma model, there is no new bone formation, only destruction, which is greatest at the proximal and distal head with little to no destruction at the mid-shaft of the bone. The prostate model also demonstrates the formation of new bone along the length of the long bone involving diaphysis, proximal, and distal end points with an increase of osteoclasts throughout the length of the intramedullary canal. These cells stimulate osteolytic remodeling inducing an inflammatory reaction mediated by macrophages. It is suspected that this macrophage induced inflammatory activity may be the basis for neuropathic type of pain found in malignancies of the bone.[12]

In those mice injected with a purely osteolytic line of cells, a greater proportion of the mouse's time was spent guarding or flinching to innocuous palpation of the mice. Human perception of allodynia or hyperpathia from lytic lesions is thought to be

analogous to the mouse findings. The osteolytic model also demonstrates demineralization and destruction throughout the length of the bone involved which leads to the potential of increased pain from the loss of structural integrity.[14] In contrast, the prostate model, which includes both areas of infiltration and destruction, may result in increased stability of the bone, such that sensory receptors in the periosteum sense less distortion from palpation.[14]

Multiple studies have demonstrated that the periosteum is richly innervated by both sympathetic and sensory nerve fibers.[15,16] The periosteum receives the greatest amount of afferent sensory fibers per unit area in bone. In addition the periosteum, bone marrow and mineralized bone are innervated by both sensory and sympathetic fibers coursing with blood vessels.[17]

Osteolytic animal models demonstrate microscopic fragmentation and disruption of the bony matrix secondary to tumor growth. In the osteoblastic model, there is evidence of destructive injury as well as an increase in the density of sensory fibers compared to normal bone. An increase in specific transcription factors has also been demonstrated, including activating transcription factor-3 (ATF-3). Expression of ATF-3 is usually detectable in peripheral nerve injury models. It is also expressed in the nucleus of sensory neurons damaged by osteolytic tumor cells. However, this transcription factor is not detectable in normal sensory neuron nuclei or in sensory neurons affected by peripheral inflammation. Animal subjects with increased ATF-3 demonstrate an increase in movement-related pain behavior. Using this model gabapentin improved pain related behavior,[18] but it did not affect tumor growth, bone destruction, or changes in peripheral sensory fibers that were impacted by tumor infiltration. These changes suggest that pain experienced secondary to tumor infiltration may be caused by the destruction of normal afferent sensory fibers.[19]

Osteoclastic induced changes in pH play a role in bone pain as well. When tumor cell growth exceeds vascular supply, tumor cell death leads to a decrease in tissue pH. Additionally as tumors grow, associated inflammatory cells which may comprise as much of 80% of the tumor mass reduce local pH. This decrease of pH in the bony matrix leads to an increased absorption of bone, manifest by osteoclastic activity.[20] Excitation of sensory neurons by decreased pH in osteoclast models leads to an increased expression of pH sensing ion channels. The two major classes of these ion channels are the transient receptor potential 1 (TRPV1) and the acid-sensing ion channel-3 (ASIC-3). Administration of a TRPV antagonist within the mouse model correlates with a decrease in pain behaviors in all stages of tumor growth, suggesting a new potential therapeutic direction to reduce cancer-related bone pain.[20]

Osteoprotegerin (OPG) is a secreted soluble receptor which is one type of the tumor necrosis factor receptor (TNFR). This receptor prevents the activation of osteoclasts via a binding–sequestering of the OPG ligand. It has been demonstrated to decrease the amount of pain-related behavior in the mouse sarcoma model. The monoclonal antibody (AMG-162) can inhibit bone destruction by reducing osteoclast function. This leads to a decrease in the inflammatory mediated changes at the level of the dorsal root ganglion or higher centers which are correlated with the onset of pain from bony metastasis.[21]

Inflammatory cells associated with tumor stroma secrete a variety of compounds which may sensitize or excite afferent neurons. Compounds include prostaglandins, tumor necrosis factor-alpha, endothelins, interleukin-1 and interleukin-6, epidermal growth factor, transforming growth factor-beta, and platelet derived growth factor. Receptors for these factors are directly expressed by afferent neurons. All may play a role in bone pain, but thus far only prostaglandin- and endothelin-targeting agents have been used in the control of pain in bone cancer. Prostaglandins have a role in both sensitization and excitation of nociceptors via direct binding to the prostanoid receptor.[21]

Nerve growth factor (NGF) is a neurotrophic factor expressed in tissue following nerve injury by both the nerves injured as well as surrounding tissues. Upregulation of NGF is thought to be a component in the hyperalgesia following nerve injury. Because of this, anti-NGF antibody therapy could be effective in the control of pain related to bone cancer as it is involved in the environment of the peripheral nerves to bone and the dorsal root ganglion (DRG).[22] In the osteolytic sarcoma mouse model, anti-NGF antibody demonstrated effectiveness in attenuation of pain behaviors, and was found to be more effective than acute administration of 10 and 30 mg/kg doses of morphine sulfate.[23]

Evaluation of the Patient with Bone Cancer

The two most important imaging modalities in the evaluation of malignancy of the bone are plain radiography and nuclear bone scan.

Radiography

Radiographic studies should be ordered first in the evaluation of patients with complaints of bone pain in the context of malignancy. Radiographic patterns fall into osteolytic, osteoblastic, or mixed presentation. Osteoblastic lesions appear opaque and sclerotic. Osteolytic lesions appear more radiolucent compared to surrounding bone. Risk of fracture is greatest if more than 50% of long bone is involved.[24,25]

Bone Scan

Nuclear bone scans are most beneficial for identification of multifocal lesions.[26] Radioisotope accumulates in areas of new bone growth and is diminished in areas of metastasis secondary to decreased blood flow to the area. Cancers such as melanoma and multiple myeloma may have false negatives when reviewed on bone scan secondary to their lack of reactive bone activity.

Computed Tomography

Computed tomography (CT) offers improved spatial resolution in the evaluation of cortical bone destruction.[27] CT is most beneficial in evaluation of the three dimensional characteristics of diseased bone identified by plain radiographs and isotope scans. It is most useful in evaluation of the pelvic and shoulder girdles as well as lesions involving the spine. Additionally, CT-guided needle biopsies may provide information as to the nature of malignancy in bone.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) provides better contrast resolution and it has advantages in defining soft tissue and marrow involvement. Also, it can define vascular relationships without contrast enhancement.[27] MRI is most beneficial in the evaluation of tumor infiltration of muscle and bone marrow, in the evaluation of spinal cord compression, and in lesions which are otherwise insufficiently imaged by the previously listed three techniques.

Treatment

The site and distribution of bone metastases and the skeletal sequelae, such as pathologic fracture and spinal cord compression, impact the patient's prognosis.[28] The focus of treatment should be directed at tumor regression, relief of cancer-related symptoms, and preservation of functional capacity. In some cases metastatic disease is so advanced as to be resistant to chemotherapy or radiotherapy. When metastatic involvement cannot be eliminated, a treatment approach that focuses on symptom management is indicated. Impaired neurologic function, pathologic frac-

tures, and debilitating pain are the most important indications for aggressive treatment. Palliation may employ radiotherapy, radiopharmaceuticals, chemotherapy, hormone therapy, bisphosphonates, calcitonin, analgesics (opioids and antiinflammatory drugs), adjuvant analgesics (e.g., corticosteroids), and surgical treatment. Details of some of these interventions can be found in Chapters 43, 44, and 48.

Analgesic medications provide pain relief during therapy with more definitive modalities (e.g., surgical fixation, radiation therapy) as well as when malignant bone pain is resistant to other modalities of treatment. Conventional opioids or nonsteroidal anti-inflammatory drugs (NSAIDs) may not produce adequate analgesia because of incidental and intermittent nature of pain and dose-limiting side effects. NSAID use is often limited by risks of gastrointestinal (GI) bleeding and inhibition of platelet function, especially in patients with low platelet counts. In these latter patients, a cyclooxygenase-2 inhibitor (COX-2) may be preferred (see later). Renal as well as cardiovascular complications result both from selective (COX-2) and nonselective NSAIDs; these comorbidities may be exacerbated in patients undergoing cancer chemotherapy and those with advanced disease. Therefore, other more targeted pharmacotherapeutic and interventional approaches are often used, alone or in combination with traditional analgesics. The remainder of this chapter will focus on those therapies that have been studied specifically for the treatment of cancer-related bone pain to supplement material presented elsewhere in this text.

Cyclooxygenase(Cox)-2-specific Inhibitors

Cyclooxygenase-2-specific inhibitors (coxibs) have demonstrated efficacy in the treatment of chronic and acute pain when comparable to traditional (nonselective) NSAIDs without the severity of GI complication during short-term use or platelet inhibition effects.[29] The superior safety profile of coxibs in conjunction with equal efficacy of conventional NSAIDs supports their use in analgesic regimens for bone cancer. Many tumors express the COX-2 isoenzyme, which is involved in the synthesis of prostaglandins.[30] In the murine sarcoma model, acute administration of a selective COX-2 inhibitor attenuated both ongoing and movement-evoked bone cancer pain, whereas chronic inhibition of COX-2 significantly reduced ongoing and movement-evoked pain behaviors and reduced tumor burden, osteoclastogenesis, and bone destruction by >50%. COX-2 is expressed in 40% of human invasive breast cancers and bone is the primary site of metastasis in cases of breast cancer.[31,32] The role of COX-2 in murine models of breast cancer metastasis to bone demonstrated COX-2 transfection enhanced the bone metastasis, and breast cancer cells isolated and cultured from the bone metastases produced significantly more prostaglandin. Additionally, COX-2 inhibition inhibited bone metastasis in both a prevention regimen and treatment regimen suggesting COX-2 produced in breast cancer cells are significant in the progression of osteolytic bone metastases in patients with breast cancer, and that COX-2 inhibition may halt this process. Furthermore, COX-2 inhibition may benefit iatrogenically caused tumor progression.[33]

Morphine has been demonstrated to stimulate angiogenesis and tumor growth in mice. COX-2 inhibition can prevent associated tumor growth without compromise of opioid-dependent analgesia in a murine breast cancer model. Chronic morphine treatment stimulated angiogenesis in breast tumors with corresponding increased metastasis and reduced survival. Administration of a coxib prevented morphine-induced effects. Additionally, coadministration of morphine and celecoxib offered improved analgesia over either agent independently.[34]

Corticosteroids

Corticosteroids are established as analgesics in the treatment of pain secondary to metastatic bone pain. This analgesia is thought to occur through the blockade of cytokine synthesis which contributes to both inflammation and nociception.[35,36] The analgesic benefits of corticosteroids are dose-dependent and limited in their duration of activity. In a small uncontrolled study, approximately 40% of patients with metastatic prostate cancer were found to have analgesic benefit with the administration of oral corticosteroids. This was speculated to be secondary to suppression of hormone-sensitive disease that was stimulated by weak androgens of adrenal origin by negative feedback on secretion of adrenocorticotropic hormone.[37] Dexamethasone is the most commonly used agent and has the least mineralocorticoid activity. The standard dose is 12 to 24 mg per day and can be administered once daily due to the long half-life of the agent.

Bisphosphonates

Bisphosphonates are pyrophosphate analogues which bind to hydroxyapatite bone mineral surfaces acting to inhibit osteoclasts and thus bone resorption.[38] The optimal dose of the several available drugs from this pharmacological class remains to be defined since dose response appears to be a function of the disease stage.[39]

Oral clodronate given to patients with breast cancer metastatic to bone reduced the frequency of skeletal events by more than one-fourth.[40] In two randomized placebo-controlled trials comparing monthly pamidronate infusions to placebo infusions for over a 1 to 2 year period as a supplement to hormone and chemotherapy, skeletal morbidity rate could be reduced by 30% to 40%.

A recent large, randomized, multicenter trial using intravenous zoledronic acid demonstrated a reduction of 20% in the risk of developing skeletal-related events compared with pamidronate for patients with breast cancer.[41] Moreover, these trials demonstrated for the first time that a bisphosphonate significantly reduces the occurrence of skeletal events in hormone-refractory prostate cancer and in non-small cell lung cancer as well as in a range of solid tumors. Evidence is accumulating from in vitro studies that bisphosphonates are able to directly affect tumor cell growth, in addition to their effects on osteoclasts.[40]

Of the available bisphosphonates, intravenous zoledronic acid has demonstrated the broadest clinical activity and is approved in many countries for the treatment of bone metastases from all solid tumors.[42,43] The indications for bisphosphonate therapy in breast cancer patients include correction of hypercalcemia and the prevention of cancer treatment-induced bone loss.[44]

In summary, bisphosphonates are now part of usual therapeutic regimens against metastatic bone pain, and at least 50% of patients have a clinically relevant analgesic effect. Placebo-controlled trials with oral or intravenous (IV) bisphosphonates have shown that prolonged administration can reduce the frequency of skeletal-related events by 30% to 40%. The superiority of zoledronic acid compared with pamidronate has been shown by a multiple-event analysis in a large randomized trial. The short infusion time of zoledronic acid also constitutes a convenient therapy. Flu-like symptoms which are manageable with standard treatment can occur. Renal monitoring is recommended, with dose reductions for patients with renal dysfunction. Osteonecrosis of the mandible has been reported in patients receiving bisphosphonates and might be avoidable with appropriate dental care.[45]

Calcitonin

The hormone calcitonin has the potential to relieve pain and also retain bone density, thus reducing the risk of fractures. Early data suggested that calcitonin might offer added adjuvant analgesia in the treatment of bone pain related to metastatic disease.[46,47] An animal study of eel calcitonin suggests a role for it both in

analgesia as well as osteoclastic activity.[48] Animals were randomly assigned to receive subcutaneously administered doses of placebo (saline), or 20 or 100 U/kg/day 7 and 14 days after having their femurs implanted with osteolytic sarcoma cells. Behavioral and pain related behaviors were assessed and radiological evaluation was followed on days 7, 14, and 21 to determine the extent of loss of bone density. Eel calcitonin dose-dependently inhibited the development of pain-related behaviors and bone destruction. This study suggested that eel calcitonin had a potential to reduce pain and advanced bone destruction in patients with bone cancer.[48]

A human clinical trial prospectively entered 22 patients to evaluate the efficacy of salmon calcitonin in controlling pain related to bone metastasis. Baseline pain control was first established via continuous subcutaneous (SC) morphine administration. In the active treatment group, increases in pain were managed with continuous subcutaneous administration of salmon calcitonin 400 IU/day. Beta-endorphin blood levels were measured prior to and after commencement of calcitonin administration at 12, 24, and 48 hours and 7 days. Pain scores, monitored by visual analogue scale, revealed significantly reduced mean pain scores in the active treatment which were also associated with an increase in beta-endorphin blood levels.[49]

Other controlled clinical trials of salmon calcitonin in the treatment of cancer-related bone pain have shown equivocal analgesic results without evidence of reducing complications due to bone metastasis or improving quality of life or survival.[50,51] Like many pain-relieving strategies, there is considerable inter-patient variability in responses. In those patients who are not responding well to other first line approaches, a trial of calcitonin may be reasonable, but close follow-up should ensure that benefits clearly outweigh harms and costs.

Opioids/Opiate Antagonists

While opioids continue to be the primary mode of controlling metastatic bone pain, new research offers a challenge as to which opioid (if any) may be most appropriate. In a murine sarcoma model of bone cancer pain, in which the progression of cancer pain and bone destruction are tightly controlled, the effects of sustained morphine treatment were evaluated. It was found that morphine enhanced, rather than diminished, spontaneous and evoked pain and that the effects were dose-dependent and naloxone-sensitive.[52] Morphine increased ATF-3 expression only in DRG cells of sarcoma mice. Morphine did not alter tumor growth in vitro or tumor burden in vivo but accelerated sarcoma-induced bone destruction and doubled the incidence of spontaneous fracture in a dose- and naloxone-sensitive manner. Furthermore, morphine increased osteoclast activity and upregulated interleukin-1 beta within the femurs of sarcoma-treated mice suggesting enhancement of sarcoma-induced osteolysis.

The results suggest that morphine may increase pain, osteolysis, bone loss, and spontaneous fracture, as well as markers of neuronal damage and expression of proinflammatory cytokines. Morphine treatment may result in ‘‘add-on’’ mechanisms of pain beyond those engaged by sarcoma alone. The data from this study suggests a need for increased understanding of the sequelae from prolonged morphine exposure.

Adjuvant Analgesics

The pain of bone cancer is often refractory to treatment with opioids and NSAIDs. This may be the result of neuropathic changes in involved bone tissues. In the murine model of bone cancer, tumor cells destroyed peripheral nerve fibers when invading bone marrow and mineralized bone.[53] Sensory fibers were found at and within the leading edge of the tumor, but within the deep stromal portion of the tumor, fibers displayed a discontinuous and fragmented appearance, ultimately undetectable by microscopy. In these same animals, there was expression of ATF-3. This factor is a member of the ATF/cyclic adenosine monophosphate response element binding protein family of transcription factors which are not expressed in normally functioning sensory afferent fibers, but expressed in sensory fibers of animal models following nerve injury. The expression suggests that bone-invading malignancies are concomitantly responsible for peripheral nerve injury and that there may be a pathophysiologic rationale for the use of agents typically used to control neuropathic pain in the control of bone cancer pain.[54]

NMDA Antagonism and Alpha-2 Agonists

Administration of alpha-2 agonists (dexmedetomidine and clonidine), N-methyl-D-aspartate (NMDA) antagonists (MK-801 and ketamine), and morphine were examined in a mouse sarcoma bone cancer pain model.[55] Pain-related behaviors were recorded following administration of stimulus to the site of tumor cells implantation. The respective drugs were administered 2 weeks after the implantation. As expected morphine produced a significant analgesic effect and the alpha-2 agonists produced analgesic effects with an efficacy similar to that of morphine, but only at doses that produced severe sedation. MK-801 demonstrated little analgesic effects, whereas ketamine yielded an analgesic effect with the same efficacy as morphine. The authors concluded that alpha-2 agonists produce an analgesic effect only at a sedative dose. Ketamine, but not MK-801, is associated with an analgesic response without overt side effects, suggesting that non-NMDA effects may be responsible for ketamine’s analgesic efficacy in this model. Applicability of these findings to humans remains untested.

Hormonal Therapy

Progression of metastasis from breast, prostate, and uterine malignancies is dependent on hormonal stimulation for survival and growth.[56,57] Antitumor hormonal treatment deprives hormone-dependent tumor cells of an important stimulus for growth and so is a common form of adjunctive therapy in breast, prostate, and endometrial cancers.[58]

Estrogen and estrogen analogue therapy in patients with breast cancer controls symptoms in 25% to 50% of patients temporarily.[59] Hormonal manipulations improve pain in 70% of patients with widespread bone metastases from prostate cancer.[60] Therapy with estrogens is efficacious but it may take 30 to 60 days before complete palliation, and serious adverse effects may exceed overall benefits. Although hormone therapy with androgen receptor antagonists (e.g., flutamide) or antigrowth factor agents (e.g., luteinizing hormone-releasing hormone analogs of somatostatin and 5-reductase inhibitor) can be used to induce tumor regression, the palliative effect may not offer long-term benefit as hormone-refractory elements continue to proliferate and metastasize to bone.[61]

Radionucleotides

Analgesic effects from radionucleotides are not dependent on tumor destruction, per se, but are thought to result from inhibition of pain mediators from normal bone cells. Therapeutic responsiveness is greatest in osteoblastic lesions. Multiple agents have been used for palliative treatment of cancer-related bone pain, including phosphorus-32, strontium-89, yttrium-90, samarium-153, and rhenium-186.

Phosphorus-32 has been used for more than 30 years and relieves the pain from osteoblastic metastases in approximately

80% of patients treated.[62] However, myelosuppression caused by this agent has encouraged development of newer agents. Strontium-89 is a bone-seeking radionuclide, whereas samarium-153 is a bone-seeking tetraphosphonate. Both agents have been shown to have efficacy in the treatment of painful osseous metastases from prostate cancer; they have also been demonstrated to offer analgesia in breast cancer and perhaps from non-small cell lung cancer. As many as 80% of selected patients[63] with painful osteoblastic bony metastases from prostate or breast cancer may experience some pain relief following strontium-89 administration.[64] Additionally, 10% or more may become pain free and the average duration of clinical response typically ranges from 3 to 6 months with minimal myelosuppression compared to phosphorus 32.[65]

Procedural Interventions

In addition to pharmacotherapy, interventional therapies to relieve the pain associated with bone cancer can be beneficial. Procedures include intralesional injections, nerve blocks, intra-articular injections, radiofrequency rhizotomy, and vertebroplasty.

Intralesional Injection

In a study of patients with rib metastases or involvement of the ribs by multiple myeloma, infiltration of tender areas with methylprednisolone under intercostal block provided significant reduction in pain-related symptoms in over half the cases.[66] Of 20 assessable patients, 11 became pain free in within 10 days with recurrence of pain in only one of these patients; in three others the pain was considerably improved. The procedure was well tolerated and there were no complications.[66] This technique has also been applied to mandibular lesions in which surgical excision of tumor runs the risk of destabilizing the affected bone.[67] This technique may be applicable to other areas of metastasis.[68] Additionally, localized injection of corticosteroid, local anesthetic and even baclofen, have been reported to offer clinically meaningful relief in areas of secondary muscular spasm.[69]

Percutaneous Vertebroplasty/Kyphoplasty

Bony metastasis to the vertebrae involve 30% to 70% of all bony lesions and compromise the strength of involved bone which can induce pathologic vertebral fractures in the absence of trauma. Additional causes include osteoporosis, malnutrition, radiation, and steroid administration. In cases of fracture secondary to pathologic bone, vertebroplasty may offer pain relief. In comparison to patients who have a nonmalignant basis for pathology of the bone such as osteoporosis, reports of analgesic benefit are not as high, but are significant with ranges reported between 50% and 80%.[70] This may be explained by the widespread nature of metastatic disease and the multifactorial nature of pain in malignant disease. The mechanism by which vertebroplasty is thought to offer pain relief are speculated to be fixation of chronically mobile bone fragments as well as thermal neurolysis secondary to the exothermic reaction of methylmethacrylate cement yielding temperatures in excess of 70° C.[71]

Rhizotomy

Minimally invasive neurodestructive techniques have been demonstrated to be effective in a number of malignancies, specifically of visceral and neuropathic nature. Techniques involve radiofrequency lesioning, cryotherapy, and chemical neurolysis using such agents as phenol, alcohol, and hypertonic saline. As we are coming to an understanding that there may be a neuropathic component to bony lesions in metastatic cancer, these techniques may offer a valuable option in the control of cancer-related bone pain. The same principles may be applied to chordoma, osteoid osteoma, or osseous metastasis. Studies of radiofrequency lesioning of bony and soft tissue malignancy have reported significant palliation of pain.[72–75]

Associated Processes

Avascular Necrosis

Avascular necrosis is found in survivors of cancer who have been exposed to corticosteroid therapy. Pain is usually the result of weight-bearing. In an MRI study of patients having survived childhood cancer, 67% of patients demonstrated osteonecrosis at the ankle.[76]

Postoperative Frozen Shoulder. In postthoracotomy or postmastectomy patients, there is a risk for the development of frozen shoulder. The site may become an independent locus of pain and can be complicated by complex regional pain syndrome. Adequate mobilization of the joint with sufficient analgesia should be implemented soon following surgery to prevent this chronic, painful, and debilitating complication.[77]

Granulocyte Colony-Stimulating Factor Related Pain

Granulocyte colony-stimulating factor (G-CSF) is used to stimulate the production of granulocytes in immunocompromised patients following chemotherapy and radiation. Bone pain and generalized muscle pain are a major secondary effect, lasting for 10 or more days.[78] Effective analgesia may require opioids.[79] G-CSF may induce an inflammatory reaction through undescribed distinct cellular signaling and by triggering histamine release.[80] Increased histamine levels can cause nociceptive c-fiber-mediated pain and can increase edema formation within bone leading to pain.[81] Antihistamines such as terfenadine and astemizole have anti-inflammatory properties in addition to their potency as histamine-1 antagonist and may benefit bone pain caused by G-CSF therapy.

CONCLUSION

The skeleton is the most common organ to be affected by metastatic cancer and the site of disease that produces a very high prevalence of morbidity. Skeletal morbidities include severe pain (spontaneous and incident-related), hypercalcemia, pathologic fracture, and spinal cord or nerve root compression. Currently bone pain is inadequately treated. Approximately 80% of patients experienced pain in the period before palliative therapy. Until there are breakthroughs in prevention and treatment of cancer-related bone pain, clinicians must continue to rely on conventional and modern assessment techniques, an understanding of the many causes of cancer-related pain, and the host of available therapies to optimally treat pain caused by bone metastasis.[82]

From randomized trials in advanced cancer, major skeletal related events occur on average every 3 to 6 months. The prognosis of metastatic bone disease is dependent on the primary site. In breast and prostate cancer, survival is measured in years; in lung cancer, survival may be measured in months. Severity and duration of tumor involvement in bone cancer are predictors of outcome. Duration of involvement is best estimated by measurement of bone-specific markers. Studies demonstrate a powerful correlation between the rate of bone resorption and clinical outcome, related both to skeletal morbidity and overall life expectancy. By understanding prognostic and predictive factors in individual cases, delivery of a tailored treatment according to the

circumstances attending each patient leads to improved palliative and cost-effective outcomes.[83]

CHAPTER 47 ■ CANCER-RELATED VISCERAL PAIN

JANET ABRAHM, EDGAR ROSS, AND ROBERT J. KLICKOVICH

EPIDEMIOLOGY REVIEW

In 2004, 1.4 million Americans were diagnosed with cancer. This number equals approximately 4000 new diagnoses per day. In the same year, over 500,000 American deaths were attributed to cancer, accounting for 22% overall mortality.[1] Currently, more than 10 million individuals in the United States carry the burden of a cancer diagnosis, which is 3% of the population.[2] Approximately 50% of patients who carry a diagnosis of cancer report pain as a symptom of the disease process. This percentage increases to 75% of patients reporting pain in the advanced stages of disease.[3,4]

After patients come to terms with the diagnosis of cancer and the implications of their disease, most patients and their families will express concern about the pain and suffering they will experience as their disease progresses. Commonly asked questions include: how much pain will there be and can it be controlled?[4] Unfortunately, despite evidence that cancer pain can be controlled, it is managed poorly in many cases. Multiple factors limit adequate treatment of cancer pain, including misperceptions of disease processes, misconceptions regarding pain medications and procedures, professionals inadequately trained in pain management, failure to consult specialists trained in contemporary pain management methods, and social stigma around opioid use, including fears of addiction by patients, family members, and professional health care providers.[5] Also, many common cancers in the advanced stages of disease, when pain is highly prevalent, are incurable and survival may be measured in months, not years. While health care professionals may only measure survival duration as a meaningful treatment outcome, patients and families may measure outcomes in terms of improvement in quality of life, alleviation of pain, and relief of other associated symptoms related to cancer and treatment.[6]

Since pain syndromes arise from cancer therapies (including chemotherapy, radiation therapy, or surgery), patients who survive their primary malignancy may be left with pain secondary to an iatrogenic process. Chemotherapy may induce a painful peripheral neuropathy. Neuropathy is well described with vincristine, platinum, taxanes, thalidomide, bortezomib, and other agents. Pain secondary to radiation may appear years to decades after completion of radiotherapy. Pain syndromes following surgery may present after mastectomy, amputation, thoracotomy, or other surgical approaches to malignancies (see Chapters 41, 42, 45, and 48).[7]

CHARACTERISTICS OF VISCERAL PAIN

Anatomy and Physiology

Visceral pain is caused by disorders of internal organs such as the stomach, kidney, gallbladder, urinary bladder, and intestines as well as changes in the central nervous system. Pain can result from distension, impaction, ischemia, inflammation, or traction on the mesentery, and can be associated with symptoms such as nausea, fever, malaise, and pain.[8] Growth of visceral tumors disrupts normal physiological processes secondary to compression and invasion of adjacent structures. Progression of disease may be asymptomatic until a critical event manifests (e.g., obstruction of a hollow viscus). Under these conditions, the first symptom a patient may experience is pain.[9–11]

Visceral pain is unique in quality of presentation when compared to pain that arises from musculoskeletal structures of the body. Visceral pain is usually vague in its presentation and may be confused by referral to a variety of somatic locations. Symptoms may seem out of proportion to physical examination and imaging.[12] Additionally, visceral pain may be attributable both to the malignancy itself and to chemotherapeutic and radiation therapies. Increased pain following symptomatic relief may suggest the local recurrence of disease or a new locus of disease requiring repeat evaluation of the patient.[13]

Some features of visceral nociception may offer a better understanding of the experience of patients with visceral pain. Visceral pain is more frequently accompanied by an autonomic response than is somatic pain or pain from skin injury. There is a poor

correlation between the extent of visceral tissue damage and the severity of pain experienced. The diffuse nature of visceral pain and its referral to superficial structures is due to the convergence of visceral and somatic afferents on the same dorsal horn neurons. Visceral pain is poorly localized because of poor representation within the primary somatosensory cortex. The majority of visceral afferents are specific to motor or reflex responses with few neural afferents that are specialized for pain transmission. Those afferents that are specialized for pain are sparsely distributed throughout the viscera; both high-threshold nociceptors and "silent" nociceptors are invoked in the pain experience.[11]

Studies have demonstrated multiple visceral pain mechanisms as well as the mechanisms by which one class of visceral pain may relate to other sources of malignant pain. There are four primary classes of visceral pain:

1. Mechanical: caused by stretch of visceral structures (bowel lumen or hepatic capsule)
2. Ischemic: caused by tumor invasion or compression of visceral blood supply
3. Inflammatory: humoral mediators of inflammation released secondary to tumor infiltration of visceral structures
4. Neuropathic: compression or invasion of neural structures supplying the viscera.[13]

Surgery, chemotherapy, or radiation therapy of cancer can also be responsible for iatrogenic damage of the viscera, associated visceral structures, or nerves. Applying a stimulus that causes tissue damage (e.g., cutting, burning, or pinching) to skin or muscle reliably produces the perception of pain but these stimuli do not reliably evoke reports of pain when applied to visceral structures. Pain secondary to distension of a hollow viscous, such as in the case of bowel obstruction, does not necessarily produce a similar perception when applied to surface structures. In controlled studies, visceral pain can be consistently demonstrated by mechanical distension of hollow organs using distending fluids or balloon devices.[14] These modalities of inducing pain most closely reproduce the natural or pathophysiological processes causing pain. Mechanical distension can be specifically applied to a given organ structure in isolation of other structures, mimicking processes involving the gastrointestinal, biliary, and urinary tracts which may occur from tumor obstruction (or adhesions) in these sites. Distension of organ capsules, such as the splenic, renal, or hepatic capsule, has also been demonstrated to produce profound pain. On the other hand, gentle or slow but progressive distension or obstruction may not produce pain until a critical point in which ischemia or rupture result. Torsion or stretch on mesenteric structures or omentum may produce states of ischemia, infarct, and inflammatory response producing reports of severe pain.[15]

Inflammatory processes in visceral structures may produce pain as a result of ischemic response, but some tumors may produce inflammatory mediators with no inciting ischemic event. Both prostaglandin E2 and serotonin have been demonstrated as independent chemical stimuli in the production of pain as malignancy invades adjacent structures.[16–18] Experimental studies have demonstrated that the application of inflammatory chemical stimuli can evoke pain behaviors, yet specific mechanical means of eliciting pain have been limited in their translation to studies of other visceral structures.[19]

Ischemic pain has also been described as occurring secondary to occlusion of visceral vasculature or by compression of visceral structures by tumor growth. When tumor growth exceeds vascular supply, necrosis may result, inducing a variety of inflammatory processes.[18] Inflammatory mediators, such as hydrogen ions, kinins, prostanoids, leukotrienes, or other cytokines, are initiators of visceral pain. These chemical agents also sensitize neurologic afferents of organ structures amplifying nociception associated with mechanical stimuli. In general, healthy viscera are typically insensate to pain while superficial structures are continually sensate.[19] When diseased, however, visceral organs produce pain severe enough to be incapacitating to other physical activity. Superficial pain may provoke physical activity. Pain from surface structures of the body evokes reflexive motion in the classic "fight or flight" response, whereas the sensation of visceral pain discourages motion or physical activity. Anecdotal evidence supports an association between pain of visceral origin and emotional response and is commonly held to be more anxiety provoking than pain from somatic structures. Some argue that this anxiety comes from a patient's inability to visualize the cause of the pain.[20] Anxiety scales are reported higher in patients with visceral pain ratings of 2 on a scale of 10 when compared to a higher-rated pain experience with visible cause on a superficial structure.[21] Furthermore, some symptomatology is more common in patients with visceral pain. Perception of both nausea and dyspnea are more commonly associated with pain of a visceral organ. An autonomic response to visceral pain is far more common than to pain of superficial structures.[22,23]

Psychological processing of visceral pain is distinct from that related to somatic pain. There are a low number of visceral nociceptors compared with somatic nociceptors. There is a lack of specialization of visceral afferents. Many visceral afferents are polymodal nociceptors. Viscera have convergence with somatic afferents on dorsal horn lamina resulting in referred pain. Viscera have unique ascending tracts through the dorsal column.[24] Viscera have poor representation within the primary somatosensory cortex. Viscera have significant input through the medial thalamus to the limbic cortex, amygdala, anterior cingulate, and insular cortex.[25] Viscera also have a close association with autonomic nerves. The perception of visceral pain may be disproportionate to pathology exhibited by physical examination or imaging. As an example, a small nephrolith may offer some of the most severe pain states whereas extensive cancer metastasis may evoke little or no discomfort. Disorders such as chronic pancreatitis demonstrate very little correlation between laboratory studies and flares in pain perception. Disorders such as irritable bowel syndrome and noncardiac chest pain syndrome appear to lack a definitive histopathologic basis for the discomfort and pain.[26,27]

Many models exist for visceral pain including intraperitoneal injection of a chemical, distension of hollow organs (cecum, colon, rectum), distension of the gallbladder and associated biliary system, distention or chemical stimulation of the bladder and other urinary tract structures, as well as distension, compression, or traction on reproductive organs. However, lesions studied in one organ are limited in that they are specific to a given stimulus and do not necessarily translate to application in other visceral structures.[28]

Sensitization

Sensitization occurring secondary to the repeated presentation of visceral stimuli has been noted in human psychophysical studies as well as animal studies. Repeated presentation of the same visceral stimuli produces increasing strength of response in neuronal, cardiovascular, and visceromotor reflex responses. Inflammation of visceral structures increases the magnitude of response to a given mechanical stimulus and decreases the stimulation thresholds for the evocation of nociceptive responses. Inflammation of visceral structures significantly modifies behavioral, neuronal, autonomic, and motor responses to visceral stimulation in experimental models. This model mirrors clinical circumstances, since inflammation in visceral structures frequently leads to reports of pain.[29]

Painful conditions such as mucositis, esophagitis, gastritis, pancreatitis, and colitis all exhibit mucosal inflammatory changes. The inflammatory sensitization may take place at primary afferents. These afferents are normally nonreactive to most stimuli and have been described as "silent" in non-pathological states. However, in the context of an inflammatory tissue response, they become spon-

taneously active and highly reactive to mechanical stimuli. Silent afferents may comprise 50% of the neuronal sample in a visceral organ, but are infrequently noted in superficial or cutaneous structures. Lack of baseline sensitivity in normal viscera may be secondary to sparsity of visceral afferentation. There are fewer afferents per unit area than similar measures of cutaneous afferents. Because of this sparse innervation, increased activity may be necessary to cross a threshold for perception. Spinal neurons responsive to visceral stimuli also change their responsiveness to visceral stimuli in the presence of inflammation. The cause of this behavior is unknown. Increased afferent activity, altered intrinsic properties of dorsal horn neurons, and altered modulatory influences or some combination may all serve a role in the process. Dorsal column pathways have been demonstrated to play a role in visceral nociception, but not in cutaneous nociception. The results of multiple studies suggest that visceral pain requires a sensitization process both in the periphery and the spinal cord. However, somatic central sensitization characterized by "wind up" of interneurons within the dorsal horn does not occur with visceral pain.[30]

Localization

Visceral pain is classically thought of as deep and diffuse in presentation. Localization of the pain generator can be difficult to identify by physical examination. Superficial pain, in contrast, can be elicited by examination with precise localization and with consideration to the site of the body examined; pain locus can be identified within millimeters. Moreover, surface pain loci reliably localize to the same site, never migrating to other body areas, in the absence of neural injury.

Visceral pain is characterized as migratory in its presentation, often perceived in several loci simultaneously or migrating regionally in spite of localization of pathology. This is evident in the presentation of appendicitis. Furthermore, the perception of pain associated with visceral pathology is not normally localized to the organ itself but to somatic structures that receive afferent inputs at the same spinal segments as the visceral afferent entry. For this reason, visceral pain is classically described as either unlocalized pain or as referred pain that may have two separate features. Sensation of the diseased viscera is transferred to a surface site (e.g., an ischemic myocardium can be felt in neck and arms) or additional sites may become hypersensitive to inputs applied directly to those other sites (e.g., flank muscle becomes sensitive to palpation with urolithiasis). This latter phenomenon is referred to as secondary somatic hyperalgesia.

Psychophysical studies of internal organ sensation have been very focused on a given organ using simple stimuli correlating the given stimuli to a given organ with perception at the respective site of stimulus. Other psychophysical studies using visceral stimuli have examined the referred sensations described by subjects. These studies have often failed to contrast referred pain to a body surface with cutaneous sensations at the same surface. Patient illustrations of referred sensations tend to extend over large surface areas, whereas studies using cutaneous stimuli generate pinpoint localization to highly precise sites.

The phenomenon of secondary somatic hyperalgesia produced by visceral pathology has been compared to sites of sensitivity with lesions produced by herpes zoster. These initial studies were fundamental to the development of dermatomal mapping. In visceral disease processes, multiple dermatomes have been identified suggesting that secondary somatic hyperalgesia is widely distributed (i.e., poorly localized).

Recent psychophysical studies have attempted to compare visceral with nonvisceral pain. In one study, the sensation produced with balloon distension of the esophagus was compared to thermal stimulation of the mid-chest skin. Subjects perceived larger areas of sensation for esophageal distension than for intensity-matched heat-evoked sensation on body maps. Temporally, there was also a difference. A rapid response was noted with heat stimulus whereas there was poor correlation with the esophageal stimulus and the perception of the sensation. Intense visceral discomfort remained after discontinuation of the distending apparatus but not after discontinuation of the cutaneous stimulation. Visceral sensation was concluded to be diffuse both spatially and temporally. Corollary observation of cerebral blood flow identified that similar cerebral areas were activated by both stimuli.

When evaluating the patient in visceral pain with malignancy, the early presentation may be misleading with vague midline discomfort. It may be poorly localized and accompanied by both an emotional response and autonomic event. Later in the evolution of disease process, patients may complain of somatic or referred pain hypersensitivity at the spinal level of the visceral nociceptor terminus. Referred pain is sharp and localized. It is often associated with allodynia and muscle spasm. Furthermore, visceral hypersensitivity may induce the perception of pain in another organ receiving innervation from the same spinal segment.

Visceral Afferentation

Visceral primary afferents differ significantly from cutaneous primary afferents in both number and pattern of distribution. Visceral sensory pathways are organized into nerve fascicles and cell body groupings extending from prevertebral regions to contact viscera predominately via perivascular pathways. Cell bodies of visceral primary afferent nerve fibers are located in the visceral dorsal root ganglia of the thoracic and upper lumbar spine, but the peripheral axons of these neurons follow a circuitous path to visceral organs passing via the paravertebral sympathetic chain and ganglia as well as nerve fascicles that are termed the cardiac and splanchnic nerves. The splanchnic nerves are divided into the greater, lesser, least, thoracic, and lumbar divisions. The pelvic nerves arise from dorsal root ganglia at sacral levels, accepting sympathetic chain input before innervating urogenital structures.

Visceral sensory processing also differs from cutaneous sensory processing because visceral neuronal synapses exist at cell bodies of prevertebral ganglia such as the celiac ganglion, superior mesenteric ganglion, and pelvic ganglion, producing changes in local visceral function outside central control. The gastrointestinal tract is also supplied by an independent enteric nervous system relating to functions of digestion and absorption. In the pelvis, structures receive dual innervation with afferents from lower thoracic-upper lumbar segments and from sacral segments. Testicle and ovary embryologically originate in the superior aspect of the abdomen and, therefore, receive thoracic innervation. The urinary bladder has a similar thoracolumbar innervation with sensory inputs extending up to the T10 level, but also receives sacral inputs (the pelvic nerve) with other tissues originating from sacral dermatomes (rectum, genital structures).

Pelvic organs also receive efferent and afferent connections from the vagus nerve and local ganglionic circuitry, resulting in a complex and diffuse neuroanatomy. Afferents with endings in a focal visceral site may have cell bodies in the dorsal root ganglia of 10 or more spinal levels in a bilaterally distributed fashion. In contrast, cutaneous afferents from a particular body surface arise from only 3 to 5 unilaterally located dorsal root ganglia.

Visceral receptors are located in mucosa, serosa, and muscle of hollow organs as well as visceral mesentery. They are not reported in parenchyma of solid organs. The specialized receptors that discriminate a variety of stimuli in somatic structures are absent in viscera. The mesentery, however, does contain Pacinian corpuscles. Hollow organs contain specialized low-threshold and high-threshold mechanoreceptors. Low-threshold receptors serve a basic regulatory function whereas high-threshold receptors are activated only with noxious mechanical stimuli. Visceral nociception results from summation of nociceptive input to regulatory

low-threshold receptors and noxious high-threshold and silent nociceptors rather than activation of stimulus-specific nociceptors.[31]

Ascending Pathways

Visceral afferent fiber activation causes an increase in nitric oxide synthase in the dorsal horn of the spinal cord, causing expression of the oncogene C-fos in laminae I, V, VII, X of the dorsal horn within the thoracolumbar spine. Similar upregulation is seen in the amygdala and paraventricular hypothalamic nuclei, and consequent elevation in norepinephrine production within the locus ceruleus.

Features of visceral pain processing differing from somatic processing include dorsal column ascending secondary sensory afferents, the spinal trigeminal to parabrachioamygdaloid tract, and the spinohypothalamic pathway. In the visceral system, both ventrolateral and dorsal column postsynaptic neurons have a role in nociception. Ascending tracts synapse at the lateral thalamus first, then limbic centers, then somatosensory cortex. While somatic nociception is represented somatotopically within the primary somatosensory cortex, visceral pain is represented in the secondary somatosensory cortex and poorly represented within the primary somatosensory cortex. Visceral pain is well represented in the limbic system, including anterior cingulate gyrus, insular cortex, and amygdala, suggesting a basis for the strong emotional component of visceral pain. While visceral pain elicits decreased patient activity, nausea, and hypotension, somatic pain elicits agitation, reactive activity, and hypertension. Nociceptive activity within the gastrointestinal tract induces inhibition of dorsal motor neurons of the vagus within the medulla leading to gastroparesis and nausea.

VISCERAL PAIN SYNDROMES

Although most pain associated with malignancy is diffuse and chronic, most acute pain syndromes in cancer are secondary to diagnostic or therapeutic interventions. Some tumors generate an acute onset of pain, which may be the result of a perforation of a hollow viscus or rupture of a visceral capsule. Any sudden onset of pain warrants a comprehensive pain assessment. Below is a list of possible pain syndromes that may be encountered by the health care provider.

Oral Mucosa

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is a mucocutaneous disorder accompanying non-Hodgkin's lymphoma and chronic lymphocytic leukemia. It is characterized by widespread shallow ulcers, hemorrhagic crusting of the lips, conjunctival bullae, and may be accompanied by pulmonary lesions, occurring secondary to autoantibodies directed against desmoplakins and desmogleins.[32]

Oropharyngeal Mucositis and Stomatitis

Mucositis and stomatitis should be distinguished as two separate processes (also see Chapter 45). Oral mucositis is an inflammation of oral mucosa resulting from chemotherapeutic agents or ionizing radiation, manifesting as erythema or ulcerations. Stomatitis is any inflammatory condition of oral tissue, including mucosa, dentition, periapices and periodontium, including inflammation secondary to infection of oral tissues. Mucositis appears 7 to 10 days after initiation of high-dose cancer therapy and is generally self-limited when uncomplicated by infection, resolving 2 to 4 weeks after completion of chemotherapy. In order to standardize assessment, a variety of scales have been created to grade the level of stomatitis by characterizing alterations in lips, tongue, mucous membranes, gingiva, teeth, pharynx, quality of saliva, and voice. The clinical syndrome usually involves the oropharynx but may involve other gastrointestinal mucosal surfaces such as the esophagus, stomach, or intestine, producing such symptoms as odynophagia, dyspepsia, or diarrhea. Any mucosal damage may become superinfected with microorganisms, most commonly *Candida albicans* and herpes simplex.[33]

Radiotherapy may also induce mucositis. Doses of radiation in excess of 4000 cGy frequently cause ulceration with pain lasting several weeks following treatment.[34] Acute pain associated with radiotherapy can be caused by acute radiation toxicity causing inflammation and ulceration of skin or mucous membranes. The syndrome produced is dependent upon the exposed field.[35,36]

Mediastinum

5-Fluorouracil-induced Anginal Chest Pain

In patients receiving 5-fluorouracil (5-FU) infusions, ischemic chest pain may develop. Painful events are more common in patients with a history of coronary artery disease and are likely secondary to coronary vasospasm.

Pleura

Lung tumors, with or without chest wall involvement, may produce visceral pain. In a large case series of patients with lung malignancies, pain was found to be unilateral in 80% of patients and bilateral in 20% of patients. Patients with hilar tumors reported sternal or scapular pain. Patients with tumors involving the upper and lower lobe experienced referral of pain into the shoulder and lower chest, respectively.[37,38] Additionally, some lung malignancies generate ipsilateral facial pain, thought to be secondary to noxious stimulation of vagal afferent neurons.[39–42]

Pancoast Syndrome

Pancoast syndrome is caused by malignant neoplasms of the superior sulcus of the lung with destructive lesions of the thoracic inlet and involvement of the brachial plexus and cervical sympathetic nerves (stellate ganglion).[43] Patients report severe pain in the shoulder region radiating toward the axilla and scapula along the ulnar aspect of the muscles of the hand, and patients may also develop atrophy of hand and arm muscles, Horner syndrome (ptosis, miosis, hemianhidrosis, enophthalmos), and compression of the blood vessels with edema.[44] Ninety-five percent of patients have either squamous cell or adenocarcinomas. Small cell carcinoma is found in fewer than 5% percent of cases in most series. Along with these symptoms and signs, additional predictors of poor prognosis are weight loss, supraclavicular fossa or vertebral body involvement, disease stage, and surgical treatment.[45,46]

These bronchopulmonary tumors may invade the bony structures of the chest. The first or second thoracic vertebra or the first, second, or third ribs may be invaded. One review has described rib erosion in 50% of patients. The tumor may invade the first or second thoracic vertebral bodies or intervertebral foramina, extending to the spinal cord and resulting in cord compression. The subclavian vein or artery may also be invaded. Advanced tumors may involve the recurrent laryngeal nerve, phrenic nerve, or superior vena cava.

Pancreas

Midline Retroperitoneal Syndrome

The most common cancer-related causes of upper abdominal retroperitoneal pain are pancreatic cancer and retroperitoneal lym-

phadenopathy, particularly celiac lymphadenopathy. These disease processes elicit afferent activity via injury to deep somatic structures of the posterior abdominal wall, distortion of pain-sensitive connective tissue, vascular and ductal structures, as well as local inflammation and direct infiltration of the celiac plexus. Patients report pain in the epigastrium, in the low thoracic region of the back, or both. Pain is described as diffuse, dull and boring, exacerbated with recumbency, and improved by sitting forward. Computed tomography (CT), magnetic resonance imaging, or ultrasound scanning of the abdomen may reveal the disease process.

Pancreatic Cancer

Patients with pain secondary to unresectable pancreatic cancer report severe abdominal pain radiating into the back. This pain is often refractory to analgesics, even strong opioids. Pain may be accompanied by obstructive jaundice (yellowing of the skin and eyes, itching, dark urine, clay-colored stool) and occurs more frequently when the cancer is located at the head of the pancreas. Other associated symptoms may include weight loss, anorexia, fatigue, and a change in bowel habits (constipation or diarrhea). Controlled trials support the use of neurolytic celiac plexus block with superior results in terms of pain relief over analgesics alone (see Chapter 44 and discussion of celiac plexus block below).[48]

Liver Pain

Hepatic Distension Syndrome

The liver has many nociceptive structures including the liver capsule, blood vessels, and biliary tract. Afferents from these structures travel via the celiac plexus, the phrenic nerve, and the lower right intercostal nerves. Hepatic metastasis typically causes pain when the tumor stretches the capsule. Patients with intrahepatic metastases or hepatomegaly secondary to cholestasis may report discomfort in the right subcostal region or right mid-back or flank.[49] Patients may experience referred pain to the right neck, shoulder, or scapula.[50] Patients describe the pain as a dull ache exacerbated by movement, pressure in the abdomen, and deep inspiration. Associated symptoms include anorexia and nausea.

Physical examination reveals a hard, irregular subcostal mass, which is dull to percussion, and descends with inspiration. Diagnostic ultrasound or CT may reveal a space-occupying lesion.

Analgesics are the first line of therapy for pain control with drug selection and titration a function of the extent of hepatic compromise. Corticosteroids reduce hepatic edema and liver pain. If a tumor is chemosensitive, chemotherapy may be the treatment of choice. Hormone therapy may decrease hepatomegaly from liver metastasis but may take several months to accomplish a goal of pain relief. As with pancreatic cancer, celiac plexus block may provide definitive relief. Two randomized controlled trials have demonstrated hepatic irradiation to be effective in palliation of hepatic pain in 80% of patients with a reduction of systemic symptoms in half as many patients.[51]

Intestinal Pain

Chronic Intestinal Obstruction

In patients with abdominal or pelvic cancers, intestinal obstruction causes diffuse abdominal pain. Pain may be secondary to smooth muscle contraction, mesenteric tension, and ischemia of the bowel wall. Obstruction may be due to tumor, autonomic neuropathy, ileus, metabolic abnormality, or medication. Pain may be continuous or intermittent (colicky) and may be associated with vomiting, anorexia, and constipation.

Peritoneal Carcinomatosis

The peritoneal cavity, enclosed by visceral and parietal peritoneum, is the largest potential space in the body. Any pathologic process involving the peritoneal cavity can easily disseminate throughout this space by means of unrestricted movement of fluid and cells. Primary malignant diseases arising from the peritoneal cavity include malignant mesothelioma, cystic mesothelioma, and primary peritoneal carcinoma. Carcinomatosis can cause peritoneal inflammation, mesenteric tethering, and malignant adhesions and ascites, all of which can trigger nociceptive activity. Patients most commonly report abdominal pain and distension. Mesenteric tethering and tension appear to cause a diffuse abdominal or low-back pain. Tense malignant ascites can produce diffuse abdominal discomfort and a distinct stretching pain in the anterior abdominal wall. Adhesions can also cause obstruction of a hollow viscus, with intermittent colicky pain.[52] CT scanning may demonstrate evidence of ascites, omental infiltration, and peritoneal nodules.

Radiation Enteritis

Acute radiation enteritis may develop in as many as 50% of patients receiving pelvic or abdominal radiotherapy. Patients with small intestinal involvement complain of cramping abdominal pain and have associated nausea and diarrhea. Patients receiving pelvic radiotherapy may develop proctocolitis, associated with pain, tenesmus, diarrhea, mucous discharge, and bleeding. These symptoms may resolve shortly after completion of therapy or may last as long as 6 months.

Intraperitoneal Chemotherapy Pain

Approximately 25% of patients receiving intraperitoneal chemotherapy may develop transient mild to moderate abdominal pain and complain of fullness or bloating.[53] A second group of patients (approximately 25%) may experience pain severe enough to require opioid analgesia or discontinuation of therapy. Pain is secondary to chemical serositis or infection. Infectious peritonitis is accompanied by fever and leukocytosis in blood and peritoneal fluid.

Pelvic Pain

Malignancy-related pelvic pain not due to bone metastases is most often secondary to presacral recurrence of rectal carcinoma or secondary to pelvic recurrence of cervical cancer. Lumbosacral plexus infiltration is common, resulting in severe pain with a significant neuropathic contribution. Analgesics or interventional therapies should be implemented according to protocols and guidelines (see Chapter 43).

Malignant Perineal Pain

Perineal pain may be secondary to tumors of the colon or rectum, female reproductive tract, and distal genitourinary system. A report of perineal pain following therapeutic resolution of malignancy may be a precursor of recurrence and should prompt complete evaluation.[54] Pain preceding evidence of disease may be secondary to microscopic perineural invasion of an insidious malignant process. Patients report pain to be constant and aching, exacerbated with sitting or standing. Associated symptoms may include tenesmus or bladder spasm.[55] If tumor invades musculature of the pelvis, patients may complain of a constant aching in the pelvis, which is exacerbated with standing. Examination of the pelvic floor may demonstrate tumor.

Ureteral Obstruction

Patients with tumor involving the pelvis may have pain due to tumor compression or infiltration of the distal ureter.[6] Obstruc-

tion of the proximal ureter is less common and is associated with retroperitoneal lymphadenopathy, an isolated retroperitoneal metastasis, mural metastases or intraluminal metastases. Cancers of the cervix, ovary, prostate, and rectum are most commonly associated with this complication. Other rare causes of ureteral obstruction include retroperitoneal fibrosis resulting from radiotherapy or graft versus host disease. Pain is described as dull chronic discomfort in the flank often with associated radiation into the inguinal region or genitalia.[6] However, patients may have obstruction without evidence of pain.

Ovarian Cancer Pain

Patients experiencing severe chronic abdominal or pelvic pain may be experiencing the harbinger of ovarian cancer. It is the most common presenting symptom and most common symptom of recurrence.[6] Two-thirds of patients experience pain in the 2 weeks prior to the onset or recurrence of the disease. In patients who have been previously treated, it is an important symptom of potential recurrence.[6]

Tumor-related Gynecomastia

In patients complaining of breast pain or tenderness, there is a risk of occult tumor of the testes or lung. Human chorionic gonadotrophin (HCG) secreting tumors of testis, including malignant and benign types as well as other HCG secreting tumors, may produce breast tenderness or gynecomastia.[56] Approximately 10% of patients diagnosed with testicular cancer complain of gynecomastia or breast tenderness.[57]

Intravesical Chemotherapy or Immunotherapy

Patients receiving intravesical Bacillus Calmette-Guérin (BCG) therapy for urinary bladder transitional cell carcinoma experience a syndrome of bladder irritability. Patients report urinary frequency and painful micturition. In rare cases, patients receiving BCG therapy may develop a painful polyarthritis.[58] Other intravesical chemotherapies, such as doxorubicin, may also cause a painful chemical cystitis.[59]

Corticosteroid-induced Perineal Discomfort

In patients receiving high-dose corticosteroid therapy, some may report an uncomfortable sensation of burning perineal pain.[60]

Adrenal

Adrenal Pain Syndrome

Patients with adrenal metastases of considerable size, common in lung cancer, may develop unilateral flank pain or abdominal pain. Patients report pain from this condition as highly variable, describing it as dull and aching to severe in presentation.[61]

Vascular Obstruction

Hypercoagulability with thrombosis is the most frequent complication associated with malignancy and the second most frequent cause of mortality in malignant disease. A thrombotic event may occur in advance of the diagnosis of cancer by months or years; therefore, thrombosis should be considered as a marker for occult malignancy. Chemotherapy and hormone therapy are associated with an increased thrombotic risk. Additionally, deep vein thrombosis (DVT) is a more common postoperative complication in patients with malignancies than in other postoperative populations.

Hypercoagulability in malignancy is secondary to tumor cell expression of tissue factor and cancer procoagulant. Apoptosis of malignant cells or penumbra of nonmalignant cells affected by invading malignant tissue activates normally dormant tissue factor, initiating a coagulation cascade and formation of thrombus. Tumor proliferation, chemotherapy, hormonal therapy, radiation therapy, and hematopoietic growth factors all increase apoptotic activity and increase the risk of thrombus. Factors contributing to the formation of thrombus include cytokine release, acute phase reaction, and neovascularization. Tumors associated with higher risk of hypercoagulability include tumors of the pelvis, pancreas, stomach, breast, and brain.

Venous Thrombosis

Patients with DVT most often present with pain and swelling of the lower extremity. Patients often report that pain is mild, dull and crampy, or a diffuse perception of pressure or heaviness. The calf is most often involved, but the sole of the foot, heel, thigh, groin, or pelvis may be the site of thrombus and pain. Exacerbating factors include standing or walking. Physical examination may reveal signs of DVT, including swelling, warmth, dilation of superficial veins, tenderness along venous tracts, and pain with stretching of the affected limb. Rarely, a patient may present with ischemia of the lower extremity or in worse cases, a gangrenous limb. This presentation may occur in the absence of arterial or capillary occlusion (phlegmasia cerulea dolens). Signs include severe pain, extensive edema, and cyanosis of the affected leg. Mortality varies, but may be as high as 40% secondary to ischemia of the affected extremity or progression of thrombus to cause pulmonary emboli.

Only 2% of DVT cases involve the upper extremity with a low rate of associated pulmonary embolism. On physical examination, upper extremity DVT most often presents with edema, dilated collateral circulation, and pain.[62] In patients with malignancy, central venous catheterization is the most frequent cause[63] along with extrinsic compression by tumor.[64]

Superior Vena Cava Obstruction

For patients with lung cancer and lymphoma, superior vena cava (SVC) obstruction develops with extrinsic compression of the SVC by tumor expansion or by enlarged mediastinal lymph nodes.[63] Intravascular catheters are an iatrogenic cause,[65] especially with left-sided ports where the catheter tip rests in the upper portion of the vessel. Physical examination reveals facial swelling, dilated neck veins, and dilated chest wall veins. Less common patient reports of symptoms associated with SVC obstruction include chest pain, headache, and mastalgia.[66]

Acute Mesenteric Vein Thrombosis

Acute thrombosis of the mesenteric veins is most commonly associated with hypercoagulability secondary to malignancy and more rarely secondary to venous compression by lymphadenopathy, extension of venous thrombosis, or iatrogenic hypercoagulable states.

Pain Syndromes Related to Intravenous Chemotherapeutic Agents

Chemotherapeutic agents may cause vascular pain secondary to venous spasm, chemical phlebitis, vesicant extravasation, and anthracycline-associated flare. Venospasm pain is not secondary to inflammation or phlebitis. Attenuation of symptoms may come from application of a warm compress or reduction of chemotherapeutic infusion rate.

Agents causing chemical phlebitis include amsacrine, dacarbazine, carmustine and vinorelbine, potassium chloride, and hyperosmolar solutions. The pain and erythema associated with chemical phlebitis should be monitored closely as it shares many

of the early features of vesicant cytotoxic extravasation that in later stages presents as desquamation and ulceration of cutaneous structures.

Venous flare reaction is often associated with the use of anthracycline or doxorubicin and presents with local urticaria, pain, or stinging.

Hepatic Artery Infusion Pain

Patients receiving cytotoxic infusions directly into the hepatic artery often report diffuse abdominal pain.[65] Pain is attributed to gastric ulceration, gastric erosion, or cholangitis. With no persistence of complications, resolution of pain occurs with completion of therapy.

Complex Visceral Pain Syndromes

Nontraumatic rupture of a visceral tumor may cause sudden, severe abdominal or pelvic pain and is most commonly associated with hepatocellular carcinoma.[67] Metastases from other tumors also cause visceral ruptures (e.g., kidney rupture from a metastasis from adenocarcinoma of the colon[68] or metastasis-induced perforated appendicitis.[69] Torsion of pedunculated visceral tumors may cause cramping abdominal pain.[70]

Postradiation Visceral Pain

Postradiation therapy pain syndromes often involve both somatic and visceral structures, regardless of the target organ. Late effects, including connective tissue fibrosis, neural damage, and secondary malignancies, can occur long after completion of radiotherapy. A recent large retrospective cohort study revealed an association between previous pelvic radiation and hip fractures, with an increase in lifetime fracture rate from 17% (control) to 27% (radiation group). Pelvic pain after radiotherapy may be due to pelvic insufficiency fracture, enteritis, visceral dysfunction, or neural damage. Chronic pelvic pain has been reported as a consequence of prostate brachytherapy. Twenty percent of patients receiving brachytherapy have been reported to complain of dysuria 1 year after treatment.

Radiation Enteritis and Proctitis

In 2% to 10% of patients receiving pelvic or abdominal radiation therapy, chronic enteritis and proctocolitis may occur.[71] The rectum and distal colon are more frequently sites of involvement. Onset may be as early as 3 months or as late as 30 years.[72] Presentations may include proctitis (bloody diarrhea, tenesmus, and cramping pain), obstruction due to stricture formation, or fistulae to the bladder or vagina.[6] Small bowel radiation damage typically causes colicky abdominal pain, which can be associated with chronic nausea or malabsorption. Barium studies may demonstrate a narrow tubular bowel segment resembling Crohn's disease or ischemic colitis. Endoscopy and biopsy may be needed to identify recurrent cancer.

Burning Perineum Syndrome

Perineal discomfort may develop 6–18 months following pelvic radiotherapy. Patients complain of burning pain in the perianal region and may involve the vagina or scrotum. For those patients with postabdominoperineal resection, phantom anus pain and recurrent tumor should be considered.

Radiation Cystitis

Radiation therapy used in the treatment of tumors of the pelvic organs (prostate, bladder, colon/rectum, uterus, ovary, and vagina/vulva) may produce chronic radiation cystitis.[6] Symptoms of radiation injury to the bladder may be as minor as temporary irritation with voiding or asymptomatic hematuria, or as severe as gross hematuria, a contracted nonfunctional bladder, persistent incontinence, and fistula formation. Other signs and symptoms may include frequency, urgency, dysuria, hematuria, incontinence, hydronephrosis, pneumaturia, and fecaluria.[6]

Postchemotherapy Visceral Pain

Painful peripheral neuropathy is frequently a dose-limiting side effect of some chemotherapeutic regimens. Once the therapy is stopped, the neuropathic pain will resolve with or without symptomatic treatment. However, in a small number of patients, the neuropathy does not resolve and may continue to be intensely painful. Prevalence during treatment varies from agent to agent, with the intensity of treatment (dose intensity and cumulative dose), with other concurrent therapies such as surgery and radiotherapy, and with the use of combination chemotherapy. Estimates of prevalence range from 4% to 76% during chemotherapy treatment.

TREATMENT

In general, treatment for cancer-related visceral pain syndromes should adhere to standard cancer pain treatment guidelines (e.g., WHO Analgesic Ladder; American Pain Society Guidelines). The reader is referred to Chapters 43, 44, and 48 for details of various pharmacotherapeutic, radiotherapeutic, and interventional treatment modalities. Therapies that target visceral pain mechanisms with some specificity that are not covered in detail in other chapters are elaborated below.

N-Methyl-D-Aspartate Receptor Antagonists

Ketamine, which blocks *N*-Methyl-D-Aspartate (NMDA) receptors, can influence visceral hypersensitivity. Primary visceral hypersensitivity is attributed to a reduction in peripheral nociceptive thresholds. Two central processes mediate secondary visceral hypersensitivity: (a) plasticity of activated C-fibers; and (b) convergence of afferents at multiple levels and maintained by glutamate release that binds to NMDA receptors. NMDA receptor activation results in nitric oxide synthase expression, nitric oxide production, and prostaglandin production.

Through these mechanisms (and perhaps others) ketamine has been found to be useful in the management of pain states that are either poorly responsive to opioids and other analgesics, or when there are dose-limiting adverse effects to other pain treatments. Ketamine use has been described, with variable success, in adults, pediatric patients, via intrathecal, parenteral, and oral routes, and in inpatient as well as outpatient settings.[73–82]

Corticosteroids

Dexamethasone inhibits neuronal nitric oxide synthase gene expression. It has been effective in treating visceral pain and bowel obstruction.[83]

Gabapentin

Gabapentin has been demonstrated to reduce glutamate levels and reduces hypersensitivity associated with celiac pain.[84]

Procedural Intervention

Ganglion Impar Block

The ganglion impar is a solitary retroperitoneal structure located at the level of the sacrococcygeal junction. This unpaired ganglion marks the end of two sympathetic chains. The ganglion receives sympathetic and parasympathetic fibers at the lumbar and sacral levels, providing sympathetic innervation to portions of the pelvic viscera and genitalia.[85] Visceral pain in the perineal area associated with malignancies may be effectively treated with neurolysis of the ganglion impar (also know as Walther's ganglion).[86] Patients who will benefit from this block frequently present with a vague, poorly localized pain that is frequently accompanied by sensations of burning and urgency. The ganglion impar block is useful to the management of sympathetically mediated pain in the perineum, rectum, and genitalia. It has been primarily used for malignancy; however, it has been used for treatment of associated syndromes such as radiation enteritis, proctalgia fugax, and reflex sympathetic dystrophy.

The ganglion impar is close in proximity to the rectum. There is increased risk of contamination through the needle track as the needle is removed. Infection and fistula are possible complications in patients who are already immunocompromised or have received radiation to the perineum.

Thoracic Sympathetic Ganglion Block

Preganglionic fibers of the thoracic sympathetics exit with respective thoracic paravertebral nerves from the intervertebral foramen. After exiting the intervertebral foramen, thoracic paravertebral nerves branch looping dorsal through the same foramen to provide innervation to the spinal ligaments, meninges, and respective vertebra. The paravertebral nerve at this level also affects the thoracic sympathetic chain through myelinated preganglionic fibers of the white rami communicantes. Preganglionic and postganglionic fibers synapse at the level of thoracic sympathetic ganglia. Postganglionic fibers provide sympathetic innervation to the vasculature, sweat glands, and pilomotor muscles of the skin as well as the cardiac plexus and terminate in distal ganglia as they course up and down the thoracic sympathetic trunk.[87]

Block of the thoracic sympathetic ganglion is useful for evaluation of sympathetically mediated pain to the thoracic and upper abdominal viscera, the thorax, and the chest wall. Differential blockade may serve as a prognostic indicator of the benefit to be expected from lesioning of the thoracic sympathetic ganglion. The block has been used in the past to treat intractable abdominal pain as well as intractable cardiac pain. It has also been demonstrated to be effective in the treatment of acute herpes zoster, postherpetic neuralgia, and phantom breast pain following mastectomy. Thoracic sympathetic chain destruction may be used to relieve pain in pain syndromes that have been improved by local anesthetic block.[88]

Because of the close proximity to the pleural space of the exiting nerve roots at the thoracic level from sympathetic ganglion, pneumothorax is a possible complication. The pleural space lies lateral and anterior to the thoracic sympathetic chain. The lower cervical ganglion fuses with the first thoracic ganglion to make the stellate ganglion. Caudad in the thoracic chain, thoracic ganglia move further anterior resting along the posterolateral surface of the vertebral body. Other possible complications include accidental injection of the epidural, subdural, and subarachnoid space. Infection is of greater concern in patients with malignancy because of their immunocompromised state.

Interpleural Catheters

The role of interpleural analgesia (IPA) in both acute and chronic pain management is still undergoing clinical scrutiny. Original work with this technique showed that IPA could provide analgesia in patients with subcostal incisions and fractured ribs.

The technique for insertion of an interpleural catheter is relatively easy, and an epidural tray can be utilized. Local anesthetics (0.5% bupivacaine or 2% lidocaine) have been traditionally utilized via intermittent bolus or a continuous infusion. Interpleural phenol has been described as an alternative for the treatment of visceral pain associated with esophageal cancer. This may be an effective technique to treat visceral pain associated with cancer of the esophagus, liver, biliary tree, stomach, and pancreas.

For analgesia associated with cancer, continuous infusions of bupivacaine or intermittent bolus doses of bupivacaine may also provide adequate analgesia. Higher concentrations of bupivacaine increase the risk of toxicity.

Complications are secondary to needle or catheter injury or are secondary to the neurolytic agent injected in the interpleural space. Pneumothorax may occur in 2% of patients, and lung injury has been reported when a rigid catheter is used. Phrenic nerve palsy may occur following this block resulting in respiratory failure. Thus, bilateral blocks should be avoided. Doses of phenol should be limited; systemic effects from drug absorption may occur since the pleural membranes are highly vascularized.

Surgery

Referral for surgical options should be pursued with diagnosis and treatment of pain in malignancy at any time during the course of care. Surgical objectives in the palliation of cancer include staging of disease, control of disease, control of pain and associated symptoms, reconstruction, and rehabilitation.[89] Patients interested in and capable of tolerating surgical options should be referred to a surgeon for consideration of options, even if there are nonsurgical options available. If no intervention is recommended, the patient will have an understanding for the surgical referral and have a sense of closure with regard to the variety of options available for palliation. Surgical consult is particularly valuable in the areas of wound management, complicated issues with regard to nutrition, and discussion of progression of disease.[88]

There is no standard set of procedures for the palliation of malignant visceral pain. The operations available are a reflection of the subjective pain experience of the patient, the specific stage of the disease, and the anatomic effects of the disease. Often, other distressing symptoms may be the reason for surgical management as well as the complaints of pain. The given surgical option should palliate as many symptoms as possible without altering benefit/risk ratios.[88] The most important preoperative measure involves reassurance to the patient that preparation is complete and that postoperative analgesia has been considered. This is best achieved with close coordination with the partnering anesthesia team and preoperative consultation regarding analgesic options. Furthermore, the operative encounter may be the foundation for continued postoperative pain management options.

Malignancy presenting with pain is likely to be advanced in nature. Resection of an organ or portion of an organ for management of pain is reasonable even in the case of uncontrollable disease, especially if the disease is resectable or partially resectable. There is little data, however, comparing the efficacy of resection with nonoperative approaches.

In visceral disease, surgical resection has proven effective for the relief of dysphagia, odynophagia, and chest pain in patients with esophageal carcinoma; the relief of painful ulceration in those with gastric carcinoma; and the preemptive control of jaundice, pain, and duodenal obstruction in those with pancreatic carcinoma.[88]

Surgery can promote comfort as well as eliminate pain. Mechanical bowel obstruction may be expected in as many as 15% of cancer patients. Pain is a reflection of the severity of the disten-

sion, the nature of the primary neoplasm, and the level of obstruction. Resection has also been offered on occasion for relief of pain associated with carcinoma of the kidney. In some situations, nephrectomy may be considered to prevent pain, hematuria, and constitutional effects of the disease. In patients with large bladder masses, total or partial organ resection may be a consideration in cases where more conservative options have been considered. Stent placement may relieve severe pain secondary to malignant ureteral obstruction by tumors of the prostate, cervix, bladder, and colon. If stent placement is not an option, percutaneous nephrostomy may be effective.[88]

Debulking of functional tumors of the liver may be beneficial in patients with carcinoid to decrease such symptoms as flushing and diarrhea. Debulking has also been used in patients with metastatic gastrinoma, ovarian cancer, and large and small bowel malignancies.

Finally, drainage of ascites which may develop in as many as half of cancer patients may relieve associated symptoms such as bloating, diffuse abdominal pain, dyspnea, nausea, early satiety, and gastric reflux.

CONCLUSION

Failure to assess and treat cancer pain, whether of somatic, visceral, neuropathic, or mixed types is still a common problem among patients in all stages of malignant disease. Barriers to adequate care have been discussed in previous chapters. Notwithstanding needed improvements in clinician education, access to pain and supportive care specialists, among other needed systems improvements, and similar to other causes of cancer pain, relief of pain in patients with visceral malignancies or treatment-related visceral pain syndromes should be organized as part of a comprehensive interdisciplinary approach to care. Visceral pain cannot be exclusively managed with pharmacotherapy, and the resources of several medical and supportive care disciplines should be considered with each patient so that pain management can be tailored to the individual requirements of each patient according to his or her unique constellation of clinical and social circumstances.

CHAPTER 48 ■ RADIOTHERAPY AND CHEMOTHERAPY IN CANCER PAIN MANAGEMENT

AJIT S. AHLUWALIA, NORA A. JANJAN, AND CAMERON MUIR

INTRODUCTION

"Cancer pain is best controlled by removing the cancer or causing it to regress."[1] These words of the renowned oncologist and palliative medicine specialist Dr. Neil MacDonald are a useful framework from which to consider the role of palliative chemotherapy and radiotherapy in the management of symptomatic disease. About 50% of cancers are still cured by surgery and only 10% by other modalities. In the year 2007, 1,444,920 new cancer cases were diagnosed and about 559,650 cancer-related deaths occurred. The trends in cancer incidence and mortality shows a 13.6% decrease in the cancer death rate between the years 1991 and 2004.[2] This trend can be attributed to the persistent efforts in research and encouraging advances in the field of oncology. On the heels of this trend is the significant burden of symptoms like pain related to oncologic disease and its treatments.

Cancer has a negative impact on almost all cancer patients' activities of daily living. Quality of life measurements have been

shown to predict survival and add to the prognostic information derived from the Karnofsky Performance Status (KPS) and extent of disease. Physical symptoms including pain, dry mouth, constipation, change in taste, lack of appetite and energy, feeling bloated, nausea, vomiting, weight loss, and feeling drowsy or dizzy often portend a poorer prognosis.[3] Palliative care is an integral component of cancer treatment with a goal to effectively and efficiently relieve symptoms and maintain the maximum functional and emotional well-being for the duration of the patient's life.[4–10]

Palliative chemotherapy has been an ambiguous term, mostly used to refer to chemotherapy given to patients in whom the likelihood of cure was minimal. In the true sense, palliative chemotherapy would mean chemotherapy delivered with an aim to relieve symptoms, improve quality of life, or both, regardless of stage of disease or likelihood of remission or cure. The primary outcomes of most studies involving disease-modifying chemotherapeutic agents, however, do not have symptom relief as an end point and only recently are the end points related to quality of life becoming part of these studies. Reduction in the size of tumor, which is the intended goal of chemotherapy, should intuitively decrease cancer pain. However, since therapeutic benefits of chemotherapy are limited by their own toxicities, their risks versus benefits need to be weighed as part of treatment planning and decision-making on a case-by-case basis.

Palliative radiation is instrumental in the management of bone pain related to bone metastasis. Seventy percent of metastatic bone lesions are painful and debilitating. The goal of treatment is to relieve pain, restore functional ability, and prevent pathological fractures.[11,12] The location of the metastasis can be a limitation in the effectiveness of a palliative intervention. Metastatic involvement of weight-bearing bones and those used in functional activities are often less likely to respond completely to palliative interventions due to applied mechanical forces put upon them. Pain relief is achieved in 73% of spine metastases, 88% of limb lesions, 67% of pelvic metastases, and 75% of metastases to other parts of the skeleton.[13]

Poorer health is a more frequent finding in lung, breast, prostate, and colon cancer patients as these primary tumor types tend to metastasize to the bones and viscera more aggressively.[14–16] After bone metastases are diagnosed, the median survivals are 12 months for breast cancer, 6 months for prostate cancer, and 3 months for lung cancer. In breast cancer, the survival decreases to only 9 months if visceral metastases are also present.[15,16] In prostate cancer, the distribution of bone metastases on scintigraphy also has prognostic significance. The rate of survival is significantly longer when the metastases are restricted to the pelvis and lumbar spine, as well as among patients who respond to salvage hormone therapy,[17–19] but lower if metastatic involvement is outside the pelvis and lumbar spine irrespective of response to salvage hormone therapy. The median length of survival is critical to evaluating response to and determining the appropriate recommendations for palliative therapy.

Economically, bone pain related to cancer results in increased utilization of health care resources and cost.[20,21] The economic implications provide a strong impetus to develop novel palliative approaches. Palliative medicine approaches are also providing patients with a positive treatment option both to augment conventional treatments or as the primary modality when disease modifying therapy for cancers fail to produce effect.[22]

RADIOTHERAPY

Role of Radiotherapy

Despite the establishment of multiple palliative medicine programs in the country and the proven efficacy of palliative radiotherapy for symptoms, radiotherapy is underutilized.[12] Even with relatively short life expectancy (weeks to months), palliative radiotherapy may be helpful, but in a survey completed in 2002, less than 3% of the patients in hospice care received radiation with a palliative intent.[23] The most common barriers to radiotherapy include radiotherapy expense, transportation difficulties, short life expectancy, and educational deficiencies among the specialties caring for patients with oncologic disease. Although the focus of this chapter is on pain management, this section will review the many indications for palliative radiotherapy, since symptoms—including pain—rarely occur alone, but rather in tandem.

Bone Disease

In the years 2000–2004, the annual prevalence of bone metastasis was estimated to be 256,137, and the rates were highest in multiple myeloma and lung cancer. The direct cost for patients with bone metastasis was $75,329 and the incremental cost was $44,442 compared to patients with cancer without bone metastasis. The national cost burden for patients with skeletal metastasis was estimated at $12.6 billion which is 17% of the $74 billion total direct medical cost estimated by NIH.[24] Although more abbreviated radiation courses may result in cost savings, the response to therapy must be critically analyzed to ensure that treatment efficacy is not compromised. Ineffective therapy may prove more costly than a more prolonged and effective radiation schedule because of the continued need for analgesics and the functional limitations caused by unrelieved pain and disability.[25,26]

Multidisciplinary evaluation of patients with metastatic disease to the bone allows comprehensive management of the associated symptoms, determines the risk for pathologic fracture, and helps coordinate administration of a wide range of available antineoplastic therapies (also see Chapter 46).[10] Bone metastases can be treated with localized, systemic, or both kinds of therapies.[11,24–38] Because radiation provides treatment only to a localized symptomatic site of disease, it is frequently used in coordination with systemic therapies such as chemotherapy, hormonal therapy, and bisphosphonates. Radiopharmaceuticals provide another systemic option that treats diffuse symptomatic bone metastases. Because the radiation is deposited directly at the involved area in the bone, radiopharmaceuticals, such as strontium 89, can also be used to treat bone metastases when symptoms recur in a previously irradiated site.[39–54] Radiopharmaceuticals can also act as an adjuvant to localized external beam irradiation and reduce the development of other symptomatic sites of disease.

Control of cancer-related pain with the use of analgesics is imperative to allow comfort during and while awaiting response to therapeutic interventions. Pain represents a sensitive measure of disease activity. Close follow-up should be performed to ensure control of cancer and treatment-related pain, and to initiate diagnostic studies to identify progressive or recurrent disease. Pain, risk for pathologic fracture, and spinal cord compression are the most common indications to treat bone metastases with localized therapy including radiation and surgery.

Clinical Applications

Radiotherapy can be delivered with curative or palliative intent. Curative treatment attempts to render the patient disease free of either primary or metastatic disease. Treatment with palliative intent is intended to control the symptoms of disease when the disease cannot be eradicated. A number of clinical, prognostic, and therapeutic factors must be considered to determine the most optimal treatment regimen for a course of palliative radiotherapy. Although any site of disease can be effectively palliated, treatment

of bone metastases is one of the most common indications for palliative irradiation with external beam therapy.[11,26,29]

The limited radiation tolerance of the normal tissues, such as the spinal cord, that are adjacent to a bone metastasis make it impossible to administer a large enough dose of radiation to completely eradicate most tumors. Palliative radiation should result in sufficient tumor regression to relieve symptoms for the duration of the patient's life. Palliative radiotherapy is often combined with chemotherapy and/or surgery to optimize therapeutic outcomes from tumor-related pain, bleeding, visceral obstruction, or lymphatic and vascular obstruction. Common sites include respiratory system structures, pelvis, skin and subcutaneous tissues, brain, and all bony structures. Potential relief of symptoms is a more important determinant for palliative radiation than whether lesions result from locally advanced or metastatic disease. Symptoms that recur after palliative radiation most commonly result from localized regrowth of tumor in the radiation field.

The palliative interventions recommended depend on the patient's clinical status, burden of disease, and location of the symptomatic site. For either locally advanced or metastatic disease, these factors are indexed to the relative effectiveness, durability, and morbidity of each palliative intervention. Each patient's prognosis represents the single most important factor in deciding the approach to palliative therapy.

Because patients with metastatic disease have a limited life expectancy, the number of radiation fractions prescribed for treatment with palliative intent depends on prognosis and not primary histology, so a lower total dose is given with palliative radiation over 1 to 2 weeks (hypofractionated radiation schedule). Based on the radiation tolerance of normal tissues, a low daily radiation dose (1.8 to 2.0 Gy) is given with conventional radiation; in contrast, large daily radiation fractions are given with hypofractionated radiation schedules. Hypofractionated radiation schedules for palliative therapy can range from 2.5 Gy per fraction administered over 3 weeks for a total dose of 35 Gy to a single 8-Gy dose of radiation. Most frequently, 30 Gy is administered in 10 fractions over 2 weeks.[10,11,28–32,55–60] Especially among patients with short life expectancies, many centers administer 20 Gy in 1 week because the rates of pain relief, mobility, and frequency of pathologic fractures are similar to more protracted radiation schedules.

RESPONSE OF TUMORS TO RADIOTHERAPY

Trachea, Bronchi, and Lungs

Locally advanced primary or metastatic involvement of the lung often requires palliative intervention because cure is possible in only a few of these cases. A variety of symptoms, some of them emergent, can manifest because of tumor involvement of the lung.[61] Pain can result from tumor invasion of the ribs and nerve roots of the chest wall. Vertebral involvement can be associated with spinal cord compression. Lower respiratory tract obstruction, bleeding, and pneumonitis can result from tracheobronchial tumor growth. Mediastinal infiltration can cause superior vena cava syndrome. All of these clinical presentations can be palliated with external beam radiation that encompasses the disease that is evident on diagnostic images and that treats pain referred along involved nerve roots. Radiation schedules that administer 30 Gy in 10 fractions over 2 weeks, two fractions of 8.5 Gy 1 week apart, or one fraction of 10 Gy (depending upon the patient's life expectancy and ability to tolerate multifraction therapy) are typically prescribed to previously unirradiated sites. Hemoptysis and chest pain can be effectively palliated; dyspnea and dysphagia are not as effectively relieved. If the area has been previously irradiated, techniques that exclude critical anatomic structures, such as the spinal cord, are applied. Other approaches can be used when the symptomatic site is well localized and accessible. Brachytherapy, which applies radioactive sources next to tumors, can be used to treat bronchial obstruction and bleeding by placing a radioactive source directly against the tumor under bronchoscopic guidance. In these cases, large doses of radiation can be delivered over a few minutes by a high-dose rate brachytherapy unit.

Pelvis

Hemorrhage with or without obstruction or compression of viscera, lymphatics, vascular structures, and nerves commonly occurs with locally advanced or metastatic disease in the pelvis. Treatment may require emergent radiotherapeutic, surgical interventions, or both. Hemorrhage is commonly associated with tumors involving the rectum and genitourinary tracts. As with tumors in the lung, radiation is an effective means of stopping active bleeding. Colorectal cancers are often diagnosed among patients with unexplained bleeding. In patients that have locally advanced tumors with months to years of life expectancy, 40 Gy in 2.5 Gy fractions to 50 Gy in 2 Gy fractions have been used with the intent to stop bleeding, render the patient operable, and provide a chance for cure. With extensive metastatic disease, 30 Gy in 10 fractions or 20 Gy in 5 fractions is used to palliate symptoms of bleeding and obstruction. Colorectal tumor involvement may also result in obstruction requiring stent placement to maintain the integrity of the visceral lumen while administering radiation. Diverting colostomy is occasionally required but is reported to have been avoided after chemohypofractionated irradiation.[61]

Tumors involving the cervix can hemorrhage and require emergent radiotherapeutic intervention. Superficial radiographs are applied directly to the bleeding cervix through a cone to treat the bleeding site and do not compromise later radiation of other pelvic structures. Usually, radiation doses between 5 and 10 Gy are administered in 1 to 3 applications of cone therapy. Brachytherapy also can be used to treat gynecologic tumors, especially in the vagina, cervix, and endometrium.

Bladder cancers or tumors that secondarily invade the bladder can also result in significant bleeding that can be palliated by external beam radiation. Urinary obstruction commonly occurs with locally advanced pelvic cancers, especially with bladder, rectum, prostate, and cervical cancers. Occasionally, placement of a urinary stent, urostomy, or nephrostomy is required until sufficient tumor regression can be accomplished by radiation to reestablish integrity of the urinary tract.[61] As with the bowel and gynecologic tracts, a bladder fistula, resulting from either the tumor itself or from tumor regression, is a concern.

The pelvic lymph nodes and major blood vessels may become obstructed by tumor. This most frequently is seen when tumors arise in pelvic structures, but can also occur with pelvic metastases from breast and other cancers. Lymph-vascular obstruction results in painful edema that is refractory to diuretic and other therapies. Other than pain and functional interference, when severe, fluid and electrolyte imbalances can occur. Pelvic radiation can relieve lymph-vascular obstruction through tumor regression.

Pelvic tumors can also invade the sacral plexus and result in intractable pain. Tumor can track along nerve roots and can be associated with bony invasion of the sacrum. Pain caused by visceral, lymph-vascular, or both kinds of obstructions often respond more rapidly to palliative radiation than the more refractory neuropathic pain seen with sacral plexus involvement. Other radiotherapeutic approaches, such as brachytherapy, are extremely limited when the cancer persists or recurs after external beam radiation. Interventional pain management techniques are frequently required to control pain associated with sacral plexus involvement (see Chapter 44).

Skin and Subcutaneous Tissues

Tumors can cause ulceration of the skin and subcutaneous tissues that are often painful and distressing because of constant drainage. Representing a source for the development of sepsis in immunocompromised patients, localized radiation can be applied to destroy tumor and allow re-epithelialization of the skin. Radiation that treats only the skin and subcutaneous tissues (electron beam therapy) is generally used to avoid radiation side effects to underlying uninvolved normal structures. Although usually 10 radiation treatments are given, the course of radiation can be abbreviated further, ranging from 1 to 5 days. Occasionally, these lesions are treated with brachytherapy. The radioactive sources can be placed in a mold that sits on top of the tumor and delivers treatment over a few minutes (high-dose rate) or a few days (low-dose rate).

Brain Metastases

Radiation is used to relieve the symptoms of headache, seizure, nausea and vomiting, and neurologic dysfunction associated with brain metastases. In patients with good performance status, surgery or radiosurgery followed by postoperative whole brain radiation is the preferred approach. Radiation is generally with a total of 30 Gy in 10 fractions or 20 Gy in 5 fractions.[62]

BONE METASTASES

There are two major sets of experience with palliative radiation for bone metastases. The Radiation Therapy Oncology Group (RTOG) conducted a prospective trial that included a variety of treatment schedules. To account for prognosis, patients were stratified on the basis of whether they had a solitary or multiple sites of bony metastases. The initial analysis of the study concluded that low-dose, short-course treatment schedules were as effective as high-dose protracted treatment programs.[63] For solitary bone metastases, no difference existed in the relief of pain when 20 Gy using 4-Gy fractions was compared with 40.5 Gy delivered as 2.7 Gy-fractions. Relapse of pain occurred in 57% of patients at a median of 15 weeks after completion of therapy for each dose level. In patients with multiple bone metastases, the following dose schedules were compared: 30 Gy at 3 Gy per fraction, 15 Gy given as 3 Gy per fraction, 20 Gy using 4 Gy per fraction, and 25 Gy using 5 Gy per fraction. No difference was identified in the rates of pain relief among these treatment schedules. Partial relief of pain was achieved in 83% and complete relief occurred in 53% of the patients studied. More than 50% of these patients developed recurrent pain, the fracture rate equaled 8%, and the median duration of pain control was 12 weeks for all the radiation schedules used for multiple bony metastases. Prognostic factors for response included the initial pain score and site of the primary cancer.

In a reanalysis of the data, a different definition for complete pain relief was used and excluded the continued administration of analgesics. Using this definition, the relief of pain was significantly related to the number of fractions and the total dose of radiation that was administered.[64] Complete relief of pain was achieved in 55% of patients with solitary bone metastases who received 40.5 Gy at 2.7 Gy per fraction as compared with 37% of patients who received a total dose of 20 Gy given as 4 Gy per fraction. A similar relationship was observed in the reanalysis of patients who had multiple bone metastases. Complete relief of pain was achieved in 46% of patients who received 30 Gy at 3 Gy per fraction versus 28% of patients treated to 25 Gy using 5-Gy fractions. In most cases, the interval to response was 4 weeks for both complete and minimal relief of symptoms.

Three important issues are identified from the RTOG experience. First, the results of the reanalysis demonstrate the importance of defining what represents a response to therapy. Second, this revised definition of response showed that the total radiation dose did influence the degree that pain was relieved.[63,64] The response rates and the radiobiologically equivalent doses are listed from the reanalysis in (Table 48.1) for each of the treatment schedules used. Patients treated with total doses of 40 Gy or more had a 75% rate of complete pain relief versus a 62% rate of complete pain relief for patients treated with total doses of less than 40 Gy.[13,65] Third, the RTOG experience identified the amount of time that was needed to experience relief of pain after

radiation for bone metastases (Table 48.2). It is important to note that only one-half of the patients who were going to respond had relief of symptoms at 2 to 4 weeks after radiation.[63,64] This underscores the need for continued analgesic support after completing radiation. Consistently, it took 12 to 20 weeks after radiation to accomplish the maximal level of relief. That period of time may reflect the time needed for reossification. Radiographic evidence of recalcification is observed in approximately one-fourth of cases, and in 70% of cases, recalcification is seen within 6 months of completing radiation treatments.[28,30,31,66] Recalcification is the basis of stabilization and prevention of fractures in the future. For pain relief, a short course of radiation is adequate; however, a longer schedule is recommended for adequate recalcification.[67,68] Again, clinical context, with a focus on life expectancy, is a key determinant of radiation type, dose, and fractionation schedule.

SINGLE FRACTION RADIATION

A single large radiation fraction is reportedly as effective in relieving pain as other radiation schedules that have more treatments. Radiobiologically, a single 8-Gy fraction would give the same side effects to late reacting tissues (i.e., tissues such as the spinal cord that do not regenerate) as if 18 Gy were given over nine treatments at 2 Gy per fraction.[69] Because tumors and acute reacting tissues, such as the esophagus and other mucosal structures, respond differently than the late reacting tissues, the radiobiologically equivalent dose to the tumor for a single 8-Gy fraction would be 12 Gy if 2 Gy fractions were used. The most common dose fractionation schedule used for palliative radiation in the United States is 30 Gy over 10 fractions. Radiobiologically, this is equivalent to 36 Gy at 2 Gy per fraction for late reacting tissues and 32.5 Gy to the tumor. When a single dose of radiation was compared with a radiation schedule with multiple radiation fractions, no difference was reported in either how quickly symptoms resolved or the duration of pain relief.[10,24,32,55,58,60,65,70–78] Pain relief was achieved in 80% after treatment and 50% of patients at 6 months irrespective of the number of fractions.[65,70–78,80,81] Complete response rates after a single 8-Gy fraction total 15% at 2 weeks, 23% at 4 weeks, 28% at 8 weeks, and 9% at 12 weeks postradiation.

Despite the radiobiological differences in the dose administered, the similarities in response may be caused by tumor regression and reossification that occurs at 3 months. The RTOG experience showed that the maximum response to therapy was seen consistently at 3 months and was independent of dose administered.[63,64] The disparity in the relationship between radiation dose and clinical response may also be attributed to limited follow-up in the single fraction study because a significant proportion of patients in the study were lost to follow-up after 3 months.[70–73] With longer follow-up, the response to a single radiation fraction may not prove to be as durable as multiple fractions that give high total radiation doses.[80–82] These data demonstrate that prognosis needs to be linked to variables such as site irradiated, total radiation dose, and reirradiation.[83]

A shorter radiation schedule, such as a single fraction, is advantageous for patients with poor prognostic factors. First, it is easier for patients with a poor KPS to complete therapy. Second, response rates are equal to single and multifraction therapy at 3 months because median survival is less than 6 months among patients with poor prognostic factors.[10,32,55,57,65,70–78] The option of retreatment after a single fraction of radiation may also provide an advantage among patients with good prognostic factors as a means to periodically reduce tumor burden and control symptoms in noncritical anatomic sites. Higher radiation doses that provide more durable pain relief are considered warranted for patients with good prognostic factors who require treatment over the spine and other critical sites.[10,11,13,29,32,55,56,60,80–82,84–90]

The projected length of survival is the critical issue to determine the optimal radiation dose and schedule for palliative radiation. In one study, only 12 of 243 patients were alive at the time of analysis, with approximately 50% alive at 6 months, 25% at 1 year, 8% at 2 years, and 3% at 3 years after palliative radiation. For breast cancer patients, the survival rates at these time points after palliative radiation were 60%, 44%, 20%, and 7%, respectively. For prostate cancer, the survival rates were 60% at 6 months, 24% at 1 year, and there were no patients who survived 2 years.[59] This survival difference may be an important observation because unrelieved pain and the resultant sequelae of immobility may contribute to mortality as well as morbidity.[3,17,18,20,91–93]

Reirradiation for persistent or recurrent pain is often precluded when higher radiation doses are administered. Because

the radiobiological dose is relatively low when a single fraction of radiation is administered, reirradiation is generally possible.[69–73,80–83] Reirradiation was necessary in 25% of patients who received a single 8-Gy radiation fraction, but all of these patients were reported to respond to the second dose of radiation.[65,70–78] Pain relief in patients with reirradiation was better in patients with longer duration of pain-free interval after the initial radiation (≥4 months), had better performance status (KPS 1 or 2) and had a single bone metastasis.[94]

Acute radiation toxicities are a function of the dose per fraction, total dose, and the area and volume of tissue irradiated. If mucosal surfaces, such as the upper respiratory and digestive tract, bowel, and bladder, can be excluded from the radiation portals, acute radiation side effects can be significantly reduced. The radiation schedule used for palliative radiation is therefore influenced by the radiation tolerance of adjacent normal tissues as well as prognosis.

PATHOLOGIC FRACTURE

The most significant morbidities of bone metastases relate to pathologic fracture and spinal cord compression. Pain that persists or that recurs after palliative radiation should be evaluated to exclude progression of disease, possible extension of disease outside the radiation portal that results in referred pain, and bone fracture. It is unclear whether osteolytic metastases are more likely to fracture than osteoblastic lesions, because osteoblastic lesions, by definition, have an osteolytic component so that new bone can be formed.[95] Reduced cortical strength can result in compression, stress, or microfractures associated with reduced cortical strength. Serial radiography is useful in following posttreatment disease progression and fractures.[30,95] Pathologic fractures occur in 8% to 30% of patients with bone metastases.[95–101] Proximal long bones are more commonly involved than distal bones. Consequently, pathologic fractures occur 50% of the time in the femur and 15% in the humerus (Fig. 48.1). The femoral neck and head are the most frequent locations for pathologic fracture because of the propensity for metastases to involve proximal bones and the stress of weight placed on this part of the femur. More than 80% of pathologic fractures occur in breast (50%), kidney, lung, and thyroid cancers.

Approximately 10% to 30% of metastatic lesions in long bones develop a pathologic fracture that requires surgical intervention. Patients with pathologic fracture caused by bone metastases have clinical outcomes after surgical repair that are comparable with patients sustaining a traumatic fracture.[97–99,102] Poor prognosis is associated with hypercalcemia and ongoing severe pain from other metastatic bone lesions. Therefore, in those cases, the decision for surgical intervention should be even more carefully weighed, based upon a relative benefit to burden analysis.[97]

Treatment of pathologic fracture or impending fracture depends on the bone involved and the clinical status of the patient. Indications for surgical intervention of pathologic fracture or impending fracture include these factors: (a) an expected survival of more than 6 weeks; (b) an ability to accomplish internal stability of the fracture site; (c) no coexistent medical conditions that preclude early mobilization; (d) metastases involving weight-bearing bones; and (e) lytic lesions more than 2 to 3 cm in size or metastases that destroy more than 50% of the cortex.[97–101] Intramedullary stabilization without resection of metastases using locking nails meets the requirements of palliative therapy. This procedure is less invasive and allows early weight bearing.[102] Postoperative radiation is often given after surgical fixation of a pathologic fracture to reduce risk of progressive disease in the bone that could result in instability of the internal fixation.[98]

SPINAL CORD COMPRESSION

Metastatic spinal cord compression (MSCC) is the most dreaded complication of cancer. Pain is the initial symptom in approximately 90% of patients with spinal cord compression.[103] Paraparesis or paraplegia occurs in more than 60%, sensory loss is noted in 70% to 80%, and 14% to 77% have bladder, bowel, or both kinds of disturbances.[56,84,85,104] Six predictive risk factors are associated with MSCC: the inability to walk, increased deep tendon reflexes, compression fractures on radiographs of spine, bone metastases present, bone metastases diagnosed more than 1 year earlier, and age less than 60 years. Patients with no risk factors had a 4% chance of developing cord compressions and a patient with all six risk factors present had an 87% chance of developing cord compression.[105,106] Breast, lung, and prostate cancer comprised 21%–24% risk of developing cord compression.[105,106,107]

The clinical course of spinal cord compression resulting from malignant melanoma is similar to that resulting from breast or prostate cancer. The time from the original diagnosis of melanoma to the development of metastatic spinal disease averages 32 months, and the average time is reported to be 27 months from diagnosis of skeletal metastases to spinal cord compression. The extent of the epidural mass influences prognosis because a complete spinal block results in greater residual neurologic impairment than a partial block. Median survival among patients with spinal cord compression is 7 months, with a 36% probability for a 1-year survival. For specific types of cancers, the mean survival time is 14 months for breast cancer, 12 months in prostate cancer, 6 months in malignant melanoma, and 3 months in lung cancer once epidural spinal cord compression is diagnosed.[14,84,96] After the diagnosis of epidural spinal cord compression, the overall survival time averages 12 months, with a median survival time of 5 months. The vertebral column is involved by metastatic tumor in 40% of patients who die of cancer. Approximately 70% of vertebral metastases involve the thoracic spine, 20% the lumbosacral region, and 10% the cervical spine.

Weakness can signal the rapid progression of symptoms, and 30% of patients with weakness become paraplegic within 1 week. Rapid development of weakness, defined as occurring in less than 2 months, most commonly occurs in lung cancer, whereas breast and prostate cancers can progress more slowly. Neurologic deficits can develop within a few hours in up to 20% of patients with spinal cord compression.[84–90,108,109] The severity of weakness at presentation is the most significant factor for recovery of function. The slower the rate of development of motor deficits, the better the functional outcome.[104,110] If no neurologic deficits are present in a magnetic resonance imaging (MRI) scan proven spinal carcinoma, then radiation can preserve function. Patients with neurologic symptoms should be treated within 24 hours.[111,112] Ninety percent of patients who are ambulatory at presentation are ambulatory after treatment. Only 13% of paraplegic patients regain function, particularly if paraplegia is present for more than 24 hours before the initiation of therapy. Notwithstanding the high mortality associated with MSCC, more than 30% of patients who develop spinal cord compression are alive 1 year later, and 50% of these patients remain ambulatory if the syndrome is recognized and treated appropriately.

Pain can be present for months to just days prior to the onset of other neurologic dysfunction. Unlike degenerative joint disease, which primarily occurs in the low cervical and low lumbar regions, pain caused by epidural spinal cord compression can occur anywhere in the spinal axis and is aggravated by recumbency. Any cancer patient with back pain, especially with known metastatic involvement of the vertebral bodies, should be assessed for spinal cord compression. The risk of spinal cord compression exceeds 60% among patients with back pain and plain film evidence of vertebral collapse caused by metastatic cancer.[56,84–90,113–117]

A **B**

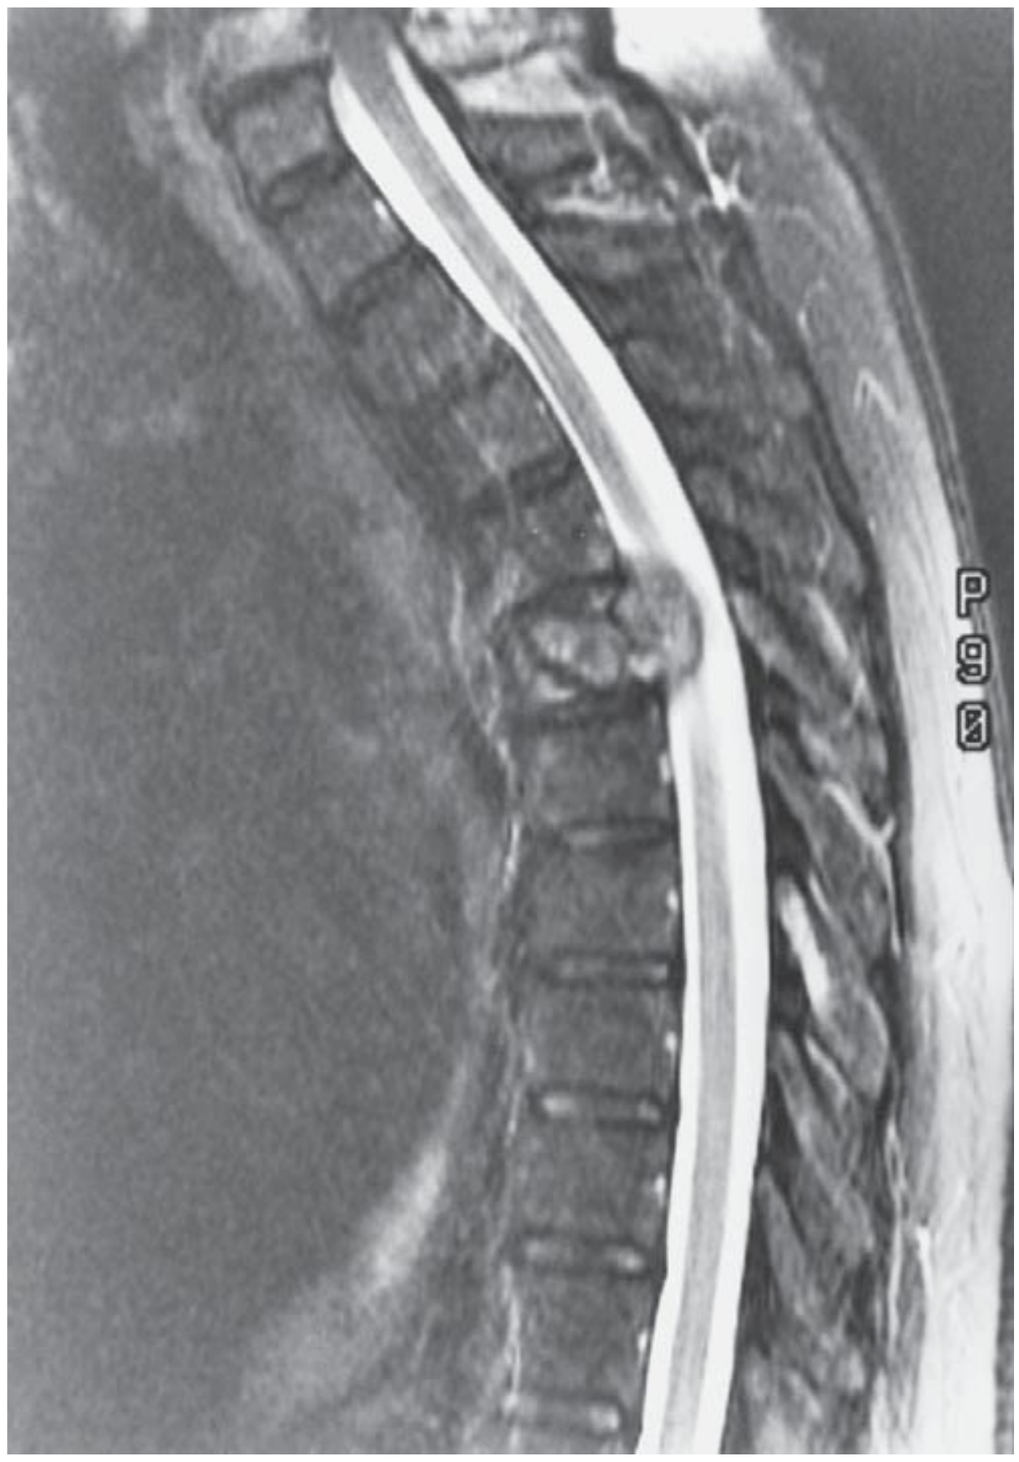

FIGURE 48.1 **(A)** An extensive lytic lesion in the proximal humerus. **(B)** Prophylactic internal fixation performed to prevent pathologic fracture. This patient, who complained primarily of pain in the hip, would have been placed on crutches to reduce stress on the involved femur. A bone scan and radiography, obtained to exclude other sites of metastatic involvement, identified this lesion in the humerus. The humerus would have certainly fractured if all the patient's weight had been displaced to the upper extremities with crutches.

Radiographic determination of the involved spinal levels is critical to radiation treatment planning. Plain film radiography shows involvement of more than one spinal level in approximately one-third of patients. If the results of MRI, tomographic studies, and surgical findings are included, more than 85% of patients have multiple sites of vertebral involvement.[84–90,108,113,116] For patients with known malignancy, a whole spine MRI is recommended as the preferred diagnostic modality.[104,118,119] With plain radiography, the destruction of the pedicles is the most common finding that identifies spine metastases. In contrast, computed tomography (CT) shows that the initial anatomic location of metastases is in the posterior portion of the vertebral body and that destruction of the pedicles occurs only in combination with involvement of the vertebral body (Fig. 48.2).[116] Symptomatic patients with a normal vertebral contour and osteoblastic changes on plain film and bone scan should also be evaluated for spinal cord compression (Fig. 48.3). Osteoblastic bony expansion, commonly seen in both prostate and breast cancers, can result in spinal cord compromise as well as osteolytic vertebral compression fractures.[115]

Emergency treatment of spinal cord compression includes corticosteroids, radiotherapy, neurosurgical intervention, or combinations of these three therapies. Radiotherapy is the treatment of choice for most cases of spinal cord compression and is a radiotherapeutic emergency (Fig. 48.4). Spinal cord compression resulting from metastatic tumor can be prevented or effectively treated when diagnosed early.[84–90,108,111,113] Radiotherapy with shorter courses (e.g., 1 fraction with 8 Gy or 5 fractions with 4

A

B

FIGURE 48.2 **(A)** CT scan showing involvement of the posterior aspect of the vertebral body resulting in partial spinal cord compression. **(B)** MRI showing involvement of the posterior aspect of the vertebral body resulting in partial spinal cord compression.

Gy) is as effective as a longer course (e.g., 30 Gy in 10 fractions) but the longer courses have lower recurrence rates. A scoring system for survival based on prognostic factors can guide the type of radiation course.[120] Patients with longer estimated survival time may benefit from the longer course of radiation.

Neurosurgical intervention for MSCC involves spinal cord decompression accomplished by a laminectomy and is indicated in a variety of clinical presentations.[84–86,88–90,117,120–123] These situations include: rapid neurologic deterioration in the setting of tumor progression in a previously irradiated area in order to provide stabilization of the spine, tumor-induced paraplegia in patients with otherwise limited disease and good probability of survival, and to establish a diagnosis. Adjuvant radiotherapy is often given to treat microscopic residual disease after neurosurgical intervention.[84,85,88,108] A statistically significant improvement in functional outcome has been reported with laminectomy and radiotherapy in treatment of epidural spinal cord compression over either modality alone.[104,121–123] In paraparetic patients who undergo laminectomy and radiation, 82% regain the ability to walk, 68% have improved sphincter function, and 88% have relief of pain. With radiation alone, 65% regained ambulation, 26% had improved sphincter function, and 70% had improvement of pain.[87,89,90,108,113,122] Laminectomy, however, carries risks associated with surgery and anesthesia. Pain may worsen after laminectomy if operative procedures fail to stabilize the spine. Vertebral collapse may occur because of cancer or vertebral instability after cancer therapy (Fig. 48.5).

Paravertebral masses are most commonly associated with lung cancer and are rare in prostate cancer. Overall, approximately 20% of patients with epidural cord compression have an associated paravertebral mass. Surgical resection combined with radiation therapy has been suggested to improve functional outcome when a paravertebral mass is associated with spinal cord compression.[96,124,125] The overall survival is worse with lung cancer and sarcoma than with breast and renal cancer.[123]

Radiation Tolerance of the Spinal Cord

Radiation tolerance is based on the dose per fraction, total dose, and the volume of tissue treated. The dose per fraction is the most important factor in the tolerance of tissues to radiation. Clinical and experimental experience has failed to demonstrate any difference in radiosensitivity in different segments of the spinal cord.[126] The risk of radiation myelitis in the cervicothoracic spine is less than 5% when 6000 cGy is administered at 172 cGy per fraction or 5000 cGy is given with daily fractions of 200 cGy per fraction. Especially among patients who have received chemotherapy, the total dose to the spinal cord is generally limited to 4000 cGy administered at 200 cGy per fraction to minimize any risk of irreversible radiation injury to the spinal cord. The total dose is also an extremely important factor defining the radiation tolerance of the spinal cord. A steep curve based on total radiation dose predicts the risk of developing radiation myelopathy; a small increase in total radiation dose can result in a large increased risk for radiation myelopathy.[126,127,128] Retreatment of a previously irradiated segment of spinal cord results in high risk for radiation-induced myelopathy because other neurologic pathways cannot compensate for an injury to a specific level of the spinal cord.

The radiation tolerance of the spinal cord can be compromised

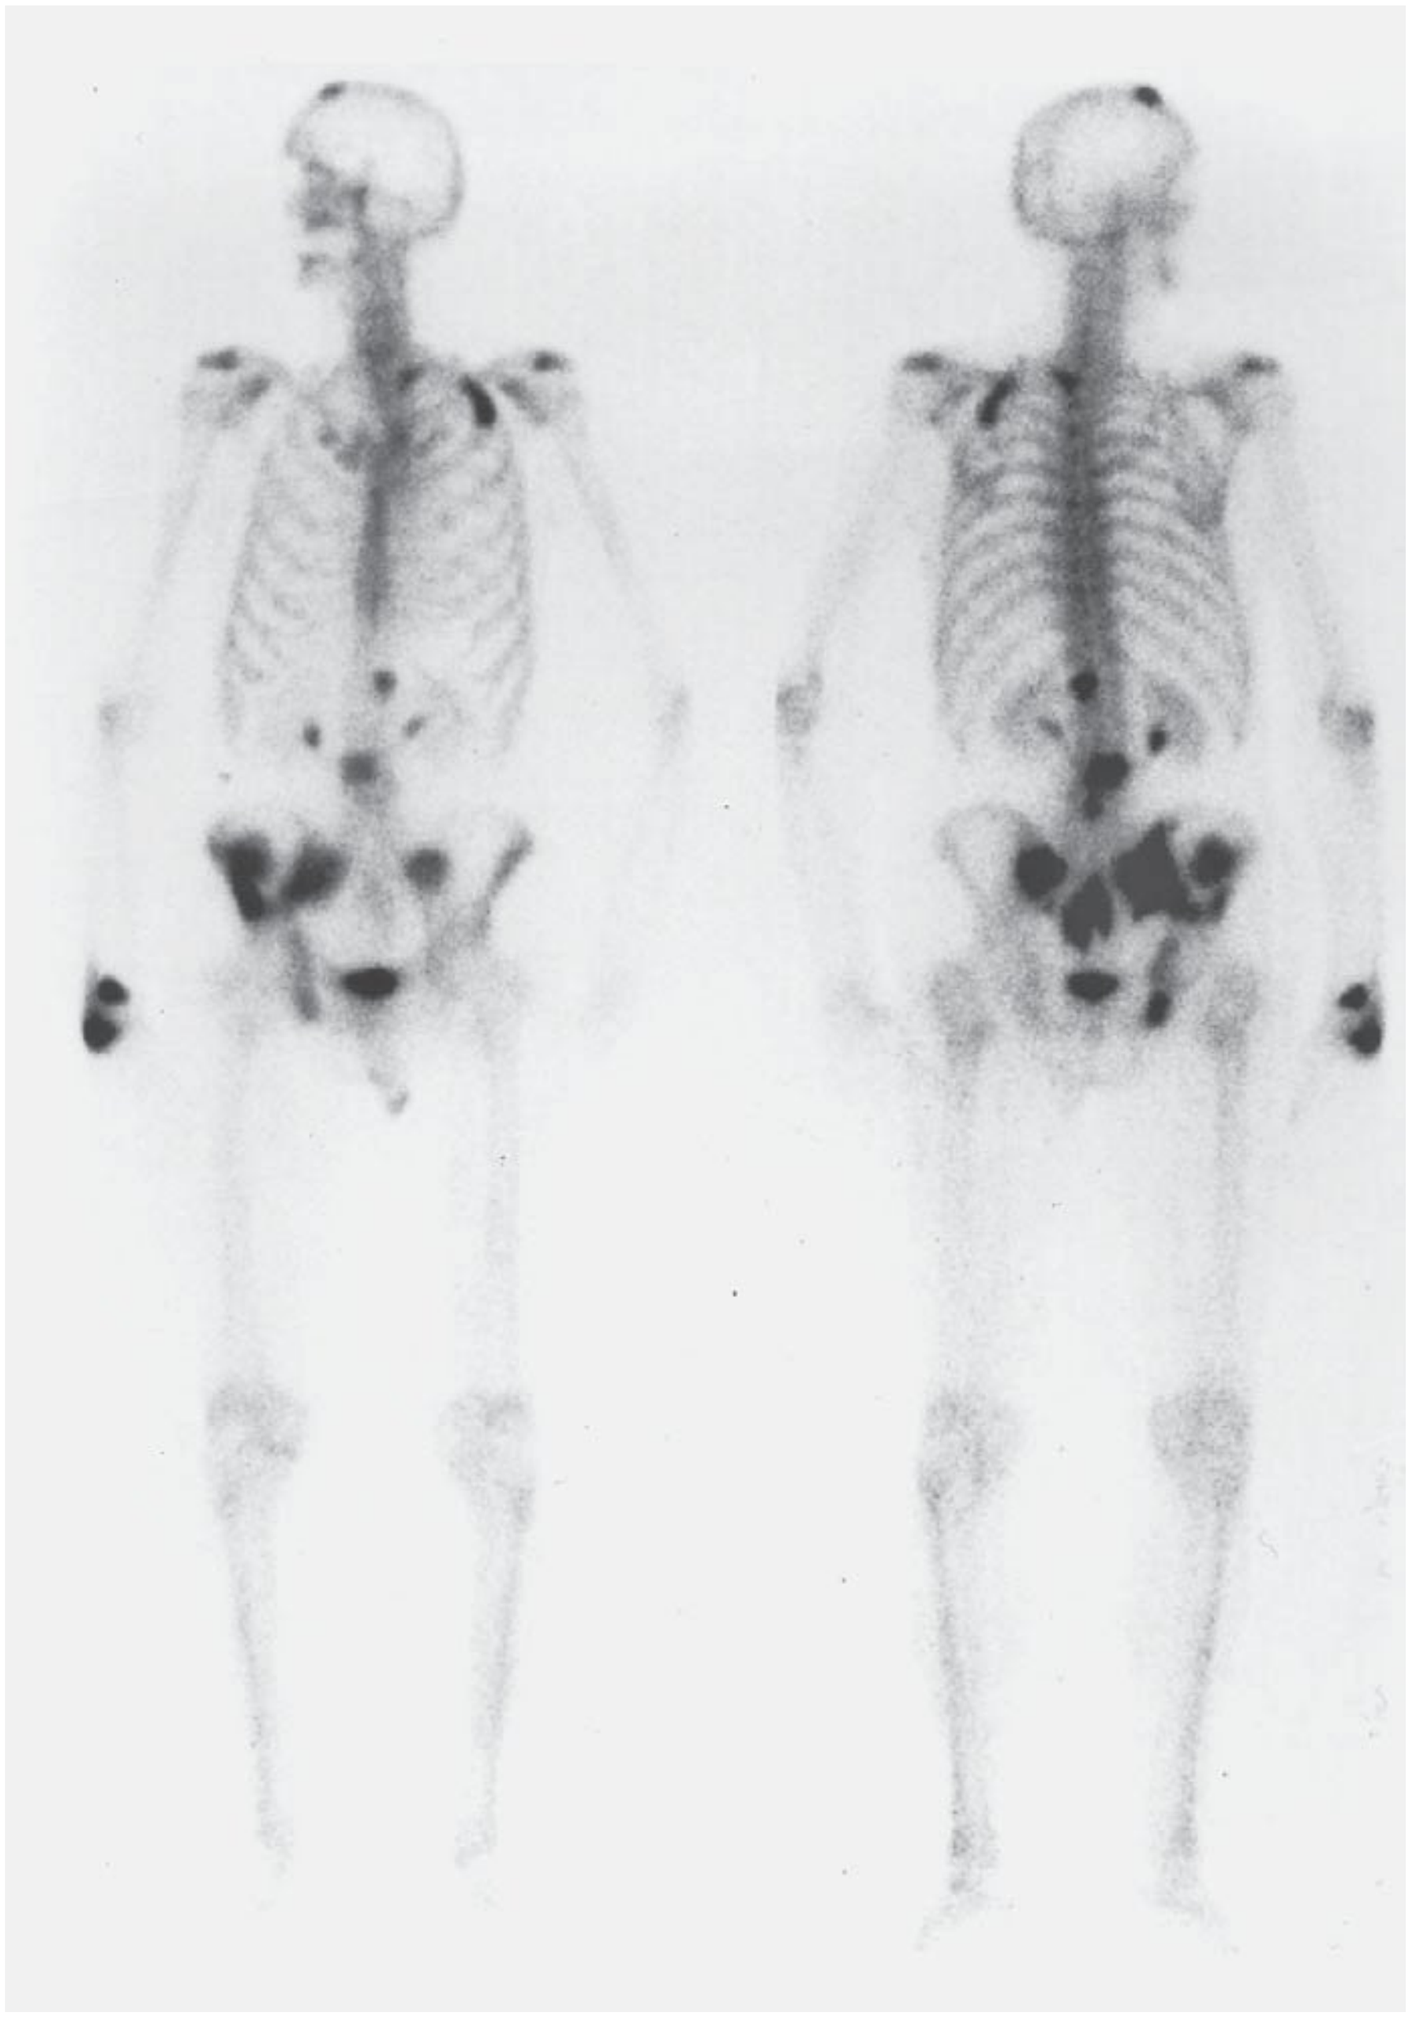

FIGURE 48.3 Bone scan that demonstrates multifocal disease involvement. Metastatic involvement in weight-bearing areas such as the pelvis and lower lumbar area significantly affects mobility.

by prior injury. Difficulty arises in differentiating pathologic and radiotherapeutic injury when there has been spinal cord compression. Vasogenic edema of the spinal cord and nerve roots can be caused by compression injury. Metastatic epidural compression results in vasogenic spinal cord edema, venous hemorrhage, loss of myelin, and ischemia. Vasogenic edema results in an increased synthesis of prostaglandin E, which can be myelotoxic. Inhibition of this inflammatory pathway is one of the putative benefits of corticosteroids or nonsteroidal antiinflammatory therapy. Other consequences of pathologic compression include hemorrhage, loss of myelin, and ischemia.[126–129]

Two separate mechanisms of radiation injury result from white matter damage and vasculopathies. White matter damage is associated with diffuse demyelination and swollen axons that can be focally necrotic and have associated glial reaction. Vascular damage has been shown experimentally to be age dependent and can result in hemorrhage, telangiectasia, and vascular necrosis.[126–129] Six major types of injuries have been shown experimentally to result from radiation to the spinal column. Five of these occur in the spinal cord and one in the dorsal root ganglia. The most severe spinal lesions, all of which are caused by vascular damage and result in neurologic dysfunction, include white matter necrosis, hemorrhage, and segmental parenchymal atrophy. The two less severe spinal lesions included focal fiber loss and scattered white matter vacuolation caused by damage to glial cells, axons, the vasculature, or all three; these less severe sequelae are seen with lower total doses of radiation and are less likely to result in neurologic dysfunction. In dorsal root ganglia, radiation damage included intracytoplasmic vacuoles and loss of neurons and satellite cells that could affect sensory function. These findings are distinct from the demyelination of the posterior columns associated with the self-limiting Lhermitte's syndrome.[129] Meningeal thickening and fibrosis can also be observed after radiation, but the clinical significance of this is unknown. Ependymal and nerve root damage from radiation is rare.

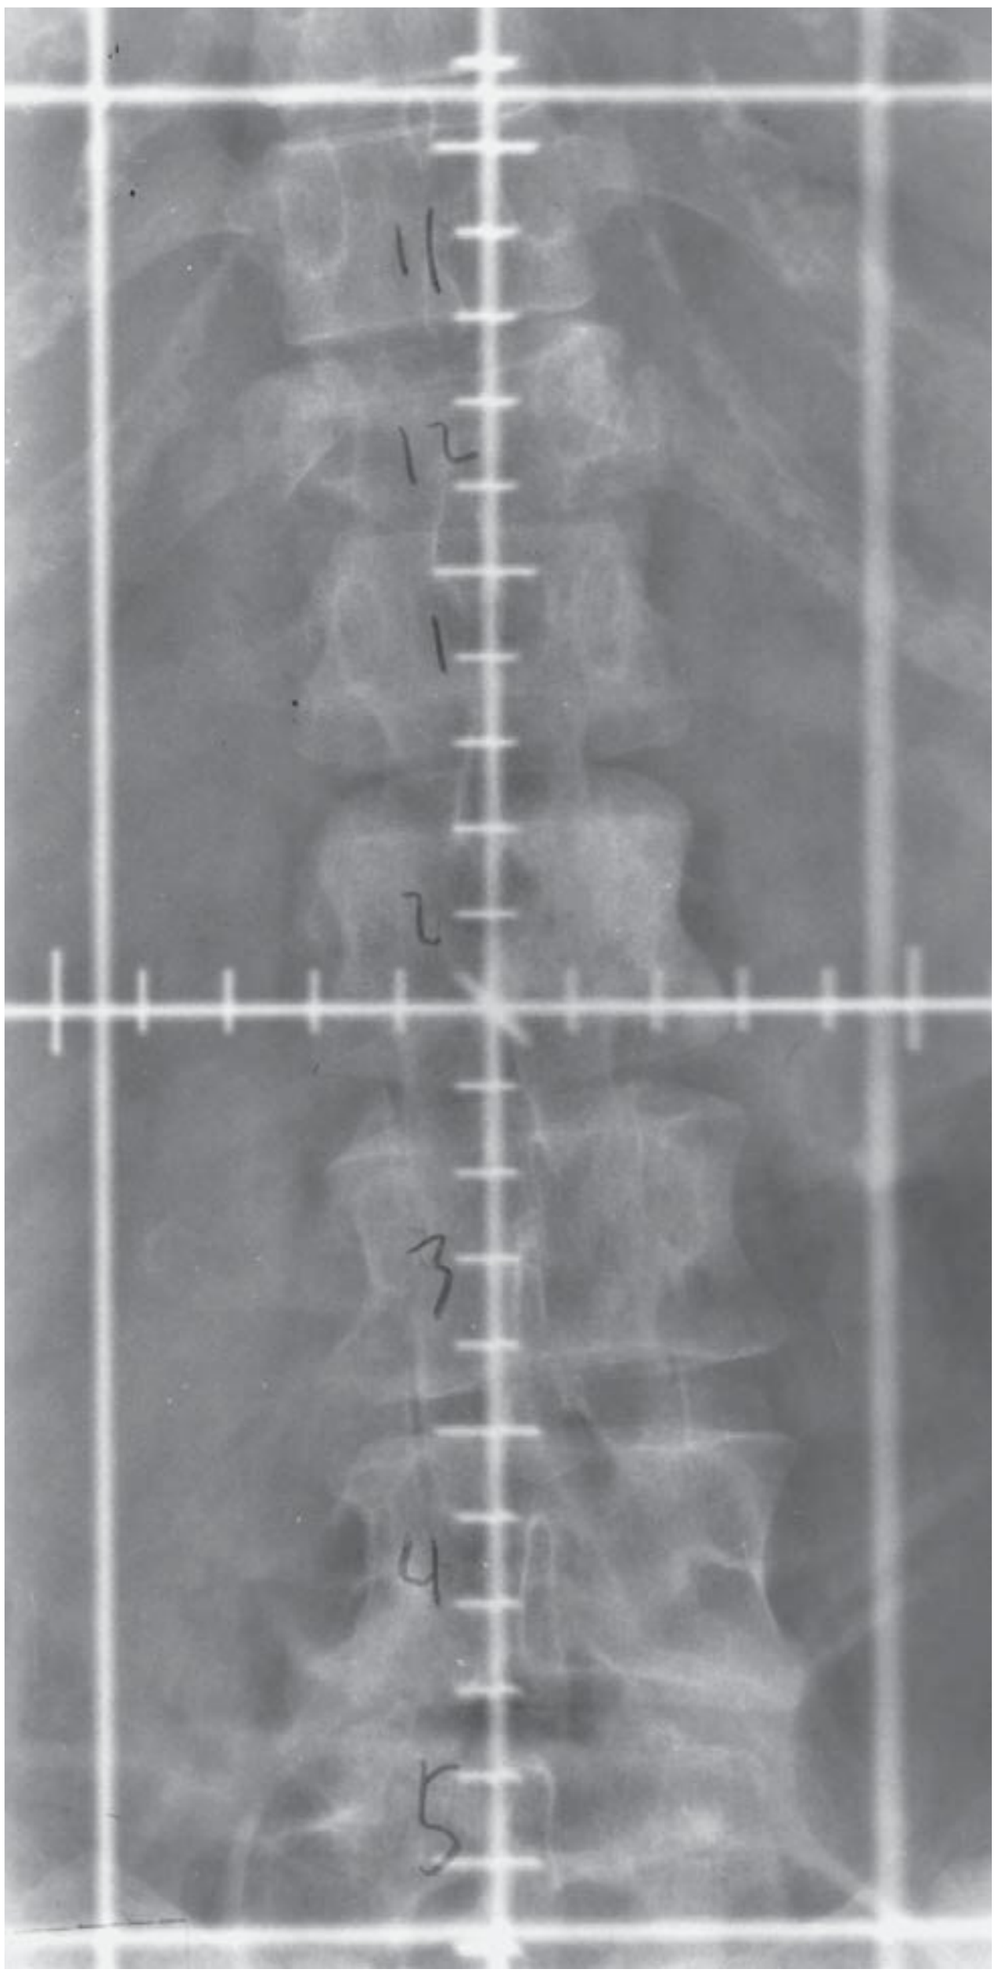

FIGURE 48.4 Typical radiation portal to treat multifocal areas of disease involvement in the vertebral bodies and epidural region.

FIGURE 48.5 Compression fracture of the twelfth thoracic vertebral body following an initial pain-free interval after palliative radiation. Vertebral weakness with rapid tumor regression resulted in a compression fracture that caused recurrent back pain because of spinal instability.

Clinical Management

Persistent pain after radiotherapy for vertebral metastases should be investigated to exclude the possibility of progressive disease inside or outside the radiation portal or mechanical spinal instability because of a vertebral compression fracture. Changes seen in the bone marrow on MRI after palliative radiotherapy initially include decreased cellularity, edema, and hemorrhage, followed by fatty replacement and fibrosis. These well-defined changes on MRI after radiotherapy can be distinguished from those seen with progressive malignant disease.[116,130–134]

Prior radiation portals may affect the ability to radiate spine metastases, especially in breast and lung cancer patients. Standard radiation portals currently used for breast cancer therapy infrequently treat the spinal axis. The upper thoracic and lower cervical region, however, may be irradiated in a field encompassing the supraclavicular nodes and axillary apex if significant axillary node involvement is documented. With techniques used in the past for breast cancer, the thoracic spine would receive a significant dose of radiation from a field that treated the internal mammary lymph nodes.[113] Treatment of the mediastinum in lung cancer generally includes the majority of the thoracic spine treated to the maximum dose tolerated by the spinal cord.[125] Unfortunately, previous radiation of the spine as part of definitive therapy does not reduce the risk for subsequent spinal cord compression as a consequence of persistent or recurrent disease.

Surgical decompression is often the only available option for therapy because previously administered radiation may preclude further radiotherapy in the region of the malignant spinal cord compression. This is often the case in lung cancer because metastases are located in the thoracic spine in over 70% of cases, and many of these patients have received mediastinal irradiation.[125] Early involvement by the radiotherapist in the management of patients with suspected spinal cord involvement is important to allow time to obtain prior radiotherapy records, determine if further radiation is possible, and expedite the safest, most efficacious clinical decision-making process.

Based on clinical and radiographic grounds, leptomeningeal carcinomatosis must also be considered in the diagnostic evaluation. Leptomeningeal carcinomatosis occurs more commonly than clinically diagnosed. For example, only one-half of breast cancer patients with leptomeningeal carcinomatosis are diagnosed before death.[84,90,113,135,136] Performing a lumbar puncture is a relative barrier to the diagnosis; at least three cerebrospinal fluid samples are necessary to cytologically exclude the diagnosis of leptomeningeal disease because in 10% to 40% of patients the initial cerebrospinal fluid sample fails to document tumor cells.[135] MRI can identify leptomeningeal disease among patients with normal cerebrospinal fluid cytology and is sensitive and specific in locating regions of nodular leptomeningeal involvement. Except in the case of nodular leptomeningeal involvement, in which localized radiotherapy may be of benefit as an adjuvant, intrathecal chemotherapy is generally the treatment of choice.[136]

TREATMENT OF DIFFUSE BONE METASTASES

Wide field radiotherapy, systemic radionuclides, and bisphosphonates have been used to treat patients with disseminated bone metastases. These approaches are useful in augmenting the therapeutic effect of localized radiation and in preventing asymptomatic bony lesions from progressing. Although usually not a significant consideration in localized irradiation, adequate bone marrow reserve is required for wide field radiotherapy and systemic radionuclides. Bone marrow scans can be performed to determine the volume of functioning marrow and assess the feasibility of delivering wide field radiotherapy or radionuclides.[10,27,43,44,47,130]

Wide Field Radiotherapy

Hemibody irradiation has been used to treat diffuse bone metastases by administering one fraction of about 6–10 Gy or fractions of 3Gy for 2 to 5 consecutive days to the upper, mid, or lower body. Delivering 3 Gy on 2 consecutive days is equianalgesic to doses of 3 Gy on 5 days for all primary cancers except prostate cancer. Fractioning reduces the need for premedication with prednisone, hydrocortisone, normal saline, or dextrose in half normal saline with potassium chloride and antinausea medication like ondansetron, prochlorperazine, and metoclopromide[34,35] and allows for higher total doses to be delivered, but the effect on pain is equivalent to single dose radiation.[137–139] Response rates are consistently reported to be greater than 70%, and more than 20% of patients have complete relief of pain. In prostate and breast cancer patients, the overall response rate is 80%, and complete relief of pain is 30%, respectively.[140–142] Approximately one-half of patients experience relief of pain within 48 hours of treatment, and the overall response rates equal 80% for all types of primary tumors. About 70% of the patients treated did not require further palliative irradiation for recurrent bone pain over the duration of their lives.[138]

An RTOG study demonstrated that hemibody radiation reduced the time to disease progression and decreased the need for subsequent palliative radiation of bone metastases at 1 year of follow-up when compared with local field irradiation alone. These results from the RTOG study are consistent with other reported experience using hemibody irradiation.[140–142] Median survival after hemibody irradiation is significantly better among patients who present with a good performance status. Approximately 90% of patients with a complete response and 70% of patients with a partial response had a good to excellent performance status before radiotherapy. Prior systemic therapy does not influence response to wide field radiotherapy. Symptomatic bone metastases that are refractory to chemotherapy or hormonal therapy are reported to have complete response rates of 70% and partial response rates of 24% with hemibody radiation. Symptoms are palliated in 88% of cases when a previously treated area is reirradiated. Premedication prevents nausea, and partial shielding minimizes lung dose and the risk for radiation pneumonitis. Hematologic depression is limited. Toxicity is observed in less than 10% of patients, whereas 50% experience stabilization of disease at 1 year.

Hemibody radiation may be an important palliative option among patients with diffuse lytic bone metastases that are refractory to other therapies. However, it is not routinely used for the treatment of focal metastases on account of the potential toxicity to the visceral structures and the difficulties in treatment setup. Concerns regarding the permanent effects on bone marrow reserve also exist relative to the subsequent need for chemotherapy.

Radiopharmaceuticals

An alternative to hemibody irradiation for the treatment of widely disseminated bone metastases is the use of systemic radioisotopes. The most commonly used radiopharmaceutical in the treatment of bone metastases is strontium 89. Strontium 89 combines with the calcium component of hydroxyapatite in osteoblastic lesions. Many studies report effective palliation of pain lasting more than 6 months in 60% to 80% of patients with breast and prostate cancers.[39–44,46,48,49,53] Improvements in functional status and quality of life have been observed, and approximately 20% of patients have complete resolution of pain. Pain control has been reported to be superior among patients with disseminated prostate cancer treated both with strontium 89 and local radiotherapy as compared with localized irradiation alone.[42] Myelotoxicity resulting in 25% reduction of platelet and white blood cell counts represents the only significant toxicity associated with strontium 89, which is usually transient and reversible within 12 weeks.[40,44,47,143,144] Hematotoxicity is more pronounced in patients with pretreatment platelet counts of less than or equal to 60×10^3, white blood cell counts of less than or equal to 2.5×10^3, or greater than or equal to 30% involvement of the red marrow–bearing bone. The radiation dose absorbed by the bone marrow is 2 to 50 times less than the dose administered by strontium 89 to the osteoblastic lesion. Radiation doses to metastatic bony lesions with strontium 89 can range from 3 to more than 300 Gy.

Clinical response to strontium 89 is comparable with wide field radiotherapy. Response to strontium 89 therapy has been documented both subjectively and objectively. Subjective response, manifested as symptomatic improvement, was reported by more than 80% of prostate cancer patients using a validated self-reporting tool. Objective evidence of response was documented by reductions in alkaline and acid phosphatase levels that corresponded with a decrease in evidence of active metastatic disease on sequential bone scans.[40–43,46,49,145] Prior therapies for prostate cancer, including local radiation therapy and systemic chemotherapy or hormone therapy, do not influence toxicity or affect clinical response to strontium 89. Administered as an adjuvant to localized external beam radiotherapy in metastatic prostate cancer, strontium 89 has been shown to improve pain relief, reduce analgesic requirements, and delay progression of disease in prospective randomized clinical trials. Quality-of-life assessments demonstrated increased physical activity along with improved pain relief after strontium 89 was administered in conjunction with localized external beam radiation therapy.[146,147] Cost-benefit analysis has also suggested an advantage to the administration of strontium 89 with reductions in costs of hospitalization for tertiary care.[42,43,53]

Several other radiopharmaceuticals are available for clinical application including samarium 153, gallium nitrate, phosphorus

32, and rhenium 186.[39,44,45,47,51,52,54,149] The therapeutic mechanism of action relates to the physical and biological half-life in the bony lesion, the mean energy, and the delivered dose of the radiopharmaceutical. Table 48.3 summarizes some of the physical characteristics and clinical data for various radionuclides. Phosphorus 32 and strontium 89 emit pure beta rays (little penetration in tissue), whereas rhenium 186 and samarium 153 emit both beta rays and relatively high-energy gamma-ray photons that penetrate tissue for some distance (103 to 159 keV).

Because samarium 153 has a gamma-ray component, it is possible to directly image the distribution of the radiation dose. The scans after injection of samarium 153 are comparable to diagnostic scans obtained with technetium 99m. The mean skeletal uptake is over 50% of the dose.[52] Nonskeletal sites receive negligible radiation doses, and complete clearance of radionuclide other than that absorbed by bone occurs within 6 to 8 hours of administration.[51] In a double-blind placebo-controlled clinical trial, samarium 153 has been shown to be an effective agent in palliating painful bone metastases in breast cancer patients. Pain relief occurred within 1 week and lasted at least 16 weeks after administration.[46,149,150] Approximately 65% of patients responded within the first 4 weeks, and 43%–72% had relief of pain of at least 16 weeks' duration. No significant bone marrow toxicities have been observed. Recommended doses range between 1.0 and 1.5 mCi per kg. In more than one-third of patients, multiple administrations are possible.[54,151] These observations suggest potential suitability of this form of palliative therapy for patients with both intermediate and limited life expectancies who are not tolerating or responding favorably to other pain-relieving treatments.

Selectively concentrating in bone, the mechanism of action of rhenium 186 is similar to that of technetium diphosphonate 99m, which is used in diagnostic bone scans. This characteristic allows direct imaging of the deposition of rhenium 186 in bony metastases. The metastatic lesion receives a highly concentrated dose of radiation after the administration of rhenium 186, whereas the radiation dose to the marrow is limited to 0.75 Gy.[39,48] Thrombocytopenia appears to be the dose-limiting toxicity but is mild, allowing therapy to be repeated.[143,152]

Phosphorus 32 has 77% of patients experiencing significant relief of pain.[39,148] The response rates and duration of response with phosphorus 32 are similar to wide field radiation and strontium 89. However, the main disadvantage of phosphorus 32 is severe hematologic toxicity.

Clinical trials are ongoing to compare the conventional radiopharmaceuticals with newer radiopharmaceuticals and their effect in combination with bisphosphonates and chemotherapy.[49] There is prolonged survival benefit in patients with hormone refractory prostate cancer if radiopharmaceuticals and chemotherapy are used in combination.[153] Although bone marrow toxicity is relatively limited in the doses of radiopharmaceuticals currently administered either alone or in combination with other agents, future dose intensity studies may require hematologic support with colony-stimulating factors.

Sequential radiography and bone scans after hormonal and radiopharmaceutical therapy for breast and prostate cancers demonstrate an osteoblastic response that reflects remodeling of the bone in osteolytic osseous metastases.[30,31] Approximately one-third of patients have evidence of increased tracer uptake on bone scans (flare) obtained 8 to 16 weeks after treatment. Of these patients with a flare response on bone scan, 72% experience a response to the treatment. By comparison, only 36% have a response to treatment when a limited response or no flare response is observed.

Relapse of disease has been associated with an increase in the osteolytic component. Osteoclast resorption in bone metastases is associated with the release of acid and acid-dependent proteases that dissolve the organic matrix of the bone. Gallium nitrate has been shown to inhibit accelerated bone turnover among patients with widespread bone metastases and has been clinically applied in the treatment of hypercalcemia. Preferentially accumulating in the cortical surface, which is the most metabolically active region of the bone, gallium nitrate acts to inhibit osteoclast resorption. Additionally, gallium nitrate increases the absorption of calcium and phosphorus and the incorporation of collagen into the bone.

CHEMOTHERAPY

Role of Chemotherapy

Chemotherapy can be used as an adjuvant to radiotherapy and/or surgery or as part of a combined antineoplastic regimen for

primary treatment. In patients with cancers like lymphomas, Wilms' tumor, rhabdomyosarcoma, and small cell lung cancer, chemotherapy is used alone as the primary therapy.[154] Systemic chemotherapy has the advantage of ubiquitous distribution throughout the body, wherever the bloodstream might take a cancer cell. Thus, adjuvant chemotherapy is used in patients who appear cured after surgery but are suspected of having residual disease or micrometastasis. Adjuvant chemotherapy has proven effective in node-positive breast cancer, Duke's B2 and C colorectal carcinoma, stage III ovarian carcinoma, testicular carcinoma, non-small cell lung cancer, Wilms' tumor, osteogenic sarcoma, and anaplastic astrocytomae.[154]

Neoadjunct chemotherapy is used as initial chemotherapy in cancers that would be only partially curable by surgery or radiation. It is often administered with anal cancer, bladder cancer, esophageal cancer, laryngeal cancer, locally advanced non-small cell lung cancer, and osteogenic sarcoma. The goals of this therapy are to: (a) decrease the size of the tumor to be removed or radiated; (b) increase the likelihood that the tumor will be surgically extirpable; and (c) decrease the likelihood of micrometastatic spread/seeding at the time of surgery.[154] Systemic chemotherapy is the primary treatment for disseminated/metastatic malignant disease.

Based on the mechanisms mentioned above, the goal of systemic chemotherapy is to interrupt the division of rapidly dividing cancer cells. It is usually administered in multiple (usually 4 to 6) cycles every 3 to 4 weeks. The timing and dosing of chemotherapy are established to maximize malignant cell kill, while at the same time not exceeding the body's ability to regenerate the normally rapidly dividing cells that are "innocent bystanders" of the cytotoxic effects of chemotherapy, namely the bone marrow progenitors, gastrointestinal epithelial cells, and hair follicles. The predominant effect of chemotherapy on the intestinal tract occurs in the first few days to a week after administration, whereas the peak effect on the blood progenitor cells occurs 10 to 14 days post-therapy. Thus, patients only require prophylactic antiemetics for the days around therapy, but they "nadir" their blood counts, with variable risks of infection and bleeding, approximately 2 weeks after receiving treatment.

Regardless of the setting of administration (primary, adjuvant, neoadjuvant, or combined modality), substantial evidence suggests that combination chemotherapy with agents that have different mechanisms of action as well as different (noncumulative) toxicities yields significantly higher efficacy than single-agent chemotherapy. On the basis of an extensive review of in vivo and in vitro laboratory research and clinical experiences acquired during the 1950s and 1960s, DeVita and Schein[155] developed a set of basic principles of combination chemotherapy for cancer patients, and these are still the guiding principles today. Among the most important of these principles are the following: (a) all of the component drugs in a combination must have activity against the neoplasm being treated; (b) drugs must be administered at dosages close to the minimum effective dosage for each drug as a single agent, or beyond if possible; (c) drugs that interrupt the synthesis of cellular macromolecules at several sites can be combined for additive or synergistic effects on the various synthetic pathways; (d) drugs in combination should have as little cross-toxicity as possible; and (e) mechanisms of tumor cell resistance to two agents in combination must not be similar.[155]

Clinical Applications

Conventionally, efficacy of chemotherapy is defined by an objective decrease in the radiographic size of the tumor (usually by CT). A complete response (CR) represents total disappearance of all observable disease for a minimum of 1 to 3 months, depending on the criteria used,[156,157] whereas a partial response (PR) represents a decrease in measurable tumor size by at least 50%. Overall response rate (RR) for a given regimen is the combination of CR + PR, and a significant RR translates into an improved survival of responders compared with nonresponders. It also translates into relief of pain related to the tumor mass—although pain relief from chemotherapy has rarely been the end point of clinical trials (Table 48.4). Currently, there are some forms of cancers, such as pediatric tumors, lymphomas, testicular cancer, and ovarian cancer, where complete remission and cure have been realized.[158]

Despite progress, there remain many patients whose malignancies are resistant to chemotherapy. They have progressive disease either shortly after the completion of therapy or, in some cases, during the time of active therapy. The category that falls between an objective response and progressive disease, in which the tumor neither shrinks nor grows in the face of active anticancer therapy, is referred to as *stable disease*. Whether or not there is any pain-relieving benefit to the administration of chemotherapy in the setting of stable disease is undetermined. Although there is speculation about the role of chemotherapy in altering peripheral sensory nerve function, thereby producing analgesia,[159] as well as relieving pain by altering the "tumor-host milieu,"[159] these hypotheses have been tested in limited trials, wherein assessment of the analgesic or symptom outcomes is a primary end point of therapy.[160–167] One of the significant barriers to these types of studies is the lack of a universally adopted system for evaluating pain along with other variables of disease progression or remission. Although some systems have been developed, they remain underused and underappreciated.[168–171] In the absence of empirically proven outcomes, clinical observations suggest that "systemically administered cytotoxic drugs do not relieve cancer pain in the absence of tumor regression."[159] Tumor regression is a function of responsiveness to a given chemotherapeutic regimen. Tumor variables that determine the course of chemotherapy and prognosis for response rate include histologic type (squamous cell carcinoma, adenocarcinoma, germ cell, lymphoma, etc.), grade (high, intermediate, low), and the degree of differentiation (well differentiated, poorly differentiated). Careful assessment of the overall performance status of patients will help to determine their ability to tolerate systemic chemotherapy and endure the likely associated toxicities.

In general, the more rapidly growing the tumor, the more frequent its cellular division; therefore, the cells are more *potentially* responsive to cytotoxic therapy: In these cases, intervention can lead to increased pain control, long-term survival, and, potentially, cure. Those rapidly growing tumors that are chemotherapy-resistant tend to be imminently fatal. Table 48.5 summarizes the most common malignancies and their likelihood of response to chemotherapy. Of the most common solid tumors (lung, colorectal, prostate, and breast), all except breast carcinoma are minimally responsive to current chemotherapeutic regimens. This and other evidence provides a basis for reviewing the palliative benefits of chemotherapy.

RESPONSE OF TUMORS TO CHEMOTHERAPY

Curable by Chemotherapy

Compared with other solid tumor types, Hodgkin's and non-Hodgkin's lymphomas (NHL) tend to respond better than most to combination chemotherapy. For Hodgkin's lymphoma, there are several active regimens, but the preferred treatment regimen of doxorubicin, bleomycin, vinblastine, and dacarbazine is highly active and produces a complete remission rate that varies from 98% for early-stage disease (overall survival of more than 93% at 6 years) to 82% for advanced stage disease (overall survival of

TABLE 48.4

EFFICACY OF CHEMOTHERAPY IN RELIEVING PAIN

Primary cancer	Source or site of pain	Degree of pain relief
Breast	Tumor ulceration	+ + +
	Chest wall infiltration	+ + +
	Bone metastasis	+ +
	Lymphedema of arm	+
Prostate	Bone metastases	+ + + +

Modified from Bonadonna G, Molinari R. Role and limits of anticancer drugs in the treatment of advanced cancer pain. In: Bonica JJ, Ventafridda V, eds. *Advances in Pain Research and Therapy*. Vol 2. New York: Raven Press; 1979,131–144.

73% at 6 years).[172–174] The therapeutic effect of this combination regimen is rapid, even in advanced cases, providing prompt pain relief in those patients who have pain (although this has never been a primary end point of clinical trials), with observed resolution of other symptoms and signs as well. In NHLs, there is a larger variability based on histology, with high-grade NHL being significantly more responsive to therapy than low-grade types. For high-grade NHL, treatment with a variety of combination chemotherapy regimens (e.g., bleomycin, doxorubicin, cyclophosphamide, vincristine, and prednisone; cyclophosphamide, doxorubicin, vincristine, and prednisone; or others with antibody therapies with rituximab) produces a 79% event-free survival.[175–177] Again, no studies of NHL have examined pain as a primary end point, although pain remits in concert with active disease. Similar results are also obtained in carcinoma of the testicle with platinum, etoposide, and bleomycin, in Wilms' tumor, and in the leukemias (especially the lymphoblastic types).[178]

Chemotherapy Has Significant Activity

Breast Cancer

In moderately chemosensitive tumors, the results obtained with the various chemotherapeutic combinations are less favorable (30% to 60% response rates), and in general, the therapeutic effect is slower in onset. Small cell lung cancer, for example, tends to be quite aggressive, and combination chemotherapy regimens with cisplatin and etoposide or cyclophosphamide, doxorubicin, and vincristine can induce an objective response in approximately 60% of cases, with CR occurring in approximately 10%. Again, this and other studies have not attempted to quantify relief from pain or dyspnea in small cell lung cancer.

The course of recurrent or metastatic breast cancer follows two dominant pathways. The hormone receptor–positive tumors tend to occur in older (postmenopausal) women and follow a more indolent course when treated with hormone therapy, with bone as the most common metastatic site. The hormone receptor–negative tumors tend to occur in younger (premenopausal) women and follow a more aggressive course, with visceral and soft tissue involvement that is usually responsive to chemotherapy.[179] Conventional chemotherapy includes cyclophosphamide, methotrexate, and prednisone and has been shown to improve quality of life. Anthracycline-containing regimens have been shown to be superior to cyclophosphamide, methotrexate, and prednisone. Single agents that contain taxanes (docetaxel, paclitaxel, and protein-bound paclitaxel), capecitabine, gemcitabine, or vinorelbine have been shown to be as effective in improving survival and quality of life as combination chemotherapy in metastatic breast cancer.[180–182] Trastuzumab, alone or in combination in Her-2/neu positive patients, has been shown to increase survival. Yet again, it is noteworthy that given the prevalence of recurrent breast cancer, few studies have specifically addressed quality of life issues,[179] and that even fewer address symptomatic benefits of therapy.

A British study evaluating patients with advanced breast cancer who received first-line palliative chemotherapy (a variety of regimens) did have primary palliative (subjective patient-centered) outcomes that were assessed by using the Rotterdam Symptom Checklist. In this study, one-fourth of the patients

TABLE 48.5

RESPONSIVENESS OF CANCER TO CHEMOTHERAPY

Cure of advanced cancer
Choriocarcinoma
Acute lymphoblastic leukemia
Malignant lymphoma (Hodgkin's disease, diffuse high grade or intermediate grade non-Hodgkin's lymphoma)
Hairy cell leukemia
Testicular cancer
Childhood solid tumors (embryonal rhabdomyosarcoma, Ewing's sarcoma, Wilms' tumor)
Acute myelocytic leukemia
Acute lymphocytic leukemia
Acute promyelocytic leukemia

Significant palliative, some cure of advanced disease
Ovarian cancer
Bladder cancer
Small cell lung cancer
Gastric cancer

Palliation, probably increased survival
Breast cancer
Multiple myeloma
Head and neck cancer
Non-small cell lung cancer

Adjunct treatment with increased cure
Breast cancer
Colon cancer
Osteogenic sarcoma
Early stage large cell lymphoma

(26%) felt better after having received chemotherapy, with statistically significant decreases in psychological distress, pain, and improvement in lack of energy and sense of tiredness. As might be expected, feeling better correlated with disease response ($p = 0.03$).[183]

Head and Neck Cancer

Head and neck cancer is one of the most challenging disease sites to treat. Cisplatin and fluorouracil make the tumor more responsive to radiotherapy, and this is the standard accepted multimodal regimen that has been shown to increase survival. In fact, studies have shown that combination chemotherapy with cisplatin and fluorouracil, hydroxyurea and fluorouracil, and taxanes like pacletaxel and cisplatin followed by radiation have all increased survival by 50% to 60%.[184] Chemotherapy with a single agent like cisplatin or carboplatin followed by radiation is also being investigated.[185] These aggressive regimens have potential toxicities and twice-a-day radiotherapy with concomitant chemotherapy have shown improved locoregional control, survival, and improved quality of life.[186]

Ovarian Cancer

Finally, ovarian cancer is one of the more sensitive malignancies to cytotoxic chemotherapy.[187,188] Combination regimens in which a platinum-based agent (cisplatin or carboplatin) is used achieve overall response rates of 60% to 80%. Newer agents, most notably the taxanes, also have significant activity in ovarian cancer, with overall response rates of 20% to 40%. The combination of carboplatin and paclitaxel has demonstrated superior response rates and has become the standard of care for ovarian cancer amenable to chemotherapy.[187,188] Doyle et al.[189] showed that although objective responses are low with palliative chemotherapy, active palliation with chemotherapy is associated with substantive improvement in patients' emotional function and global quality of life.

Chemotherapy has Minor Activity

Many of the adenocarcinomas (lung, colorectal, esophageal, pancreatic, and prostate), malignant melanoma, malignant brain tumors, and sarcoma of bone and soft tissue are poorly responsive to chemotherapy, so long-term alteration of the course of disease is rarely obtained with chemotherapeutic drugs. In this group of tumors, anticancer modalities are rarely effective in reducing the size of the tumor (achieving neither PR nor CR), and as a result, the associated pain and other symptoms are unlikely to be affected significantly by chemotherapy. There are many factors responsible for the limited efficacy of chemotherapy in these tumors. First, the cellular biology of these solid tumors that often produce pain is such that they have limited response to current drug regimens. Second, the size of the tumor is inversely related to the incidence of satisfactory drug penetration into the mass. Thus, the larger the mass, the poorer the cytotoxic response. Furthermore, given that these tumors generally do not exhibit long-term responses to first-line therapy, additional therapy with second- or third-line drug treatments often yields a minimal (usually less than primary therapy) response rate. Finally, in certain target sites (e.g., head and neck, pelvis) prior radical surgery and/or prior radiation therapy impair the vascular supply to the tumor bed, thus interfering with delivery of an effective drug concentration to the target site.

Since this group represents the most challenging to demonstrate objective response rates to chemotherapy, it is the ideal patient population in which to demonstrate a purely palliative benefit of chemotherapy, represented by decreases in pain, dyspnea, and fatigue and increases in performance status, appetite, and weight gain. A few investigators have pursued these outcome measures with meaningful results. The initial Food and Drug Administration approval of gemcitabine was granted not by data showing its benefits on overall survival or objective response rate, but by improvements in pain control, weight gain, and performance status in patients with pancreatic cancer.[190]

Non-small cell lung cancer is the most prevalent cancer type, and combinations of chemotherapeutic drugs like vinorelbine, gemcitabine, docetaxel, and paclitaxel provide modest survival and probable quality-of-life benefit in a significant number of patients when contrasted with best supportive care.[191–193] These agents show response rates in the 11% to 25% range when combined with platinum-based therapy. No study has examined the effects of therapy on pain or dyspnea, although a few have evaluated improvements in performance status and weight gain.[194] However, oral topotecan has been shown to improve pain, dyspnea, sleep, and fatigue, as well as increased survival, in patients with recurrent small cell lung cancer compared with best supportive care.[38]

In the realm of gastrointestinal malignancies, the role of chemotherapy is limited.[195] The fluoropyrimidines (5-FU and its derivatives) are the conventional agents with demonstrated efficacy in gastrointestinal malignancies. 5-FU has resulted in disappointingly low response rates of approximately 20%. In a large study of more than 400 patients conducted by the North Central Cancer Treatment Group,[196] 70% of patients who received 5-FU/low-dose leucovorin had improvements in performance status and weight gain; there was no assessment of pain as a primary

end point. The combination of 5-FU and leucovorin with newer agents like oxaliplatin (FLOFIRI) and irinotecan (FOLFOX) have shown improvement in quality of life.[36,197,198]

In pancreatic cancer, the approval of gemcitabine for pancreatic cancer was based on the palliative end point of "clinical benefit" over the conventional 5-FU therapy. In this study, clinical benefit was defined by a composite of pain, performance status, and weight gain.[190] This was one of the first studies to directly assess the primary end point of pain via patient report of pain intensity together with analgesic consumption. Several recent systematic reviews have shown that gemcitabine-based combinations have shown improved survival as well as quality of life.[199,200]

Prostate cancer is yet another prevalent disease that is poorly responsive to conventional chemotherapy. There is more palliative end-point evidence supporting the use of chemotherapy in prostate cancer than any other disease, in part because it is a slow-growing tumor that tends to cause significant pain and disability for a prolonged period of time. The most widely discussed study is Tannock's Canadian study[201] which used mitoxantrone and prednisone for hormone-refractory metastatic prostate cancer where the primary end point was pain relief. In this study, pain relief was again defined differently from previous studies as a "2-point decrease in pain as assessed by a six-point pain scale. . .without an increase in analgesic medication and maintained for two consecutive evaluations at least 3 weeks apart."[201] They found that this chemotherapy combination produced a positive effect above the benefit of prednisone alone in 29% of patients, with a 50% decrease in analgesic requirements. Other studies suggest the positive impact of docetaxel-based chemotherapy in providing relief of pain in hormone-refractory metastatic prostate cancer.[202,203]

Finally, soft tissue sarcomas demonstrate a response rate of approximately 35% to combination chemotherapy with doxorubicin and ifosfamide, with no studies assessing quality of life or symptomatic benefit from chemotherapy in this disease.[37]

DECISION MAKING ABOUT CHEMOTHERAPY

The diagnosis of cancer is often quite traumatic for both the patient and the family. On the one hand, the administration of chemotherapy is, by definition, cytotoxic—to malignant cells as well as normal host cells. On the other hand, the risks of not treating the disease are also quite significant. Given the fact that pain is a prevalent feature of both early- and advanced-stage cancer—present in nearly 50% of patients with early-stage disease and in 70% to 90% of cases of advanced cancer—the challenge is to strike a balance between therapeutic and toxic (including fatal) effects of chemotherapy. Thus, it is imperative that an interdisciplinary team of clinicians with expertise in oncologic surgery, radiation therapy and medical oncology, nursing, palliative medicine, and pharmacology evaluate patients to determine the treatment plan that is likely to provide the greatest cumulative benefit for the patient. If, as ought to be the ideal, the patient is always to be kept at the center of the decision-making process, then studies that assess patient-centered outcomes (pain, dyspnea, fatigue, appetite, weight loss, performance status, anxiety, well-being, and other quality of life measures) for chemotherapy merit a higher priority. Newer targeted therapies need to be evaluated for benefits related to reduction of symptom burden from neoplastic disease. Although it is generally accepted that patients with a poor performance status do not usually benefit from systemic chemotherapy, it is not known whether patients with, for example, lung cancer have improvements in dyspnea as a result of chemotherapy.

An additional challenge for the medical oncologist is decision making if first-line chemotherapy fails to control the tumor. For some disease types, there is clear objective benefit from second-line therapy. For many, however, second-line therapy is more likely to lead to enhanced cumulative toxicities rather than objective tumor response. A sensitive and thoughtful discussion with the patient and the family regarding the goals and priorities of care is needed. Emphasis must be placed on the ability to successfully manage the symptoms of progressive advanced disease with nonchemotherapeutic modalities when burdens are likely to outweigh benefits.

SIDE EFFECTS AND COMPLICATIONS

Toxicities and the predictable side effects of each of the chemotherapeutic agents are listed in Table 48.6. Perhaps the most common painful sequela of chemotherapy administration is a toxic peripheral neuropathy manifested as painful paresthesias, hyporeflexia, and, less frequently, sensory or motor loss or autonomic dysfunction.[157] The drugs most commonly associated with this complication are the plant alkaloids, especially vincristine; antimetabolites; the taxanes, especially paclitaxel; platinum-based compounds like cisplatin; vinorelbine, procarbazine, and interferon.[204–208] In some cases, the painful peripheral neuropathy not only limits the dosing of anticancer therapy, but also significantly affects quality of life and can be more difficult to treat than the more common nociceptive pain syndromes associated with the disease.

Dermatologic complications can occur from extravasation of chemotherapeutic agents into the subcutaneous tissues. This is especially problematic with drugs like vinca alkaloids, anthracyclines, and taxanes that cause severe local pain and ulceration with progressive tissue destruction.[207]

Another painful complication of cancer and its therapy is acute herpes zoster and postherpetic neuralgia, which occur with increased frequency in patients with cancer—especially in those receiving chemotherapy or immunosuppressive drugs. Lastly, although the palliative benefits of glucocorticoids on mood, pain (as an antiinflammatory coanalgesic), and appetite are well known, chronic steroid therapy can cause myopathy, as well as necrosis of the femoral and humeral heads.[209] Furthermore, one should be aware of the fact that withdrawal of glucocorticoids can cause a sense of decreased well-being, with increased pain, decreased energy, and apathy called *pseudorheumatism*.[210]

ENDOCRINE THERAPY

In the 1890s, Beatson[211] was the first to demonstrate hormonal control of breast cancer when he induced regression of metastatic tumor by ovariectomy. In 1941, Huggins and Hodges[212] reported the successful use of exogenous estrogen administration for prostatic carcinoma. Since then, several other tumors have been shown to respond to hormonal manipulation, which is achieved either by ablating endocrine glands or by administration of an exogenous hormone or hormone antagonist.

Mechanism of Action

The mechanism of action of these agents has been clarified by the demonstration that receptors that bind with estrogen exist in the cytosol of normal and malignant cells.[213] Hormones bind to receptors in the cytoplasm and sterically alter the shape of the receptive protein itself, which, after transport to the cell nucleus, interacts with DNA, and results in altered messenger RNA production and protein synthesis.[213]After this interaction, cytoplasmic receptor concentration is restored and the cycle can be repeated. Estrogen receptors can be quantitated as 8S and 4S proteins.[213] Primary tumors in humans have estrogen receptor

TABLE 48.6

COMMONLY USED CYTOTOXIC ANTICANCER AGENTS

Class (Drug)*	Toxicities‡			Indications
	Bone marrow	Nausea, vomiting suppr.	Other toxicity	
A. ALKYLATING AGENTS				
Mechlorethamine (Mustargen)	4 +	3 +	Vesicant to skin, phlebitis	Hodgkin's disease, non-Hodgkin's lymphoma, lung cancer, mycosis fungoides
Cyclophosphamide (Cytoxan)	3 +	2 +	Alopecia and cystitis, SIADH	Lymphomas; breast, lung, and ovarian cancer; myeloma; leukemias; head and neck cancer
Ifosfamide (Ifex)	3 +	2 +	Cystitis, nephrotoxicity, CNS toxicity	Germ cell tumors, sarcoma, non-Hodgkin's lymphoma, cervical and lung cancer
Melphalan (Alkeran)	3 +	1 +	Persistent thrombocytopenia on long use, pulmonary toxicity	Breast and ovarian cancer, myeloma
Busulfan (Myeleran)	3 +	1 +	Pigmentation, pulmonary fibrosis, hepatotoxicity	Pre–bone-marrow transplantation, chronic myelogenous leukemia
Chlorambucil (Leukeran)	3 +	0	Pancytopenia with long-term use hepatotoxicity	Chronic lymphocytic leukemia, nodular lymphomas
CCNU (Lomustine)	4 +	2 +	Cumulative marrow suppression, chronic renal failure, pulmonary toxicity	Brain tumors, lung and colon cancer, lymphomas
BCNU (Carmustine)	4 +	4 +	Chronic renal failure, pulmonary fibrosis, tanning of skin, nephrotoxicity	Hodgkin's disease, non-Hodgkin's lymphoma, myeloma, brain tumors
MeCCNU (Semustine)	4 +	2 +	Pronounced thrombocytopenia, chronic renal failure	Colon and gastric cancer, brain tumors, lymphomas
Streptozocin (Streptozotocin, Zanosar)	0	2 +	Hepatotoxicity, renal tubular acidosis, renal failure	Islet cell tumors of pancreas, Hodgkin's disease, carcinoid tumors
Cisplatin (cis-platinum, Platinol)	1 +	3 +	Nephrotoxicity, ototoxicity, peripheral neuropathy	Testicular tumors, ovarian and lung cancer, lymphomas
Temozolomide (Temodar)			Photosensitivity	Melanoma, brain tumors
B. ANTIMETABOLITES				
Methotrexate: high dose with rescue	1 +	2 +	Fatigue, buccal ulcerations, hepatotoxicity, lung disease	Breast, lung, cervical, and head and neck cancers, sarcomas, acute lymphocytic leukemia, meningeal leukemia, carcinomatosis
Methotrexate: no rescue	4 +	1 +		
	1 +	0		
5-Fluorouracil (5-FU)	3 +	2 +	Mucositis, diarrhea, photophobia, alopecia, cerebellar ataxia, myocardial ischemia	Colon, breast, ovarian, gastric, pancreatic, head and neck cancer
6-Mercaptopurine (Purinethol)	2 +	1 +	Hepatotoxicity, skin rashes	For maintenance phase of acute lymphocytic leukemia
6-Thioguanine	2 +	1 +	Cholestasis, hepatotoxicity	Acute myelogenous leukemia and ALL

TABLE 48.6

CONTINUED

Class (Drug)*	Toxicities‡			Indications
	Bone marrow	Nausea, vomiting suppr.	Other toxicity	
Cytarabine (cytosine arabinoside, Cytosar-U)	4 +	2 +	Mucositis, alopecia, hepatotoxicity, pancreatitis, cerebral dysfunction, corneal damage, pulmonary edema, "Ara-C syn"	Acute myelogenous leukemia, non-Hodgkin's lymphoma, meningeal leukemia, carcinomatosis
Hydroxyurea	3 +	1 +	Megaloblastosis	Alternate to busulfan for chronic myelogenous leukemia, rapid reduction of high WBC in acute or chronic myelogenous leukemia, cervical, head, and neck cancers
Fludarabine (Fludara)	3 +	1 +	Neurologic and pulmonary toxicity	CLL
C. PLANT ALKALOIDS AND INHIBITORS OF CHROMATIN FUNCTION				
Vinblastine (Velban)	3 +	1 +	Mild peripheral neuropathy	Hodgkin's disease, head and neck tumors, testicular tumors, breast, bladder, and renal cancer
Vincristine (Oncovin)	1 +	1 +	Local necrosis, peripheral neuropathy (paresthesias, etc.), alopecia, ileus, motor weakness, SIADH	Lymphomas, acute lymphocytic leukemia, childhood sarcomas, breast cancer
Etoposide (VP-16)	1–2 +	1 +	Mucositis, bronchospasm, hypotension with rapid IV infusion, CNS toxicity.	Small cell lung cancer, breast cancer, lymphomas (relapsed), testicular cancer, choriocarcinoma
Docetaxel (Taxotere)	3 +	1 +	Hypersensitivity reaction, fluid retention, neuropathy, arthralgias	Breast, prostate, lung ovarian, esophageal, gastric, bladder cancer
Paclitaxel (Taxol)	3 +	1 +	Hypersensitivity reaction, neuropathy, arthralgias, cardiotoxicity	Metastatic breast cancer, lung, ovarian, esophageal, gastric cancer
Irinotecan (Camptosar)	2 +	2 +	Diarrhea	Colorectal cancer
Vinorelbine (Navelbine)	2 +	2 +	Hyperbilirubinemia, asthenia, neuropathy	Lung cancer
D. ANTIBIOTICS AND NONCOVALENT DNA BINDING DRUGS				
Doxorubicin (Adriamycin)	4 +	2 +	Mucositis, alopecia, myocardiopathy, red urine	Breast, lung, ovarian, pancreatic, gastric, and thyroid cancer, leukemia and lymphomas, sarcomas
Bleomycin (Blenoxane)	1 +	1 +	Pneumonitis, mucositis, pulmonary fibrosis, alopecia, skin changes, hypersensitivity reaction	Head and neck tumors, cervical carcinoma, lymphoma
Dactinomycin (Cosmegen)	3 +	2 +	Mucositis, phlebitis, diarrhea, alopecia, skin changes	Wilms' tumor, gestational, trophoblastic neoplasia, soft tissue sarcoma, childhood solid tumors

TABLE 48.6

CONTINUED

Class (Drug)*	Toxicities‡			Indications
	Bone marrow	Nausea, vomiting suppr.	Other toxicity	
Daunorubicin (Cerubidine)	4 +	2 +	Mucositis, hepatotoxicity, myocardiopathy	Acute nonlymphatic and lymphatic leukemias, childhood solid tumors
Mithramycin (Mithracin)	3 +	3 +	Hemorrhage, skin flushing, thrombocytopenia, hypocalcemia	Malignant hypercalcemia, testicular tumor (salvage therapy)
Mitomycin C (Mutamycin)	3 +	2 +	Mucositis, pneumonitis, renal failure	Breast, lung, colon, gastric, pancreatic, and bladder carcinoma
E. MISCELLANEOUS				
Gemcitabine (Gemzar)	2 +	2 +	Pain, fever, rash	Pancreatic cancer
Procarbazine (Matulane)	3 +	2 +	Side effects of monoamine oxidase inhibitors, skin rash	Lung and testicular cancer, brain tumors, lymphoma
L-Asparaginase (Elspar)	0	2 +	Pancreatitis, CNS toxicity, hypofibrinogenemia	Acute myelogenous leukemia, T-cell lymphoma
Hexamethylmelamine	1 +	3 +	Anorexia, central and peripheral neuropathy	Ovarian and small cell lung carcinoma
F. TARGETED THERAPIES				
Imatinib (Gleevec)	2 +		Fluid retention, hypophosphatemia	CLL, gastrointestinal stromal tumors
Bortezomib (Avastin)	2 +		neuropathy, asthenia, hypotension	Relapsed multiple myeloma
Erlotinib (Tarceva)	1 +		Rash, diarrhea, interstitial lung disease	2nd and 3rd line non-small cell lung cancer
Lenalidomide (Revimid)	2 +		Diarrhea, pruritus, rash fatigue, leg cramps	Myelodysplasia, myelomas
Nexavar (Sorafenib)	1 +		Rash, hand and foot fatigue, diarrhea, hair loss	Renal cell carcinoma
Rituximab (Rituxan)	1 +		Hypersensitivity reaction, Lymphopenia	Relapsed low grade non-Hodgkin's lymphoma
Thalidomide (Thalomid)	1 +		Teratogenicity, sedation, constipation, neuropathy, rash	Myeloma
Trastuzumab (Herceptin)	0		Hypersensitivity reaction	Metastatic or adjunct Her-2/neu-positive breast cancer

ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; WBC, white blood cells
*The names of drugs in parentheses represent proprietary names and in some instances other generic names.
‡Degree of toxicity: 4 + marked, 3 + severe, 2 + moderate, 1 + minimal or mild, 0 none.

values that range from zero to almost 1000 fmol per mg cytosol protein. Receptors also exist for progesterones and androgens, and receptors for corticosteroids have been identified in the cytosol of leukemic cells.[213]

Hormonal ablation can be achieved by surgical means, as occurs with oophorectomy, adrenalectomy, and hypophysectomy; by irradiation of the ovaries or ablating the pituitary gland with the various radioactive compounds; by injecting alcohol; or by surgical extirpation. Medical adrenalectomy can be achieved by administering aminoglutethimide, a potent inhibitor of the conversion of cholesterol to pregnenolone in the adrenal gland.[213] Hormone additive therapy is achieved by the administration of estrogens, progestins, androgens, antiestrogens, corticosteroids, and thyroid hormones. Table 48.7 lists the hormonal agents used

TABLE 48.7

HORMONALLY ACTIVE AGENTS IN CANCER TREATMENT

Agents	Toxicity	Indications
Estrogen		
Diethylstilbestrol	Feminization of men, fluid retention, thromboembolic phenomenon, induction of endometrial cancer	Breast and prostate cancer
Estradiol	Feminization of men, fluid retention, thromboembolic phenomenon, induction of endometrial cancer	Breast and prostate cancer
Antiestrogens		
Tamoxifen (Nolvadex)	Hot flashes, nausea, vomiting, vaginal bleeding or discharge, hypercalcemia, visual disturbances, thrombocytopenias, endometrial cancer, rare liver dysfunction	Adjunct and metastatic cancer
Progestins		
Medroxyprogesterone (Provera, Depo-provera)	Weight gain, thromboembolic phenomena, fetal hazard	Breast and endometrial cancer
Megestrol acetate (Megace)	Weight gain, thromboembolic phenomena, fetal hazard	Breast and endometrial cancer
Aromatase Inhibitors		
Aminoglutethimide	Dizziness and rash	Breast and prostate cancer
Letrozole (Femara)	Hot flashes, arthralgias	Adjunct and metastatic breast cancer in postmenopausal women
Anastrazole (Arimidex)	Hot flashes, arthralgias	Adjunct and metastatic breast cancer in postmenopausal women
Exemestane (Aromasin)	Hot flashes, arthralgias	Metastatic breast cancer in postmenopausal women
Gonadotropin Releasing Hormone Analogues		
Leuprolide (Lupron, Lupron Depot)	Increased bone pain, hot flashes, thromboembolic phenomena	Prostate and breast cancer
Goserelin (Zoladex)	Worsening bone pain, hot flashes	Breast and prostate cancer
Antiandrogens		
Flutamide (Eulexin)	Worsening bone pain, hot flashes, gynecomastia	Prostate cancer (usually in conjunction with LHRH antagonist)
Bicalutamide (Casodex)	Worsening bone pain, hot flashes, gynecomastia	Prostate cancer (usually in conjunction with LHRH antagonist)
Nilutamide (Nilandron)	Worsening bone pain, hot flashes, gynecomastia, visual disturbances, interstitial pneumonitis	Prostate cancer (usually in conjunction with LHRH antagonist)
Androgens		
Fluoxymesterone (Halotestin)	Masculinization in women, hepatotoxicity	Breast cancer
Glucocorticoids		
Dexamethasone (Decadron)	Cushingoid appearance, hyperglycemia, fluid retention, osteoporosis, muscular weakness, peptic ulcer disease, cataracts, psychosis, aseptic necrosis	ALL, lymphomas, myeloma, CLL
Prednisone (Deltasone)	Cushingoid appearance, hyperglycemia, fluid retention, osteoporosis, muscular weakness, peptic ulcer disease, cataracts, psychosis, aseptic necrosis	ALL, lymphomas, myeloma, CLL

ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia

in the treatment of various cancers and side effects. Such hormone changes can cause complex endocrine effects, such as pituitary inhibition of luteinizing hormone, follicle-stimulating hormone, and prolactin, as well as changes in endogenous steroid hormone production.[213]

Endocrine Therapy for Relief of Cancer Pain

At the First International Symposium on Cancer Pain[214] and at another symposium held subsequently,[215] Pannuti and colleagues presented a comprehensive summary of the results reported by a number of oncologists. Table 48.8 contains mean data presented by Pannuti et al.[214,215] that provide an overview of the response to hormonal therapy of patients with four types of cancers. These reports were some of the first in which the efficacy of hormonal therapy on pain relief was correlated with the efficacy of these agents on tumor remission. Unfortunately, a significant number of reports on advanced cancer had no discrete data on pain relief but only measurements of volume reduction of tumor size. Pannuti and colleagues[214] further pointed out that there was no universally accepted rating system or qualification of pain relief on the part of oncologists, and this obviously led to heterogeneous results that could not be compared.

As can be noted in Table 48.8, Pannuti et al.[214] gave progestin therapy in the form of high doses of injectable medroxyprogesterone acetate (MAP-HD) and noted pain relief in 83% of breast cancer patients with predominantly bone metastasis, although only 45% had objective evidence of tumor remission. Patients with estrogen receptor (ER) and progesterone receptor (PR) positive tumors have greater pain relief.[216] In view of the corticosteroid-like side effects from these large doses of MAP-HD, it is possible that much of the subjective response was due to nonspecific steroid action. Hypophysectomy has been proven to provide a high degree of pain relief.[217,218] With regard to advanced cancer of the prostate, MAP-HD and hypophysectomy produced the highest degree of pain relief. For hypophysectomy, pain relief was significant, even in the absence of tumor remission. With regard to renal carcinoma, androgens and progestins (particularly in the form of MAP-HD) provided pain relief and tumor remission in approximately 40% of the patients.

Although ovarian carcinoma contains steroid receptors, very

TABLE 48.8

RESULTS WITH HORMONAL THERAPY IN ADVANCED CANCER

Agent or technique, by type of tumor	Number of reports	Tumor remission (% of tumors)		Pain relief (% of patients)
		Objective	Subjective	
Breast				
Androgens	7	14	37	44
Antiestrogens	2	24	43	33
Progestins (other than MAP)	3	32	50	44
MAP-LD	4	28	51	21
MAP-HD	4	45	ND	83
Corticosteroids	2	4	16	12
L-DOPA	1	33	33	33
Hypophysectomy Surgical	4	30	42	82
Chemical (alcohol injection)	2	30	ND	90
Adrenalectomy	2	36	41	44
Prostate				
Estrogens (DES-P)	3	42	76	81
Cyproterone acetate (CP)	2	80	ND	80
MAP-LD	1	ND	ND	75
MAP-HD	2	ND	100	100
Surgical hypophysectomy	3	ND	35	71
Adrenalectomy	3	20	ND	71
Orchidectomy	1	ND	71	ND
Clear Cell Renal Cancer				
Progestins (other than MAP)	2	8	53	ND
Androgens	1	ND	100	ND
MAP-LD	2	8	53	75
MAP-HD	2	ND	100	86
Corticosteroids	1	ND	100	ND
Endometrial				
MAP-LD	2	35	75	ND
17-Hydroxyprogesterone	2	33	70	ND

DES-P, diethylstilbestrol diphosphate; HD, high dose (1000–1500 mg/day); LD, low dose (<500 mg/day); MAP, medroxyprogesterone acetate; ND, no data available.

Modified from Pannuti F, Martoni A, Rossi AP, et al. The role of endocrine therapy for relief of pain due to advanced cancer. In: Bonica JJ, Ventafridda V, eds. *Advances in Pain Research and Therapy*. Vol 2. New York: Raven Press; 1979:145–166 and Pannuti F. Hormonal treatment. In: Twycross RF, Ventafridda V, eds. *The Continuing Care of Terminal Cancer Patients*. New York: Pergamon Press; 1980:79–89.

little objective response to hormone therapy has been demonstrated.[214] Subjective response to the tumor occurred in some patients with progestin therapy, but no information is available concerning pain relief. Well-differentiated papillary thyroid carcinoma, found particularly in women younger than the age of 40, is likely to be dependent on thyroid-stimulating hormone, and pituitary thyroid-stimulating hormone secretion can be suppressed by thyroxine administration, but no data are available concerning pain relief.

Side Effects

Endocrine therapy is generally much better tolerated than chemotherapy. None of these agents produces bone marrow suppression. Corticosteroids and high doses of medroxyprogesterone acetate (MPA), given for long periods of time, are associated with classic Cushingoid side effects, and parenteral MPA can cause administration site abscess.[214] Sex hormones, particularly estrogens, can cause intermittent uterine bleeding, which can be upsetting, especially for postmenopausal women. Androgens cause virilization and increased libido in some women. Estrogen given to men causes alopecia, testicular atrophy, gynecomastia, loss of libido, and impotence. Long-term administration of estrogen is also associated with a decrease in mortality from cardiac and cerebrovascular disease—presumably on the basis of favorable effects on lipoproteins—whereas androgens are thought to increase the risk of cardiovascular disease. Adrenalectomy causes side effects similar to those of estrogens, with the exception of the excess cardiovascular complications. Surgical adrenalectomy and hypophysectomy are both major operative procedures and carry a small but significant mortality risk (see Table 48.7).

CHAPTER 49 ■ CANCER PAIN IN CHILDREN

JACQUELINE CASILLAS AND LONNIE K. ZELTZER

OVERVIEW OF CHILDHOOD CANCER

Epidemiology

There are approximately 12,400 children diagnosed with cancer each year in the United States.[1] As recently as the 1970s, a diagnosis of cancer during childhood was considered a uniformly fatal disease. However, through enrollment in clinical trials available through the cooperative pediatric oncology group(s), there is now an overall 80% survival rate across the major 12 diagnostic categories of childhood cancer. *The International Classification of Childhood Cancers*, Third Edition (ICCC-3) include: (1) leukemias, myeloproliferative and myelodysplastic diseases, (2) lymphomas, (3) central nervous system neoplasms, (4) neuroblastoma and other peripheral nervous cell tumors, (5) retinoblastoma, (6) renal tumors, (7) hepatic tumors, (8) malignant bone tumors, (9) soft tissue and other extraosseous sarcomas (e.g., rhabdomyosarcoma), (10) germ cell tumors, (11) other malignant epithelial neoplasms and malignant melanomas (e.g., thyroid and nasopharyngeal carcinomas), and (12) other, unspecified malignant neoplasms.[2] Certain types of cancer are more common in specific age groups of children. For example, acute leukemias, neuroblastoma, and renal tumors are more common in the younger age groups (ages 2–6 years), whereas the malignant bone tumors and lymphomas are more common during the adolescent years.

Treatment

Despite the low incidence rates of pediatric malignancies, there is a rapidly growing population of childhood cancer survivors reaching public health epidemic rates. This is due to better supportive care and use of aggressive, multimodal treatment strategies of chemotherapy, radiation, and surgery. Because the majority of pediatric cancer patients are enrolled in cooperative group clinical trials, there is a very uniform approach to treatment through the use of nationally available standardized treatment protocols.[3] There are "roadmaps" that are followed by the treating pediatric oncologists and communicated to the family and patient so that they know when to expect the next cycle of chemotherapy, including when the next invasive procedure can be anticipated to occur. As a result, there may be certain periods of higher anxiety, resulting in greater pain for pediatric cancer patients during the cancer treatment continuum as they anticipate the upcoming procedures. However, with careful planning, an effective pain management regimen can be developed and implemented.

Survivorship

The end result of the aggressive treatment regimens for pediatric cancer patients is a success story for the 21st century. The current estimated survival rate for a pediatric cancer patient is 80%. However, despite these advances for 5-year survival rates, there continues to be a high risk for the development of chronic health conditions (late effects) years after the cancer treatment is completed. Complications of treatment include risk for second malignant neoplasms, cardiac and/or pulmonary dysfunction, skeletal problems, and neurocognitive deficits.[4] There is nearly a 75% risk of childhood cancer patients having a chronic health problem by 30 years postdiagnosis.[5] Another important childhood cancer statistic that impacts the field of pain management is the current estimated prevalence rate of childhood cancer survivors; this number of survivors within the United States is over 300,000.[1] Thus, given this rapidly growing population of childhood cancer survivors, it is important to be familiar with the unique challenges faced both during and after completion of treatment for cancer during childhood because the population of survivors continues to increase in numbers and has unique pain management issues, as this chapter will further elucidate.

PAIN IN CHILDREN: HOW DOES THIS DIFFER FROM THAT IN ADULTS?

The model of pain for the adult population is a comprehensive one consisting not only of a physical domain but also psychological and social domains—the biopsychosocial model. In children, the biopsychosocial model of pain is more complex because the developmental level of the child needs to be considered in this model. Childhood is a period in which there are complex and rapid neurodevelopmental changes occurring from birth to young adulthood. Children grow and develop through five stages of development: (1) infancy, (2) toddlerhood, (3) preschool period, (4) school age period, and (5) adolescence. These levels of development are important because they directly impact the assessment and management of pain in children. For example, it was previously believed that newborns and infants could not experience pain because of immature neurological systems and only as the child developed could pain be experienced. However, ongoing basic research has dispelled this myth and newborns and infants can experience pain and mount a stress response to noxious stimuli. Furthermore, a noxious stimulus transmitted through neural afferent systems to a newborn brain may even be experienced as more painful than for an adult because the pain inhibitory system is not fully developed at birth.

Infants–Preschool

From birth through early childhood, a normal developmental assessment evaluates five main areas: gross motor skills, fine motor skills, language skills, personal/social skills, and cognitive skills. Changes occurring in these areas impact the pain assessment and emotional response of the child to the painful stimuli. For example, the language skills of a 2-year-old include a 50-word vocabulary and two-word sentences. During this period, if

the child is not able to effectively communicate the pain sensation and inadequate pain treatment occurs, then there can be more fear and anxiety with each subsequent painful procedure. One year later, at 3 years of age, there is an expected 250-word vocabulary, three-word sentences, and speech is intelligible to strangers 75% of the time. This child may be able to more effectively communicate with their parents and doctors and have a treatment for the pain initiated more promptly, a factor related to these enhanced communication skills that can serve to decrease anxiety for future procedures.

School Age–Adolescence

A school-age child will have a progressive ability to effectively communicate with the health care team. In turn, the providers must clearly communicate with the child about their treatment plan in order to minimize the anxiety children can experience from medical interventions. During adolescence, normal development of increasing desire for autonomy necessitates direct communication by the health care team, not only with parents, but also directly with the adolescent based on the adolescent's desire for independent decision-making (when possible). However, in all levels of normal development, the impact of illness can cause a pediatric patient to regress and become more dependent on their parents to support their physical and emotional needs, with parents often providing the primary input to the health care team about children's pain and effectiveness of pain management. When possible, it is always helpful for the health care team to also attempt to get the child and adolescent's self-report of pain.

PEDIATRIC CANCER PAIN

The vast majority of pediatric cancer patients do not have a chronic medical condition at the time of diagnosis and therefore have not experienced chronic or recurrent episodic pain. Instead, they have mainly interfaced with the health care system for well child checks with the associated immunization schedules and for acute, intermittent self-limiting infections or minor injuries. Thus, it is not surprising that the diagnosis and rapid initiation of treatment of the cancer can overwhelm a child with fear and anxiety because of the number of invasive, painful medical procedures that are required, but for which the child is not psychologically prepared. In addition, acute pain associated with the first medical procedure at the time of diagnosis can set the expectations of pain to be experienced by the child for all future procedures. Studies have demonstrated that even posttraumatic stress symptoms can be experienced by childhood cancer survivors due to memory recall of invasive procedures during treatment, and these painful memories continue beyond the treatment into the survivorship period.[6]

Pain Evaluation and Treatment Plans for Children with Cancer

The importance of eliciting and listening to all details of the pain narrative of the pediatric cancer patient is critical. Again, what is asked of the child and expected of the child is dependent on the developmental level of the child. For the school-aged child or adolescent, the pain assessment should occur early on, where there is the support of family, and in a nonthreatening environment. In tertiary care centers that care for large numbers of pediatric cancer patients, there are child life services available that serve as another resource to help elucidate a clear description of the pain narrative. For the infant or toddler, the health care provider is dependent upon the parents' narratives of the painful experience because they are the source of safety and communication for the young child. Across the entire developmental continuum of pediatrics, the physical examination is critical to provide additional information about physical factors that contribute to the experience of pain. During the physical examination, it is also critical for the health care provider to recognize and identify psychosocial factors, such as parental fear or anxiety, that can also increase the suffering associated with pain for the pediatric cancer patient. After a careful history and physical examination, a targeted treatment plan can then be developed. Further details of treatment plans for the various etiologies of pain in the pediatric cancer population will be discussed in the sections below.

ETIOLOGIES FOR PAIN IN PEDIATRIC CANCER PATIENTS

There are seven main categories of reasons for pain in children with cancer that include: (1) pain associated with medical procedures used for cancer diagnosis and treatment, (2) pain associated with bone marrow infiltration by malignant disease, (3) neuropathic pain and pain due to central nervous system tumors, (4) bone pain and amputation, (5) visceral pain, (6) pain associated with bone marrow transplantation, and (7) stress and other symptoms.

Pain Related to Medical Procedures

Invasive, painful procedures for the childhood cancer patient include diagnostic tests such as bone marrow biopsies, lumbar punctures (LPs), surgery for tissue biopsy, venipunctures for diagnosis and/or treatment administration, and access to a subcutaneous central venous port-a-catheter. Not only does the pediatric cancer patient face many painful stimuli repeatedly, but these pain-evoking procedures can occur in a relatively short period of time (within a few days, weeks, or months). In addition to the physical pain that invasive procedures cause related to tissue damage by insertion of a needle or device through the skin and/or bone, the procedures themselves produce a great deal of psychological distress, including fear and anxiety.[7] This anxiety can result in a quick recall of the procedure that will impact future pain management for all future painful procedures. Children with acute lymphoblastic leukemia (ALL) on current treatment protocols, for example, receive lumbar punctures on a regular basis ranging from once weekly to once every 3 months (which is considered a less intensive period of treatment). The initial LPs that are done at time of diagnosis and for the initial induction treatment therefore set the stage for the pain anticipated and experienced for children during their 2 to 3 years of ongoing chemotherapy. Studies in ALL cancer patients have clearly demonstrated that children do have accurate memories of their painful procedures. The more negative a memory a child had about a previous LP, the higher the likelihood of increasing distress related to future LPs.[8]

There may also be specific groups of pediatric cancer patients that are at higher risk for distress due to painful, invasive procedures. Early studies have suggested that differences in reactions to painful stimuli can be attributed, at least in part, to a child's temperament, including the dimensions of distractibility and persistence.[9–12] Chen has shown that having a higher level of pain sensitivity (i.e., *pain perception*) is associated with greater anxiety and pain both prior to and during an LP procedure.[13] In addition, the psychological stress and corresponding coping experienced by the parent can affect the child's coping responses to the painful stressor. It has been shown that mothers of childhood cancer survivors do experience posttraumatic stress symptoms well into the survivorship period years after their child was treated for cancer.[14] Thus, given that a child is dependent on their parents

for both physical and emotional support throughout the cancer care continuum, a child can be at increased risk for distress due to pain if their caretaker is not able to soothe or provide a safe, consistent environment because of their own maladaptive coping.

Treatment Plans for Painful Invasive Procedures

Pain Assessment

Various methods of identifying and quantifying pain in children have been employed by both researchers and health care providers and fall into three categories: physiologic, behavioral or observation, and self-report. For example, for infants and young children who are not able to verbally express their feelings, pain is often assessed by physiologic parameters that include elevations in heart rate and blood pressure. Similarly, health care providers often use behavioral cues such as facial expressions and/or stiffening of the body to indicate that an infant or preverbal child is experiencing pain. Even with physiologic parameters and behavioral cues to assist a health care provider with identifying pain in a child, it has been found that health care providers may underestimate a child's pain experience. Thus, it has been suggested that screening tools, such as visual analog scale pain scores (when developmentally possible, likely by age 4 because of the sufficient personal and social skills to interact with a health care provider), should be employed to identify at-risk children.[15,16]

Various other pain assessment tools have been evaluated regarding their effectiveness to identify pain and distress in children. One such example is the use of dolls with different facial expressions to identify pain in a culturally diverse group of children with cancer undergoing the invasive medical procedure of subcutaneously accessing a port-a-cath.[17] This tool may be helpful for a young child because a doll is nonthreatening and is a familiar object that can cognitively engage a young child. von Baeyer and Spagrud have completed a systematic review of observational measures of pain used for children between 3 and 18 years and have included the level of scientific evidence to support their use.[18] In this review they have identified two scales for use in assessing pain intensity associated with medical procedures: Face, Legs, Arms, Cry, Consolability (FLACC) and the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS).[19,20] In addition, for the older child, visual analog scales are used most commonly in the clinical setting when the self-report of pain can be provided. Thus, when the child experiences pain from a procedure, the first step is to complete a comprehensive pain assessment that includes the child's and parent's pain narrative, pain measurement scales where developmentally appropriate, and all in combination with the physical changes that can help accurately quantitate the pain experience.

Pharmacologic Treatments

Up-front treatment plans for first-time invasive procedures for a pediatric cancer patient include the use of pharmacologic treatment of the pain. A child's first LP, for example, should include the integration of pediatric pain service and/or pediatric anesthesia team so that effective systemic anesthesia (in addition to local) can be administered; appropriate physiologic monitoring can also be done to minimize risk from the pharmacologic intervention. Propofol can be considered if a patient has a central line because induction occurs rapidly with this anesthetic and can be easily titrated to produce a deep sedation to eliminate painful stimulation the child experiences during the procedure.[9] Local anesthetic, such as lidocaine, should be administered even when the patient is receiving conscious sedation so that the total dose of propofol to be administered can be minimized and pain control can be maximized. When deciding upon the use of bolus versus a continuous infusion of propofol, there is data to suggest that bolus dosing can result in a more rapid recovery after completion of the invasive procedure because it results in a cumulative lower dose of the anesthetic.[21]

Nonpharmacologic Treatments

Importantly, there are also several cognitive–behavioral interventions that can be employed to minimize the anxiety associated with painful procedures. These can include an emphasis on the family-centered care model, which includes the parent being present with the patient while undergoing induction anesthesia and at the time the pediatric cancer patient regains consciousness. Child life services can assist with preparing the patient to understand the various mechanical procedures that will occur, betadine/alcohol prepping, palpation of landmarks, application of the local anesthetic agent, etc. Relaxation therapies that can be used for painful procedures include focused attention, such as mindfulness meditation, and hypnosis/guided imagery.[22,23] For example, guided imagery has been shown to lower postoperative pain ratings, decrease hospitalization stays, and decrease anxiety in pediatric patient populations. [24]

Distraction methods are also another category of cognitive–behavioral therapies employed to decrease the pain experience during invasive medical therapies. They include use of bubbles, music therapy, mutual storytelling, pop-up books, videos, and simple conversation so that the attention is taken away from the procedure and focused onto another target. For example, by offering music therapy to the adolescent who may feel a lack of control due to the required invasive procedure, the opportunity to exert some autonomy over the painful experience (such as through singing) can occur through the freedom of expression of his/her feelings about the procedure as well as the change in focus of attention.[25,26]

Pain Due to Bone Marrow Infiltration

The acute leukemias, ALL and acute myelogenous leukemia (AML), are the most common diagnostic category of pediatric cancer.[28] The rapid growth of the leukemic blasts within the bone marrow commonly results in the experience of diffuse bone pain. The clinical presentation of the bone pain, however, is variable depending on the age of the patient. Very young children, such as toddlers who are most commonly affected by ALL, may present with a limp or inability to walk. A school-age child who is able to provide a pain narrative may report diffuse, not well localized, total body pain. An adolescent patient may have back pain that he or she associates with a sports injury and may localize the pain to a specific area in a long bone. There are also solid tumors, such as neuroblastoma, which most commonly presents during the toddler years, that can metastasize to both the bone marrow and bone and can also present as a limp or, alternatively, as localized pain to a specific bony area.

Treatment Plans for Pain Due to Bone Marrow Infiltration or Bony Metastases

Pain Assessment

Given the importance of pain narrative from a patient, the assessment of bone marrow infiltration pain in an infant or toddler becomes even more complex because the clinician is required to move beyond the traditional communication dyad of the doctor–patient relationship to one that is a triad doctor–child–parent relationship. For example, a toddler with bone pain due to leukemic infiltration who cannot clearly verbalize his or her painful experience often requires the parent to report the painful

experience on behalf of the child. Thus, the pain is often described as total body pain because the toddler no longer has the strength to walk. The physical examination is critical to supplement the parent's narrative because there may be additional physical factors contributing to the leukemic bone pain. For example, there may be point tenderness on examination that is due to an occult bone fracture from cortical thinning related to the acute leukemia that would require more than chemotherapy to treat the bone pain. However, whenever possible, it is critical to ask the child himself or herself about the pain.

Pharmacologic Treatments: Chemotherapy and Radiation Therapy

The most effective method of eradication of pain due to bone marrow infiltration begins with treatment of the primary disease. For ALL, induction chemotherapy regimens generally place children into remission within a 1-month treatment course.[28] For most standard risk ALL patients, by day 7 of treatment, there is a significant reduction in the leukemic burden to less than 25% of the bone marrow being affected. This decrease in leukemic burden results in marked improvement in the bone pain. Adolescents with acute leukemias, however, often have more resistant disease and may have longer periods of acute pain due to the persistence of blasts within the bone marrow and may require analgesics throughout the induction chemotherapy regimen.[29] For patients with bony metastases from solid tumors, such as neuroblastoma, effective treatment may also include local radiation therapy to the affected site.

Pharmacologic Treatment: Analgesic Therapy

Pharmacologic regimens for the treatment of pain from bone marrow infiltration for both children and adolescents includes the use of opioids, such as morphine or hydromorphone. These opioid analgesics may be administered through bolus dosing regimens if the pain is not constant. However, for those patients experiencing constant pain, the delivery of the opioid should include the use of patient-controlled analgesia (PCAs). PCAs are extremely effective at reducing pain because there is no lag time in the delivery of the analgesic, there can be both continuous and demand delivery, and there are lock-out mechanisms for total doses given, thereby increasing the safety profile. Hospitals have different protocols in place for the use of PCAs where some do not allow for their use in very young children because it requires a parent or nurse to administer the boluses and is no longer "patient-controlled." Alternatively, other hospitals, such as those with well-integrated pain management services within their pediatric oncology division, do allow for the use of parent-controlled or nurse-controlled PCAs for the younger or cognitively impaired child.[9] Often, health care providers will use adjuvant pain medications, such as acetaminophen or nonsteroidal anti-inflammatory agents (NSAIDs), together with opioid analgesics to optimize pain control and minimize the side effects of opioids, such as respiratory depression at high doses.[30] However, in the patient with bone marrow infiltration there is also bone marrow suppression and resultant thrombocytopenia. As a result, the use of NSAIDs is not recommended for these patients because of the NSAIDs' antiplatelet effects that may place the pediatric cancer patient at increased risk for hemorrhage secondary to both the quantitative and qualitative platelet defects.

Neuropathic Pain

Pediatric cancer patients can experience neuropathic pain for a variety of reasons, including nerve invasion, inflammation of a nerve root due to the malignancy or infectious process, and/or from cancer treatment side effects. These etiologies include: (1) chemotherapy-related peripheral neuropathies, such as with vincristine neurotoxicity; (2) neural compression or invasion by tumors, such as pelvic Ewing's sarcomas; and (3) infectious related, such as herpes zoster reactivation due to immune suppression. Vincristine is a vinca-alkaloid chemotherapeutic agent used as an effective cytotoxic agent for many types of pediatric malignancies including leukemias, lymphomas, and various solid tumors. Vincristine binds to tubulin and inhibits microtubule formation and disrupts the formation of the mitotic spindle, which is thought to be one of the mechanisms by which it causes peripheral neuropathies, including jaw pain, leg pain, and abdominal pain.[31] In addition, direct injury of the nerve can occur with soft tissue sarcomas arising in the pelvis, such as Ewing's sarcoma or rhabdomyosarcoma, and the child may present with complaints of abdominal pain, lower extremity weakness, and/or bladder and bowel dysfunction.

Treatment Plans for Neuropathic Pain

Pharmacologic Treatments

The medications that can be used for neuropathic pain include the use of tricyclic antidepressants (TCAs), such as amitriptyline, anticonvulsant medications, such as gabapentin, and local anesthetics, including the topical application of the 5% lidocaine patch.[32,33] Although there has been clinical observation and scientific evidence that TCAs are effective at treating neuropathic pain, not all types of antidepressants have been shown to be effective. A Cochrane review of the adult pain literature, for example, has recommended that future research on the treatment of neuropathic pain should include the assessment of effectiveness for other "naturally occurring" antidepressants such as St. Johns Wort and L-tryptophan because there is currently insufficient data to support their use or disuse.[34] Opioids, including methadone, can also be used for severe neuropathic pain that has not been effectively treated with TCAs or anticonvulsant medications.[35] However, methadone is also associated with a heightened risk profile that has not been studied widely in children. In general, opioid-based regimens are often less effective in treating neuropathic pain. Thus, when considering the use of opioids for neuropathic pain, one should first try to maximize the total recommended daily dose of the TCAs and antineuroleptic agents, such as gabapentin, given their relatively low toxicity profile before initiating a long-term opioid regimen.

Nonpharmacologic Treatments

Mechanical approaches are also important to consider in the treatment regimen for neuropathic pain. These include the use of physical therapy and acupuncture. Physical therapy can be considered for those patients who have neuropathic pain, particularly due to vincristine because this agent can also cause motor weakness. Although physical therapy can be an effective therapeutic modality, there are several barriers to its utilization in cancer patients,[36] such as financial and/or insurance barriers. A pediatric cancer patient may be fatigued and not want to engage in exercises. With persistence and coupling of the child to a therapist who can gently but firmly encourage the patient to participate regularly in the recommended exercise regimen, physical therapy can be an effective, nonpharmacologic modality to supplement pharmacologic regimens that are insufficient at relieving the neuropathic pain.

Pain Associated With Central Nervous System Tumors

Central nervous system (CNS) tumors are the most common form of solid tumors diagnosed during childhood. Because of the mass effect of the brain tumor, the child often presents with symptoms

of headaches due to increased intracranial pressure. To decrease the intracranial pressure and thereby treat the pain/headache for the child, different therapeutic approaches can be used. For some brain tumors that are locally invasive without metastatic potential, such as low grade gliomas (astrocytomas), complete surgical removal is the treatment of choice. Often, the child will be placed on a corticosteroid pulse postoperatively to decrease associated cerebral edema. If the child continues to have headaches postoperatively, nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, can be considered if there is no plan for chemotherapy and/or radiation therapy. If an NSAID is used in the pain treatment regimen, a histamine H_2-receptor antagonist to inhibit stomach acid production is also required.

For malignant brain tumors with metastatic potential, such as medulloblastomas, chemotherapy and radiation therapy are included in addition to the surgical treatment regimen. Not all primary resections of malignant brain tumors result in complete surgical removal of the tumor, so pain may persist due to residual disease. Opioids, such as morphine sulfate (MS), administered intravenously are the preferred pharmacologic medication of choice. When using high dose or prolonged courses of opioids for the treatment of central nervous system pain from brain tumors the treatment plan must also include a bowel regimen to reduce the likelihood of constipation. Constipation may already be a significant problem for the child prior to the use of opioids because certain types of chemotherapeutic agents used to treat CNS tumors, such as vincristine, can cause severe impaired gut peristalsis. There are several different classes of medications that can be used to treat or prevent constipation including polyethylene glycol (often preferable because it is a tasteless and odorless powder that can be mixed with any liquid), senakot (a stimulant laxative), docusate (a lubricating laxative), milk of magnesia (which contains magnesium hydroxide, an osmotic laxative) and/or mineral oil (a lubricant).

Benzodiazepines, such as midazolam, can also be used indirectly for the treatment of pain due to CNS tumors even though this class of medications does not have direct analgesic effect. Their mechanism of action for the treatment of pain in children includes decrease in anxiety, decrease in muscle spasm that may occur postoperatively, and facilitation of night sleep.[37] Postoperatively after the resection of the CNS tumor, the child may remain within the intensive care unit (ICU) because of the need for monitoring intracranial pressure. In this setting, benzodiazepines may be used as a continuous infusion or with frequent bolus dosing so that agitation is minimized.[38] Benzodiazepines are often used concomitantly with opioid analgesics in the ICU setting when significant postoperative pain is reported, observed, or expected.

Pain Associated With Primary Malignant Bone Tumors

Primary malignant bone tumors, such as osteosarcoma or Ewing's sarcoma, can result in significant pain for the childhood cancer patient. Bone pain from osteosarcoma, for example, is due to both destruction of normal trabecular bone pattern from direct tumor invasion in combination with intense soft tissue inflammation from the periosteal new bone formation. Thus, the pain can often be very severe and often requires the use of opioid analgesic medications. NSAIDs could also be considered but should be used with caution given that there is a higher risk for bleeding in the patient receiving chemotherapy because of the bone marrow suppression and resultant thrombocytopenia. Cognitive development is also a consideration in developing the pain management regimen for pediatric cancer patients with bone tumors. Given that the most common primary malignant bone tumors, osteosarcoma and Ewing's sarcoma, often occur during adolescence, patient-controlled analgesia (PCA) can be considered when frequent bolus dosing is required for treatment of acute pain. For continued longer-term pain associated with bone tumors for home pain management, oral methadone is a good opioid of choice because of its long half-life and its effects on both opioid and NMDA receptors.

Phantom Limb Pain

Amputation and limb-salvage procedures may be used as surgical approaches to achieve local control of a bone tumor and each can result in a chronic pain syndrome coined *phantom limb pain*. Phantom limb pain is experienced when the pediatric patient continues to have pain appearing to come from where the affected amputated limb used to be. There are multiple possible etiologies for the occurrence of phantom limb pain that include possible damage to the nerve endings in the surgical stump with abnormal regrowth postoperatively leading to abnormal painful discharges to spinal cord and brain. There may also be abnormalities in the central nervous system response to the loss of limb in which there may be loss of inhibitory sensory input from the amputated limb. Phantom limb pain is often a severe pain and very challenging to treat. Systematic analyses of studies to effectively treat chronic postoperative phantom limb pain have not clearly demonstrated an effective treatment option in randomized control trials.[39,40] Central strategies, such as hypnotherapy, aimed at altering metabolic activity in pain perception areas of the brain, such as the anterior cingulate cortical area, may be more effective than peripheral strategies or opioids (see Chapters 26 and 54).

Pharmacologic Treatments

The first important principal in treatment of phantom limb pain is to effectively treat the bone pain preoperatively before the amputation. This can include the use of anesthetic techniques, such as epidurals, with the use of opioids or local anesthetic to prevent dorsal horn sensitization.[41] Following the surgical amputation, treatment of the acute postoperative pain must be initiated promptly in attempt to minimize the development of a chronic pain syndrome. Strategies for the acute postoperative pain for amputees include focal or epidural blocks given that by blocking the specific group of nerves (i.e., a plexus or ganglion) one can block the sensation of pain to the affected area. Given that long-term opioid use is not usually effective for phantom limb pain syndrome, gabapentin has been tried given its low toxicity profile. It should be noted, however, that randomized control trials have not demonstrated its effectiveness when compared to placebo control.[42] Similarly, amitriptyline has been used to pharmacologically treat chronic pain syndromes but has not been proven effective when compared to placebo in an amputee population.[43]

Nonpharmacologic Treatment

Complementary and alternative medicine (CAM) options for the treatment of chronic pain due to phantom limb pain include the use of hypnotherapy, massage, and acupuncture.[44–46] Hypnotherapy, for example, focuses on calming of the nervous system. Through the use of guided imagery techniques during hypnosis, there is a modification of the sensation and perception of the painful stimuli. Neuroimaging research has demonstrated that specific areas of the brain have decreased arousal. Thus, it is thought that there is a reinterpretation of the chronic pain experience.[47]

Visceral Pain

The four major etiologies of visceral pain include: (1) organ invasion with capsular wall stretching, (2) organ compression, (3) hollow organ obstruction (e.g., ureter or bowel), and (4) tumor regrowth within the organ or peritoneal cavity bleeding.

Treatment Plans for Visceral Pain Due to Organ Invasion

For visceral pain due to organ invasion with capsular wall stretching or tumor regrowth the primary treatment to decrease the pain is to decrease the tumor size. For solid organ abdominal malignancies, such as Wilms' tumor (a primary renal tumor), treatment employs a multimodal approach including surgery, chemotherapy, and/or radiation therapy. Surgical resection of the abdominal tumor can result in significant postoperative pain, so where technically possible, laparoscopic surgery consisting of small incisions into the abdominal wall musculature should be considered. Removal of the diseased organ is often not possible through laparoscopic surgery and so it is critical to promptly initiate the treatment of the pain due to a large abdominal wall incision with opioid analgesics to expedite postoperative recovery. Clinicians can be hesitant to use opioid analgesic medications postoperatively because of the concern that their use may have a further impact on slowed bowel function that occurs because of bowel surgery. If postoperative abdominal pain is not treated effectively, however, several additional postoperative complications can occur. These include longer and more intense pain, which, in turn, inhibits mobility and places the patient at risk for pulmonary atelectasis and/or infection.

Regional pain blocks are also a consideration for the treatment of visceral pain due to tumor invasion of a solid organ or nerve plexus. They can be used in the pediatric population with knowledgeable pediatric anesthesia consultation. Regional anesthetic blocks include epidurals or fluoroscopically guided celiac plexus blocks and can be very effective for pain control for unresponsive abdominopelvic tumors, such as bladder rhabdomyosarcoma or neuroblastoma. These types of anesthetic approaches allow targeted pain control within a specific neural plexus while minimizing the sedating effects that a high dose, systemic opioid infusion may cause. There have been recent reports of newer radiographic techniques to facilitate the correct placement of celiac plexus blocks in children, including three-dimensional rotational angiography.[48]

Treatment Plans for Pain Due to Intestinal Obstruction

Visceral abdominal pain can also be due to intestinal obstruction from the tumor mass. The sporadic form of Burkitt's lymphoma, for example, commonly involves the ileocecal region and can result in intestinal obstruction because of the extremely rapid growth of these cancer cells. Because Burkitt's is a type of non-Hodgkin lymphoma, surgery is not an effective treatment and emergency treatment of the abdominal obstruction consists of chemotherapy and/or radiation therapy. Chemotherapy can work quickly and effectively at reducing or eliminating the abdominal obstruction. Thus, bolus doses of opioid analgesics may only be required briefly while awaiting the tumor kill by the cytoreductive chemotherapeutics. Induction chemotherapy for rapidly growing tumors, particularly Burkitt's lymphoma, can result in tumor lysis syndrome and thus careful management of fluids and electrolytes is critical and must be considered in the treatment plan.

For all etiologies of visceral abdominal pain, it is important to initiate treatment of the pain early in an attempt to prevent visceral hyperalgesia and subsequent central pain. Visceral hyperalgesia results from an insult, such as tumor invasion or surgical manipulation, to the celiac plexus consisting of the hepatic plexus, splenic plexus, gastric plexuses, pancreatic plexus, supra/renal plexuses, testicular plexus, superior mesenteric plexus, and the inferior mesenteric plexus. If the treatment of the visceral pain is not initiated promptly or is ineffective, then the ongoing nocioception ultimately results in central pain that can be very difficult to treat. Given that the visceral pain sensation consists of a feedback system from the abdominal neural plexus to the central nervous system, cognitive–behavioral therapies (CBT), including those that promote coping and reduction of anxiety, also reduce pain perception and must be included. There are questionnaires available that can be used to systematically assess children's pain coping strategies, and this information can then be factored into the treatment plan.[49] CBT includes the use of distraction, relaxation strategies, and also specific comfort measures for young infants such as use of a pacifier, oral sucrose, and swaddling.

Pain Associated With Bone Marrow Transplantation

Pediatric cancer patients requiring bone marrow transplantation (BMT) as part of their treatment regimen are considered a high-risk group of patients for the development of acute and chronic pain given the intensity of this treatment regimen. Cancer diagnoses that may require BMT, either allogeneic or autologous, for curative therapy include ALL, AML, myelodysplastic syndrome, and neuroblastoma. Pediatric cancer patients who have received a BMT have unique risk factors for the development of acute pain, including mucositis, graft-versus-host disease (GVHD), and tissue erosive infectious complications. Thus, pain management is critical in the care of the BMT patient and, if not treated adequately, can result in decreased quality of life.

Mucositis

Although mucositis occurs when chemotherapy alone is given, mucositis is often more prolonged and severe for the BMT patient.[50] There is often a longer period for stem cell recovery extending beyond the 7 to 10 day nadir occurring postexposure to chemotherapy. The grading scale for describing the severity of oral mucositis established by the World Health Organization (WHO) begins with mild, grade I mucositis, in which the oral mucosa is red and tender, to severe, grade IV mucositis in which the pediatric cancer patient is unable to eat and maintain his or her own nutrition.[51] The severity of the mucositis often corresponds to the description of the severity of the pain by the patient. Grade I mucositis may only require bolus dosing of an opioid analgesic. In the BMT setting, however, mucositis pain often requires use of an opioid PCA given the chronicity of the pain (over a several week period) and the extensive tissue injury involving the entire gastrointestinal tract. An effective approach to PCA delivery of the opioid analgesic is to have a low basal rate that is augmented with the demand dosing for breakthrough pain.[52] If the demand dosing is frequent, resulting in a lock out of demand dose administration, then an increase in the basal rate is warranted. The pediatric BMT patient may require several weeks use of an opioid PCA because the pain from mucositis can be severe and occur over a prolonged time period of several weeks while awaiting engraftment. However, when engraftment occurs and counts recover, the PCA can often be weaned off quickly. The caveat to this is that there may be withdrawal symptoms, including agitation and/or diarrhea, and a methadone taper should be considered.

Additional Treatments for Pain Due to Mucositis

Topical agents, such as lidocaine, which can be "swished and spit" can also help decrease the chronic pain from mucositis. Mucositis can be complicated by a secondary candidal infection presenting as white plaques overlaying the erythematous oral mucosa tissue. Treatment of the thrush with topical antifungal agents such as nystatin is also an important adjuvant therapy for treatment of mucositis pain (see Chapter 45).

Graft-Versus-Host Disease (GVHD)

GVHD is a unique complication of childhood cancer patients who undergo BMT. GVHD occurs due to the host (recipient) cells appearing foreign to the engrafted hematopoietic stem cells.

There are two forms of GVHD, consisting of acute and chronic GVHD. Acute GVHD occurs within the first 100 days of the BMT, causing dermatitis, enteritis, and/or hepatitis. Acute GVHD can be clinically manifested by skin rash, right upper quadrant pain, and/or diarrhea and abdominal pain. The skin rash can range from mild erythema of the palms and soles of the feet to bullous desquamation in the severe form. Chronic GVHD occurs 100 days beyond the hematopoietic stem cell infusion and is thought to be an autoimmune process. Chronic GVHD primarily has skin manifestations that include scleroderma-type changes often accompanied by joint stiffness and immobility.

Treatment Plans for GVHD

Treatment of pain due to acute gut GVHD, often presenting as crampy abdominal pain due to the diffuse enteritis, requires the use of an opioid analgesic in the form of a PCA. If the BMT patient has been on a PCA due to mucositis pain, the basal dose can be titrated up to meet the demand from the additional painful stimuli from the GVHD. Conversely, chronic GVHD is often an outpatient disease and requires a chronic pain management plan because the autoimmune process can cause muscle and organ invasion, resulting in chronic neuropathic pain. In the setting of chronic pain, oral opioid use may be required until the neuropathic pain is adequately treated with alternative agents, including anticonvulsants such as gabapentin or tricyclic antidepressants. Nonpharmacologic therapies, including the use of acupuncture, massage therapy, and other relaxation strategies, should also be considered.

Other Factors Important to Pain Assessment and Development of the Treatment Plan for the BMT Pediatric Patient

There can be significant anxiety experienced by the pediatric patient due to prolonged hospitalization, up to and even beyond 3 months in duration for successful outcomes post-BMT. Thus, both pharmacologic and psychological services to decrease anxiety for the child are critical. Facilitation of night sleep is also important and may require the use of amitriptyline, diphenhydramine, or trazodone. Other symptoms that can decrease a child's pain tolerance include nausea, vomiting, diarrhea, and pruritis, and these symptoms should be treated or prevented as well. Lastly, if there are surgical interventions or other painful procedures required as part of the supportive care of the BMT patient, such as chest tube placement, careful attention to and pharmacologic treatment of associated pain must occur. Distraction methods can also be considered adjunctively because they have been reported as effective methods for the pediatric cancer patient and include the use of bubbles and hand-held video games.[53]

OVERVIEW OF OPIOID ANALGESIA IN CHILDREN

Opioid and non–opioid analgesia in children include the use of typical mu opioid agonists (e.g., morphine sulfate [MS] and methadone) NSAIDs, atypical opioid analgesics (e.g., tramadol), and ketamine. Opioid rotation is commonly used as a means of optimizing analgesia while minimizing opioid-related adverse effects. It has been shown that in the pediatric cancer population opioid monotherapy is the *most* effective method for treating moderate to severe pain.[54] It is not effective, however, for *all* pediatric cancer patients due to various etiologies including opioid-induced tolerance and opioid-induced hyperalgesia.[55] The analgesic response to any given opioid dose depends on the tolerance of the patient. An opioid tolerant patient will require a higher dose for the same analgesic response when compared to the opioid naïve patient. Adverse effects of opioid analgesics, for both the opioid naïve as well as the opioid tolerant patient, include somnolence, constipation, pruritis, nausea, vomiting, urinary retention, and sweating.

Dependence and Addiction

There can also be barriers to the use of high dose or long-term use of opioid analgesia in children due to parents' and health care providers' concerns regarding the risk of dependence or addiction.[56] Some of the more common symptoms of withdrawal in a child with physiologic opioid dependence include severe dysphoria, diarrhea, anxiety, restlessness, and chills and usually occur when the opioid analgesic is stopped abruptly. The symptoms observed in pediatric patients can vary from those observed in adults. For example, an infant can have a high pitched cry and inability to be soothed with a pacifier, bottle, or swaddling. A toddler's signs of withdrawal may include only diarrhea and temperature instability. Conversely, addiction is a complex behavior characterized by the compulsive use of a drug and psychological craving. Addiction is not commonly seen in the pediatric population but may be observed in the older adolescent who has complex psychosocial issues resulting in maladaptive coping to pain.

Tolerance to Opioids

Given that tolerance to opioid analgesics can limit their clinical effectiveness, various approaches can be used to prevent or reverse tolerance in children who require prolonged exposure to high-dose opioids. One proposed approach to prevent tolerance includes the use of N-methyl-D-aspartate (NMDA) antagonists concomitantly with the opioid. Ketamine has been studied and shown to have a role in mitigating opioid-induced tolerance in children and adolescents who experience cancer pain. Finkel et al. have used ketamine at lower doses than used for anesthetic purposes. Specifically, they used ketamine from 0.1 to 1.0 mg/kg/hour in patients who had signs of opioid tolerance or had severe side effects such as profound sedation.[57] With this regimen, they found that adjuvant ketamine infusions used in combination with opioid analgesics (including morphine, methadone, and hydromorphone) resulted in improved pain control. Tramadol hydrochloride is an atypical opioid that has a weak affinity for the μ-opioid receptor, as well as being a weak inhibitor of serotonin and noradrenaline reuptake. The advantage of tramadol is that it has negligible respiratory depression.[58] It is hepatically metabolized and renally excreted, factors that must be taken into consideration when using this medication in the pediatric cancer patient because chemotherapy can result in hepatotoxicity. The active metabolite is O-demethyltramadol (M1) and recent pharmacokinetic studies in children have demonstrated that it is possible to produce enough of the active metabolite to achieve adequate pain relief.[59] Safe dosing regimens for children ≥12 months of age include 1–2 mg/kg per oral route of administration every 4 to 6 hours with a maximum dose of 8 mg/kg/day.[60]

There are several new unique delivery systems of opioid analgesics and ketamine being tested that might prove useful in the pediatric cancer population to avoid the fear and pain associated with injections. Currently, oral transmucosal delivery of fentanyl citrate (including the trade names of Actiq [a lozenge on a handle] and Fentora [an effervescent tablet]) are the only two formulations that are commercially available with indications for the treatment of breakthrough pain in opioid tolerant adult patients.[61]

Another noninvasive method of opioid drug delivery includes the use of fentanyl transdermal therapeutic (TTS) systems. One practical advantage is that when the oral route of tablet, capsule, or liquid administration is contraindicated or not well-tolerated by a child, the transdermal drug delivery method allows for an

alternative route. There are emerging numbers of pharmacokinetic studies on the use of TTS in children compared to adult dosing regimens as discussed in a recent review by Zernikow et el.[69] In this critical review, they discuss the approximate conversion factor of 45 mg per day of MS to fentanyl TTS 12.5ug/hour for initial therapy for children and adolescents requiring long-term morphine therapy. The data supporting the transdermal route over traditional MS is minimal but there are studies emerging that demonstrate child and parent satisfaction with the TTS delivery system of fentanyl in both pain relief and quality of life in the pediatric palliative care setting.[62]

PALLIATIVE CARE FOR CHILDREN WITH CANCER

A chapter on pain management for children with cancer is not complete without highlighting the important topic of palliative care given that overall 20% of children will not be cured of their disease. The WHO's definition of palliative care is "the active total care of patients whose disease is not responsive to curative treatment. Control of pain, other symptoms, and psychological, social, and spiritual problems is paramount. The goal of palliative care is achievement of the best possible quality of life for patients and their families."[63] The "other symptoms" in addition to pain that can be experienced by the child without the option of curative therapy include fatigue, dyspnea, poor appetite, nausea, vomiting, constipation, and/or diarrhea.[64] Thus, symptom control for children facing end of life is imperative. Studies have demonstrated that when the multidisciplinary approach of palliative care is employed, families and patients report improved satisfaction with their care, improved informed decision making, and a decrease in the number of emergency room visits and inpatient admissions.[65]

The American Academy of Pediatrics (AAP) has put forth a policy statement promoting the use of palliative care at the end of life for children with life-limiting disease. Their statement highlights that palliative care can improve the quality of life for terminal patients and their families through the treatment of symptoms and by addressing the psychological, social, or spiritual aspects of facing a noncurable disease.[66] Despite this policy statement on the importance of the provision of palliative care services for children with life-threatening disease, there are barriers that currently exist and thereby impede its implementation across the U.S. health care system. First, there can be differences in parents' understanding of prognosis of their child's illness when compared to their health care providers' knowledge, a discrepancy that in turn can impact a parental informed decision for end-of-life care, including pain management.[67] Secondly, for parents whose children have an incurable cancer diagnosis, they rate doctor–patient communication as the principal determinant of high-quality physician care. Conversely, physicians' care ratings depend on biomedical rather than doctor–patient relationship aspects of care.[68] It is, therefore, critical for physicians caring for the dying child to listen to the concerns of the patient and the parent particularly for those related to descriptions of pain. By listening to a patient's description of pain and thereby classifying the etiology of the pain one can determine the best therapeutic approach (as discussed above). By being aggressive with symptom management, the pain and suffering at the end-of-life for a terminal pediatric cancer can be minimized.[69]

Pediatric palliative care requires evaluation and re-evaluation of symptoms. In addition to the assessment of pain, the provider needs to assess for symptoms of fatigue, dyspnea, anxiety, nausea, and sleep patterns. There should also be the assessment of caretaker function and support because fatigue or anxiety in the primary caretaker can in turn affect the symptoms associated with pain manifested by the child. Treatment of other end-of-life symptoms, such as dyspnea, can require the use of MS to decrease the sensation of air hunger. If the child is heavily sedated and the family or caretaker has minimal awake time with the child, psychostimulants (e.g., methylphenidate, modafinil) can be used in the morning to override some of the sedative side effects of high-dose opioids needed for pain. In addition, nondrug therapies, such as music therapy or hypnotherapy, can be used concurrently with pain medications. The pediatric palliative care model as described above can be delivered both in the inpatient setting as well as in the home if pediatric hospice services are available. In either setting, the goal of maximizing quality of life for the quantity of time that remains for a child without curative therapy should be emphasized. It should be noted that many clinicians now consider palliative care to begin with a serious diagnosis, such as cancer, even if the likelihood for cure is high, because some children even with low-risk cancers, like ALL in the young child, will die. Thus, a focus on maximizing quality of life and reducing distressing symptoms should be as important a focus in the child with cancer as is the aim for cure.

COMPLEMENTARY AND ALTERNATIVE MEDICINE (CAM) IN THE PEDIATRIC CANCER PATIENT

There are multiple nonpharmacologic therapies that can be employed for pain management in the pediatric cancer patient (Table 49.1). These include massage therapy, yoga, hypnotherapy, meditation, biofeedback, relaxation, spirituality, acupuncture, botanicals, physical therapy, and energy therapies including the use of magnets. The definition of complementary and alternative medicine (CAM) is those interventions that are not generally provided by U.S. hospital clinics, nor widely taught in medical school.[70] Thus, although these CAM techniques may not be familiar territory for physicians trained within the United States, there is an emerging body of literature discussing the state-of-the-science of CAM use in both adult and pediatric populations.[71] In addition, the latest literature in medical education has documented a clear trend of higher usage rates of CAM by anesthesia training programs across the United States.[72] Thus, CAM interventions should be considered as adjuvant therapy for the treatment of pediatric cancer pain.

Acupuncture

Acupuncture consists of inserting fine needles into the skin's surface, or using heat, pressure, or other stimulation in areas that correspond to specific points along "meridians" (i.e., energy channels within the body). These meridians in which the body's life forces (spiritual, emotional, mental, and physical) flow can be out of balance and cause the physical sensations of pain, imbal-

- Spirituality/religiosity
- Therapeutic yoga

ance, and sickness. Insertion of the needles into specific points along meridians through the practice of acupuncture helps to restore the balance of forces within the body and thereby eliminate the pain by achieving a flow of energy or Qi (pronounced chi). Although the practice of acupuncture is more widely accepted within Eastern societies, the use of acupuncture for treatment of pain has been increasing across the United States.[73,74] Approximately half of the states within the United States require licensure for the practice of acupuncture. For those states that do not regulate the practice, the health care provider should ask for certification by the National Commission for the Certification of Acupuncturists (see Chapter 93).

There is a growing body of literature evaluating its effectiveness for alleviating pain.[75,76] The available literature on the use and effectiveness of acupuncture in the treatment of pain in the pediatric population suggests it being an acceptable treatment modality for adolescents with chronic pain, as well as being an effective modality for other common symptoms experienced by the childhood cancer patient, including headache, nausea, and vomiting.[77–79] Nonetheless, acupuncture has not been widely disseminated into pain treatment regimens for the pediatric population. One reason is the preexisting beliefs by health care practitioners in the United States that children are afraid of needles and thus they do not make referrals for acupuncture.[80,81] On the contrary, it has been shown that for those children who have been referred to acupuncture for various chronic pain syndromes, over two-thirds report that it was a positive experience and an effective modality for treatment of their pain.[82] Acupuncture, therefore, can be considered as a possible adjuvant treatment modality for neuropathic pain in the pediatric cancer patient.

Hypnotherapy

Hypnosis is a cognitive strategy that helps the child achieve a narrowed focus of attention, relax, and learn how to dissociate from the current sensory environment. Liossi and others in randomized controlled studies of children with cancer undergoing medical procedures have shown hypnotherapy to be effective in reducing procedure-related pain and anxiety.[83–85] In addition, a recent review article by Wood and Bioy provides a succinct review on the effectiveness of this technique, an understanding of the physiologic effect of hypnosis, and the practical application of its use to treat pain in children.[86] For example, Rainville and colleagues have demonstrated, through the use of positive emission tomography (PET) changes, in regional cerebral blood flow, when hypnosis is used.[87] In hypnotic states, there is increased blood flow to the occipital cortical areas. This increase in blood flow to the occipital region is thought to result in a reduction of inhibitory processes that occur normally during high levels of attention.[88] Thus, hypnosis results in an acceptance of specific, altered sensations, thereby mediating changes in perception of the painful experience.

Several studies on the effect of hypnosis for symptom management in children, including the effect on pain perception, anxiety, and nausea/vomiting have been completed. Early studies have demonstrated the feasibility of being able to hypnotize children.[89] Subsequent studies by Zeltzer et al. have demonstrated the effectiveness of hypnosis in decreasing other symptoms experienced by pediatric cancer patients, including nausea.[90] More recent studies have demonstrated the effectiveness of hypnosis in decreasing pain and anxiety in children undergoing the invasive painful procedures of lumbar punctures and bone marrow biopsies.[91] Thus, there continues to be increasing evidence of both the feasibility of administration and the effectiveness of hypnosis in the pediatric population, and it should be considered when a pediatric cancer patient is undergoing invasive, painful procedures. As the review paper by Wood and Bioy discusses, practical considerations of using hypnosis include the child's age (as younger children are more responsive to the hypnosis when compared to adolescents), cognitive development, and therapeutic relationship with his or her provider.[92]

Massage

Massage is the practice of light body stroking or deep tissue stroking that is thought to work by increasing serotonin and reducing cortisol. The basic principle of massage is that when muscles are overworked, there is a release of waste products that accumulate in the area that can be relieved using the hands of the therapist to manipulate muscles and surrounding tissues. Massage therapy has been used as an adjuvant therapy in pain management with a number of studies demonstrating its effectiveness. For example, it has been shown that when massage therapy was used in addition to a standard pharmacologic regimen for postoperative pain management, the experimental group demonstrated decreased pain intensity, pain unpleasantness, and anxiety when compared to the control group.[92] Massage therapy is also a CAM modality that can be easily instituted at the bedside for the cancer patient.[93] There are few studies to date completed in the pediatric population on the use and effectiveness of massage therapy. Nonetheless, the studies that have been completed do demonstrate decreased pain in the group receiving a standardized massage protocol.[94] In a study of children with ALL, a daily massage over a 1-month period was found to have an impact on the immune system as demonstrated by an increased white blood cell count, as well as an improvement in children's negative affect.[95] Studies have also demonstrated the positive effect in decreasing anxiety in an ethnically diverse sample (Latino) of children with pain due to arthralgias.[96] Given the promising application of massage therapy to decrease pain in children, future research is warranted to evaluate the effectiveness of the healing powers of touch (i.e., massage) in a randomized controlled trial for pediatric cancer patients.

Biofeedback

Biofeedback involves measuring physiologic parameters, including blood pressure, heart rate, skin temperature, sweating, and muscle tension, and conveying the changes that occur while the child is learning breathing and imagery strategies to alter these bodily processes. This bodily feedback information can be provided through the use of computer-generated, audio-generated, or other forms of visual-generated systems with skin temperature or muscle contraction being the most commonly measured parameter. The basic concept of biofeedback is that by providing physiologic information to a patient who is usually unaware of these bodily processes, while also teaching the child cognitive and breathing strategies that alter these processes, the child can learn to reduce muscle tension and autonomic arousal, thereby reducing pain. For children, it provides proof that the mind can affect the body by being able to gain physiologic control of the part of the nervous system that is activated by pain or stress.

Studies on the use of biofeedback have primarily been focused on adult patients, particularly those with headaches. Meta-analysis of this mind–body approach for the treatment of headache pain indicates that it is effective when used alone or in combination with other CAM modalities.[97] Studies completed in pediatric patients again are limited in number, but those that have been completed also have focused on the treatment of pediatric migraine headache. Similar to the adult literature, meta-analysis on the use of biofeedback, as well as other behavioral methodologies to treat headache in children, demonstrate that it can be considered as an important adjunct to the pain treatment regimen.[98] Given that there are minimal side effects and there is data suggesting its effectiveness, biofeedback can also be considered as another adjunctive therapy to pain management in the pediatric cancer patient. There is no license to practice biofeedback although the majority of practitioners have other medical licensures, such as registered nursing (RN), physical therapy (PT) or marriage and family therapy (MFT). Hospitals and clinics with pediatric pain programs can often provide referral lists of biofeedback therapists.

Botanicals

The use of herbal or alternative medicines requires at least brief mention in the treatment of cancer pain given the increasing frequency of use within the U.S. population with or without data suggesting its effectiveness.[99] The studies that have evaluated the use of herbal medicine in pediatric patients have been for the treatment of otalgia and have been completed outside the United States.[100] One such study evaluating the use of the naturopathic ear drop, Otikon, concluded that it was as effective as anesthetic ear drops for acute otitis media associated with ear pain.[101] Thus, given the paucity of studies documenting effectiveness of botanicals, this CAM option cannot be recommended in the treatment of pediatric cancer pain. The lesson that must be taken away, however, is that it is important for practitioners to ask if botanicals (including megavitamins and herbs) are being used by the parent to help treat their child's pain because there may be drug interactions that may interfere with the cancer treatment regimen.

Magnets

The use of magnets to treat chronic pain is another CAM modality that has been under investigation in adult populations. Interestingly, despite the lack of clear data documenting the effectiveness, one study documented that magnet use was the second most common CAM modality used by adult patients with arthritis, second only to the use of a chiropractor.[101] The basic mechanism of magnet use is that they produce a type of energy, a magnetic field, that can affect the pain sensation, although the exact mechanism by which pain reduction occurs has not been identified. There are various magnet products for use in health care including shoe insoles, shoe inserts, mattress pads, bandages, belts, pillows, bracelets, and headwear.[102] Despite all of these various health care products, there are limited data documenting the effectiveness of this CAM modality. A recent systematic review and meta-analysis of randomized trials demonstrated no significant difference in pain reduction.[103] There may be a placebo effect for the patient who places a magnet on the body in the form of a bracelet or bandage.[104] The only reports in the literature of magnets in pediatric populations refer to the dangers of magnet ingestions resulting in gastrointestinal injuries.[105] Thus, the use of magnets to treat young pediatric cancer patients is another CAM modality that cannot be recommended at this point in time and may be associated with risk of ingestion by a young child.

Spirituality/Religiosity

Spirituality (i.e., religiosity) is an important domain that must be considered when conceptualizing the model of palliative care for children with pain.[106] Spirituality must be discussed as another CAM modality because it is commonly used by cancer patients to cope with their diagnosis, aggressive treatment plans, and the associated painful experiences. Spirituality has been shown to be an important coping mechanism for adult cancer patients. For example, it has been shown that breast cancer patients who rate their spirituality as high have lower rates of depression although no effect on pain ratings.[107] Similarly, when mothers of childhood cancer patients were asked to rate their religiosity concomitantly with the measurement of depression using the Beck Depression Inventory-II, it was shown that those mothers who reported lower levels of religious beliefs and behaviors had higher rates of depressive symptoms.[108] It has therefore been recommended that health care providers consider—when they have patients practicing prayer or prayer-like behaviors—to include a discussion on the benefit of this behavior at improving health through the mind–body connection.[109] In addition, given that most major medical centers caring for children with cancer have access to a chaplain or spiritual support, consulting this service should be considered (where appropriate) when developing a pain management plan for the pediatric cancer patient.

Therapeutic Yoga

Therapeutic yoga, including Iyengar yoga, has been used in children to reduce pain, anxiety, and correct health problems. Iyengar yoga, for example, uses poses (asanas) and breathing to correct body structure, enhance internal organ function, facilitate mindful awareness, and achieve a sense of mind–body–spiritual well-being. Studies conducted in adolescents have demonstrated the practice of yoga results in improvement of mood, a decrease in the stress hormones, and decreased pain and disability.[110] In the practice of Iyengar yoga, a teacher who has studied for a minimum of 5 years teaches various poses to a child that can be beneficial in decreasing pain. For the pediatric cancer patient with unique needs, including an impaired immune system, private yoga lessons are preferred over group lessons, with therapeutic Iyengar yoga our preferred method of yoga because of extensive teacher training, the use of supportive props, and selection of specific poses based on the needs of the child.

SUMMARY

Although pediatric cancer statistics are currently at an all time high with an overall survival rate of 80%, cancer-related morbidity, including the risk for the development of significant acute and chronic pain, persists. Thus, a comprehensive approach to pain management in the pediatric cancer patient, especially through empowerment of the child through a mind–body therapeutic approach to their pain management, is critical. There are several pharmacologic treatments that can be used to treat the various types of pediatric cancer pain including opioid analgesia, NMDA antagonist agents, NSAIDs, atypical opioid medications, tricyclic antidepressants, and anticonvulsants. Integration of CAM modalities as an adjuvant or alternative to pharmacologic interventions is also important because there can be limitations in the traditional pharmacologic approach to pain, particularly for chronic pain syndromes. Although not all CAM therapies have a long track record in the scientific literature regarding their effectiveness, it does not mean these options should be excluded from pain management consideration, but rather a discussion with families of the strengths and limitations of such approaches is warranted.

In summary, the foundation to the pain evaluation and treatment plans for children with cancer is a focus on the whole child. The importance of eliciting and listening to all details of the pain narrative of the pediatric cancer patient is critical. Child self-report will be dependent on the developmental level of the child and child pain evaluation encompasses the parental role in the pain experience, a proxy reporter of the pain narrative. For both the child and the parents, the pain assessment should occur early on, in a nonthreatening environment, where the strong triad relationship between the pediatric cancer patient, the parent and the health care provider can be an effective one. In this family-centered care approach, the common goal of alleviating the child's pain can be achieved through education, empowerment, and the provision of mind–body therapeutics.

CHAPTER 50 ■ ACUTE PAIN MANAGEMENT IN CHILDREN

CHRISTINE GRECO AND CHARLES B. BERDE

INTRODUCTION

Nociception alerts the organism to potential or actual sources of harm. Nociceptive functions are active at birth even in preterm neonates, and the experience of pain or pleasure has a powerful impact on learning and neurologic development.[1] Fitzgerald and coworkers,[1] using neurobiological studies in infant rats and psychophysical studies in infant humans, showed that the infant nervous system is in many respects hyperresponsive to noxious stimuli compared to the mature nervous system. Infant rats and humans withdraw their limbs from milder mechanical or thermal stimuli compared to older rats or humans. Infant rats and humans develop hyperalgesia following tissue injury, with evidence for spinal sensitization even in preterm neonates.

While in the 1980s there was a growing acceptance that peripheral and spinal mechanisms of nociceptive are active in preterm and term neonates, controversy persisted regarding maturation of supraspinal mechanisms and regarding how to view pain as conscious experience or suffering in neonates. Recent studies have examined correlates of brain activation using near-infrared spectroscopy, which is sensitive to regional changes in blood flow. A noxious stimulus to the heel (performed for clinically-indicated blood sampling) evoked increased signal overlying the contralateral, but not ipsilateral, cerebral cortex, which has been interpreted as a specific pattern of activation not solely dependent on global changes in autonomic arousal and blood pressure. These and other lines of evidence suggests that painful stimulation reaches the brain in neonates, though they do not per se establish the nature of pain viewed as conscious experience or suffering in neonates. Additional discussion follows later in the chapter regarding potential consequences of either untreated pain or pain treatment in critically ill neonates.[1]

Care of infants and children with acute pain has changed considerably over the past 25 years, and available evidence suggests that undertreatment of acute pain has become less prevalent in economically developed countries over this time period. Changes in practice appear to be the combined result of a series of developments in basic research, in clinical trials, and in advocacy by parents as well as by clinicians, as listed in Table 50.1.

TABLE 50.1

SOME PROMINENT FACTORS POSSIBLY CONTRIBUTING TO INCREASED AWARENESS OF AND TREATMENT OF PAIN IN INFANTS AND CHILDREN OVER THE PAST 25 YEARS

1. Studies demonstrating maturation of nociceptive pathways in infant animals and in infant humans
2. Clinical trials demonstrating improved outcomes of neonates undergoing surgery under adequate anesthesia
3. Pharmacologic studies examining pharmacokinetic, pharmacodynamic, and clinical outcomes of analgesics in infants and children
4. Development of acute pain services in pediatric tertiary centers
5. Advocacy by parents

PAIN ASSESSMENT IN INFANTS AND CHILDREN

Assessing pain in infants and children is a fundamental but challenging aspect of pediatric care. Uniform assessment of pain should be part of the standard of care for hospitals caring for children. Typical adult pain measures are not applicable to preverbal children and young children. Infants and very young children are dependent on adult caregivers to adequately interpret their behavior and other signs in determining whether they have pain. Methods of measuring pain in preverbal patients and in toddlers (ages 2 and 3) generally involve combinations of behavioral observation (including facial expression, crying, limb postures, and consolability) and physiologic parameters (including oxygen saturation and heart rate and a variety of other indices of autonomic arousal). Preschool and early school-aged children (i.e., ages 3 or 4–8) are generally able to give some degree of self-report, and pain scales in this age group add self-report measures to other parameters. Fear and anxiety in children may complicate pain assessment and, in some cases, either overrate or underrate pain. For this reason, many behavioral scales are taken to be measures of "distress," which combines pain, fear, and anxiety. For example, a 2-year-old child fearful of having a relatively painless ear examination may appear to have extreme pain based on behavioral measures. A 7-year-old child may deny pain because of the fear of having to receive a "shot" if he admits to having pain. Valid and reliable pain measures have been developed for children based on developmental levels reflecting a child's ability to communicate and understand concepts of pain. In general, behavioral measures tend to underrate persistent pain relative to self-report.

Pain assessment in infants, neonates, and premature infants is especially challenging. Previously, infants were not thought to be fully capable of experiencing pain which led in part to inadequate efforts of treating pain in infants. Numerous studies have examined the response of neonates and preterm infants to pain and have shown various response patterns including changes in stress hormones levels, observed behavioral responses, and alterations in heart rate, heart rate variability, oxygen saturation, and other physiologic responses.[2–5] Studies have shown that neonates who are subjected to heel lancing for blood sampling consistently swipe the foot being lanced with the unaffected foot, indicating that neonates have the ability to localize to the site of pain.[6,7] Other data have shown that hospitalized infants display graded responses of heart rate, oxygen saturation, mean arterial pressure, and behavioral state with varying degrees of pain intensity, indicating that infants have the ability to distinguish severity of pain.[8] Pain assessment scales for infants are typically composite pain scores consisting of behavioral parameters such as facial grimacing, posture, and crying combined with more objective data such as heart rate, blood pressure, and oxygen saturation. Pain ratings may be erroneous in critically ill infants, since sepsis, hypotension, respiratory failure, and other conditions will change many of the physiologic and behavioral parameters in composite pain scales. The Crying Requires Oxygen Increased Vital Signs Expres-

DATE/TIME						
Crying – Characteristic cry of pain is high pitched. 0 – No cry or cry that is not high pitched 1 – Cry is high pitched but baby is easily consolable 2 – Cry is high pitched but baby is inconsolable						
Requires O2 for SaO2 < 95% - Babies experiencing pain manifest decreased oxygenation. Consider other causes of hypoxemia, e.g., oversedation, atelectasis, pneumothorax. 0 – No oxygen required 1 - < 30% oxygen required 2 - > 30% oxygen required						
Increased vital signs (BP and HR) – Take BP last as this may awaken child making other assessments difficult. 0 – Both HR and BP unchanged or less than baseline 1 – HR or BP increased but increase in < 20% of baseline 2 – HR or BP is increased > 20% over baseline						
Expression – The facial expression most often associated with pain is a grimace. A grimace may be characterized by brow lowering, eyes squeezed shut, deepening nasolabial furrow, or open lips and mouth. 0 – No grimace present 1 – Grimace alone is present 2 – Grimace and non-cry vocalization grunt is present						
Sleepless – Scored based upon the infant's state. 0 – Child has been continuously asleep 1 – Child has awakened at frequent intervals 2 – Child has been awake constantly

FIGURE 50.1 Crying Requires oxygen Increased vital signs Expression Scale (CRIES).

sion Scale (CRIES) scale and the Premature Infant Pain Profile have been validated for infants and premature infants (Figs. 50.1 and 50.2).[9,10]

Concrete thinking and stages of cognitive and language development of preschool-age children can present difficulties in pain assessment. Many toddlers, when ill, hospitalized, or confronted with strangers, refuse to cooperate with self-report or formal testing of pain. Involving parents or other familiar caregivers in the assessment of pain for toddlers can provide useful information. Studies comparing parents' to clinicians' ratings have sometimes shown good agreement, sometimes shown disparities.[11]

The Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) and the Behavioral Observational Pain Scale (BOPS) have been validated for assessing postoperative pain in toddlers and young children.[12,13] The Face Legs Activity Cry Consolability (FLACC) scale is a very widely used scale involving the five items in the title, each scored from 0–2 to give a composite score ranging from 0–10 (Fig. 50.3).[14] The FLACC scale has become widely used because it is quick, versatile, and its components appears reasonable for a wide range of patient groups, including infants and older patients with developmental disabilities.[14,15]

Several validated self-report pain scores have been developed for children 4 years and older, including photos or drawings of faces where numerical anchors signify gradations of pain and a slide rule device where increasing color intensity indicates increasing pain intensity (Figs. 50.4 and 50.5).[16] Young children are able to differentiate pain intensity when presented with facial expressions, although more than five choices of facial expressions interfere with the child's ability to reliably indicate pain. Most older school-age children and adolescents have the cognitive and emotional maturity to use adult numerical visual analogue scales, nevertheless, pain, illness, hospitalization, and separation from

parents cause some older children and teenagers to regress emotionally, making scales used for younger children, such as faces scale, more applicable. There has been considerable dispute regarding relative merits of different presentations of face-type scales.[14,17–21]

ANALGESIC PHARMACOLOGY IN INFANTS AND CHILDREN

Age-related differences in analgesic pharmacology involve a combination of pharmacokinetic and pharmacodynamic factors. Neonates and young children have delayed maturation of hepatic enzymes involved in the metabolism of analgesics such as opioids and amide local anesthetics, increasing the risk of drug accumulation and toxicity. Most neonates and young infants will have considerable maturation of hepatic enzyme systems involved in biotransformation and conjugation by the age of 6 months, although enzyme maturation rates can vary considerably; examples will be cited below. Neonates and young infants have decreased plasma concentrations of albumin and α-1 acid glycoprotein which leads to decreased protein binding and greater concentrations of unbound, pharmacologically active drug. Neonates also have reduced glomerular filtration rates in the first few weeks of life resulting in slower elimination of many renally excreted drugs and many active metabolites of drugs that have undergone hepatic metabolism. A number of specific age-related differences in pharmacokinetics and in drug actions and risks will be detailed with each drug class below.[22,23]

NONOPIOID ANALGESICS

Nonopioid analgesics refer to aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and selective cyclooxygenase (COX-2) inhibitors. Many of these analgesics were thought of as primarily peripherally active; however, analgesia does occur from a combination of peripheral as well as central actions involving inflammatory processes in the spinal cord and brain, especially involving activation of microglia. Nonopioid analgesics are often first-line drugs used for mild–moderate pain in infants and children since they do not produce respiratory effects and are generally nonsedating.

DATE/TIME						
Face 0 – No particular expression or smile 1 – Occasional grimace or frown, withdrawn, disinterested 2 – Frequent to constant quivering chin, clenched jaw						
Legs 0 – Normal position or relaxed 1 – Uneasy, restless, tense 2 – Kicking or legs drawn up						
Activity 0 – Lying quietly, normal position, moves easily 1 – Squirming, shifting back and forth, tense 2 – Arched, rigid or jerking						
Cry 0 – No cry (awake or asleep) 1 – Moans or whimpers, occasional complaint 2 – Crying steadily, screams or sobs, frequent complaints						
Consolability 0 – Content, relaxed 1 – Reassured by occasional touching, hugging or being talked to, distractable 2 – Difficult to console or comfort

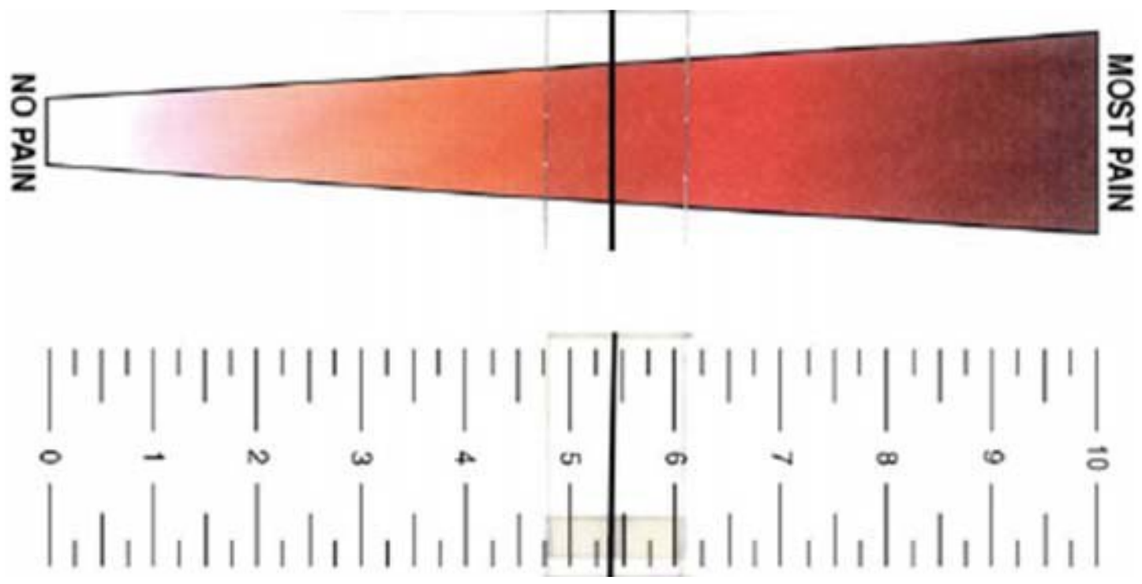

FIGURE 50.5 Color Analogue Scale.

Ontogeny of Prostanoid Biosynthesis and Cyclo-oxygenases

A variety of prostanoids are produced during fetal life, and COX inhibition can alter essential functions, including patency of the ductus arteriosus. Recent studies by Ririe and coworkers[24] in infant rats suggest that COX-mediated processes in spinal microglia are quite immature at birth. These studies raise the question of whether commonly used analgesics acting on COX isoforms might be ineffective in infants due to this delayed maturation of a prominent site of action.

Aspirin and Other Salicylates

The use of aspirin in children has diminished significantly, in part because of its association with Reye Syndrome. The elimination of aspirin is reduced in infants. In our practice, aspirin is almost never prescribed as an analgesic; its use is confined to situations in which antiplatelet actions are required. Nonacetylating salicylates such as choline magnesium salicylate have been used in children with arthritis and other forms of pain. Adult studies indicate that the nonacetylating salicylates are associated with relatively reduced risks of gastropathy and bleeding compared to traditional NSAIDs.[25] Elixir formulations are available.

Acetaminophen

Acetaminophen is the most commonly used analgesic and has been safely used in children of all ages. It is typically used for mild to moderate pain and is commonly combined with opioids to provide additional analgesic effect. The mechanisms underlying acetaminophen's analgesic and antipyretic actions remain controversial. Multiple central targets of acetaminophen's actions have been described, including COX-2 isoenzyme (type 3 as well as type 2) inhibition, on endogenous cannabinoid receptors, and on TRPV1 receptors. Clinically, acetaminophen by itself appears to produce minimal gastropathy, minimal effect on platelet function, and much milder anti-inflammatory actions compared to NSAIDs. Acetaminophen combined with NSAIDs can produce additional analgesic benefits, with synergism in some models, and with potential for exacerbation of some toxicities. For example, in adults chronically receiving NSAIDs, daily administration of higher dose, but not lower dose, acetaminophen increased the relative risk of gastropathy. The elimination of acetaminophen is primarily through glucuronidation and sulfation and elimination rates are similar among infants, children, and adults.[26] Various formulations are available with different concentrations. Inadvertent dosing errors have led to reports of fulminant hepatic failure among infants and children.[27] Typical oral dosing is 10–15 mg/kg/dose. The maximum daily dosing is 40 mg/kg/day for premature infants, 75 mg/kg/day for term infants, and 100mg/kg/day for children. Rectal dosing can be used for children who are unable to tolerate oral dosing, although absorption of rectal dosing can be variable.[28,29] Maximal concentration after rectal dosing occurs at approximately 2–3 hours. Typical rectal dosing is 30–45 mg/kg initially followed by 20 mg/kg every 6 hours.[28,29]

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs are commonly used for mild–moderate pain and for fever control in children. They are often combined with opioids to augment analgesic efficacy and to potentially reduce opioid use and opioid side effects. The use of several NSAIDs in postsurgical patients has been shown to reduce opioid use by approximately 30% to 40%. NSAIDs produce their anti-inflammatory effect by reversibly inhibiting COX-1 and COX-2 isoforms and inhibiting the conversion of arachidonic acid to prostanoids.[30] The clearance of ibuprofen, ketorolac, and several other NSAIDs is more rapid in toddlers and preschool children compared to adults.[31]

Based on epidemiologic studies and pooled data from clinical trials, NSAIDs have a generally good safety margin in children and in infants from roughly age 6 months onward, particularly with short-term use. The incidence of side effects is quite low in children receiving NSAIDs for postoperative pain relief. A large scale study in children administered short-term use of ibuprofen showed a very low overall risk of severe side effects.[32] The risks of renal and hepatic toxicities are increased in states of decreased renal and hepatic blood flow such as with significant surgical blood loss. There are limited safety data on the use of NSAIDs among neonates and young infants. Indomethacin has been used for closure of patent ductus arteriosis in neonates. Elimination of indomethacin is slower in neonates and has the associated risk of hyponatremia and renal toxicity in this age group.[33] Much of the safety data for long-term use of NSAIDs in children is based on experience in treating juvenile rheumatoid arthritis (JRA.) Long-term use is associated with a higher incidence of mild gastrointestinal distress but significant gastropathy and gastrointestinal bleeding in children is less common when compared to adults.

Although NSAIDs inhibit platelet aggregation and can prolong bleeding time, clinically significant bleeding is uncommon in healthy children. The use of NSAIDS after tonsillectomy procedures remains somewhat controversial. Children requiring tonsillectomy often have obstructive sleep apnea and are at increased risk of hypoventilation and apnea with opioids, making nonopioid analgesics an attractive alternative. Nausea and vomiting are also common after tonsillectomy, and opioids exacerbate these problems. Life-threatening bleeding can occur after tonsillectomy in the immediate postoperative period and for approximately 7–10 days after the patient has been discharged from the hospital. Most individual clinical trials are not sufficiently large to achieve sufficient statistical power to address this risk.[34]

Two meta-analyses came to different conclusions. One found no significant increase in bleeding, while the other reported a three-fold increase in bleeding episodes of sufficient severity to require reoperation.[35,36] While NSAIDs are widely used following tonsillectomy in many centers worldwide, the prevailing practice at this institution is to avoid them before and after this operation.

An additional concern with NSAID use is impaired bone healing after orthopaedic surgeries that involve osteoclast activation and new bone formation. In vitro studies, animal models, and some case-control studies in adults suggest a higher incidence of impaired bone healing and nonunion with NSAID use.

However, compared to adults, children are less likely to have impairment of bone formation with similar orthopaedic procedures. For surgeries requiring a high degree of active bone formation, our view is that it is generally reasonable to avoid NSAIDs. For surgeries with lower risk of nonunion, or for selected patients with greater than average risks or side effects from opioids, judicious use of NSAIDs for brief time periods may be considered.

Selective COX-2 inhibitors were developed with the advantage of a lower incidence of gastrointestinal symptoms and slightly decreased effect on platelet function in randomized control trials in adult patients compared to traditional NSAIDs. The risk of nephropathy with selective COX-2 inhibitors is similar to that of traditional NSAIDs.[37] Anti-inflammatory and analgesic effects of COX-2 inhibitors are also similar to those of traditional NSAIDs. COX-2 inhibitors have been associated with cardiovascular complications in adults with both short-term and long-term use. Rofecoxib and valdecoxib have been withdrawn from the market in response to these reports of cardiovascular complica-

Further modifications in dosing are required for use of these agents in term and preterm neonates and in infants. Modifications are detailed in the text.

tions in adults. The cardiovascular risk of COX-2 inhibitors in infants and children remains unclear. The use of COX-2 inhibitors may be considered in children with JRA who experience good analgesia with traditional NSAIDs, but who have significant gastrointestinal symptoms, or in children with bleeding disorders, such as hemophilia, to achieve analgesia with less risk of bleeding than with traditional NSAIDs. Surprisingly, two trials of COX-2 inhibitors for analgesia after tonsillectomy were disappointing. One study found better analgesia with ibuprofen compared to placebo.[38] Some studies suggest that COX-2 inhibitors might be less likely to interfere with active bone formation. Please see Table 50.2 for dosing guidelines of common nonopioid analgesics.

OPIOIDS

Opioids are among the most widely used of analgesics for treating moderate to severe pain in infants and children. As with adults, they are extremely useful, but require careful patient selection, titrated dosing, and active treatment of side effects.

Ontogeny of Opioid Actions

The ontogeny of opioid actions has been studied in human clinical trials, in case series, and in a number of infant animal models. Infant animal models have provided useful information, though there are marked differences among species in opioid actions. Age-related differences in analgesia and side effects involve pharmacokinetics as well as pharmacodynamics. As previously discussed, opioids (except for remifentanil) have prolonged actions in neonates and infants due to immature hepatic enzyme systems and immature renal excretion of active metabolites. Effects of hepatic and renal dysfunction on opioid clearance are discussed in a separate section below. Additional factors that influence opioid pharmacokinetics include developmental changes in expression of P-glycoproteins both in the gastrointestinal tract and in the blood–brain barrier and changes in protein binding.

Pharmacodynamic studies of opioids in neonates and younger infants have examined analgesia and side effects, with a major emphasis on measures of respiratory depression. These studies are made difficult by a number of factors, including the imprecision inherent in observational pain measures in neonates, on the state-dependence of behavioral responses, on the confounding effects of critical illness on measures, and on the variability of painful stimuli. Major sites of opioid actions, including the periaqueductal grey matter and descending pathways, containing the dorsilateral funiculus, appear immature in infant rats. Conversely, opioids administered systemically or via the epidural route show strong analgesic responses in infant rats at developmental stages corresponding to preterm neonates. In human studies, opioids have given mixed results in studies of procedural pain in neonates, and studies randomly assigning ventilated neonates to receive morphine infusions versus placebo infusions (with both groups receiving morphine for painful procedures) have not shown clear advantages in the morphine infusion groups.[39,40]

Children who are at particular risk for respiratory depressant effects of opioids include those with tonsillar hypertrophy associated with obstructive sleep apnea, children with certain neurologic conditions, and children with craniofacial abnormalities as well as neonates and young infants. Neonates and infants, particularly premature infants, have an increased risk of apnea and hypoventilation in response to opioids on a pharmacodynamic as well as pharmacokinetic basis. Careful dosing, cardiorespiratory monitoring, and close nursing observation are warranted for neonates and younger infants receiving opioids.

Codeine

Codeine is an opioid typically used orally to treat mild–moderate pain; it is available as an elixir and in pill form. For reasons to be detailed below, our opinion is that codeine is in general a suboptimal choice as an analgesic in children in most settings.[41] Codeine is essentially a prodrug: it is extensively metabolized in the liver and a portion of it is demethylated to morphine, which accounts for the analgesic effect.[42] A study of children undergoing surgery receiving a fairly large dose of codeine found that roughly one third of the subjects generated undetectable blood concentrations of morphine, which would result in no discernible analgesic effect. Conversely, there are genotypes associated with ultrarapid metabolism of codeine to morphine; in these subjects, standard recommended codeine doses can produce apnea. Standard dosing is 0.5–1 mg/kg every 4 hours. Dose escalation beyond this range appears to generate a higher incidence of side effects, particularly nausea and vomiting. In standard doses, codeine is a very weak analgesic. Studies in adult patients comparing efficacy of codeine to ibuprofen have shown that 30–45 mg codeine has less analgesic effect than 600 mg of ibuprofen. Because of the relatively high incidence of the impaired inability to demethylate codeine and the higher incidence of side effects, other oral opioids such as oxycodone, morphine, hydromorphone, and hydrocodone are preferred to codeine, especially in patients with moderate–severe pain. Intramuscular codeine has the double disadvantage of being a weak and inconsistent analgesic delivered by a noxious route.

Codeine is often dispensed in combination with acetaminophen to increase efficacy. When prescribing codeine combined with acetaminophen, care is required to avoid inadvertent administration of toxic doses of acetaminophen, particularly when increased dosages are prescribed for pain or when patients

are taking other over-the-counter preparations containing acetaminophen. Codeine is also used commonly prescribed as an antitussive.

Oxycodone

Oxycodone can be used for moderate pain in doses of 0.05–0.1 mg/kg every 4 hours and for moderate to severe pain in starting doses of 0.1–0.2 mg/kg every 4 hours. Although historically prescribed in smaller doses, oxycodone dosing can be escalated as needed much like any of the so-called "strong opioids." Oxycodone is generally well-tolerated by children either alone or in combination with acetaminophen. Our impression is that it is associated with fewer side effects than codeine when used to treat moderate–severe pain. Oxycodone is metabolized in the liver to oxymorphone, which is metabolically active.[43] Since oxymorphone is renally eliminated, it can accumulate in patients with renal failure. Oxycodone is commonly used in children postoperatively when transitioning from parenteral opioids to oral opioids in preparation for discharge.

A sustained-release preparation of oxycodone is available for use in the treatment of chronic pain. It has a bioavailability of approximately 60% and reaches peak analgesic effect after 60–90 minutes. Sustained-release oxycodone was originally marketed as a long-acting opioid that would avoid the stigma and addiction potential of other long-duration opioids, such as sustained-release morphine or methadone. Oxycodone is no longer devoid of such stigma, and diversion for abuse has been a major public health issue in the United States.[44]

Morphine

Morphine is often the first-line opioid chosen for parenteral use in children. It has a long track record in pediatrics, has received extensive pharmacologic study at all age groups, is inexpensive, and can be administered via oral, sublingual, intravenous, subcutaneous, rectal, and neuraxial routes.

The duration of morphine's clinical effects are related in a complex manner to distribution into and out of the central nervous system, hepatic metabolism, and excretion of active metabolites, including morphine-6-glucuronide. Morphine primarily undergoes glucuronidation in the liver to morphine-3-glucuronide, which has predominantly excitatory actions, and morphine-6-glucuronide, which has analgesic, sedative, and respiratory depressant actions similar to that of morphine. Since morphine-6-glucuronide is renally eliminated, it can accumulate in patients with renal failure, producing delayed sedation and hypoventilation. In addition, accumulation of morphine-3-glucuronide can contribute to delirium, agitation, and seizures. Other opioids such as fentanyl and methadone should be considered for patients with severely reduced glomerular filtration rate or renal failure. The elimination half-life of morphine in older children and adults is approximately 3–4 hours. The elimination half-life is approximately 7 hours in full-term newborns and even longer in premature infants. Long-acting preparations of morphine are typically used for children with sickle cell pain, cancer pain, and other types of chronic pain.

Dosing of morphine in children, as with all opioids, should be titrated to effect and individualized based on severity of pain, underlying medical conditions, age, side effects, and weight. See Table 50.3 for dosing guidelines for oral and parenteral morphine.

Hydromorphone

Hydromorphone is a commonly used opioid for acute pain management in children for both parenteral and oral use. Like morphine, it is used in children for patient-controlled analgesia (PCA), continuous infusions, oral dosing, intermittent intravenous boluses, and epidural analgesia. Hydromorphone can provide effective analgesia in children with cancer pain and mucositis. In steady-state dosing, hydromorphone is 5–6 times more potent than morphine when given intravenously in children.[45]

While hydromorphone is commonly prescribed to patients with renal insufficiency, this practice is not evidence-based. Hydromorphone is metabolized to glucuronides that can also accumulate in patients with renal insufficiency. Information on metabolism of hydromorphone in neonates and young infants is very sparse.

Methadone

Methadone is a long-acting opioid with a slow elimination and prolonged duration of analgesia.[46,47] The elimination half-life is highly variable, ranging from 6–30 hours. Methadone has a high oral bioavailability of 70% to 100%. Due to these unique properties, methadone is convenient to use as a prolonged duration opioid. Intermittent intravenous dosing at prolonged intervals (e.g., every 4, 6, or 8 hours) can provide a basal level of analgesia similar to that achieved by continuous infusions or frequent intravenous boluses of other opioids.[48]

Methadone is available as an elixir and is often used in place of sustained-release opioid preparations to treat chronic pain in young children or in children unable to swallow pills. Conversely, methadone requires careful titration and vigilance to avoid overdosage, both because of extreme pharmacokinetic variability and for pharmacodynamic reasons detailed below.

Methadone is prepared as a racemic mixture of l- and d-isomers. The l-isomer acts as a μ-receptor agonist; the d-isomer acts as an antagonist at the *N*-methyl-D-aspartate (NMDA) receptors in the brain and spinal cord. Antagonism at the NMDA receptors results in analgesia and reduced hyperalgesia, as well as partially reversing tolerance to opioids.[49]

The NMDA antagonism of methadone is also a rationale for its use in the treatment of neuropathic pain. The combined μ-agonist and NMDA antagonist actions of methadone result in incomplete cross tolerance. Thus, the dose conversion ratios between methadone and morphine and other mu opioids are different for opioid-naïve versus opioid-tolerant patients. For opioid-naïve patients, the average daily intravenous methadone requirement is roughly one third of the corresponding intravenous morphine requirement; however, average daily methadone requirements for opioid-tolerant patients may be as little as 10% to15% of the total daily morphine dosing.[50] This is particularly relevant when converting morphine to methadone for children with advanced cancer and when weaning nonventilated infants and children following prolonged opioid therapy, especially following intensive care. Careful titration and frequent patient assessment for respiratory depression is warranted in dosing methadone. For patients showing signs of oversedation or respiratory depression, it is often necessary to hold multiple doses of methadone because of its prolonged duration of action. For opioid-naïve patients, methadone has been used in our practice for acute, postoperative pain management as an every 4 hour "sliding scale" where, following initial loading doses, dosing for little/no pain is 0.025 mg/kg, dosing for moderate pain is 0.05 mg/kg, and dosing for severe pain is 0.075 mg/kg. After the first 24 hours of "sliding scale" dosing, patients can be typically transitioned to a more regular dosing schedule. For adults, there is a very convenient website that rapidly permits equipotent conversions among opioids via multiple routes of administration, with allowances for degrees of opioid tolerance.[51] It remains to be studied whether these conversion ratios are reasonable guides for dosing conversion in children.[52]

TABLE 50.3

INITIAL DOSING GUIDELINES FOR OPIOIDS

Drug	Equianalgesic Doses and Intervals		Parenteral Dosing		Ratio	Oral Dosing	
			Usual Starting Intravenous or Subcutaneous Doses			Usual Starting Oral Doses and Intervals	
	Parenteral	Oral	Child <50 kg	Child >50kg		Child <50kg	Child >50kg
Codeine	120 mg	200 mg	NR	NR	1:2	0.5–1.0 mg/kg every 3–4 h	30–60 mg every 3–4 h
Morphine	10 mg	30 mg (long-term) 60 mg (single dose)	Bolus: 0.1 mg/kg every 2–4 h Infusion: 0.03 mg/kg/h	Bolus: 5–8 mg every 2–4 h Infusion: 1.5 mg/hr	1:3 (long-term) 1:6 (single dose)	Immediate release: 0.3 mg/kg every 3–4 h Sustained release: 20–35 kg, 10–15 mg every 8–12h; 35–50 kg, 15–30 mg every 8–12 h	Immediate release: 15–20 mg every 3–4 h Sustained release: 30–45 mg every 8–12 h

NA, not applicable; NR, not recommended.
Doses are for patients over 6 months of age. In infants under 6 months, initial per kilogram doses should begin at roughly 25% of the per kilogram doses recommended here. Higher doses are often required for patients receiving mechanical ventilation. All doses are approximate and should be adjusted according to clinical circumstances. Recommendations are adapted from previous summary tables, including those of a consensus statement from the World Health Organization and the International Association for the Study of Pain.
*Methadone requires additional vigilance because it can accumulate and produce delayed sedation. If sedation occurs, doses should be withheld until sedation resolves. Thereafter, doses should be substantially reduced, the interval between doses should be extended to 3 to 12 hours, or both.
†The use of meperidine should generally be avoided if other opioids are available, especially with long-term use, because its metabolite can cause seizures.
Adapted from Berder CB, Sethna NF. Analgesics for the treatment of pain in children. *N Engl J Med* 2002;347(14):1094–1103.

Fentanyl

Fentanyl has a rapid onset and brief duration of action after single-dose administration, and it is often used for brief painful procedures in children such as lumbar punctures, bone marrow aspirations, fracture reductions, and dressing changes. Fentanyl is also used for PCA in children with acute and chronic pain and in highly selected situations as a transdermal patch for children with chronic pain.

Fentanyl primarily undergoes glucuronidation in the liver to inactive metabolites, making it a preferred opioid for patients with renal or liver failure. Fentanyl is 50–100 times more potent than morphine with single-dose administration and roughly 30–50 times more potent with continuous infusions. The action of fentanyl after single-dose administration is terminated by rapid redistribution; however, after prolonged infusion or repeated boluses, the termination of fentanyl effect is determined more by elimination than redistribution and results in a prolonged duration of action. Continuous infusions or repeated boluses in neonates can cause a particularly prolonged effect. Rapid administration is associated with glottic and chest wall rigidity, which can be especially pronounced in neonates and young infants. Neuromuscular blockade and assisted ventilation are usually necessary for treatment, particularly in neonates and young infants. Naloxone may sometimes be effective in reversing fentanyl-induced rigidity, but this action is not reliable.

For brief painful procedures, incremental doses of fentanyl at 0.5–1 mcg/kg every 1–3 minutes usually provide effective analgesia. Cardiorespiratory monitoring and immediate availability of airway equipment and personnel skilled in airway management are necessary. Oral transmucosal fentanyl has also been used for brief painful procedures in children and for breakthrough cancer pain. The oral transmucosal dose is partially absorbed across the buccal mucosa and partially swallowed; overall, the bioavailability is approximately 50%. It is generally well-tolerated by children although almost 90% of children experience facial pruritus. Additionally, the peak analgesic effect after a standard 15–20 mcg/kg dose is 30–45 minutes, which may be limiting for some procedures. Transdermal fentanyl is used in children with cancer pain and other forms of chronic pain requiring regular opioid dosing. It is indicated in a small subgroup of children who are unable to swallow pills, who have limited intravenous access, or for children who have experienced side effects with a number of other opioids. Approximately 12–24 hours are necessary to achieve steady state plasma levels after applying the transdermal fentanyl patch, and it is therefore not indicated for acute fluctuations in pain intensity. Additional short-acting opioids are necessary to treat breakthrough pain. Transdermal fentanyl is indicated for opioid-tolerant patients who have relatively constant pain. Adverse events have been reported among opioid-naïve patients who were treated with transdermal fentanyl for acute postsurgical pain. There has been a series of manufacturing problems that have led to inconsistent delivery for some batches of transdermal fentanyl. We emphasize here that transdermal fentanyl is not recommended for opioid-naïve patients.[53]

Meperidine

Meperidine is a synthetic opioid roughly one tenth the potency of morphine when administered intravenously. It has some anticholinergic actions as well. It is metabolized to normeperidine which can cause seizures, hallucinations, and agitation, particularly with repeated dosing. Metabolism in infants is quite variable.[54] Life-threatening reactions can occur with the use of meperidine in patients taking monoamineoxidase inhibitors, leading to hyper-reflexia, seizures, hemodynamic instability, and death.

Meperidine does have the unique property in subanalgesic doses of treating rigors associated with blood product transfusions or shivering following general anesthesia. Because of the serious adverse effects of meperidine and because it offers no particular advantage for pain control, its use should generally be limited to the treatment of rigors or shivering.

OPIOID ADMINISTRATION IN INFANTS AND CHILDREN

As in adult patients, there are several means for systemic opioid delivery in pediatric patients. The choice of which method depends to a certain extent on available resources, coexisting medical conditions, types of pain, patients' mobility, and other factors.

Regardless of method of opioid delivery, protocols for safe opioid administration should be in place to detect excess sedation, signs of respiratory depression, and impending respiratory failure. Protocols should include regular nursing assessments, documentation of vital signs and levels sedation, and, where appropriate, use of electronic cardiorespiratory monitoring. Patients who should be considered for cardiorespiratory monitoring include infants who are younger than 6 months, infants who have a history of apnea and bradycardia or prematurity, and opioid-naïve children who require a continuous opioid infusion. Children at increased risk for airway obstruction while receiving opioids such as those with tonsillar hypertrophy and obstructive sleep apnea or children with craniofacial abnormalities should also be considered for cardiorespiratory monitoring. There is considerable variation in practices regarding methods to detect and prevent opioid-induced respiratory depression. Many recommendations are based on reasonable extrapolation from physiologic considerations. Nevertheless, evidence to quantify the risk reduction from specific forms of monitoring is quite sparse.

Intermittent Intravenous Bolus Dosing

In clinical care areas other than the intensive care units or the postanesthesia care units, in our institution, most intermittent bolus dosing of opioids are administered as an infusion over 20 minutes rather than "intravenous push." Although a slow administration is thought of as a somewhat safer method of intermittent dosing, careful monitoring and repeated patient assessments remain important during and after the opioid infusion. Intermittent systemic boluses cause wide fluctuations in plasma opioids concentrations. Patients therefore experience probably few side effects but increased pain just prior to their next bolus opioid dose. After the dose is administered, patients experience pain relief often with excessive side effects as the plasma–opioid concentration reaches supratherapeutic levels. To avoid wide variations in plasma concentrations with resultant fluctuations in analgesia and side effects, continuous infusions and PCA are commonly used.

Continuous Opioid Infusions

Continuous opioid infusions offer the advantage of providing steady state plasma levels and results in good analgesia in infants and children who experience relatively constant levels of pain intensity. Additional intermittent boluses are necessary for periods of increased pain, such as endotracheal tube suctioning or chest physiotherapy. Recommended starting infusion rates have been adjusted for age, based on both pharmacokinetic considerations, on studies of respiratory responses, and on clinical outcome

studies. Starting infusion rates for morphine have been recommended as around 0.025 mg/kg/hour for children and infants >6 months of age, with reductions to 0.015 mg/kg/hour from 1–6 months, ranging down to 0.005 mg/kg/hour for preterm neonates at 32 weeks postconception. These recommendations should be taken as population averages; individual rates should be adjusted according to clinical conditions, expected intensity of painful stimuli, and behavioral and physiologic signs.

Patient, Nurse, and Parent-Controlled Analgesia

PCA is widely used among pediatric centers for variety of acute painful conditions such as cancer pain, sickle cell pain from vaso-occlusive crises, and acute postoperative pain. Most children 6 years of age and older have the cognitive ability to understand cause and effect relationships of pushing the PCA button and obtaining pain relief. In rare cases, experienced children younger than 6 who have had long-standing pain are able to use PCA. For most children younger than 6 years, PCA has a higher failure rate, in part because of a lack of development of understanding of a causal connection between button-pressing and delivery of medication to provide pain relief. However, nurse-controlled analgesia (NCA) has been shown to provide effective analgesia with good patient, parent, and caregiver satisfaction in younger children. NCA is also used for children with cognitive and physical limitations who are unable to use the PCA.[55–57] In our hospital, NCA is the most common method of systemic opioid administration following major surgery in infants and in children with cognitive or physical limitations to self-administration.

Commonly used opioids for PCA/NCA are morphine, hydromorphone, and fentanyl. Use of a basal infusion along with PCA boluses has been a subject of controversy and some controlled studies in adults and children. In some studies, a basal infusion improves pain scores, patient satisfaction, and the quality of nighttime sleep. In other studies, a basal infusion increased surrogate measures of hypoventilation, including brief respiratory pauses. Our view is that the recommendations regarding addition of a basal infusion depend on patient medical conditions and risk factors, on psychologic factors, on expected intensity of painful stimuli, and on history of previous opioid use. For example, we commonly omit a basal infusion for children who have received a regional block intraoperatively, for children with increased respiratory risks, or for those undergoing surgical procedures expected to be only moderately, but not severely, painful. Conversely, we generally include a basal infusion for patients who are opioid tolerant or those with pain due to cancer or sickle cell disease, and in these subjects we generally aim to adjust the basal infusion to provide at least 50% of daily opioid requirements. For those undergoing very painful operations, such as scoliosis surgery, open lateral thoracotomy, or major hip surgery, we generally maintain a basal infusion at least through the first postoperative night.

Parent-controlled analgesia is widely accepted for use among children with advanced cancer or children in palliative care. However, use in the setting of acute postoperative pain or opioid-naïve children is controversial. There have been several serious adverse events reported, including apnea and death with the use of parent-controlled analgesia in children with risk factors and with insufficient protocols for patient observation. Our view is that parent-controlled analgesia for opioid-naïve children should be restricted to institutions which have formal programs for parent education, protocols for frequent assessments by nurses, and protocols for cardio-respiratory monitoring. Please see Table 50.4 for PCA dosing.

TABLE 50.4

TYPICAL STARTING DOSES FOR PATIENT-CONTROLLED ANALGESIA

Drug	Bolus dose (μg/kg)	Continuous rate (μg/kg/h)	4-hour limit (μg/kg)
Morphine	20	4–15	300
Hydromorphone	5	1–3	60
Fentanyl	0.25	0.15	4

The usual lockout interval is 7 minutes.

Treatment of Opioid Side Effects

Opioids are alike in that all produce side effects including nausea, vomiting, constipation, pruritus, urinary retention, respiratory depression, and sedation. In some cases, severe side effects are as distressing to children as pain. Although children may have particular side effects with individual opioids, there are few data to suggest that side effects differ greatly among the more commonly used opioids.

Kehlet[58] and others have argued for multimodal approaches to postoperative analgesia that emphasize opioid-sparing, in part because of the detrimental impact of opioid side effects on the course of postoperative recovery.

There is an important role for standardized protocols for treatment of opioid side effects and for rapid institution of therapy for many patients. Nevertheless, along with prompt intervention, there is a role for clinical assessment and for consideration of a differential diagnosis. Two examples: (1) a patient may be itching due to opioids, but could also have itching as part of an allergic response to a variety of other medications or physiologic processes, and (2) a patient with advanced cancer, worsening back pain, and increasing opioid dosing may have urinary retention due to the opioid, but urinary retention could also be a harbinger of impending compression of the spinal cord or caudal equina. Clinicians need to balance prompt intervention with consideration of alternative diagnoses underlying these symptoms.

Opioid side effects occur by actions at both peripheral and central sites. For example, opioid-induced nausea and vomiting involves activation of receptors in the brainstem, as well as in the gastrointestinal tract.[59] Similarly, some opioids may produce itching by peripheral histamine release, but the observation of profound itching with very small doses of intrathecal morphine supports the view that a predominant mechanism of opioid-induced itching is neurogenic and central, involving an imbalance of afferent signaling and neurotransmission in the spinal dorsal horn and nucleus caudalis.

Traditionally, treatment of opioid side effects has emphasized antagonists at nonopioid-receptors such as the use of antagonists of dopamine or serotonin receptors for treatment of nausea and vomiting or use of antihistamines for treatment of itching. These drugs may generate their own side effects, including extra pyramidal reactions from dopamine antagonists (phenothiazines, butyrophenones, metoclopramide), headache from serotonin antagonists (ondansetron, granisetron), and sedation, constipation, and urinary retention from antihistamines (diphenhydramine, hydroxyzine). Extra pyramidal reactions from dopamine antagonists may be prophylaxed or treated with antihistamines or central muscarinic anticholinergics, though prophylactic coadministration of antihistamines further complicates management In our experience, extrapyramidal reactions may be misdiagnosed by some clinicians as seizures. Even among patients who do not have overt extrapyramidal signs, occasional patients report extreme

dysphoria following administration of these agents. Dopamine antagonists and serotonin antagonists are partially effective in treatment of opioid-induced nausea and vomiting, but the numbers-needed-to-treat are higher than commonly believed by clinicians. The evidence for effectiveness of antihistamines in the treatment of opioid-induced itching is quite weak.[60] Local hives or itching at a site of opioid injection does not imply an allergic response.

There is a growing body of evidence supporting treating opioid side-effects, especially nausea, vomiting, and itching, at least in inpatients postoperatively, by ultra-low dose infusions of opioid antagonists such as naloxone.[61] Low dose naloxone infusions are not simply reversing opioid actions altogether, rather they are exploiting a differential dose response for reversing side effects versus reversing analgesia, in part due to differential binding to opioid receptors coupled to G-stimulatory versus G-inhibitory proteins. We could not identify studies that would guide low dose naloxone infusions for side effect treatment in highly opioid-tolerant patients, though a preliminary report in patients with sickle cell disease suggested that a slightly higher naloxone infusion rate of 1 mcg/kg/hour might be recommended.[62] Nalbuphine is widely used for treatment of opioid-induced itching and nausea, though one pediatric study showed no benefit compared to placebo.[63]

A related approach is to design opioid antagonists that are constrained to different body compartments. Methylnaltrexone is a quaternized opioid antagonist that has access to the area postrema (which lacks a blood brain barrier), but which is excluded from prominent sites of central analgesic action, such as the periaqueductal grey matter. Alvimopan is an enterally constrained opioid antagonist that blocks opioid actions in the gastrointestinal tract, with minimal uptake in the portal vein and efficient first-pass hepatic clearance of the small quantities that do reach the liver. Available evidence suggests that these two approaches hold promise for more effective treatment of opioid side effects, including nausea, vomiting, constipation, and other forms of postoperative gastrointestinal dysfunction. Pediatric studies are unavailable.

Constipation is commonly seen in patients requiring opioids even for short-term use. It is such a prevalent side effect of opioids that one should consider a proactive approach of prescribing laxatives for patients expected to require more than just few doses of opioids. Please see Table 50.5 for management of common opioid side effects in children.

Local Anesthetics and Regional Anesthesia in Infants and Children

Local anesthetics are widely used for a range of indications in infants and children, including topical analgesia for needle procedures, cutaneous infiltration for minor procedures, wound infiltration for surgery, peripheral and plexus blocks, and epidural and spinal anesthesia and analgesia. Work over the past 30 years has examined pharmacokinetics, safety, and clinical outcomes of local anesthesia in infants and children.

Pharmacokinetic information is available for many of the commonly used local anesthetics. Amino amides, including lidocaine, bupivacaine, and ropivacaine, have reduced clearance in neonates and younger infants due to immaturity of hepatic metabolism. In the case of lidocaine, the predominant hepatic metabolite, MEGX, can accumulate in neonates, with a resultant risk of seizures. The amino ester chloroprocaine is rapidly metabo-

TABLE 50.5

MANAGEMENT OF COMMON OPIOID SIDE EFFECTS

Side effect	Comments	Drug dosage
Nausea	Consider switching to different opioid Use antimetics Exclude other processes (e.g., bowel obstruction)	Ondansetron 10–30 kg: 1–2 mg intravenously q 8 h >30 kg: 2–4 mg intravenously q 8 h Naloxone infusion 0.25–1 mcg/kg/h Metoclopramide 0.1–0.2 mg/kg PO/intravenously q 6 h
Pruritus	Exclude other causes (e.g., drug allergy) Consider switching to different opioid Use antipruritics	Nalbuphine 10–20 mg/kg/dose intravenously q 6 h Naloxone infusion 0.25–1 mcg/kg/h Diphenhydramine 0.25–0.5 mg/kg PO/intravenously q 6h
Sedation	Add nonsedating analgesic (e.g., ketorolac) and reduce opioid dose Consider switching to different opioid	Methylphenidate 0.05–0.2 mg/kg PO bid (morning and midday dosing) Dextroamphetamine 5–10 mg every day
Constipation	Regular use of stimulant and stool softener laxatives	Naloxone infusion 0.25–1 mcg/kg/h Ducosate Child: 10–40 mg PO daily Adults: 50–200 mg PO daily Dulcolax Child: 5 mg PO/PR daily Adult: 10 mg PO/PR daily Methylnaltrexone, alvimopam dosing is extrapolated from adults

bid, twice a day; PO, orally; PR, rectally; q, every

lized by plasma esterases even in neonates and may be useful if prolonged infusions are required in neonates.[64]

Cutaneous Analgesia

Needle procedures are a prominent source of distress for infants and children. A number of local anesthetic formulations can produce good analgesia for superficial needle procedures. Several approaches can accelerate transfer across the skin, including eutectic mixtures, heating elements, iontophoresis, and jet injection. Selection among approaches may depend in part on local availability, cost, desired onset time, and impact of vasodilatation or vasoconstriction on the planned procedures.[65,66]

Wound Infiltration

Infiltration of the layers of surgical wounds is a simple approach to providing postoperative analgesia. This may be accomplished by one-time infiltration before wound closure or by placement of wound catheters for prolonged infusions of local anesthetics. With single injection of currently available local anesthetics, duration of analgesia is rarely longer than 4–6 hours. (Disclaimer: one of the authors [CBB] conducts research on the development of prolonged-duration local anesthetics.)

EPIDURAL ANALGESIA IN INFANTS AND CHILDREN

Epidural analgesia has widespread use in infants and children for postoperative pain management, and can be considered in selected cases for children with cancer pain, and for certain chronic pain conditions such as complex regional pain syndrome. While epidural infusions can provide outstanding analgesia for children, they require specific expertise both in the techniques of placement and in management, and in our view they should not be undertaken without a system of pediatric-specific management protocols.

A unique difference between adults and children concerns the fact that most pediatric regional anesthesia, including epidural analgesia, is performed after induction of general anesthesia or sedation, since many children will not tolerate having some needle procedures while awake. While the safety track record of placement of epidural needles and catheters has been good in several published pediatric case series, there remains some controversy regarding the risk-benefit ratio.[67–69]

Placing a lumbar epidural catheter in an anesthetized child is generally considered to be safe among experienced pediatric anesthesia providers. There is more controversy over direct needle placement of thoracic epidurals in anesthetized children, particularly in infants. As an alternative to direct thoracic needle placement in infants, a common technique is to advance an epidural catheter from the caudal space to the desired surgical dermatome. Several studies have shown success in placing thoracic epidural catheters in infants using this technique.[70] Since neonates and infants have an increased risk of amide local anesthetic toxicity, proper placement of the epidural catheter tip is crucial in order to provide optimal analgesia while using safe local anesthetic infusion rates.

For anesthetized patients who are receiving direct thoracic placement or for cephalad advancement of catheters to thoracic levels from the caudal route, our own strong personal preference is to encourage some method of objective confirmation of positioning whenever possible. Three methods can be used in different situations: (1) electrical nerve stimulation using Tsui's technique,[71](2) radiographic confirmation, especially using fluoroscopy, and (3) ultrasound. Confirming the location of intended caudal-to-thoracic epidural catheter tip placement is strongly recommended since failure rates as high as 30% have been reported using a "blind" technique. As described by Tsui,[71] electrical stimulation employs a saline-filled, wire-wrapped catheter, with twitches seen at the myotomal level of the catheter tip in a current range generally between 2 and 15 mA. This technique also confirms that a catheter is not subarachnoid (in which case, bilateral twitches in a broad distribution are seen at a current $<$0.5–1 mA) and not threaded out from a nerve root foramen (in which case unilateral twitches in a narrow distribution may be seen at a current $<$1.5 mA). In brief, as catheters are advanced cephalad, one sees the following progression of twitches: ankle dorsi- or plantar-flexion (lumbosacral junction), knee extension (midlumbar), hip flexion (upper lumbar), abdominal or flank muscle contractions without hip flexion (thoracic above T12), intercostal muscle contractions (midthoracic), and hand twitches (around C8–T1).

Our experience with combined use of nerve stimulation and fluoroscopy also suggests that Tsui's[71] method gives a reasonable prediction of sidedness. If we are placing an epidural for one-sided surgery (e.g., hip osteotomy or lateral thoracotomy), we are comfortable with bilateral twitches, or preferentially ipsilateral twitches, but our practice is to reposition the catheter if the twitches are predominantly wrong-sided. Studies in adults and our own experience suggest that sidedness matters to clinical effectiveness.[72]

Confirming location of the epidural catheter tip in infants can be accomplished by obtaining a chest radiograph after injecting a small volume of radiocontrast dye or through the use of a radiopaque epidural catheter which can easily be seen on plain chest radiograph or fluoroscopy. An additional method of confirming epidural catheter tip location is to advance the catheter from the caudal space under direct visualization using fluoroscopy.

Ultrasound guidance can be used in guiding and confirming placement of epidural catheters in neonates and younger infants, though this technique requires two operators and significant experience in ultrasound techniques. Neuraxial structures, such as ligamentum flavum, dura, and epidural space, as well as depth from skin to epidural space, can be clearly visualized using ultrasound, in part because of incomplete ossification of the vertebrae in neonates and younger infants.[73]

In clinical areas outside of the operating room, it is sometimes necessary to check position of an epidural catheter when patients appear to be uncomfortable despite generally adequate rates of continuous epidural infusions. This can be particularly challenging in infants and preverbal patients. One method is to inject a small volume of approximately 0.5 mL of radiocontrast dye into the epidural catheter which then can be detected on plain radiograph. Another method that we use frequently in our institution is a "chloroprocaine test" as detailed below.

Drugs and Drug Dosing Used for Epidural Analgesia

Continuous epidural analgesia in infants and children generally consists of dilute solutions of local anesthetics combined with fentanyl, hydromorphone, or α2 agonists such as clonidine.

Bupivacaine is the most commonly used amide local anesthetic for epidural analgesia because it has long duration of action with slightly greater selectivity of sensory block compared to motor block. Pharmacokinetic studies of bupivacaine in children over the age of 6 months have reported good safety for infusion rates of bupivacaine of below 0.4 mg/kg/hour with plasma bupivacaine levels in a safe range of $<$2–3 μg/mL.[74] Neonates have reduced clearance of bupivacaine; pharmacokinetic studies in neonates

receiving continuous bupivacaine infusions have shown a continuous rise in plasma bupivacaine levels after the first 48 hours.

As a result of various pharmacokinetic studies, we use a maximum dose of 0.4 mg/kg/hour of bupivacaine for continuous epidural infusions in children over the age of 6 months. For children less than 4–6 months of age, we restrict the dose of bupivacaine to 0.2 mg/kg/hour. Because of the limitations in dosing of bupivacaine in young infants, it is reasonable to use adjuvants to epidural infusions which will have a synergistic effect with bupivacaine such as opioids and clonidine in order to maximize analgesia.

Ropivacaine is a long-acting amide local anesthetic shown in adults to have less central nervous system and cardiac toxicity and slightly more sensory selectivity when compared to bupivacaine. Pharmacokinetic studies in infants and children receiving single boluses of epidural ropivacaine show that as with bupivacaine, clearances for ropivacaine are reduced in infants. In different studies, clearances for ropivacaine have ranged from around 4–8.5 mL • min-1 • kg-1 with generally lower values in younger infants. Data to support a less extensive motor block for ropivacaine have been mixed. Overall, infusion rates of 0.4 mg/kg/hour in older infants and children and 0.2–0.3 mg/kg/hour in neonates and younger infants appear quite safe. It is plausible that slightly higher rates than these will be shown to be safe as well.[75–77]

Chloroprocaine is used as an alternative to amide local anesthetics for continuous epidural infusions in neonates and very young infants to avoid the limitations of reduced clearance of amide local anesthetics and to safely permit sufficient epidural infusion rates for optimal analgesia. Even in neonates, chloroprocaine is rapidly metabolized with an elimination half-life of less than 6 minutes, making it an attractive choice for continuous epidural infusions in neonates. Studies of continuous epidural chloroprocaine infusions in term and preterm infants have shown good sensory blockade with no signs of neurotoxicity.[64]

Compared to infusions of ropivacaine or bupivacaine, higher weight-scaled infusion rates of chloroprocaine are required to achieve similar degrees of blockade. For preterm and term infants, we use 1.5% chloroprocaine infused at around 0.5 mL/kg/hour for midthoracic epidural catheters and 0.6–0.7 mL/kg/hour for lumbar and lower thoracic catheters. Even for neonates, our preference is to include additives in most of these infusions, but at roughly a ten-fold lower concentration compared to those recommended above for infusions used for older children with bupivacaine or ropivacaine. For example, fentanyl is often included at a concentration of 0.2 mcg/mL and clonidine is often included at a concentration of 0.04 mcg/mL.

We also use chloroprocaine to test previously placed epidural catheters as a second loading dose. The rationale for using chloroprocaine rather than lidocaine or other amide local anesthetics for a second loading dose is based on the concern that since most patients will have had intraoperative infusions of amide local anesthetics, additional amide local anesthetics as a bolus test dose may cause serum amide local anesthetic levels to reach toxic levels. Injecting approximately 0.5 mL/kg of 3% chloroprocaine (up to a maximum total dose of around 18 mLs for patients >50 kg) incrementally into the epidural catheter should result in some evidence of sensory and motor block, thereby confirming position of the catheter in the epidural space. If the patient is tachycardic or hypertensive due to pain, then these parameters generally trend more toward normal values within 5–10 minutes if the catheter is in an epidural location, and the patient shows behavioral signs of improved analgesia. Once proper position of the epidural catheter has been confirmed, then good analgesia should be able to be obtained through the use of appropriate epidural solutions and infusion rates. In many cases, if the chloroprocaine test shows epidural positioning, a next step would be to give a small loading dose of epidural hydromorphone (e.g., about 5 mcg/kg), followed by addition of hydromorphone to the subsequent epidural infusion. Because of its hydrophilicity and cephalad spread, hydromorphone can help rescue a situation in which the catheter tip is at a level below the dermatomal level of the surgery.

Neuraxially-administered opioids have a synergistic analgesic effect when combined with local anesthetics. Due to the hydrophilic property of hydromorphone, there is a slight preference to using hydromorphone for postoperative analgesia for more extensive surgical procedures involving several dermatomes. However, due to more rostral spread of hydromorphone, the risk of respiratory depression is greater, and generally we restrict the use of epidural hydromorphone to infants over the age of 4 months, or to younger infants with considerable degrees of opioid tolerance. Fentanyl and hydromorphone are most commonly used for epidural analgesia since epidural morphine offers no particular advantage but may be associated with higher incidence of side effects. All neuraxially-administered opioids can cause side effects including nausea, vomiting, urinary retention, pruritus, sedation, respiratory depression, and constipation. The incidence of vomiting in patients receiving epidural fentanyl has been reported to be between 28% and 52% depending on the population studied and concentration of epidural fentanyl. Nausea, vomiting, and other side effects from epidural opioids are treated much in the same way that side effects from parenteral opioids are treated. Low-dose naloxone infusions significantly reduce opioid side effects without reversing opioid-induced analgesia; the recommended starting dose for naloxone in treating opioids-induced nausea or pruritus is 0.25 μg/kg/hour, though higher naloxone infusion rates are currently under study.

Clonidine is often added to epidural local anesthetic infusions to enhance analgesia without increasing nausea, vomiting, pruritus, or respiratory depression. Studies of combinations of epidural clonidine with local anesthetics in children have shown a low side effect profile.[78]

Controlled trials of single doses of clonidine administered caudally with bupivacaine have showed variable prolongation of analgesia by approximately 50% to 75% than epidural bupivacaine alone. Pharmacokinetic studies of single-dose epidural clonidine in children show wide variation in plasma concentration as well as wide variation in the time for clonidine absorption from the epidural space. Increasing a single dose of epidural clonidine from 1–5 μg/kg with local anesthetics to local anesthetics alone in children 1 year of age and older showed variable prolongation of analgesia, greater sedation without respiratory depression, and reductions in heart rate and blood pressure which were not clinically significant. Other studies have not shown significant prolongation of single-shot caudal analgesia with clonidine doses as high as 2 mcg/kg.[79]

While some clinicians perform single-shot caudal blocks routinely with clonidine doses in the range of 2 mcg/kg, our view is that this dose frequently results in prolonged sedation, especially if other sedatives or systemic opioids are administered as well. Our practice for children 1 year of age and older is to use 0.5–1 μg/kg, to a maximum of 15 μg as a single-bolus for caudal blocks and roughly 0.12–0.16 μg/kg/hour (0.3–0.4 mL/kg/hour of a solution containing 0.4 mcg/mL) added to continuous epidural local anesthetic infusions (except for neonates, where lower doses and concentrations are used, as noted above). Please see Table 50.6 for recommended doses for epidural infusions.

PERIPHERAL NERVE BLOCKS IN CHILDREN

Peripheral nerve blocks (PNB) provide reliable and safe postoperative pain management. A report by the French Language Society of Pediatric Anesthesiologists showed that among 24,000 regional blocks in children, the complication rate for PNB was 0 in 1000.[68]

In a retrospective review of 339 continuous PNBs in children

TABLE 50.6

RECOMMENDED EPIDURAL INFUSION RATES

Solution	(mL/kg/hr)* <1 month	1–4 months	>4 months †

*Infusion rates and solutions should be modified according to clinical circumstances. Little information is available on how best to adjust these rates based on degrees of prematurity.
Rates shown reflect upper end of usual infusion rates, based largely on both systemic accumulation of local anesthetics and on expected extent of sensory and/or motor blockade. Solutions containing hydrophilic opioids such as hydromorphone may pose a higher risk for delayed respiratory depression, so appropriate frequency of observation and continuous electronic monitoring is recommended. Higher concentrations of opioids may be considered for selected patients who are opioid tolerant.
†Weight scaled infusion rates should plateau at values recommended for patients weighing around 45 kg, such as maximum infusion rates for larger patients should rarely exceed 15 mL/hr.

over a 4 year period, no major adverse events were noted. Forty-five percent had minor adverse events; most commonly catheter leakage or dislodgement and nausea and vomiting. Two patients were noted to have fever and local inflammatory signs, however culture of the catheter was negative for both patients. Only 1.6% reported failure of pain relief. A general trend in clinical trials of PNB is the observation of very good analgesia with a very low side effect profile that compares favorably to either systemic opioids or epidural infusions. In a randomized trial comparing popliteal block versus epidural analgesia for foot and ankle surgery, popliteal block resulted in superior analgesia with reduced incidences of nausea, vomiting, and urinary retention.[80]

The use of ultrasound has been shown in some studies to increase the duration of analgesia with reduced volumes of local anesthetic solutions.[81] Advantages of ultrasound guidance include direct visualization of nerves and other structures such as arteries which may reduce the likelihood of intraneural or intravascular injection and direct visualization of local anesthetic spread. Combining the use of ultrasound with peripheral nerve stimulation is sometimes used when advancing catheters for continuous use to further confirm catheter placement. The addition of clonidine to PNBs in children has been shown to significantly increase duration of sensory blockade by approximately 4 hours; however, the incidence of motor blockade was also significantly increased.[82]

Like epidural anesthesia, the placement of PNB may require general anesthesia or deep sedation for most younger children. Motivated older children and adolescents will often require only minimal sedation; it is often helpful to apply a topical anesthetic to the anticipated needle insertion site to minimize pain from needle insertion. Indications for using peripheral nerve blocks as the sole anesthetic technique include risk of malignant hyperthermia, risk of postoperative apnea, and patient preference.

Recommendations regarding dosing of local anesthetics for PNB in children vary among authors. Where immediate onset is required, one group has recommended 0.5 cc/kg of a mixture of 1% lidocaine with 1:200,000 epinephrine and 0.5% ropivacaine. Several groups employ continuous perineural infusions with 0.1–0.15 mL/kg/hour of ropivacaine in a concentration range between 0.1% to 0.2%.

Supraclavicular

A supraclavicular block is applicable to all surgeries of the upper extremity excluding shoulder surgery. A continuous catheter technique is often used in the treatment of complex regional pain syndrome in children. Supraclavicular block has been successfully used as the sole anesthetic for children younger than 12 years of age undergoing closed reduction of arm fractures.[83] (Using 1.5% lidocaine with epinephrine, the mean time to sensory blockade was 2.3 minutes with duration of block 3.5 hours).

The trunks of the brachial plexus are located between the anterior and medial scalene muscles in the interscalene groove. Using ultrasound guidance, the first rib and subclavian artery should be located, with the pleura located just beneath the first rib. The anterior and middle scalene muscles are then located as they insert onto the first rib cephalad to the subclavian artery. The brachial plexus is located between the anterior and middle scalene muscles and superficial and lateral to the subclavian artery. Under direct ultrasound visualization, the needle is inserted from a lateral to medial direction toward the plexus, with particular attention to avoiding directing the needle medial to the anterior scalene muscles or caudally beneath the first rib to prevent pneumothorax. Only a single injection is required due to the close proximity of the trunks of the plexus in this region. If using a continuous catheter technique, we typically recommend tunnelling supraclavicular catheters, particularly for patients requiring

aggressive postoperative physical therapy and for catheters of longer duration such as in the treatment of complex regional pain syndrome.

Infraclavicular

Infraclavicular block is indicated for all distal upper extremity surgeries such as syndactyly repair and repairs of open forearm fractures. In the infraclavicular region, the plexus is located posterior to the pectoralis major and minor. The cords of the brachial plexus are located medial, lateral, and posterior to the axillary artery. Under direct ultrasound visualization with the ultrasound probe medial and caudal to the coracoid process, the pectoralis muscles and the axillary artery and vein should be identified. The axillary vein is located caudal to the axillary artery. The needle is inserted under direct ultrasound visualization and advanced laterally; once the sheath surrounding the plexus is reached, spread of local anesthetic should be visualized spreading to the cords of the plexus.

Sciatic Nerve Block

The sciatic nerve block is useful in providing analgesia for a variety of surgical procedures of the of lower leg or foot, for painful physical therapy following surgery, and for treatment of complex regional pain syndrome affecting the lower leg or foot. One study showed excellent pain relief and excellent rehabilitation with no adverse events using a continuous infusion of 0.2% ropivacaine at 0.1 mL/kg/hour for 96 hours.[84]

In the study of foot and ankle surgery by Dadure et al.,[84] the children with continuous popliteal nerve blocks received a continuous infusion of 0.2% ropivacaine at 0.1 cc/kg/hour and a 100% satisfaction rate was reported.

Studies in adult patients comparing continuous sciatic nerve block with PCA have shown superior analgesia, reduced morphine use, and reduced frequency of nausea, vomiting, and sedation for adult patients with continuous popliteal sciatic catheters. Two commonly used approaches for sciatic nerve block in children are the subgluteal approach and the popliteal approach. A single-injection technique is indicated after relatively minor surgery when postoperative pain is expected to be mild and of short duration. A continuous catheter technique will provide prolonged analgesia after more extensive surgical procedures.

Sciatic-Subgluteal Approach

Since patients will need to be positioned in the prone position for a subgluteal approach to a sciatic nerve block, younger children will require general anesthesia for placement. Cooperative older children and adolescents can often tolerate the procedure in a prone procedure with sedation. The technique described below uses ultrasound guidance with peripheral nerve stimulation for further confirmation. With the patient in a prone position, ultrasound is used to locate the sciatic nerve; a line marking the midpoint between the ischial tuberosity and the greater trochanter can be useful in estimating position of the sciatic nerve. Under visualization, an insulated 17-gauge stimulating needle is advanced approximately 1–2 cm below the midpoint mark and is directed medially and superiorly. Initially, twitching of the gluteal muscles can be observed but will disappear as the needle advances further. Dorsi- and plantar-flexion of the foot is observed with stimulation of the sciatic nerve. A 20-gauge stimulating catheter is advanced approximately 3 cm beyond the tip of the needle; angling the needle slightly caudally may facilitate advancing the catheter. Further nerve stimulation of the catheter confirms proper catheter placement.[85]

Popliteal Approach

Block of the sciatic nerve can also be achieved at the level of the popliteal fossa. The sciatic nerve divides into the tibial and common peroneal nerves in the popliteal fossa, proximal to the popliteal fossa crease. For this block, patients can be positioned either prone or supine with the hip and knee flexed. Our general preference is to use the prone approach when catheter placement is being considered, since it makes it easier to maintain sterility and to perform tunneling of the catheter. Ultrasound is used to locate the structures in the popliteal fossa; the popliteal artery and vein are located deep and proximal to the sciatic nerve. The course of the sciatic nerve should be seen and the point at which the sciatic nerve bifurcates should be located. The tendon of the biceps femoris is located laterally and the tendons of the semimembranosus and semitendinosus muscles are located medially. Ultrasound viewing and needle advancement can be performed using several approaches, including an in-plane approach, with the needle advancing in a lateral-to-medial direction, or an out of plane approach, with the needle advancing in a sagittal direction. Injection of local anesthetic should show local anesthetic spread around the tibial and common peroneal nerves.[81]

A multiple regression model estimated that the depth of needle insertion (mm) to reach the sciatic nerve in the popliteal fossa in children was -0.86 height (cm) $+$ 1.60 weight (kg) $+26$ with a minimal distance of 13 mm.[86] For catheter placement, ultrasound can be used alone or in combination with stimulating needles and catheters. An 18-gauge insulated stimulating needle can be advanced under ultrasound to the sciatic nerve. Muscle twitching of the toes or foot movement confirms proper needle placement. A 20-gauge stimulating catheter is then advanced approximately 3–5 cm beyond the needle. Stimulation of the catheter should reconfirm proper placement.

Femoral Block

A femoral nerve block provides effective analgesia for knee surgery, for surgery on the anterior thigh such as a muscle biopsy, and for femur surgery or fractures. It will also provide analgesia to the medial lower extremity below the knee by blocking the saphenous nerve. Compared to PCA morphine and epidural analgesia, continuous femoral nerve block provides more effective analgesia with fewer side effects. Results indicate that using ultrasound guidance produced prolonged duration of sensory blockade with less volume of local anesthetic compared to using nerve stimulation. The typical landmarks for a femoral nerve block are the inguinal crease and the femoral arterial pulse. The femoral nerve is located lateral and deep to the femoral artery as it courses below the inguinal ligament. With the patient positioned in a supine position, ultrasound is used to locate the position of the femoral vein, artery, and nerve in the inguinal crease. Under ultrasound visualization, an insulated block needle is inserted just lateral to the arterial pulse and directed slightly cephalad. Proper placement of the needle should be seen on ultrasound, positioned *alongside* the femoral nerve. Nerve stimulation is an alternative method to confirm proper placement of the needle. With proper needle placement, twitching of the quadriceps and patella should be seen. Quadriceps movement alone without signs of patellar movement is due to stimulation of the sartorious muscle and does not confirm proper needle placement. If the femoral nerve is not readily located, it will be necessary to redirect the needle slightly laterally. When placing a catheter for continuous femoral block, the needle is angled slightly more cephalad and the catheter is advanced. If using nerve stimulation, twitching of the quadriceps and patella will indicate correct catheter placement. Infection rates for continuous femoral catheters appear to be low when used for short-term use. In a study examining bacterial coloniza-

tion and infection rates in continuous femoral catheters, 57% of catheters had positive bacterial colonization with staphylococcus epidermis as the most common organism. However, there were no septic complications or serious infections for catheters in place for 48 hours.[87]

PAINFUL CONDITIONS IN PEDIATRIC HOSPITAL CARE

Cancer Pain

Infants and children with cancer experience pain from cancer treatment such as painful mucositis, postamputation pain, and peripheral neuropathies as well as from tumor spread causing bone pain, neuropathic pain, or headaches from raised intracranial pressure. Repeated painful needles procedures such as bone marrow biopsies and lumbar punctures are a great source of pain and distress. Several surveys have shown that as successful chemotherapeutic protocols, radiation therapy, and surgical techniques have advanced, cancer treatment and painful procedures account for greater sources of cancer pain in infants and children.

Frequent diagnostic and painful procedures are common for infants and children with cancer. For minor needle procedures, such as intravenous line insertions and assessing implanted vascular access ports, topical analgesia should be routinely used. A number of approaches to cutaneous analgesia have been used, including local anesthetic creams or patches, with or without physical methods to accelerate transit of drug across the stratum corneum. Cognitive–behavioral interventions such as hypnosis and other relaxation techniques have also been shown to be effective for procedural pain. Children can also apply these techniques to nausea, headaches, and other symptoms. Conscious sedation or general anesthesia is typically used for more invasive needle procedures such as bone marrow biopsies and lumbar punctures. Safe sedation protocols have been developed by the American Academy of Pediatrics and are widely used by pediatric oncologists and other pediatric subspecialists for procedural sedation. Pediatric anesthesiologists are consulted for patients with risk factors that place them at increased risk for conscious sedation, for patients who fail conscious sedation, or for more invasive procedures such as central line insertions. Brief general anesthesia is typically used for children who require daily radiation therapy. There is ongoing controversy regarding choice of drugs and safety practices for sedation by nonanesthesiologists.

Mucositis is a common side effect in children receiving chemotherapy or radiation; it is especially severe and prolonged with bone marrow transplantation. Initially, pain from mucositis is often treated with topical agents although evidence for efficacy in the prevention and treatment of mucositis has been mixed. Opioids are used for pain that persists despite topical agents. Data supports the safety and efficacy of opioid infusions and PCA for the treatment of mucositis.[55,88] Since many children with mucositis will require opioids for weeks, our practice is to eventually administer approximately 60% of the total daily opioid dose as a basal rate in order to provide sustained analgesia. NCA is used for young children.

Although a majority of children have resolution of the cancer pain after initial chemotherapy induction protocols, some children will continue to experience visceral, somatic, and neuropathic pain due to tumor invasion of solid organs, bone, nerves, and plexuses. Opioids are provided by the oral route whenever feasible. It is common practice to use a long-acting opioid, either methadone elixir or tablets or capsules of a sustained-release preparation of morphine, hydromorphone, or oxycodone, along with short-acting opioids for rescue or breakthrough pain. Currently, methadone is the most widely available long-acting opioid available as an elixir formulation. Several sustained-release opioids are available as capsules containing microbeads. Although they are recommended for use in adults sprinkled specifically on apple sauce immediately prior to use, the package inserts recommend against this use in children. If the microbeads are chewed, crushed, or left in contact with liquids for extended periods of time, they release their contents, negating the sustained-release feature and giving the potential for overdosage. Some patients with rapidly escalating pain or patients unable to tolerate oral opioids may require opioids via parenteral routes, including intravenous and subcutaneous routes. Continuous infusions and PCA or NCA allow rapid titration for escalating pain. In the setting of neuropathic cancer pain, we frequently prescribe anticonvulsants and antidepressants, largely by extrapolation from adult practice. Fatigue, somnolence, sleep disturbance, and depressed mood are a commonly overlapping group of symptoms in children with advanced cancer. Opioids and other sedating medications may contribute to these symptoms, but they may exist even in children not receiving opioids or sedatives. Along with treating specific or remediable causes of these symptoms, our common practice, again extrapolated from adult clinical trials, is to consider a trial of a stimulant such as methylphenidate.

A subgroup of children with cancer pain will have persistent pain despite massive dose escalation. Many of these children will have unremitting neuropathic pain associated with tumor extension to the epidural space, onto a plexus, or along the course of major nerves. One approach to persistent pain in this setting is to add a low-dose ketamine infusion. At rates below 0.2 mg/kg/hour, dysphoria and dissociation are relatively uncommon.[89]

Oral ketamine has been used as well, with a provisional dose ratio of about 3:1 compared to intravenous dosing in steady state. In selected cases of refractory pain, our practice is to use regional anesthetic techniques, and we most commonly in this setting favor implanted intrathecal ports with the catheter generally advanced to the dorsal horn level appropriate to the patient's location of greatest pain.[90] Note that for tumors predominantly in the pelvis, lumbar spine, or lower extremities, this implies having the catheter tip advanced up to around T11. The choice of drugs for these infusions must be individualized, based on the nature of the patient's pain, and quality of life issues, including considerations of weakness, bowel and bladder dysfunction, sedation, etc. In the majority of cases, we have found it necessary to include small doses of local anesthetics along with opioids, and in some cases we have included other additives such as clonidine or ketamine. There is a small subgroup of children for whom it appears that the most feasible option for achieving relief of pain, distress, or terminal dyspnea is to provide sedation using a range of agents, including benzodiazepines, barbiturates, or other drugs.[91]

The principle of double-effect is widely cited in discussions of opioid administration in palliative care. As noted by Quill, Dresser, and Brock,[92] there are some conceptual and practical difficulties in the application of this principle for opioid titration in palliative care; these difficulties become even greater in the use of sedatives in end-of-life care. An alternative view, favored by these authors, concerns an emphasis on patient autonomy and choice in decision-making.[92]

Central principles in treating cancer pain in children includes basing decision-making on consideration of patients' and their families' goals and hopes, collaborative care, emphasis on frequent pain assessments, individualized drug dosing, and proactive treatment of opioid side effects.

Children with Developmental Disabilities

Children with cognitive and developmental disabilities such as cerebral palsy and neurodegenerative disorders present unique challenges in assessing and managing pain. Many children with disabilities experience daily pain associated with muscle spasms, hip dislocation, and other musculoskeletal pains and undergo

frequent painful invasive procedures such as scoliosis repair, tendon releases, and surgical treatment of gastroesophageal reflux. Children may have little or no cognitive deficits but significant motor and communication impairments, making pain assessment especially difficult. Often, parents and caretakers are able to distinguish subtle behavioral signs indicating pain. A number of pain assessment tools such as FLACC tool, and the Noncommunicating Children's Pain Checklist have been used for children with cognitive and developmental disabilities. In comparing several pain assessment tools for children with cognitive limitations, physicians and nurses rated the FLACC as having higher clinical utility.[17,93]

Other children with severe cognitive impairment will have persistent agitation and screaming without a clear etiology and are admitted to the hospital for diagnostic evaluation and therapeutic trials. Patients should be evaluated for treatable causes of pain such as fractures, hip dislocations, esophagitis, and constipation. In some cases where no underlying cause can be eventually identified, therapeutic trials of anticonvulsants and antispasmodics may provide relief.[94]

Pain Associated with Sickle Cell Vaso-Occlusive Episodes

Pain is a common consequence of sickle cell disease due to acute vaso-occlusive episodes as well as pain from compression fractures, avascular necrosis, acute cholecystitis, splenic sequestration, and stroke. Painful vaso-occlusive episodes are the most common cause of pain in children with sickle cell disease and can occur in children as young as 6 months of age as fetal hemoglobin and its protection against vaso-occlusive crises decreases. Children can demonstrate a range of severity and frequency of vaso-occlusive episodes, from occasional episodes managed at home with oral analgesics to baseline daily pain with frequent exacerbations requiring numerous hospitalizations and systemic opioids administration. PCA is commonly used for severe pain in hospitalized patients, along with NSAIDs. Larger opioid boluses may be necessary than are typically used for postoperative pain management for patients with extreme pain or for patients who are opioid tolerant. Often, basal infusions are necessary, particularly at night to permit periods of uninterrupted sleep. Published case series indicate that even with generous PCA parameters, pain scores remain high for a high percentage of patients.[95]

CONCLUSION

Evidence is available to support safe and effective treatment of acute pain in infants, children, and adolescents in a majority of circumstances. Analgesic pharmacology has received extensive study in pediatrics over the past 25 years. Individual analgesics often provide incomplete relief in standard doses, and there is a rationale for analgesic combinations and multimodal analgesia in many situations. Opioids can provide good analgesia at all ages, but with a spectrum of side effects that require active treatment and with specific requirements for observation and monitoring according to age and patient condition-related risk factors. Techniques have been developed for neuraxial and peripheral regional anesthesia at all ages. There is a growing emphasis on ultrasound, nerve stimulation, selective use of fluoroscopy, and other approaches to provide objective confirmation of needle and/or catheter positioning. Pediatric acute pain management, whether by an acute pain service or by other delivery models, can be improved by system-wide approaches that emphasize systematic assessment of pain and other symptoms, communication, clinician education, clarification of responsibilities, and protocols for analgesic administration, side effect management, and monitoring.

CHAPTER 51 ■ ACUTE PAIN IN ADULTS

ROBERT W. HURLEY, STEVEN P. COHEN, AND CHRISTOPHER L. WU

INTRODUCTION

Acute pain is the normal and predicable neurophysiologic response to noxious mechanical, thermal, or chemical stimuli; is generally time-limited; and resolves with the cessation of the noxious stimuli. The etiology, more often than not, is known or understood. It is typically associated with invasive procedures, trauma, or medical diseases. The pain sensation is usually limited to the area of trauma or damage or the area that immediately surrounds it. Perhaps most importantly, the painful sensations associated with such an injury are expected to resolve over time when adequate wound healing has occurred. In contrast, chronic pain persists beyond either the course of an acute injury or illness or its expected time for healing and repair. Acute pain states can then be further divided by duration, etiology, mechanism, intensity, and/or symptoms. In this chapter, acute pain will be discussed using postsurgical or postprocedural and posttraumatic pain as models.

A revolution in the management of acute pain has occurred over the past few decades. Widespread recognition of the undertreatment of acute pain by clinicians, economists, and health policy experts has led to the development of a national clinical practice guideline for acute pain management by the Agency for Healthcare Quality and Research (formerly the Agency for Health Care Policy and Research) of the U. S. Department of Health and Human Services. This landmark document includes acknowledgment of the historic inadequacies in perioperative pain management, importance of good pain control, need for accountability for adequate provision of perioperative analgesia by health care institutions, and a statement on the need for involvement of specialists in appropriate cases. In addition, several professional societies, including the American Society of Anesthesiologists,[1,2] and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), have developed clinical practice guidelines for acute pain management or provided new pain management standards.

With their knowledge of and familiarity with pharmacology, various regional techniques, and the neurobiology of nociception, perioperative physicians such as anesthesiologists are continually on the forefront of clinical and research advances in acute pain, especially acute postoperative pain management. Anesthesiologists have traditionally been leaders in the development of acute postoperative pain services, application of evidence-based practice to acute postoperative pain, and creation of innovative approaches to acute pain management. However, the treatment of acute pain (including postprocedural pain) needs to involve a multidisciplinary approach similar to that which has evolved in the treatment of chronic pain. The physical and psychosocial effects of acute pain, though time-limited by definition, remain a significant morbidity that can affect patients' quality of recovery.

ACUTE AND CHRONIC EFFECTS OF ACUTE PAIN

Uncontrolled acute pain may produce a range of detrimental acute and chronic effects. Attenuation of periprocedural pathophysiology that occurs during a procedure or surgery through reduction of nociceptive input into the central nervous system (CNS) and optimization of periprocedural analgesia may decrease complications and facilitate the patient's recovery during the immediate postprocedural period[3] and after discharge from the hospital.

The perioperative period is associated with a variety of pathophysiological responses that may be initiated or maintained by peripheral nociceptive input. Although these responses may have had a beneficial purpose in nature, the same response to the modern day surgery may actually be harmful. Uncontrolled perioperative pain may therefore be considered a major morbidity for the patient. Furthermore, attenuation of postprocedural or acute medical pain may decrease perioperative morbidity and mortality.[4]

The transmission of pain stimuli from the periphery to the spinal cord and supraspinally results in the neuroendocrine stress response. The dominant neuroendocrine response to pain involves hypothalamic–pituitary–adrenocortical and sympathoadrenal interaction, resulting in increased sympathetic tone, increased catecholamine and catabolic hormone secretion including cortisol, adrenocorticotropic hormone, antidiuretic hormone, glucagon, aldosterone, renin, angiotensin II; and decreased secretion of anabolic hormones. The outcome of these changes includes sodium and water retention and increased levels of blood glucose, free fatty acids, ketone bodies, and lactate. A hypermetabolic, catabolic state results as metabolism and oxygen consumption are increased, and metabolic substrates are mobilized from storage depots. The negative nitrogen balance and protein catabolism may impede the patient's recovery and contribute to morbidity or mortality. Sympathetic activation may increase myocardial oxygen consumption and decrease myocardial oxygen supply, which may be important in the development of myocardial ischemia and infarction.[4,5] Sympathetic activation may also delay return of postprocedural gastrointestinal motility that may develop into an ileus.

Postprocedural acute pain may initiate several detrimental spinal reflex pathways. Respiratory function can be markedly diminished, especially with acute pain involving the upper abdomen, flank, and/or thorax. Reflex inhibition of phrenic nerve activity is an important component of this decreased pulmonary function.[4,5] However, control of acute pain is also important, because patients with poor pain control may have poor inspiratory effort, have an inadequate cough, and be more likely to develop pulmonary complications.[4]

NEUROBIOLOGY OF ACUTE PAIN

The neurobiology of pain is extremely complex, with redundancy and plasticity such that there is no "final common pathway" for the process of nociception. However, understanding the neurobiology of pain is crucial when contemplating which nociceptive processes to target in the treatment of acute pain. Identification of new molecular and cellular processes involved in the process

of nociception has increased the number of potential targets for analgesic therapies.

Primary Afferents and Peripheral Nerve Neurotransmitters

A variety of mechanical, thermal, or chemical stimuli can result in the sensation of pain. Information about these painful or noxious stimuli is carried to higher brain centers by receptors and neurons that are distinct from those that carry innocuous somatic sensory information. This topic will be covered at length in Chapters 3 and 4. In brief, small diameter Aδ and C fibers primarily transmit nociceptive information, but subsets of Aδ and C fibers are thermo receptors that transmit nonpainful cold and warm information, respectively.[6] Neurotransmission by the Aδ and C fibers is performed by numerous peptides and amino acids. Substance P (SP) was the first peptide to be defined as specific to the small diameter primary afferents and is released by noxious thermal, mechanical, and chemical stimulation of the periphery.[7–9] Exogenous application of SP into the spinal cord of rats results in dorsal horn neuronal activation[10] and behavioral responses consistent with pain.[11] Neurokinin-1 (NK-1), the receptor for SP, is found on superficial and deep neurons in the dorsal horn of the spinal cord consistent with their role in pain transmission.[12] Other peptides present in the small diameter afferents include calcitonin growth-related protein (CGRP), galanin, vasoactive intestinal polypeptide (VIP) and somatostatin (SST); however, their role in the modulation of nociceptive transmission is less well understood. In addition to these peptides, the excitatory amino acid glutamate is also present within small diameter primary afferents, released by noxious stimulation[13] and activates the second order dorsal horn neurons.[14] The effects of glutamate are predominantly mediated by three receptor classes: alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/Kainate, N-methyl-D-aspartate (NMDA), and metabotropic glutamate receptors (mGluR). AMPA receptors are found on postsynaptic neurons predominantly within the superficial dorsal horn.[15] NMDA receptors are found both pre- and postsynaptically (i.e., on nociceptive primary afferents and apposing second order neurons within the superficial and deep dorsal horn).[16] Metabotropic GluR receptors are predominantly found postsynaptically on the cell body and dendrites of dorsal horns neurons.

The primary afferent's presynaptic nerve terminal in the dorsal horn of the spinal cord represents a site for a therapeutic intervention. Primary afferent fibers transmit the pain signal to the spinal cord and possess numerous receptor systems that can reduce this transmission by reducing transmitter release such as the alpha$_2$-adrenergic, glycinergic, serotoninergic, opioidergic, and GABAergic receptors[17–19] as well as ion channels sensitive to local anesthetics and anticonvulsants including voltage gated calcium, sodium, and potassium channels.

Spinal Cord and Supraspinal Structures

Aδ and C fiber neurons synapse primarily within Lamina I, II, and V of the dorsal horn of the spinal cord. These primary afferents release neurotransmitters and neuropeptides that activate the second order projection neurons of the spinal cord. Pain transmission through the spinal cord may be modulated by an endogenous descending pain inhibitory system and may be influenced by exogenously administered medications. The primary components of this descending pain inhibition system is the "triad" of the periaqueductal gray (PAG), the rostral ventromedial medulla (RVM), and the dorsal lateral pontine tegmentum (DLPT), which includes the locus coeruleus (LC) and the A7 nuclei. The PAG is an important site for the production of analgesia following systemic administration of opioids. The endogenous opioid [Met^5]-enkephalin is present within this nucleus[20] and opioid receptors of each subtype are present in this region.[21] The PAG provides dense projections to the RVM[22] and brainstem noradrenergic nuclei LC and A7.[23] Although each of these regions has direct projections to the spinal cord, it has been proposed that their projections to the RVM are important components in the modulation of pain by these regions.[24] The RVM can function as a relay nucleus in the production of antinociception by more rostral midbrain structures (PAG), but it also has a primary role in the suppression of nociceptive transmission at the level of the spinal cord. The suppression of nociceptive reflex behavior is thought to be mediated by the axons of RVM neurons that descend within the dorsolateral funiculus and terminate bilaterally in laminae I, II, V, VI, and VII of the spinal cord. Anatomical studies have shown these axons terminate coincident with spinothalamic tract cells and interneurons of the dorsal horn that are related to pain transmission.[25,26] Consistent with the anatomical terminations of the RVM axons, physiological studies have shown that stimulation of the RVM results in the inhibition of a population of pain-specific neurons within the dorsal horn.[27,28] Spinally projecting neurons of the RVM possess numerous neurotransmitters including serotonin, enkephalin, GABA, glutamate, and substance P.[29–31] The DLPT contains all of the noradrenergic neurons that project to the RVM and the spinal cord.[32,33] In animal models, electrical stimulation of the DLPT sites produces analgesia[34,35] and the analgesia produced by the activation of these nuclei is mediated by the alpha$_2$ adrenergic receptor.[35,36] The pain physician can pharmacologically manipulate each of these neurotransmitter systems to modulate pain transmission throughout the central nervous system.

PREVENTION

Preemptive Analgesia

The development of central and/or peripheral sensitization after traumatic injury or surgical incision can result in the amplification of acute pain. Preventing the establishment of altered central processing by analgesic treatment may, in the short term, result in the reduction of postprocedural or traumatic pain and accelerated recovery. In the long term, the benefits may include a reduction in the development of chronic pain and an improvement in the patient's quality of recovery and satisfaction. Although experimental animal studies convincingly confirm the ability of preemptive and preventative analgesia to decrease postinjury pain, the results of clinical trials are mixed.[37–39]

The precise definition of preemptive versus preventative analgesia is one of the major controversies in this area of medicine and contributes to the question of whether preemptive analgesia is clinically relevant. Definitions of "preemptive analgesia" include 1) any attempt to give medications prior to surgical incision, 2) administration of medications during the intraoperative or intraprocedural period, or 3) administration of medications during the intraoperative and postoperative period.[40] The first two definitions are relatively narrow and may contribute to the lack of a detectable effect of preemptive analgesia in clinical trials. For the purpose of this text, preemptive analgesia is defined as an analgesic intervention started before the noxious stimulus arises in order to block peripheral and central pain transmission. "Preventative analgesia" most closely resembles the third definition and encompasses an attempt to block pain transmission prior to the injury (incision), during the noxious insult (surgery itself) and following the injury and throughout the recovery period. Unfortunately, few trials have examined the concept of preventative analgesia in a rigorous fashion. Preemptive analgesia abiding by the first one of the above three definitions have been loosely examined. Although some argue that the timing of the intervention[37–39] may not be as clinically important as other aspects of preemptive analgesia including intensity and duration of the intervention, this notion may be based on semantic confusion or poor study design. For example, an intervention administered

before surgical incision is not necessarily preemptive if it is incomplete or insufficient such that the development of peripheral or central sensitization would not be prevented. Incisional and inflammatory injuries are important in initiating and maintaining both peripheral and central sensitization. Confining the definition of preemptive analgesia to only the immediately preoperative or intraoperative (incisional) period may not be clinically relevant or appropriate because the inflammatory response may last well into the postoperative period and continue to maintain this sensitization. Other methodological and study design issues also may complicate the question of whether preemptive analgesia is clinically relevant. A variety of agents and techniques[37–39] have been used to study preemptive analgesia. Using the broader definition of preemptive analgesia termed preventative analgesia that covers the preoperative, the intraoperative and postoperative periods, the combination of experimental data and positive clinical trials strongly suggests that preventative analgesia is a clinically relevant phenomenon. Furthermore, it has been suggested that simple preoperative therapy such as the inclusion of a single dose of the anticonvulsant, gabapentin, can reduce postoperative pain and opioid use with minimal side effects in a number of different surgeries.[41] Maximal clinical benefit is observed when there is complete blockade of noxious stimuli with extension of this blockade into the postoperative period. Recent preclinical and clinical studies provide substantial evidence that central sensitization and persistent pain after surgical incision is predominantly maintained by the incoming barrage of sensitized peripheral pain fibers throughout the perioperative period.[42] By preventing central sensitization and the peripheral input maintaining it, preventative analgesia along with intensive multimodal analgesic interventions could theoretically reduce acute postprocedure pain/hyperalgesia and chronic pain after surgery or trauma.[43] In a systematic review of clinical trials examining preemptive or preventative analgesic approaches, Katz[44] reported an analgesic benefit of preventative analgesia but no such benefit with the preemptive strategy.

Multimodal Approach to Perioperative Recovery

A multimodal approach to analgesia is broad definition which may include a combination of interventional analgesic techniques (epidural catheter or peripheral nerve catheter analgesia) and systemic pharmacologic therapies (nonsteroidal anti-inflammatory agents [NSAID] or opioid administration), multiple systemic pharmacologic therapies (the combination of NSAIDs, opioids, and anticonvulsants) and/or the multiple pharmacologic therapies delivered through the interventional catheter (local anesthetics plus opioids or other adjuvants). Postprocedural or posttraumatic pain is best managed through a multimodal approach.[45] Regardless of the manner technique employed; the principles of a multimodal strategy include sufficient diminution of the patient's pain to instill a sense of control over their pain, enable early mobilization, allow early enteral nutrition, and attenuate the perioperative stress response. A secondary goal of this approach is to maximize the benefit (analgesia) while minimizing the risk (side effects of the medication being used). These goals are often achieved through the use of regional anesthetic techniques and a combination of analgesic agents. The use of epidural anesthesia and analgesia is an integral part of the multimodal strategy because of the superior analgesia and physiologic benefits conferred by epidural analgesia.[3,46]

A multimodal approach to the management of acute pain to control postinjury pathophysiology and facilitate rehabilitation may result in accelerated recovery and decreased length of hospitalization.[47] A multimodal approach involving a combination of neuraxial analgesia and systemic analgesics during the recovery from radical prostatectomy resulted in reduced use of opioids; reduce pain scores and a decreased length of stay.[48] A recent meta-analysis examining the use of epidural analgesia following colorectal surgery found superior pain relief, faster return of bowel function and higher initial costs but lower total costs in those who received epidural analgesia as a sole regimen.[49] Although this study was supportive of the use of epidural analgesia as a sole regimen, it did not show decreased length of stay for patients in the epidural group. Multimodal analgesia in the form of systemic administration of multiple analgesics from different classes has also been found to provide adequate analgesia with low side effects as compared to epidural analgesia alone.[50] Patients undergoing major abdominal or thoracic procedures and who participate in a multimodal strategy have a reduction in hormonal and metabolic stress, preservation of total-body protein, shorter times to tracheal extubation, lower pain scores, earlier return of bowel function, and earlier fulfillment of intensive care unit discharge criteria.[47,51] By integrating the most recent data and techniques from surgery, anesthesiology and pain treatment, the multimodal approach may be seen as an extension of "clinical pathways" or "fast track protocols" by revising traditional care programs into effective postoperative rehabilitation pathways.[47] This approach may potentially decrease perioperative morbidity, decrease the length of hospital stay, and improve patient satisfaction without compromising safety. However, the widespread implementation of these programs requires multidisciplinary collaboration, change in the traditional principles of postoperative care, additional resources, and expansion of the traditional acute pain service, which may be difficult in the current economic climate.

TREATMENT METHODS

Many options are available for the treatment of acute pain, including systemic (i.e., opioid and nonopioid adjuvant) analgesics and regional (i.e., neuraxial and peripheral) analgesic techniques. By considering patients' preferences and an individualized assessment of the risks and benefits of each treatment modality, the clinician can optimize the analgesic regimen for each patient. Essential aspects for postoperative monitoring for patients receiving various postoperative analgesic treatment methods are listed in Table 51.1.

Systemic Analgesic Techniques

Opioids

Opioid analgesics are the gold standard treatments for postprocedural, traumatic and acute medical pain. These agents generally exert their analgesic effects through *mu* opioid receptors in the CNS and the periphery following an inflammatory injury, including surgical incision.[52] A theoretical advantage of opioid analgesics is that there is no analgesic ceiling. Another advantage is that opioids may be administered multiple routes including subcutaneous, transcutaneous, transmucosal, and intramuscular routes. Opioids also may be administered at specific anatomic sites such as the intrathecal (subarachnoid) or epidural space (see "Single-Dose Neuraxial Opioids" and "Continuous Epidural Analgesia" sections below). Unfortunately, the effectiveness of opioids is limited by side effects including nausea, vomiting, sedation, or the most concerning, respiratory depression. The repetitive use of opioids may induce the development of tolerance.

The most common routes of systemic opioid analgesic administration in the acute pain setting are oral (PO), intravenous (IV), and intramuscular (IM). Commonly, parenteral administration of medications is necessary in the acute pain setting because the patient is unable to tolerate oral intake. Possible parenteral routes of administration include IV, IM, transdermal (TD), and iontophoretic/transdermal (ITD). The treatment of moderate to severe acute pain often requires rapid and reliable onset of analgesia. To achieve this, the preferred medication route has tradition-

TABLE 51.1

MONITORING AND DOCUMENTATION OF POSTOPERATIVE ANALGESIA

Analgesic Medication*
Name, concentration, and dose of drug Settings of PCA device: demand dose, lockout interval, continuous infusion Limits set (e.g., 1-hour limits on dose administered) Supplemental or breakthrough analgesics
Routine Monitoring
Amount of drug administered including number of unsuccessful and successful doses Vital signs: temperature, heart rate, blood pressure, respiratory rate, 0–10 pain score Analgesia Pain at rest and with activity, percent pain relief Use of breakthrough medication
Common Side Effects
Cardiovascular: hypotension, bradycardia, or tachycardia Pulmonary: respiratory rate Gastrointestinal: Nausea and vomiting, pruritis, urinary retention Neurological: motor and sensory function, level of sedation
Instructions Provided
Treatment of side effects Parameters for triggering notification of covering physician Contact information should be provided (24 hours/7 days per week) if problems occur Emergency analgesic treatment if PCA device fails

*Postoperative analgesia includes systemic opioids and regional analgesic techniques. This list incorporates some of the important elements of preprinted orders, documentation, and intravenous PCA and epidural analgesia daily care described in the ASA Practice Guidelines for Acute Pain Management.
CNS, central nervous system; PCA, patient-controlled analgesia.

TABLE 51.2

GUIDELINES FOR EQUIANALGESIC DOSING OF OPIOID AGONISTS IN MILLIGRAMS#

Medication	Parenteral (IV, SC, IM)	Oral	Transdermal
Codeine	120	200	n/a
Fentanyl	0.1	n/a	5.5 mcg/hr
Hydrocodone	n/a	20	n/a
Hydromorphone	1.5	7.5	n/a
Levorphanol	2	4	n/a
Meperidine	75	300	n/a
Methadone (opioid naïve)	5	10	n/a
Morphine	10	30	n/a
Oxycodone	n/a	20	n/a
Oxymorphone	1	10	n/a
Tramadol	n/a	100	n/a

*Methadone conversion is dependent on starting dose of morphine equivalent secondary to atypical pharmacokinetics and dynamics (see Table 51-7)
#Equianalgesic doses are approximate and are intended to serve only as an estimate of opioid requirements. Actual doses may vary, in part because of wide interpatient variability in response to opioids. Doses should be individualized and gradually titrated to effect. IV, intravenous; IM, intramuscular; SC, subcutaneous, n/a, not applicable.

ally been IV or IM. The development of ITD fentanyl and the validation of its efficacy in postoperative patients may expand the parenteral administration possibilities.[53] Traditional transdermal fentanyl is not ideal for the use in the acute pain setting because of its slow onset of analgesia. The full analgesic benefit of this medication can be up to 24–36 hours after application to the skin. The other important criterion for acute pain management includes reliable and predictable analgesia. Unfortunately, there is wide intersubject and intrasubject variability in serum concentration and analgesic response after systemically administered opioids in the treatment of postoperative pain.[54] The IM route of administration may result in a wider variability than the IV or ITD routes and therefore may be a less ideal alternative. However, because it possesses a rapid onset time, it may be the best alternative to those who do not have the option of ITD or do not have immediate IV access.

The transition from parenteral to oral administration of opioids usually occurs after the patient is able to tolerate oral intake and his/her pain has been stabilized with parenteral opioids. The conversion from IV or IM medications can be performed by converting the parenteral opioid into the 24-hour "parenteral morphine equivalents (PME)" and converting this into the oral equivalent of the short- and long-acting opioid of choice. The division of long-acting versus short-acting medications is highly dependent on the patient, the nature of their pain, the diurnal variation of their pain, but a general rule is 50% of the daily requirement can be provided as a sustained preparation and 50% as a immediate release breakthrough preparation. Numerous "standard" tables exist for these conversions that are based on pharmacokinetic data and physician experience. Other sources of conversion tables or calculators are available commercially and for educational use on the Internet including Epocrates and the Hopkins Opioid Program (www.hopweb.org), respectively (Table 51.2 and 51.3).

Tramadol. Tramadol is a synthetic opioid that exhibits weak μ-agonist activity and inhibits reuptake of norepinephrine and serotonin. Although tramadol exerts its analgesic effects primarily through central mechanisms, it may exhibit peripheral local anesthetic properties.[55] Tramadol is effective for treating moderate postoperative pain and comparable in analgesic efficacy to aspirin (650 mg) and acetaminophen (1000mg) (see Table 51.4). The advantages of tramadol for mild to moderate acute pain treatment include the relative lack of respiratory depression,

TABLE 51.3

METHADONE CONVERSION BASED ON PATIENT HISTORY OF OPIOID CONSUMPTION

Current Oral Morphine Equivalent (OME) (mg)	Methadone Equianalgesic Conversion (mg)
<100	OME / 4
101–300	OME / 8
301–600	OME / 10
601–800	OME / 12
801–1000	OME / 15
>1000	OME / 20

major organ toxicity, or depression of gastrointestinal motility; and it has a low potential for abuse.[56] Common side effects with an overall incidence ranging from 1.6% to 6.1% include dizziness, drowsiness, sweating, nausea, vomiting, dry mouth, and headache.[57] Tramadol should be used with caution in patients with seizures or increased intracranial pressure and in those taking monoamine oxidase inhibitors or serotonin reuptake inhibitors, including most antidepressants.[58]

Nonsteroidal Anti-Inflammatory Agents

NSAIDs such as aspirin, ibuprofen, and naproxen exert their analgesic effect through the inhibition of the cyclooxygenase (COX) and synthesis of prostaglandins (PG). COX enzymes and PGs are important inflammatory mediators and may play an important role in the generation and maintenance of peripheral and central sensitization. Nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit both cyclooxygenase (COX) I and II enzymes and thereby decrease the production of prostaglandin E_2 (PGE_2) and other prostaglandins derived from arachidonic acid. Prostaglandins act at peripheral, as well as central sites to alter nociceptive thresholds.[58] For example, administration of PGE_2 directly into the hindpaw[59] or onto the spinal cord[60] of animals produces peripheral edema and hyperalgesia. Several studies have highlighted the importance of a peripheral site of action for NSAIDs. Administration in the periphery of monoclonal antibodies to PGE_2 is associated with a decrease in paw edema and hyperalgesia.[61] More recently, studies have highlighted a central component for NSAID action. In the spinal cord, PGE_2 can act presynaptically to increase the release of glutamate from primary afferent C-fibers[60,62] and postsynaptically to directly excite dorsal horn neurons by activation of nonselective cation currents.[63] Both effects promote the development and maintenance of central sensitization and enhanced pain states. The systemic administration of NSAIDs reduces inflammation and the behavioral correlate of central/peripheral sensitization—hyperalgesia.[64]

NSAIDs provide effective analgesia for mild to moderate acute pain and are a useful supplement to opioids for treatment of moderate to severe pain. The NSAID may provide some opioid-sparring properties through an additive or synergistic analgesic effect. NSAIDs such as ketorolac, which can be administered either orally or parenterally, are considered an integral part of a multimodal analgesic regimen by producing analgesia through different mechanisms than opioids or local anesthetics. As with opioids, NSAIDs by themselves do not appear to have a significant impact on mortality or major morbidity when compared to other analgesic agents. However, NSAIDs may improve analgesia and patient-oriented outcomes (e.g., satisfaction and quality of life) in part by reducing opioid analgesic requirements, decreasing opioid-related side effects, and facilitating patient recovery.[65,66] When given in addition to systemic opioids, NSAIDs will improve postoperative analgesia and reduce opioid requirements by up to 50%, which may reduce opioid-related side effects and facilitate return of gastrointestinal function, reduce nausea, decrease respiratory depression and improve patient satisfaction. However, not all studies note a decrease in opioid-related side effects with concurrent NSAID use.[67]

An analgesic benefit of aspirin over placebo has been shown for the 650 mg and 1000 mg doses (Table 51.4). The number of patients needed to treat for at least a 50% reduction in pain (NNT) was 4.4(4.0–4.9) and 4.0 (3.2–5.4), respectively. Single-dose aspirin (650 mg) produced significantly more drowsiness and gastric irritation than placebo, with a number-needed-to-harm (NNH) of 28 (19–51) and 38 (22–174) respectively. The authors also found that the type of pain model, pain measurement, sample size, quality of study design, and study duration had no significant impact on the results.[68] Similar NNT were obtained for naproxen 400–500 mg in postoperative patients.[69,70] The COX-II selective inhibitor, celecoxib, when given at 200mg has a NNT of 4.5 when compared to placebo in postoperative patients.[71] Neither naproxen nor celecoxib were associated with an increase in adverse events.

TABLE 51.4

RELATIVE EFFICACY OF SINGLE DOSE ORAL ANALGESICS

Medication	NNT*	95% CI
Aspirin (650 mg)	4.4	4.0–4.9
Aspirin (1000 mg)	4.0	3.2–5.4
Ibuprofen (400 mg)	2.7	2.5–3.0
Ibuprofen (600 mg)	2.4	1.9–3.3
Diclofenac (50 mg)	2.3	2.0–2.7
Ketorolac (10 mg)	2.6	2.3–3.1
Celecoxib (200 mg)	3.5	2.9–4.4
Celecoxib (400 mg)	2.1	1.8–2.5
Acetominophen (650 mg)	5.3	4.1–7.2
Acetominophen (1000 mg)	3.8	3.4–4.4
Tramadol (50 mg)	7.1	4.6–18.0
Tramadol (100 mg)	4.8	3.4–8.2
Codeine (60 mg)	9.1	6.0–23.4
Oxycodone (15 mg)	2.4	1.5–4.9
Codeine (60 mg) + Acetominophen (650 mg)	3.6	2.9–4.5
Codeine (60 mg) + Acetominophen (1000 mg)	2.2	1.7–2.9
Oxycodone (5 mg) + Acetominophen (325 mg)	2.5	2.0–3.2

*NNT in this case refers to the number of patients who must be treated to obtain more than 50% pain relief for moderateto-severe postoperative pain. NNT conveys statistical and clinical significance, is useful to compare treatment efficacy for different interventions, and summarizes treatment effects in a clinically relevant way. A lower mean NNT number implies greater analgesic efficacy in this example.

CI, confidence interval; NNT, number needed to treat

Acetaminophen is commonly used for acute pain management as an alternative to NSAIDs, but its site of action at the molecular level is still controversial and not well defined. There are, however, some lines of evidence supporting its role in the inhibition of cyclooxygenase. Acetaminophen has been demonstrated to inhibit a variant of COX-II enzymes in vivo[72] and be similar to the COX-II selective inhibitors: it inhibits prostaglandin synthesis in intact cells at low concentrations of added arachidonic acid further suggesting that it may inhibit COX-II function.[73] It has also been suggested that the molecular target of acetaminophen is a splice variant of COX-I, named as COX-III,[74] but its low expression level and activity suggests that this selective interaction is unlikely to be clinically relevant.[75] This suggests that acetaminophen inhibits COX-II activity in vivo and that its analgesic effect may be a function of decreased peripheral PGE_2 synthesis in addition to centrally mediated analgesic effects of acetaminophen on descending serotoninergic pathways.[76]

Acetaminophen is very effective in the treatment of acute pain, especially that of postprocedural pain. The number of patients needed to treat for at least a 50% reduction in pain over 4–6 hours (NNT) for 1000 mg of acetaminophen is 4.4, which is similar to that of 650 mg of aspirin or 100 mg of ibuprofen.[77] However, it was less effective than higher dose ibuprofen (400 mg) or diclofenac (50 mg) with NNTs of 2.3 and 2.4, respectively. Fortunately, acetaminophen is rarely associated with adverse effects in the short term, however is associated with hepatotoxicity after chronic use or overdose. In countries outside of the United States, intravenous propacetamol, the prodrug of acetaminophen

or acetaminophen itself is administered to postoperative patients who are not able to tolerate oral analgesics. In clinical trials conducted in patients with moderate to severe pain after orthopedic and gynecologic surgery, the analgesic efficacy of propacetamol was similar to that of NSAIDs[78,79] While providing fast and significant pain relief as well as a significant opioid-sparing effect,[78,80] it is not associated with the increased incidence of nausea, vomiting, and respiratory depression observed with opioids or the deleterious gastrointestinal, hematological, cardiovascular, and renal effects associated with NSAIDs and selective COX-II inhibitors. Lack of inhibition of COX-I peripherally by acetaminophen may explain its favorable safety effect.[81] These results have been replicated with intravenous acetaminophen in patients recovering from major orthopedic surgery.[82]

Excitatory Amino Acids

The excitatory amino acid neurotransmitter, glutamate, has a central role in the transmission of nociceptive signals from the periphery to the supraspinal structures and in the modulation of those signals in brainstem and spinal cord through descending bulbospinal tracts. The NMDA receptor, in particular, has been shown to have a crucial role in the development of persistent pain states including neuropathic pain.[83] Although this receptor represents an obvious target for the production of analgesia, pharmacologic antagonism has met with little clinical success. Intravenous administration of the NMDA antagonist ketamine produced a reduction in neuropathic pain; however this came at the cost of high incidence of side effects.[84] Ketamine has had better results in the treatment of cancer pain as both a direct analgesic, and by improving opioid-based analgesia.[85,86] Clinical trials of dextromethorphan and memantine have failed to show any beneficial effect when compared to placebo.[87,88] The role of NMDA antagonists in acute postprocedural or posttraumatic pain has met with less disappointing but somewhat mixed results. In one study, the addition of low-dose ketamine (0.25mg/kg) to postoperative pain management with morphine was not found to be beneficial.[89] The addition of ketamine did not reduce the patient's pain scores, opioid consumption, need for rescue analgesia or increase in the quality of recovery. However, the use of low-dose (subanesthetic doses) of ketamine has been successfully used to reduce morphine requirements, need for rescue analgesia and pain scores in patients recovering from abdominal surgery, orthopedic surgery, and trauma.[90–93]

Anticonvulsants

Anticonvulsants, including gabapentin, carbamazepine, lamotrigine, and pregabalin, have traditionally used for the treatment of chronic neuropathic conditions. Gabapentin is an anticonvulsant that was developed as a spasmolytic and adjunct for the treatment of generalized or partial epileptic seizures resistant to conventional therapies. Although it was originally designed as a structural analog of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), it does not bind to GABA receptors and the mechanism of action of this class of drugs is not fully understood.[94] It is likely that its analgesic effects result from an action at the $alpha_2delta_1$ accessory unit of voltage-dependent Ca_2 channels for which it has substantial affinity[95] and which are upregulated in the dorsal root ganglia and spinal cord after peripheral nerve injury[96] as can be produced by surgical incision.[97,98] Gabapentin may produce analgesia by binding to and inhibiting presynaptic voltage-dependent Ca_2 channels, decreasing calcium influx and thereby inhibiting the release of neurotransmitters including glutamate from the primary afferent nerve fibers that synapse on and activate pain responsive neurons in the spinal cord.[99]

In clinical studies, several open-label single center and multicenter, double-blind trials established that gabapentin was also effective for the treatment of chronic pain conditions, including postherpetic neuralgia, diabetic neuropathy, central pain, phantom pain, malignant pain, trigeminal neuralgia, and human immunodeficiency virus–related neuropathy, which may be difficult to treat with more conventional therapies.[100–105] The role of gabapentin in the treatment of acute pain is more controversial. Although in animal and human models of acute pain the administration of gabapentin produces no analgesia, when it is administered prior to a variety of surgical procedures, patients report decreased pain and decreased opioid use postoperatively.[41] A recent study by Gilron et al. [106] also showed synergism between gabapentin and morphine in patients suffering from neuropathic pain. This synergistic effect may have played a role in the decreased pain scores of those receiving gabapentin because concomitant opioids were routinely administered in the postoperative period. Unfortunately, there is little evidence in the literature regarding the use of the anticonvulsant medications for the management of acute pain. In one trial, postoperative administration of gabapentin was found to have no benefit for patient's status post total abdominal hysterectomy in the acute postoperative period but was beneficial in the reduction of chronic pain associated with the surgery in the same patients.[107] Therefore, with the exception of the well-documented effectiveness of carbamazepine in the treatment of the acute exacerbation of trigeminal neuralgia, there is no evidence for the effectiveness of anticonvulsants in the treatment of acute pain not related to an operation or trauma.

Alpha-Adrenergic Medications

Alpha-adrenergic receptors are widely distributed throughout the CNS and peripheral nervous system (PNS). $Alpha_1$ receptors play an essential role in the regulation of vascular tone, but no significant role in nociception. Activation of $alpha_2$ receptors produces analgesia. They are linked to an inhibitory G-protein on the presynaptic terminus of Aδ and C fibers and are activated by descending noradrenergic tracts from the brainstem locus coeruleus (LC) and A7, which hyperpolarizes the primary afferent and reduces afferent transmitter release and pain transmission. However, depending on the particular $alpha_2$ receptor subtype 2a, 2b, or 2c, different physiologic consequences may occur. The $alpha_{2b}$ subtype produces hemodynamic responses (hypotension), while the $alpha_{2a}$ receptor is responsible analgesia.[108,109] Clonidine is the prototypic $alpha_2$ agonist used for analgesia, although it has substantial hemodynamic side effects because of its lack of absolute alpha subtype selectivity. A newer agent, dexmedetomidine (DEX), is a more selective $alpha_2$ receptor agonist that is analgesic and sedating with fewer cardiovascular effects.[110,111]

In experimental models of acute transient pain, systemically administered clonidine had no analgesic benefit.[112] In studies of postoperative patients, intravenous clonidine has been found to augment the local anesthetic block of the psoas compartment for hip surgery.[113] However, the benefit was short lived and provided approximately 7 hours of additional analgesia. Preoperative and perioperative administration of systemic clonidine has been found to have a very modest analgesic (and anxiolytic) effect following abdominal hysterectomy.[114,115] Perioperative use of systemic clonidine has been found to reduce overall opioid requirements following spinal surgery when given as a bolus of 3 mcg/kg and followed by an infusion of 0.3 mcg/kg/hour; however, modest changes in blood pressure and heart were also noted.[116]

Dexmedetomidine, though more selective for $alpha_2$ receptors and more subtype selective ($alpha_{2a}$), does not produce significant analgesia in human experimental models of acute heat or electrical pain at doses that produce modest to severe sedation.[117] In one study, dexmedetomidine infusion reduced healthy volunteer's cold pressor–induced pain by 30% at doses that produced sedation and memory loss but did not produce hemodynamic perturbations.[110] Preoperative administration of dexmedetomi-

dine reduced postoperative opioid consumption but had no effect on postprocedure pain scores or recovery time.[118] Perioperative administration reduces opioid requirements after thoracotomy[119] and tubal ligation[120] but resulted in significant sedation and heart rate instability in some patients.

Serotoninergic Medications

Serotoninergic receptors found in the spinal dorsal horn have a complex relationship to the modulation of nociceptive transmission. Three of the subtypes of serotoninergic receptors play a role in nociceptive transmission, $5HT_1$ and $5HT_2$ hyperpolarize neurons within the dorsal horn and inhibit pain transmission, whereas $5HT_4$ receptors depolarize dorsal horn neurons and augment the transmission of nociceptive information.[121] Presynaptic terminals of descending neurons from the RVM appear to appose $5HT_1$ and $5HT_2$ receptors of primary afferents and interneurons in the spinal cord producing a reduction in pain like behavior in animals following activation of the RVM. Unfortunately, no subtype specific serotoninergic agonists are available for human use for analgesia. Interestingly, a recent study found that activation of the $5HT_4$ receptor in the brainstem eliminates the respiratory depression associated with administration the opioid fentanyl,[122] thus having an indirect but very beneficial effect on the treatment of pain.

The only clinically available serotonergic agonists or indirect serotoninergic agonists consist of the selective serotonin reuptake inhibitors (SSRIs) that are primarily used for the treatment of depression and anxiety disorders. Unfortunately, the data regarding the use of SSRIs in acute pain are lacking or negative. The lack of clinical studies assessing the analgesic value of this class is likely due to the lack of analgesic benefit of this class of drugs in the treatment of chronic pain.[123]

Nonselective Noradrenergic and Serotoninergic Medications

Although the group of nonselective noradrenergic and serotoninergic reuptake inhibitor medications, the tricyclic antidepressants (TCA) does not carry a FDA indication for pain, they are a mainstay of treatment of a variety of neuropathic and nonneuropathic chronic pain states. TCAs suppress nociceptive transmission independent of their effects upon depressed affect in the psychological domain. The exact mechanism of analgesic action remains unclear. As a class of agents, TCAs act to inhibit the reuptake and destruction or storage of biogenic amines including norepinephrine and serotonin. One possible mechanism is the accentuation of the descending serotoninergic and noradrenergic bulbospinal pathways on the spinal cord dorsal horn, by acting locally on $5HT_1$, $5HT_2$ and $aalpha_2$ receptors. Interestingly, selective serotonin reuptake inhibitors have little if any analgesic potential,[124] yet the TCAs with the greatest analgesic efficacy as those that have their greatest effect upon serotonin reuptake.[125] Alternate mechanisms including histamine receptor blockade,[126] calcium channel blockade,[127] antagonism of the NMDA receptor,[128] anti-inflammatory effects,[129] and blockade of sodium channels[130] have been suggested.

The results for TCAs in experimental models of acute pain are somewhat mixed. The secondary amine, desipramine, which has the greatest norepinephrine reuptake inhibitor selectivity, has no effect on pain scores in a capsaicin-induced mechanical allodynia model.[131] In contrast, imipramine the tertiary amine precursor to desipramine produced a reduction in pain resulting from noxious stimulation of the nasal mucosa.[132] A single study found that the administration of the tertiary tricyclic amine, amitriptyline, during the acute stage of herpes zoster decreased the prevalence of postherpetic neuralgia.[133] TCAs have not been found to be effective in the treatment of postoperative pain.[134,135]

The role of the selective serotonin and norepinephrine reuptake inhibitors, duloxetine and venlafaxine, has not been fully elucidated. Like the TCAs, these drugs have been used successfully to treat chronic pain conditions. However, there is no evidence for the effect or lack of effect on acute pain relief from duloxetine and the one study examining the use of venlafaxine for postoperative pain was negative.[136] The atypical antidepressant bupropion has not been investigated in trials of acute pain; however, it is not effective in the treatment of nonneuropathic chronic back pain.[137]

Intravenous Patient-Controlled Analgesia

Various factors, including the interpatient and intrapatient variability in analgesic needs, variability in serum drug levels (especially with intramuscular injections), and administrative delays, may contribute to inadequate postoperative analgesia. There may be difficulty in compensating for these factors with the use of a traditional PRN analgesic regimen. By circumventing some of these issues, intravenous patient-controlled analgesia (IVPCA) optimizes delivery of analgesic opioids and minimizes the effects of pharmacokinetic variability among individual patients. IV PCA is based on the premise that a negative-feedback loop exists, when pain is experienced, analgesic medication is self-administered, and when pain is reduced, there are no further demands. When the negative-feedback loop is violated, excessive sedation or respiratory depression may occur.[138] Although some equipment-related malfunctions have been reported, the PCA device itself is relatively free of problems, and most problems related to PCA use result from user or operator errors.[138]

A PCA device can be programmed for several variables, including the demand (bolus) dose, lockout interval, and background infusion (Table 51.5). The optimal demand or bolus dose is integral to intravenous PCA analgesic efficacy because an insufficient demand dose may result in inadequate analgesia, whereas an excessive demand dose may result in a higher incidence of undesirable side effects such as respiratory depression.[139] Although the optimal demand dose is uncertain, available data suggest that the optimal demand dose for morphine is 1 mg and that for fentanyl is 40 μg for opioid-naïve patients; however, the actual dose for fentanyl is often less in clinical practice.[138,139] The lockout interval may also affect the analgesic efficacy of intravenous PCA and is a safety feature of intravenous PCA. Although the optimal lockout interval is unknown, most intervals range from 5 to 10 minutes, and varying the interval within this range appears to have no effect on analgesia or side effects.[138] Most PCA devices allow the addition of a continuous or background infusion in addition to the demand dose. Initially, routine use of a background infusion was thought to confer certain advantages, including improved analgesia especially during sleep; however, subsequent trials failed to demonstrate any analgesic benefits of a background infusion in opioid-naïve patients.[140] Although the routine use of continuous or background infusions in intravenous PCA in adult opioid-naïve patients is not recommended, there may be a role for use of a background infusion for opioid-tolerant or pediatric patients. A Cochrane database meta-analysis revealed that IV PCA (compared to PRN opioids) provided significantly greater analgesia and patient satisfaction; however, patients who had IV PCA used more opioids with a higher incidence of pruritus but no difference in the incidence of other adverse events compared to PRN opioids.[141]

The incidence of opioid-related adverse events from intravenous PCA does not appear to differ significantly from that administered intravenously, intramuscularly, or subcutaneously. The rate of respiratory depression associated with intravenous PCA is low (<0.5%) and does not appear to be higher than that with systemic or neuraxial opioids.[142,143] Factors that may be associ-

TABLE 51.5

INTRAVENOUS PATIENT-CONTROLLED ANALGESIA REGIMENS FOR ACUTE PAIN

Medication	Pharmacodynamics	Bolus *	Lockout interval (min)
Morphine	*Mu* opioid receptor agonist	0.5–2.5 mg	5–10
Fentanyl	*Mu* opioid receptor agonist	10–20 mcg	5–10
Hydropmorphone	*Mu* opioid receptor agonist	0.5–0.25 mg	5–10
Alfentanil	*Mu* opioid receptor agonist	0.1–0.2 mg	5–8
Sufentanil	*Mu* opioid receptor agonist	2–5 mcg	4–10
Methadone	*Mu* opioid receptor agonist NMDA receptor antagonist	0.5–2.5 mg	8–20
Meperidine	*Mu* opioid receptor agonist	5–25 mg	5–10
Oxymorphone	*Mu* opioid receptor agonist	0.2–0.4 mg	8–10
Buprenorphine	*Mu* opioid receptor partial agonist *Kappa* opioid receptor antagonist	0.03–0.1 mg	8–20
Nalbuphine	*Mu* opioid receptor antagonist *Kappa* opioid receptor agonist	1–5 mg	5–15
Pentazocine	*Mu* opioid receptor antagonist *Kappa* opioid receptor agonist	5–15 mg	5–15

*All doses are for adult patients. The anesthesiologist should proceed with titrated intravenous loading doses if necessary to establish initial analgesia. Individual patient's requirements vary widely, with smaller doses typically given for elderly or compromised patients. Continuous infusions are not initially recommended for opioid-naïve adult patients.

ated with occurrence of respiratory depression with intravenous PCA include use of a background infusion, advanced age, concomitant administration of sedative or hypnotic agents, and coexisting pulmonary disease such as sleep apnea.[142,143]

Regional Analgesic Techniques

A variety of neuraxial and peripheral regional analgesic techniques may be employed for the effective treatment of acute pain. The majority of these techniques were initially developed for the management of acute postoperative pain; however, their application is appropriate for the treatment of any severe acute pain. In general, epidural and peripheral techniques when local anesthetics are used can provide superior analgesia compared with systemic opioids,[144] and use of these techniques may even reduce morbidity and mortality in the postoperative population.[4,5] However, there are risks associated with the use of these techniques, and a risk versus benefit analysis of these techniques should be performed on an individual basis in to determine the appropriateness of neuraxial or peripheral regional techniques for each patient, especially in light of some of the controversies about the use of these techniques in the presence of anticoagulation.

Single-Dose Neuraxial Opioids

A single dose of opioid may provide significant analgesia when administered as a sole or adjuvant analgesic agent when administered intrathecally or epidurally. One of the most important factors in determining the clinical pharmacology for a particular opioid is its degree of lipid solubility. Once inside the cerebrospinal fluid (CSF) through direct intrathecal injection or gradual migration from the epidural space, hydrophilic opioids (i.e., morphine and hydromorphone) tend to remain within the CSF and produce a delayed but longer duration of analgesia along with a generally higher incidence of side effects due to its cephalad spread. Neuraxial administration of lipophilic opioids, such as fentanyl and sufentanil, tends to provide rapid onset of analgesia, and the rapid clearance from the CSF may limit cephalad spread and development of certain side effects such as delayed respiratory depression but not pruritis.[145] The site of analgesic action for hydrophilic opioids is overwhelmingly spinal, but the primary site of action (spinal versus systemic) for single-dose neuraxial lipophilic opioids is not as certain.[146]

The differences in pharmacokinetics between lipophilic and hydrophilic opioids may influence the choice of opioid in an attempt to optimize analgesia and minimize side effects for a particular clinical situation. Single-dose intrathecal administration of a lipophilic opioid may be useful in situations (e.g., ambulatory surgical patients) in which rapid analgesic onset (minutes) combined with a moderate duration of action (<4 hours) and minimal risk of respiratory depression is needed.[147] Single-dose hydrophilic opioid administration provides effective postoperative analgesia and may be useful in patients monitored on an inpatient basis for which a longer duration of analgesia would be beneficial.

Single-dose epidural administration of lipophilic and hydrophilic opioids is used to provide analgesia, with considerations generally similar to those discussed with single-dose intrathecal administration of opioids. A single bolus of epidural fentanyl may be administered to provide rapid postoperative analgesia; however, diluting the epidural dose of fentanyl (typically 50 to 100 μg) in at least 10 mL of preservative-free normal saline is suggested to decrease the onset and prolong the duration of analgesia, possibly as a result of an increase in the initial spread and diffusion of the lipophilic opioid.[148] Single-dose epidural morphine is effective for postoperative analgesia and may decrease postoperative patient morbidity in selected patients.[149,150] Use of a single-dose hydrophilic opioid may be especially helpful in

TABLE 51.6

RECOMMENDED DOSAGE FOR NEURAXIAL ADMINISTRATION OF OPIOIDS

Medication	Intrathecal Single Dose	Epidural Single Dose	Epidural Continuous Infusion
Fentanyl	5–25 mcg	50–100 mcg	25–100 mcg/hr
Morphine	0.1–0.3 mg	1–5 mg	0.1–1 mg/hr
Morphine-extended release	Not recommended	5–15 mg	Not recommended
Hydromorphone	0.005–0.1 mg	0.5–1 mg	0.1–0.2 mg/hr
Sufentanil	2–10 mcg	1–50 mcg	10–20 mcg/hr
Alfentanil	Not recommended	0.5–1 mg	0.2 mg/hr
Methadone	Not recommended	4–8 mg	0.3–0.5 mg/hr

Doses are based on the use of the neuraxial opioid alone. No continuous intrathecal infusions are provided. Lower doses may be effective when administered to elderly patients. Units vary across medications for single dose (mcg versus mg) and continuous infusions (mcg/hr versus mg/hr)

providing postoperative epidural analgesia when the epidural catheter's location is not congruent with the surgical incision (e.g., lumbar epidural catheter for thoracic surgery). Lower doses of epidural morphine may be required for elderly patients and thoracic catheter sites. Commonly used dosages for intrathecal and epidural administration of neuraxial opioids are provided in Table 51.6.

An extended-release formulation of (single-dose) epidural morphine (Depo-Dur™) encapsulated within liposomes resulting in up to 48 hours of analgesia has been introduced.[151] The greatest benefit of liposomal morphine is its extended release formulation and the prolonged duration of effect which may be important with the increasing use of long acting low molecular weight heparin medications for postoperative patients for thrombosis prophylaxis. Liposomal morphine exhibits a dose dependent increase in analgesia, but unfortunately also a dose-dependent increase in adverse events including respiratory depression. This formulation is relatively new and therefore no long term data have been developed looking at patient outcomes including overall adverse event rates or any reduction in thrombosis rates as compared to traditional epidural catheter based long term management. As with traditional single-dose neuraxial opioids, clinicians should provide a lower dose of liposomal extended-release morphine in the elderly or those with decreased physiologic reserve or coexisting diseases, and liposomal extended-release morphine has not been approved for use in pediatric patients.

Continuous Epidural Analgesia

Analgesia delivered through an indwelling epidural catheter is a generally safe and effective method for management of acute pain.[152] Postoperative epidural analgesia can provide superior analgesia compared with systemic opioids.[46]

Epidural Medications. Epidural infusions of local anesthetic alone may be used for postoperative analgesia, but in general, they are not as effective in controlling pain as local anesthetic–opioid epidural analgesic combinations.[46] The rationale for using local anesthetic only epidural infusions has been to avoid the side effects of epidural opioids. Unfortunately, this practice results in a significant failure rate of the technique including regression of sensory block providing inadequate analgesia and relatively high incidence of motor block and hypotension. These outcomes can lead to decreased patient and provider satisfaction in the technique.

Opioids may be used alone for postoperative epidural infusions in order to avoid the motor block or hypotension from local anesthetic induced sympathetic blockade.[152] This advantage might be desirable in patients following abdominal aortic aneurysm operations as well as surgery with large fluid shifts in patients with significant cardiac or cerebrovascular disease. There are differences between continuous epidural infusions of lipophilic (e.g., fentanyl, sufentanil) and hydrophilic (e.g., morphine, hydromorphone) opioids. The analgesic site of action (spinal versus systemic) for continuous epidural infusions of lipophilic opioids is not clear, although several randomized clinical trials suggest that it is systemic[155] because there were no differences in plasma concentrations, side effects, or pain scores between those who received intravenous or epidural infusions of fentanyl. Although some data suggest a benefit from epidural of lipophilic opioids when compared to IV administration,[154] the overall advantage of administering continuous epidural infusions of lipophilic opioids alone is marginal at best. Hydrophilic opioids are quite different because of their relative lack of diffusion into the systemic circulation; the primary site of their analgesic action is spinal.[155] Hydrophilic opioids can distribute throughout the cerebrospinal fluid therefore the continuous infusion of these opioids may be especially useful for providing postoperative analgesia when the site of catheter insertion is not congruent with the site of surgery. Continuous epidural infusions of hydrophilic opioids provide superior analgesia compared with traditional PRN administration of systemic opioids.[156]

The combination of local anesthetics and opioids in a continuous epidural infusion may have advantages over infusions using a local anesthetic or opioid alone. Compared with a local anesthetic or opioid alone, a local anesthetic–opioid combination provides superior postoperative analgesia including improved dynamic pain relief, limits regression of sensory block, and possibly decreases the dose of local anesthetic administered,[157] although the incidence of side effects may or may not be diminished.[152] Continuous epidural infusion of a local anesthetic–opioid combination also provides superior analgesia compared with intravenous PCA with opioids.[46] It is unclear whether the analgesic effect of the local anesthetic and opioid in the epidural analgesia is additive or synergistic. Experimental studies demonstrate a synergistic effect between local anesthetics and opioids[158]; however, clinical trials suggest an additive effect[159] and the lack of improvement in side effects when used in combination supports the clinical experimental data.

The choice of local anesthetic for continuous epidural infusions varies. In general, bupivacaine or ropivacaine over lidocaine is chosen because of the differential and preferential clinical sensory blockade with minimal impairment of motor function.[160]

The concentrations used for postoperative epidural analgesia (≤0.125% bupivacaine or ≤0.2% ropivacaine) are lower than those used for intraoperative anesthesia. The choice of opioid also varies, although many clinicians choose to use a lipophilic opioid (fentanyl, 2 to 5 μg/mL, or sufentanil, 0.5 to 1 μg/mL) to allow for rapid titration of analgesia.[152,155] However, the use of the lipophilic opioid may just provide greater analgesia than local anesthetics alone; it is not clear whether use of these highly permeable medications does not simply provide a stable systemic concentration of opioid. The use of a hydrophilic opioid (morphine, 0.05 to 0.1 mg/mL, or hydromorphone, 0.01 to 0.05 mg/mL) as part of a local anesthetic–opioid epidural analgesic regimen may is more consistent with the goal of spinal delivery of opioid and also provides effective postoperative analgesia.[155]

A variety of adjuvant medications may be added to epidural infusions to enhance analgesia while minimizing side effects, but none has gained widespread acceptance. Two of the more studied adjuvants are clonidine and epinephrine. Clonidine mediates its analgesic effects primarily through its action at alpha$_2$ receptors in the spinal cord, and the epidural dose typically used ranges from 5 to 20 μg/hour.[161,162] The clinical application of clonidine is limited by its side effects: hypotension, bradycardia, and sedation.[161,162] Hypotension and bradycardia are both dose dependent. Epinephrine may improve epidural analgesia, can increase sensory block, and is generally administered at a concentration of 2 to 5 μg/mL[163] but it is also associated with a worsened motor block.[164] Epidural epinephrine added to local anesthetics is also associated with longer stage two labor and decrease APGAR scores in parturient.[164] Epidural administration of NMDA antagonists, such as ketamine, has been performed on a limited basis. Lauretti et al[165] found no analgesic benefit when ketamine was added to the clonidine epidural infusion following orthopedic surgery. This contrasts with another trial showing a pre-emptive analgesic benefit of epidural ketamine prior to a thoracotomy incision.[166] The theoretical explanation for the latter result is that ketamine attenuates the development of central sensitization and might potentiate the analgesic effect of epidural opioids. The caveat to this is that the safety of neuraxial ketamine infusions is controversial and may result in neuronal apoptosis.[167] Further safety and analgesic data are needed to justify its use.

Side Effects of Neuraxial Analgesic Drugs. Many medication-related (opioid and local anesthetic) side effects can occur with use of postoperative epidural analgesia. However, before automatically ascribing the cause to the epidural analgesic regimen, it is important to first consider other causes of the most common adverse effects of epidural analgesia namely hypotension, respiratory insufficiency/depression. These can include low intravascular volume, bleeding, and low cardiac output for hypotension and cerebrovascular accident, pulmonary edema, and evolving sepsis. Standing orders and nursing protocols for analgesic regimens, neurological, hemodynamic and respiratory monitoring; treatment of side effects; and physician notification about critical parameters should be standard for all patients receiving neuraxial and other types of postoperative analgesia.

Local anesthetics used in an epidural analgesic regimen may block sympathetic fibers and contribute to postoperative hypotension. Although the incidence of postoperative hypotension with postoperative epidural analgesia may be as high as approximately 7%, the average is closer to 0.7% to 3%.[168] Strategies to treat noncritical hypotension due to epidural analgesia include decreasing the overall dose of local anesthetic administered, or use of opioid-alone epidural since it is unlikely that neuraxial opioid alone would contribute to postoperative hypotension.[152]

Use of local anesthetics for postoperative epidural analgesia may also contribute to lower extremity motor block in approximately 2% to 3% of patients[168] and this may contribute to development of pressure sores in the heels.[169] A lower concentration of local anesthetics and catheter-incision congruent placement of epidural catheters for abdominal or thoracic procedures may decrease the incidence of motor block.[170] Although motor block resolves in most cases after stopping the epidural infusion for approximately 2 hours, persistent or increasing motor block needs to be promptly evaluated, and spinal hematoma, spinal abscess, and intrathecal catheter migration should be considered as part of the differential diagnosis.

Nausea and vomiting associated with neuraxial administration of a single dose opioid occurs in approximately 20% to 50% of patients,[171] and the cumulative incidence among those receiving continuous infusions of opioids may be as high as 45% to 80%.[172] Clinical and experimental data suggest that the incidence of neuraxial opioid–related nausea and vomiting is dose dependent.[173] Nausea and vomiting from neuraxial opioids may be related to the cephalad migration of opioid within the CSF to the area postrema in the medulla.[171] Use of fentanyl alone or in combination with a local anesthetic in an epidural infusion is associated with a lower incidence of nausea and vomiting compared with infusions using morphine.[172,174] A variety of agents have been successfully used to treat neuraxial opioid–induced nausea and vomiting, including naloxone, droperidol, metoclopramide, dexamethasone, and transdermal scopolamine.[175,176]

Pruritus is one of the most common side effects of epidural or intrathecal administration of opioids, with an incidence of approximately 60% compared with about 15% to 18% for epidural local anesthetic administration or systemic opioids.[177] Although the cause of neuraxial opioid–induced pruritus is uncertain, it does not appear to be associated with peripheral histamine release but may be related to central activation of an "itch center" in the medulla or opioid receptors in the trigeminal nucleus or nerve roots with cephalad migration of the opioid[171] or through the activation of a separate population of primary afferents that mediate nonhistamine itch.[178] It is unclear whether the incidence of neuraxial opioid–related pruritus is dose dependent because a quantitative systematic review[177] suggests no evidence of a relationship, whereas other clinical and experimental studies indicate a significant correlation.[179] Use of an epidural infusion of fentanyl alone or as part of a local anesthetic–opioid combination appears to be generally associated with a lower incidence of pruritus compared with morphine.[174] A variety of agents have been evaluated for the prevention and treatment of opioid-induced pruritus. Intravenous naloxone, naltrexone, nalbuphine, and droperidol appear to be efficacious for the pharmacologic control of opioid-induced pruritus.[177] Although pruritus is a common side effect, it often mild, it is relatively easy to treat.[180]

Neuraxial opioids used in appropriate doses are not associated with a higher incidence of respiratory depression than that seen with systemic administration of opioids. The incidence of respiratory depression associated with neuraxial administration of opioids is dose dependent and typically ranges from 0.1% to 0.9%.[181] The incidence of respiratory depression with continuous infusions of epidural opioids appears to be no greater than that seen after systemic opioid administration.[181] Although some institutions require patients with continuous epidural infusions of hydrophilic opioids to receive monitoring in an intensive care unit setting, many large-scale trials have demonstrated the relative safety (incidence of respiratory depression <0.9%) of this technique on regular hospital wards.[182] Neuraxial lipophilic opioids are thought to cause less delayed respiratory depression than hydrophilic opioids, although administration of lipophilic opioids may be associated with significant, early respiratory depression.[183] Delayed respiratory depression is primarily associated with the cephalad spread of the hydrophilic opioids, which typically occurs within 12 hours after injection.[184] Risks factors for respiratory depression with neuraxial opioids include increasing dose, increasing age, concomitant use of systemic opioids or sedatives, and possibly prolonged or extensive surgery, presence of comorbidities, and thoracic surgery.[184] Treatment with nalox-

one and airway management, if necessary, is effective in 0.1–to 0.4-mg increments; however, the clinical duration of action is relatively short compared with the respiratory-depressant effect of neuraxial opioids, and a continuous infusion of naloxone (0.5 to 5 μg/kg/hour) may be needed.[185]

Urinary retention associated with neuraxial administration of opioids is the result of an interaction with the opioid receptors in the spinal cord that decreases the detrusor muscle's strength of contraction.[171] The incidence of urinary retention seems to be higher with neuraxially administered opioids than that given systemically. Urinary retention does not appear to depend on opioid dose and may be treated with the use of low-dose naloxone, although at the risk of reversing the analgesic effects.[185] Epidural administration of local anesthetics is also associated with urinary retention, with a reported rate of approximately 10% to 30%.[186] Higher epidural infusion rates of local anesthetics (with a greater extent of sensory block and higher incidence of motor block) may be associated with a higher incidence of urinary retention.[187]

Patient-Controlled Epidural Analgesia. Epidural analgesia has been traditionally delivered as a fixed rate or continuous infusion (CEI); however, the administration of epidural analgesia through a patient-controlled device (PCEA) has become more common. Like intravenous PCA, PCEA allows for individualization of postoperative analgesic requirements and may have several advantages over CEI, including lower drug use and greater patient satisfaction.[188] PCEA also provides superior analgesia compared with intravenous PCA. PCEA is a safe and effective technique for acute analgesia in hospitalized. Observational data from two series of more than 1000 patients each reveal that more than 90% of patients with PCEA receive adequate analgesia, with a median pain score of 1 (of a possible 10) at rest and 4 with activity.[168,189] Incidences of side effects are 1.8% to 16.7% for pruritus, 3.8% to 14.8% for nausea, 13.2% for sedation, 4.3% to 6.8% for hypotension, 0.1% to 2% for motor block, and 0.2% to 0.3% for respiratory depression.[168, 189] These rates are comparable to those reported with CEI, with an incidence of 10.2% to 22% for pruritus, 3.1% to 22% for nausea, 7.4% for sedation, 0.7% to 6.6% for hypotension, 3% for motor block, and 0.1% to 1.6% for respiratory depression.[182,190] The optimal PCEA analgesic solution and delivery parameters are unclear. Use of a continuous or background infusion in addition to the demand dose is more common with PCEA than with intravenous PCA and may provide analgesia superior to the use of a demand dose alone.[191] In general, most acute pain specialists are gravitating toward a variety of low-concentration local anesthetic–opioid combinations (Table 51.7) in an attempt to improve analgesia while minimizing side effects.

Outcome Studies of Epidural Analgesia. Use of perioperative epidural anesthesia and analgesia, especially with a local anesthetic–based analgesic solution, can attenuate the pathophysiological response to surgery and may be associated with a reduction in mortality and morbidity compared with analgesia with systemic (opioid) agents.[4,5] A meta-analysis of randomized data (141 trials enrolling 9559 subjects) demonstrated that perioperative use of neuraxial anesthesia and analgesia versus general anesthesia and systemic opioids reduced overall mortality (primarily in orthopedic patients) by approximately 30%.[192] In a Medicare database analysis of 68,000 surgical patients, postoperative epidural-based analgesia was associated with a decrease in overall mortality.[193] Furthermore, use of epidural analgesia can decrease the incidence of postoperative gastrointestinal, pulmo-

TABLE 51.7

NEURAXIAL PATIENT-CONTROLLED ANALGESIA REGIMENS FOR ACUTE PAIN

Location of Incision	Analgesic Solution	Continuous Rate (ml/hr)	Demand Dose (ml)	Lockout interval (min)
General regimen				
	0.05% Bupivacaine + 4 mcg/ml fentanyl	4–10	2–6	10
	0.0625% Bupivacaine + 5 mcg/ml fentanyl	4–6	3–4	10–15
	0.1% Bupivacaine + 5 mcg/ml fentanyl	6	2	10–15
	0.2% Ropivacaine + 5 mcg/ml fentanyl	5	2	20
Thoracic				
	0.0625% to 0.125% Bupivacaine + 5 mcg/ml fentanyl	3–4	2–3	10–15
Abdominal				
	0.0625% Bupivacaine + 5 mcg/ml fentanyl	4–6	3–4	10–15
	0.125% Bupivacaine + 0.5 mcg/ml sufentanil	3–5	2–3	12
	0.1% to 0.2% Ropivacaine + 2 mcg/ml fentanyl	3–5	2–5	10–15
Lower extremity				
	0.0625% to 0.125% Bupivacaine + 5 mcg/ml fentanyl	4	2	10

Patient-controlled epidural analgesic regimens commonly used at the Johns Hopkins Hospital

nary, and possibly cardiac complications.[4,5] By inhibiting sympathetic outflow, decreasing the total opioid dose, and attenuating a spinal reflex inhibition of the gastrointestinal tract,[4] postoperative thoracic epidural analgesia can facilitate return of gastrointestinal motility without contributing to bowel dehiscence.[194] Randomized clinical trials demonstrate that use of postoperative thoracic epidural analgesia with a local anesthetic–based analgesic solution allows earlier return of gastrointestinal function and fulfillment of discharge criteria.

Perioperative use of epidural analgesia with a local anesthetic–based regimen in patients undergoing abdominal and thoracic surgery decreases postoperative pulmonary complications by preserving postoperative pulmonary function by providing superior analgesia and attenuating a spinal reflex inhibition of diaphragmatic function.[4] A meta-analysis of 48 randomized clinical trials and another large, randomized clinical trial demonstrated that use of thoracic epidural analgesia with a local anesthetic–based regimen decreased the incidence of pulmonary infections and complications.[195,196] However, patients who receive postoperative epidural opioids, intercostal blocks, wound infiltration, or intrapleural analgesia do not have a significant decrease in the incidence of pulmonary complications.

Use of postoperative thoracic, but not lumbar, epidural analgesia may decrease the incidence of postoperative myocardial infarction,[192] possibly by attenuating the stress response by improving postoperative analgesia, and providing a favorable redistribution of coronary blood flow.[198] The finding that only thoracic epidural analgesia decreases the incidence of postoperative myocardial infarction corroborates experimental data on the physiologic benefits of thoracic epidural analgesia, such as a reduction in the severity of myocardial ischemia or size of infarction, attenuation of sympathetically mediated coronary vasoconstriction, and improvement of coronary flow to areas at risk for ischemia.[198]

Although postoperative epidural analgesia appears to decrease postoperative gastrointestinal, pulmonary, and possibly cardiac morbidity, the benefits of postoperative epidural analgesia are not as clear for other areas such as postoperative coagulation, cognitive dysfunction and immune function. Despite the fact that many randomized clinical trials and meta-analyses show that use of *intra*-operative regional anesthesia decreases the incidence of hypercoagulable-related events such as deep venous thrombosis, pulmonary embolism, or vascular graft failure[192,199] evidence of a beneficial effect of *post*operative epidural analgesia in decreasing the incidence of hypercoagulable-related events is not compelling.

The ability of postoperative epidural analgesia to attenuate postoperative pathophysiology and improve outcomes also depends on the type of drugs used (opioids versus local anesthetics). Maximal attenuation of perioperative pathophysiology occurs with use of a local anesthetic-based epidural analgesic solution. The use of a local anesthetic–based or local anesthetic/opioid combination versus opioid-alone analgesic solution is associated with an earlier recovery of gastrointestinal motility after abdominal surgery and less frequent occurrence of pulmonary complications. Epidural analgesia is not a generic entity because different catheter locations and analgesic regimens may differentially affect perioperative morbidity.

Use of postoperative epidural analgesia may be associated with an improvement in postoperative analgesia and patient-reported outcomes such as patient satisfaction and health-related quality of life (HRQL).[200] Compared with systemic opioids, epidural local anesthetics consistently provide superior analgesia.[46] The data on the analgesic superiority of postoperative epidural analgesia reflect those seen with epidural analgesia during labor.[201] Although the concept of satisfaction is complex and difficult to measure accurately, the analgesic benefits of postoperative epidural analgesia may contribute to greater patient satisfaction and improve HRQL.[200]

Risks of Epidural Analgesia. The benefits of perioperative epidural anesthesia-analgesia must be weighed against the risks of this technique. Risks and benefits should be evaluated for each patient. There are complications associated with placement of an epidural catheter, with several risks associated with indwelling epidural catheters including epidural hematoma and abscess should be discussed in the context of postprocedure and/or acute pain management with epidural analgesia. The concurrent use of anticoagulants and of neuraxial anesthesia and analgesia has always been a relatively controversial issue but has been highlighted over the past decade with the increased incidence of spinal hematomas after the introduction of low-molecular-weight heparin in North America in 1993. Traditionally, the incidence of spinal hematoma is estimated at approximately 1 in 150,000 for epidural block, with a lower incidence of 1 in 220,000 for spinal blocks. Before its introduction in North America, low-molecular-weight heparin was used in Europe without significant problems; however, the incidence of spinal hematoma rose to as high as 1 in 40,800 for spinal anesthetics and 1 in 6600 for epidural anesthetics (1 in 3100 for postoperative epidural analgesia) in the United States between 1993 and 1998.[202] The estimate of the higher incidence of spinal hematomas after epidural catheter removal is based in part on the Food and Drug Administration's MedWatch data, which suggest that epidural catheter removal may be a traumatic event, although this is still a relatively controversial issue.[203] Different types and classes of anticoagulants have different pharmacokinetic properties that affect the timing of neuraxial catheter or needle insertion and catheter removal. Despite a number of observational and retrospective studies investigating the incidence of spinal hematoma in the setting of various anticoagulants and neuraxial techniques, there is no definitive conclusion regarding the absolute safety of neuraxial anesthesia and anticoagulation. The American Society of Regional Anesthesia and Pain Medicine (ASRA) lists a series of consensus statements based on the available literature for administration (insertion and removal) of neuraxial techniques in the presence of various anticoagulants, including oral anticoagulants (warfarin), anti-platelet agents, fibrinolytics-thrombolytics, standard unfractionated heparin, and low-molecular-weight heparin.[204,205] These guidelines will be updated shortly to include the newer long-acting anticoagulants that have been approved since the consensus guidelines were composed. Two of the newer agents, Fondaparinux and Dabigatran etexilate have half-lives of 17 and 14–17 hours respectively. It has been recommended to delay insertion of an epidural catheter until two half-lives have past to de crease the risk of epidural hematoma.[206] The ASRA consensus statements include the concepts that the timing of neuraxial needle or catheter insertion or removal should reflect the pharmacokinetic properties of the specific anticoagulant, that frequent neurological monitoring is essential, that concurrent use of multiple anticoagulants may increase the risk of bleeding, and that the analgesic regimen should be tailored to facilitate neurological monitoring, which may be continued in some cases for 24 hours after epidural catheter removal. An updated version of the ASRA consensus statements on neuraxial anesthesia and anticoagulation can be found on their web site (www.asra.com), and some of these statements address the newer anticoagulants.

Infection associated with postoperative epidural analgesia may result from exogenous or endogenous sources.[152] Serious infections such as epidural abscess and meningitis associated with epidural analgesic are rare (<1 in 1,000, <1:50,000, respectively).[207] Epidural infections are associated with many sources of the bacteria including needle contamination, catheter contami-

nation, epidural medication contamination, lack of the use of in-line bacterial filters, duration of catheter implantation and patient predisposing factors for infection.[208] The use of epidural analgesia in the general surgical population with a typical duration of postoperative catheterization (approximately 2–4 days) is generally not associated with epidural abscess formation.[168] A trial of postoperative epidural analgesia (mean catheterization of 6.3 days) in more than 4000 surgical cancer patients did not reveal any abscesses. Even though serious infectious complications appear to be rare after short-term (<4 days) epidural infusions, there may be a relatively higher incidence of superficial inflammation or cellulitis (4% to 14%) and even higher rate of catheter colonization (20% to 35%), with the proportion of positive cultures increasing with the duration of catheterization; however, catheter colonization rate may not be a good predictor of epidural space infection.[209]

Peripheral Regional Analgesia

The use of peripheral regional analgesic techniques as a single injection or continuous infusion can provide superior analgesia for acute pain when compared with systemic opioids and may even result in improvement in various outcomes.[210] A variety of wound infiltration and peripheral regional techniques (e.g., brachial plexus, lumbar plexus, femoral, sciatic-popliteal, and scalp nerve blocks) can be used to provide postprocedural and acute analgesia. Peripheral nerve regional analgesic techniques may have several advantages over systemic opioids including superior analgesia and decrease in opioid-related side effects and over neuraxial techniques including decreased risk of epidural hematoma formation.[211] A one-time injection of local anesthetic for peripheral regional techniques may be used primarily for intraoperative anesthesia or as an adjunct for postprocedure analgesia but can be used for acute traumatic pain management such as long bone fractures or rib fractures. Compared with placebo, peripheral nerve blocks with local anesthetics provide superior analgesia and are associated with decreased opioid use, decreased opioid-related side effects, and improvement in patient satisfaction.[210] The duration of postoperative analgesia resulting from the local anesthetic in the peripheral nerve block varies but may last up to 24 hours after injection. Continuous infusions of local anesthetics can be administered through peripheral nerve catheters. The use of continuous infusions or patient-controlled peripheral analgesia results in superior analgesia decreased opioid-related side effects, and greater patient satisfaction in comparison with systemic opioids.[211] Unfortunately, the optimal parameters including the local anesthetic, the medication concentration, the inclusion of opioid or other adjuvant medications, or continuous versus PCA versus intermittent boluses for peripheral analgesia have not been determined.

Several nonepidural regional analgesic techniques can be used for management of postoperative thoracic pain, including paravertebral and intercostal blocks, interpleural (intrapleural) analgesia, and cryoanalgesia. The most promising technique appears to be the thoracic paravertebral block, which has been used for thoracic, breast, and upper abdominal surgery and for treatment of rib fracture pain.[212] The possible sites of analgesia for the thoracic paravertebral block include direct somatic nerve, sympathetic nerve, and epidural blockade. The thoracic paravertebral block can be administered as a single injection or continuous infusion through a catheter may provide equal or superior analgesia compared with thoracic epidural analgesia, and is a valuable alternative to thoracic epidural analgesia.[213] The analgesic efficacy of interpleural analgesia is controversial.[214] In a meta-analysis of randomized-controlled trials examining interpleural analgesia, no difference was observed between interpleural analgesia and placebo injections. Interpleural analgesia appears to be inferior to epidural and paravertebral analgesia for postoperative pain control, preservation of lung function after thoracotomy, and reduction of postoperative pulmonary complications.[214] Intercostal blocks may provide short-term postoperative analgesia and may be repeated postoperatively; however, the incidence of pneumothorax increases with each intercostal nerve blocked (1.4% per nerve, with an overall incidence of 8.7% per patient).[215] Like interpleural analgesia, intercostal blocks do not reduce the incidence of pulmonary complications postoperatively compared to epidural analgesia. Cryoanalgesia can be used for postoperative analgesia after thoracotomy but, like interpleural analgesia and intercostal blocks, does not appear to provide any analgesic advantage over epidural analgesia and is not effective for other types of postoperative pain.[216]

Intra-articular Analgesia

Local peripheral administration of opioids including intra-articular injections after knee procedures may provide analgesia for up to 24 hours after surgery.[217] Peripheral opioid receptors are found on the peripheral terminals of primary afferent nerves and are upregulated during inflammation of peripheral tissues.[52] The results of the several randomized clinical trials investigating this topic are summarized.[217] Use of a higher dose of intra-articular morphine (5 mg versus 1 mg) results in superior analgesia; however, there may be no advantage in the degree of analgesia provided between intra-articular and systemic opioids. The systemic absorption and action of intra-articular morphine injection have not yet been excluded. Intra-articular injection of local anesthetics may provide a limited duration of postoperative analgesia, but the clinical benefit from intra-articular local anesthetics injections is unclear.[218]

ANALGESIA IN SPECIAL POPULATIONS

This chapter has provided a general approach to the principles and practice of acute pain management, but this approach may not be applicable to certain populations that may have unique anatomic, physiologic, pharmacologic, affective, and cognitive issues. The management of acute pain should be tailored to the specific needs of a particular population. Although each topic by itself could merit a separate chapter in some textbooks, the general principles and essence of the issues associated with each population are outlined, and references are made to other more extensive sources.

War Trauma

The treatment of traumatic battlefield pain is largely a function of the type and acuity of injury, stability of the patient, level of treatment (Table 51.8), availability of resources, and patient diagnosis. The chain of casualty evacuation is built up levels or echelons of care, which were developed in WWII to facilitate the rapid evacuation of wounded soldiers based on their medical condition and needs. In order to maximize efficiency and ensure the continued availability of resources, healthcare providers at each level provide no more care than that which is necessary to either return the soldier to duty or safely evacuate the casualty to the next highest level. For first level treatment, pain management consists of parenteral morphine or NSAIDs or acetaminophen, which some units dispense to individual soldiers as part of "wound packs."[219] COX-2 inhibitors possess the advantage of having minimal inhibitory effects on platelet function, which can prolong bleeding. One concern about NSAIDs is the possible increased incidence of renal failure in dehydrated and hypovolemic soldiers,[220] but this risk is mitigated by the young age, and lack of concomitant medical problems and medication usage in most

TABLE 51.8

LEVELS OF CARE IN A WAR ZONE

Level (Echelon)	Location	Type of medical unit	Primary functions/ personnel
First	Combat Zone	Battalion Aid Station	Pain relief, stabilization and preparation for medical evacuation. Self care/ Corpsmen care/ Buddy care
Second	Combat Zone	Mobile Field Surgical Teams or Forward Surgical Teams	Resuscitation and surgical stabilization by surgeons, anesthetists, and nurses.
Third	Controlled Area of Combat Zone	Combat Support Hospital or Mobile Army Surgical Hospital	Medical and surgical care. Broad array of physicians and nurses.
Fourth	Communication Zone	Military Medical Centers in United States or overseas.	Medical and surgical care. May provide definitive treatment (in United States) or rehabilitation services in retained active duty personnel.
Fifth	United States	VA Hospitals	Definitive long-term treatment and rehabilitation in wounded or medically boarded soldiers.

deployed soldiers. Acetaminophen may be marginally safer than NSAIDs, but is generally less effective as an analgesic.[221]

Morphine is the standard opioid analgesic used for battlefield pain control, having been first administered orally in the War of 1812 and parenterally in the U. S. Civil War. Intramuscular morphine can be given on the battlefield or battalion aid station (BAS), ideally by a medical corpsman, or alternatively by a colleague or the soldier himself. Although IM administration generally provides rapid and reliable analgesia, the liabilities of this delivery mode include variable absorption during shock and with certain wounds, and the risk of infection. Intravenous administration is more reliable than IM use, but is often impractical and requires specialized equipment and trained personnel.[222] The U. S. military is currently investigating the feasibility of providing oral transmucosal fentanyl citrate (OTFC) in ''wound packs'' to small, highly disciplined units that tend to operate independently without the benefit of an organized, medical support system (e.g. Special Forces). The pharmacokinetics of transmucosal delivery are comparable to that of IM administration, with therapeutic blood levels being reached within 10–15 minutes, and peak plasma concentration occurring about 20 minutes after administration.[223] Approximately 25% of OTFC is absorbed via the oral mucosa, with another 25% being slowly absorbed through the gastrointestinal tract.[223] The pharmacokinetics of OTFC appears to be independent of age, unaffected by multiple dose regimens, and less prone to hemodynamic variations,[224,225] which may make it an ideal drug for battlefield analgesia. Kotwal et al.[226] recently reported using high dose (1600 mcg) OTFC to treat 22 soldiers with acute orthopedic injuries in an out-of-hospital setting in Operation Iraqi Freedom (OIF). Excellent pain relief without the need for additional analgesia was reported in 19 patients, with minor, self-limiting side effects occurring in 8 soldiers. One patient, who received a repeat dose of fentanyl followed by subsequent intravenous opioids, experienced respiratory depression requiring reversal with naloxone 4 hours following administration. Other rapidly acting analgesics that may someday be used in lieu of parenteral opioids include intranasal butorphanol, intranasal ketamine and fentanyl buccal tablets.

Second level medical treatment facilities include mobile field surgical teams and forward surgical teams (FST), whose providers include surgeons, anesthetists and nurses. The primary functions of FSTs are resuscitation and stabilization, with the typical duration of stay being measured in hours. Pain control at this echelon of care generally involves oral opioid and nonopioid analgesics, and intravenous opioids, which can be safely monitored by nurses and other personnel trained in postanesthesia recovery. Patient-controlled analgesia may be used at these facilities as resources dictate, but is often unavailable.

Care at third level military treatment facilities includes intensive care units and medical wards, which may administer continuous infusions of opioid and nonopioid (e.g. Ketamine and epidural infusions of local anesthetics) analgesics for acute and subacute injuries. When pain management–trained anesthesiologists have been deployed to CSH, more advanced interventions such as sympathetic and paravertebral blocks have been performed. Recently, anesthesiologists have begun to employ peripheral nerve catheters for intermediate-term pain control (Table 51.9).[227,228] In addition to providing safe and titratable pain relief, peripheral nerve catheters can be used for anesthesia in patients requiring repeat surgery or wound debridement. With proper maintenance and monitoring, tunneled peripheral nerve catheters can be reliably used for up to 3 weeks after placement. The limitations of peripheral nerve catheters at CSH include shortage of personnel, speed of exodus, infection risk, and concerns about compartment syndrome.

To a lesser degree, care at this level also focuses on reducing the long-term sequelae of acute injuries. The U. S. military has attempted to reduce the incidence of chronic pain following

TABLE 51.9

ADVANTAGES OF PERIPHERAL NERVE CATHETERS FOR WAR INJURIES

Can provide anesthesia for repeat surgery or wound debridement
Can provide excellent, limb-specific analgesia
Stable hemodynamics
Minimal side effects
Reduced need for opioid and other analgesics
Improved alertness
Requires only simple, easily transportable equipment

trauma or surgery by the preventive use of neuropathic pain medications such as gabapentin. When used preemptively before surgical procedures associated with a high incidence of severe acute and chronic pain, gabapentin and other drugs used to treat neuropathic pain have been shown to reduce both perioperative pain scores and opioid requirements.[41] At fourth and fifth echelon treatment centers, acute and chronic pain management is similar to that delivered in civilian trauma centers and pain management clinics, as outlined in this and other chapters.

In summary, pain management in the operational setting is fraught with a unique set of challenges almost unimaginable in civilian pain treatment facilities. Because of wide variations in medical resources and personnel, there is no "optimal" pain treatment for war injuries. Instead, treatment should be individually tailored based on a patient's injury, hemodynamic condition, available resources, and the ability to monitor treatment response. In modern warfare, the most common cause of soldier attrition is not battle-related injury, but rather acute and recurrent non–battle-related injuries, similar to those encountered in civilian pain treatment facilities and primary care offices. Recent evidence suggests that high return-to-unit rates can be obtained by the deployment of aggressive pain management capabilities in mature theaters of operation.

Ambulatory Surgical Patients

The percentage of surgical procedures being performed on an outpatient basis continues to increase. There is an increase in the number of outpatient surgical procedures and in the complexity of operations being performed and comorbidities of the surgical outpatients. Optimizing treatment of postoperative and postdischarge pain is especially important in patients undergoing outpatient surgery because inadequate control of postoperative pain is one of the leading causes of prolonged stays or readmission after outpatient surgery.[229] Although there has been much effort to minimize symptoms such as pain and nausea in the postanesthesia care unit and subsequent (phase II) recovery area to facilitate discharge after outpatient surgery, increasing data suggest that postdischarge pain is common and may interfere with patients' recovery and the overall health-related costs of outpatient surgery.[230,231] Despite the advances in surgical techniques that minimize surgical trauma and postoperative pain, the incidence of moderate to severe postdischarge pain is still approximately 25% to 35%[232] and can be especially troublesome for certain patients, such as those undergoing tubal ligation and orthopedic procedures.[233] After discharge, poorly controlled nausea and vomiting may interfere with the intake of oral analgesics. In light of these considerations, the traditional reliance on opioid analgesia may not be appropriate for patients undergoing ambulatory surgery because of the opioid-related side effects that may delay hospital discharge and postdischarge recovery after outpatient surgery. A multimodal or "balanced" analgesic approach using a combination of opioid and nonopioid analgesic adjuvant medications including NSAIDs or acetaminophen; and local anesthetics wound infiltration or regional anesthetic techniques may be more appropriate in this surgical population. The use of local anesthetics has decreased postoperative pain, and the drugs can be administered as peripheral nerve blocks, tissue infiltration, wound instillation, or topical analgesics. Similar results have been achieved using systemic NSAIDs and acetaminophen.

Although multimodal analgesia may be especially effective in the immediate postoperative period, not all of the options may be routinely available after the patient is discharged to home. For example, use of local anesthetics in peripheral nerve blocks, tissue infiltration, or wound instillation may be effective in the immediate postoperative period; however, a single dose of local anesthetic rarely provides more than 24 hours of analgesia. Realistically, most outpatients rely on a combination of short-acting analgesics including an opioid and acetaminophen or NSAID for postoperative pain control after hospital discharge.[55] Routine use of acetaminophen, especially when an NSAID is added to the regimen, is recommended to maximize postoperative analgesia,[234] although it is important to remember that when acetaminophen is used as a co-analgesic agent in combination products this limits the number of combination analgesic tablets that the patient may consume because of liver toxicity. The future of postoperative pain control in ambulatory surgical patients may include postdischarge (home) use of continuous infusion of local anesthetic solutions or even use of long acting, "sustained-release" local anesthetics or opioids.

Elderly Patients

The elderly population, which is expected to increase by 33% over the next 2 decades, accounts for approximately 12.5% of the total U. S. population and 38% of all health care spending (approximately 5% of the U. S. gross domestic product). There are changes in the physiology, pharmacodynamics, pharmacokinetics, and processing of nociceptive information that may influence the effectiveness of postoperative pain control in the elderly. There may be communication, affective, cognitive, social, and ideological barriers to effective postoperative pain control in this group. The elderly generally have decreased physiologic reserves and increased co-morbidities compared with younger counterparts, which may result in a higher incidence of postoperative complications such as postoperative delirium, especially in the presence of severe or uncontrolled postoperative pain.

There is a clinically significant reduction in the intensity of pain perception or symptoms with increasing age.[235,236] For instance, silent myocardial ischemia is more common in the elderly, who may instead present with other angina equivalents. Experimental studies demonstrate a decrease in Aδ and C-fiber nociceptive function, delay in central sensitization, increase in pain thresholds, and decrease in sensitivity to low-intensity noxious stimuli.[237,238] However, elderly patients may have an increased response to higher-intensity noxious stimuli, decreased pain tolerance, and decreased descending modulation (i.e., serotonin and noradrenergic), which may contribute to the relatively high incidence of chronic pain in elderly patients.[237,239] Despite the methodological issues in available studies evaluating age-related differences in the perception of pain, there appears to be a clinically relevant decrease in pain perception with increasing age. However, this should not be interpreted that elderly patients experience less pain than younger patients when they do report the presence of pain.

The physiologic and pharmacokinetic effects of aging on acute pain management are complex, and the clinical implications include the slow titration of opioids that produces longer circulation times, smaller total doses because of increased sensitivity, and expectation of a longer duration of action due to reduced clearance. In general, analgesic requirements decrease with increasing age. Age has been shown to be the best predictor for postoperative requirements of intravenously and neuraxially ad-

ministered morphine.[240] Similar to that seen in younger patients, there is large inter-patient variability in postoperative analgesic requirements. Use of intravenous PCA in the elderly is appropriate to compensate for the wide interpatient variability, although postoperative titration of intravenous morphine can also allow successful and safe administration to elderly patients. Age per se is not an impediment to effective postprocedure or acute pain use of intravenous PCA or PCEA.[241] Use of postoperative epidural analgesia for elderly patients, especially in those with decreased physiologic reserves, may attenuate perioperative pathophysiology and is reported to improve postoperative outcomes such as facilitating return of gastrointestinal function after abdominal surgery, decreasing the incidence of myocardial ischemia, lowering pain scores, and decreasing pulmonary complications.

Postoperative pain management in the elderly may be especially challenging because of some of the affective, cognitive, social, and ideological barriers. Health care providers treating geriatric patients tend to have an unfounded level of fear of complications associated with treating perioperative pain as reflected by the inadequate treatment of pain in elderly patients, even relative to younger patients.[239] Elderly patients may also contribute to inadequate pain control by their own reluctance to report pain or take opioid medications. Elderly patients have a higher incidence of affective or cognitive impairments such as depression or dementia that may interfere with effective pain management.[239] One of the most devastating complications in the elderly surgical patient is postoperative delirium, which is associated with increased mortality rates and longer hospital stays.[242] The cause of postoperative delirium is unknown, although it is believed to result from an imbalance of neurotransmitters, particularly acetylcholine and serotonin, in the presence of decreased neurophysiologic reserve and inflammatory mediators.[243, 244] Although the cause of postoperative delirium is multifactorial, uncontrolled postoperative pain may be an important contributor to its development.[245] Higher pain scores predict a decline in mental status and an increased risk of delirium.[246] A multimodal analgesic approach may be useful in elderly patients but must be used with caution because adverse drug reactions in the elderly increase as the number of medications administered increases. Although the benefits of intra-operative regional anesthetic techniques on postoperative cognitive function are unclear, the postoperative or acute pain use of epidural analgesia may diminish postoperative or pain-related delirium in part through superior analgesia and a decrease in pulmonary complications.

Opioid-Tolerant Patients

Postprocedural or acute pain may be difficult to manage in the opioid-tolerant patient because the standard approaches used for assessment and therapy in opioid-naïve patients is inadequate for opioid-tolerant patients. Although opioid-tolerant patients typically require higher doses of analgesic medications in the immediate postprocedure period, many health care providers still do not provide adequate postprocedural pain relief, in part because of the fear of addiction or medication-related side effects. In dealing with patients with chronic opioid use, health care providers often mistakenly interchange several pharmacologic terms (i.e., tolerance, physical dependence, and addiction), a practice that may contribute to misunderstanding and inappropriate treatment decisions.

Tolerance refers to the pharmacologic property of an opioid in which an increasing amount is needed to maintain a given level of analgesia. Physical dependence is another pharmacologic property of opioids characterized by the occurrence of a withdrawal syndrome on abrupt discontinuation of the opioid or administration of an antagonist. Tolerance and physical dependence are pharmacologic properties of opioids and not synonymous with the aberrant psychological state or behaviors associated with addiction, a chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user and continued use despite that harm. The exaggerated fear of addiction contributes to the under-treatment of postprocedural and acute pain by health care providers; however, the data suggest that there is minimal risk of iatrogenic addiction with use of opioids for pain control in patients who do not have a prior history of addiction.[247,248] Several principles for pain assessment and treatment can be applied in the postprocedural or acute pain opioid-tolerant patient. The physician should expect high self-reported pain scores[249]; base treatment decisions on objective pain assessment (e.g., ability to deep breathe, cough, ambulate) in conjunction with patients' self-reported pain scores; recognize the need to identify and treat two major problems, maintenance of a basal opioid requirement and control of incisional/procedural/acute pain; and recognize that detoxification is usually not an appropriate goal in this period. Likewise, several general strategies can be employed for the treatment of postprocedural or acute pain in the opioid-tolerant patient. The physician can create a treatment plan early and discuss it with the patient, procedural team, and nursing staff; replace the patient's baseline or basal opioid requirements; anticipate an increase in postprocedural analgesic requirements; maximize the use of adjuvant drugs; consider use of regional analgesic techniques; and plan for the transition to an oral regimen.[249] Although chronic pain patients are not synonymous with opioid-tolerant patients, many of these patients are opioid-tolerant, and the same general principles and strategies may be applied to chronic pain patients who are opioid-tolerant. Recognizing and treating nonnociceptive sources of distress may be especially important for chronic pain patients. Although there is no specific threshold or timeframe for when a patient becomes opioid tolerant, after an opioid-tolerant patient is identified, a strategy for acute pain control should be created and discussed with the patient. This may include anticipation or arrangement for a longer than normal length of hospital stay, consultation with the anesthesiology or pain service, and confirmation of the patient's daily opioid intake to facilitate calculation of the patient's basal or maintenance opioid requirement in the hospitalized period. Administration of a PRN analgesic regimen alone for opioid-tolerant patients is highly discouraged because replacing the basal opioid requirement in the acute period can optimize pain relief and possibly prevent opioid withdrawal. Basal opioid requirements can be administered systemically (typically intravenously or transdermally) until the patient can tolerate an oral analgesic regimen.[138] For example, 50% to 100% of the patient's baseline opioid requirement can be administered as a continuous infusion as part of an intravenous PCA regimen, with a demand dose to cover the additional incisional pain. Conversion tables (Table 51.2 and 51.3) may facilitate equi-analgesic conversion of opioids; however, these tables provide only estimations to assist health care providers in initiating opioid titration.[250] Opioid-tolerant patients generally require increased postoperative analgesic levels, including a larger demand dose.[249] Patients may require frequent adjustment (e.g., two to three times each day) of the intravenous PCA demand dose or continuous infusion, depending on the analgesic requirements. There is individual variability in response to different opioids, and if a decision is made to switch opioids, the choice of opioid may not as important as using an equi-analgesic dose. Patients may experience different side effects with different opioids, and rotating to another opioid may be reasonable if the patient is not tolerating the first opioid.[251] Adjuvant agents such as NSAIDs should be administered on a regularly scheduled basis to optimize analgesic efficacy and possibly provide an opioid-sparing effect. Use of regional analgesic techniques with neuraxial opioids may provide excellent analgesia in opioid-tolerant patients while preventing withdrawal symptoms.[252] After the patient is tolerating oral intake, the conversion from intravenous opioids to a form of oral or transdermal administration that would be more suitable for discharge to home may be initiated.

Opioid-tolerant patients typically can be converted to a combination of a regularly administered, controlled-release formulation of opioid such as sustained-release morphine or transdermal fentanyl and a short-acting, immediate-release opioid on a PRN basis. Although the conversion of intravenous opioid to an oral or transdermal form can be accomplished over a period of 1–2 days in opioid-tolerant patients, this process may take several days in extremely difficult cases. Converting from an intravenous to oral or transdermal form of opioid is not an exact science, and available conversion tables can serve only as a rough guide because of significant inter-patient and intra-patient variability in the sensitivity to opioids, lack of complete cross-tolerance between opioids which may lead to greater than anticipated potency of a new opioid, and changes in the levels of pain, which may rapidly decrease in the immediate postoperative period.[250]

Obesity, Obstructive Sleep Apnea, and Sleep

Patients with obesity and obstructive sleep apnea (OSA) may be at higher risk for postoperative complications. Obesity and OSA are separate disease states, but there is some association between the two, because OSA occurs in a relatively higher percentage of obese than non-obese patients.[253] Although some data suggest that epidural analgesia may decrease postoperative complications in the obese patient,[254] the optimal postoperative analgesic and monitoring regimen for patients with OSA is not clear. Data suggest that sleep is disrupted in the immediate postoperative period and may influence postoperative morbidity and patient-oriented outcomes.

Obesity is defined as a body mass index (BMI) of more than 30 kg/m^2, with morbid and super-morbid obesity defined as a BMI of more than 35 kg/m^2 and 55 kg/m^2, respectively. The prevalence of obesity has increased to include approximately 22.5% of the U. S. population.[255] Although obese patients do not necessarily have OSA, obesity is the most important physical characteristic associated with OSA. Approximately 60% to 90% of OSA patients are obese, and at least 5% of morbidly obese patients have OSA, which is defined as more than five episodes per hour of cessation of airflow for more than 10 seconds despite continued ventilatory effort.[253] It is estimated that approximately 4% of men and 2% of women (18 million Americans overall) have OSA and that up to 95% of persons with OSA are underdiagnosed.[253] Patients with OSA are generally at higher risk for chronic cognitive impairment, pulmonary hypertension, cardiomyopathy, systemic hypertension, and possibly for myocardial infarction.[256,257] The pathophysiology of airflow obstruction is related primarily to upper airway pharyngeal collapse, including the retro-palatal, retro-glossal, and retro-epiglottic pharynx, during sleep, especially during rapid eye movement (REM) sleep.[253] During these obstructive episodes, OSA patients may exhibit hypoxia, bradyarrhythmias or tachyarrhythmias; myocardial ischemia, abrupt decreases in left ventricular stroke volume and cardiac output, or increases in pulmonary and systemic blood pressure.[257] Based on our understanding of the pathophysiology of OSA, it is easy to see how acute pain management can be difficult in this population. Patients with OSA are at higher risk for respiratory arrest.[258] Use of sedative doses of benzodiazepines and opioids may result in frequent hypoxemia and apnea, which may be especially dangerous in the OSA patient.[258] Avoiding respiratory depressants by optimizing use of NSAIDs and epidural analgesia with a local anesthetic–based regimen may attenuate the risk for respiratory depression and arrest because the use of epidural and systemic opioids is associated with sudden postoperative respiratory arrest.[259]

The American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea created guidelines that include acute pain management in patients with OSA.[260] Although the consultants acknowledged that the conclusions regarding postoperative analgesic options were based on insufficient literature evaluating the effects of various analgesic techniques, the presence of equivocal literature regarding the use of epidural opioids compared with intramuscular or intravenous opioids in reducing respiratory depression, and insufficient literature regarding the addition of a basal infusion to systemic patient-controlled opioids, the consultants nevertheless recommended that regional techniques rather than systemic opioids should be used in an attempt to reduce the likelihood of adverse outcomes in patients at increased peri-operative risk from OSA.[260] In addition, the consultants recommended the exclusion of opioids from neuraxial postoperative analgesia to reduce perioperative risk, and the use of NSAIDs to reduce adverse outcomes through their opioid-sparing effect. The consultants were equivocal regarding whether avoiding a basal infusion of opioids in patients with OSA reduces the likelihood of adverse outcomes.[260] Unfortunately, there is a paucity of randomized clinical trial data to provide definitive high-quality evidence-based recommendations in the provision of postoperative analgesia for OSA patients.

GENDER OR SEX DIFFERENCES IN ANALGESIA

A large body of data has been collected in the past 20 years concerning differences between the sexes in response to pain, including pain thresholds, and in the tolerance and response to acute pain treatment. However, the exact differences as well as their relevance are far from clear. According to the International Association for the Study of Pain (IASP), "pain is an unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage." This definition does not differentiate between "pain" as a woman experiences it from "pain" as a man experiences it and thus fundamental questions still remain.

Females report more severe pain, more frequent bouts of pain, more anatomically diffuse and longer-lasting pain than males with similar disease processes, even when male and female specific disorders including male urologic and female gynecologic pain are excluded from the analysis. Females have a higher prevalence of pain related to musculoskeletal or to visceral origin, as well as pain related to autoimmune disease (Table 51.10).[262] Substantial amounts of the accumulated data rely heavily on the subjective signs of the pain experience. These are highly influenced by sociocultural variables that have little to do with a biological difference of pain threshold or perception between women and men. An inherent reporting bias exists in the epidemiological research related to the incidence of pain in the sexes. Females are more likely to visit a physician and are more likely to report pain as a symptom than males[263,264] reviewed in[265] which can therefore lead to an overestimation of the differences between the sexes.

In a meta-analysis of studies examining sex differences in pain response in healthy subjects less than 60 years old, the authors found women report higher pain severity at lower thresholds and have less tolerance to noxious stimulation than males.[266] In a large multicenter trial, Rolke and colleagues[236] used quantitative sensory testing (QST) to determine sensory detection thresholds and pain thresholds for thermal and mechanical noxious stimuli. Females had lower pain thresholds, with the greatest disparities for sex differences found for heat pain threshold, followed by cold pain and pain to blunt pressure.

Many other physiological, socio-cultural, and psychological variables have been identified as contributing to the differences between the two sexes with regard to pain. One factor includes the end point being examined, such as pain threshold vs. pain tolerance.[266–268] Pool and colleagues[269] showed that pain tolerance is highly malleable and strongly influenced by the subject's "gender" norms. Males who are highly identified with the "male" role tolerate higher levels of noxious stimuli, but those males who do not have this belief tolerate noxious stimuli at the same level

TABLE 51.10

SEX PREVALENCE OF CLINICAL PAIN SYNDROMES OR DISEASES

Bodily area		Prevalence	
		Female > Male	**Female < Male**
Head	*Headache*	Chronic tension Migraine with aura Postdural puncture Cervicogenic Temporal arteritis Occipital neuralgia	Cluster Migraine without aura Posttraumatic War injury
	Oral	Odontalgia Burning mouth Temporomandibular disorder Trigeminal neuralgia	Para-trigeminal syndrome Trigeminal postherpetic neuralgia
Extremities	*Arms*	Carpal tunnel syndrome Raynaud's disease CRPS Type I Scleroderma	Brachial plexus neuropathy War Injuries CRPS Type II
	Legs	Chronic venous insufficiency Peroneal muscular atrophy Piriformis syndrome Raynaud's disease CRPS type I	Meralgia paraesthetica Gout Intermittent claudication CRPS Type II
Viscera	*Bowel*	Chronic constipation Irritable bowel syndrome Proctalgia fugax	Duodenal ulcer
	Esophagus	Esophagitis	
	Pancreas		Pancreatic disease
	Gall Bladder	Postcholecystectomy pain	
Autoimmune		Lupus erythematosus Multiple sclerosis Rheumatoid arthritis	Reiter's syndrome

as females. The age of the subject also modifies the pain threshold. Advancing age is positively associated with pain threshold.[235,236] Pickering and colleagues[268] found that the difference in score between males and females decreased with advancing age. The significant sex difference seen in thermal and mechanical threshold and in tolerance in younger volunteers became non-significant in volunteers greater than 40 years old.

As discussed above, the sex difference in humans is neither a universal nor a large effect. Furthermore, no difference between sexes is found in at least one-third of the published studies, and effect sizes are often in the small to moderate range.[266] Other investigators have sought objective measures of pain as a result of the numerous factors that have been shown to influence and in some cases abolish the pain threshold and tolerance differences between the sexes. Paulson and colleagues[267] used positron emission tomography (PET) to investigate regional brain activation after a painful somatic thermal stimulus in healthy normal volunteer male and female subjects. They reported that females had significantly greater activation of the contralateral prefrontal cortex, the contralateral insula and the thalamus compared to males suggesting sexual dimorphism in response to pain. Unfortunately, this study reflected a difference in brain activation that was more likely the result of different pain intensities rather than a true sex difference. In a later study also using PET technology, the pain intensity was matched between the sexes and the results were the opposite of the earlier study — males had greater activation than females.[270] Finally, a study using matched pain intensity and functional magnetic resonance imaging (fMRI) showed no sex-based difference in brain activation.[271] Other PET studies have described sex differences in responses to visceral pain from rectal balloon distension, although principally with chronic visceral pain patients.[272,273] However, the differences reported were predominantly in the direction of greater activation in men. These studies were replicated using fMRI with similar results of a male predominance of neuronal activation in pain-related areas of the brain.[272]

Pain thresholds in humans vary by internal factors such as sex, gender, female menstrual phase and psychological variables including catastrophizing, anxiety, and depression. External factors also affect the outcome including testing environment, sex, and gender of the examiner, and the modality of the noxious stimuli. In the largest study assessing the role of sex on pain thresholds using multiple modalities, it was found that females had lower pain thresholds in thermal and mechanical pain testing.[236] Unfortunately, this subjective difference has not been consistently supported by other confirmatory techniques including PET or fMRI brain imaging. Awareness of the possible differences between males and females in response to pain is the only clinical application of the present data with no guidance for particular situations.

Unlike the abundance of literature addressing the question of drug-induced sex differences in experimental pain in rodents, the human literature is not as voluminous. The majority of the literature addresses the response to *mu* opioid receptor agonists and

the remainder addresses *kappa* opioid receptor agonists. There has not been testing of other clinically available medications on humans in models of experimental pain. In multiple studies, either no difference[274–276] was noted between sexes or females had a significantly greater response to the medication.[277–279] Although initial studies attributed the difference to pharmacokinetic differences,[280] the metabolism of morphine to morphine-6-glucuronide (M6G), more recent work by Romberg and colleagues[275] demonstrate that no sex differences exist in M6G concentrations. In order to further exclude pharmacokinetic explanations for the sex differences, the same investigative group, subsequently published findings using the potent synthetic *mu* opioid receptor agonist alfentanil. The subject's response to alfentanil did not differ based on their sex.[281]

The human response to *kappa* opioid receptor agonists is somewhat variable. In a postsurgical model of pain, females had a greater analgesic response to kappa agonist-antagonist medications including pentazocine, nalbuphine, and butorphanol.[282–284] However, in experimental models of pain either no difference between males and females was noted[285] or males had an increased sensitivity to the medications.[286] Mogil and colleagues[286] suggest that the increased responsiveness to *kappa* opioid receptors agonists may be related to the absence of the MC1r gene. In an elegant study, this group studied women with fair skin and red hair who often have a functional reduction in MC1r. The women with a genetically proven loss of function polymorphisms experienced an accentuated analgesic response to pentazocine. Their analgesic response was indistinguishable from the male subjects in the study.[286] This finding has led to the proposal that the MC1r gene product acts as an anti-opioid and therefore when removed unmasks the true *kappa* opioid effect. This enhanced effect would be inconsistent with the finding that females have an increased response to *kappa* opioid receptor agonists in clinical models of pain (e.g. postoperative) because fair-skinned redheaded females represent only a minority of women in general. Unfortunately, it does not explain the lack of difference or the greater analgesic response of females to *mu* opioids in clinical and experimental models or *kappa* opioids in experimental models of pain.

Unfortunately, the data with regard to opioid analgesics garnered from human trials is not sufficient to guide clinical practice. The studies, so far, do not justify the conclusion that males or females have a greater responsiveness to *mu* or *kappa* opioid receptor agonists and therefore they should continue to receive similar acute pain management until more definitive studies are conducted.

ACUTE PAIN SERVICES

Although dedicated individuals can improve postoperative pain control for a few patients, more comprehensive perioperative pain management programs (i.e., acute pain services) developed specifically to treat this problem can address the needs for all patients within an institution. The organizational aspects of such comprehensive services are considerable, necessary for effective and safe care, and may include issues such as education; administration, nursing, and documentation (Table 51.11). With skills in regional anesthetic techniques and knowledge of the neurobiology of nociception and the pharmacology of analgesics and local anesthetics, anesthesiologists have been leaders in postoperative pain relief and development of acute pain services. Provision of perioperative analgesia, along with other services such as critical care medicine and preoperative evaluation, is highly compatible with the emerging identity of anesthesiologists as perioperative physicians and enhances the role of anesthesiologists as valued consultants outside the operating room.

TABLE 51.11

ORGANIZATIONAL ASPECTS OF AN ACUTE PAIN SERVICE

Educational Activity
Health care providers: Anesthesiologists, Surgeons, Nurses, Pharmacists
Hospital administrators
Patients and families

Nursing
Continuing education and training
Defining of roles in patient care
Nursing policies and procedures
Pain service nursing
Documentation
Educational packages
Policies and procedures
Preprinted forms
Bedside pain management assessment flow sheet
Daily consultation notes

Although there are several models for the development of acute pain services[287,288] the key organizational aspects are similar. Development and maintenance of acute pain services require a commitment and financial support at the national and local level. In the United States, there appears to be a dichotomy at the national and third-party payer level between the call for improved postoperative pain control with the introduction of practice guidelines or expanded roles for acute pain services and decreased reimbursement for the provision of such services. Because there are financial burdens associated with the establishment of an acute pain service, high-volume or larger hospitals are more likely have acute pain services and have access to more high-tech analgesic techniques such as epidural analgesia.[289,290] Whether acute pain services actually improve outcomes is unclear. Two systematic reviews have examined the impact of acute pain services on patients outcomes[291] and while systematic reviews suggest that the introduction of acute pain services is associated with a decrease in pain scores, the effect of acute pain services on the incidence of analgesic-related side effects such as nausea and vomiting, satisfaction, and overall costs or cost reductions are uncertain.[291] Despite the direct costs (e.g., personnel, equipment, medication) associated with managing an acute pain service, there is no available properly conducted pharmaco-economic study to examine the cost-effectiveness of an acute pain service. Use of postoperative epidural analgesia in the context of acute pain services may decrease the cost of patient care through shorter intensive care unit stays and a decreased rate of complications.[5] Despite the costs associated with implementation of an acute pain service and acute pain management practice guidelines, acute

pain services provide a valuable service at the individual, institutional, and societal levels.

LONG-TERM IMPACT OF ACUTE PAIN

Chronic postsurgical pain [CPSP] is a largely unrecognized problem which may occur in 10% to 50% of postoperative patients (depending on type of surgery) with 2% to 10% of these patients experiencing severe CPSP.[292] Poorly controlled acute postoperative pain or acute pain in general may be an important predictive factor in the development of chronic pain.[43,293] Increasing experimental and clinical evidence suggests that the transition from acute to chronic pain occurs very quickly and that long-term behavioral and neurobiological changes occur much earlier than previously anticipated.[294] CPSP is relatively common after procedures such as limb amputation (30% to 83%), thoracotomy (22% to 67%), sternotomy (27%), breast surgery (11% to 57%), and gallbladder surgery (up to 56%).[43] Although studies suggest that the severity of acute postoperative pain may be an important predictor in the development of CPSP, a causal relationship between severity of acute postoperative pain and subsequent CPSP has not been definitively established and other factors may be more important in predicting the development of CPSP.

Control of acute pain may improve long-term recovery or patient-oriented outcomes including quality of life or return of function. Patients whose pain is controlled in the early postoperative period (especially with use of continuous epidural or peripheral catheter techniques) may be able to actively participate in postoperative rehabilitation, which may improve short- and long-term recovery after surgery.[295] In a recent study, a multimodal approach to acute analgesia using either epidural or spinal analgesia reduced the patient's area of hyperalgesia and allodynia in the acute phase and diminished their long-term pain as well.[296] Another study examined the showed that acute postoperative pain was an important risk factor for the development of chronic pain.[297] Optimizing treatment of acute postoperative pain can improve health-related quality of life (HRQL) [200]. Postsurgical chronic pain that develops as a result of poor acute pain control can interfere with patients' activities of daily living and reduce a person to a less functional status.

CHAPTER 52 ■ REGIONAL ANESTHESIA TECHNIQUES FOR ACUTE PAIN MANAGEMENT

STEVE MELTON AND SPENCER S. LIU

INTRODUCTION

This chapter focuses on regional anesthesia techniques for acute postoperative pain management. Central neuraxial, paravertebral, and peripheral nerve blocks including single-shot injections, continuous perineural catheters, and ultrasound-guided techniques are discussed. Included in this discussion are the indications, mechanisms of action, side effects and complications of regional anesthetic techniques, and the associated outcomes and evidence in the application of these techniques for acute postoperative pain management.

BLOCK PREPARATION

Whether performing regional anesthetic techniques in the operating room or a separate block-area, all patients should have an intravenous (IV) infusion line, standard monitors (continous pulse oximetry, electrocardiogram, intermittent noninvasive blood pressure), supplemental oxygen, and appropriate sedation for the procedure. Airway management and medications for emergency cardiopulmonary resuscitation, including intralipid infusion, should be immediately available. All regional anesthetic techniques are performed using strict aseptic technique.

CENTRAL NEURAXIAL

Subarachnoid and epidural analgesia are commonly practiced regional anesthesia techniques for acute postoperative pain management. As a means of postoperative pain control, single-shot techniques with perispinal additives and/or continuous or patient-controlled catheter techniques with local anesthetics and/or perispinal additives may be used. The practice of neuraxial anesthesia requires an appreciation of both surface and underlying spinal anatomy, including the relationship between the cutaneous dermatomes, spinal nerves, and vertebrae.[1]

Subarachnoid Analgesia

Indications

Spinal analgesia may be used for postoperative analgesia following obstetric, gynecologic, hernia repair, genitourinary, and orthopedic surgeries of the lower extremity. Additionally, spinal analgesia offers postoperative pain control for cardiac, abdominal, vascular, spine, and thoracic surgery. Obstetric analgesia will not be included in our discussion. Intrathecal (IT) additives including fentanyl, sufentanil, morphine, hydromorphone, and clonidine are discussed below.

Technique

Subarachnoid block may be performed with the patient in the sitting, lateral (Fig. 52.1), or prone position through a midline or paramedian approach (Fig. 52.2). After patient positioning, the appropriate interspace is identified, prepped, and draped in sterile fashion. Local anesthetic is infiltrated at the needle insertion site. The introducer needle is placed midline and advanced in the midline plane with slight cephalad angulation through the supraspinous ligament and into the interspinous ligament. The depth to the subarachnoid space must be anticipated to avoid inadvertent dural puncture with the introducer needle in thin patients. The spinal needle is then advanced through the introducer, stabilizing the introducer with the nondominant hand. As the needle passes through the ligamentum flavum, an increase in resistance is appreciated, followed by a loss of resistance, with a characteristic "pop" indicating penetration of the dura and entry into the subarachnoid space. The spinal needle stylet is removed, and free cerebrospinal fluid (CSF) flow is confirmed through the needle. If free CSF flow is not visualized, the hub of the needle may be rotated 90 degrees, followed by slight advancement of the needle if necessary. If CSF free flow is unable to be confirmed, the needle is slowly withdrawn in slight increments, with 90 degree rotation at each increment to allow for free CSF flow. Upon obtaining free flow of CSF, the dorsal aspect of the nondominant hand is firmly placed against the patient's back with the index finger and thumb stabilizing the spinal needle hub for injection. In the dominant hand, the syringe with local anesthetic and additive is attached to the spinal needle hub and injected. If redirection of the spinal needle is necessary secondary to bone contact, paresthesia, or failure to obtain CSF, the anatomy should be re-evaluated and the introducer repositioned as necessary at the same or a new level. If a paresthesia is encountered at any time, needle advancement or injection should be stopped, and resolution of paresthesia confirmed before and during subsequent advancement and or injection.

The paramedian-lateral and paramedian-lateral oblique approaches offer alternatives to the midline approach in patients

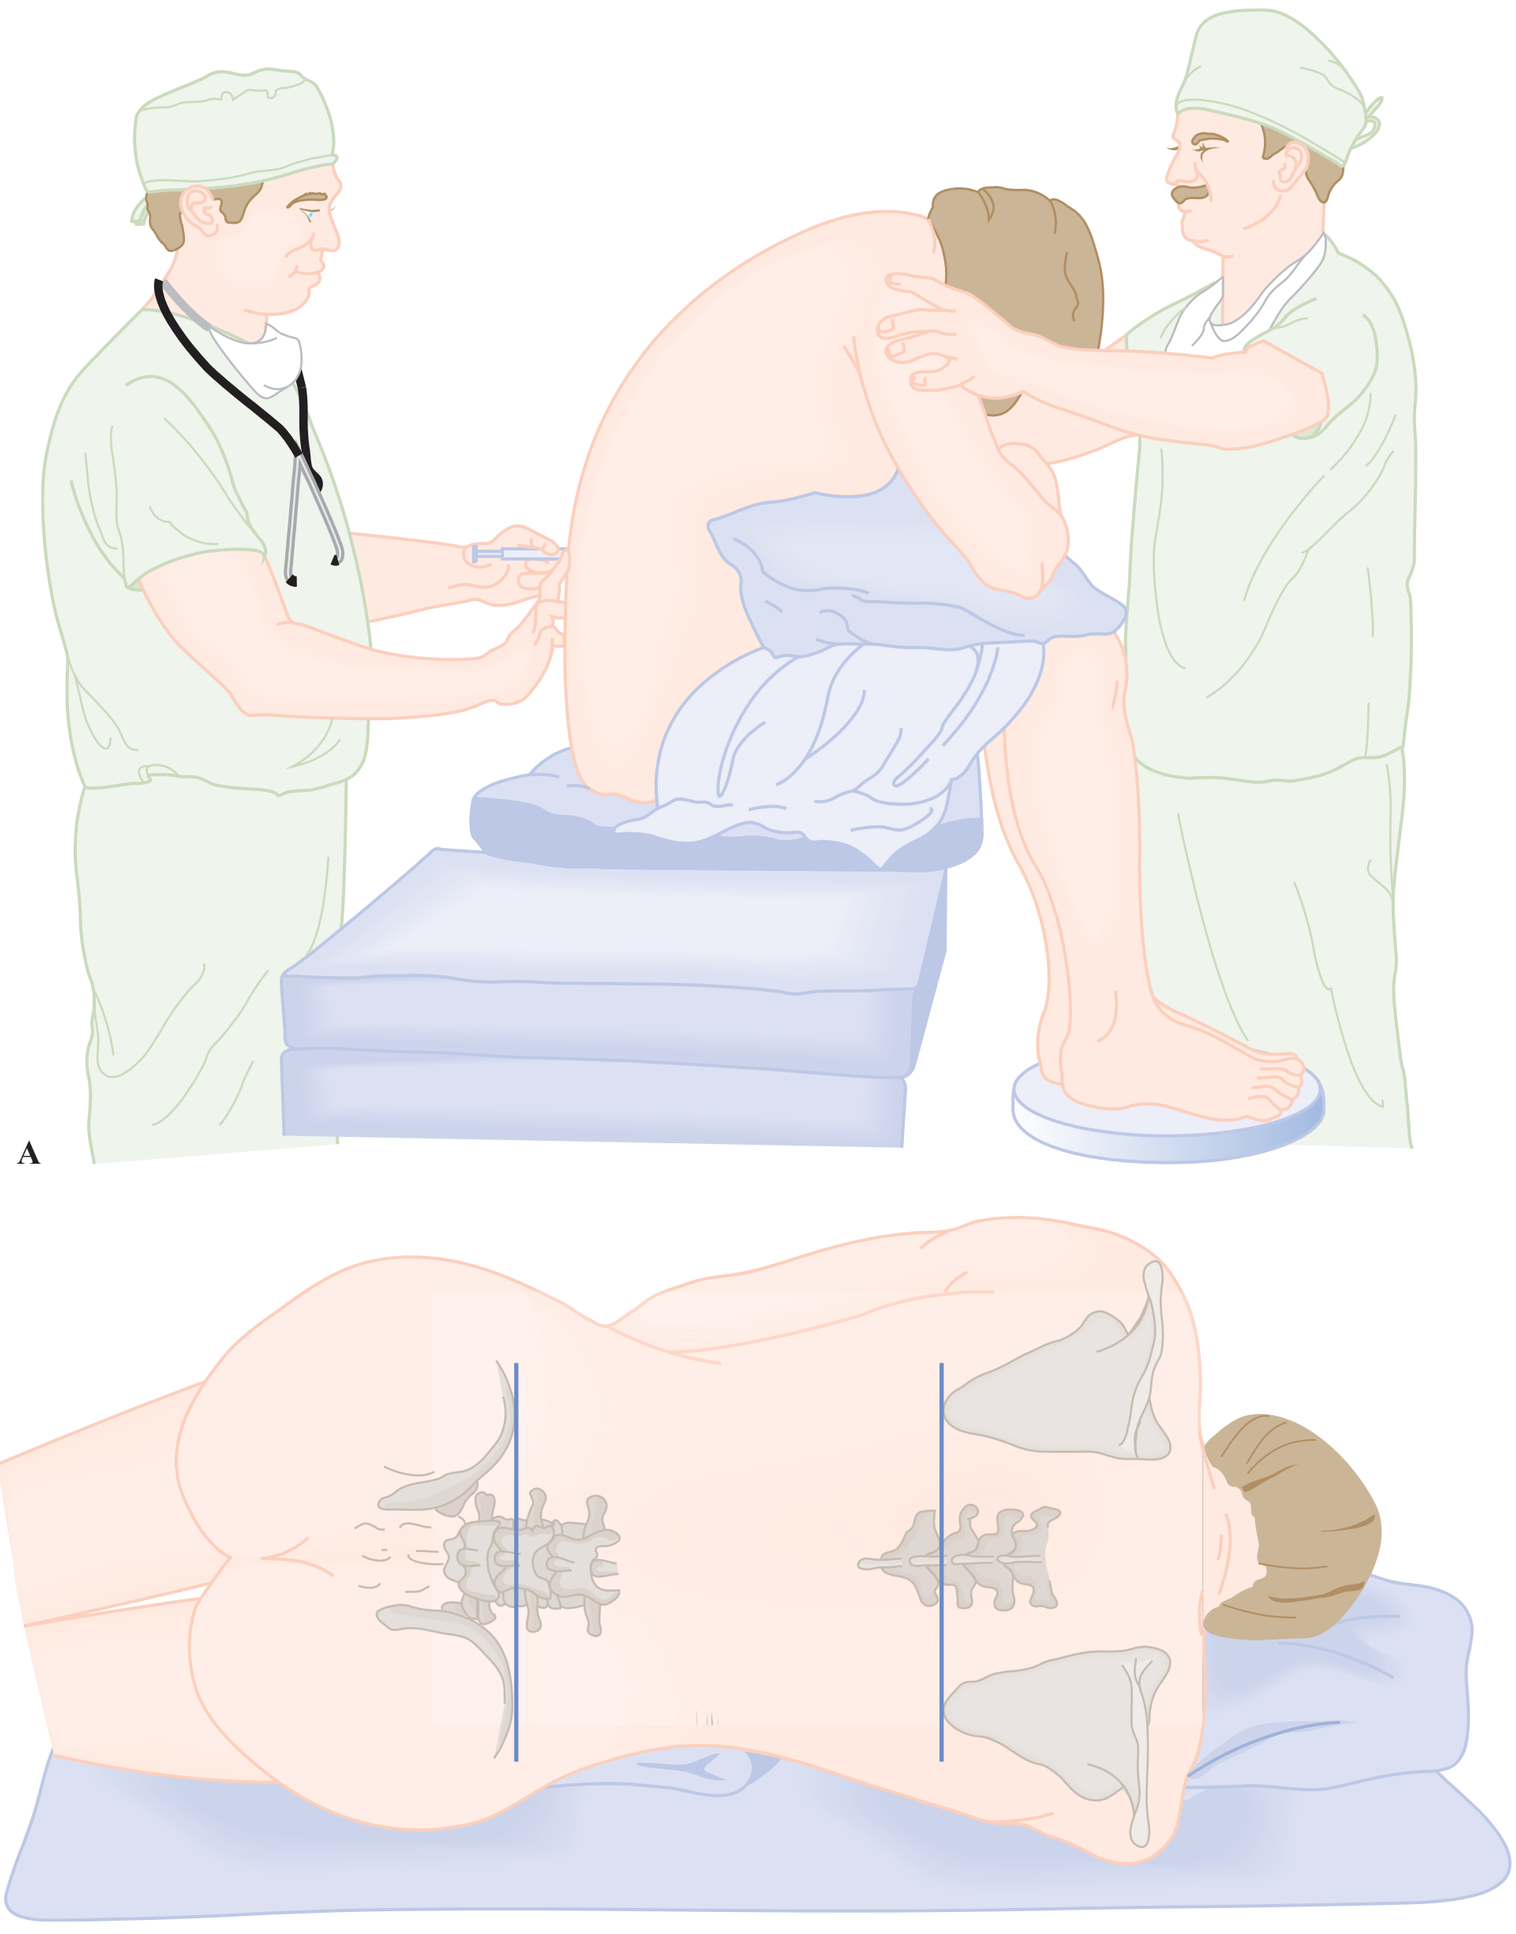

FIGURE 52.1 Sitting **(A)** and lateral **(B)** position position for neuraxial block. A line drawn between the superior aspects of the iliac crests will cross the L4 spinous process or L4-L5 interspace. A line drawn between the inferior angles of the scapulae will cross the T7 spinous process.

with narrow interspinous spaces for both subarachnoid and epidural blocks.

For the paramedian-lateral approach, the spinal introducer insertion site is approximately one fingerbreadth lateral to the insertion site of the midline approach. The introducer is oriented with slight medial and cephalad direction to allow the spinal needle to bypass the supraspinous and interspinous ligaments, pass through the triangular-shaped ligamentum flavum, and enter the subarachnoid space at the midline (see Fig. 52.2).

Using the paramedian-lateral oblique approach, the caudad spinous process of the desired interspace is identified. The needle is inserted approximately one fingerbreadth lateral to this point and directed with cephalomedial orientation to bypass the supraspinous and interspinous ligaments, pass through the triangular-shaped ligamentum flavum, and enter the subarachnoid space at the midline. Alternatively, the needle is initially oriented perpendicular to the skin in all planes and advanced with the intent to contact lamina. Upon contact with lamina, the needle is walked off the superior edge of the lamina and advanced through the ligamentum flavum to enter the subarachnoid space (see Fig. 52.2).

Intrathecal Opioids

The advantages of IT opioids lay in the absence of sympathetic blockade and postural hypotension, potentially easier ambulation of patients, and avoidance of cardiovascular collapse or convulsions—the major complications of local anesthetic blockade.

Mechanism of Action

IT opioids selectively decrease nociceptive afferent input from A-delta and C-fibers without affecting dorsal root axons or so-

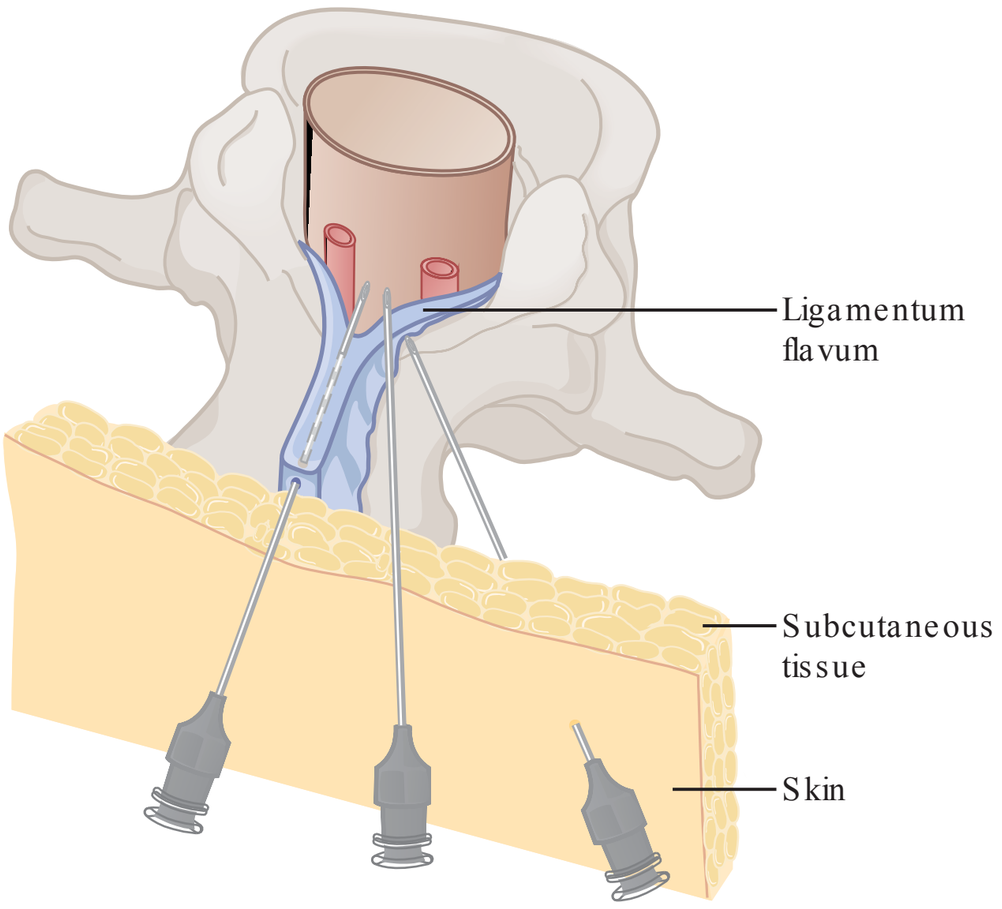

FIGURE 52.2 Midline, paramedian-lateral, and paramedian-lateral oblique approaches to the subarachnoid and epidural space.

matosensory evoked potentials.[2] Opioid receptors in the ventral medial medullary reticular formation may be involved in activation of bulbospinal noradrenergic pathways. Additionally, a descending inhibitory pathway projecting through the dorsolateral funiculus may reinforce other analgesic mechanisms.[3,4]

A single-dose injection of neuraxial opioids can provide effective postoperative analgesia as a sole analgesic agent or in combination with other agents such as local anesthetics or alpha-2 agonists. The analgesic profile of neuraxially administered opioidsis primarily dependent on the degree of lipophilicity versus hydrophilicity of the agent. Hydrophilic opioids, such as morphine and hydromorphone, produce a longer duration of analgesia as compared to lipophilic opioids such as fentanyl or sufentanil. The pharmacokinetic differences in analgesia between hydrophilic and lipophilic opioids should be tailored to the surgical procedure and venue (inpatient versus outpatient) to optimize analgesia and minimize side effects. A single IT injection of a hydrophilic opioid such as morphine, which provides 12 to 18 hours of postoperative analgesia, is appropriate for surgical inpatients with appropriate monitoring of side effects. For outpatient postoperative analgesia, however, utilizing a lipophilic opioid such as fentanyl, with a rapid analgesic onset and short duration of action, is more appropriate, minimizing the risk of delayed respiratory depression.[5]

Morphine/Hydromorphone. Hydrophilic opioids such as morphine and hydromorphone provide excellent selective spinal analgesia because of a small volume of distribution and slow clearance from the spinal cord.[6] However, slow spinal cord penetration and prolonged duration in the CSF caused by hydrophilicity also results in slow onset (>30 minutes), prolonged duration of action (6 or more hours), and risk of delayed respiratory depression from rostral spread in CSF.

Sufentanil. Sufentanil is a lipophilic opioid. Lipophilic opioids have a more favorable clinical profile of fast onset (minutes), modest duration (1–4 hours), and little risk of delayed respiratory depression. Clinical studies suggest that IT administration of sufentanil may produce selective spinal analgesia; however, laboratory studies suggest that systemic uptake followed by supraspinal analgesia may be the dominant mechanism of action. Because of the extreme lipid solubility of sufentanil, it has a very large volume of distribution in the spinal cord with rapid clearance into the spinal cord vasculature and epidural space in pig models.[6] This laboratory finding implies that very little spinal sufentanil is available for interaction with spinal cord opioid receptors because of sequestration in lipid soluble white matter and systemic redistribution. Thus, there is little support for the spinal administration of sufentanil in order to achieve selective spinal analgesia.

Fentanyl. Fentanyl is a lipophilic opioid, and thus, has a more favorable clinical profile of fast onset (minutes), modest duration (1–4 hours), and little risk of delayed respiratory depression.[2] Fentanyl, however, is less lipid soluble than sufentanil and will maintain modest spinal selectivity when injected intrathecally.[6,7] Dose-response data indicate that spinal fentanyl alone provides dose-dependent analgesia with a minimally effective dose of approximately 10 mcg.[8] Risk of early respiratory depression is also dose dependent, with significant risk occurring with doses greater than 25 mcg.[9] Thus, the best risk-benefit dose range would be limited to easily treated pruritis (~60%) [10,11] while minimizing the risk of early respiratory depression and urinary retention.[9,10,12]

Side Effects

Side effects of neuraxial opioids are caused by the presence of drug in either the CSF or systemic circulation. More common side effects include depression of ventilation, pruritis, nausea, vomiting, urinary retention, and sedation.[13]

Depression of Ventilation. The most feared side effect is respiratory depression and arrest. It has been demonstrated that the risk of respiratory depression is dose related,[14] with few instances of clinically significant depression reported at doses less than 0.4 mg of IT morphine.[15] Respiratory depression, however, has been noted at even smaller doses on rare occasions.[16] The incidence of respiratory depression is less than 1% for opioids regardless of route of administration.[17] Respiratory depression typically occurs within minutes to hours for lipophilic opioids (fentanyl, sufentanil) with early respiratory depression (minutes) not being reported with a hydrophilic opioid such as morphine. For morphine, delayed respiratory depression characteristically occurs 6 to 12 hours after administration but has been reported up to 19 hours after IT injection.[18] Clinically significant respiratory depression has never been reported beyond 19 hours after IT morphine administration. The following factors may contribute to the development of respiratory depression after IT opioid administration: opioid-naïve state, concurrent use of systemic opioids or sedatives, increasing age, and sleep or obstructive sleep apnea. Frequent monitoring of patients who have received IT opioid is recommended; however, the need for an intensive care-like unit setting for postoperative monitoring of these patients is controversial.[19]

Pruritis. The most common side effect after IT opioids is pruritis. Although IT opioid-induced pruritis is likely due to cephalad migration of the drug and interaction with opioid receptors in the trigeminal nucleus located superficially in the medulla,[18] the exact etiology is unclear. Itching is not histamine-related nor is it related to systemic absorption of the drug. The incidence has been reported anywhere from 20% to 100% in various studies and may be dose-dependent.[18,20–22] It appears that patients who receive morphine have a higher incidence of pruritis than those who receive fentanyl.[18,23]

Nausea and Vomiting. Nausea and vomiting are also common and troubling side effects after IT opioid injection. Although the incidence is lower than that seen with pruritis, patients may require treatment more frequently. Nausea occurs in approximately 20% to 40% of patients receiving IT opioids. Nausea usually occurs within 4 hours of injection and may be more likely when

IT morphine is utilized.[18] The mechanism is likely due to the cephalad migration of drug and subsequent interaction with opioid receptors in the area postrema.[18,24] Although the mechanism is not related to systemic absorption, the incidence is comparable to IV and epidural administration.

Urinary Retention. Urinary retention following IT opioids is much more common than after equivalent doses given intravenously. Urinary retention induced by IT opioids is not dose-related, may be more frequent when IT morphine is administered, and is likely related to opioid receptor-induced inhibition of sacral parasympathetic nervous system outflow, resulting in detrusor relaxation and an increase bladder capacity.[18]

Sedation. Sedation is a dose-dependent side effect of IT opioids that occurs with all opioids.[25] The difference in levels of sedation from IT, IV, and epidural routes is not well documented, but appears to be common regardless of route of delivery. The incidence may be higher with sufentanil than other opioids.[18,26,27]

Intrathecal Clonidine

Research has demonstrated the antinociceptive properties and the mechanisms involved in the production of spinal analgesia after administration of alpha-2 adrenergic drugs. Clonidine is the best characterized alpha-2 adrenergic agonist and provides dose-dependent analgesia.[28]

Mechanism of Action

Clonidine's analgesic activity is mediated through pre- and postsynaptic alpha-2 receptors localized in the superficial layers of the spinal dorsal horn. Clonidine attenuates nociceptive input from A-delta and C-fibers and acts synergistically with spinal local anesthetics.[29] Additionally, neuraxial placement of clonidine inhibits spinal substance P release and nociceptive neuron firing produced by noxious stimulation.[13]

Side Effects

Side effects of IT clonidine include hypotension, bradycardia, and sedation. It is not associated with side effects of spinal opioids such as respiratory depression and pruritis and has less potential for causing urinary retention than spinal opioids.[30] Much smaller bolus doses of clonidine are needed through the IT route to produce potent and long-lasting analgesia than via the epidural or systemic routes. Doses of 15 to 30 mcg may be equally efficacious as larger doses while decreasing side effects.

Clinical Subarachnoid Analgesia

Opioids

Highly lipophilic, short-acting opioids, such as fentanyl, can be added to local anesthetics to improve short-term analgesia for inpatient or outpatient procedures.[31–33] The addition of 10 mcg fentanyl to bupivacaine 0.5% (hyperbaric) significantly improves the quality and duration of analgesia, with no further advantage occurring if the dose is increased up to 40 mcg.[34] Hydrophilic opioids, however, provide extended postoperative analgesia in the inpatient setting. Dose response trials demonstrate that low doses of hydrophilic opioids maximize postoperative analgesia with a lower incidence of side effects (Table 52.1) For example, Cole et al.[35] demonstrated that 0.3 mg of IT morphine significantly reduces pain and patient-controlled analgesia (PCA) requirements compared to placebo following knee arthroplasty with no significance difference in hypoxemia and apnea between groups. For opioid-tolerant patients, higher doses are probably acceptable, while doses of less than 0.3 mg may be ideal for opioid-naïve individuals.[36] IT opioids have been used for cardiac surgery with improved analgesia; however, concerns with bleeding complications in patients who are receiving heparin and studies demonstrating prolonged extubation times may have limited its use.[19] Alhashemi et al.[37] demonstrated that 250 mcg is the optimal dose of IT morphine to provide significant postoperative analgesia without delaying tracheal extubation after coronary

artery bypass graft surgery. IT opioid combinations provide superior analgesia versus systemic opioids in patients undergoing vascular and thoracic procedures. Compared to those who received IV PCA morphine, patients who received a mixture of either 20 mcg of sufentanil with 0.2 mg of morphine or 50 mcg of sufentanil with 0.5 mg of morphine have improved pain control with minimal side effects other than an increased frequency of urinary retention.[5,38] Although epidural analgesia with local anesthetics and opioids is likely superior to IT opioids in decreasing pulmonary complications after thoracotomy,[39] IT opioids may be a good alternative to epidural analgesia in situations where an epidural catheter cannot be maintained.[19]

Clonidine

Studies demonstrate that intrathecal clonidine at doses from 15 to 150 mcg improve postoperative analgesia while minimizing side effects. Coadministration of 25 to 75 mcg of clonidine with morphine 250 mcg to a bupivacaine spinal anesthetic demonstrated decreased 24h IV morphine consumption and improved 24h visual analog scale (VAS) scores as compared to 250 mcg intrathecal morphine added to bupivacaine spinal anesthetic alone.[40–42]

Epidural Analgesia

Indications. Epidural analgesia provides segmental analgesia. Continuous catheters allow flexibility in the depth and duration of analgesia. Epidural analgesia is effective for thoracic, abdominal, gynecologic, urologic, and orthopaedic surgery of the lower extremity. Obstetric analgesia will not be included in our discussion.

Block Technique.

Epidural. Epidural blockade may be performed with the patient in the sitting or lateral (see Fig. 52.1) position through a midline or paramedian approach. After patient positioning, the appropriate interspace is identified, prepped, and draped in sterile fashion. Local anesthetic is infilitrated at the needle insertion site. Using the midline approach, the epidural needle is oriented in the same plane as the spinous processes with slight cephalad angulation toward the interlaminar space. The epidural needle is directed through the skin wheal and slowly advanced through the supraspinous and interspinous ligaments to enter the ligamentum flavum. Upon entering the ligamentum flavum, a subtle change of resistance is appreciated. The ligamentum flavum is usually reached at a depth of 3.5 to 5 cm from the skin in the normal adult. When the resistance of the ligamentum flavum is appreciated, the stylet is removed from the epidural needle and a loss-of-resistance syringe containing either air and/or 3 cc of saline with a small air bubble is attached to the hub. Constant pressure is applied to the plunger of the syringe as the needle is slowly advanced. Alternatively, intermittent pressure is applied to the plunger between small, gentle advances of the epidural needle. Upon entering the epidural space, there is a sudden, significant loss of resistance to plunger displacement. The dorsal aspect of the nondominant hand is firmly placed against the patient's back with the index finger and thumb stabilizing the hub for injection. A test dose of 3 cc of a local anesthetic with 1:200,000 epinephrine is injected, and the patient is observed for signs and symptoms of IT or intravascular injection. The local anesthetic should be administered in 5 mL increments until the appropriate total dose is given. A 20-gauge radio-opaque catheter with 1 cm graduations is passed through the epidural needle. The catheter is advanced 4–5 cm beyond the needle tip into the epidural space. The needle is then withdrawn over the catheter and the catheter secured to the patient's back.

Alternatively, a paramedian-lateral or paramedian-lateral oblique approach to the epidural space may be used. For this approach, the epidural needle insertion site is approximately one fingerbreadth lateral to the insertion site of the midline approach. The epidural needle is directed with slight cephalomedial orientation to allow the needle to bypass the supraspinous and interspinous ligaments as the needle is advanced to enter the triangular-shaped ligamentum flavum. Upon entering the ligamentum flavum, the loss-of-resistance technique is used to enter the epidural space at the midline (see Fig. 52.2).

Using the paramedian-lateral oblique approach, the caudad spinous process of the desired interspace is identified. The epidural needle is inserted approximately one fingerbreadth lateral to this point and directed with cephalomedial orientation to bypass the supraspinous and interspinous ligaments as the needle is advanced to enter the ligamentum flavum. Upon entering the ligamentum flavum, the loss-of-resistance technique is used to enter the epidural space at the midline. Alternatively, the needle is initially oriented perpendicular to the skin in all planes and advanced with the intent to contact lamina. Upon contact with lamina, the needle is walked off the superior edge of the lamina and advanced through the ligamentum flavum using the loss-of-resistance technique to enter the epidural space at the midline (see Fig. 52.2).

While the paramedian approach may be used for both lumbar and thoracic epidurals, it is extremely advantageous in the mid-thoracic vertebrae (T4–T10) where the steep angle of the spinous processes limits midlines access to the interlaminar foramen (Fig. 52.3).

Combined spinal epidural technique. The benefits of both spinal and epidural anesthesia/analgesia may be obtained using the combined spinal epidural (CSE) technique. Using the epidural technique as described above, the epidural needle is advanced into the epidural space. After loss of resistance to plunger displacement indicating entrance into the epidural space, the plunger is carefully removed and a spinal needle is passed through the epidural needle until the characteristic "pop" is felt, indicating penetration of the dura and entry into the subarachnoid space (Fig. 52.4). After free CSF flow is confirmed, the dorsal aspect of the nondominant hand is firmly placed against the patient's back with the index finger and thumb stabilizing the hub for injection. Local anesthetic with additive is injected and the spinal needle is withdrawn. A 20-gauge radio-opaque catheter with 1 cm graduations is passed through the epidural needle. The catheter is advanced 4–5 cm beyond the needle tip into the epidural space. The needle is then withdrawn over the catheter, and the catheter secured to the patient's back. Prior to dosing the catheter a test dose should be administered through the catheter.

Epidural Opioids

Epidural opioids as a single injection or continuous infusion are an important postoperative analgesic option.

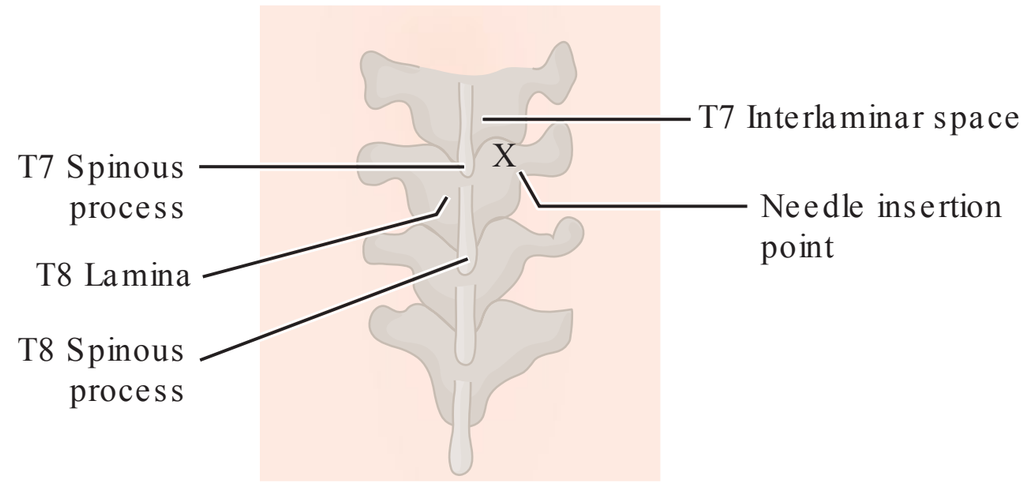

FIGURE 52.3 Surface and underlying anatomy for thoracic epidural block.

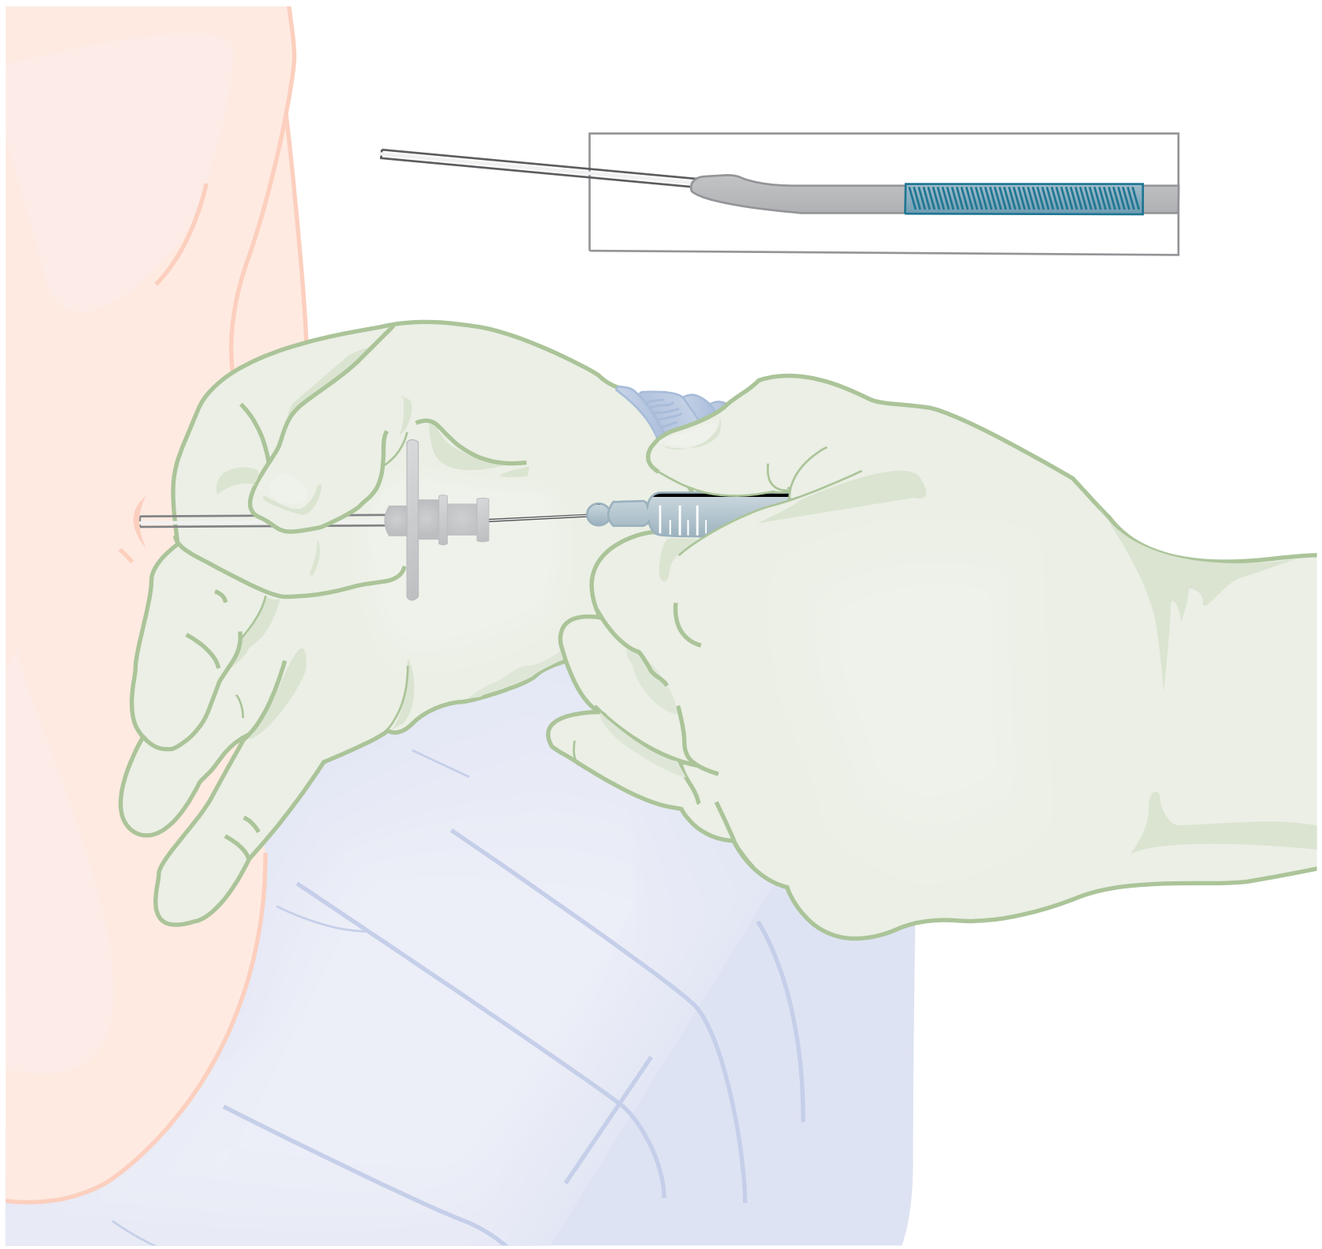

FIGURE 52.4 Combined spinal epidural technique.

Mechanism of Action

There are two mechanisms by which epidurally administered opioids can act to produce analgesia: spinal and supraspinal/systemic analgesia. Supraspinal analgesia is mediated by the systemic uptake of epidurally administered opioids and their subsequent redistribution to the brainstem. Spinal analgesia produced from epidurally administered opioids is achieved via diffusion through the spinal meninges into the CSF. Once inside the CSF, epidurally administered opioids interact with spinal opioid receptors located in lamina II of the spinal cord dorsal horn and achieve antinociception via presynaptic reduction of afferent neurotransmitter release and postsynaptic hyperpolarization of dorsal horn neurons.[42] A key pharmacologic property of an epidurally administered opioid that determines its analgesic and side effect profile is the extent of its lipophilicity. After single-dose epidural administration, lipophilic opioids, such as fentanyl and sufentanil, have a faster onset but shorter duration of action when compared to that of more hydrophilic opioids, such as morphine and hydromorphone. Furthermore, the extent of lipophilicity affects the side effect profile. Lipophilic opioids with relatively rapid clearance from the CSF limit the development of delayed respiratory depression.[2] Epidural opioids do not predominately produce analgesia through a spinal mechanism. The degree to which lipophilic opioids produce analgesia via a spinal or supraspinal mechanism is still somewhat controversial.[42,43] It is generally thought that lipophilic opioids (especially when administered in a continuous infusion) will produce analgesia primarily by systemic uptake and redistribution of the lipophilic opioid to brainstem opioid receptors.[42] On the other hand, it is clear that hydrophilic opioids primary site of analgesic action is selectively spinal.[44,45] Epidurally administered hydrophilic opioids, after penetrating the dural membrane and entering the CSF, will remain within the CSF to produce spinal analgesia and spread rostrally in the CSF (due in part to its low lipid solubility) to act at the brainstem.[45] An opioid administered in the epidural space will also diffuse into the surrounding tissues including epidural fat and veins. Opioids that diffuse into fat are no longer available to bind to opioids receptors and thus unavailable for analgesic affect.

Morphine. A single epidural dose of a hydrophilic opioid such as morphine is especially efficacious for prolonged postoperative analgesia. Epidural morphine, when administered as a single bolus, has been shown to provide effective postoperative analgesia for major abdominal and vascular surgery.[46] The dose of epidural morphine may need to be reduced for elderly patients and thoracic epidural catheter sites.[47]

Extended-Release Epidural Morphine. Extended-release epidural morphine (EREM) consists of a lipid-based delivery system designed to provide 48 hours of pain relief without the need for an indwelling epidural catheter.

The absence of an indwelling catheter offers potential advantages over continuous epidural infusions, particularly in patients being treated with anticoagulation therapy. EREM is approved by the U.S. Food and Drug Administration at dose levels of 10–20 mg, noting that older patients may require less medication than younger patients. EREM is not recommended in patients over 65 years of age in doses exceeding 15mg. The side effect profile of EREM is consistent with that of other epidurally administered opioids analgesics. Close monitoring of respiratory function is indicated in all patients having received EREM.[48–50]

Fentanyl. A single epidural bolus of a lipophilic opioid like fentanyl may be administered to provide a rapid (onset within 5 to 10 minutes) but relatively transient (up to 4 hours) postoperative analgesia. Diluting the epidural dose of fentanyl (typically 50 to 100 mcg) in at least 10 mL of preservative-free normal saline may hasten onset and prolong the duration of analgesia possibly as a result of an increase in the initial spread and diffusion of fentanyl.[51] Combining a hydrophilic opioid such as morphine and a lipophilic opioid such as fentanyl in a single epidural injection combines the short onset time produced by the lipophilic

opioid and the long duration of analgesia produced by the hydrophilic opioid.[52]

Hydromorphone. Lumbar epidural morphine and hydromorphone afford comparable analgesia, but the occurrence of moderate to severe pruritus on the first postoperative day is reduced by the use of hydromorphone.[53]

Side Effects

Respiratory Depression. Respiratory depression associated with epidural administration of opioids is dose-dependent and the incidence is typically reported from 0.1% to 0.9%.[17,25,54–57] The incidence of respiratory depression with epidural opioids (when used in appropriate doses), whether single injection or continuous infusion, is not higher than that seen with systemic administration of opioids.[17,54] Factors that may increase the risk of developing respiratory depression in patients who have received epidural opioid include thoracic surgery, presence of comorbidities, increasing age, an opioid-naïve state, and concomitant use of systemic opioids and sedatives.[54]

Nausea and Vomiting. Nausea and vomiting occurs in 20% to 50% of patients after a single dose of epidural opioids,[58–60] and the overall incidence in those receiving continuous infusion of epidural opioids is reported at 45% to 80%.[61–63] The development of opioid-induced nausea and vomiting after the administration of epidural opioids appears to be dose-dependent.[21,64,65] Nausea and vomiting from epidural opioids is the result of interaction with opioid receptors in the area postrema and chemotactic trigger zone of the medulla.

Pruritis. The etiology of epidural opioid-induced pruritis is unclear and may be related to activation of an "itch-center" in the medulla and interaction with opioid receptors in the trigeminal and upper cervical spinal cord with cephalad migration of the opioid; however, opioid-induced pruritis does not appear to be associated with peripheral histamine release.[18] Pruritis from epidural opioid administration may occur in as many as 60% of patients as compared to a 15% to 18% incidence with systemic opioid use.[66,67] It is not clear whether pruritis from epidural opioid administration is a dose-dependent relationship.[68]

Urinary Retention. Administration of epidural opioids may result in urinary retention, which is related to a decrease in detrusor muscle strength contraction secondary to spinal opioid receptor activation.[18] The 70% to 80% incidence of urinary retention from epidurally administered opioids appears to be much higher than the 18% incidence of urinary retention associated with systemically administered opioids.[18,66] The development of urinary retention does not appear to be dose dependent.[69]

Epidural Clonidine

Mechanism of Action

Clonidine induces dose-dependent spinal cord antinociception, primarily through stimulation of alpha-2 adrenoceptors in the dorsal horn, mimicking the activation of descending inhibitory pathways.

Side Effects

Side effects associated with commonly used doses of epidural clonidine include hypotension, bradycardia, and sedation.[70] It is not associated with side effects of spinal opioids such as respiratory depression and pruritis.

Clinical Effects

In healthy volunteers, the reduction in pain intensity after epidural clonidine correlates with its concentrations in the CSF, but not in the serum.[28] In a review of clonidine in combination with epidural opioids as compared to clonidine or epidural opioids alone, the trials[71–73] provided weak and scattered evidence that administering clonidine with an opioid spinally is more effective than either clonidine or the opioid used alone for acute pain management.[74] Walker et al [74] attributed these results to the marginal doses of epidural clonidine used in these trials (range: 70 to 300 mcg) and to the small number of patients enrolled per study group.

Epidural Infusions

Continuous infusions of epidural local anesthetic and/or opioids will provide superior postoperative analgesia when compared to parenteral opioids for a variety of surgical procedures (Table 52.2).

Epidural Combined Local Anesthetic and Opioid Infusion

Although continuous infusions of epidural opioids may be used alone and are effective in controlling postoperative pain, continuous infusions of epidural opioids are more commonly administered in conjunction with a local anesthetic. This combination may confer analgesic advantages over infusions using either a local anesthetic alone or opioid alone, although the incidence of side effects may or may not be diminished.[18,75,76] The choice of opioid varies among clinicians: many will choose to use a lipophilic opioid (fentanyl, 2 to 5 mcg/mL, or sufentanil, 0.5 to 1 mcg/mL) as part of a patient-controlled epidural analgesia (PCEA) regimen to allow for rapid titration of analgesia[55,60]; however, use of a hydrophilic opioid (morphine, 0.05 to 0.1 mg/mL, or hydromorphone, 0.01 to 0.05 mg/mL) as part of a local anesthetic-opioid epidural analgesic regimen may also provide effective postoperative analgesia.[55]

While these studies support improved analgesic efficacy with the combination of a local anesthetic and an opioid compared with either drug alone, another study found no difference in analgesic efficacy between the combination versus either single drug.[77] Most studies indicate that combination therapy reduces dose requirements for either local anesthetic or the opioid as compared to when they are administered as single drugs alone. This dose reduction is associated with reduced local anesthetic-related side effects including hypotension and motor block and reduced opioids-related side effects including sedation, vomiting, and pruritis (Table 52.3).

Complications of Neuraxial Techniques. Despite the analgesic benefits conferred by neuraxial techniques, there are many risks associated with these techniques. Postoperative backache occurs in approximately 11% and 30% of patients undergoing spinal and epidural anesthesia, respectively.[78] While there are many factors that influence the incidence of postdural puncture headache, the overall incidence has been reported to be 6.7% for males and 8.6% for nonpregnant females.[79,80] Serious events related to neuraxial blocks include cardiac arrest, respiratory failure, seizures, infection, bleeding, and neurologic complications (Tables 52.4 and 52.5). The rate of neurologic complications after central nerve blockade is 0.4%, including radiculopathy/neuropathy, cauda equine syndrome, paraplegia, and intracranial events.[81] Prospective data collected over a 16-year period at a large tertiary teaching institution with a nonobstetric general surgical population identified 8210 epidural catheters inserted for postoperative analgesia. Epidural abscess was rare (<0.1%), and spinal hema-

toma was very rare (<0.05%).[82] The American Society of Regional Anesthesia and Pain Medicine (ASRA) consensus statement concludes that patients taking antiplatelet drugs or receiving subcutaneous unfractionated heparin for deep vein thrombosis prophylaxis are not viewed as being at increase risk of spinal hematoma; however, when taken in combination, these patients may be at increased risk. Patients receiving fractionated low-molecular-weight heparin, thrombolytic, fibrinolytic, or "fully anticoagulated" patients (elevated protime or prothrombin time) are considered to be at increased risk of neuraxial bleeding, and the ASRA consensus statement recommendations should be followed.[83]

PERIPHERAL NERVE BLOCKS

Introduction

Single injection and continuous peripheral nerve blocks (CPNBs) for postoperative pain management to be discussed in this chapter include interscalene, supraclavicular, infraclavicular, axillary, lumbar plexus, femoral, sciatic, popliteal, ankle, and paravertebral blocks. Common ultrasound-guided techniques are included. Indications, outcomes, side effects, and complications are reviewed.

Single injection peripheral nerve blocks provide superior pain control with decreased side effects as compared to opioids. Single injection block techniques, despite their efficacy, provide only a finite length of postoperative analgesia.[84] Efforts to prolong the analgesia of peripheral nerve block local anesthetic solutions with the addition of adjuncts, including but not limited to morphine,[85–87] fentanyl,[88–90] sufentanil,[91,92] buprenorphine,[86,93,94] tramadol,[95,96] ketamine,[97] and clonidine[98–104] have been investigated. Crucial to all investigations of perineural analgesia adjuncts is the inclusion of systemic control groups, providing evidence for or against a peripheral perineural site of action as opposed to a systemic effect of an adjunct administered peripherally. We will review those studies when available for applicable blocks.

Continuous perineural infusion of local anesthetic with or without adjuvants provides the ability to extend the duration and benefits of single injection techniques. CPNBs may be used to extended postoperative analgesia for more painful surgeries and to facilitate early, intense postoperative rehabilitation. Although PCEA and IV PCA provide adequate pain management for inpatients with postoperative pain, these techniques are unsuitable for postoperative pain management after outpatient surgical procedures. The use of CPNBs as a means of postoperative pain management may provide faster inpatient discharge,[105–108] and allow procedures otherwise requiring inpatient hospitalization for pain management to be performed in the outpatient setting.[84,106–111] There is strong evidence that home CPNBs improve postoperative analgesia and patient satisfaction, while decreasing supplemental opioid requirements and opioid-related side effects.[110] Data suggests the risk of injury in patients discharged with an insensate extremity is relatively small,[112] and that doses of local anesthetic associated with home infusion regimens are very unlikely to be associated with systemic local anesthetic toxicity.[113] Appropriate patient selection, education, and follow-up are crucial when sending these patients home and prescribing outpatient infusions in an unmonitored environment.[111] Perhaps the greatest testament to the viability, efficiency, safety, and effectiveness of ambulatory CPNBs are reports of their successful use as a viable and important long-term analgesic technique in the military, from evacuation to rehabilitation, providing patients with anesthesia and analgesia for multiple, sequential operations over an extended period of time.[114,115]

A meta-analysis of randomized controlled trials (RCTs) to determine the analgesic efficacy of postoperative perineural catheter analgesia compared with opioids found a statistically and clinically significant improvement in postoperative pain control with peripheral nerve catheters compared to opioids and a decrease in opioid related side effects. These improvements were noted through postoperative day 3. When analyzed according to catheter location (i.e., interscalene, femoral, etc.) and type of pain assessment (resting versus maximal), CPNB provided superior postoperative analgesia compared with opioids, with fewer side effects, improved patient satisfaction, better sleep patterns, improved rehabilitation, and shorter hospital stays. CPNB did not generally obviate the needs for opioids entirely.[116]

Ultrasound guidance for regional anesthetic techniques may offer benefits for the practicioner skilled in its application. A safe and successful ultrasound-guided nerve block requires (1) appropriate imaging and detection of target nerve and adjacent anatomic structures, (2) proficiency in tracking needle advancement in real time, and (3) assessment of local anesthetic spread around the target nerve.[117] Future, large, multicentered trials are necessary to evaluate the impact of ultrasound guidance on regional anesthetic techniques for acute pain management.

Upper Extremity Nerve Blocks

Peripheral nerve blockade following upper extremity surgery avoids the limitations associated with the use of IV PCA. Ambula-

tory perineural catheters allow for early inpatient discharge or surgery in the outpatient setting. Additionally, peripheral nerve block analgesic techniques may improve early rehabilitation (Table 52.6).

Interscalene Block

Indications. The interscalene block (ISB) is performed at the level of the roots and trunks. It provides both brachial (C5–C7) and cervical plexus (C3-C4) blockade; however, incomplete anesthesia of the inferior trunk (C8,T1) is not uncommon. As a result of phrenic nerve (C3–C5) blockade, there is a 100% incidence of ipsilateral hemidiaphragmatic paresis with the interscalene approach.[118] Thus, this approach should be avoided in patients with pre-existing pulmonary disease who are unable to tolerate a potential 25% reduction in pulmonary function.[119] Side effects after interscalene block may include a transient Horner's syn-

TABLE 52.6

UPPER EXTREMITY PERIPHERAL NERVE BLOCK DOSING

Local Anesthetic (20–40 mL)	Anesthesia (hrs)	Analgesia (hrs)
3% 2-Chloroprocaine (+HCO3 + epinephrine)	1.5	2.0
1.5% Mepivacaine (+HCO3)	2–3	2–4

drome and recurrent laryngeal nerve block resulting in hoarseness. The transient and benign nature of these side effects should be discussed with the patient prior to block placement. The ISB performed as a single-shot injection or continuous catheter technique provides postoperative analgesia for operations on the shoulder, clavicle, or upper arm.

Landmarks. The patient is positioned supine or with the head of the bed slightly elevated. The head is gently turned toward the nonoperative side. The clavicular head of the sternocleidomastoid muscle is identified. Having the patient briefly lift their head will accentuate this landmark. At the C6 level, the anterior scalene muscle is palpated along the posterior border of the sternocleidomastoid clavicular head. The fingers are rolled laterally over the anterior scalene muscle into the groove between the anterior and middle scalene muscles. The "interscalene groove" at the C6 level is the initial needle insertion site. The external jugular vein which often overlies the sternocleidomastoid muscle at this point must be avoided (Fig. 52.5).

Needles. Insulated needles used: 24-gauge, 2.5 cm or 22-gauge, 5 cm. Insulated Tuohy needles for catheter placement: 18-gauge, 3.8 cm or 5 cm. Catheters are inserted 5 cm beyond the needle tip.

Technique.

Nerve stimulation. The nerve stimulator is initially set at 1.0 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is introduced slowly in a caudad, posterior, and medial direction (Fig. 52.6). The brachial plexus is rarely deeper than 2 cm from the skin. An evoked motor response in the deltoid, biceps, triceps, forearm, or hand at 0.5 mA or less indicates acceptable needle tip position for local anesthetic injection. An evoked motor response of the trapezius muscle indicates posterior needle tip position and a response of the diaphragm indicates anterior needle tip position.

Ultrasound. Ultrasound visualization of the brachial plexus at the interscalene groove may be approached by imaging in the axial oblique plane with a linear, high-frequency ultrasound probe, identifying sonoanatomic landmarks from a medial to lateral direction at the C6 level. The roots/trunks of the brachial plexus are seen in cross section between the anterior and middle scalene muscles as round hypoechoic structures. Alternatively, placing the probe in the supraclavicular fossa in the coronal oblique plane obtains the perivascular position of the brachial plexus around the hypoechoic subclavian artery in cross section

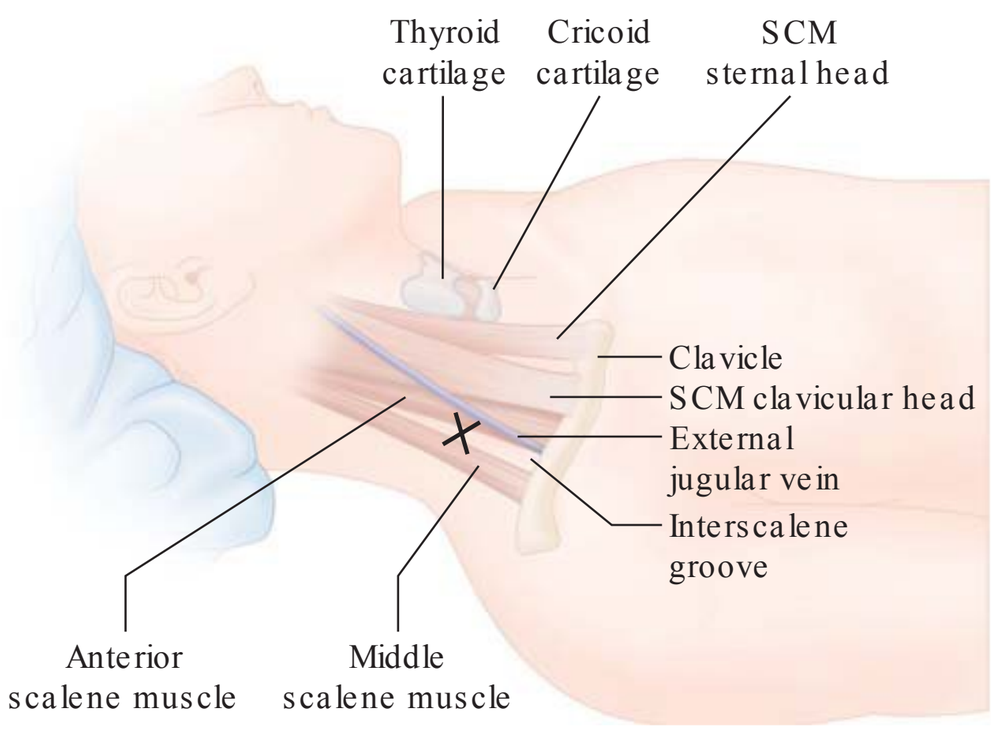

FIGURE 52.5 Landmarks for the interscalene approach to the brachial plexus. X, needle insertion site.

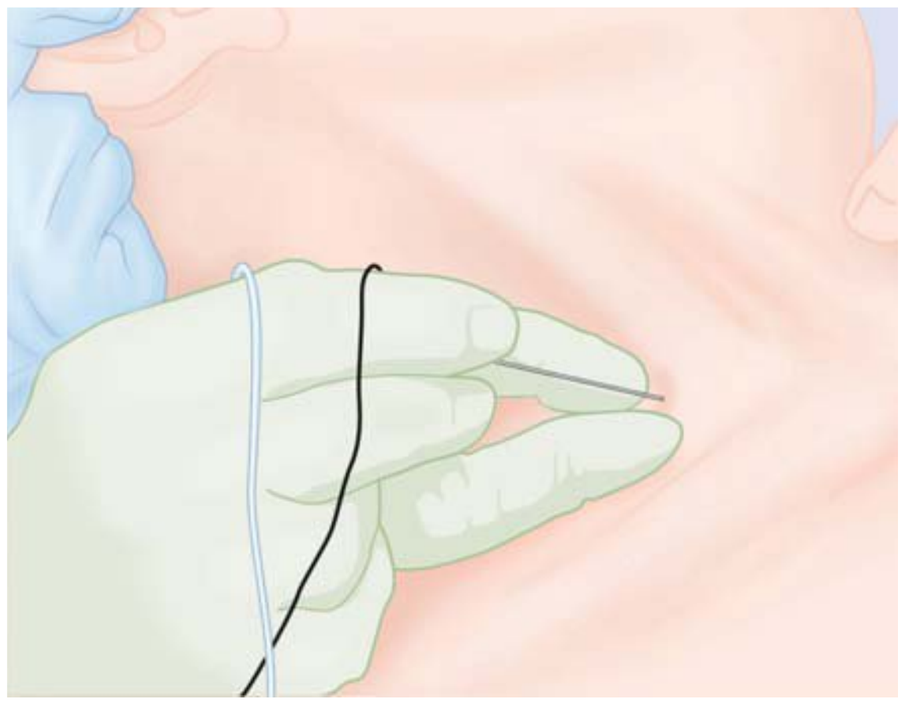

FIGURE 52.6 Needle orientation for interscalene block of the brachial plexus.

just above the hyperechoic first rib. At this level, the trunks/proximal divisions appear lateral and superior to the subclavian artery. Upon scanning the cephalad, the brachial plexus can be followed to its position between the anterior and middle scalene muscles at the C6 level (Fig. 52.7). Introducing the block needle from the lateral end of the ultrasound probe in-plane with the beam allows direct visualization of needle tip advancement and local anesthetic spread. Alternatively, the needle may be introduced in the middle of the ultrasound probe, out-of-plane with the beam, providing a cross-sectional image of the needle tip when it is beneath the ultrasound beam. While the in-plane technique is generally preferred for single-shot injections and provides tunneling for continuous catheter placement, the out-of-plane technique may provide more optimal needle orientation for continuous catheter advancement.

Clinical Effects. ISB for postoperative analgesia as compared to opioids, suprascapular nerve block, subacromial bursa block, or intra-articular administration of local anesthetics for shoulder surgery demonstrated reduction in pain visual analog scores

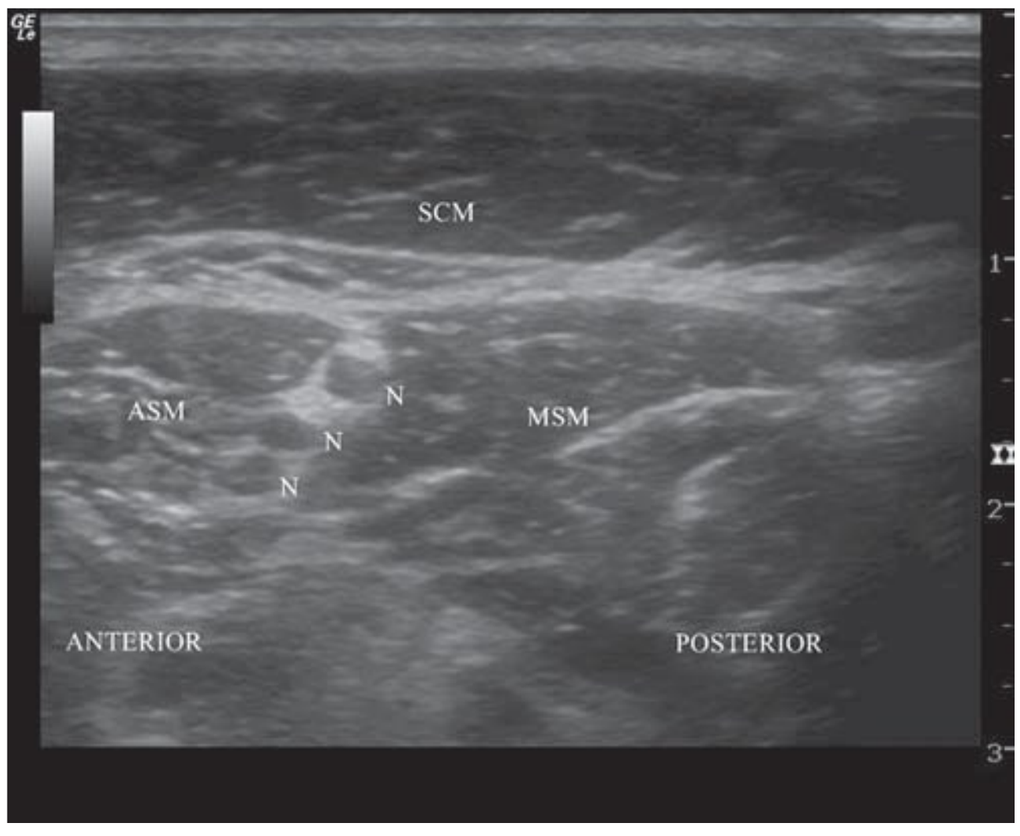

FIGURE 52.7 Sonographic landmarks for ultrasound-guided interscalene nerve block. ASM, anterior scalene muscle; MSM, middle scalene muscle; N, nerve trunk SCM, sternocleidomastoid muscle.

(VAS),[120–123] delayed time until first analgesic use [120] and reduced total opioid requirements.[120,121,124] Furthermore, the use of ISB demonstrated a reduced incidence of postoperative nausea and vomiting,[120,121] improved postoperative mood,[122] improved sleep the night after surgery,[125] quickened discharge of the ambulatory patient,[120] reduced inpatient length of stay,[125] and lowered rates of unanticipated hospital admission.[121,126,127] Continuous interscalene block (CISB) is effective for postoperative analgesia for major shoulder surgery.[105,108,128–130] While single-shot injection techniques may provide up to 18 hours of analgesia, upon block resolution patients may experience severe pain requiring treatment with parenteral opioids. + Continuous infusion of perineural local anesthetic allows continued analgesia when single injection techniques subside. CISB as compared to single-shot injection and opioids for postoperative pain, decreased VAS pain scores,[105,131–136] reduced opioid consumption,[105,132,133] reduced side effects,[131,135] improved rehabilitation,[105,108] and improved patient satisfaction.[105,131,132,135] Likewise, CISB for outpatient infusions[105,108,133,137–142] provided reliable postoperative analgesia enabling prompt hospital discharge,[105] decreasing average and maximum VAS pain scores,[133,137,138] reducing opioid consumption,[105,138] decreasing side effects,[138] improving sleep,[110] and diminishing breakthrough pain upon single-shot block resolution.[143] Ilfeld et al.[108] reported in a subset of patients without major comorbidities that it may be feasible to convert total shoulder arthroplasty into an ambulatory procedure discharging patients with a continuous interscalene infusion as part of a multimodal analgesic regimen provided at home.

Supraclavicular Block

Indications. The supraclavicular block of the brachial plexus is performed at the level of the trunks and divisions. Due to the compact arrangement of the brachial plexus at the supraclavicular level, this block provides a complete block of the brachial plexus. A supraclavicular brachial plexus block performed as a single injection or continuous catheter technique provides postoperative analgesia for operations on the humerus, elbow, forearm, wrist, or hand.

Landmarks. The patient is positioned supine or, if using the ultrasound technique, the head of the bed may be elevated. The head is gently turned toward the nonoperative side. The clavicular head of the sternocleidomastoid muscle is identified. Having the patient briefly lift their head will accentuate this landmark. At the C6 level, the anterior scalene muscle is palpated along the posterior border of the sternocleidomastoid clavicular head. The fingers are rolled laterally over the anterior scalene muscle into the groove between the anterior and middle scalene muscles. The fingers are then moved inferiorly down the interscalene groove until they are approximately 1 cm from the clavicle (Fig. 52.8). This is the initial needle insertion site. The subclavian artery can often be palpated just caudad to this point and must be avoided.

Needles. Insulated needle used: 22-gauge, 5 cm. Insulated Tuohy needle for catheter placement:18-gauge, 5 cm. Catheters are inserted 5 cm beyond the needle tip.

Technique.
Nerve stimulation. The nerve stimulator is initially set at 1.0 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is directed slightly lateral to the parasagital plane and parallel to the plane of the bed (Fig. 52.9). The needle should never be directed medial to the parasagital plane in order to avoid the dome of the pleura. The brachial plexus at the supraclavicular level is usually reached at a depth of 4–5 cm from the skin. Flexion of the fingers or thumb at 0.5 mA or less indicates acceptable needle tip position for local anesthetic injection. Biceps contraction or forearm pronation indicates lateral needle tip position. Pectoralis muscle contraction indicates anterior needle tip position. Latissimus dorsi contraction indicates posterior needle tip position. Bright-red blood with aspiration indicates anterior needle-tip position with entrance of the needle into the subclavian artery.

Ultrasound. Ultrasound visualization of the brachial plexus at the supraclavicular level is achieved with placement of a linear, high-frequency ultrasound probe in the supraclavicular fossa in the coronal oblique plane. This image obtains the perivascular position of the brachial plexus around the hypoechoic subclavian artery in cross section just above the hyperechoic first rib (Fig. 52.10). At this level, the trunks/divisions appear lateral and superior to the subclavian artery. Introducing the block needle from the lateral end of the ultrasound probe and advancing in line with the plane of the beam allows direct visualization of needle tip advancement and local anesthetic spread.

Clinical Effects. Few studies have investigated the postoperative analgesic efficacy of single injection or continuous supraclavicular block with placebo or IV PCA with opioids. Up to 17 hours of analgesia has been reported following single-shot injection of bupivacaine or ropivacaine for upper limb surgery.[144,145] Supraclavicular catheters for patients undergoing surgery or physiotherapy of the upper limb for treatment of reflex sympathetic dystrophy associated with painful shoulder provided effective postoperative analgesia for 24 to 48 hours.[146]

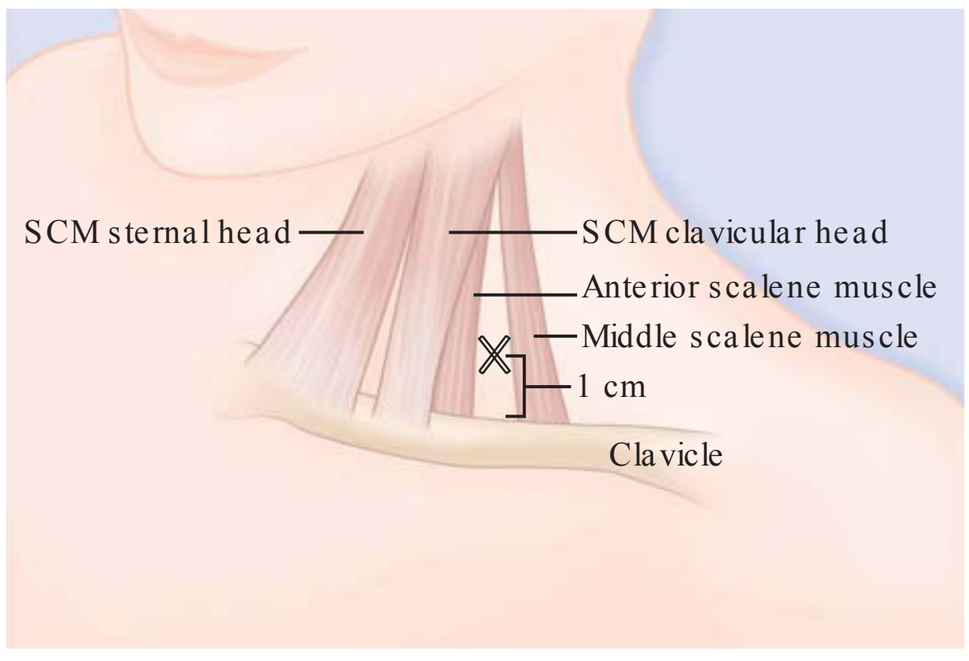

FIGURE 52.8 Landmarks for the supraclavicular approach to the brachial plexus. X, needle insertion site.

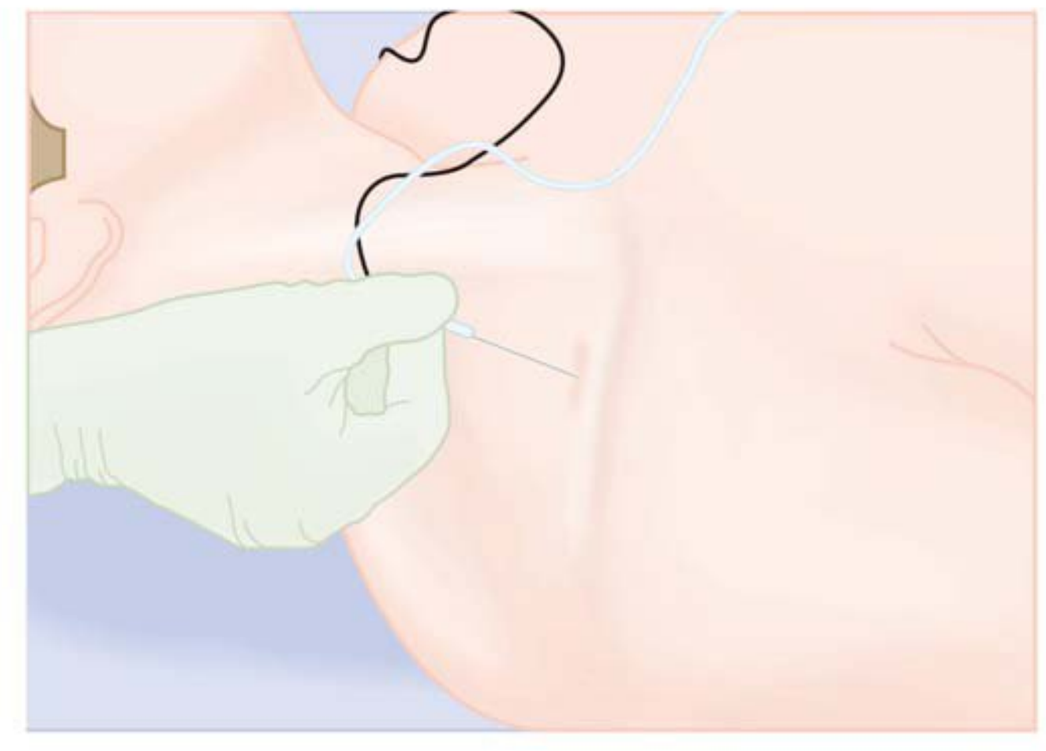

FIGURE 52.9 Needle orientation for supraclavicular block of the brachial plexus.

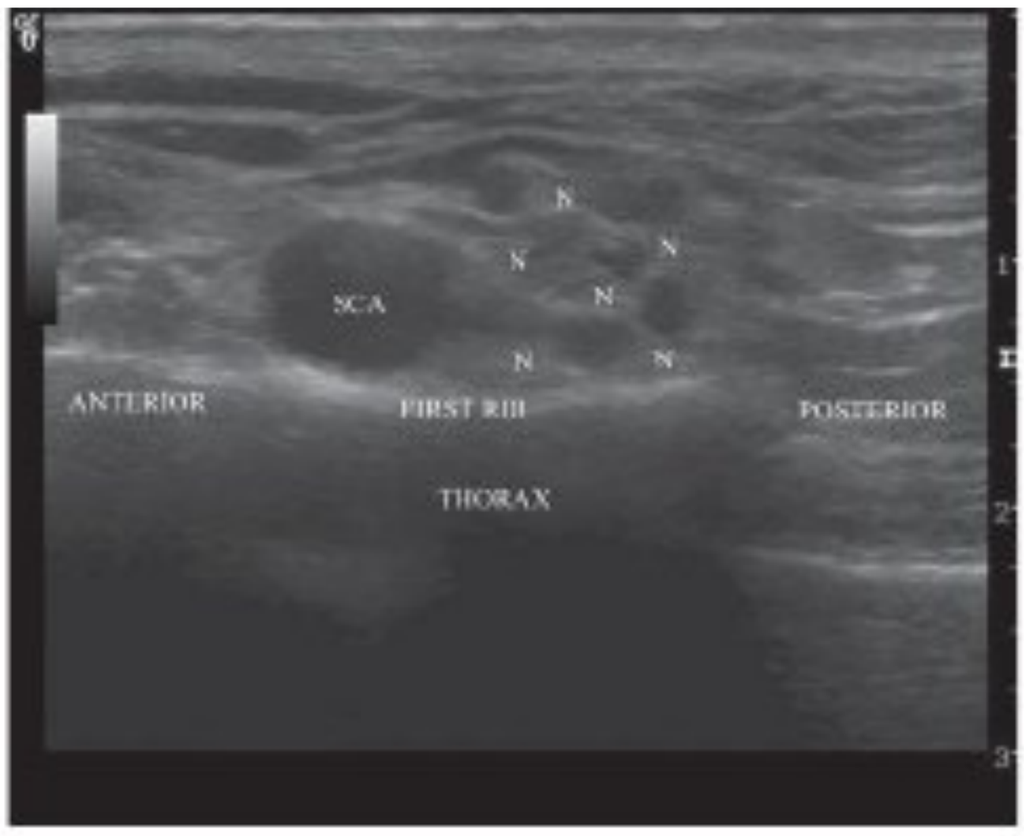

FIGURE 52.10 Sonographic landmarks for ultrasound-guided supraclavicular nerve block. N, divisions of the brachial plexus; SCA, subclavian artery.

Infraclavicular Block

Indications. The infraclavicular block targets the brachial plexus at the level of the cords. The lateral, posterior, and medial cords are named for their position around the axillary artery. The infraclavicular approach to the brachial plexus can be performed as a single-shot or continuous catheter technique to provide postoperative analgesia for operations on the elbow, forearm, wrist, or hand. Perineural catheters at this level are very stable due to limited movement at the catheter insertion site below the clavicle.

Landmarks. With the operative arm at the patient's side or abducted and externally rotated, the coracoid process is palpated. The needle insertion site is 2 cm medial and 2 cm caudad from the coracoid process (Fig. 52.11).

Needles. Insulated needle used: 21-gauge, 10 cm. Insulated Tuohy needle for catheter placement:18-gauge, 10 cm. Catheters are inserted 5 cm beyond the needle tip.

Technique.

Nerve stimulation. The nerve stimulator is initially set at 1.0 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is oriented perpendicular to all planes and directed posteriorly. Initial advancement of the needle will elicit pectoralis muscle contraction contraction from direct muscle stimulation. Finger and/or thumb flexion at 0.5 mA or less indicates acceptable needle tip position for local anesthetic injection. Biceps contraction or forearm pronation indicates lateral needle tip position. If initial needle advancement fails to elicit the appropriate motor-evoked response, the needle should be redirected slightly caudad within the parasagittal plane.

Ultrasound. A linear or curvilinear, low-frequency ultrasound probe is placed in the parasagittal plane at the deltopectoral groove. At this level, the hyperechoic cords of the brachial plexus, the hypoechoic pulsatile axillary artery, and the hypoechoic compressible axillary vein can be identified in cross section, deep to the pectoralis major and minor muscles (Fig. 52.12). Introducing the block needle from the superior end of the ultrasound probe and advancing in line with the plane of the beam allows direct visualization of needle tip advancement and local anesthetic spread. While the cords of the brachial plexus can be difficult to visualize, needle tip placement posterior to the artery with local anesthetic spread circumferentially around the artery indicates a high likelihood of success. Subsequent medial and/or lateral redirection of the needle may be necessary to achieve circumferential local anesthetic spread.

Clinical Effects. Hadzic et al.,[147] comparing single-shot infraclavicular block to general anesthesia, demonstrated superior immediate postoperative analgesia, but the use of short-acting local anesthetic resulted in similar VAS pain scores and opioid consumption at 24 and 48 hours. Continuous infraclavicular blocks for postoperative pain management demonstrated decreased opi-

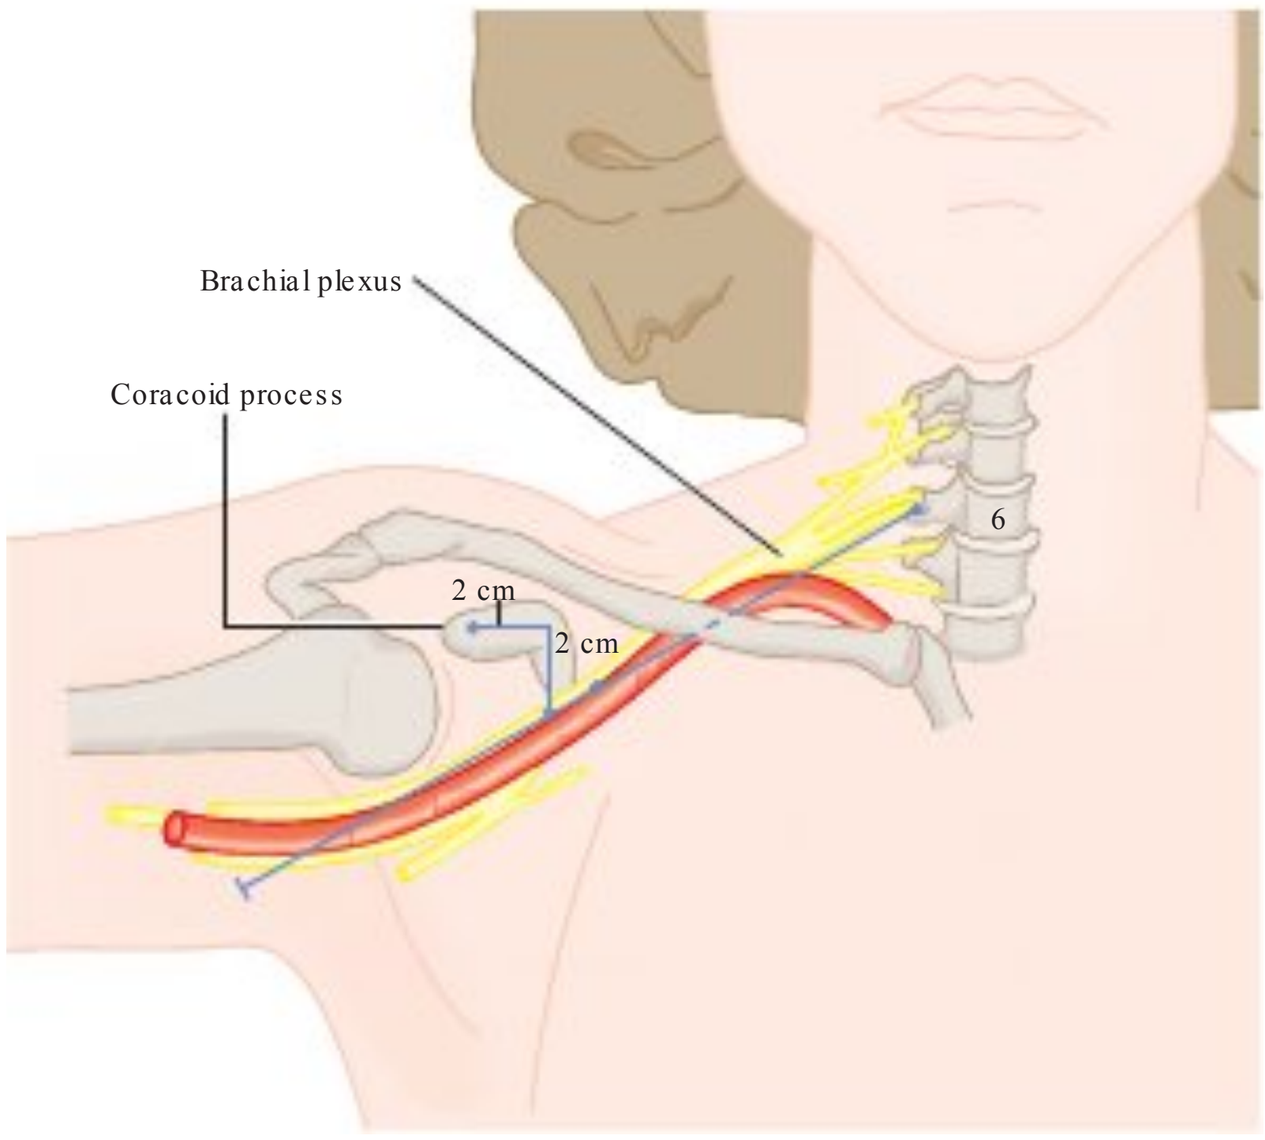

FIGURE 52.11 Landmarks for the infraclavicular approach to the brachial plexus.

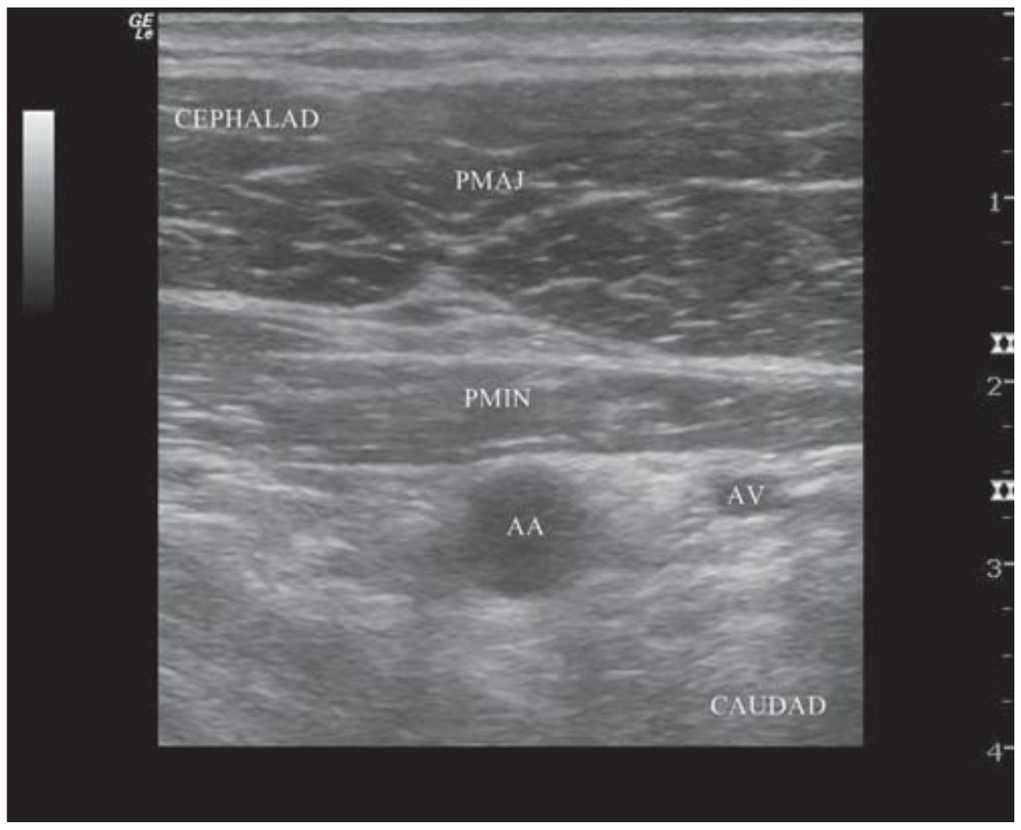

FIGURE 52.12 Sonographic landmarks for ultrasound-guided infraclavicular nerve block. AA, axillary artery; AV, axillary vein; PMAJ, pectoralis major muscle; PMIN, pectoralis minor muscle.

oid consumption, decreased average and maximum VAS pain scores, decreased side effects, and improved patient satisfaction as compared to opioids.[148–150] In a subset of patients without major comorbidities, it is feasible to convert total elbow arthroplasty into an ambulatory procedure using a continuous infraclavicular block as part of a multimodal analgesic regimen provided at home.[109]

Axillary Nerve Block

Indications. The axillary nerve block targets the terminal branches of the brachial plexus. It is performed as a single injection or continuous catheter technique to provide anesthesia and postoperative analgesia for operations on the hand, wrist, and forearm. At the level of the axilla, the musculocutaneous nerve is often located within the belly of the coracobrachialis, separated from the median, ulnar, and radial nerves (Fig. 52.13). Thus, an additional musculocutaneous nerve block is recommended to provide analgesia of the entire forearm.

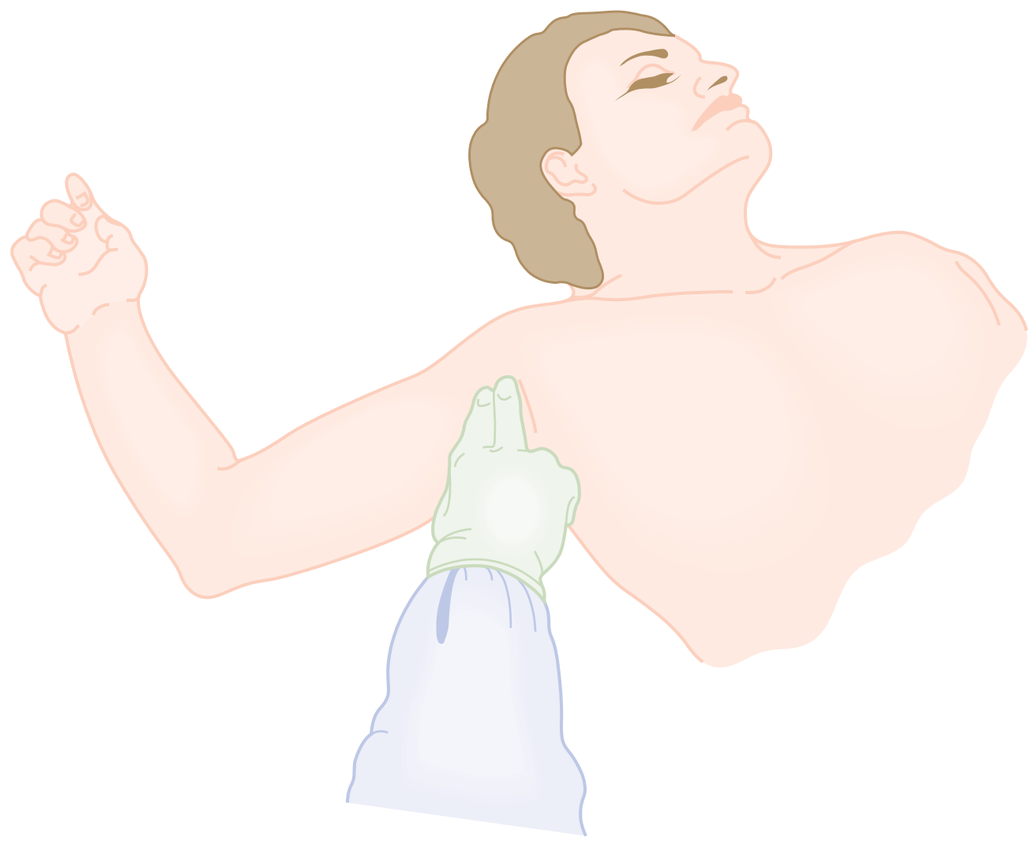

FIGURE 52.14 Position and axillary artery palpation for axillary nerve block.

Landmarks. The patient is positioned supine with the operative arm abducted 90 degrees and externally rotated. The axillary artery is palpated at its most proximal point in the axilla (Fig. 52.14). The coracobrachialis muscle is palpated medial to the biceps muscle.

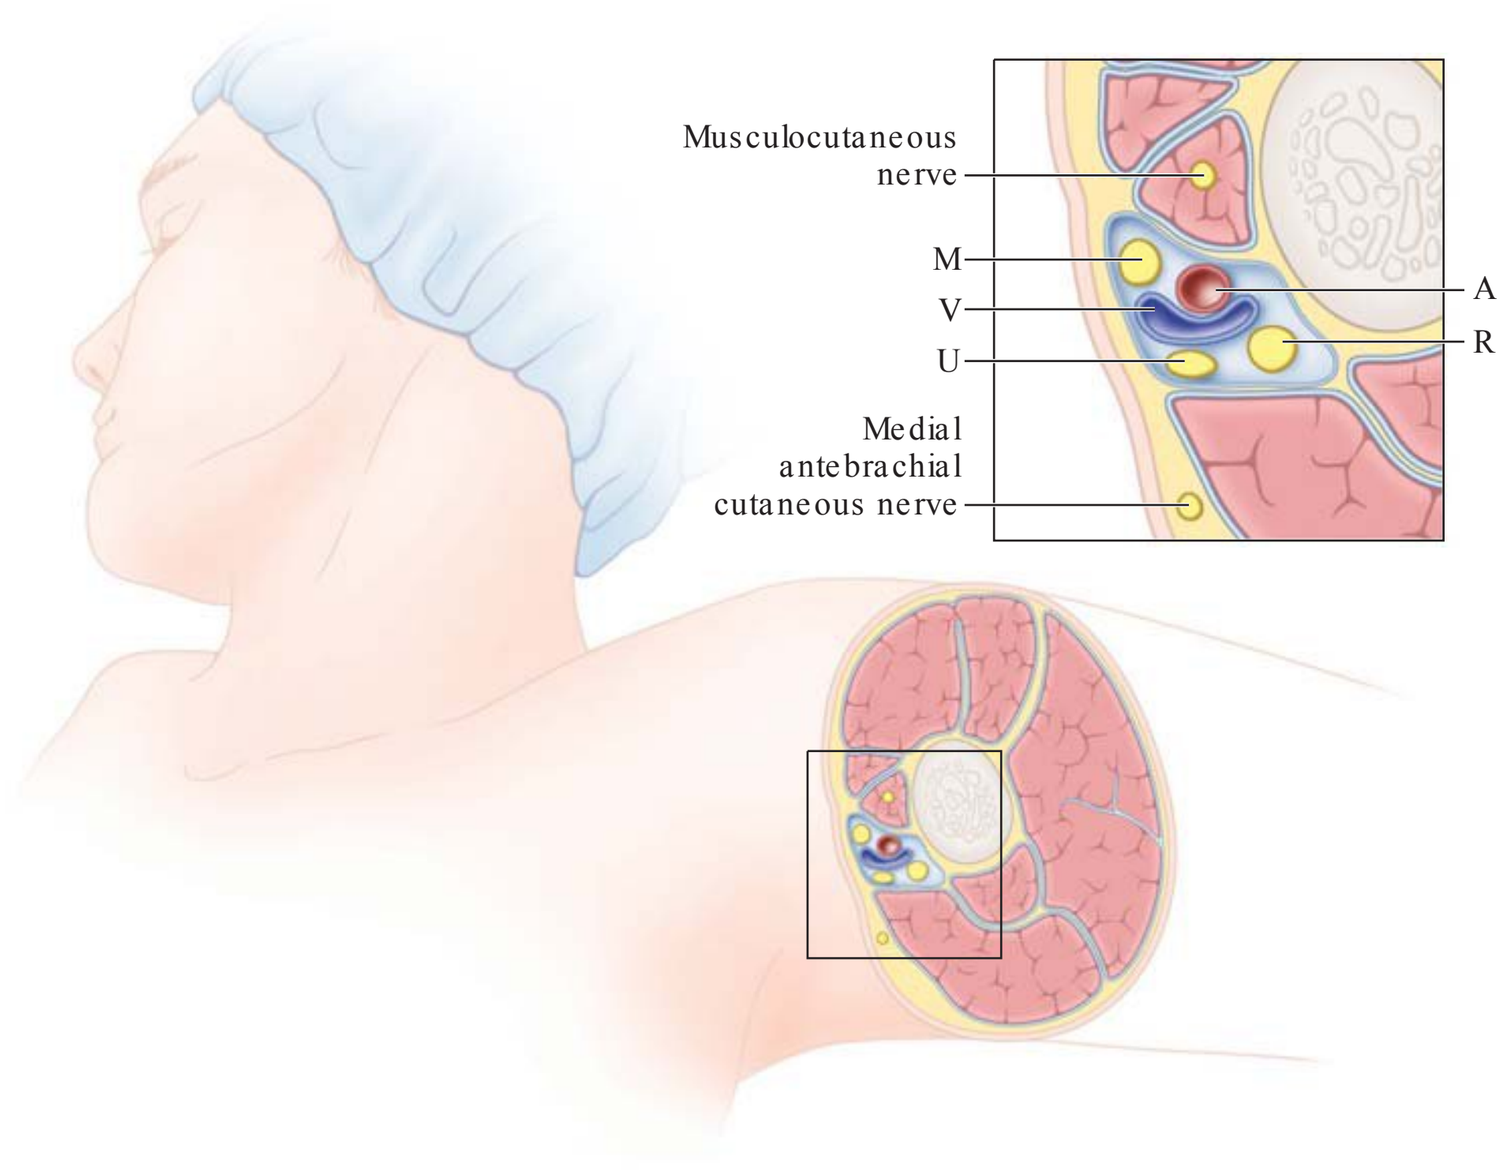

FIGURE 52.13 Axilllary cross section.

Needles. Insulated needle used: 22-gauge, 5 cm. Insulated Tuohy needle for catheter placement: 18-gauge, 5 cm. Catheters are introduced 5 cm beyond the needle tip.

Technique.

Nerve stimulation and transarterial.

MEDIAN, ULNAR, AND RADIAL NERVES. The nerve stimulator is initially set at 1.0 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is inserted superior to the point of maximal axillary artery palpation, entering at a 30 to 45 degree angle to the skin. Finger flexion and/or thumb opposition at 0.5 mA or less indicates appropriate needle tip position for local anesthetic injection. An evoked motor response of the musculocutaneous nerve cannot be accepted. Again, at the level of the axilla, the musculocutaneous nerve is often found traveling independently within the belly of the coracobrachialis, separated from the median, ulnar, and radial nerves (see Fig. 52.14). Aspiration of bright-red blood indicates the needle has entered the axillary artery. At this point, the transarterial technique should be used and nerve stimulation abandoned. Using the transarterial technique, the needle should be advanced slowly with continuous aspiration until blood can no longer be aspirated. Incremental local anesthetic injection after negative aspiration at this location will provide blockade of the plexus. Intermittent purposeful re-entry of the block needle into the vessel after stopping local anesthetic injection can confirm needle tip location just beyond the artery. After needle re-entry into the vessel indicated by positive aspiration of blood, the needle is again slowly advanced beyond the vessel with continuous aspiration until blood can no longer be aspirated. At this point, local anesthetic injection is resumed.

MUSCULOCUTANEOUS NERVE. The nerve stimulator is set at 2.0 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is inserted into the coracobrachialis muscle at the midhumeral level to block the musculocutaneous nerve (Fig. 52.15). The needle is fanned through the coracobrachialis muscle until vigorous biceps contraction from musculocutaneous nerve stimulation is elicited, as opposed to unintentional direct stimulation of the biceps muscle itself. It is not necessary to dial down the current. Ten mL of local anesthetic is injected.

Ultrasound. Using a linear, high-frequency ultrasound probe at the axillary fold in an abducted and externally rotated arm, terminal branches of the brachial plexus can be identified in cross section. They appear as round to oval hypo- or hyperechoic structures approximately 1 cm from the skin surface in close proximity to the hypoechoic axilary artery (Fig. 52.16). The terminal branches are variable in their position around the artery; however, the radial nerve is most commonly identified in a posterior position, the median nerve in an anterior position, and the ulnar nerve in a medial position. The musculocutaneous nerve is identified within the coracobrachialis muscle (Fig. 52.17). Introducing the block needle from the lateral end of the ultrasound probe and advancing in line with the plane of the beam allows direct visualization of needle tip advancement and local anesthetic spread.

Clinical Effects. Postoperative analgesic advantages of single injection axillary nerve block include extended time to first requested analgesic,[151] decreased opioid use,[151,152] and decreased VAS pain scores.[151] There was no difference in pain, opioid consumption, adverse effects, or patient satisfaction identified at 24

hours in these studies,[151,152] likely due to the short-acting local anesthetic used. Continuous axillary nerve blocks have demonstrated successful postoperative analgesia with home catheters after hand surgery.[141,153]

Lower Extremity Peripheral Nerve Blocks

Peripheral nerve blockade following lower extremity surgery avoids the limitations associated with the use of IV PCA and PCEA. Peripheral nerve blocks of the lower extremity allow reduced side effects, regional analgesia techniques in the setting of anticoagulation, and ambulatory catheters for early patient discharge or surgery in the outpatient setting. Additionally, peripheral nerve block analgesic techniques may improve early rehabilitation (Table 52.7).

Posterior Lumbar Plexus Block

Indications. The lumbar plexus is formed within the psoas major muscle by the ventral rami of L1–L4 with a variable contribution from T12. At the L4-L5 level, the terminal nerves of the lumbar plexus are formed including the lateral femoral cutaneous, femoral, and obturator nerves. Posterior lumbar plexus block (LPB) as a single injection or continuous catheter technique is effective for postoperative pain management following procedures of the hip, knee, and femur.

Landmarks. The patient is placed in the Sims' position. The intersection of the intercristal line with a line drawn from the posterior superior iliac spine (PSIS) parallel to the vertebral spinous processes determines the initial needle insertion point. In most patients, this corresponds to 5 cm lateral from the midline (Fig. 52.18).

Needles. Insulated needle used: 21-gauge, 10 cm. Consider a 15-cm needle in patients with an increased body mass index (BMI). Insulated Tuohy needle for catheter placement: 18-gauge, 10 cm. Catheters routinely are inserted 5–10 cm.

Technique. The nerve stimulator is initially set at 1.5 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is inserted perpendicular to all planes. If contact with the transverse process of L4 is made, the needle is redirected slightly caudal and advanced 1–2 cm beyond the transverse pro-

TABLE 52.7
LOWER EXTREMITY PERIPHERAL NERVE BLOCK DOSING

Local Anesthetic (20–40 mL)	Anesthesia (hrs)	Analgesia (hrs)
3% 2-Chloroprocaine (+HCO3 + epinephrine)	1.5	2.0
1.5% Mepivacaine (+HCO3)	2–3	2–4
1.5% Mepivacaine (+HCO3 + epinephrine)	2.5–4	3–6
2% Lidocaine (+ HCO3 + epinephrine)	3–6	5–8
0.5% Ropivacaine (+ epi)	6–8	8–12
0.75% Ropivacaine (+ epi)	8–10	12–18
0.5% Bupivacaine (+ epi)	8–10	16–18

Continuous infusion ropivacaine 0.2% or dilute concentration of bupivacaine or levobupivacaine; 8–10 mL/hour or 5 mL/hour with 5 mL hourly bolus or 8 mL/hour with 4 mL Q30min bolus.

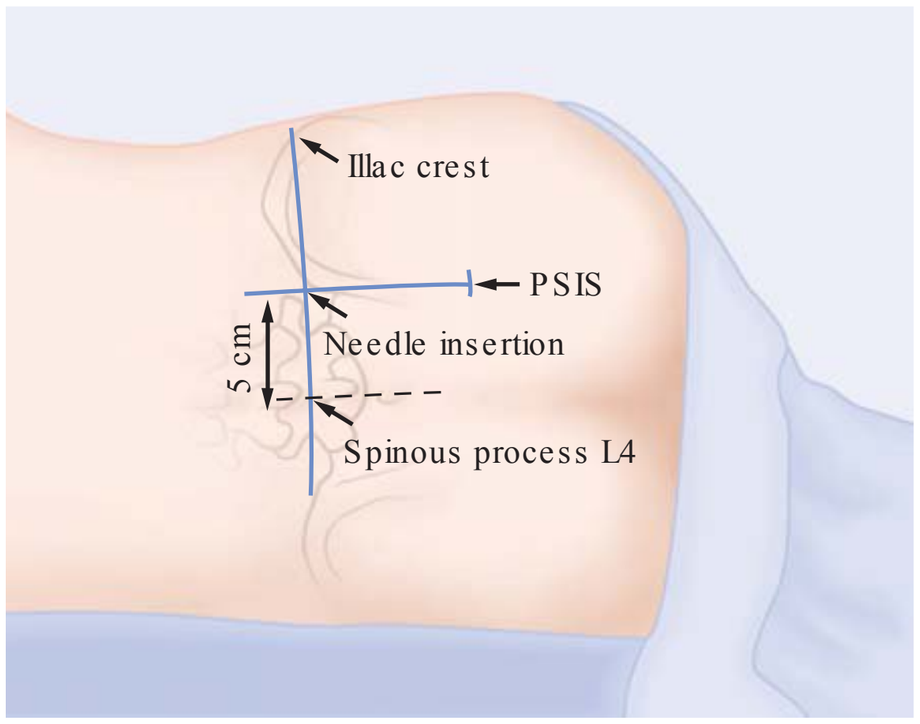

FIGURE 52.18 Landmarks for posterior LPB.

cess. The lumbar plexus is usually encountered at a depth of 6–10 cm. An evoked motor response of the quadriceps muscle at 0.5 mA indicates acceptable needle tip position for local anesthetic injection. An evoked motor response of the adductor muscles indicates medial needle tip position. Elicitation of hamstring contraction, foot dorsiflexion, or plantarflexion indicates stimulation of the lumbosacral trunk and caudomedial needle tip position in relation to the lumbar plexus. If initial passes fail to elicit an evoked motor response providing feedback for needle position, the needle should be withdrawn to the skin level and redirected in 5 to 10 degress increments cephalad, and then caudad. Susequent to these maneuvers, the needle is withdrawn to skin and cautiously redirected medial in 5 to 10 degree increments. The operator must remember that slight variations in the needle angle at the skin translate to larger variations at the needle tip as the needle depth increases. Medial placement of the needle tip may increase the potential risk of unitential central neuraxial anesthesia.

Clinical Effects. A single injection posterior lumbar plexus block provides 6 to 12 hours of postoperative analgesia. Continuous lumbar plexus block (CLPB) improves analgesia and patient satisfaction as compared to parenteral opioids and side effects as compared to epidural analgesia. Continuous catheters are beneficial for anterior cruciate ligament repair (ACLR), total hip arthroplasty (THA), and total knee arthroplasty (TKA). For TKA, the addition of a single injection sciatic nerve block improves analgesia. CLPBs and continous femoral nerve blocks (CFNBs) demonstrate similar analgesic efficacy for TKA. Given the potential risks associated with LPB, CFNB might be the continuous technique of choice for TKA. The results of a prospective study suggest that for a subset of patients without major comorbidities, it might be feasible to convert THA into an overnight-stay procedure using an ambulatory continuous psoas compartment nerve block as part of a multimodal analgesic regimen provided at home.[106]

Femoral Nerve Block

Indications. A femoral nerve block (FNB) will reliably block the femoral and lateral femoral cutaneous nerves, but inconsistently block the obturator nerve. Single-shot or continuous FNBs provide postoperative analgesia for operations on the knee and femur.

Landmarks. With the patient supine, the femoral artery pulse is palpated at the level of the femoral crease. The initial needle insertion site is approximately one fingerbreadth lateral to the femoral artery pulse (Fig. 52.19).

Needles. Insulated needle used: 22-gauge, 5 cm. Insulated Tuohy needle for catheter placement: 18-gauge, 10 cm. The catheter is inserted 5 cm beyond the needle tip.

Technique.
Nerve stimulation. The nerve stimulator is initially set at 1.0 mA. Initial needle insertion is approximately one fingerbreadth lateral to the femoral artery pulse. After cleaning the area with antiseptic solution, using sterile technique, the needle is directed perpendicular to the skin or slightly cephalad. An evoked motor response of the quadriceps with a current of 0.5 mA or less indicates acceptable needle tip position for local anesthetic injection. The femoral nerve is superficial, rarely beyond 3 cm from the skin. An evoked motor response of the sartorius muscle indicates stimulation of the anterior division of the femoral nerve, necessitating deeper needle advancement to obtain the appropriate motor response.

Ultrasound. Using a linear, high-frequency ultrasound probe at the infrainguinal location, the femoral nerve will appear in cross section as a hyperechoic triangular structure just lateral to the femoral artery, medial to the iliacus muscle, inferior to the fascia iliaca, and superior to the psoas muscle (Fig. 52.20). Introducing the block needle from the lateral end of the ultrasound probe and advancing in line with the plane of the beam allows direct visualization of needle tip advancement and local anesthetic spread. The femoral nerve lies deep to the fascia iliaca and outside of the femoral sheath which contains the femoral artery, vein, and lymphatics (Fig. 52.21). This is an important consideration when evaluating needle tip position and local anesthetic spread. Local anesthetic will be visualized spreading beneath the fascia iliaca, circumferentially around the femoral nerve. While the in-plane technique is generally preferred for single-shot injections and provides tunneling for continuous catheter placement, the out-of-plane technique may provide more optimal needle orientation for continuous catheter advancement.

Clinical Effects. FNB improves analgesia after ACLR.[154,155] Further improvement has been demonstrated with the addition of a sciatic nerve block.[156] CFNB extends the duration of analgesia for ACLR.[156] FNB provides improved analgesia for TKA, and one study demonstrated improvement with rehabilitation.[157] Studies did not all agree that sciatic nerve block in addition to FNBs further improve postoperative analgesia for TKA.[158–162] Some studies question whether CFNB offers additional benefit after TKA.[163,164] A majority of studies suggest that extended pain relief is achieved with CFNB. Additionally, CFNB has demonstrated improved rehabilitation after TKA.[165,166] Given the potential risks associated with LPBs, CFNB might be the continuous technique of choice for TKA. The addition of a single injection sciatic nerve block to CFNBs further improves postoperative analgesia after TKA and additional improvement is seen with combined continuous femoral and sciatic nerve blocks[160,161]; however, concerns with compartment syndrome or perioperative nerve injury may necessitate postoperative examination by the surgical team.[160] In these circumstances, it is possible to dose a catheter previously placed, when the surgery team has completed their exams or the observation period has ended. CFNB provided equivalent analgesia and rehabilitation performance as epidural with fewer side effects.[166]

Sciatic Nerve Block: Classic Labat Approach

Indications. The sciatic nerve, the largest nerve in the body, is formed from the convergence of the L4–S3 ventral rami at the

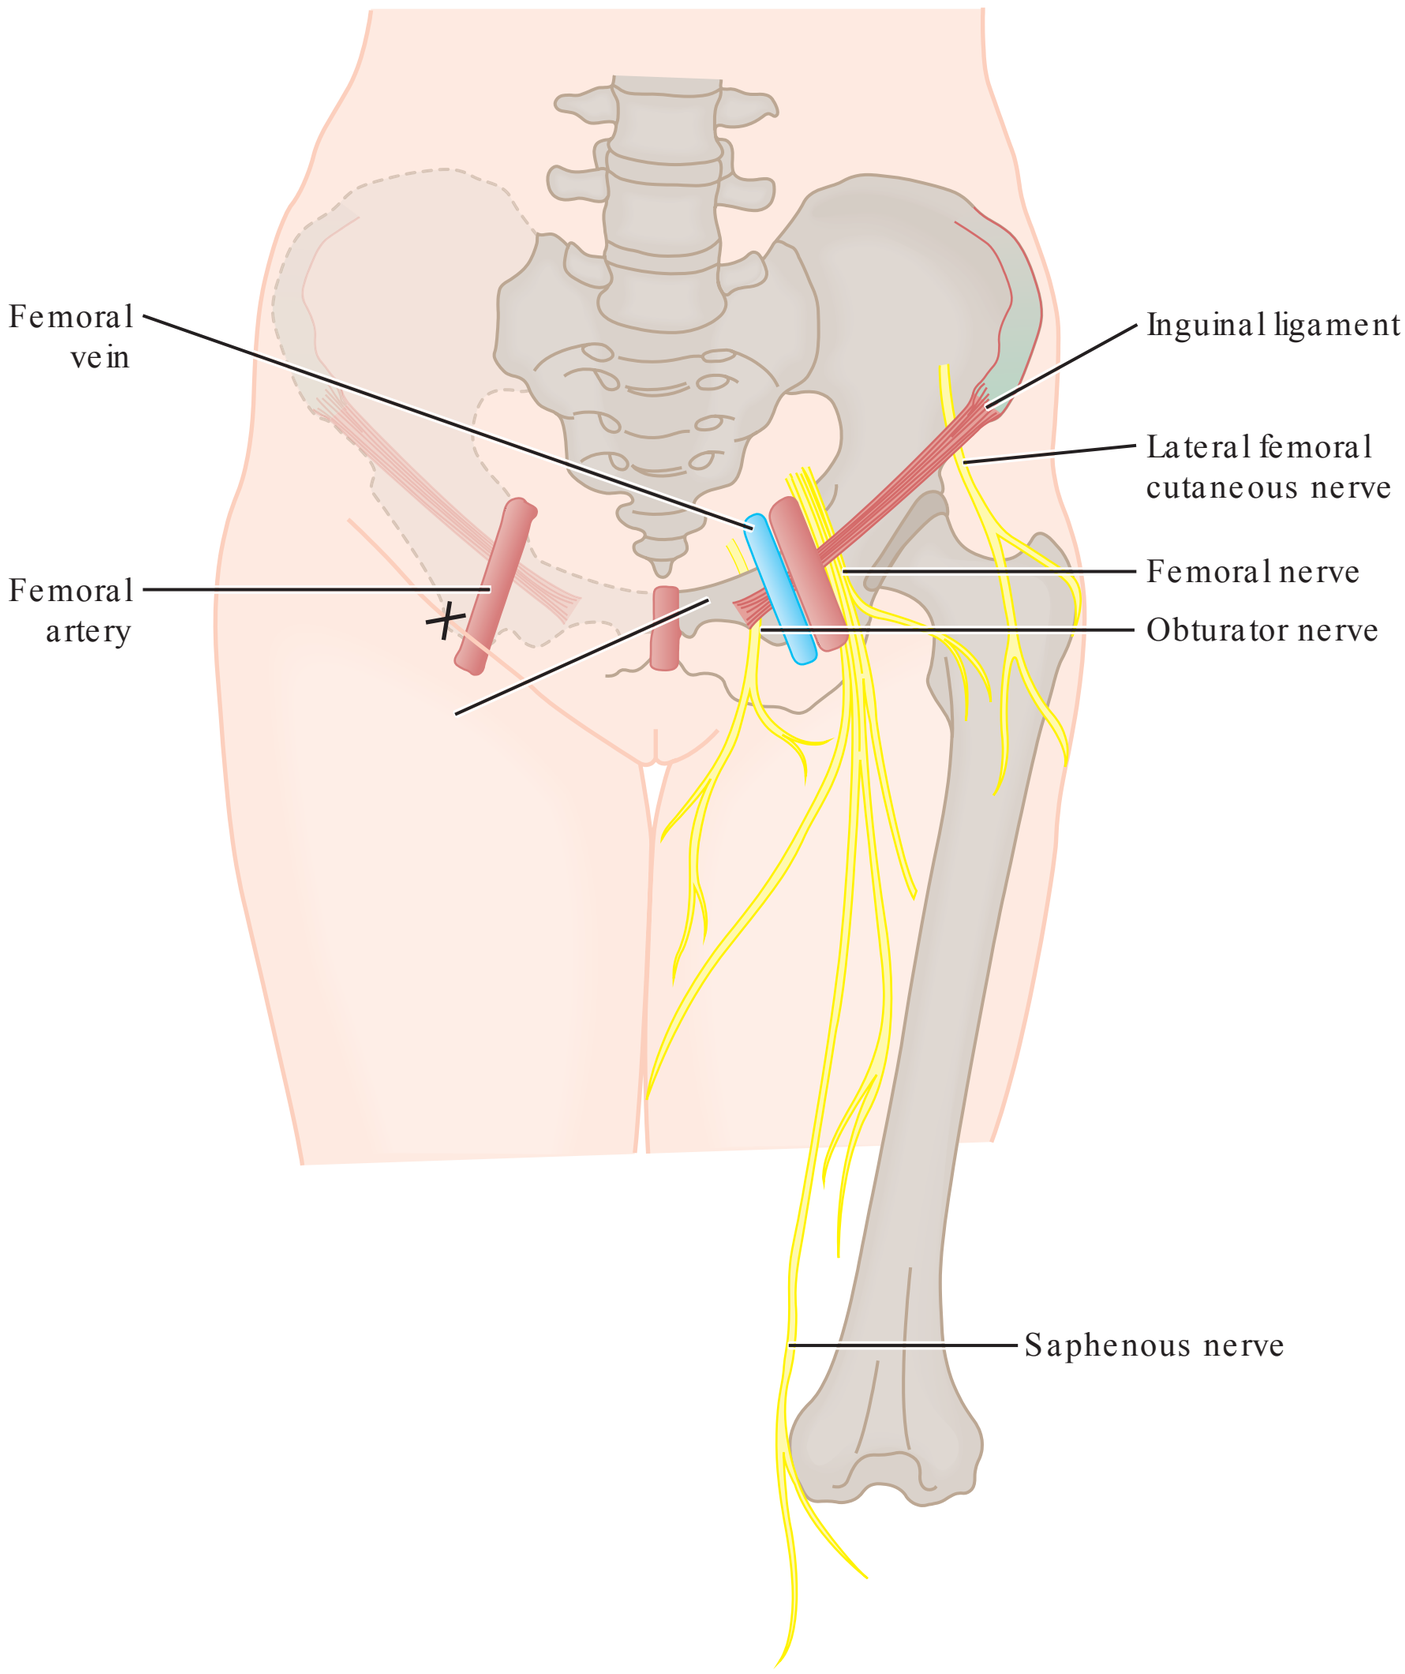

FIGURE 52.19 Landmarks for femoral nerve block. X, needle insertion site.

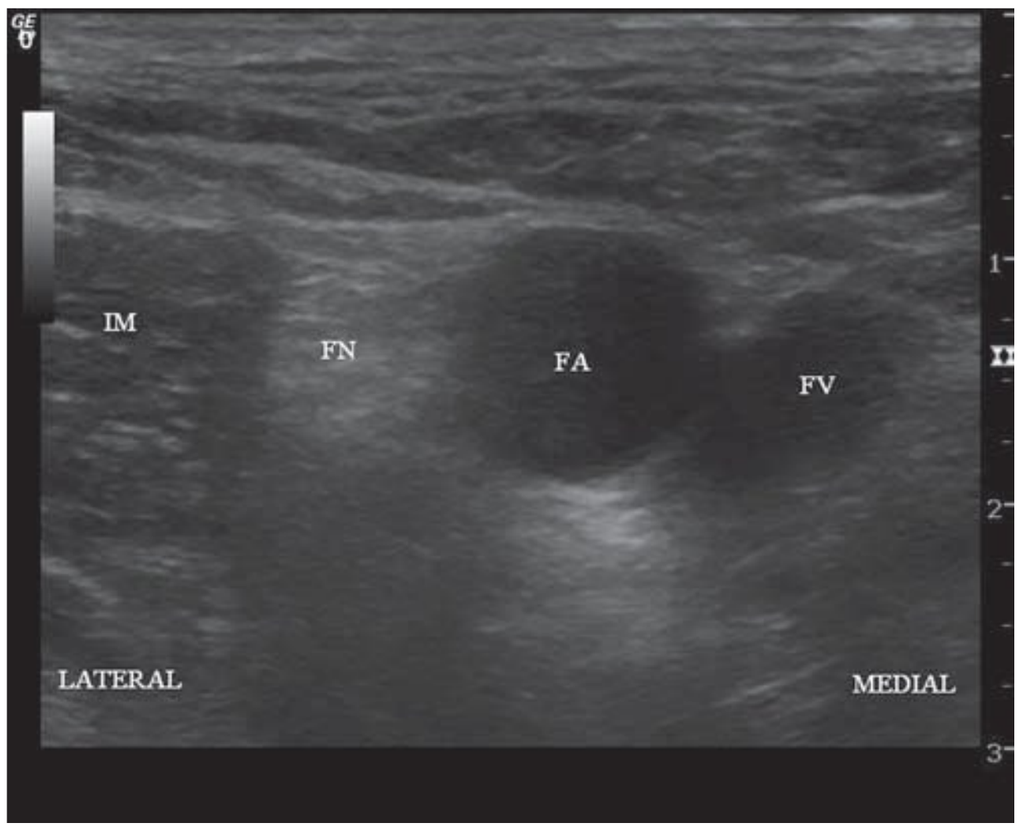

FIGURE 52.20 Sonographic landmarks for ultrasound-guided femoral nerve block. FA, femoral artery; FI, fascia iliaca; FN: femoral nerve; FV: femoral vein; IM, iliacus muscle; PM: psoas muscle.

inferior border of the piriformis muscle. The sciatic nerve consists of two nerves, the tibial and common peroneal nerves, bound together by epineurium. Usually, these nerves separate distal to the midthigh level; however, separation may occur prior to entering the gluteal region with the peroneal division passing through or superior to the piriformis muscle. A sciatic nerve block as a single injection or continuous catheter technique provides analgesia for operations on the foot and ankle, excluding the saphenous nerve sensory distribution. Additionally, a sciatic nerve block as a single injection or continuous catheter technique can be an important addition to a femoral or lumbar plexus block in providing analgesia for knee surgery.

Landmarks. The patient is placed in the Sims' position. A line is drawn from the greater trochanter to the PSIS. A second line is drawn from the greater trochanter to the patient's sacral hiatus. A third line is drawn perpendicular from the midpoint of the first line to its intersection with the second line. This point of intersection is the initial needle insertion site. Alternatively, a single line is drawn from the greater trochanter to the PSIS, and a second line is drawn perpendicular from the midpoint of this line to a point 5 cm medial. This point represents the initial needle insertion site (Fig. 52.22).

Needles. Insulated needle used for the majority of patients: 21-gauge, 10 cm. Consider 15-cm needle in patients with in-

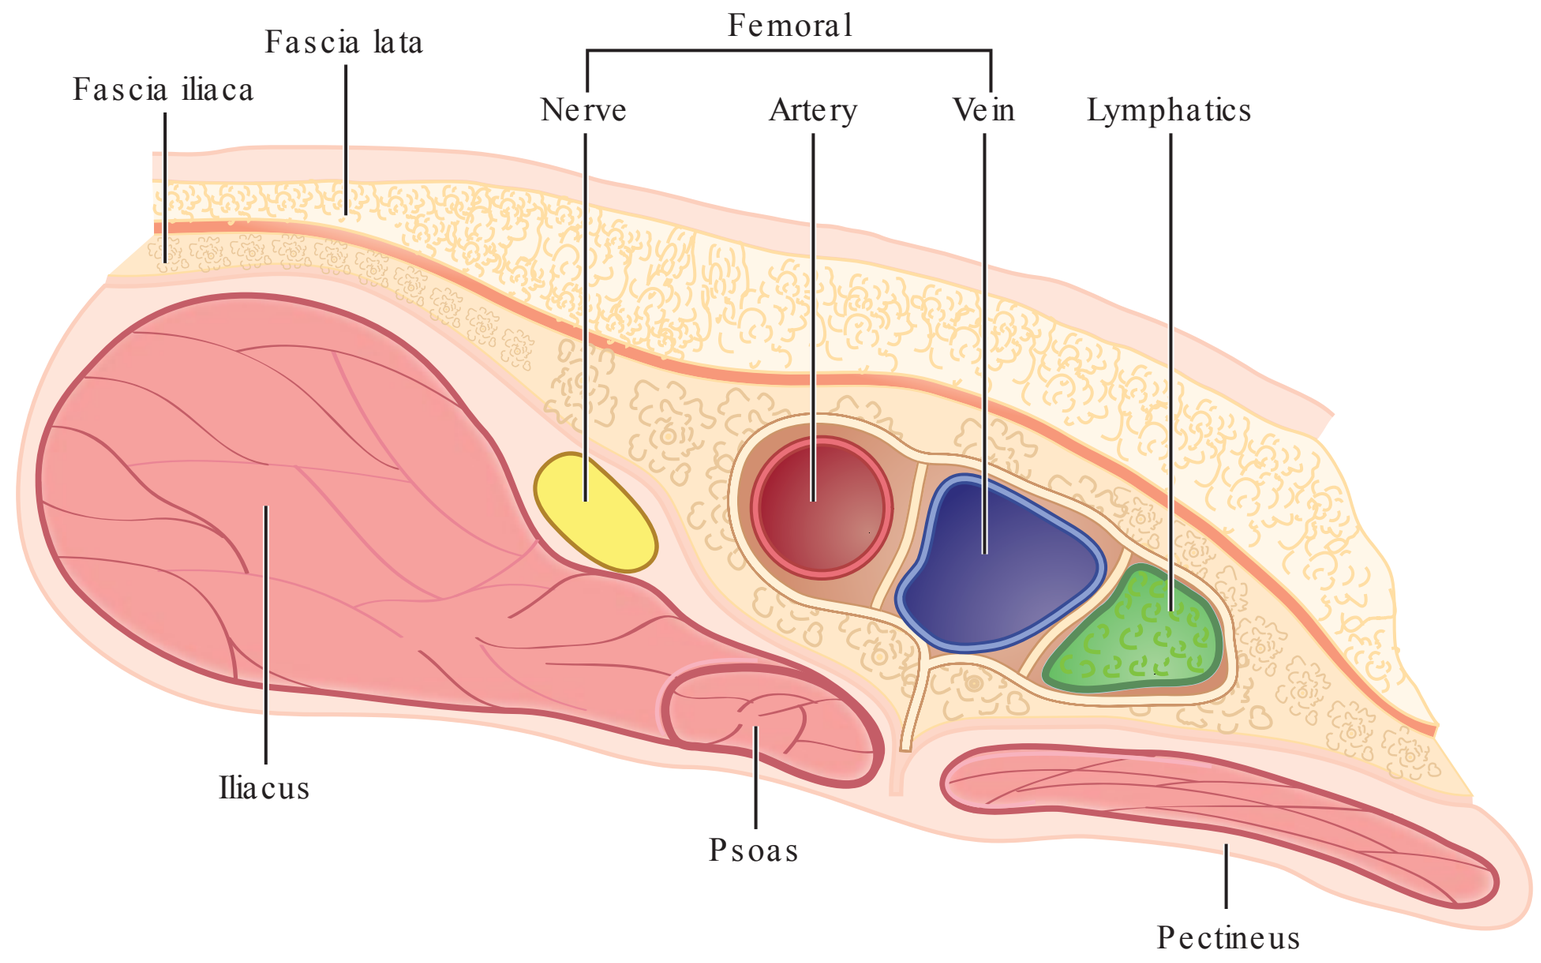

FIGURE 52.21 Transverse section of superior thigh. The femoral sheath containing the femoral artery, vein, and lymphatics lies deep to the fascia lata. The femoral nerve lies outside of the femoral sheath and deep to the fascia iliaca.

creased BMI. Insulated Tuohy needle for catheter placement: 18-gauge, 10 cm. Catheters are inserted 5 cm beyond the needle tip.

Technique. The nerve stimulator is initially set at 1.0 to 1.5 mA. The foot on the side to be blocked should be free, allowing unobstructed movement with nerve stimulation and direct visualization of response. After cleaning the area with antiseptic solution, using sterile technique, the needle is inserted perpendicular to all planes. Initial needle advancement will often elicit direct gluteus maximus and/or piriformis muscle contraction. With further needle advancement, plantarflexion/inversion or dorsiflexion/eversion of the foot at 0.5 mA of current or less indicates accept-

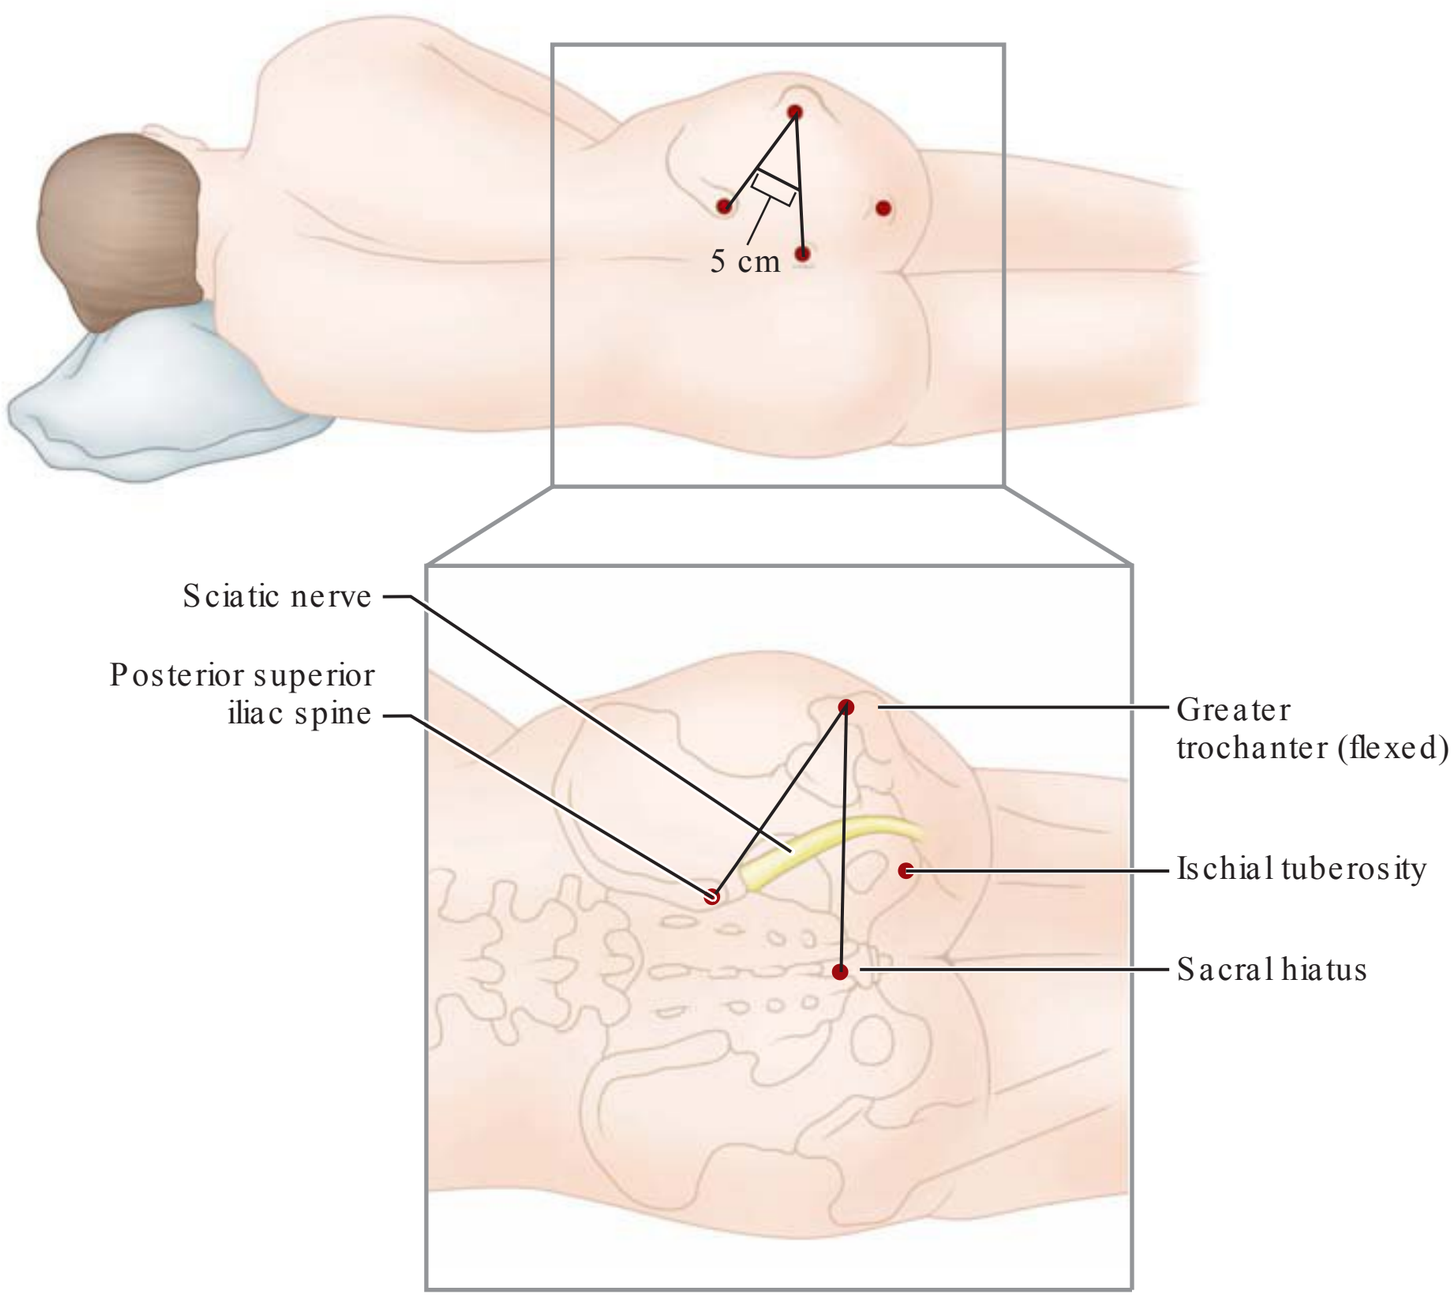

FIGURE 52.22 Landmarks for classic Labat's sciatic nerve block.

able needle tip position for local anesthetic injection. Hamstring muscle contraction indicates medial needle tip position.

Sciatic Nerve Block: Raj Approach

Indications. The Raj approach targets the sciatic nerve at a shallow location in an easily palpable groove between the semitendinosus and biceps femoris muscles. Patient positioning and monitoring of stimulation response, however, require assistance. The Raj approach as a single injection or continuous catheter technique provides postoperative analgesia for operations on the foot and ankle.

Landmarks. The patient is positioned supine and with the help of an assistant the operative leg is raised 90 degrees. Midpoint on a line connecting the greater trochanter to the ischial tuberosity is the initial needle insertion site. This point should correspond to the groove between the semitendinosus and biceps femoris muscles (Fig. 52.23).

Needles. Insulated needle used: 21-gauge, 10 cm. Insulated Tuohy needle for catheter placement: 18-gauge, 10 cm. Catheters are inserted 5 cm beyond needle tip.

Technique. The nerve stimulator is initially set at 1.0 to 1.5 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is directed perpendicular to all planes. Plantarflexion/inversion of the foot at 0.5 mA or less indicates acceptable needle tip position for local anesthetic injection. Dorsiflexion/eversion of the foot indicates lateral needle tip position, and direct adductor muscle contraction indicates medial needle tip position.

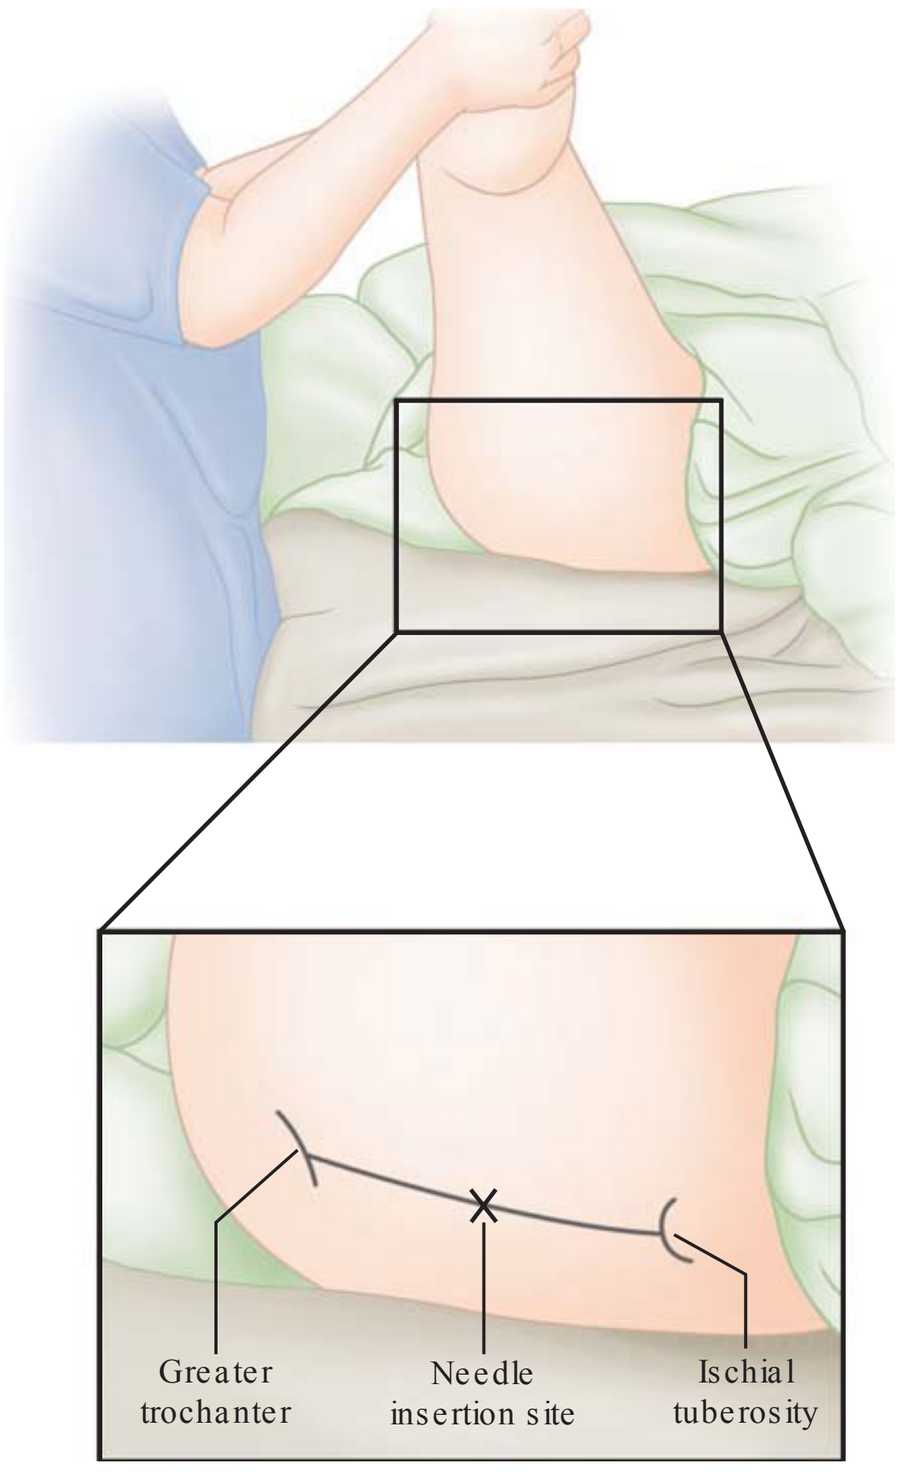

FIGURE 52.23 Patient position and landmarks for sciatic nerve block using Raj approach.

Sciatic Nerve Block: Infragluteal-Parabiceps Approach

Indications. The infrugluteal-parabiceps sciatic nerve block is performed using easily identifiable soft tissue landmarks. As a single injection or continuous catheter technique, it provides postoperative analgesia for operations on the foot and ankle.

Landmarks. The patient is positioned prone or alternatively in the lateral decubitus position with the extremity to be blocked up and rolled forward with the knee flexed 90 degrees. The most proximal gluteal crease is identified and marked. The lateral border of the biceps femoris muscle is identified and marked at it intersects the gluteal crease. The initial needle insertion site is 1 cm distal to the gluteal crease at the lateral border of the biceps femoris muscle (Fig. 52.24).

Needles. Insulated needles used: 22-gauge 5 cm or 21-gauge 10 cm. Insulated Tuohy needle for catheter placement: 18-guage, 5 or 10 cm. Catheters are inserted 5 cm beyond the needle tip.

Technique. The nerve stimulator is initially set at 1.0 to 1.5 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is inserted with slight cephalad and anterior orientation within the parasagital plane. Plantarflexion/inversion of the foot at 0.5 mA or less indicates acceptable needle tip position for local anesthetic injection. Dorsiflexion/eversion of the foot indicates the lateral needle tip position.

Sciatic Nerve Block: Anterior Approach

Indications. The anterior approach to the sciatic nerve, requiring minimal positioning of the surgical extremity for block placement, is advantageous for patients experiencing pain with movement of the extremity and/or those with external fixators in place, making positioning difficult. The anterior sciatic nerve block as a single injection technique provides postoperative analgesia for operations on the foot and ankle. Continuous catheters are not recommended with this approach.

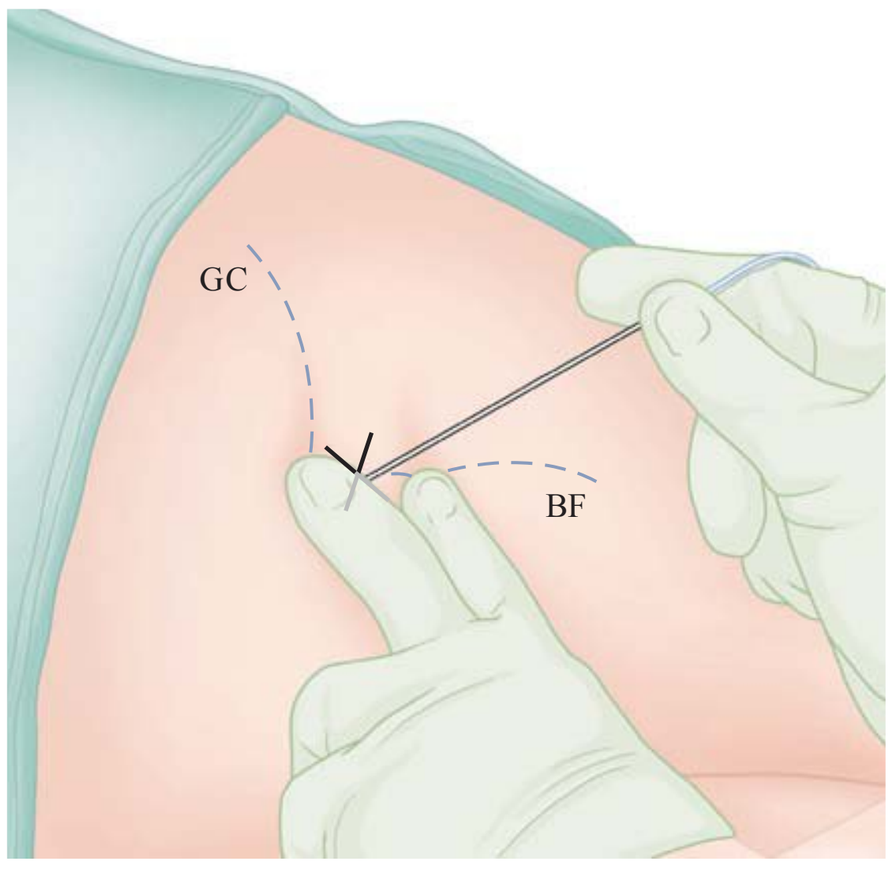

FIGURE 52.24 Landmarks and needle orientation for infragluteal-parabiceps sciatic nerve block.

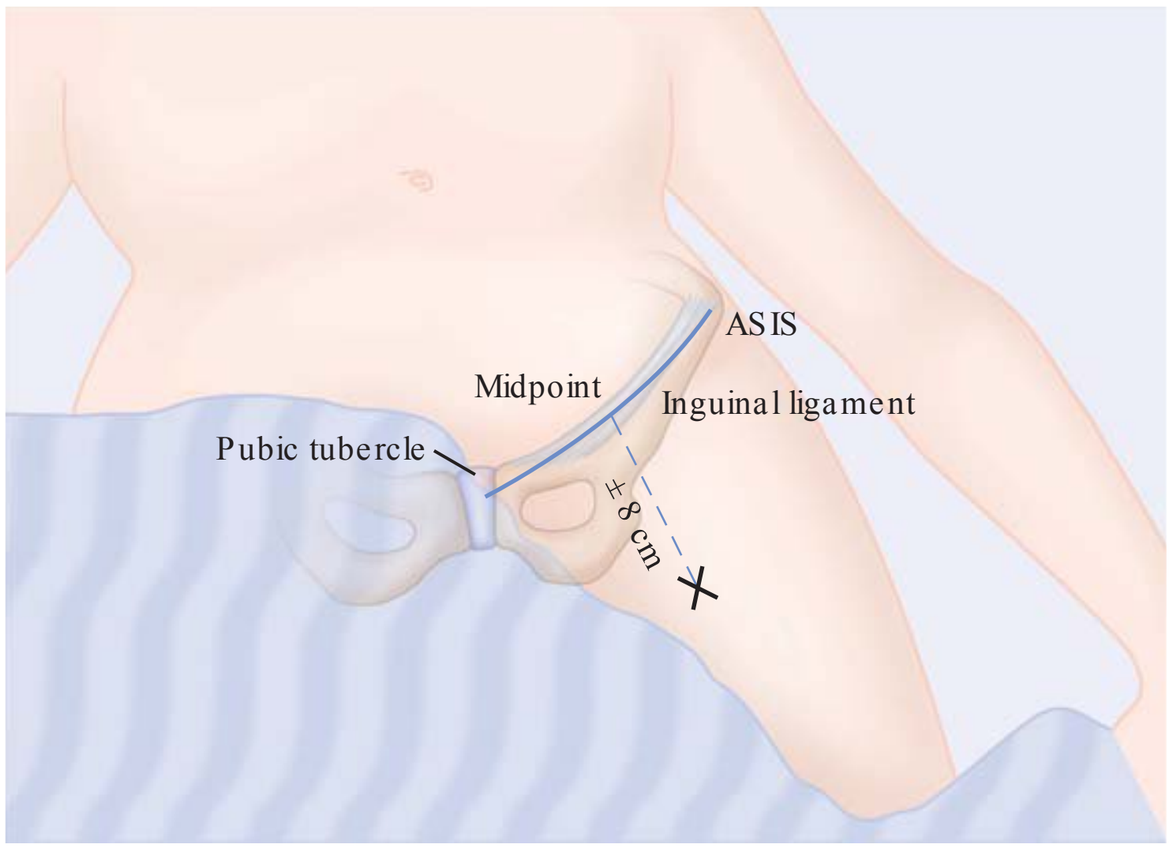

FIGURE 52.25 Landmarks for anterior approach to sciatic nerve block. X, needle insertion site.

Landmarks. The patient is positioned supine. A line is drawn from the anterior superior iliac spine to the pubic tubercle and marked at its midline. A second line is drawn perpendicular to first line from its midpoint to a point 8 cm caudally which represents the initial needle insertion site (Fig. 52.25). Alternatively, the femoral artery pulse is identified along the femoral crease. A line is drawn perpendicular to the femoral crease to a point 4 to 5 cm distal from the femoral artery pulse. This point 4 to 5 cm distal from the femoral artery pulse, along the line drawn perpendicular to the femoral crease, is the initial needle insertion site.

Needles. Insulated needle used: 21-gauge, 15 cm.

Technique.
Nerve stimulation. The nerve stimulator is initially set at 1.5 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is inserted perpendicular to all planes and advanced until the femur is contacted. The needle tip is then redirected slightly medial until plantarflexion/inversion of the foot is elicited at a current of 0.5 mA or less, indicating acceptable needle tip position for local anesthetic injection. If subsequent medial passes continue to contact bone, internal rotation of the leg will displace the lesser trochanter, optimizing the anterior approach to the sciatic nerve. Dorsiflexion/eversion of the foot indicates lateral needle tip position.

Ultrasound. Using a curvilinear, high-frequency ultrasound probe placed in the transverse plane at the medial aspect of the upper midthigh, the sciatic nerve will appear in cross section as a hyperechoic circle or triangular structure medial to the femur and deep to the adductor magnus muscle (Fig. 52.26). Introducing the block needle from the lateral end of the ultrasound probe and advancing in line with the plane of the beam allows direct visualization of needle tip advancement and local anesthetic spread.

Sciatic Nerve Block: Popliteal Approach

Indications. The popliteal nerve block as a distal block of the sciatic nerve preserves hamstring function and facilitates ambulation. It can be performed from a posterior or lateral approach. A disadvantage of either approach is that the tibial and common peroneal components of the sciatic nerve may separate prior to reaching the popliteal fossa, potentially resulting in an incomplete block if local anesthetic does not spread to each division. Popliteal nerve block using a single injection or continuous catheter technique provides postoperative analgesia for operations on the foot and ankle.

Landmarks: Posterior Popliteal Approach. The patient is positioned prone with the operative foot slightly elevated and free so that the motor evoked response is unobstructed. The popliteal crease is identified and marked. The tendons of the biceps femoris and semitendinosus muscles are identified and accentuated by having the patient bend the knee against resistance. The needle insertion site is marked approximately 7 cm proximal to the popliteal crease, midpoint between the biceps femoris and semitendinosus tendons (Fig. 52.27).

Needles. Insulated needles used: 22-gauge, 5 cm or 21-gauge 10 cm. Insulated Tuohy needle for catheter placementL 18-gauge, 5 cm. Catheters are inserted 5 cm beyond the needle tip.

Technique.
Nerve stimulation. The nerve stimulator is initially set at 1.0 to 1.5 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is inserted slightly cephalad in the parasagittal plane. Plantarflexion/inversion of the foot at 0.5 mA or less indicates acceptable needle tip position for local anesthetic

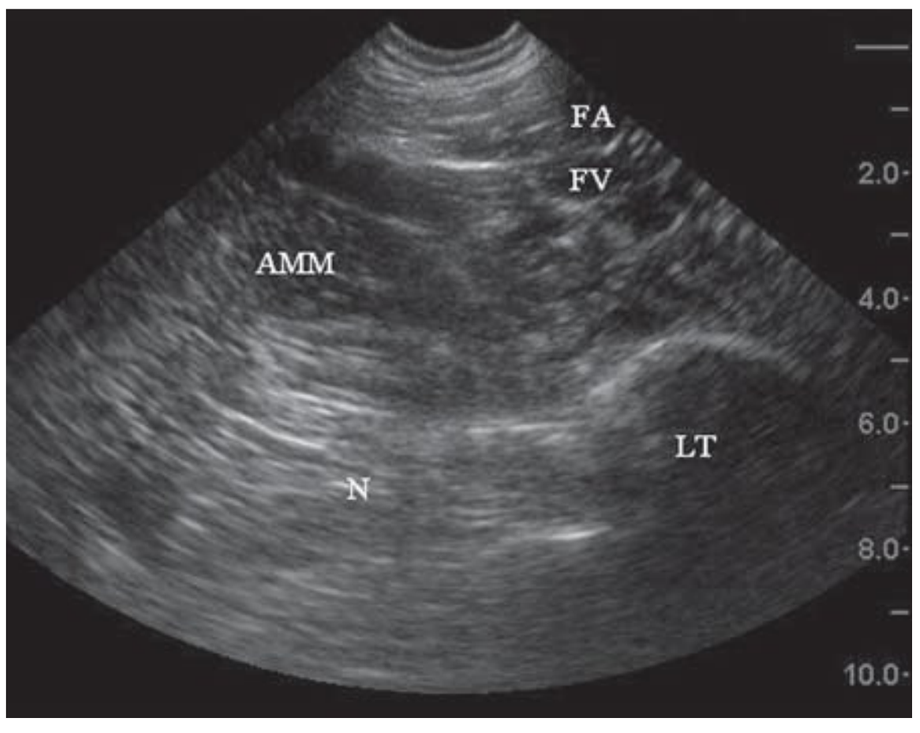

FIGURE 52.26 Sonographic landmarks for ultrasound-guided anterior sciatic nerve block. AMM, adductor magnus muscle; FA: femoral artery; FV: femoral vein; LT: lesser trochanter; N: sciatic nerve.

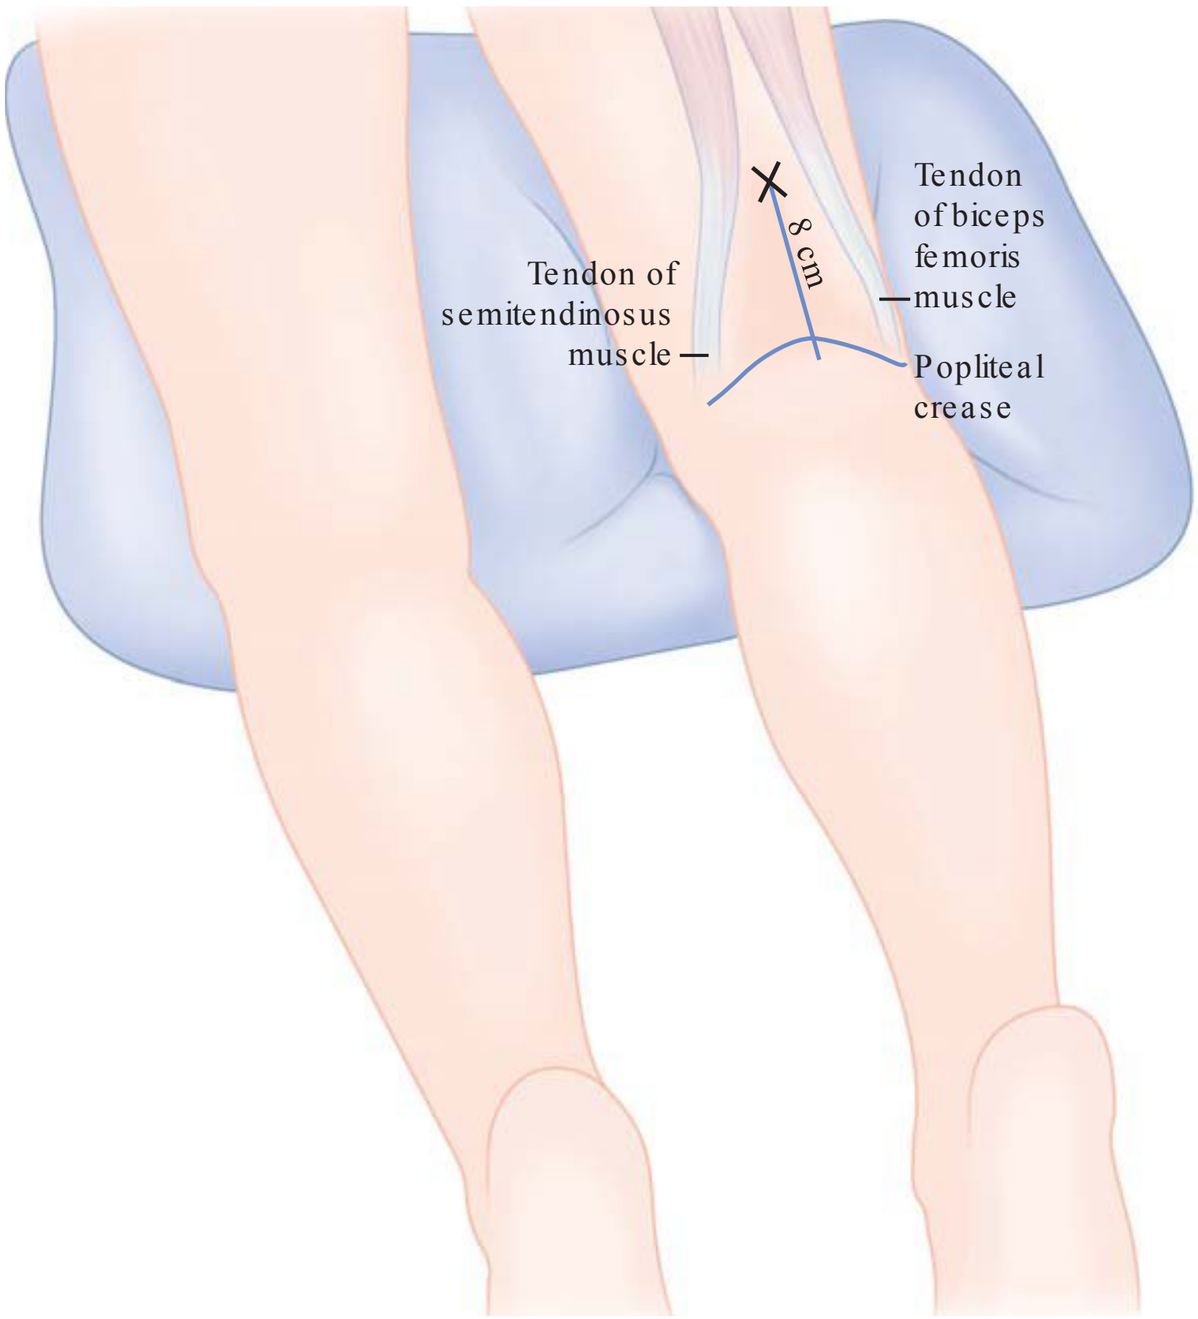

FIGURE 52.27 Landmarks for posterior popliteal nerve block. X, needle insertion site.

injection. Dorsiflexion/eversion of the foot indicates lateral needle tip position. Motor response of the semitendinosus mucle indicates medial needle tip insertion, and the needle should be redirected laterally. Motor response of the biceps femoris muscle indicates lateral needle tip insertion, and the needle should be redirected medially. Aspiration of blood indicates medial needle tip position.

Ultrasound. Using a linear,-low frequency ultrasound probe placed in a transverse plane in the popliteal fossa at the level of the popliteal crease, the popliteal artery can be imaged in cross section. The tibial nerve can be found posterior and medial to the popliteal artery and the common peroneal lateral to the artery Fig. 52.28). Both components of the sciatic nerve appear as round to oval hyperechoic structures. Slowly moving the ultrasound probe proximally will demonstrate the common peroneal nerve moving medial to join the tibial nerve (Fig. 52.29). At the level these nerves join, introducing the block needle from the lateral end of the ultrasound probe and advancing in line with the plane of the beam allows direct visualization of needle tip advancement and local anesthetic spread.

Landmarks: Lateral Popliteal Approach. The patient is placed in the supine position with the legs placed in the neutral position. The foot of the operative leg is slightly elevated so that it remains free and the motor evoked response unobstructed. The popliteal crease is noted and marked at its lateral extension. The groove between the vastus lateralis and biceps femoris is palpated and accentuated by having the patient lift his or her foot off the table. The needle insertion site is 8 to 10 cm cephalad to the popliteal crease within the groove (Fig. 52.30).

Needles. Insulated needle used: 21-gauge, 10 cm. Insulated Tuohy needle for catheter placement: 18-gauge, 10 cm. Catheters are inserted 5 cm beyond the needle tip.

Technique.
Nerve stimulation. The nerve stimulator is initially set at 1.0 to 1.5 mA. After cleaning the area with antiseptic solution, using sterile technique, the needle is advanced parallel to the bed to contact the femur. The needle is then withdrawn to the skin and redirected 30 degrees posterior (Fig. 52.31). If initial passes fail, subsequent attempts are made more anteriorly or posteriorly. Plantarflexion/inversion of the foot at 0.5 mA or less indicates acceptable needle tip position for local anesthetic injection. Dorsiflexion/eversion of the foot indicates lateral needle tip posi-

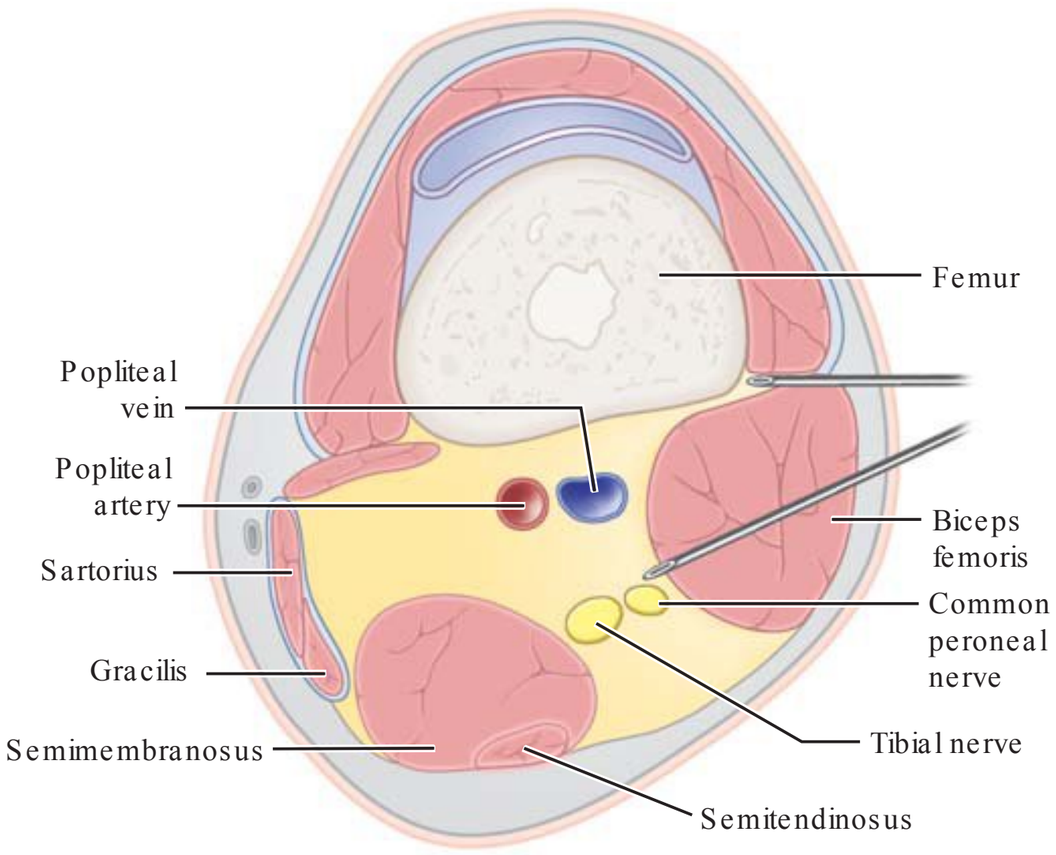

FIGURE 52.31 Anatomy of lateral politeal approach.

tion. Motor response of the hamstring suggests medial needle tip placement. Aspiration of blood indicates anterior and medial needle tip position.

Ultrasound. The patient is placed in the lateral position or alternatively in the supine position with the leg elevated to allow placement of a linear, low-frequency ultrasound probe in the transverse plane in the popliteal fossa at the level of the popliteal crease. At this point, the popliteal artery can be imaged in cross section. The hyperechoic tibial nerve can be seen in cross section posterior and medial to the popliteal artery, and the hyperechoic common peroneal nerve can be seen in cross section lateral to the artery (see Fig. 52.28). Slowly moving the ultrasound probe proximally will image the common peroneal nerve moving medial to join the tibial nerve (see Fig. 52.29). At this level, introducing the block needle from the lateral end of the ultrasound probe or from a more traditional lateral approach allows the needle tip to be advanced toward the sciatic nerve in line with the plane of the beam. This allows direct visualization of needle tip advancement and local anesthetic spread.

Clinical Effects. For outcomes associated with the addition of single injection or continuous sciatic nerve blocks to femoral or posterior lumbar plexus blocks, please refer to those sections. Sciatic nerve blockade by means of the classic posterior approach, the modified subgluteal posterior approach, or the lateral popliteal approach with 30 mL of 0.75% ropivacaine provides postoperative analgesia for up to 16 hours with similar time to resolution of motor block and patient satisfaction.[167]

Popliteal nerve block can provide analgesia for up to 20 hours after foot and ankle procedures[168] with a high level of patient satisfaction.[169] In patients undergoing foot and ankle procedures, polpiteal nerve block provided a significant increase in analgesic duration as compared to ankle block and subcutaneous local anesthetic infiltration.[170] Postoperative analgesia with popliteal nerve block provided 18 hours of analgesia as compared to 11.5 hours with the ankle block and 6.3 hours with local infiltration.

Continuous popliteal nerve blocks for postoperative analgesia reduce supplemental opioid requirements and opioid related side effects.[171,172] Additional benefits include improved sleep,[173] reduced hospital length of stay,[171] reduced outpatient admissions,[171] reduced perioperative costs,[171] and high patient satisfaction.[171,173] One small study examined the ability of continuous sciatic analgesia to allow conversion of inpatient foot surgery to outpatient surgery,[171] and although more patients in the perineural analgesia group were able to be discharged home, the difference was not statistically significant.

Ankle Block

Indications. The ankle is innervated by four branches of the sciatic nerve (posterior tibial, deep peroneal, common peroneal,

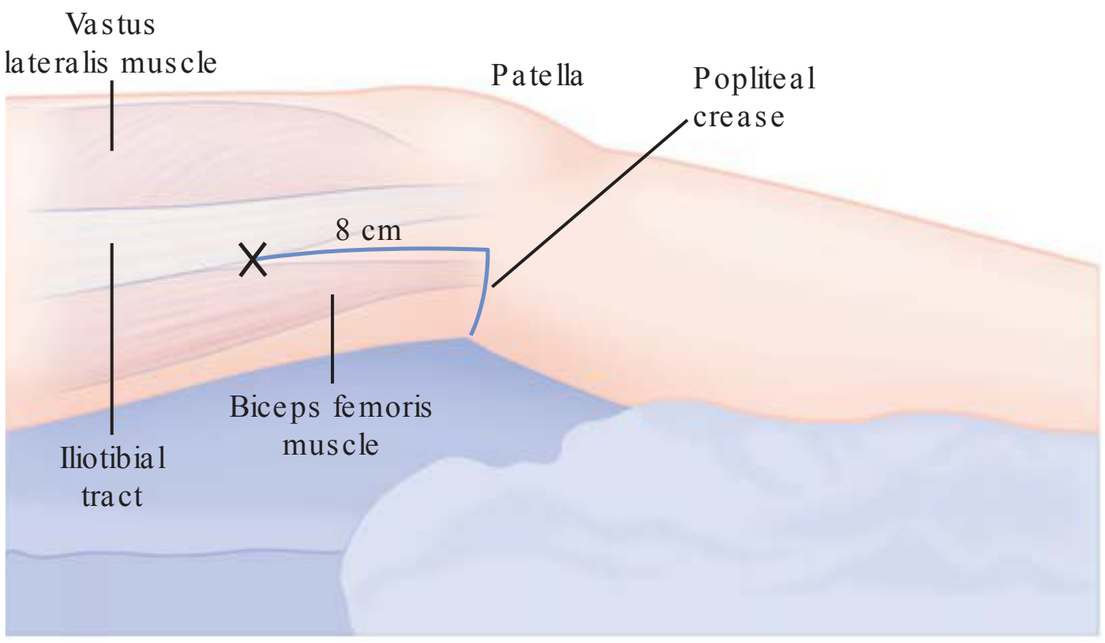

FIGURE 52.30 Landmarks for lateral politeal nerve block. X, needle insertion site.

sural) and one branch of the femoral nerve (saphenous). The ankle block provides analgesia for operations on the forefoot and facilitates early ambulation.

Needles. Needle used: 22–25-gauge, 3.7 cm, 1.5 inch. If using nerve stimulate for tibial nerve, a 22-gauge, 5 cm insulated needle is used.

Landmarks and Technique

Place patient supine with the leg resting on a pillow so that the foot is free to rotate internally and externally.

Tibial nerve. The leg is externally rotated with the knee flexed. The posterior tibial artery is palpated at the inferior border of the medial malleolus and 1 to 2 cm anterior to the Achilles tendon (Fig. 52.32). After cleaning the area with antiseptic solution, using sterile technique, the needle is directed posterior to the artery and advanced until the flexor retinaculum is pierced or bone contact with the tibia is made. If bone is contacted, the needle is withdrawn slightly prior to injection. Ten mL of local anesthetic without epinephrine is injected after negative aspiration. If a nerve stimulation technique is used, the nerve stimulator is initially set at 2 mA. Flexion of the great toe indicates acceptable needle tip position for local anesthetic injection. It is not necessary to dial down the current.

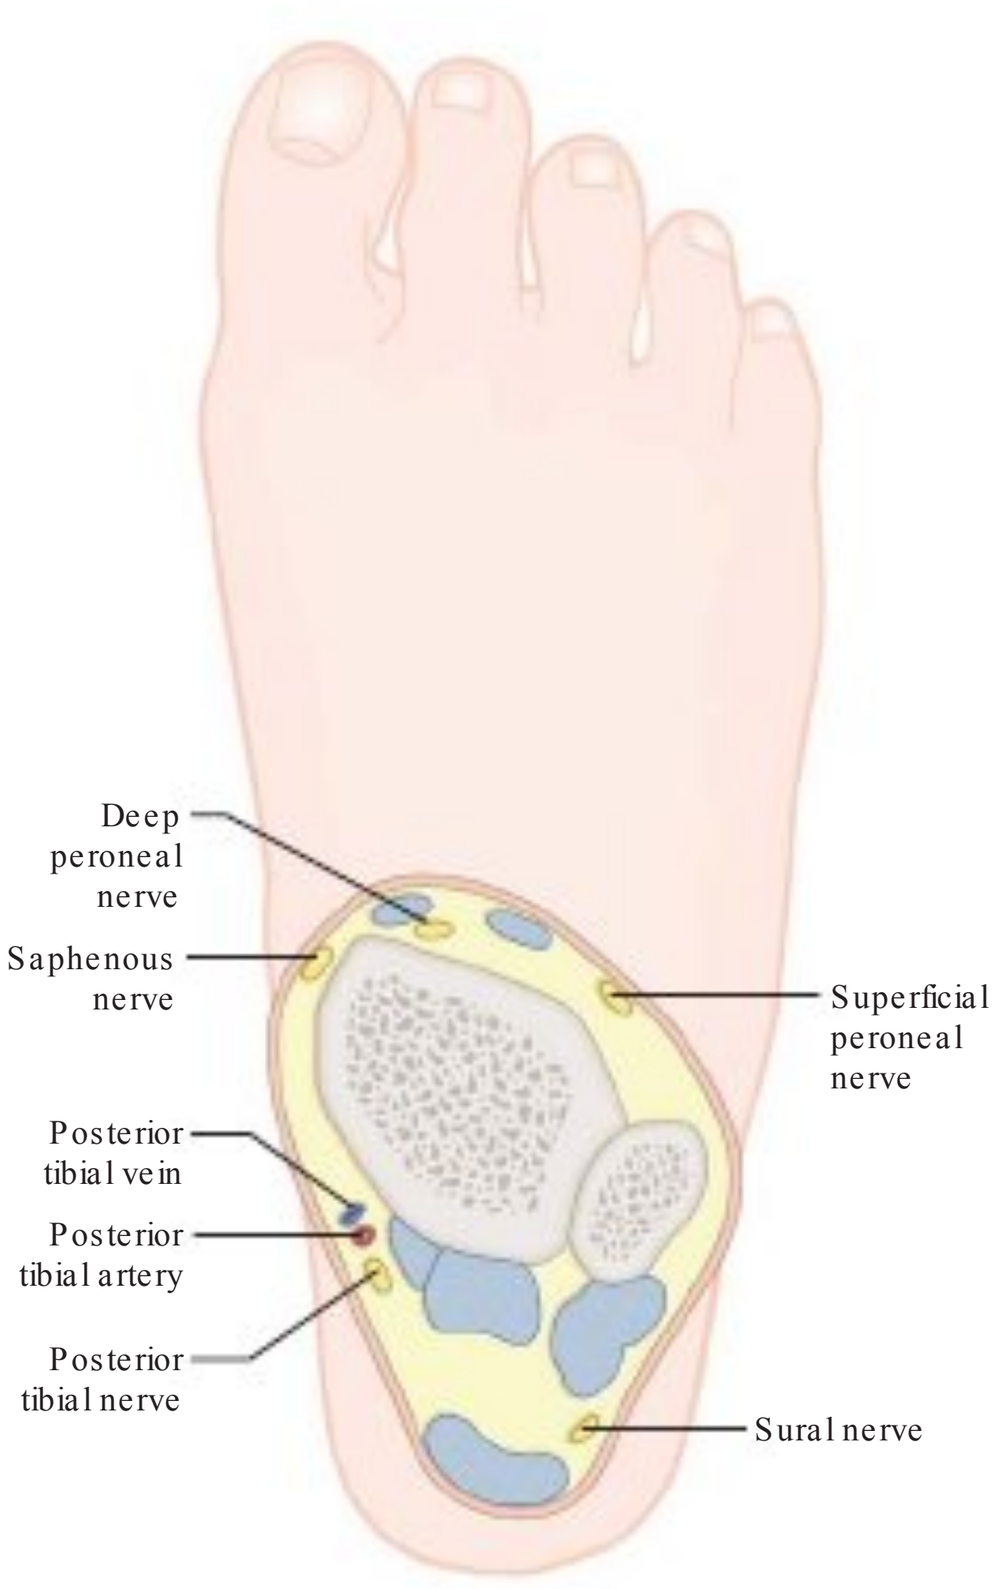

FIGURE 52.32 Landmarks for ankle block.

Deep peroneal nerve. Block of the deep peroneal nerve is accomplished by asking the patient to extend the foot and first toe against resistance. This allows palpation of the extensor digitorum and extensor hallucis longus tendons above the ankle joint at the level of the malleoli. After cleaning the area with antiseptic solution, using sterile technique, the needle is directed perpendicular to the skin, medial to the anterior tibial artery and between the tendons until the extensor retinaculum is penetrated or bone contact with the tibia is made (see Fig. 52.32). If bone is contacted, the needle is withdrawn slightly prior to injection. After a negative aspiration, 2 to 4 mL of local anesthetic without epinephrine is injected deep to the fascia.

Superficial peroneal, saphenous, and sural nerves. After cleaning the area with antiseptic solution, using sterile technique, the saphenous, sural, and superficial peroneal nerves are blocked with a subcutaneous ring of local anesthetic just proximal to the malleoli extending across the anterior portion of the ankle from the lateral aspect of the Achilles tendon to the medial malleolus (see Fig. 52.32).

Clinical Effects. In patients undergoing foot and ankle procedures, polpiteal nerve block provided a significant increase in analgesic duration as compared to ankle block and subcutaneous local anesthetic infiltration.[170] Postoperative analgesia with popliteal nerve block provided 18 hours of analgesia as compared to 11.5 hours with the ankle block and 6.3 hours with local infiltration.

Paravertebral Blocks

The paravertebral space is an anatomically triangular area whose borders are defined by the parietal pleura or iliopsoas muscle anterolaterally; the superior costotransverse ligament (thoracic levels) posteriorly; the vertebra, vertebral disk, and intervertebral foramina medially; and the heads of the ribs superiorly and inferiorly (Fig. 52.33). Within this space, the spinal root emerges from the intervertebral foramina and divides into dorsal and ventral rami. Paravertebral blocks provide segmental anesthesia and analgesia (Table 52.8).

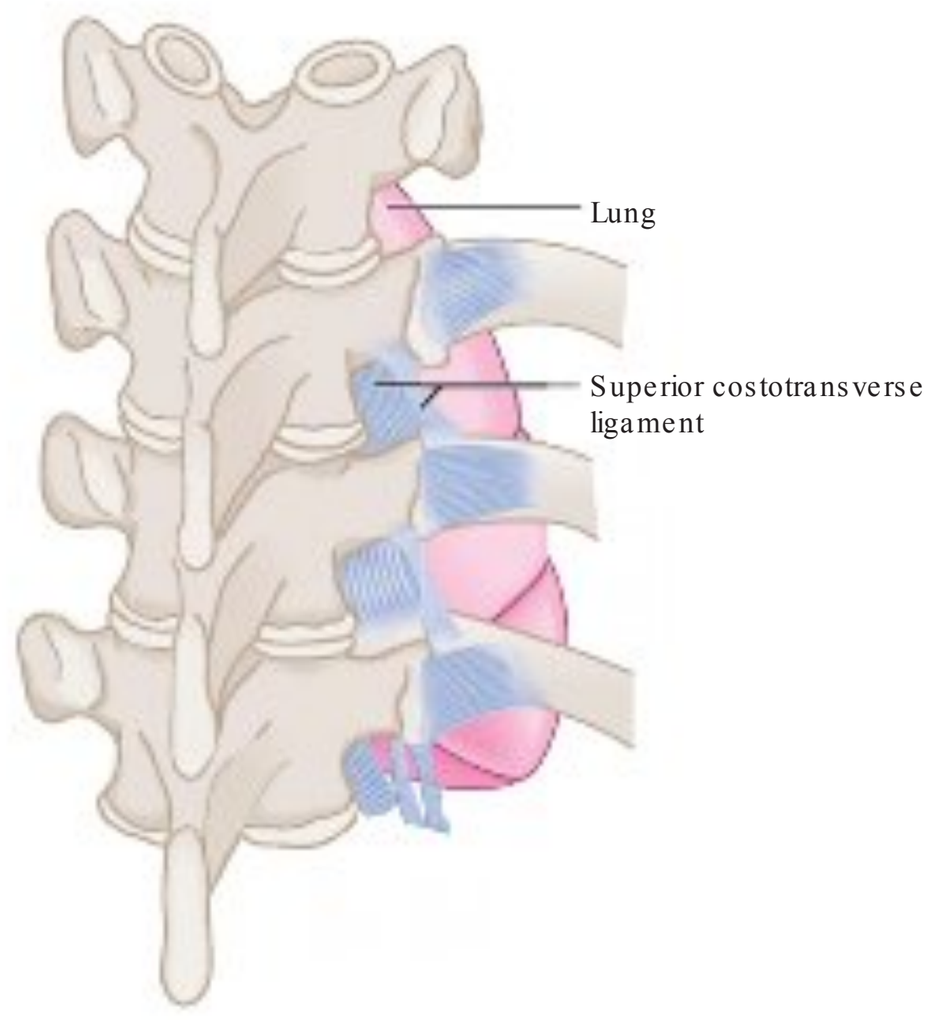

FIGURE 52.33 Anatomy of the paravertebral space. Medial portion of superior costotransverse ligament removed at arrow identifying paravertebral space.

TABLE 52.8

LOWER THORACIC/LUMBAR PARAVERTEBRAL BLOCK DOSING

Local Anesthetic (3–5 mL at each space for multiple-injection technique or 15–20 mL for single-injection technique)	Anesthesia (hrs)	Analgesia (hrs)
1.5% Mepivacaine (plus HCO3; plus epinephrine)	2–3	3–4
2% Lidocaine (plus HCO3 + epinephrine)	2–3	3–4
0.5% Ropivacaine	3–5	8–12
0.75% Ropivacaine	4–6	12–18
0.5% Bupivacaine (plus epinephrine)	4–6	12–18
0.5% L-Bupivacaine (plus epinephrine)	4–6	12–18

Continuous infusion ropivacaine 0.2% or dilute concentration of bupivacaine or levobupivacaine; 10 mL/hour or 5–6 mL/hour with 4–5 Q30 min boluses.
Table modified from Hadzic A, Vloka JD. *Peripheral Nerve Blocks, Principles and Practice*. Columbus, OH: McGraw-Hill; 2004.

Indications

Paravertebral nerve blocks (PVBs) using single injection or a continuous catheter techniques provide anesthesia and analgesia to the chest and abdomen. PVBs are highly versatile, serving as the primary anesthetic for breast surgery, herniorrhaphy, soft tissue mass excisions, and harvesting of iliac crest bone grafts. PVBs are also an effective analgesic adjunct in laproscopic surgery, cholecystectomy, nephrectomy, appendectomy, thoracotomy, thoracoscopy, obstretric analgesia, minimally invasive cardiac surgery, and hip surgery.

Landmarks

The patient is placed in the sitting position with the neck and back flexed and the shoulders forward. The spinous processes correlating to the levels to be blocked are identified and marked. Additional marks are then made 2.5 cm laterally on the side to be blocked from the midpoint of the superior aspect of each spinous process (Fig. 52.34). In the thoracic area, due to the steep angulation of the spinous processes, the transverse process is located lateral to the spinous process of the vertebral body above it. Thus, the spinous process of the vertebra above the level to be blocked is identified. In the lumbar area, the transverse process is located lateral to the spinous process of the same vertebral body. Thus, the spinous process of the level to be blocked is identified.

Needles

A 22-gauge Tuohy needle with extention tubing is used. An 18-gauge insulated Tuohy needle with hemostasis valve/sideport assembly and 50 mm tubing is used. Catheters are placed 2–2.5 cm beyond the needle tip into paravertebral space.

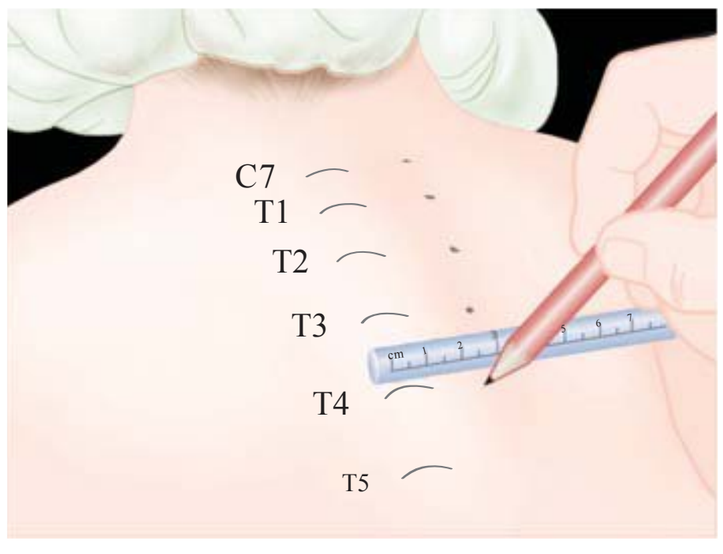

FIGURE 52.34 Identifying landmarks for paravertebral blocks.

Technique

After cleaning the area with antiseptic solution, skin wheals of local anesthetic are raised at each needle insertion site. The needle is inserted perpendicular to the back in all planes, parallel to the neuroaxis, and advanced until it contacts the transverse process, paying careful attention to limit the initial attempt to a predetermined appropriate depth. The transverse process is usually contacted at a depth of 2–5 cm from the skin. If the transverse process is not contacted at an appropriate depth, the needle tip is assumed to lie between adjacent transverse processes, requiring redirection of the needle cephalad and then caudad, parallel to the neuroaxis. Upon successful contact with the transverse process, the depth is noted. The needle is then withdrawn to the subcutaneous tissue and redirected caudad to "walk off" the inferior border of the transverse process, passing the needle 1 cm beyond the depth at which the transverse process was contacted at the thoracic level or 0.5 cm beyond the depth at which the transverse process was contacted at the lumbar level due to the thin lumbar transverse processes. Caudad redirection of the needle is important to minimize the possibility of a pneumothorax by preventing initial inadvertent contact with the rib from being interpreted as the transverse process. If initial inadvertent contact with the rib is mistaken for the transverse process, caudad redirection will correctly identify the transverse process with subsequent contact of periosteum at a more superficial level; however, cephalad redirection at this point will lead to penetration of the pleura. At the thoracic levels, it is common to appreciate a subtle loss of resistance as the needle passes through the superior costotransverse ligament into the paravertebral space. In the lumbar region, there is no superior costotransverse ligament. If a distinct loss of resistance is sensed here, the needle has likely pierced the psoas fascia and the needle should be withdrawn to a more shallow depth.

Clinical Effects

Single-shot injection PVBs are effective regional analgesic techniques for minor and major breast cancer procedures as well as cosmetic and reconstructive breast augmentation,[174–179] providing up to 23 hours of analgesia,[174] with reduction in pain VAS scores,[177,180] opioid consumption,[176,177,180] pain with movement,[177] postoperative nausea and vomiting (PONV),[176,177,180] and hospital length of stay.[176,181] In doing so, PVBs have improved postoperative pain management and side effects facilitat-

CI, confidence interval; NA, not analyzed; NS, no significant difference; S, significant difference.
Tile estimated rate of occurrence was calculated using a random effects general linear model (see text).
Table modified from Brull R, McCartney CJ, Chan VW, et al. Neurological complications after regional anesthesia: contemporary estimates of risk. *Anesth Analg* 2007;104:965–974.

ing these surgeries in the outpatient surgical setting[174,176] with tremendous potential for cost savings.[174] A recent retrospective analysis suggests that paravertebral anesthesia and analgesia for breast cancer surgery may reduce the risk of recurrence or metastasis during the initial years of follow-up. Additionally, single-shot injection PVBs provide effective postoperative analgesia for inguinal hernia repair,[180,182,183] providing up to 14 hours of postoperative analgesia with delayed time to the first dose of opioid up to 22–24 hours[180,182] with one study reporting a zero incidence of PONV.[180]

Continuous PVB for analgesia after breast cancer surgery has been reported.[184] Continuous PVB for postthoracotomy analgesia provides analgesia of similar or better quality than epidural analgesia,[185–188] with a lower incidence of side effects, including urinary retention,[185] hypotension,[188] and PONV.[187] Additional reports exist on the safe and effective use of single injection and continuous catheter techniques for cardiac[189–191] and vascular surgery.[192]

Complications of Peripheral Nerve Blocks

While complications after regional anesthesia are uncommon, the exceedingly large number of patients needed to investigate a true incidence of these complications limits such a study.[81] Potential risks of peripheral nerve blocks are block specific and include, but are not limited to, local pain, discomfort, bruising, bleeding, infection, transient neuropathy, permanent neuropathy, paralysis, seizures, pneumothorax, respiratory failure, cardiac arrest, and death (Tables 52.9 and 52.10).[81] The incidence of neurologic deficit after surgery associated with peripheral nerve block is unclear. Determining the incidence of block-related nerve injury is limited by a variety of factors. Among such factors are inconsistent follow-up, the use of self-reporting and survey analysis of complications, the lack of standardized documentation of preoperative and postoperative neurologic function, the absence of routine postoperative neurodiagnostic testing, and the limited ability of these tests to determine the precise etiology of nerve injury, including surgical factors such as tourniquet duration, tourniquet inflation pressure, retractor injuries, and stretch injuries producing neurologic deficits.[193] Horlocker et al.[194] reported that 89% of neurologic deficits after 1614 axilllary nerve blocks were related to the surgical procedure itself.[194] Four percent of patients undergoing shoulder arthroplasty sustain brachial plexus injuries in the absence of PNB.[195] Prospective analyses of more than 70,000 patients using carefully conducted survey studies suggest incidence rates of 0.02%.[194,196] Other studies report nerve injury rates from 0% to 10% after single-shot upper extremity blocks and rates less than 0.5% for lower extremity blocks. Reports with CPNB techniques report a similar incidence. Capdevilla et al.[197] demonstrated a 0.21% incidence of nerve injuries after 1416 upper and lower extremity CPNBs, as did Swenson et al.[129] in a similar analysis of 620 CPNBs. A report on neurologic outcomes occurring after 1065 consecutive peripheral nerve blocks over a 1-year period from a single institution followed for up to 12 months reported the incidence of block-related neuropathy was 0.22% (Tables 52.11 and 52.12).[198]

The reported incidence of clinical pneumothorax in a prospective study of over 500 interscalene blocks was 0.2%.[199] In data gathered prospectively from 1001 subclavian perivascular brachial plexus blocks with a nerve stimulator, no clinical pneumothorax was reported.[200] Greengrass et al.[201] reported a 0.035%–0.5% incidence of pneumothorax with paravertebral blocks.

The associated risk of bleeding following peripheral regional anesthetic techniques in the setting of prophylactic or therapeutic anticoagulation remains undefined. In the context of LPBs, this issue is especially important as all of the cases involving PNBs and bleeding in association with anticoagulation in the 2003 ASRA consensus statement were associated with LPBs.[83,202,203] Case reports of retroperitoneal hematoma have been in the setting of low-molecular-weight heparin use. For this reason, LPBs have

TABLE 52.13

ENOXAPARIN ANTICOAGULATION GUIDELINES FOR SINGLE INJECTION PERIPHERAL NERVE BLOCK AND CONTINUOUS PERIPHERAL NERVE BLOCK AT WALTER REED ARMY MEDICAL CENTER

Definitions
- Prophylactic enoxaparin: 30 mg twice daily or 40 mg once daily.
- Therapeutic enoxaparin: 1 mg/kg twice daily or 1.5 mg/kg once daily.
- CPNB: continuous PNB (catheter).
- Single injection PNB (no catheter).

Prophylactic Enoxapatin
- Wait 10–12 hours to place/pull catheter or administer single injection block.

Therapeutic Enoxaparin
- Do not place CPNB catheters until 24 hours after last enoxaparin dose. Do not place lumbar plexus catheters if therapeutic enoxaparin will continue.
- Single injection PNBs are administered at the discretion of the staff anesthesiologist 12–24 hours after the last enoxaparin dose.

CPNB catheter is in place and enoxaparin increased from prophylactic to therapeutic dose
- Lumbar plexus catheter: recommend removal of the catheter 24 hours after last enoxaparin dose.
- Other catheters including thoracic paravertebral CPNB (the thoracic paravertebral spaces are relatively avascular): recommend continuation of CPNB therapy.
- Consider adding neurologic checks (motor function) to daily anesthesia note for patients with catheter(s) on therapeutic enoxaparin.

Catheter Removal Guidelines
- Prophylactic enoxaparin: remove the catheter 10–12 hours after the last enoxaparin dose.
- Therapeutic enoxaparin: remove the catheter ~24 hours after the last enoxaparin dose.
- Hold the next enoxapmin dose until ~2 hours after pulling a CPNB catheter.

Table modified from Buckenmaier CC, Shields CH, Auton AA, et al. Continuous peripheral nerve block in combat casulties receiving low-molecular weight heparin. *Br J Anaesth* 2006;97:874–877.

reportedly been managed more conservatively in the setting of low-molecular-weight heparin use as compared to other PNB techniques.[203,204] In a report collectively involving 305 CPNB catheters placed in 187 patients in the setting of enoxaparin use, amounting to 3082 catheter days, there were no catheter-related bleeding complications (see Tables 52.10 and 52.13).[204] Additional data is necessary to make definitive recommendations regarding nonneuraxial regional techniques in the anticoagulated patient. Conservatively, the ASRA Consensus Statements on Neuraxial Anesthesia and Anticoagulation may be applied to plexus and peripheral techniques. However, this may be more restrictive than necessary.[83]

Major infectious adverse events are rare. Among 969 catheters (68%) submitted for culture in a multicenter study by Capdevila,[197] 278 had positive bacterial colonization (28.7%) with a single organism in 242 cases. Three percent of patients had

Couture (2004)	Femoral	Clonidine 1 mcg/kg	Bupivacaine 0.5% 30 mL	No difference	Yes	No	Negative

BP, blood pressure; HR, heartrate; NA, not applicable.
Table modified from Murphy DB, McCartney CJ, Chan VW. Novel analgesic adjuncts for brachial plexus block: a systematic review. *Anesth Analg* 2000;90: 1122–1128.

local inflammatory signs. The bacterial species most frequently found were coagulase-negative staphylococcus (61%) and gram-negative bacillus (21.6%). A *Staphylococcus aureus* psoas abscess (0.07%) was reported in one diabetic woman who had a femoral catheter after a total knee replacement. No bacteremia was found. Risk factors for local inflammation/infection were postoperative monitoring in intensive care, catheter duration greater than 48 hours, male sex, and absence of antibiotic prophylaxis.[197]

Analgesic Adjuncts for Peripheral Nerve Blocks

Efforts to prolong analgesia of PNB local anesthetic solutions with the addition of adjuncts, including but not limited to morphine,[89–91] fentanyl,[92–94] sufentanil,[95,96] buprenorphine,[90,97,98] tramadol,[99,100] ketamine,[101] and clonidine[107,108] have been investigated. A recent systematic qualitative review of double-blind RCTs on the benefit of clonidine as an adjunct to PNBs demonstrated that clonidine improved duration of analgesia when used as an adjunct to intermediate-acting local anesthetics for axillary nerve blocks. Studies to date do not allow for definitive conclusions regarding clonidine as an adjunct for other upper and lower extremity single injection and continuous nerve blocks.[205] Crucial to all investigations of perineural analgesia adjuncts is the inclusion of systemic control groups, providing evidence for or against a peripheral perineural site of action as opposed to a systemic effect of an adjunct administered peripherally (Table 52.14).

CHAPTER 53 ■ BURN PAIN

SAM R. SHARAR AND DAVID R. PATTERSON

INTRODUCTION

If burn injuries in themselves are not the most painful type of trauma a person can sustain, then they likely reach this status once the nature of their treatment is considered. Contemporary treatment of burn injuries involves a multitude of invasive and rehabilitative procedures that continue—often on a daily basis—for days, weeks, or months. Each intervention is critical to achieving optimal wound healing and long-term physical/occupational function, yet has the potential for inflicting more pain, on a repeated basis, than that of the initial trauma. Burn injuries are

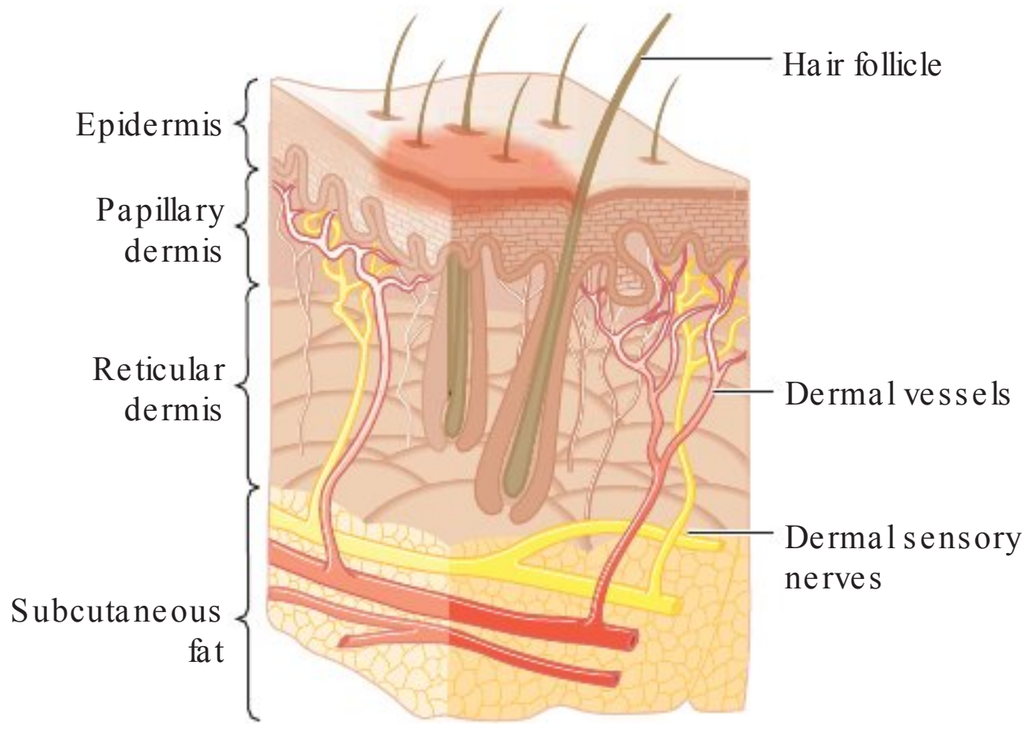

FIGURE 53.1 Anatomic layers of skin. Graphic representation of skin layers including the outer epidermis, the thin papillary dermis, the collagen-dense reticular dermis, and the deep subcutaneous fat. The dermal sensory neurons of mechanoheat receptors and dermal capillaries are shown, relative to a first-degree burn injury (confined to the outer epidermal skin layer). pervasive in both industrial nations and developing countries around the world, and affect individuals across a wide demographic span. In the United States, it is estimated that 1.25 million people annually sustain burn injuries, resulting in 51,000 acute hospitalizations and 5,500 deaths.[1] As death rates for burn injuries have recently declined (33% between 1985 and 1995[2]), due primarily to improved surgical care, more patients with large burns are surviving and pose unique physical and psychological rehabilitation challenges with issues such as scarring, contractures, amputations, psychological adjustment, and pain. Despite this increased challenge to provide effective pain relief, there has long been substantial evidence that pain from burn injuries is undertreated, particularly in children.[3,4] Further, the magnitude of pain reported after burn injury and during burn care correlates strongly with long-term adverse psychological outcome in this patient population.[5,6] Thus, there are humane, medical, and economic reasons to better control burn pain in a practical and cost-effective fashion. Associated with this emphasis, a recent review of research presented at the American Burn Association annual meeting reported that the research category of "pain/anxiety/patient comfort" was the third most popular of 10 burn-related clinical and laboratory research areas.[7]

THE NATURE OF BURN PAIN

Treating the human suffering from burn pain is challenging, from the perspectives of both the patient and clinician. It is well known that a burn injury results in one of the most intense types of sensory nociception imaginable, attributable to the unique tissue injury that results from a thermal insult to the dermal sensory organs and a resulting acute inflammatory response that, at least in the early postburn period, is related to the depth of tissue injury (Figs. 53.1 and 53.2). First-degree burns (e.g., sunburn) are characterized by tissue injury that is limited to the epidermal skin layer and an inflammatory response in the superficial dermal layers and results in hyperemia (manifest as erythema), an intact epidermis (no skin blistering), and sensitization of dermal sensory organelles producing hyperalgesia and mild to moderate pain. Second-degree or *partial thickness* burns involve tissue injury that extends to variable depths into the dermis; *superficial second degree* burns involve only the upper, papillary dermis and are more likely to heal spontaneously, while *deep second degree* burns involve the deeper, collagen-dense reticular dermis and are

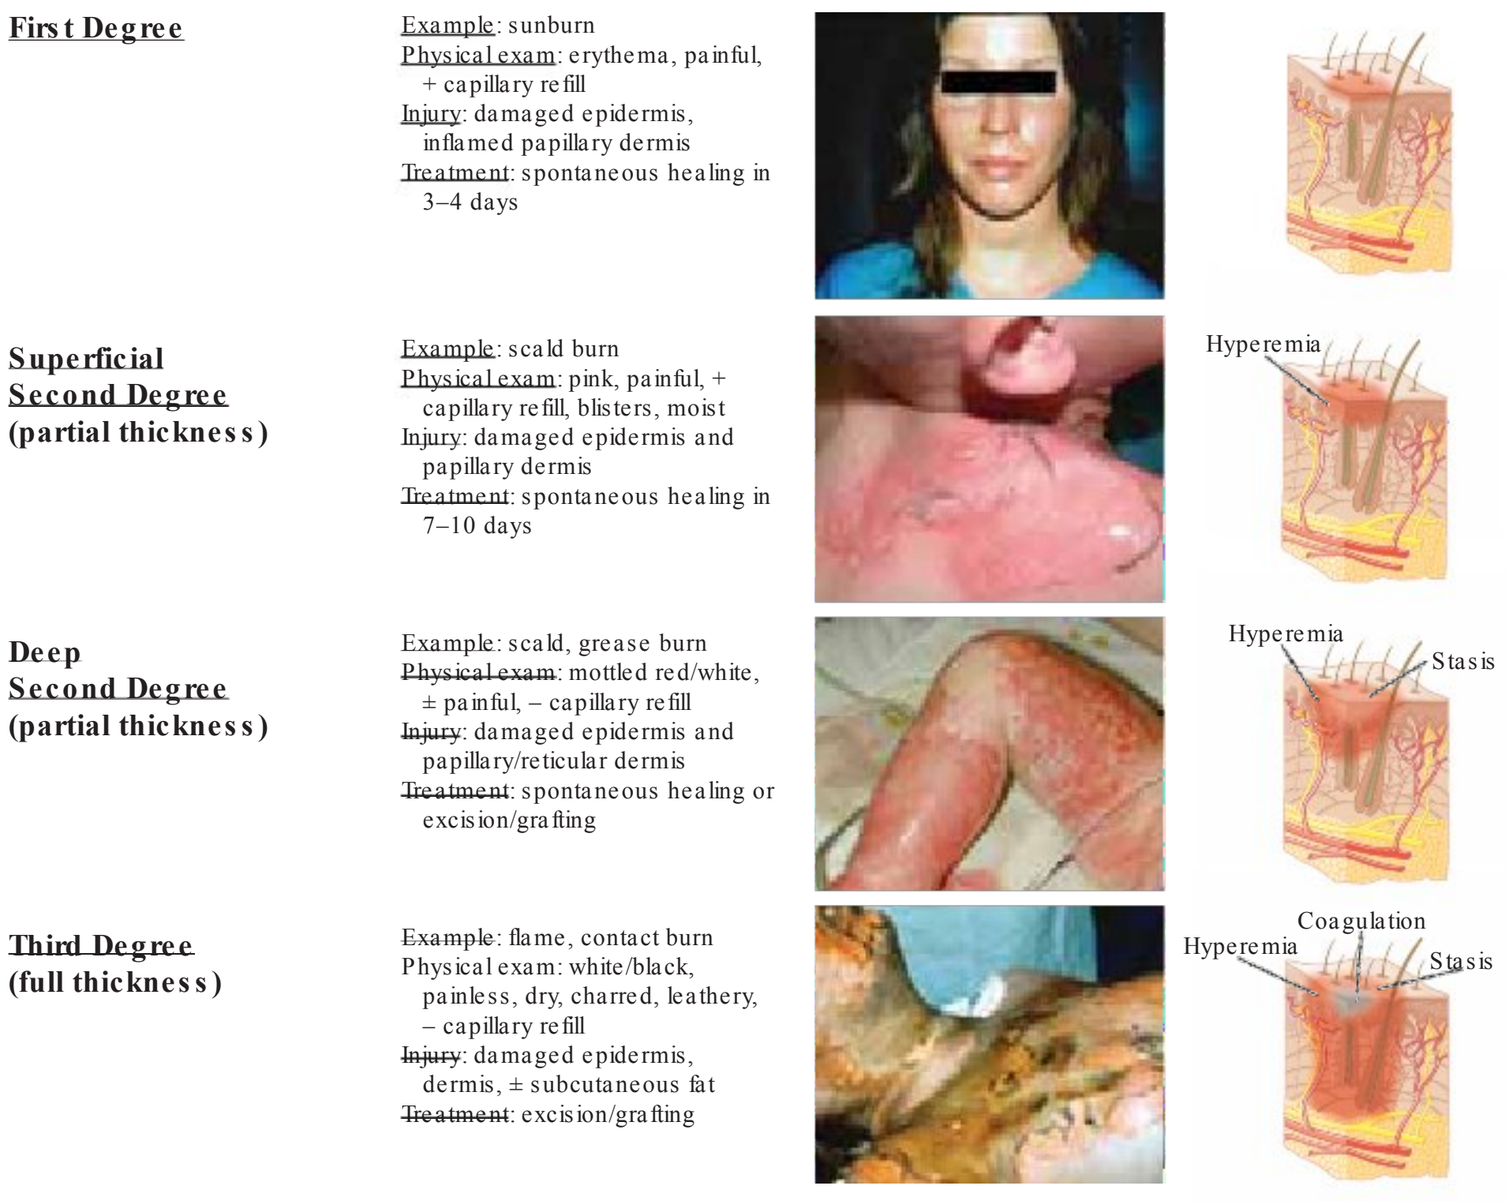

FIGURE 53.2 Definitions and examples of partial- and full-thickness burn injuries. Superficial and deep skin burns are defined, including clinical characteristics (etiology, physical exam findings, tissue injury, and usual treatment), photographic examples, and graphic representations of tissue injury (including zones of hyperemia, stasis, and coagulation). (Reproduced with permission from Sharar SR, Patterson DR, Wiechman-Askay S. Burn pain. In: Waldman SD ed. *Pain Management*. Philadelphia: Saunders-Elsevier, 2007:240–256.)

more likely to require surgical treatment. Because second-degree burns consistently injure and/or inflame sensory receptors in the dermis, these burns are associated with marked hyperalgesia and produce moderate to severe pain. Third-degree burns are characterized by complete destruction of the dermis, including its sensory and vascular structures, such that, although pain may still be a presenting symptom, hypalgesia to cutaneous stimulation, a leathery skin texture, and lack of capillary refill are common. Complaints of acute pain with third-degree burns are typically minimal but can be variable and are universally present with respect to the transition zone between burned and unburned skin. All burn injuries involving the dermis (i.e., second- and third-degree) result in sensitized and reorganized states of both peripheral mechanoheat receptors and dorsal horn neurons. Models of these cellular alterations provide a conceptual framework for understanding how such peripheral neuronal injuries that are present after a burn can cause acute and subacute pain, hyperalgesia and chronic pain, and are described in detail elsewhere.[8,9]

As noted previously, in addition to the significant pain caused by the burn injury itself, the major clinical analgesic challenge results from procedural and postoperative pain associated with contemporary burn care, involving a series of aggressive procedures that stimulate nociceptive peripheral afferent fibers on a daily basis for days, weeks, or months after the initial injury. In the typical treatment paradigm, a burn injury will first be assessed as to its depth and then treated accordingly. Shallow burns will be left to heal on their own, and full thickness thermal injuries will typically be excised and covered with a skin graft. Burns of indeterminate depth in many burn centers will undergo a series of wound débridements and dressing changes, typically on a daily basis, until burn depth can be more accurately determined. Burn care-related pain can be anticipated and treated, to a large degree, based on the clinical setting in which the pain occurs. Wound débridement, limb/joint mobility exercises, therapeutic skin stretching, and other medical procedures result in *procedural pain*, which is of high intensity but limited duration. Patients who are between procedures and have minimal physical activity, continue to experience *resting pain* that is relatively less intense, but almost constant in duration. When pain control interventions fail to control resting pain, patients will experience *breakthrough pain*. Finally, because surgical interventions are a frequent treatment for severe burn injuries, *postoperative pain* is an additional type of pain to be considered. Each of these four types of burn pain has specific treatment strategies, as described later in this chapter.

In addition to the four clinical settings described, burn pain varies somewhat temporally with the phase of treatment, most often divided into the resuscitative, healing, and remodeling phases.[9] In the *resuscitative phase* immediately after the injury, the patient is stabilized hemodynamically and initial wound treatments are performed. This phase is usually of short duration (e.g., hours), but depending on the size of injury can last up to 72 hours, as in the case of large surface area burns. Initial wound care in this phase is often intensely painful and, in the rush of treating life-threatening events, analgesia may be unintentionally de-emphasized. Pain in the *healing phase* is characterized by repeated episodes of burn wound care and dressing changes, wound examinations, needle sticks for intravenous access or blood sampling, and surgical procedures including débridement and grafting. The healing phase can last from days to several weeks depending on the severity of the burn and progress of the systemic response to the injury. It has been reported that hyperalgesia is more severe during this phase, independent of the size and degree of the burn. In the *remodeling phase* the systemic and local inflammatory responses decrease, wound healing is nearing completion, and rehabilitative activities gain emphasis. Depending on the characteristics of the wound scar, this phase is characterized by reductions in resting pain, but ongoing episodic procedural pain associated with physical and occupational therapy sessions. It is important to note that the duration and sequence of these phases can vary depending on the clinical progress of wound treatment. For example, a patient who has progressed to the remodeling phase can return to the healing phase after a surgical procedure recreates an open wound (e.g., burn site or skin graft donor site).

Although the clinical and temporal settings of burn care can provide some prediction as to the pain a patient might experience, the magnitude and quality of a given individual's pain experience have proven extremely difficult to anticipate. The sensory and affective qualities of burn pain have received scant attention in the literature, and few studies have addressed pain patterns over the course of hospitalization. For example, Choiniere and colleagues observed the evolution of burn pain experienced over the course of hospitalization and found that it varied substantially both within and across patients over time.[10] They also reported that burn pain was not accurately predicted by social–demographic factors or burn size (the latter finding is contrary to the inaccurate assumptions of many clinicians inexperienced in treating burns). Similarly, patient pain reports do not correlate with the quantity of opioid analgesics received, a finding first published in 1981[11] and still reported over two decades later.[4] This unpredictable and often opioid-resistant nature of burn pain has been hypothetically linked to underlying sensory nerve damage,[12,13] and contributes to the difficulty of effectively treating burn pain.

Although capturing the pain experience of an individual patient will likely continue to prove elusive for the reasons listed, it remains important to continue to treat burn pain aggressively. Not only can burn recovery (like that from any trauma) be hindered by the presence of acute pain,[14–16] burn pain has been reported to influence posthospitalization emotional recovery more than the size of the burn, the duration of hospitalization, or even the patient's preinjury mental health. Ptacek and Patterson[5] reported that inpatient pain scores in adults correlated more strongly with distress and quality of life scores at 1 month after discharge than did any other independent variable studied, a finding that persisted at 1-year and 2-year follow-up periods.[6] Similarly, Saxe et al. reported that the amount of morphine received by burn-injured children may impact their subsequent development of posttraumatic stress disorder.[17] Future studies will likely further substantiate the practical utility of adequately treating burn pain.

PSYCHOLOGICAL FACTORS

It is well known that pain processing is largely subjective and that the degree to which pain is interpreted as a threat will influence how much patients will suffer. A burn injury is a form of trauma that has dire emotional consequences for many survivors, and the threat value of the injury will likely have an impact on the amount of pain they perceive. Moreover, the nature of a patient's preinjury psychological makeup also has a great deal to do with how much pain they will perceive. In considering psychological factors, it is then important to consider the preinjury status of patients, as well as their emotional adjustment during and after hospitalization.

Burn injuries often occur when people are at risk because of low social resources or because of personality and/or psychiatric factors. The estimates of preinjury psychological problems in some studies of burn patients are so high that injuries of this type should be considered to be, in part, a symptom of social ills.[18] Estimated rates of psychiatric diagnoses in patients admitted for burn care have ranged from 25% to 75%, with the most prevalent diagnoses including depression, character disorder, and substance abuse.[18] In addition, the nature in which the burn injury occurred is often cause for concern: suicide attempts, child and elder abuse (or neglect), adult battering, and juvenile fire-setting are all, unfortunately, common sources of the injury. Psychological disturbances that predate the burn injury have the potential to increase complications, lengthen hospital stays, and lead to more serious long-term adjustment problems.[19–21] A number of these preinjury complications have direct relevance to pain control. Patients with drug and alcohol histories may show lower

pain tolerance, higher drug seeking behaviors, and greater tolerance to opioid analgesics. DSM-IV Axis II character disorders can present a particular challenge to clinicians. Patients with such personality predispositions may not only show drug-seeking but also dramatic acting out behaviors, manipulation, staff-splitting, and low frustration tolerance. Patients with borderline personality disorders, in particular, engage in parasuicide behavior and self-mutilation. All of these factors might complicate pain control, in addition to making the patient's overall management a challenge.

Both the burn care environment and psychological reactions to burn injuries contribute to pain and complications in its management. Patients with large unhealed burn areas or other significant medical complications are usually placed in intensive care units. In the critical care setting, delirium and other psychotic reactions are common[21,22] with infections, alcohol withdrawal, and metabolic complications being the most frequent etiologies.[23] Poor communication from altered mental status or endotracheal intubation may further impede pain assessment. Anxiety is commonly reported by burn-injured patients, both at greater levels than reported to be tolerable and for prolonged periods throughout hospitalization.[24] As a result, anxiety assessment tools specific for burn-injured patients have been reported and validated and may predict burn pain and postdischarge functional capacity better than other anxiety assessment tools.[25] As hospitalization persists and patients show greater mental capacity, depression becomes increasingly common and is well known to interact with pain.[26] Depressive symptoms have a prevalence as high as 54% during postburn hospitalization[27] and are a significant predictor of physical health at 2 months postdischarge.[28] Posttraumatic stress disorder is another complication that can negatively impact pain control. One potential symptom of acute and posttraumatic stress disorder is withdrawal, and this reaction can lead to staff underestimating patients' pain (through a lack of observed emotion or verbosity).[29]

The manner in which the burn environment and patients' personality factors can amplify pain is particularly notable in children, for whom the burn unit environment can be extremely strange and frightening. There is little opportunity for the burn staff to prepare children psychologically for the repeated medical procedures they must endure, and conditioned anxiety to the stimuli associated with burn care can be expected. Children will also often demonstrate regression and behavioral acting out in response to hospitalization, making pain control during procedures a particular challenge. It should be noted that although many burn centers have pediatric-specific pain protocols, their emphasis is appropriately on safety; hence, they are often not aggressive enough to adequately address pain or prevent procedural anxiety in every child. As previously mentioned, aggressive treatment of pain may serve to reduce the subsequent development of posttraumatic stress disorder in children.[17] A comprehensive review of issues specific to pediatric burn pain can be found elsewhere.[30]

There is growing evidence that although pain was once thought to be a problem only during the early phases (e.g., resuscitative and healing phases) of burn care, a significant number of patients experience ongoing pain long after hospital discharge. For example, a long-term, neuropathic pain syndrome has been recently described in burned patients, presenting approximately 4 months after the initial injury[31] and persisting for an average of 13 months. Similarly, in a survey of 358 respondents of a burn survivor support group,[32] 52% reported ongoing pain, 66% said that it interfered with their rehabilitation, and 55% said the pain interfered with their daily lives. Respondents in this study also reported that thoughts of the accident and depression made their pain worse. The pathophysiology and ideal treatment for such chronic, postburn pain is currently unknown and an area of current study. Furthermore, patients may show persistent depression, anxiety, or posttraumatic stress disorder that can interfere with pain control, with both depression and anxiety predicting worse outcomes in pain, fatigue, and physical functioning assessments up to 2 years postdischarge.[33] Sleep problems are prevalent, yet frequently overlooked in postdischarge phase, and may reflect inadequate pain treatment.[34] When psychological or pain problems persist long after hospital discharge the possibility of social or financial disincentives should be entertained. Although some patients will certainly have internally generated psychological problems, for others, the issues will persist because of such factors as litigation or the desire to avoid returning to an undesirable job.

GENERALIZED TREATMENT PARADIGM FOR BURN PAIN

Because burn pain is highly variable and cannot be reliably predicted by either clinical assessment of the patient or their burn wound, we recommend a structured approach to burn analgesia that incorporates both pharmacologic and nonpharmacologic therapies, targets specific pain issues unique to the burn patient, and can be tailored to anticipated variations in patient need and institutional capability. One clear goal of such a paradigm is to avoid the undertreatment of burn pain, an unfortunate reality in the settings of adult[35] and pediatric[3,36] burn care, and more historically described for other acute pain settings.[37] Perry and colleagues[38] noted that burn staff members failed to medicate patients adequately with opioids, despite education regarding the low risks for addictive and other side effects. These investigators offered a psychodynamic conceptualization of this issue, proposing that staff members who were required to perform repeated and painful procedures on these patients had a need for patients to demonstrate pain as a means to create a psychological distance between themselves and the realities of burn care. Alternatively, the fear of creating psychological dependence on opioids may explain the reluctance of some burn care staff to aggressively treat burn pain. However, there is currently no evidence that opioid addiction occurs more commonly in burn patients than in other populations requiring opioids for acute pain (~1/3000).[39]

In the generalized burn pain management paradigm, selection of an analgesic regimen is individualized and based on two broad categories: (1) the clinical need for analgesia (i.e., treatment of background vs. procedural vs. postoperative pain), and (2) limitations imposed by the patient (e.g., presence of intravenous [IV] access, endotracheal tube, or opioid tolerance) or by clinical facilities (available monitoring capabilities and personnel). The presence or absence of IV access directly influences analgesic drug choice, particularly in children in whom IV access may be problematic. Patients who are endotracheally intubated and ventilated are "protected" from the risk of opioid-induced respiratory depression; thus, opioids may be more generously administered in these individuals, as is often indicated for complex burn debridement procedures in patients with more extensive or severe burn injuries. Individual differences in opioid efficacy should be considered in all patients, including opioid tolerance in patients requiring prolonged opioid analgesic therapy or in those with preexisting substance abuse histories. Due to the development of drug tolerance with prolonged medical use or recreational abuse of opioids (both commonly seen in burn patients), opioid analgesic doses needed for burn analgesia may significantly exceed those recommended in standard dosing guidelines. One clinically relevant consequence of drug tolerance is the potential for opioid withdrawal to occur during inpatient burn treatment. Thus, the period of inpatient burn care is not an appropriate time to institute deliberate opioid withdrawal or detoxification measures in the substance-abusing patient, because such treatment ignores the very real analgesic needs of these patients. Similarly, when reductions in analgesic therapy are considered as burn wounds heal, reductions should occur by careful taper, in order to prevent acute opioid withdrawal syndrome.

Institutional capability to provide adequate monitoring (pulse oximetry, independent patient observer, etc.) as required for "moderate sedation" (as defined by the American Society of Anesthesiologists, Table 53.1)[40] may also dictate which agents

TABLE 53.1

AMERICAN SOCIETY OF ANESTHESIOLOGISTS CONTINUUM OF DEPTH OF SEDATION

	Minimal sedation (anxiolysis)	Moderate sedation/ analgesia (conscious sedation)	Deep sedation/analgesia	General anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful* response to verbal or tactile stimulation	Purposeful* response following repeated or painful stimulation	Unrousable even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

* Reflex painful withdrawal from a painful stimulus is NOT considered a purposeful response.
Approved by the American Society of Anesthesiologists House of Delegates on October 13, 1999, and amended on October 27, 2004.
(Reproduced with permission from American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-anesthesiologists. Practice guidelines for sedation and analgesia by non-anesthesiologists. *Anesthesiology* 2002;96:1004–1017.)

are used for procedural analgesia, as some of the more potent opioids (e.g., fentanyl) and anesthetic agents (e.g., ketamine, propofol) may unpredictably result in potentially dangerous levels of sedation (“deep sedation” or “general anesthesia”). The use of potent opioids and anxiolytics should only occur in settings with adequate monitoring, personnel, and resuscitation equipment appropriate for the degree of sedation anticipated. For many burn wound débridement procedures and most rehabilitative therapy sessions in the hospital ward or outpatient clinic setting, opioid analgesia with “minimal sedation” is sufficient and no special monitoring is required. Larger or more potent doses of opioids, or the concurrent use of anxiolytic sedatives (e.g., benzodiazepines) may produce more pronounced sedation (“moderate sedation”), but could also progress to “deep sedation” where patient–staff communication and/or patient consciousness are lost. Current guidelines of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO),[41] as well as adult[40] and pediatric[42] physician specialty professional organizations, dictate both general and specific levels of monitoring (e.g., continuous pulse oximetry, presence of an independent observer specifically responsible for monitoring ventilation and vital signs) for patients requiring each of these levels of procedural analgesia and sedation.

Because nociception at the burn site is the predominant mechanism of pain and suffering in these patients during the resuscitative and healing phases, pharmacologic treatment with potent opioids, anxiolytics, and other agents (e.g., ketamine) is the first line of therapy. However, nonpharmacologic methods of treating burn pain are also extremely useful. Some nonpharmacologic pain control techniques should be second nature to the staff and integrated into standard care (e.g., minimizing the number and intrusiveness of dressing changes, limb elevation, brief educational approaches). Other, more novel nonpharmacologic analgesic techniques are more practically implemented after a stable pharmacologic regimen is established or may require special expertise (e.g., hypnosis). To reinforce a consistent approach to analgesic management, particularly in centers where house staff physicians or nursing staff may rotate or change frequently, the establishment of succinct yet detailed institutional guidelines may help physicians and nurses with choosing and administering analgesics that target specific analgesic needs,[43,44] as shown in Table 53.2. To maximize simplicity and utility, it is recommended that such guidelines be safe and effective over a broad range of ages, be explicit in their dosing recommendations, have a limited formulary to maximize staff familiarity, and allow the bedside nurse to continuously evaluate efficacy and safety.[44] In addition, the regular use of a weight-based pediatric medication worksheet (placed at the bedside and in the patient record), containing all analgesic and resuscitation drugs likely to be administered, provides a supplemental safeguard against accidental overdose, particularly in the young pediatric age group.[45]

In recent years, a number of comprehensive reviews of burn pain management that emphasize such a systematic and multidisciplinary approach to burn pain management have been published,[9,30,46,47] including practice guidelines from the American Burn Association.[48] The reader is referred to these sources for additional perspective and detail.

PHARMACOLOGIC APPROACHES

In describing pharmacologic approaches for burn analgesia, three consistent observations can be made. First, for patients with injuries extensive enough to require hospitalization, pain from the burn itself is severe. Thus, potent opioids form the cornerstones of pharmacologic pain control in these patients, leaving few indications for the mild to moderate analgesia provided by nonsteroidal antiinflammatory drugs (NSAIDs) or acetaminophen, with notable exceptions of the rehabilitative phase of care and outpatient treatment. Second, because burn pain has well-defined components described previously—background, procedural, and postoperative pain—pharmacologic choices for analgesia should target each pain pattern individually. Finally, because burn pain will vary somewhat unpredictably throughout hospitalization due to surgical intervention, activity levels, etc., analgesic regimens should be continuously evaluated and reassessed to avoid problems of under- or over-medication.[6] Pain assessment is facilitated by the regular use of standardized, self-report scales for adults and older children, and observational scoring systems for the very young, as described in Chapter 20. A reliance on nurse assessment of patients’ burn pain can be problematic, however, as it is well documented that nurses’ and patients’ assessment of burn pain and analgesia are not always comparable,[35,49,50] with nursing staff typically underestimating the need for analgesic therapy.

Opioids

Opioid agonists are the most commonly used analgesics in the treatment of burn pain, in part because (1) they are effective, (2) the benefits and risks of their use are familiar to the majority of care providers, and (3) they provide some dose-dependent degree of sedation that can be advantageous to both burn patients and staff, particularly during burn wound care procedures. The wide

TABLE 53.2

HARBORVIEW MEDICAL CENTER/UNIVERSITY OF WASHINGTON BURN CENTER BURN ANALGESIA AND SEDATION GUIDELINES FOR ADULTS

	ICU No PO intake	ICU taking PO	Ward large open areas	Ward small open areas/predischarge
Background pain	continuous morphine sulfate (IV) drip	scheduled methadone or MS Contin	scheduled methadone or MS Contin	scheduled NSAIDs/ acetaminophen or scheduled oxycodone or none
Procedural pain	morphine sulfate (IV) or fentanyl (IV)	oxycodone, fentanyl IV, or fentanyl Actiq	oxycodone, fentanyl IV, Nitrox (IH) or fentanyl Actiq	oxycodone
Breakthrough pain (PRN dosing)	morphine sulfate (IV) or fentanyl (IV)	oxycodone	oxycodone	NSAIDs/ acetominophen or oxycodone
Background anxiolysis	scheduled lorazepam (IV) or continuous lorazepam (IV)	scheduled lorazepam	none or scheduled lorazepam	none
Procedural anxiolysis	lorazepam or midazolam	lorazepam	none or lorazepam	none
Discharge or transfer pain medications	N/A	For transfer to ward: wean drips, establish PO pain meds early, anticipate dose tapering as needs decrease	oxycodone for procedural pain; methadone taper or MS Contin taper if applicable	oxycodone or NSAIDs for procedural pain

Medications are to be given orally unless otherwise specified. Exception: fentanyl Actiq is given transmucosal.
Analgesic and anxiolytic choices are simplified to a minimum number of agents to encourage staff familiarity, and are targeted to specific pain and anxiety needs. Therapy can be individualized to include agents not in this guideline when clinically indicated. This chart is laminated and prominently displayed in all patient care areas. IH, inhalation; IV, intravenous; NSAIDs, nonsteroidal antiinflammatories; Nitrox, 50% nitrous oxide/ 50% oxygen inhaled.

spectrum of opioids available for clinical use (see Chapter 78) provides dosing flexibility (i.e., variable routes of administration, variable duration of action) that is ideal for the targeted treatment of burn pain. The pharmacokinetics of opioids in burn patients are not consistently different from nonburn patients,[51,52] although decreased volume of distribution and clearance, and increased elimination half-life have been reported for morphine.[53] Similarly, pharmacodynamic potency of opioids has inconsistently been reported as increased[54] and decreased[53] in burn patients.

The route of opioid administration is an important consideration in burn patients, with the principal choice between IV, oral, or transmucosal administration dictated by the severity of burn (critically ill patients require IV access and may have abnormal gut function) and high risk of burn patients for developing IV catheter-related sepsis (hence, physician reluctance to maintain long-term IV access).[55] Intramuscular opioid administration is avoided because of the need for repeated, painful injections and because of variable vascular absorption due to unpredictable compartmental fluid shifts and muscle perfusion in burn patients, particularly in the resuscitative phase. Patient-controlled analgesia (PCA) with IV opioids offers the burn patient a safe and efficient method of achieving more flexible analgesia for both background and procedural analgesia. PCA also offers the patient some degree of control over his/her medical care, this being a major issue for burn patients whose waking hours are often completely scheduled with care activities ranging from wound care to physical and rehabilitation therapy. Some studies comparing PCA opioid use to other routes of administration in the burn population have shown potential benefits of PCA.[56,57] The PCA administration of potent, short-acting opioids (e.g., fentanyl,[58] alfentanil,[59] remifentanil) for procedural analgesia may also have a useful role in burn analgesic management, but this has not been extensively investigated.

Because IV access is infrequently present in hospitalized burn patients outside of the critical care setting (for reasons noted previously), oral and transmucosal opioid delivery are frequently employed. For background pain, long-acting oral opioids (e.g., methadone) or sustained release opioids are often utilized. However, the latter agents are not available in appropriate dose ranges for pediatric patients, so a reliance on shorter acting oral opioids is often necessary. For background pain control in this population, the use of regularly scheduled oral opioids is recommended over pro re nata (PRN) dosing, so that more stable plasma opioid concentrations and analgesic effects may be obtained.[60] Similarly, the use of short-acting oral opioids is common for anticipated procedural pain, emphasizing early administration of the drug so that adequate plasma levels and associated analgesia are present prior to beginning the procedure. Alternatively, oral transmucosal administration of opioids is reported in burn patients to be particularly advantageous in those patients without IV access and in children, in both the inpatient[61] and outpatient clinic[62] settings.

Nonopioids

The list of nonopioid analgesics in widespread use for the treatment of burn pain is relatively extensive, although clinical evidence to support such use is variably found in the published literature. Oral NSAIDs and acetaminophen, as outlined previously, are only mild analgesics and exhibit a ceiling effect in their dose-response relationship, rendering them unsuitable for the treatment of typical, severe burn pain. However, they are of benefit in treating minor burns, particularly in the outpatient setting. Topical application of NSAIDs on burn wounds can theoretically

inhibit nociception at the injury site with minimal systemic uptake,[63] yet does not result in significant analgesia.[64] The opioid agonist-antagonist drugs (e.g., nalbuphine, butorphanol) produce "mixed" actions at the opiate receptor level, theoretically providing analgesia (agonist property) with lesser side effects (antagonist properties), but also exhibit ceiling effects. Although studies have shown this class of drugs to be effective in treating burn pain,[65] experience with them is both limited and suggestive of efficacy in patients with only relatively mild burn pain.

Antidepressants, anticonvulsants, antipsychotics, and alpha-2-agonists have been proposed as potential analgesic agents for burn pain[66] based on their known mechanisms of action in other pain states, yet have not been studied extensively in the setting of burns. As neuropathic pain can occur in patients with healed burns,[13,31,32] these agents may have specific application in this setting, as suggested by a preliminary reports with a variety of nonopioid agents including gabapentin,[67,68] dexmedetomidine,[69] clonidine,[70] and haloperidol.[71]

Anxiolytics

Current, aggressive therapies for cutaneous burn wounds, together with the persistent and repetitive qualities of background and procedural pain, make burn care an experience that is likely to engender anxiety in both adult and pediatric patients. It is also recognized that anxiety can exacerbate acute pain.[14] This has led to the common practice of using anxiolytic drugs in combination with opioid analgesics, a practice has persisted since the 1980s.[72] A recent survey of North American burn centers reported that up to 39% of hospitalized pediatric burn victims regularly receive anxiolytics as part of their pain and sedation management regimen.[73] Intuitively, this practice is particularly useful in premedicating patients for daily wound care procedures, due to the anticipatory anxiety experienced by these patients prior to and during debridement. Although previously shown that benzodiazepine therapy improves postoperative pain scores in nonburn settings,[74] it is also reported that low-dose benzodiazepine administration significantly reduces burn wound care pain reports.[75] It appears that the patients most likely to benefit from this therapy are not those with high trait (premorbid) anxiety, but rather those with high state (at the time of the procedure) anxiety or those with high baseline pain scores.

Anesthetics

Inhaled nitrous oxide is an analgesic agent safe for administration by nonanesthesia personnel to achieve moderate sedation. It provides safe and effective analgesia without loss of consciousness for moderately painful procedures in other healthcare settings (e.g., dentistry), and is also a commonly used, although less well-studied agent for the treatment of burn pain.[76,77] It is typically used as a 50% mixture in 50% oxygen, and is self-administered by an awake, cooperative, spontaneously breathing patient via a mouthpiece or mask. A secondary benefit of nitrous oxide use, like that of PCA opioid administration, is the element of control given to the patient for his/her care. Nitrous oxide is less useful with critically ill or uncooperative patients. It has also been implicated in a very small, but measurable incidence of toxicity issues (e.g., spontaneous abortion, bone marrow suppression) to patients or staff exposed for prolonged periods,[78,79] although not in the setting of burn pain treatment.

Although it is obvious that general anesthesia is required for the surgical excision and grafting of deep burn wounds, it is not uncommon to encounter specific wound care procedures that are on a scale below that of surgical burn care, yet are nevertheless difficult to perform on a conscious patient, particularly a child. These procedures are ideally suited for deep sedation or general anesthesia and include (1) the removal of hundreds of skin staples from recently grafted wounds, (2) meticulous wound care of recently grafted, and often tenuous skin on the face or neck, and (3) wound care procedures in variably cooperative children. Historically, IV, intramuscular, or oral ketamine have been used for these procedures,[80–82] and there is limited evidence that ketamine administration acutely after experimental skin burns may prevent hyperalgesia and "wind-up."[8] More recently, some high-volume burn centers have developed specific training and skill retention programs in ketamine administration by nonanesthesiologists, and report that satisfactory sedation for bedside procedures can be achieved in children with a low incidence of side effects.[84] However, ketamine is a dose-dependent anesthetic that can produce deep sedation and general anesthesia in an unpredictable manner; thus, appropriate patient monitoring is requisite, and nonanesthesiologists administering the drug must have specialized training and airway management skills, as well as anesthesiologist back-up. In addition, its use is limited by the potential risk of associated emergence delirium reactions (5% to 30% incidence), particularly in the elderly.

The extension of full anesthetic care capabilities with anesthesiology staffing outside of the operating room and into the burn unit has been successfully implemented in some specialized burn centers.[85,86] This has been facilitated by the recent introduction into clinical anesthetic practice of a variety of drugs with a rapid onset and short duration of action, a more rapid awakening/recovery, and fewer associated side effects—ideal qualities for agents to be used for procedural burn wound care. These agents include IV propofol and remifentanil, and inhaled sevoflurane and desflurane. Propofol is particularly advantageous, and can be titrated to effect both in terms of level of consciousness and duration of action using continuous IV infusion techniques.[87] The provision of brief, dense analgesia/anesthesia in a comprehensively monitored setting by individuals specifically trained to provide the service appears safe and efficient, both in terms of allowing wound care to proceed rapidly under ideal conditions for patient and nursing staff, and in terms of cost-effective use of the operating room only for true surgical burn care procedures.

Local anesthetics are of obvious use in regional blockade for wound care procedures, but have also been used for burn pain analgesia as a topical gel or IV infusion. Topical local anesthetic use on the burn wound is controversial. Prilocaine-lidocaine cream (EMLA) has no effect on burn pain in volunteers,[88] however, topical 5% lidocaine applied at 1 mg/cm^2 offers analgesic benefit without associated side effects.[89] Topical lidocaine use is significantly tempered by reports of local anesthetic-induced seizures due to enhanced systemic absorption at the open wound site.[90] The analgesic benefit of an IV lidocaine bolus (1 mg/kg) and 3-day continuous infusion (40 mg/kg/min) has also been reported acute burn injuries,[91] although whether its mechanism is due to antiinflammatory or analgesic actions is unclear. Neuraxial administration of local anesthetics (and/or opioids) via epidural catheter would seem to be of benefit in patients with lower extremity burns, resulting in both analgesia (particularly during procedural burn care) and sympathectomy (of theoretical benefit to wound healing). However, such use has only been reported anecdotally.[92] A major drawback of this technique is the use of an indwelling catheter in patients densely colonized with infectious organisms at the wound site, thus increasing the risk for epidural abscess formation.[93] Nonneuraxial regional blocks have recently been reported to be of benefit for the pain associated with surgical skin donor site preparation on the anterolateral thigh, both a single injections[94] and as continuous infusions.[95]

Pharmacologic Options for Background Pain Management

Because background pain is relatively constant, it is best treated with mild-to-moderately potent analgesics administered so that plasma drug concentrations remain relatively constant throughout the day. Examples include the continuous IV infusion of fentanyl or morphine (± PCA), the oral administration of long-acting opioids with prolonged elimination (methadone) or pro-

longed enteral absorption (sustained-release morphine, sustained release oxycodone), or oral administration on a regular schedule of short-acting oral analgesics (oxycodone, hydromorphone, codeine, acetaminophen). Background pain generally decreases with time as the burn wounds (and associated donor sites) heal, so that analgesics can be slowly tapered (in the absence of significant analgesic tolerance).

Pharmacologic Options for Procedural Pain Management

In contrast to background pain, procedural pain is significantly more intense, but shorter in duration; therefore, analgesic regimens for procedural pain are best comprised of moderately-to-highly potent opioids that have a short duration of action, with a sedation target level of moderate sedation. IV access is helpful in this setting, with ketamine and short-acting opioids (fentanyl, alfentanil) offering a potential advantage over more longer-acting agents (morphine, hydromorphone). In the absence of IV access, orally administered opioids (morphine, hydromorphone, oxycodone, codeine) are commonly used, although their relatively long durations of action (2–6 hours) may potentially limit postprocedure recovery for other rehabilitative or nutritional activities. Oral ketamine, oral transmucosal fentanyl, and nitrous oxide are agents of particular use when IV access is not present, due to their rapid onsets and short durations of action. Finally, when a particularly painful dressing change or one that requires extreme cooperation in a noncompliant patient (e.g., face débridement in a young child) is anticipated, the provision of brief deep sedation or general anesthesia with appropriate patient monitoring, administered by anesthesiologists or appropriately trained nonanesthesiologists may be helpful.

Pharmacologic Options for Postoperative Pain Management

Postoperative pain deserves special mention because of the increased analgesic needs that should be anticipated following burn excision and grafting. This is particularly true when donor sites have been harvested, as these are often the principal source of increased postoperative pain complaints, rather than the grafted burn. Typically, this increased analgesic need is limited to 1–4 days following surgery before returning to preoperative levels.

NONPHARMACOLOGIC APPROACHES

Cognitive Interventions and Coping Styles

In terms of pain control, cognitions can be thought of as behaviors that can be modified and that may influence the amount of pain that patients experience. Although such approaches are common in chronic pain control, there are few studies of cognitive–behavioral interventions in patients with burn injuries.[96,97] In understanding such interventions, it is important to emphasize that burn injuries are unexpected and have far-reaching consequences for patients. Further, as noted previously, the aggressive procedural medical care typically associated with burn injuries adds further stress and uncertainty through the daily demands of surgery, rehabilitation, dependency on caregivers, and pain. Such uncertainty often leads to feelings of helplessness in both adult and pediatric burn patients. It is almost impossible to predict the style with which an individual patient reacts and responds to such stress; however, if one is able to determine some characteristics of the patient's cognitive style, this insight can be useful in choosing the most appropriate psychologically based interventions.

Burn patients bring different cognitive styles in the manner in which they respond to stressful medical procedures. One critical distinction lies in how much information patients desire regarding their injury and care. Whereas some patients will seek out as much information as possible, others would just as soon leave their care to healthcare professionals.[98,99] In applying cognitive interventions to burn patients, it will behoove the clinician to be aware of how they cope with stressful medical procedures. Paramount to such thinking is whether the patient will approach procedures with a tendency toward cognitive avoidance, in which case they will distract or dissociate themselves from painful stimuli. This is in contrast to patients who tend to respond to acute pain by focusing on the procedures. Such patients may take a hypervigilant stance toward pain and may find distractions difficult. Patients often fall into position along a continuum of coping styles, from an approach coping style to an avoidance coping style. If one can determine where they fall along this continuum, it is easier to determine what type of psychological intervention will be most useful[47] (Fig. 53.3).

If patients fall on the avoidance end of the continuum, too much information and focus on the details of care procedures will likely make them more anxious. In contrast, distraction will likely be useful for patients who possess this coping style. In the burn unit, simple distraction is more likely to be of benefit with brief procedures such as blood draws or line placements, and studies have reported that music can be effective for such simple distraction with burn pain.[100] Children at certain development levels may benefit from not seeing their wounds or by being more engaged by the clinicians. Such distraction will be less effective with older children or adults during the more extensive wound care procedures. In such instances, engaging patients in deep relaxation with distracting imagery will likely be more useful, although imagery often requires substantially more training time for both patients and staff. A particularly elaborate form of distraction involves the use of computer-generated immersive virtual reality (see later).

In contrast, when patients cope with painful procedures by

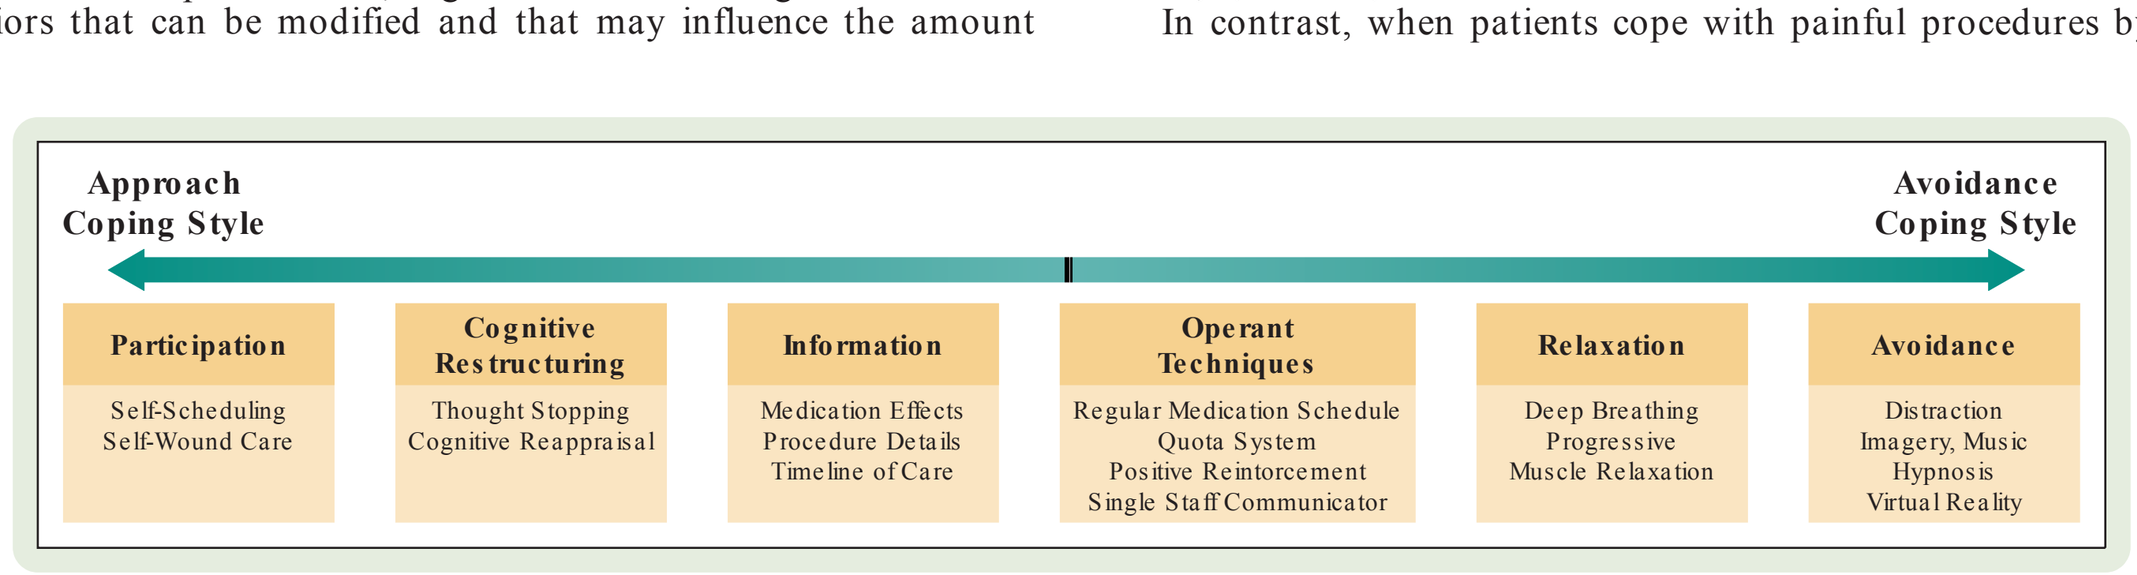

FIGURE 53.3 Control coping continuum and associated nonpharmacological techniques. The spectrum of coping styles from approach to avoidance is depicted, including specific clinical interventions for patients whose coping styles fall on different positions along the continuum (see text for details).

carefully focusing on them and even participating in their own care (i.e., approach coping style), they are usually less viable candidates for distraction techniques. Such patients may benefit by reappraisal techniques. Rather than focusing away from pain, reappraisal techniques might encourage patients to attend to their nociception. They can then be encouraged to differentiate sensory from affective components of pain, as well as evaluate the meaning of the sensation. As is the case with chronic pain, patients may benefit from being taught to differentiate "hurt from harm" with respect to their pain sensations.[101] It is also useful to teach such patients that increased pain sensation is usually a positive sign with respect to burn wound healing. Specifically, full thickness burns often destroy nerve endings and the capacity for nociception, but as these burn wounds heal, skin buds emerge which are highly enervated and sensitive to pain and temperature. Teaching patients the latter two principles will likely be useful to them independent of their cognitive styles in response to acute pain. Further, with enough focus on pain sensations, some patients are able to gain the sense that they are able to modify them, and thus be in more control of their perceptions.

PREPARATORY INFORMATION

Providing patients with information about impending procedures can provide a powerful means of mitigating pain and anxiety. Such interventions have been found to enhance pain control with acute pain from a variety of different procedures.[102] Patients may be provided with preparatory information (what steps will be taken during a procedure) or sensory information (what they will likely feel). The use of preparatory information has not been studied with burn patients, but there is evidence that it can be useful with a variety of medical procedures such as cardiac catheterization, endoscopies, cast removal, and surgery.[103–105] Unfortunately, burn injuries often do not easily lend themselves to such interventions. Certainly, it is not possible to anticipate that a burn injury will occur and medical procedures are often performed quickly, and in an invasive matter. There is little time to prepare patients, and this can be particularly difficult for children. In addition, with some medical procedures in nonburn settings, understanding what will occur may reduce anxiety and pain associated with those procedures. Unfortunately, the frequent challenge with burn care is that the procedures are very painful, invasive, and truly threatening, unlike many other types of medical procedures that simply have the appearance of being threatening.

Preparation is particularly relevant to two phenomena associated with burn care. First of all, nociceptive input may often increase as a burn wound heals. As mentioned earlier, full thickness burn injuries may not be that painful, while healing injuries with new skin buds may be particularly sensitive. Care providers should take care to communicate to such patients that increased pain is actually a sign that the wound is healing, information that may help allay patient anxiety. The second beneficial instance of preparatory information involves informing patients' family members of important medical issues. For example, burn patients often show periods of delirium when in the intensive care unit, a clinical phenomenon that can be frightening to both patients and their family members. Letting them know in advance that such confusion is a common and usually benign occurrence can mitigate subsequent anxiety.

Another application of preparatory information is to address irrational fears related to the use of opioid analgesics. Patients may believe that pain medications lead to addiction or are a sign of weakness; this may particularly be the case with patients recovering from an alcohol or chemical dependency. Information about the negligible rates of opioid addiction among burn patients can be useful in this regard. Also, it is useful to let patients know that adequate analgesia likely promotes recovery. Certainly, our own research indicates that high levels of pain are one of the most significant predictors of posthospital adjustment.[5,6] It can also be explained that poor pain control may actually lead to more potential substance abuse, as opposed to protocols that manage pain aggressively on an a priori basis.

BEHAVIORAL INTERVENTIONS

Behavioral interventions might seem more applicable to chronic pain conditions, yet have surprising relevance to burn pain treatment. The application of such principles to burn can be divided into classical (stimulus) and operant (respondent) strategies. Stimulus conditioning applications have to do with the patient's state prior to wound care. Certainly, decreasing the patient's level of arousal through relaxation training, or any other means available, can minimize the ensuing cycle between anxiety and nociception. With children, the stimulus context of painful procedures can be particularly relevant. Children (and many adults) will often show heightened anxiety and fear just by being exposed to the stimuli associated with painful procedures (e.g., nursing scrubs, procedures rooms). If the threatening nature of the wound care environment can be reduced, pain control can be enhanced by virtue of stimulus–response principles. As a nonburn example, some children's hospitals have instituted the creative approach of having a magnetic resonance imaging (MRI) scan tunnel appear as a cave in a jungle environment (rather than the morgue-like drawer such equipment more typically seems to resemble). What follows from this logic is that the burn-injured child's room should be considered a safe environment in which painful procedures do not occur.

Operant (reinforcement) principles are also highly applicable to burn pain management. One application has to do with medication scheduling. The tendency in many acute care settings is to simply medicate patients on an "as-needed" or PRN schedule, an approach that is nonsensical for several reasons in burn care. Certainly, the notion of waiting until the patient hurts does not make sense from a pharmacologic perspective.[3,60,106] However, operant principles would also suggest that PRN medication schedules reinforce patients' pain complaints, both in terms of the euphoria-producing properties of opioid analgesics and the attention received from caregivers. Providing opioid analgesics on a regular schedule that reflects their pharmacokinetic properties will minimize the potential for operant factors to exacerbate the pain problem. For emotionally dependent or anxious patients, as-needed pain scheduling can actually create a paradigm for creating more pain behaviors and pain perception.[101]

A regular analgesic drug administration schedule is particularly important with patients who have substance abuse histories. Such patients may demonstrate frequent pain complaints and/or drug seeking behaviors on the burn unit. The tendency of such patients to approach multiple caregivers for analgesics has the potential to create "staff splitting" and resentment (i.e., countertransference) toward the patients. Accordingly, the burn unit staff may hold punitive attitudes about the patient's substance abuse history and/or the excessive nature of his or her pain complaints. Regularly scheduled medications will often minimize such conflict, as well as provide more transparent management of the patient's pain. In addition, channeling communications and negotiations about changing doses or types of medication through a single caregiver can be very useful in decreasing conflict between the patient and staff members.

In rare instances, the patient's pain behavior might be so exaggerated in the face of apparently adequate analgesia that burn staff must consider an operant based model of pain management. Effective burn team members are trained to be highly attentive to the pain complaints of their patients. However, occasional patients may show excessive complaints based on such factors as strong dependency needs or somatic tendencies. As in any case, it is important that such patients receive adequate doses of anal-

gesics. However, operant approaches, in which discussions of pain are minimized and patients are distracted from their complaints,[101] may become the prominent intervention. In other words, there would be discussions with the patient that medications changes will be limited to circumscribed periods and, in between such times, the patient will be encouraged to focus away from the issue of pain.

Burn rehabilitation involves continuously increasing activity levels, and patients may become simply overwhelmed with the pain associated with such movements. The quota system[107] represents a useful application of operant principles to burn care in such instances. The repeated, invasive nature of burn care has the potential to create a state of learned helplessness in patients.[108] The quota system uses rest as a reinforcement for activity, and keeps activity levels well within the patient's level of physical endurance. Ehde and colleagues have reported that with overwhelmed, seemingly unmotivated patients, it is useful to encourage the burn team to reduce their overall demands, take baseline behaviors, and gradually increase demands on what the patient's baseline behavior suggests is within their range of tolerance.[107] Such interventions can create steady increases in activity in patients who have been overwhelmed by care, and also a sense of mastery, as they are able to see steady improvement in their activities.

Avoiding the rewarding of escape behavior during procedures is a final application of operant principles. With children, it is particularly essential to do all the interventions possible to enhance pain control during procedures such as adequate analgesics and anxiolytics, sufficient emotional preparation, optimizing the wound care environment, and including parents when appropriate. Children also do better if allowed to have control of their wound care procedures, perhaps by doing their own dressing removal.[108] However, there are times when it is important to set firm limits during wound care by following through with procedures; otherwise, pain behaviors can exacerbate. Establishing this balance can certainly be a challenge for caregivers since it is not appropriate to force treatment when children are inadequately medicated. The point here is that once all that can be done that is possible in terms of analgesia, the timing of when a child can refuse or rest during wound care becomes an important issue in operant management.

HYPNOSIS

In terms of randomized controlled studies, hypnosis is one of the areas where the most evidence exists for psychologically based interventions in burn care. In 1987 there were at least 14 papers published on this subject,[109] and such investigations continue.[110] A recent review by Patterson and Jensen[111] indicates that burn pain constitutes some of the best evidence in the literature that hypnosis can be effective. Further, a number of additional reports have focused on the use of hypnosis to treat complications from burns other than pain, although with few exceptions, these reports have been anecdotal.[109,112]

There are a number of reasons why burn patients appear to be such good candidates for hypnotic based pain control interventions[113] First, because burn patients are in high levels of pain, they are motivated to engage in hypnosis, a technique that they might ordinarily resist. In support of this, patients with high levels of initial pain seem to show a better analgesic response to hypnosis.[114,115] Second, patients with unanticipated traumatic injuries, such as burns, may be more cooperative because of the dependency that might often be a normal reaction to trauma care (i.e., a willingness to allow others to take care of one). Third, the dissociation that may accompany a burn injury may also be a factor that moderates hypnotizability. Certainly, dissociative tendencies have been related to hypnosis,[116] as well as the acute stress disorder is a typical early reaction to burn injuries. Finally, and on a more simplistic level, hypnosis is most effective when it can be applied to a predictable, discreet event—a description that characterizes most burn wound care procedures, as painful as they are.

Ewin[117,118] has published anecdotal data to suggest that hypnosis used early in burn care can not only enhance pain control, but might even facilitate wound healing. This work has received a great deal of attention, but also criticism given the lack of controlled studies to support the underlying premise.[119] The question of whether hypnosis can have such powerful effects when used early in burn care will hopefully be the subject of future controlled studies. However, it would be of great utility to determine what effects aggressive pain interventions of any modality have when used very early in the patient's care.

There have been two recent publications describing the delivery of hypnosis through immersive virtual reality technology (see later) in order to treat burn pain.[120,121] The advantage of this approach is that the clinician can rely on technology to achieve hypnotic induction and suggestion; thus, extensive training for hypnosis is not required. Although these reports are anecdotal, their preliminary results with this technology demonstrate analgesic effects that are equivalent to those obtained when a "live" clinician is used.

VIRTUAL REALITY

Immersive virtual reality is a particularly attention-grabbing distraction technique, and is designed to give users the illusion of going inside a computer-generated virtual environment (Fig. 53.4). Virtual reality appears to provide significant cognitive distraction to users because it is interactive and places significant cognitive demand on patients through the provision of multisensory input (visual, aural, and sometimes tactile). In addition, it utilizes a head-mounted display that blocks visual and aural input to the user from the immediate and often frightening, real world burn care environment. Thus, virtual reality may exert its analgesic effect by diverting conscious attention away from concurrent nociceptive stimulation, resulting in an attenuated subjective pain experience. Functional brain imaging studies have shown the virtual reality results in pain reduction that is similar to that of systemic opioid administration, both in terms of magnitude of

FIGURE 53.4 Virtual reality environment "SnowWorld." as seen by the patient/user. Snow/ice motif and blue/white/lavender colors suggest a cool temperature setting in direct contrast to the hot setting in which most burn injuries occur. Virtual igloos, penguins, and snowmen on canyon walls facilitate user interaction with the virtual world through user-targeted shooting of virtual snowballs at these virtual objects.

FIGURE 53.5 Clinical use of virtual reality distraction during burn wound care. A burn patient undergoes postburn skin stretching and passive joint range-of-motion while experiencing immersive virtual reality analgesia. Both auditory and visual stimulation are provided through a lightweight head-mounted display that can track the users position in the virtual environment by assessment of head position, and user interaction with objects in the virtual environment is controlled by manual trackball.

analgesia and brain activity changes, and is also additive to opioid analgesia when administered concurrently.[122] The use of adjunctive, immersive virtual reality was first reported to provide clinically meaningful pain relief in the setting of burn wound débridement,[123] with findings subsequently replicated in larger populations of burn patients.[124,125] Virtual reality analgesia is also advantageous for the less severe pain associated with certain types of postburn rehabilitation activities[126] (Fig. 53.5), and has been combined with hypnotic suggestion (as noted previously) to provide nonpharmacologic analgesia for burn wound care.[120,121]

CONCLUSION

Effective treatment of burn injuries requires an appreciation of the unique patterns of nociception caused by this trauma and their interaction with psychological factors. Aggressive use of opioid analgesics tailored to the nature of the pain (e.g., procedural, background, postoperative) serves as the cornerstone of a multifaceted approach to burn pain. Procedural pain often involves consideration of a variety of supplemental pharmacologic approaches, ranging from mild sedation to general anesthesia. Nonpharmacologic approaches should be woven into the structure of burn care as adjuncts to pharmacologic analgesia (i.e., multimodal analgesia). The under-treatment of burn pain remains an unfortunate reality, particularly since adequate analgesia may facilitate recovery and posthospital adjustment, as well as represent a more humane course of treatment.

CHAPTER 54 ■ PERSISTENT PAIN IN CHILDREN

NEIL L. SCHECHTER, TONYA M. PALERMO, GARY A. WALCO, AND CHARLES B. BERDE

Persistent pain problems in children, as in adults, may stem from a wide variety of causes. They may be associated with ongoing illnesses such as cancer or sickle cell disease (SCD), may be the residua of pathologic processes that have resolved but have sensitized the peripheral or central nervous system such as postinfectious myalgias, or may represent a nonprogressive disorder whose main manifestation is pain such as headaches, widespread musculoskeletal pain, or functional abdominal pain. Regardless of the etiology of the pain, its assessment, its impact, and often the modalities used to treat are remarkably similar and often distinct from approaches used to address acute pain. For example, while the broader context of pain, including an array of genetic, developmental, environmental, and individual factors, is rarely a major focus of assessment in acute pain, these factors are essential to consider when pain is recurrent or persistent. Likewise, treatment goals may shift from pain eradication in acute pain to pain reduction, rehabilitation, and improved coping in chronic pain.

In this chapter, we will describe the epidemiology of chronic pain, define its impact on children and families, and offer general approaches to its evaluation and treatment. Discussion of cancer pain is contained elsewhere in this volume as are more detailed descriptions of specific pain problems.

EPIDEMIOLOGY OF CHRONIC PAIN IN CHILDREN

The epidemiology of the various chronic pain problems in children is often hard to ascertain primarily due to variability in the methodologies in the available research. While this fact is an issue for adults as well, the limitations of the pediatric literature in the area of chronic pain, the often more complex diagnostic criteria which must factor in developmental change, child variants of adult disorders, and the limitations in the child's ability to report symptoms give us pause as we sift through data on the prevalence of persistent pain syndromes in children. A sample of the epidemiology of selected persistent pain problems in children follows.

Musculoskeletal Pain

One of the most common sites for pain in children and adolescents is the musculoskeletal system, including joint pain, bone pain, and muscle pain. Discomfort may arise from disease processes (e.g., inflammation associated with arthritis), it may be related to central pain processing difficulties (e.g., juvenile fibromyalgia syndrome or Pain Associated Disability Syndrome), or may be related to trauma or injury, typically focusing on a specific area of the body (e.g., back pain or neck pain).

Arthritis

Estimates of the prevalence of juvenile arthritis have shifted a good deal over the years due to a number of factors, including diagnostic difficulties, changes in the classification schemas used, differences in research methodology, cohort effects, and factors occurring with the passage of time. Estimates of prevalence range from 10–220 cases per 100,000. Recent estimates suggest that 294,000 children between 0 and 17 years of age are being affected by "arthritis or other rheumatic conditions".[1]

Regarding pain in this population, Schanberg et al.[2] found that children with polyarticular juvenile arthritis had pain an average of 73% of the days. Although for most children this pain was in the mild to moderate range, 31% reported pain in the severe range.

Nonrheumatologic Musculoskeletal Pain

A number of studies have tried to identify the prevalence of musculoskeletal pain in children and adolescents not associated with arthritis or other rheumatologic conditions. De Inocencio[3] reported on a review of 6500 office visits of children 3 to 14 years of age and found that 6.1% were for musculoskeletal complaints, the majority of which were for arthralgias and soft tissue pain. Common etiologies included trauma as well as mechanical or overuse pathology.

More generally, many children and adolescents report significant episodes of chronic nonspecific pain at least once in their lifetime, including limb pain (4.2% to 33.6%), knee pain (up to 18.5%) and back pain (7.6% to 34%).[4] Mikkelsson et al.[5] followed third and fifth graders over 1 year and found that pain occurring at least once per week persisted in 52.4%, with neck pain having the highest persistence. Thus, although the range of prevalence rates is very broad, it is clear that specific and pervasive musculoskeletal pain is quite common in children and adolescents. It also appears that overall the prevalence and cumulative incidence of these symptoms increase with age, and are more common and appear slightly earlier in females compared to males.

Complex Regional Pain Syndrome (CRPS). There are few studies reporting on the prevalence of CRPS in children and adolescents. Available data indicates a very high female to male ratio (about 6:1) and more common occurrences in the lower extremity than upper.[6] In a more recent study of children presenting to a pediatric pain program in Australia, Low et al.[7] reported that patients were 90% girls, with lower limbs affected in 85% of cases, and most typically (80% of the time) precipitated by minor trauma.

Fibromyalgia Syndrome. The prevalence of fibromyalgia syndrome in children and adolescents is difficult to determine. Mikkelsson et al.[8] used a structured pain questionnaire in a large sample of Finnish third and fifth grade children and found that 22 of them (1.25% overall) met criteria for fibromyalgia syndrome. In a retrospective review of patients referred to a pediatric rheumatology clinic between 1989 and 1995, 7% were diagnosed with fibromyalgia syndrome.[9] Female gender predominance is also a well-replicated finding.[10] Although various studies have shown correlates to the presence of the syndrome, such as joint hypermobility,[11] temperament,[12] familial aggregation,[13] and psychiatric symptoms,[8] causal relationships have not been shown.

Temporomandibular Disorders (TMD). TMD pain is often underrecognized in children and adolescents. In a prospective study of 11-year-olds, 7% were assigned a diagnosis of TMD.[14] It appears that precursors to these difficulties may be found in children as young as 7 years and progress throughout childhood. Significant correlates include bruxism and tooth-grinding, as well as bite and tooth positioning.[15]

Headache

Another area of inquiry that has received a good deal of attention is headache in childhood, particularly in adolescence. In a recent review by Hershey et al.,[16] it was concluded that up to 75% of children have had significant headaches by the age of 15 years, with up to 28% of adolescents describing symptoms consistent with migraine headaches. In general, meta-analytic reviews suggest a gradual increase in headache incidence over childhood with 37% to 51% of children reporting a significant headache by 7 years and up to 82% by 15 years.[17]

The distinction between migraine and tension type headache is often complex, particularly in pediatric headache. For example, when applying International Classification of Headache Disorders-II criteria to a large sample of German children age 7–14, Kröner-Herwig and colleagues[18] found that 7.5% of the headaches could be classified as migraine, 18.5% as tension-type, and the majority were unclassifiable. Virtanen et al.[19] found that among children who were classified as having migraines at age 6 years, half were unchanged at age 13, while for 32%, there was a shift toward tension-type headaches. Other authors found a similar lack of stability in headache type over time with headache types shifting or disappearing entirely. Therefore, the precise relationship between various types of headaches in children remains unclear.

In addition, various authors report close relationships between headache pain and other difficulties, including neck pain,[20] back pain,[21] abdominal pain,[22] sleep disturbances,[23] fatigue,[24] epilepsy,[25,26] epistaxis,[27] psychiatric difficulties, and risk of suicide.[28–30]

In summary, headaches in children appear to be quite common. Precisely what differentiates migraine headache from tension-type headaches is difficult to discern at times, although recent shifts in diagnostic criteria and increased awareness of the syndromes should be helpful. Headaches increase in frequency and severity with age with a clear shift around the time of puberty, are more common and problematic in females, and health-related quality of life (HRQOL) may be significantly impacted.[31]

Chronic Abdominal Pain

Chronic abdominal pain accounts for 2% to 4% of pediatric visits. Hyams et al.[32] found that 75% of middle school and high school students reported abdominal pain, while 21% reported it was severe enough to affect activities and 8% visited a physician for it. Like other pain problems, various definitions and correlates of persistent abdominal pain (recurrent abdominal pain, chronic abdominal pain, functional abdominal pain (FAP), nonorganic abdominal pain, and psychogenic abdominal pain) have led to varying perspectives in its prevalence. The Rome II criteria for abdominal pain not due to gastrointestinal pathology have become the commonly accepted nosology. The categories are now functional dyspepsia, irritable bowel syndrome, FAP syndrome, and abdominal migraine.[33] A revision of these criteria, Rome III, was published in 2006, which further differentiates FAP from FAP syndrome.[34]

It appears that the roots of nonspecific abdominal pain may be identified quite early in development based on chart reviews of a cohort of children followed from birth to 5 years. Chitkara et al.[35] found an incidence of abdominal pain of unknown origin of 4.5/1000 person years leading to repeated visits to the pediatrician. Finally, as was the case with prior pain problems, there is growing evidence the difficulties with chronic abdominal pain early in life are associated with the risk of future abdominal pain, other pain problems (e.g., headache), and broader somatic concerns later in childhood and beyond.[36,37]

Disease- or Treatment-Related Pain

Sickle Cell Disease

For many years, the focus of pain management in children and adolescents with SCD were episodes of vaso-occlusion. Dampier and colleagues[38] gathered pain diary data in children and adolescents with SCD. They found that vaso-occlusive pain is experienced on 2% of days in preschool-age children and on 5% to 10% of days in school-age children and young adolescents. School-age children tended to have less intense pain than adolescents, and girls tended to report a higher number of painful sites than boys. Subsequent data[39] showed that 40% to 50% of school-age children experience one pain episode a month, while about 10% experience more than two episodes a month. While the majority of these episodes lasted one day or less, about 5% of episodes in older children last longer than 2 weeks.

More recently, however, it is clear that children with SCD are affected by a number of recurrent chronic pain concerns beyond those related to vaso-occlusion. Although Niebanck et al.[40] found that overall the prevalence of tension type and migraine headaches in children with SCD approximates that of healthy peers, they found that headache was more common in younger children with SCD and that there were relationships noted between frequency of headache and frequency of vaso-occlusion. This suggests that factors related to SCD may increase the risk of headache pain. In addition, sequelae of splenic sequestration may lead to ongoing visceral pain in the left upper quadrant and irreversible joint damage, such as related to aseptic necrosis, may cause ongoing discomfort.

Cystic Fibrosis

Koh et al.[41] evaluated 46 children with cystic fibrosis (CF) and found that nearly half of the sample described pain occurring at least weekly with primary locations of the abdominal and pelvic region, chest, head, and neck. Although most children reported mild pain intensity and relatively short duration, a small subgroup reported moderately intense pain in the chest that was of longer duration. Pain in this group was thought to be musculoskeletal in nature, related to pulled or torn intercostal muscles, costochondritis, pleuritis, pneumothorax, or rib fracture. A web-based study of adolescents and young adults with CF found that about half experienced moderate daily pain of 2 hours duration or less, with disability highest in areas of recreation, occupation, and social activities.[42]

Phantom Limb

Phantom pain occurs when a limb has been amputated and the individual continues to feel pain in a part of the body that is no longer there. In an early attempt to ascertain the prevalence of such conditions in children, Krane and Heller[43] conducted a retrospective survey of 5- to 19-year-olds who had undergone limb amputation in the preceding 10 years. Amputations were secondary to congenital deformity, trauma/infection, or cancer. Phantom sensations were experienced in all patients, and the overwhelming majority stated they experienced phantom pain as well. Melzack et al.[44] reported that phantom limbs are experienced by 20% of those with congenital limb deficiencies and 50% of those who underwent amputation before age 6 years. Phantom pain was reported in 20% and 42% of these groups, respectively. Using diary data, Wilkins et al.[45] found recurrent episodes of phantom pain due to congenital limb deficiencies, surgery, and trauma, with an average intensity of 6.43 out of 10.

Additional Considerations

The above review should make it clear that there is an array of chronic and recurrent pain problems that affect children and

adolescents. It is unwise, therefore, to focus on ''chronic'' or ''recurrent'' pain as a unified entity, but rather as diverse syndromes, perhaps with certain common factors. As will be discussed below, a broad biopsychosocial perspective is deemed optimal, which embraces genetic, developmental, and environmental influences.

In the remainder of this chapter, we will discuss the impact of persistent pain on children and offer a general approach to evaluating and managing it. A more detailed review on a number of more common entities will be offered as well. Additional information on many of these problems is available in other sections of this volume, such as Chapters 25, 49, 57, and 61.

IMPACT OF PERSISTENT PAIN ON CHILDREN AND FAMILIES

Recurrent and chronic pain can have a major impact on the daily lives of children, adolescents, and their families. While some children experiencing pain symptoms have minimal day to day impairment, other children exhibit psychologic problems and have significant activity limitations due to pain. The children who seek treatment for their chronic pain symptoms likely represent the group which is experiencing the most impairment.[46] For many children, chronic pain has been associated with poorer HRQOL, psychosocial difficulties, academic problems, and disruptions in peer and family relationships.[47,48]

Disability or activity limitation that results from chronic pain is a separate concept from pain itself, and it is equally important to consider in assessment and management of pediatric pain patients.[49] Disability refers to those areas in an individual's life that are limited due to pain.[50] The domains of functioning that seem to be particularly impacted by chronic pediatric pain are participation in physical and social activities, school and academics, sleep, and family functioning. Specifically, chronic pain has been associated with more frequent school absences and academic difficulties.[51,52] Missed schooling can have direct effects on academic performance and school success as well as important effects on socialization and maintenance of peer relationships. Difficulties with peer relationships have been found in children with chronic pain, with one study of children with juvenile fibromyalgia reporting that children were more isolated, less well-liked, and less socially accepted than their healthy peers.[53]

Pain can also interfere with the quality and quantity of children's sleep, with over half of children and adolescents with chronic pain reporting sleep difficulties.[48] These problems typically include difficulty initiating sleep, maintaining sleep, and early morning awakening. Sleep problems have been shown to correlate with depressive symptoms.[54] Sleep deprivation can also reduce children's abilities to cope with pain and enhance pain sensitivity.[55] For example, in children with SCD, high daily pain was associated with poor sleep quality that night, which in turn predicted high pain levels the following day.[56]

Activities limited due to pain vary depending on the level of pain children experience. Higher levels of pain intensity and longer pain duration have been associated with greater activity limitations and impairment.[57–59] Specific domains of activity restriction have also been associated with pain level. In one study of children with SCD, while children decreased participation in all activities (school, play, sports, social) when pain was high, they were able to maintain school attendance and social activities when pain levels were low.[58] Future research is needed to better understand the relationship between pain and activity restriction among different populations.

Persistent pain also has a substantial impact on the emotional status of children and adolescents. In general, children with recurrent pain experience more stress and feel less cheerful and more depressed compared to children without pain.[60] Chronic pain is associated with psychiatric comorbidity, particularly anxiety and mood disorders, at least in some selected populations. For example, in a sample of children seen in primary care for recurrent abdominal pain, 79% of children met criteria for an anxiety disorder and 43% for a depressive disorder.[61] Children and adolescents with chronic pain have also demonstrated lower levels of self-esteem, more internalizing (e.g., somatization) and externalizing behaviors,[62,63] and higher levels of neuroticism and fear of failure compared to healthy children.[64] Moreover, children's coping style (particularly maladaptive coping) and catastrophizing behaviors are associated with increased psychologic problems and physical limitations.[65] In one study of children with mixed chronic pain conditions, maladaptive coping was correlated with depression and disability, with children with musculoskeletal pain having the most difficulty coping and greatest physical impairment.[47]

HRQOL refers to an individual's perception of the impact a disease or condition has on his or her physical health status, psychologic functioning, and emotional well-being. Youth with chronic pain and their parents report lower HRQOL than healthy children. For example, in one study of adolescents with recurrent headache, participants with head pain reported lower HRQOL in physical, social, and psychologic functioning domains compared to headache-free adolescents.[66] Similarly, in another study examining HRQOL in children with FAP, both children and their parents reported significantly lower HRQOL compared to healthy participants, with parents of children with FAP reporting the lowest quality of life ratings overall.[67]

Chronic pain also has a negative impact on family life. Parents often experience significant financial burden due to the evaluation and management of their child's recurrent and chronic pain, including direct costs of pain treatment such as hospitalization, doctor's visits, and costs of medications. Indirect costs include parental time off work, transportation costs, childcare, and incidental costs totaling over $15,000 per child per year.[68] The stress of chronic pain on families is also associated with increased levels of family conflict and poorer family functioning. Previous studies have shown more family problems in children with chronic headaches compared to healthy children[69] and that poorer family environments are associated with increased headache-related disability.[70,71] Moreover, frequent quarreling within families significantly increased the occurrence of weekly and monthly head pain in children and adolescents.[18]

Parenting children with chronic pain is also related to problems with emotional functioning, particularly elevated levels of parental depression, anxiety, and parenting stress.[72] One study of mothers of adolescents with chronic pain found that mothers reported feelings of guilt, inadequacy, and uncertainty in parenting competence due to their child's pain.[73] Chronic pain in children has also been associated with increased restrictions on parental socialization and high levels of parental strain, anger, and hostility.[74]

ASSESSMENT

Accurate pain assessment is critical for individualizing pain treatment strategies and to assess treatment progress in achieving important goals of pain reduction and increased function. Measurement of aspects of recurrent and chronic pain require tools that measure the frequency, intensity, duration, time course, and activity interference due to pain. Validated measures have been developed to capture most of these domains.[75,76] Diaries are often used in the clinical management of children with recurrent and chronic pain to provide information for evaluation purposes and to document treatment progress. Pain diaries may be useful for obtaining estimates of intensity, frequency, and duration of pain as well as possible patterns (e.g., differences between school days and nonschool days) and triggers (e.g., exams, performance stress, etc.). If a diary is used, it should be for a short time only

to understand more about the pain. Prolonged use of a diary may unduly focus attention to the pain and subsequently increase pain complaints.

A critical area to assess is function. Measures such as the Functional Disability Inventory,[50] the Pediatric Quality of Life Inventory,[77] the Child Activity Limitations Interview,[78] and the Bath Adolescent Pain Questionnaire[79] all provide information about child functioning in normal daily activities. These measures are all brief and can be administered easily to document children's functional disability at baseline and treatment progress.

Psychosocial assessment is an important component in the assessment of a child with chronic pain in order to evaluate psychologic, social, and family functioning which may contribute to pain or pain-related disability. Psychosocial assessment may consist of clinical interviews, administration of standardized psychologic measures, and observation of child and family members. A detailed clinical interview should cover developmental, behavioral, and psychiatric concerns in the patient's and family's history. Potential stressors and areas of maladaptive coping should be inquired about as well as a comprehensive school history, and history of peer and social relationships. Ideally, a separate psychosocial assessment is conducted with child and parent alone in order to obtain their individual perspectives. Many outpatient pediatric pain clinics use intake questionnaire packets that cover demographics, developmental history, and other aspects of psychologic functioning in order to consistently obtain this information in the evaluation of new patients. Review of intake packets may then provide details that serve as a springboard for more focused clinical interviews or additional psychologic assessments during the intake visit.

Depending upon the particular presenting concerns, standardized psychologic measures may be administered to screen for mental health diagnoses, in particular, anxiety and depressive symptoms, to assess coping behaviors, and family functioning. A variety of standardized instruments can be used in the clinical setting with the advantage of obtaining a quick assessment of children's psychologic functioning given the limited time available for in-depth psychologic evaluation in the medical setting. For example, screening for anxiety and depression can be accomplished using scales such as the Children's Depression Inventory,[80] the Revised Manifest Children's Anxiety Scale,[81] or the Revised Child Anxiety and Depression Scale.[82] When psychologic measures are used to screen for psychologic distress, it is important to consider the limitations of self-report and in particular that children may want to present themselves in a favorable light (social desirability response bias), which has been described in children and adolescents with chronic pain.[83]

Parental and family functioning has also been a major area of focus in pediatric chronic pain assessment.[84] Parental response to pain behaviors can be assessed using the Adult Response to Child pain behaviors,[85] and family functioning can be evaluated using a variety of measures such as the Family Assessment Device.[86] For a comprehensive review of measures available to assess parental impact of chronic pain, see Eccleston et al.[75]

There are also measures of child coping that have been validated on pediatric chronic pain samples including the Pain Response Inventory[87] and the Pain Coping Questionnaire.[88] Measures of specific areas of coping, including catastrophizing, are available such as the Pain Catastrophizing Scale, child version PCS-C.[89]

CLINICAL EVALUATION OF THE CHILD WITH CHRONIC PAIN

Background

The evaluation of a child with chronic pain is often complex and time-consuming, yet it often falls unfortunately on the already overburdened shoulders of the office-based primary care practitioner. The typical child with chronic pain has been evaluated by many practitioners from multiple disciplines. If the source of the pain is obvious such as previously or newly identified organic disease (e.g., ulcerative colitis, SCD, cancer), the focus is on addressing the underlying illness while simultaneously treating the associated pain. In other situations, the source of the pain may be known but not amenable to direct treatment and therefore the focus must be solely on the pain itself (e.g., persistent postoperative, posttraumatic, or postviral pain). For both of these groups of children, there is no need for an extensive search for an explanation for their pain, and the clinician can focus on its treatment.

The more challenging situation and the emphasis of the majority of this chapter occurs when no obvious pathophysiologic source of the pain has yet been identified. The child is suffering, the parents are frustrated, and no treatable disease process has emerged to explain the pain. In these situations, the clinician must attempt to identify those children who may have an as yet undiagnosed underlying progressive disease process and separate them from those who have chronic pain syndromes, which although uncomfortable, do not represent life-threatening illness. This is not an easy task, given the inherent vagueness of the symptoms, the inadequacies of children as historians, and the vast differential diagnosis.

It is critical, however, in the attempt to rule out potentially serious or life-threatening causes of pain, that physicians avoid an endless search for the underlying etiology of the discomfort. Continued laboratory investigation often convinces the child and family that there must be a biological explanation for the problem and suggests to them that the "answer" may be found in the next laboratory test. Clinicians often report that they are ordering additional tests "for the sake of completeness" and both clinicians and families often find it difficult to draw a diagnostic line in the sand where all are content with extent of the investigation. Konijnenberg and colleagues[90] highlighted this problem in a series of papers in which 17 different pediatricians reviewed the medical records of 134 children with unexplained chronic pain. There was disagreement on diagnostic approach in over a third of the patients and on the primary cause of the pain in over one half.[90] Unfortunately, this diagnostic uncertainty leads to further excessive and expensive laboratory and imaging studies. It is particularly unfortunate if, after completing an extensive battery of tests, which are negative, the doctor implies that the problem must be psychologic and refers the child to a mental health professional.

Therefore, one of the most critical aspects of the evaluation of the child with unexplained chronic pain is the acceptance by child, family, and provider that medical investigation has been sufficient to allow the primary focus of the encounter to be on the management of the pain, regardless of its etiology.

History

General

The traditional elements of the pain history for adults are applicable to chronic pain in children. Although younger children are developmentally less capable of presenting a coherent narrative, they certainly are capable of reporting on specific aspects of their pain. These include pain intensity (with the aid of developmentally appropriate tools), radiation, exacerbating and relieving factors, and quality of the pain. For chronic pain, which tends to occur in older children and adolescents, as mentioned earlier, a strong focus of the interview should involve the impact of the pain on the child's functioning—school attendance and work quality, social relationships, and mood. Roth-Isigkeit and colleagues[48] studied 750 German schoolchildren and found that 30% to 40% reported restrictions in daily living secondary to

pain. Chalikidis'[91] study of chronic pain in Australian youth revealed that 71% of children had difficulty sleeping and over 90% were unable to be involved in sports. Improvement in function may occur well before decreased pain intensity and is therefore an important marker of response to treatment.

It is important to be aware of the child's medical history. Emerging data from multiple streams suggest that early exposure to painful stimuli (e.g., multiple surgeries, stormy neonatal course, multiple painful procedures) potentially predisposes the infant to changes in nociception. An extensive body of work by Fitzgerald and colleagues[92–95] in rat pups has demonstrated long lasting hypersensitivity to pain from early tissue injury. Grunau and coworkers,[96–99] in a series of papers, compared toddlers who were born prematurely to babies of normal gestation and birth weight and found differences in pain sensitivity and somatization. Far less pronounced but measurable differences between the groups were found even when the children had reached 8–10 years. Anand[100] has even suggested that there are increased rates of ADHD, substance abuse, and anxiety in children who have been exposed to repeated neonatal pain and stress.

Another essential element to query is the history of pain problems in the family. Although some authors, such as Borge,[101] question whether chronic pain symptoms run in families, on the whole, the majority of studies have suggested that parent and family history of pain are predictors of child pain. This pattern has been identified in children with rheumatologic disease,[102] recurrent abdominal pain, migraine, and fibromyalgia. The mediators of this phenomenon are unclear. They may be physiologic (such as altered pain thresholds) or psychologic (e.g., social modeling of catastrophizing behavior) or most likely a combination of both. Eccleston and colleagues[65] report that parents who have chronically ill children are often anxious and depressed (60% and 40%) and these symptoms may be a response to parenting a sick child or may predate the child's illness. They have identified factors that are associated with a higher level of emotional distress in parents of children with chronic pain. These include depression in the child, long duration of pain, and young age of the child. Regardless of the mediators for this phenomenon, it is essential that family history of pain be examined, as data are fairly conclusive that children of parents with chronic pain are at risk for somatic and emotional issues. The child's pain cannot be adequately addressed if the parent's pain is not recognized.

Psychologic and social factors should be explored in every child with chronic pain, regardless of its suspected etiology. Such an exploration does not imply causation, but there is a transactional relationship between chronic pain and anxiety and depression. Many families may become angry when psychologic issues are raised and assume that the physician is ignoring the very genuine pain the child may be experiencing. The family should understand that all pain, particularly chronic pain, has physiologic and psychologic components and any comprehensive treatment program addresses all domains. Questions regarding anxiety, depression, and excessive irritability should be posed to both the child and his or her family. The use of existing standardized questionnaires has been described earlier in this chapter.

The child's school experience should also be explored.[103] As stated earlier, increased school absenteeism is commonly reported in most chronic pain syndromes,[104] widespread musculoskeletal pain,[5] and abdominal pain.[105] Certainly, learning disabilities and attentional problems may be a source of stress which may increase the child's awareness of discomfort and cause it to be intolerable. Likewise, social difficulties and bullying may similarly increase stress and concomitant pain. Frequent absences themselves may be a source of distress for the child. School with its academic and social demands is stressful for many children. Reintegrating after frequent or prolonged absences, however, when the child still may feel vulnerable and have to deal with accumulated work, loss of contact with peers, and complex social encounters ("Where have you been?" "What is wrong with you?" "You don't look like you have a disease.") let alone the school environment, can be so overwhelmingly stressful as to preclude the child from returning. These factors, however, should not be construed as the "cause" of the pain per se but may have a role in amplifying the child's interpretation of the pain signal. Therefore, frank discussion about the child's grades and competencies, social skills, friendships, and existing school accommodations should be part of the history gathering. A detailed discussion regarding school and chronic pain is contained in the treatment section of this chapter.

Specific

The previously described information is important when gathering the history of any chronic pain problem. There are specific questions, however, associated with each chronic pain condition that may help us determine if the pain fits the traditional syndrome or may represent a problem which requires additional investigation. The red flags in history and physical examination which suggest ongoing progressive disease for three common chronic pains (headache, widespread musculoskeletal pain, and functional gastrointestinal pain) are discussed in specific sections on these entities at the end of this chapter.

Physical Evaluation

Information gathered from the physical examination in conjunction with the history can help differentiate a chronic pain syndrome from pain secondary to an underlying disease. The child's general appearance (sickly or well appearing) may be helpful, although individuals who are in pain for a prolonged period of time may look pale and wan. It is essential to monitor growth parameters as chronic illness may well impede growth. There is an association between chronic pain and postural orthostatic tachycardia syndrome and therefore heart rate should be obtained both supine and standing.

The child should be asked to localize his or her pain. The differential diagnosis and intervention strategies are very different for generalized discomfort versus highly localized pain. Specific discussion of the examination of the back, abdomen, and joints are beyond the scope of this review but regardless of the origin of the pain, the clinician should obtain general impressions of the child's mood, cooperativeness, irritability, and eye contact. The child's gait and posture should be noted.

Emerging literature supports the association of chronic musculoskeletal pain with hypermobility. This may be secondary to central sensitization which may be induced by constant subluxation and slippage or may have other etiologies. Regardless of the origin, a Beighton score should be calculated on all children with chronic musculoskeletal pain.[106] Preliminary research suggests an association with cervical hypermobility and headache as well.[107]

Clinical Formulation

The task for the clinician is to examine the data that emerged from the history and physical and determine whether or not there are sufficient red flags to warrant further investigation for progressive disease. If there are, the child and family should be informed that the investigation is ongoing. If there are not, the clinician should report to the child and family that the child most likely has a chronic pain syndrome. In either situation, the pain should be treated appropriately although the approach, both philosophically and practically, will vary between the two. If the pain is thought to be a manifestation of a time-limited disease process, although the approach will be multifactorial, there will often be an emphasis on more aggressive pharmacologic intervention while the disease process runs its course. If the pain is associated

with a chronic condition or represents a chronic pain syndrome, the emphasis is more typically on coping and function with supplemental analgesia.

Feedback With Family

The initial feedback session with the child and family after the evaluation has been completed sets the tone for the subsequent relationship. If the child has ongoing disease, the pain care physician should be part of a coordinated effort to address the child's problems. If it is decided that additional interventions to address an underlying disease process are not necessary, care coordination remains critical and one health care provider should assume that responsibility. Chronic pain patients often see multiple traditional as well as alternative health care providers and may acquire extensive medical records. Case management is a critical role.

Regardless of the etiology of the pain, it is imperative that the clinician informs the family that he or she is familiar with the symptom complex, even if the exact problem is not clearly defined. Chronic pain treatment has key dimensions that should be addressed such as sleep, school, and physical and social activities regardless of the etiology of the pain. It is also essential for chronic pain that the family be aware that pain persistence does not have the warning protective function that it does in acute pain. The notion that the pain "hurts" but is not causing "harm" is essential to convey to alleviate familial anxiety.

The current conceptualization of chronic pain in children is that it results from the interplay between biologic vulnerabilities and psychologic and environmental variables. Biologic vulnerability may result from abnormalities of sensory processing which may stem from peripheral tissue damage or inflammation. This burst of nociceptor activity increases the strength of the connection between the nociceptor and the spinal cord neurons. This may yield enhanced responsiveness and excitability in the central nervous system known as "central sensitization." Such hyperresponsiveness is associated with decreased pain thresholds and hyperalgesia and has been linked to functional gastrointestinal disorders as well as fibromyalgia in adults. It may well be that many chronic pain conditions are associated with central sensitization or autonomic dysregulation.[108–110]

As mentioned, however, there are psychologic and environmental variables that amplify or dampen that vulnerability. Multiple studies, as previously mentioned, support the relationship of abdominal and musculoskeletal pain as well as headache with internalizing symptoms such as anxiety and depression. The massive stress of school, the loss of normal opportunities to socialize with friends, and the impact of the immobilization and sleep deprivation often accompanying chronic pain further contribute to that relationship.

All of this must be conveyed to the family in a supportive, nonjudgmental manner. Their acceptance of a multidisciplinary approach is fundamental to its success.

Treatment

General Principles of Treatment

A number of general principles have evolved to define the treatment of chronic pain in children. If there is a specific identified etiology, direct measures to address it should be undertaken. For children with an identified etiology as well as those without, a multimodal approach focusing on function is key. Initially, the family should be informed that the child will be carefully monitored through frequent scheduled appointments. A symptom diary may provide interim data between appointments. This monitoring reassures anxious parents that someone will be watching their child if new symptoms emerge which suggest a previously unrecognized disease process. This approach has been labeled "watchful waiting." If the pain problem does not evolve significantly over time, it mitigates against an ongoing progressive disease. Any monitoring should focus not only on pain intensity but also on function (sleep, mood, school attendance, etc.).

Interventions typically employed to address chronic pain must allow the child to return to a "normal" life. As a result, drugs which significantly alter the child's sensorium are inadvisable as are prolonged hospital or home stays. Drugs which reduce central sensitization such as amitriptyline and gabapentin are often the mainstay of pharmacologic treatment regardless of the etiology of the chronic persistent pain. Other antidepressants and anticonvulsants are frequently used, but few are approved for use in children. Analgesics may be helpful but the risk of rebound headache or abdominal pain secondary to excessive nonsteroidal usage is genuine. Opioids are occasionally necessary. Long-acting opioids should always be prescribed with a short-acting breakthrough opioid.

Physical therapy is of particular value in musculoskeletal pain syndromes such as fibromyalgia but is valuable in any pain syndrome in which the child's activity level has been diminished and he or she has become deconditioned. A graded exercise program increases the child's feelings of well-being and provides reassurance and confidence as the child regains lost abilities. Other physical and occupational therapy modalities such as desensitization, transcutaneous electrical nerve stimulation, and stretching or strengthening particular muscle groups are also helpful. Biofeedback, a technique to gain conscious control of physiologic functions which are typically beyond voluntary control through the use of a computer, has demonstrated efficacy in headache reduction but may be helpful for other chronic pain conditions.

There is a strong body of evidence that suggests that psychologic interventions are effective for chronic pain treatment in children. Multiple reviews and meta-analyses attest to the strength of the impact of these approaches which include cognitive-behavioral as well as psychotherapeutic strategies.[111,112] Although many of the cognitive-behavioral strategies were developed to help coping with procedures, many such as meditation, hypnosis, reframing, and help with coping and avoiding catastrophization all have efficacy in chronic pain as well. A psychotherapist can function as a life coach, helping the child with strategies that might soften the impact of school re-entry, decrease anxiety, and provide advice to parents who are overwhelmed.

School is the work of childhood and chronic pain is often associated with frequent school absence. Parents often need help ushering the crying, complaining children off to school when the path of least resistance is to allow them to remain in bed. Specific criteria for school attendance should be developed. In general, school attendance should be mandatory except for those times when the child has a fever. This eliminates parental vacillation and second thoughts and allows them to be consistent and to shift the blame to the health care provider. Modification can be made for work load, length of day, extended time, physical education attendance, etc., but the child should develop the rhythm of daily school attendance. More detailed information on the importance of school and school reintegration is offered later in this chapter.

There are certainly situations where the parent's response is detrimental to the child's coping. Occasionally, parents may be so insistent on identifying an etiology that the child is dragged to a continuous parade of specialists, subjected to unnecessary procedures, and school absence is promoted. There is emerging literature which suggests that children whose parents are overly apologetic or overly solicitous report more pain than children whose parents are matter of fact.

In summary, the treatment of chronic pain in children needs to address the pain itself as well as the life context in which that pain is occurring. As a result, analgesia often needs to be coupled with antidepressants and/or anticonvulsants. Sleep, school, cop-

ing, activity level, and family functioning all are important dimensions of the treatment of chronic pain.

SPECIFIC INTERVENTIONS FOR CHRONIC/PERSISTENT PAIN

Children who receive care in a multidisciplinary pediatric pain clinic are typically offered a multicomponent treatment plan which often involves psychologic therapy, physical therapy, and medication management. Philosophically, most programs incorporate a rehabilitation approach in which pain is accepted as a symptom that will be diminished but might not be entirely eradicated. Therefore, the focus is typically on improving function and quality of life. The specific structure of each program differs depending on local factors with some providing inpatient rehabilitation while others are solely outpatient. Many new programs are developing in the United States and abroad. Zeltzer and Schlank[113] list many pediatric pain programs in the United States, Canada, and internationally.

Pharmacologic Interventions

Pediatric analgesic pharmacology is summarized in greater detail elsewhere in this volume (see Chapter 50). The current discussion emphasizes specific uses of analgesics in the setting of chronic persistent pain, as opposed to acute pain. Pharmacotherapy of chronic pain in children and adolescents requires patience and balance of risks, benefits, and side effects. For most patients coming to a chronic pain clinic, pharmacotherapy should not be used in isolation, but only as a component of a multimodal treatment program. In considering a medication trial, clinicians' discussions with patients and parents strike a difficult balance. The aims of drug therapy and expected benefits should be outlined. Side effects and risks should be discussed in a manner that is honest, but tailored to the style of the individual patient and family. There is a growing literature on how patients hear risk discussions.[114]

Discussions of side effects do have the potential to generate nocebo (negative placebo) effects.

For some conditions, treatments can be specific and mechanism-driven. For example, for children with rheumatoid arthritis, pharmacotherapy is largely directed at underlying inflammatory processes, and for most patients, treatment of inflammation serves to treat the pain. Similarly, pharmacotherapy for migraine and for specific subtypes of chronic abdominal pain may be directed at underlying mechanisms in some cases.

Acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are widely used for pediatric acute pain management, and NSAIDs are an integral component of management of chronic inflammatory disorders. Daily use of either of these classes of medications can produce rebound headaches. There is comparatively little studied on chronic daily administration of acetaminophen in children. Chronic administration of NSAIDs in children with rheumatoid arthritis has been associated with gastropathy and nephropathy, but overall with a lower risk than has been reported in adults.

A majority of trials of cyclooxygenase (COX)-2 inhibitors in children have involved short term use. A recent 3-month trial comparing celecoxib to naproxen showed equal efficacy and no statistically significant difference in adverse events.[115]

Opioids have been extensively studied for pediatric acute pain management and for pain in children with cancer. As with adults, there is little consensus regarding which children with chronic noncancer pain have a favorable risk-benefit ratio for long-term opioid analgesia. Overall, prospective studies on adults in pain clinic populations with nonlife-shortening conditions have not shown good effect of long-term use of opioids on either pain scores or measures of quality of life or functioning. Those who defend chronic opioid therapy in adults may argue that these studies did not address ideal patient subgroups. With children and adolescents, there are additional concerns. First, opioid tolerance and opioid-induced hyperalgesia are likely to proceed more rapidly for children compared to adults.[116,117] Secondly, long-term opioid administration may have detrimental effects on endocrine function. Thirdly, with many chronic medical conditions in childhood, longevity is difficult to predict, and advances in treatment have changed prognosis for many chronic illnesses of childhood and young adult life. For these reasons, we do use opioids on a long-term basis for a small subset of children with chronic pain not due to life-limiting illnesses, but we do so with some caution and with consideration of alternatives. There is a theoretical argument in favor of selection of either methadone or buprenorphine for long-term opioid therapy in younger patients, based on a hypothesis that relates the development of tolerance and hyperalgesia to differential activation of receptor-mediated activation of second messenger systems versus receptor-mediated endocytosis.

For adults with many forms of chronic pain, especially neuropathic pain disorders, there is evidence for efficacy of several anticonvulsant and antidepressant medications. We will cite some limited pediatric information below, but at present most information regarding efficacy must be extrapolated from clinical trials in adults. In adults, these medications are side effect prone, inconsistently effective; they generally produce partial, rather than complete, pain relief. In adults, there are very few randomized controlled trials (RCTs) that compare one antidepressant to another,[118] or that compare an antidepressant to an anticonvulsant. There is remarkably sparse evidence for selecting one medication over another in general for adults with chronic pain, except for specific conditions that are uncommon in pediatrics, such as trigeminal neuralgia.

One publication is cited here mainly to recommend caution in its interpretation. The authors use an "indirect meta-analysis" to compare duloxetine to the anticonvulsants gabapentin and pregabalin for treatment of neuropathic pain in adults. What is actually done is to use outcomes from active treatment groups in studies comparing duloxetine to placebo to the active treatment groups in studies comparing gabapentin or pregabalin to placebo.[119]

For antidepressants in trials for neuropathic pain in adults, numbers needed to treat (NNTs) range from 2–4 for trials involving tricyclics (mostly with "global improvement" as an endpoint) to as high as 5 for trials involving duloxetine with 50% pain relief as a primary endpoint. Overall, tricyclics appear to be more effective than selective serotonin reuptake inhibitors (SSRIs) for neuropathic pain in adults.

For children and adolescents, we commonly choose nortriptyline as a first line tricyclic. We encourage starting at a very low dose (e.g., 10 mg every night for adolescents and older children and 5 mg every night for younger children). The rate of dose escalation is determined by clinical circumstances and side effects. For an outpatient who experiences no adverse symptoms, dosing might be increased every 3 days until there is good analgesia or he or she reaches a dose around 40 or 50 mg daily. Dosing is occasionally even more rapid for inpatients with severe neuropathic cancer pain. Conversely, if the child does experience side effects, dose escalation proceeds more slowly. If there is no indication of analgesia or side effects by the time dosing is escalated to 50 mg/daily (and if we are convinced that the child is taking the medication), we will often obtain a blood level prior to further dose escalation. Clearance of tricyclics in children is enormously variable. An electrocardiogram is widely recommended either prior to initiating treatment or after dose escalation. We adhere to this recommendation while recognizing that there is little evidence that electrocardiography can identify patients at risk for sudden cardiac events.

There are a number of clinical trials and case series on antidepressants for migraine prophylaxis in pediatrics, including amitriptyline, nortriptyline, and trazodone, though many have involved open label designs or crossover comparisons to other drugs.[120,121]

There is a widely quoted case series on the SSRI citalopram for treatment of recurrent abdominal pain in children. While there is apparent improvement in a large percentage of patients, this should be interpreted with great caution because of the open-label and uncontrolled design of the study.[122]

There has been extensive controversy regarding potential risks of antidepressants in triggering suicidal ideation and completed suicide among adolescents. What is clear to us is that these medications require close monitoring for changes in a child's mood and behavior. Prescribing should begin in low doses, doses should be escalated in a gradual and stepwise manner, and there should be a system for frequent reassessments, ideally including regular phone calls in between clinic visits. For guidance of families, there is a well-written statement on the National Institutes of Mental Health website.[123]

Anticonvulsants are also widely used for treatment of neuropathic pain in adults. As with antidepressants, side effects are common, treatment responses tend to be partial rather than full, and NNTs generally range from as low as 3 to over 5.

Gabapentin emerged as a widely prescribed medication for neuropathic pain in the 1990s, in part because of the widespread belief that it was safer or easier to prescribe compared to other anticonvulsants. There is a remarkable dearth of trials comparing anticonvulsants to each other for neuropathic pain in adults.

As with tricyclics, our recommendation for gabapentin dosing is to start with small doses and escalate slowly, particularly in ambulatory patients. Different clinicians begin adolescents in a dose range from 100 mg daily to 300 mg daily. Our preference is to start for a few days with night-time-only dosing, to begin morning and then afternoon dosing after about 3 days, and to escalate every few days as tolerated until there is pain relief, significant side effects, or dosing reaches a range around 1800 mg daily over a period of about 3 weeks. Again, some patients tolerate escalation with no side effects, and others may tolerate daily doses as low as 300 mg. We commonly recommend giving half the daily dose at night, with one quarter in the morning and one quarter in the afternoon. As with tricyclics, dose escalation of gabapentin may be considerably more rapid for children with advanced cancer and refractory neuropathic pain.[124]

In our view, if trials of gabapentin or pregabalin produce minimal benefit or problematic side effects, there is reason to consider trials of anticonvulsants with different mechanisms. In particular, for peripheral neuropathic pain, we often try anticonvulsants with actions on sodium channels, such as oxcarbazepine.[125,126]

In our practice, topiramate is used primarily for migraine prophylaxis. Among the anticonvulsants, topiramate has a relatively high risk for neurocognitive side effects, especially effects on memory, word-finding, and mental clarity.[127]

Some of our colleagues have tended to select anticonvulsants rather than antidepressants as first-line agents because of the aforementioned controversy regarding suicidal ideation and suicide attempts with antidepressants in pediatrics. Unfortunately, anticonvulsants may increase these risks as well. An analysis of placebo-controlled trials of anticonvulsants for a range of indications found increased frequencies of suicidal ideation and attempts in the active drug groups compared to control groups, and this increased risk was apparently not limited to a particular drug class or a particular patient group.[128]

Psychological Interventions

Although there is a well-established evidence base for the effectiveness of psychologic treatments for chronic pain in adults,[129] there is a more limited evidence base in children and adolescents. The first systematic review of published RCTs of psychologic therapy for children and adolescents with chronic pain (with a subset meta-analysis of pain relief) was published several years ago.[111] These authors concluded that although there were few published RCTs, strong evidence emerged that psychologic therapies, principally relaxation and cognitive-behavioral therapy (CBT), are effective in reducing the severity and frequency of chronic pain in children and adolescents.

The CBT interventions included in these studies primarily involved brief, standardized treatments where children were taught specific coping skills (e.g., positive self-statements, relaxation) in the outpatient setting. A number of limitations, however, were noted in the pediatric chronic pain trials included in this review, particularly the relatively small numbers of trials (especially for nonheadache chronic pain), small sample sizes, and lack of non-pain outcomes such as function, mood, and disability.

Teaching parents appropriate strategies for managing their child's pain-related behaviors (e.g., reinforcing adaptive coping, discouraging maladaptive pain behaviors) is beneficial in treatment, and these strategies are increasingly being incorporated into psychologic therapies. For example, in a recent study, a cognitive-behavioral family intervention was compared to standard pediatric care for recurrent abdominal pain.[130] Children in the cognitive-behavioral family intervention group received five 40-minute sessions and were trained in relaxation skills and positive self-talk, and parents were taught to limit secondary gains from children's sick behaviors. The standard medical care group received customary medical treatment consisting of follow-up office visits, education, support, and medications as deemed appropriate by the treating physician. Children who received the cognitive-behavioral intervention reported significantly less pain after treatment, and at 1-year follow-up compared to children receiving standard care, providing support for the use of cognitive-behavioral family interventions in children with abdominal pain.[130]

Research has also shown that including parental behavior management strategies in conjunction with children's CBT can lead to improvements in parents' psychologic functioning. In one study using an interdisciplinary cognitive-behavioral program to treat adolescents with chronic pain, both youth and their parents obtained significant reductions in levels of anxiety, depression, and stress immediately following treatment and at a 3-month follow-up.[72]

Studies utilizing minimal therapist contact and self-administered treatments for chronic pain are the largest treatment advance to make CBT more accessible to children and families. These self-administered treatments focus on relaxation, and CBT for children with headaches have produced equal or better results as equivalent therapist-led treatments.[131–133] Importantly, self-administered treatments are more than three times more cost-effective compared to in-office treatments,[134] making such CBT interventions ideal for pediatric pain patients to be implemented on a large scale.[135]

More recently, two small pilot studies have been published using innovative technologies to deliver minimal therapist contact psychologic treatments for children with chronic or recurrent pain. Hicks and colleagues[136] evaluated the efficacy of distance CBT delivered via the internet and telephone for children ages 9 to 16 years with recurrent pain. They found significant reduction in pain levels for children receiving the distance treatment versus a standard medical care control group. In another recent study of a minimal therapist-contact treatment for recurrent pain, Connelly and colleagues[137] evaluated a CD-ROM pain management program (focused on relaxation training) in children ages 7–12 years with recurrent headache. They also found significant improvements in headache activity (less intense and frequent pain) in children who received the 4-week CD-ROM intervention versus children receiving standard care. These studies are important

for demonstrating feasibility in the delivery of CBT to children with recurrent pain using computer technologies and hold promise for future treatment developments in this area.

Pilot studies are emerging in the application of acceptance and commitment therapy (ACT) to children with chronic pain.[138] ACT is an increasingly popular form of CBT that emphasizes the importance of accepting pain symptoms and working toward valued goals, using interventions such as exposure, cognitive defusion, and mindfulness. Parents are also integrated into treatment using similar interventions emphasizing exposure to previously avoided private experiences, acceptance, and defusion exercises. In a pilot study of adolescents with idiopathic chronic pain, Wicksell and colleagues[138] reported that after 7–10 treatment sessions, patients showed a 63% reduction in functional disability, a 68% drop in school absences, 27% reduction in internalizing/catastrophizing symptoms, and a 46% decrease in pain intensity. Reductions were sustained at 3- and 6-month follow-ups. ACT appears promising, and it is anticipated that larger scale studies will be forthcoming using this approach to treat children and adolescents with chronic pain.

Complementary and alternative medicine (CAM) interventions are becoming increasingly popular in the treatment of chronic pain and have been successful in helping children and adults manage pain symptoms.[139] CAM refers to therapies (e.g., hypnosis, acupuncture, yoga, and biofeedback) commonly used in conjunction with conventional medical treatment. Biofeedback is one type of CAM therapy effective in the treatment of persistent pediatric pain. Biofeedback involves connecting a patient to a machine that monitors physiologic responses (e.g., muscle tension, heart rate). One form of feedback, thermal biofeedback, involves using electronic instruments (e.g., a temperature probe on the finger) to measure temperature, and a computer monitor to display reinforcing information back to the patient. Using relaxation approaches, patients can use the objective biofeedback information to learn to increase peripheral temperature.

Biofeedback, especially thermal biofeedback, has undergone empirical evaluation in children with migraine and tension headache, and there is evidence to recommend biofeedback and/or relaxation to any child who suffers from headaches.[140] Recently, biofeedback has been evaluated in children with chronic abdominal pain.[141,142] While results from these studies suggest that biofeedback is effective in reducing pain, RCTs using larger sample sizes are needed. Like CBT, research shows that incorporating parenting strategies into biofeedback treatment may increase the effectiveness of treatment. Children whose parents received behavior management strategies in combination with the child's standard biofeedback treatment demonstrated more clinically significant improvement in headache pain and showed greater reductions in headache frequency than those who received biofeedback alone.[143,144]

School and Social Reintegration

School and social functioning are impaired in many children with chronic pain. In industrialized societies, school is the work of children. Numerous studies have documented that children with chronic pain have difficulties with consistent school attendance and making progress with academic work, although there may also be specific impairments in peer and social relationships that are amplified in the school setting. On average, children with chronic pain miss more school days than do children with other chronic health conditions, and they often identify school as the most problematic stressor.[49] For example, Stang and Osterhaus[104] estimated that several hundred thousand school days are missed each month as a result of pediatric headache alone. In a sample of children with SCD-related pain, Shapiro and colleagues[145] reported that on average, children missed 21% of school days, which is the equivalent of 6–8 weeks of the school year.

There is also evidence that children with chronic pain may experience problems with social competence and peer relationships in the school setting. In one study, adolescents with juvenile fibromyalgia syndrome were perceived as being less popular, more isolated, and withdrawn compared to matched classroom comparison peers.[47] Moreover, these adolescents were less well liked, were selected less often as a best friend, and had fewer reciprocated friendships. Negative peer interactions were explored in one study,[146] finding that children with chronic abdominal pain had higher levels of relational victimization in comparison to pain-free peers.

The school setting may also be perceived as stressful due to problematic interactions with teachers and perceptions that adults are not supportive of children with chronic pain. In a study using vignettes, teachers' attributions about the causes of chronic pain revealed a lack of knowledge of the biopsychosocial framework and a primary perception that pain was either physical or psychologic.[147] Teachers responded more positively to students when medical evidence supporting the pain problem was available, and responses were associated with parental attitudes toward the school. Teachers were more likely to report children who were entitled to accommodations if parents approached the school in a collaborative manner rather than using a confrontational approach.[148]

There is variability in how children and families respond to impairments that may arise in the school setting. Some children and adolescents have worked out accommodations that allow them to have reduced class time, in-home tutoring, or online courses. Several mechanisms in public education laws can be used in this regard including individualized education plans and section 504 plans for other health impairments. Some families opt to remove their child from the school setting and engage in home schooling.

Regardless of the exact setting where school is to occur, addressing the impairments in school and social functioning is a primary focus of treatment for the child with persistent pain. Some children and adolescents have spent extensive time outside of their usual school and social settings and therefore graded plans for reintegration into these settings are needed. In the context of CBT, parent management guidelines have been implemented in clinical settings and in treatment studies focused on operant techniques. In general, parents are encouraged to establish a reduction of attention paid to pain symptoms in favor of increased attention paid to functional improvement. Such guidelines often include recommendations to reduce status checks; that is, allowing the child to communicate directly about pain symptoms, rather than having the parent repeatedly check in with the child about his or her pain level. Most parents experience tremendous relief in being released from the role of documenting the child's pain level. Often the focus on pain intensity and a specific numerical value (e.g., 8 out of 10) provides little in the way of adaptive coping behaviors and may lead to difficulties making decisions to reintegrate in school and social settings because of lack of change in pain levels.

Formal operant systems can be devised with families where children earn points or rewards for school attendance and participation in other social activities. The goal is to shift the pattern of contingencies so that the child experiences reinforcement for their efforts in school or social activities. An example of a point system would include specifying a target activity such as attendance at school for 4 hours each day, and then developing rewards for reaching the goal (such as full computer and television privileges) and consequences for failure to achieve the goal (such as removal of access to computer and television). Psychologists and other members of the pain team can work in treatment with children and parents to develop clear, graded plans for increasing activity. Typically, an explanation to children and parents is pro-

vided that functional improvement often precedes rather than follows pain relief. It is important to start at the same place as the child in terms of their perceived ability to sit in a chair and focus on school work for an operant system to be successful. Sometimes, very short time periods of school attendance (e.g., 1 hour) will need to be built upon gradually, and the child will need to have some control over his or her schedule. For example, it can be helpful to have the child choose what time of the day (and what classes) he or she would like to begin with upon the reintegration to school.

Carrying out a graded plan for increasing school and social functioning requires considerable effort from the parents who must arrange transportation and other logistics with getting the child to the school setting at specific times. Clinicians need to communicate sensitively to parents about their role and make clear the logical sequence of the plan to ensure its success. Additional interventions may be needed to assist children with problems related to peer relationships, interactions with teachers, or specific problems related to the school setting. There are not yet any published treatment studies evaluating school-related interventions for children with chronic pain.

Sleep

Sleep difficulties are commonly reported by children and adolescents with chronic pain. For example, in a large epidemiological study of children with chronic pain in the community,[48] over half reported some sleep problems. Self-reported sleep problems have also been documented in clinical samples of children and adolescents with juvenile rheumatoid arthritis (JRA),[149] headache,[23] SCD,[56,150] and CRPS.[151] Most commonly, children and adolescents with chronic pain describe difficulties falling asleep, frequent night and early morning awakening, and excessive daytime sleepiness.[152]

Important consequences of sleep problems have also been identified, including decrements in children's HRQOL, mood, and physical functioning.[54,153] Day-to-day variability in pain, mood, and sleep have been examined in children with SCD[150] finding that negative mood partially explained the relationship between more intense pain and poor quality sleep on the same and subsequent days. Other studies have demonstrated that depression is a strong predictor of poor sleep quality and insomnia symptoms in adolescents with chronic pain.[154]

Despite the known prevalence and significant impact of sleep problems on youth with chronic pain, there has been very limited attention to either the assessment or management of sleep problems. This is in contrast to the adult pain population where insomnia related to chronic pain has long been recognized among the most costly forms of illness in terms of prescription medications and lost work productivity.[155,156]

In clinical practice, it can be very informative to assess sleep problems in all pediatric patients with chronic pain and to offer specific sleep interventions to those patients with significant sleep disturbances. In particular, a detailed history of sleep patterns should be obtained to identify problems related to insufficient sleep duration, poor sleep habits, phase delays, or difficulties falling asleep or staying asleep. Insufficient sleep duration is common during adolescence with reported sleep in healthy samples of about 7 hours per night,[157] although optimal developmental sleep requirements for adolescents have been estimated at 9 hours per night.[158] In chronic pain samples, similar restricted sleep of about 7 hours per night has been reported.[154,159] Poor sleep habits including use of caffeine in the evening, lack of consistent bedtime routines, and the presence of electronics in the bedroom can also be clear barriers to children receiving adequate sleep duration. Children with chronic pain may also develop a high level of vigilance and arousal at bedtime and a high focus on pain when the distractions of the day are not present. These children may describe negative thoughts, worries, and somatic tension that interfere with falling asleep.

Interventions may be needed to help children increase their duration of sleep, to modify problematic sleep habits, and to teach behavioral strategies to reduce insomnia symptoms. Although interventions are being evaluated for adults with chronic pain and secondary sleep problems,[160] only one published study has separately evaluated a sleep intervention in a pediatric pain population. In this study by Bruni and colleagues,[161] the benefits of sleep hygiene education (e.g., education about age appropriate sleep duration, keeping consistent weekday and weekend sleep schedules) were assessed in a group of children and adolescents with migraine headaches and sleep problems. These investigators found that children who received sleep hygiene education obtained an improvement in migraine attacks (lower frequency and shorter duration) compared to children in a control group who did not receive sleep hygiene education. The development and evaluation of treatments for comorbid sleep disturbances in youth with chronic pain is an important clinical need.

SPECIFIC ENTITIES

Functional Gastrointestinal Pain

The conceptual framework through which we view chronic abdominal pain has evolved over the years, as has the definition. At this point, chronic abdominal pain is defined as long-lasting intermittent or constant abdominal pain that is either functional or organic (disease-based). Red flags for organic disease include pain that awakens the child from sleep, nocturnal diarrhea, persistent vomiting, weight loss, persistent right upper or lower quadrant pain, or dysphagia. If the history and concomitant physical examination do not suggest underlying pathology then, more than likely, the patient has one of the FAP syndromes. FAP is defined by a lack of demonstrable evidence of a pathologic condition and typically has a minimum of 3 months duration which, according to the Rome II criteria, need not be consecutive.[162,163] FAP is further subcategorized as functional dyspepsia (pain in the upper abdomen), irritable bowel syndrome (pain associated with alteration in bowel movements), abdominal migraine (intense pain with features of migraine such as anorexia, nausea, vomiting, and occurring paroxysmally), and FAP syndrome in which the symptoms do not fit any of the other functional syndromes and in which the pain is nearly continuous and has no relation to physiologic events such as eating, menses, or defecation.

In addition to the general strategies for addressing chronic pain, there are unique approaches to addressing the various categories of functional gastrointestinal pain in children. An evidence-based review of the literature completed prior to the development of the Rome III criteria identified only 10 randomized controlled intervention studies to address recurrent abdominal pain. It found that there was evidence to support the efficacy of famotidine, pizotifen, CBT, biofeedback, and peppermint oil enteric coated capsules. Dietary interventions such as increasing fiber had mixed results.[142]

The Rome III committee endorsed specific treatments for each of the subtypes of functional gastrointestinal pain recognizing the limitations of the literature. For functional dyspepsia, they suggested treatment with antisecretory agents such as H2 blockers or proton pump inhibitors are appropriate for pain predominant symptoms while prokinetics seem appropriate for symptoms dominated by discomfort such as bloating. For irritable bowel syndrome, they suggested peppermint oil. Antidepressants and serotonergic agents had limited support in pediatrics despite their efficacy in adults. For abdominal migraine, avoidance of potential triggers such as caffeine was advised. Treatment with the preventative agents used for migraine (cyproheptadine, sumatriptan)

seems appropriate when paroxysms are frequent. Pizotifen has been studied in children and found to be effective. Finally, for functional gastrointestinal pain syndrome, reduction of psychosocial stressors, behavioral treatment, and antidepressants such as citalopram appear most effective.[34,162,163]

Headache

A critical goal of the evaluation of pediatric headache is to determine whether the headache is primary or secondary headache.[163] Primary headaches include migraine, tension type headache, and cluster headaches. They are classified by their features as compared to secondary headaches which are classified by the underlying disorder responsible for them. Secondary headaches are those attributed to head and neck trauma, intracranial vascular and nonvascular disorders, substance administration or withdrawal, infection, or pain associated with disorders of the eyes, cranium, ears, sinuses, or teeth. Red flags in the history which suggest secondary headache are sudden onset of a severe headache, headache associated with systemic illness, new headache type in a patient with cancer or human immunodeficiency virus, sudden onset of the "worst headache in your life," a pattern of gradually increasing headache pain and frequency, or headache in a child under 3. Positive answers to these questions clearly demand additional investigation as well as imaging studies.[164]

The distinctions between different types of primary headache[165,166] are often blurred in children, and headache type may change with age. Zebenholzer and colleagues[167] found that in a 1.5-year period, 30% of children were headache free, 20% had swapped headache type, and 50% continued having the same type of headache. Such fluidity makes diagnosis complex and treatment is often empiric. Criteria for the diagnosis of migraine in children require 5 or more headaches that last between 1 and 48 hours (shorter duration than in adults), are bilateral or unilateral, have a pulsating quality, and are aggravated by physical activities. They are typically accompanied by nausea and vomiting and photophobia and phonophobia which tend not to occur simultaneously in adults.[168] Tension headaches are typically categorized by their frequency: infrequent (less than once monthly), frequent (greater than once per month but less than 15 days per month), and chronic daily headache (basically every day). These headaches are typically bilateral, are not pulsating, and not aggravated by physical activity, without nausea and vomiting or photophobia or phonophobia.

The general approach to headache treatment is similar to that of other chronic pains. Reassurance is critical. Maintaining regular school attendance is a cornerstone. For headache, it appears that maintenance of regular routines (arise and bedtimes, mealtimes, etc.) is helpful, as is regular exercise.[169] There is limited evidence to generally support a specific diet or dietary exclusion, although there may well be individuals for whom food is an important trigger.[166]

There are strong data that behavioral interventions are effective at reducing headache burden regardless of the headache type. These include biofeedback, progressive muscle relaxation, distraction, and hypnosis. In a systematic review of the RCTs of psychologic interventions for chronic pain (12 headache and one recurrent abdominal pain trial), Eccleston and colleagues[111] reported the odds ratio for a 50% reduction in pain was 9.62, indicating the success of psychologic interventions. Hermann,[170] in another review, found in particular that thermal biofeedback was more effective in the treatment of migraine headaches than other psychologic modalities and the more commonly used prophylactic drug regimens. A more recent review of the literature concurred and suggested that psychologic treatments were effective in children under 12. In particular, biofeedback and relaxation training either alone or in combination produced significant reductions in headache pain. The findings, although still positive, were less dramatic for tension or mixed headache diagnoses.[171]

The literature on pharmacologic treatment of pediatric headache, in particular, migraine, is less persuasive. Subcommittees of the American Academy of Neurology and the Child Neurology Society reviewed the evidence for acute and preventative treatment. They found that ibuprofen was effective in the acute treatment of migraine and acetaminophen was probably effective. They endorsed the use of sumatriptan nasal spray but did not find convincing evidence to support the use of any other oral or subcutaneous triptan.

Regarding preventive therapy, they felt that the lack of sufficient or contradictory evidence prevented them from endorsing the use of cyproheptadine, amitriptyline, divalproex sodium, topiramate, levetiracetam, propranolol, or trazodone. They were not discounting the possibility that these medications might be beneficial but merely stating that there was inadequate information available to judge their efficacy at the present time.[172] Clinicians may well have had positive experiences with these medications for specific patients.

There is emerging literature on the use of specific vitamins and minerals for headache prevention. High dose riboflavin (400 mg per day) has been found to reduce migraine frequency and appears safe. There have been no trials in children or adolescents.[173] Similarly, high dose magnesium has been shown to reduce headache frequency.[174]

In summary, there is convincing evidence that cognitive-behavioral approaches are beneficial in primary pediatric headaches, regardless of etiology. Lifestyle changes which reduce stress are noninvasive and make empiric sense although they have been infrequently studied. The evidence on analgesic and preventative medications is not as plentiful or as methodologically sound but a number of analgesics, 5-HT receptor agonists, anticonvulsants, antidepressants, beta blockers, and calcium channel blockers have been shown to be efficacious in adults and have been used with success in children.

Widespread Musculoskeletal Pain

The differential diagnosis of musculoskeletal pain is vast. Two questions can help sort out the chronic pain syndromes (such as fibromyalgia) from progressive disease. The first concerns the diffuseness of the symptom. Is the pain localized or widespread? The second concerns the child's general well-being. Does the child appear well or unwell? If the pain is localized and the child is well, the differential diagnosis includes "growing pains," CRPS, mechanical pain, pauciarticular juvenile rheumatoid arthritis, and spondyloarthropathy. If the child is unwell, the infectious arthritides should be considered. If the pain is diffuse and the child is unwell, malignancies or autoimmune diseases top the list. If the child is well, hypermobility and fibromyalgia should be considered. Red flags in the history that help us include pain in the morning, swelling, nocturnal pain not relieved by analgesics, poor growth, or bony tenderness.[175]

The distinction between fibromyalgia and other widespread musculoskeletal problems is somewhat arbitrary, particularly in children. Intriguingly, a number of studies have identified an increased association between fibromyalgia and hypermobility. Therefore, there may be more linkages between these groups than is presently assumed.[176,177] It is also important to address syndromes that are associated with hypermobility such as Ehlers-Danlos or Marfan syndromes which may have other problems associated with them.

Treatment for widespread musculoskeletal pain, whether based on fibromyalgia, hypermobility, or Ehlers-Danlos syndrome, usually has physical therapy at its cornerstone.[178] There is the attempt to restore the normal range of movement, even if the joint is hypermobile, strengthen the surrounding musculature

to add to joint stability, and improve the general level of fitness in the individual. Premedicating with an analgesic prior to therapy may be warranted as pain may promote noncompliance with the prescribed regimen. Improving the child's level of fitness may help with sleep promotion and improve his or her general sense of well-being. Bulbena and others have reported an association between hypermobility and anxiety disorder in adults and believe that the tissue disorder is a predisposing factor for trait anxiety.[179–181] Even in children without hypermobility who have chronic musculoskeletal pain, cognitive-behavioral and, if necessary, pharmacologic interventions which reduce catastrophizing and panic and promote coping are often appropriate. Finally, it is possible that the repeated microtrauma that hypermobility causes in joints and ligamentous structures and associated pain leads to disordered sensory processing. Disordered sensory processing has been identified in many individuals with widespread musculoskeletal pain. Regardless of its origin, anticonvulsants and/or antidepressants may have a role in dampening central sensitization and therefore in the management of chronic musculoskeletal pain. Eccleston and colleagues[72] report on their multidisciplinary program which emphasizes family oriented CBT, physical activity, goal setting, pacing, relaxation, and communication. It appears that models which address the disordered sensory processing and its manifestations holistically are most likely to be successful.

Complex Regional Pain Syndromes (CRPS)

CRPS1, also known as reflex sympathetic dystrophy (RSD) involves limb pain with neuropathic descriptors (allodynia, paresthesias, dysesthesias) and variable combinations of neurovascular disturbances (coldness, mottling, nonarticular swelling, cyanosis or rubor, delayed capillary refill), sudomotor disturbances, motor abnormalities (spasms, dystonia, ''jumping movements''), and trophic changes, including atrophy, abnormal hair growth, or joint contractures. Where these findings occur with clinical signs of injury to a nameable nerve trunk, the terms CRPS2 or causalgia are used. For purposes of current discussion, we will use the term RSD/CRPS to refer to these disorders inclusively.

CRPS in children and adolescents has distinct epidemiological features. It is much more common in girls than boys, it is uncommon before age 6, the apparent onset is most common from around ages 10–12, and the lower extremities are affected much more commonly than the upper extremities.[182]

For a majority of children with CRPS, an effective treatment program emphasizes patient and parent education about the nonprotective character of the pain, intensive rehabilitation that involves active exercise, resumption of weight-bearing, desensitization, and psychologic interventions based primarily on individual and family-based CBT. For some children, this can be accomplished on an outpatient basis.[183] For others who fail to improve with outpatient treatment, a next step is to do this type of multidisciplinary rehabilitation program in an inpatient or intensive day-hospital program.[184]

In adult pain medicine practice, at least in the United States, there is a considerable emphasis on early use of nerve blocks and other invasive approaches, especially sympathetic nerve blocks, spinal cord stimulation, operative, chemical, or radiofrequency sympathectomies, and more recently intravenous ketamine infusions in the treatment of RSD/CRPS. In our view, these approaches are not evidence-based in adults, and they are even less supported by evidence for children and adolescents. In a previous case series, even though some of the patients did receive regional anesthetic interventions and even though some reported benefit, there was no clear association between the duration of symptoms prior to blockade and the eventual benefit.[185]

Some pediatric case series report marked improvement in function and pain scores with no use of nerve blocks.[184] Overall, most case series suggest a good long-term prognosis for the majority of children and adolescents with CRPS. Hence, in our view, the initial therapeutic approach should be to emphasize intensive rehabilitation whenever possible.

We do make selective use of regional anesthetic approaches for patients who fail to progress despite a very good rehabilitation program and for selected patients with very severe limb swelling, dystonia, or very limited limb movement. In general, our preference is to use combined somatic-sympathetic blockade using continuous catheter approaches rather than selective sympathetic blockade or other repeated single-shot blocks. For lower extremity CRPS confined to a stocking distribution in the lower leg, our practice is to place continuous popliteal fossa sciatic perineural catheters under combined ultrasound-nerve-stimulation guidance.[186]

For lower extremity involvement in a wider distribution, we place an epidural catheter using fluoroscopy and/or nerve stimulation guidance to ensure proper dermatomal level and sidedness. For upper extremity CRPS, brachial plexus catheters are placed in either supraclavicular or infraclavicular sites using combined ultrasound and nerve stimulation guidance. For all forms of continuous regional anesthesia, catheters are placed with meticulous attention to sterile technique in the operating room, and they are tunneled to facilitate skin care and to reduce the chances for dislodgment. Prophylactic antibiotics are used. Patients are typically admitted to the hospital for infusions and intensive rehabilitation for periods of 5–8 days. While outpatient rehabilitation assisted by peripheral blockade has been described, in our view there is merit to inpatient admission to optimize intensive rehabilitation during the course of the infusions. In addition, our preference is to run higher infusion rates at nighttime and lower rates during the day to facilitate ''cycle-breaking'' at night and active mobilization during the day.

Evidence is lacking for efficacy of many types of analgesic medications commonly prescribed for adults with CRPS. Pediatric data are limited to case reports and uncontrolled case series. We do try tricyclic antidepressants and anticonvulsants for many of these patients. Responses are inconsistent.

Back Pain

Back pain is very common in adults, and a major contributor to absence from the workplace. Persistent back pain is relatively common in adolescents but uncommon in younger children, and in younger children, its occurrence mandates earlier consideration of a range of diagnostic possibilities, including infections (osteomyelitis, pyelonephritis, intervertebral discitis), tumors, and congenital anomalies of the spine and central nervous system (tethered spinal cord, diastematomyelia).[187,188]

In specialist referral practice, back pain in adolescents is commonly seen in athletes, dancers, gymnasts, and cheerleaders, and in children who are significantly overweight. For many patients with features suggestive of muscular pain and a normal neurologic exam, initial treatment should emphasize resumption of daily activities, a moderate exercise program including core stabilization and postural exercises, and avoidance of high impact, high velocity, or repetitive stresses on the spine. For patients with significant obesity, dietary counseling may be appropriate. Axial low back pain that worsens with back extension is commonly seen with spondylolysis and spondylolisthesis.[189,190] There is some support for bracing in the treatment of these conditions.[191]

Symptomatic lumbar disc disease is uncommon in children and relatively less common in adolescents. In our referral practice,

lumbar disc disease is most commonly seen in adolescent athletes. There is an extensive literature on the advantages and disadvantages of operative treatment for lumbar radiculopathy in adults; pediatric literature is mostly limited to relatively small case series, and, with few exceptions, to relatively short-term follow-up. We recently reviewed experience with fluoroscopically-guided epidural steroid injections for lumbar radiculopathy in children and adolescents. A majority of patients reported reductions in pain and improvements in straight-leg raising, and the safety profile was excellent. In 2–5 year follow-up, less than 40% of patients in this case series came to discectomy.[192]

BARRIERS TO CARE

Most health care systems are stymied by the complicated care necessary to address the issues raised by children with chronic pain. The family's search for a satisfying answer may cause them to solicit multiple opinions for the pain problem. Additionally, children with chronic pain often report pain in more than one site and, as a result, multiple specialists are often involved in their care, each one focusing on one particular pain complaint. For example, headache and abdominal pain are frequent fellow travelers. The family may seek the opinion of a neurologist for the headache and a gastroenterologist for the abdominal pain. They may seek out alternative providers such as chiropractors, acupuncturists, or naturopaths as well. Laboratory and imaging studies are frequently performed in multiple settings. The primary care provider who typically provides care coordination must collate the records, reconcile often disparate opinions, be alert to the possibility of interactions among the drugs prescribed by the myriad of involved physicians, and be on the front line to address each new symptom and concern without overmedicalizing it. Care coordination is, therefore, a critical time consuming and often unreimbursed aspect of the care for children with chronic pain and its absence is a barrier to adequate treatment.

Another problem is the lack of facilities and practitioners capable of addressing both the biologic and psychologic dimensions of chronic pain. In the outpatient arena, few individuals are comfortable addressing both realms, and multidisciplinary teams, an alternative, are often not viable economically. Inpatient facilities are rarely geared to individuals who may have both psychologic and physical problems. A busy inpatient unit with desperately ill children is not the appropriate setting for a child with chronic pain, as it tends to overmedicalize the problem. Likewise, the typical psychiatric ward is often unprepared to deal with the patient who is moaning in pain and may have an as yet undiagnosed medical illness.

Finally, the inherent vagueness and poignancy of the symptom of persistent pain often leads families to seek out additional opinions and to feel that their search is never quite completed. This can create uneasiness between provider and patient which may interfere with the therapeutic alliance.

CONCLUSION

Persistent pain is a relatively common experience for children and may stem from a variety of causes: ongoing organic disease, persistence of pain which resulted from organic disease, as well as disorders whose primary manifestation is pain. Regardless of its origin, however, it has significant impact on the child and his or her family. In general, the goal of the clinician is to identify red flags for organic disease and if not present, focus on symptom reduction and increasing function. Specific attention should be given to sleep, mood, school, activity, and family functioning. Typical interventions include analgesia, physical therapy, cognitive-behavioral strategies, and other medications targeted to specific symptoms. Success in the management of chronic pain should be monitored by improvement in function and not specifically through immediate reduction in pain intensity.

CHAPTER 55 ■ PAIN IN THE OLDER PERSON

PAUL ARNSTEIN AND KEELA HERR

OVERVIEW

Medical science continues to expand its capacity to forestall death. As a result, people are living longer but increasingly spend their final years with daily, unrelenting pain.[1–3] Pain is emerging as a more formidable foe than death, whose conquest will demand stretching the limits of our technology and ability to provide compassionate care. The number of pain-producing surgical interventions and outpatient procedures is increasing, as is the prevalence of chronic diseases like arthritis, diabetes, and cancer.[4] Because of its increasing incidence, high economic costs, and negative impact on quality of life of patients and their families,[5] uncontrolled pain has become a public health priority.

Those over age 65 make up the fastest growing segment of our population, as the number of older adults in the United States doubled to 35 million between 1960 and 2000. Estimates have that number doubling again in less than 30 years as the "baby boomers" permeate this age group. The number of centurions are growing at an even faster pace, as their numbers have doubled between 1990 and 2006.[6] Longevity is being enjoyed around the world, but "it is very hard to be reflective, perceptive, and wise when. . .everything hurts." [7] Although not all older adults have severe or ongoing pain, a majority do when they seek health care services.[8–12]

The Prevalence of Pain in Older Adults

Delineating the prevalence of pain with advancing age is a challenge because epidemiologic studies differ in the age cut-points, methods of data collection, and the types of pain studied. A national telephone-based survey in the United States asked people of

all ages about current, recent, and persistent discomforts. Older adults reported similar prevalence rates of current pain as their younger counterparts. Among respondents over age 65 who had current pain, almost 60% indicated that it lasted for at least a year. This was significantly more than their younger and middle-aged counterparts (37% and 44%, respectively).[3] Despite evidence that the incidence of persistent* pain peaks in the middle years,[13] other studies support that over age 60 people are twice as likely as younger counterparts[14]; and by 80, adults are three times more likely to have persistent pain than those under 18 years of age.[15]

PAIN IN THE OLDER PERSON

Impact of Pain on Functioning and Quality of Life

Overall, 25% to 50% of community-dwelling seniors are estimated to have pain that interferes with normal function.[16] Residents of long-term care facilities have even higher rates of impaired functioning from unresolved pain with estimates as high as 80%.[17] Unrelieved pain interferes with nutrition and sleep, which may contribute to the overall decline in health and function observed in people with pain. Combined with impaired physical health, the decline in social and recreational activities produces emotional distress, contributing to depression[18] which is capable of worsening both pain and disability.

Physiologically, aging alters functions, including a degeneration of peripheral neuronal structure[19] that slows transduction and transmission involved in signaling pain.[13] Once pain is established, the lower density of descending inhibitory circuits[20] and an impaired ability to recover from hyperalgesic or allodynic states[21] is attributed to aging. The decline in function of the endogenous antinociceptive mechanisms as well as the capacity to reverse spinal and supraspinal sensitization[22] places older patients at greater risk for developing persistent pain following an illness, surgery, or trauma.[23]

Physiologic changes in the cardiovascular system increase myocardial demand, producing tachycardia, hypertension, and a risk of hypercoagulation in response to pain. Combined, these increase the risk of cardiac damage during a heart attack.[24] Hormonal, metabolic,[25,26] and immunologic suppression resulting from pain can worsen the primary disorder[27] and/or increase the risk of infections, poor healing,[28] atelectasis, or pneumonia.[29]

Severe acute postoperative pain also appears to put the older adult at risk for the development of persistent pain.[30,31] Prospective studies of older adults after hip surgery demonstrated the link between more postoperative pain and prolonged length of stays with more complications, poorer participation in rehabilitation therapies, and poorer functional outcomes at 6 months.[10] Avoiding opioids or using subtherapeutic doses actually increases the risk of delirium. Cognitively intact patients with undertreated pain are nine times more likely to develop delirium than patients whose pain is adequately treated.[32]

Psychologically, similar patterns of beliefs about pain and coping strategies are seen across adulthood.[13] Affective distress, like anxiety and depression, is linked to higher pain intensity levels regardless of age as pain and decreased physical/mental functioning occur when pain is severe or persistent. Although a decline in functional abilities, strength, and balance can occur with aging, the rate and extent of deterioration is more pronounced in those with pain.[33–35]

Undertreatment of Pain in Older Persons

Given these potentially serious pain-related consequences, evidence that pain is commonly undertreated or untreated in older adults is disturbing. Among those with pain, a significant portion of those over age 65 do not receive analgesics, including over a quarter of older adults with cancer pain,[36] almost 30% of institutionalized elders,[12,37] 40% of elders with hip fracture in the Emergency Department,[8] and 40% to 80% of elders living with pain in the community.[38–40]

The diagnosis and treatment of pain in older persons is more difficult in those who present with multiple medical problems and a history that reveals many potential sources of pain. Although there is an undeniable need to prevent harm from pain-relieving treatments, this focus must be balanced with a concerted effort to avoid pain-induced harm. Guidelines for the assessment, treatment, and monitoring of older patients with pain have been widely distributed advocating for individualized approaches to pain and balancing concerns for the safety and efficacy of treatments.[40–42]

It is time to replace unrealistic fears and mistaken beliefs with guidelines that delineate prudent, safe, effective use of available treatments. Perhaps the greatest opportunity for improvement is halting the practices of using placebos as a proxy for mind/body therapy[43] or recommending treatments such as acetaminophen alone for severe pain knowing that would be ineffective for the types of discomfort experienced.[44]

Change in Pain Threshold and Tolerance

Over a dozen studies have investigated the effect of aging on pain threshold with some inconsistency in findings.[13] Although inconclusive due to methodological heterogeneity, evidence supports an age-related increase in thresholds to thermal, pressure, and electrical stimulation.[22,45] Although it is possible that ischemic pain thresholds are lower,[13] other research concludes that pain thresholds consistently differ in the direction of elevated thresholds with age whether or not levels of statistical significance are achieved.[22]

Age differences in the perception of painful stimuli have been assessed using direct, indirect, and multimethod forms of testing. Despite a contrary finding,[46] older persons rate mild suprathreshold thermal stimuli as less intense and unpleasant than do younger subjects.[47,48] At higher intensities, however, older adults rate the stimulus as more intense and unpleasant than do younger subjects.[49] This pattern supports the notion that with advancing age, pain threshold increases while tolerance of pain decreases.

Several other investigators have also found a lower tolerance for experimentally-induced pain in older adults. Conflicting research exists here as well, with some investigators failing to find a difference in pain tolerance attributable to age.[50,51] It is likely that in addition to age, interacting attributes such as gender, genetics, affect, motivation, social, and cultural factors play a role in determining the amount of pain any individual would tolerate in the context of a research study. In clinical settings, comorbid conditions, numerous psychosocial factors, and medications are likely to further influence pain threshold/tolerance levels.

Clinical Presentation of Acute Pain

Although common characteristics of acute pain (e.g., pattern, onset, duration) are relevant, an important distinction in older

*The terms chronic pain and persistent pain are often used interchangeably to denote pain that lasts for more than 3 months. Persistent pain is used in this text to avoid negative connotation often associated with the label "chronic pain," as is recommended by the American Geriatrics Society.

adults is that pain may be absent or atypical in acute infectious, metabolic, or traumatic disorders. Acute myocardial infarction (MI) almost always presents with severe chest pain in younger adults. In older adults, however, it may be asymptomatic, referred in an atypical pattern, or present with vague signs like confusion, restlessness, aggression, anorexia, and fatigue.[52] Up to 30% of older adults with MI report an absence of acute symptoms, while another 30% (especially women) have an atypical presentation.[53] Similar age patterns have been documented in the presentation of different gastrointestinal disorders.[54,55]

Persistent Pain

Older adults may be more vulnerable to the development of persistent pain after an acute illness or injury. A clear example is the risk of developing postherpetic neuralgia. Increasing age is the greatest predictor of postherpetic neuralgia, with one study calculating that adults over age 50 were 15 times more likely to have pain 1 month after the initial shingles reactivation than younger counterparts.[56] Among patients over age 70, half have pain for at least 1 year, compared to 3% of those under 60 years old.[57]

The risk of developing persistent pain after a low back strain, surgery, or trauma is not clearly linked to age[58]; however, persistent musculoskeletal pain clearly increases with advancing age. Osteoarthritis of the knee, hip, foot, back, neck, and shoulder account for a majority of cases.[59] Conditions with widespread persistent pain, like fibromyalgia, peak in prevalence in the seventh decade, then decline.[60–62] This decline in pain with advanced age may be related to the tendency of people living with regional or widespread pain to die at a younger age than their pain-free counterparts.[63]

Cancer Pain

Older adults make up the largest proportion of cancer patients, with many reporting moderate to severe pain.[64] Among institutionalized older adults with cancer, risk factors for higher levels of pain include being widowed, deemed terminal, and having impaired physical or mental functioning.[36] It could be argued that some of the impaired functioning was actually a consequence of intense pain, known to have a detrimental effect on physical, psychologic, social, and spiritual functioning.[65]

Older adults are at risk for inadequate pain control because of either their own reluctance to take analgesics or that of professionals who prescribe and administer these medically necessary drugs.[36,66] It is unconscionable that 26% of older adults with daily cancer pain do not receive any analgesics.[36] The greatest risk of cancer pain is during active treatment of the disease and at the end of life, which can be prevented or effectively relieved in a majority of cases.[67] Even metastatic bone pain, the most common cause of persistent cancer pain,[68] has analgesic and adjuvant options that are underutilized.

ASSESSMENT OF PAIN IN THE OLDER PERSON

Clinical Evaluation of Pain

Without self-report, pain often goes undetected and subsequently untreated. Thus, methods of assessment must be used to identify pain in all patients. Like patients in other age groups, self-report of pain is the criterion standard for assessment. The numeric rating scale, verbal descriptor scale, and faces pain scale are the most established tools for the alert, cognitively intact older adults. The Iowa Pain Thermometer demonstrated comparable results to these scales and was most preferred by a sample of older adults.[69]

There is some evidence, however, that these one-dimensional scales are ineffective screening tools for a substantial segment of the population, including older persons. Krebs and colleagues[70] found in a primary care setting that about 40% of patient visits were for pain and over a third of patients were seeking care because of disabling pain. Routine use of the numeric rating scale revealed a "no pain" score for 28% of those presenting for pain and 21% of patients with pain-related disability.[70] Examining the Minimum Data Set that is required for all U.S. nursing home residents, 94% scored "0" on the pain scale, despite research that consistently estimates between 45% to 80% of residents have pain.[71]

These scales can be used more effectively in older persons by addressing sensory deficits (uses eyeglasses, hearing aids, large font/bold print written tools, etc.) and determining understanding of the scale before using it.[72] Responder burden can be reduced by using simply worded tools with few items (e.g., numeric rating scale or verbal descriptor scale when possible). Showing the older adult a printed version while explaining the assessment tool is recommended.[72] The revised Faces Pain Scale is preferred by some older adults[73] and validated versions are available in 31 languages.[74] The Brief Pain Inventory (BPI) is useful in many settings as it records dimensions of pain in addition to intensity (e.g., interference with functionality). A short version of BPI was recently validated to facilitate assessing older adults in long-term care settings.[75]

It is useful to adopt a few validated tools for use in clinical settings to accommodate needs of different patients. When a patient has difficulty understanding the first-line scale, back-up methods are available. It is critical to allow sufficient time for older patients to process questions and formulate responses before accepting or rejecting one tool as the best. Once the best pain assessment tool for a particular patient is found, all team members (including caregivers) need to use it consistently for all pain assessments. Follow-up assessments after interventions intended to relieve pain should be conducted at intervals aligned with anticipated peak of desired or adverse effects, as "current pain" measures are more accurate than pain recall. In addition to evaluating analgesic effects, assessing adverse effects evaluate the safety of the treatment.

Evaluation of Pain in Research

The verbal descriptor scale, numeric pain rating scale, revised faces pain scale, and Iowa Pain Thermometer have high completion rates, good validity, and acceptable reliability for use in researching older adults with pain. The visual analog scale, however, is more difficult for older adults to complete[76] and has more measurement error,[77] with as many as 30% of cognitively intact elders unable to use this scale.[78] To get a more comprehensive measure of the effect of treatments, the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) group recommends measuring pain intensity, physical, and emotional functioning, as well as the participant's perception of overall improvement.[79] Visit the group's website at www.IMMPACT.org for useful tools and recommendations.

The McGill Pain Questionnaire (MPQ) measures the sensory, affective, evaluative, and miscellaneous components of pain.[80] Although older adults consistently rate sensory and affective components of their pain lower than younger counterparts, the validity, reliability, and subscale distinctions of the MPQ are similar in young and older persistent pain populations.[13] The short form of the MPQ (SF-MPQ)[81] is similarly appropriate, with no apparent age-related measurement errors.[78] An expanded and revised version of this short form (SF-MPQ-2) has been validated and is in the process of being published. The revised faces pain scale is the tool for measuring intensity preferred by many older adults,

including those who are from ethnic minorities or those with mild–moderate cognitive impairment.[73,82]

Nonverbal, Cognitively Impaired Older Adults

When the patient is unable to reliably self-report the presence or nature of pain due to severe cognitive impairment or critical illness, clinicians rely on a combination of assessment strategies to fill this void. Measures of pain behaviors are often combined with surrogate reports from those who know the patient best and the patient's response to analgesics. Even if the patient is unconscious, intubated, or chemically paralyzed, the clinician's understanding of the pain typically associated with the medical conditions/procedures allows them to make assumptions, termed "Assume Pain is Present" to guide pain prevention and treatment interventions regardless of cognitive/verbal abilities.[83,84] A good history and physical examination provides information on pain-related diagnoses and conditions that support a judgment of pain present.

A large number of behavioral pain assessment tools have been developed for use in this population in the last decade; however, there is a lack of consensus about recommending one tool for use with all patients. The characteristics of the specific patient sample and the setting are important in selecting an appropriate behavioral measure. Readers are referred to the following website for information and critiques of existing English behavioral tools: http://prc.coh.org/elderly.asp. For example, The Pain Assessment in Advanced Dementia tool rates pain (0–10 scale) based on breathing, vocalizations, facial expressions, body movements, and consolability and may be useful for repeated observations of patients that present with common pain-related behaviors.[83] However, this instrument will miss or underestimate pain in patients whose presentation of pain is manifested as a change in daily activities, interpersonal interactions, or mental changes and use of a tool that incorporates these factors, such as the Pain Assessment Checklist for Seniors with Limited Ability to Communicate, may be more appropriate when monitoring for more subtle changes in behavior suggestive of pain.[85] Adding surrogate reporting of pain by people who know the patient best or observing the response to empirical treatment with analgesics has merit in this population.[84]

Behavioral Indicators of Pain

Among the behaviors displayed by people unable to communicate their pain, facial expression is often the first or most common indication of pain,[86] and it may be the only one. Common facial expressions suggestive of pain include grimacing, clenched teeth, and tightly shut eyes. Other common behavioral indicators of pain are:

- Vocalizations, such as moaning, groaning, crying or screaming
- Immobilization, guarding, holding, or rubbing the hurt body part
- Stiff or awkward movements (e.g., limping)
- Mental status changes including depressed mood, irritability, or confusion
- Changes in interpersonal interactions, ranging from withdrawn to aggressive
- Changes in activity patterns or routines

Purposeless body movements, such as tossing and turning in bed or flailing extremities, can also indicate pain. The patients should be observed for evidence of pain-related behaviors unique to that individual during activities known to be painful (e.g., injections, dressing changes, repositioning).

PHARMACOLOGIC TREATMENT OF PAIN IN OLDER PERSONS

Pharmacokinetics and Pharmacodynamics Associated With Aging

With the exception of the rectal route, the rate of medication absorption is typically not affected by aging. The pattern of drug distribution does change because of less total body water, and more body fat is seen in older adults. This favors the distribution and accumulation of lipophilic (fentanyl) agents, while decreasing that of hydrophilic (morphine) drugs. The decline in serum protein concentrations with age can increase the bioavailability of drugs, like nonsteroidal anti-inflammatory drugs (NSAIDs), that are highly protein-bound.[11,13] This effect is magnified when patients take multiple medications that displace NSAIDs from protein binding sites, further increasing free serum concentration of the active analgesic.

This protein binding can also slow the metabolism and excretion of NSAIDs that is already compromised due to the smaller size, lower blood flow, and reduced function of the liver with age. These hepatic changes, combined with fewer drug-metabolizing enzymes, increase drug elimination time and slow the metabolism required to produce active metabolites. Reductions in renal size, glomerular filtration rate, and renal blood flow raise the risk of side effects and toxicity to drugs that accumulate due to slowed elimination of the unchanged drug as well as active and toxic metabolites.[11] NSAIDs can further contribute to this slowed clearance by lowering renal blood flow and glomerular filtration rate through its antiprostaglandin effect.

Pharmacodynamic changes have also been noted with aging. The density and sensitivity of mu receptors change and often increase sensitivity to both the desired and undesired effects of opioids.[11,13] Combined with other age-related changes in the neurologic and pulmonary systems, there is a greater risk of sedation and respiratory depression with the initial administration of opioid analgesics. These collective pharmacokinetic and pharmacodynamic changes warrant using lower doses and longer dosing intervals with advanced age, especially with known hepatic or renal impairment.

Safe, Effective Use of Nonsteroidal Anti-Inflammatory Drugs in the Older Person

Acetaminophen is considered the safest nonopioid analgesic and is the first-line analgesic of choice for older patients[16] when pain is mild or moderate. Compared to other nonopioids, it has similar or lower analgesic potency without gastroduodenopathy or an effect on platelet function. When combined with warfarin, overanticoagulation can result.[87] Persistent excessive use of acetaminophen may impair renal function and cause hepatotoxicity, especially in patients with chronic alcoholism and liver disease or in patients who drink three or more alcoholic beverages per day. Dosage limits of 2–3 g per day will minimize the risk of renal or hepatic toxicity. However, because acetaminophen is included in many drug compounds, care must be taken to avoid inadvertent exposure.

Concerned that medication-related problems are a leading cause of hospitalization and death among older adults, Dr. Mark Beers and a team of leading gerontologists developed a list of 48 medications and drug classes that should be avoided in older adults, regardless of frailty. As a class, all NSAIDs (both nonselective and COX-2 selective) made the list with a "high severity" designation, as did the individual agents indomethacin and ketorolac.[88] An estimated 10% to 20% of older adults are prescribed NSAIDs, which account for 3300 deaths and 41,000 hospitaliza-

tions in the United States annually,[89] mostly from gastrointestinal (GI) bleeding. Within the class, ibuprofen appears to have the best efficacy and GI safety among widely available oral NSAIDs. Diclofenac sodium and naproxen have intermediate (doubled) risks, while piroxicam and ketorolac have the greatest (four-fold) risk of GI ulcerations or bleeds.[90,91]

NSAIDs will also worsen established hypertension, congestive heart failure, and renal impairment. Renal dysfunction, a history of aspirin hypersensitivity, serious skin disorders (e.g., Stevens-Johnson syndrome), anticoagulant therapy, a history of organ transplantation, blood disorders (e.g., coagulopathy, neutropenia), hypertension, or congestive heart failure often disqualifies patients as candidates for NSAID therapy. The risk of taking NSAIDs when patients are on warfarin, digoxin, anticonvulsants, or oral antidiabetic agents needs to be carefully considered and avoided when possible.

The COX-2 selective NSAIDs appear to have less risk of GI ulcerations and bleeding in the elderly than do nonselective NSAIDs.[91] However, the GI safety advantages of COX-2 selective NSAIDs are significantly reduced when used in combination with low-dose aspirin in high doses, with multiple NSAIDs, or after a year of continuous therapy. The COX-2 inhibitors have no advantages in regard to renal function compared to nonselective agents.

The occurrence of rare but serious cardiovascular events and skin problems prompted a withdrawal of rofecoxib from the worldwide market in September of 2004. Valdecoxib was later voluntarily withdrawn from the market amid evidence of similar problems. In a retrospective analysis of a large cancer prevention study, rofecoxib has been found to double the risk of endpoints that include fatal and nonfatal heart attacks, strokes, and deaths from unknown causes. These events declined slowly, remaining significantly elevated for at least a year after rofecoxib was discontinued.[92] Celecoxib remains on the U.S. market, with other COX-2 agents available elsewhere, awaiting the definitive research delineating whether these risks are drug-specific or a drug-class effect.

Safe Nonsteroidal Anti-Inflammatory Drug Product Selection and Monitoring Use

The decision to use a NSAID in the management of persistent pain in older adults requires individualization considering comorbidities, concomitant medications, and associated risk factors with benefits outweighing the risks. If short-term NSAID therapy is considered and GI risk is considered low, it may be reasonable to select ibuprofen or naproxen.

Prolonged NSAID therapy should be used with extreme caution, and baseline and periodic monitoring for these potential problems and occult GI bleeding is recommended. Given an analgesic ceiling, patients are started at a low dose and asked to record the analgesic effect for 1–2 weeks before increasing the dose. If, after titrating to a higher dose, there is no analgesic advantage, return to the lower dose.

To lessen the risk of GI and renal toxicity, urge the patient to drink a full glass of water with the NSAID and maintain adequate hydration throughout therapy. If therapy extends over a few weeks or longer, a gastroprotective drug, such as a proton pump inhibitor (PPI) or misoprostol, is advised.[93] For patients at highest GI risk (history of ulcers), the use of a COX-2 inhibitor with a PPI is considered.[93] Patients who are taking aspirin for cardioprotective purposes need special consideration since some NSAIDs (e.g., ibuprofen) inhibit its cardioprotective actions and increase GI risk. In general, NSAIDs with the highest safety margin should be used in the lowest effective dose for the shortest duration after acetaminophen is deemed inadequate or contraindicated.[94]

Other options for high-risk patients include nonacetylated salicylates or topical NSAIDs and may have better safety margins than more traditional options.[95,96] Choline magnesium trisalicylate has advantages of minimal GI toxicity, no effects on platelets, a twice daily dosing regimen and is available in pill or liquid form.[96] Topical agents are particularly beneficial when pain is localized as it places a higher concentration at the target tissue, has fewer systemic side effects, and enjoys a high degree of acceptance by many older persons. Topical options include an expanding variety of NSAIDs, opioids (e.g., morphine gel), adjuvant, and experimental options.[97]

Safe, Effective Use of Opioids in the Older Person

Potential Risks of Opioid Analgesics

Opioid therapy is the cornerstone of treatment for moderate and severe levels of pain. Opioids must be used cautiously in older adults who have increased sensitivity to their effects,[98] especially in the presence of renal or hepatic dysfunction.[99] The most serious risk is respiratory depression, which occurs infrequently when opioids are dosed and titrated cautiously.[16] Respiratory depression is more common with acute or intermittent therapy rather than long-term opioid therapy. The greatest risk is during the first day of opioid therapy and during periods of dose escalation. At greatest risk are patients with pre-existing respiratory dysfunction, including chronic obstructive pulmonary disease, emphysema, kyphoscoliosis, severe obesity, or cor pulmonale. Especially concerning is the tendency of older adults to experience oxygen desaturations at night due to sleep apnea.[99] As many as 30% of older adults with sleep apnea who take opioids are at risk for these respiratory effects.[100] Methadone in particular is associated with a higher risk for sleep-related problems.[101]

Opioids can also cause peripheral vasodilatation which may produce orthostatic hypotension and a corresponding risk of falling. Endocrine and immune system suppression occurs with opioids, the significance and reversibility of which in the older adults is currently being investigated.[102,103]

Still, long-term use of opioids poses a lower risk of life-threatening events than sustained NSAID therapy.[16] The most common side effects, with the exception of constipation, diminish over the first couple of weeks of therapy. Several days at a steady dose without visual or cognitive impairment should be evident before advising patients to resume driving or other potentially dangerous activities. Reluctance to prescribe opioid drugs has probably been overinfluenced by political and social pressures to control illicit drug use.[16] Although substance abuse, diversion, and addiction disorders do occur in older adults,[104] many are deprived prescriptions or refuse them because of overstated risks.

One active area of research is that of opioid-induced hyperalgesia, a phenomenon linked to high-dose, long-term opioid therapy. Over the course of treatment, patients become more sensitive to pain or develop new areas of pain in addition to a loss of the drug's original potency.[105] Awareness of this phenomenon has stimulated much debate and research into the best ways to treat patients on long-term opioids. One strategy is to limit the dose and duration of opioid therapy; another is to switch patients to a different opioid. The incidence, effects, and prevention strategies pertaining to opioid-induced hyperalgesia in the older adult remain to be elucidated.

Opioids to Avoid in Older Adults

The revised Beers Criteria do not identify the class of opioids as high risk, but do list propoxyphene, meperidine, and pentazocine as drugs to avoid in older adults.[88] Pentazocine often leads to central nervous system excitement, confusion, and agitation, and its use should be avoided in frail older patients. Propoxyphene is no more effective than acetaminophen, yet has been associated with the same adverse effects as other opioid drugs. A year-long

prospective study of over 350,000 older adults found a two-fold increased risk of hip fractures among older adults taking propoxyphene compared to nonusers, with a dose-response relationship.[106] Propoxyphene typically is combined with high-dose acetaminophen, adding liver toxicity to its list of potential problems.

Although the duration of meperidine analgesia is 4 hours or less, its toxic metabolite normeperidine has approximately a 30 hour half-life, which is even longer with impaired renal function. At doses of 600 mg per day or when used for more than 48 hours, the risk of neurotoxicity-induced seizure is high. Normeperidine can also cause tremulousness, dysphoria, myoclonus, and a potentially fatal interaction with monoamine oxidase inhibitors.[107] Methadone did not make the most recent Beers Criteria list of medications to avoid in older adults, but due to its complex pharmacokinetics, its link to hypertension and sleep apnea, caution is advised in older adults.[101,108] It should be used only by clinicians with considerable clinical experience with this drug.[16,109] Despite these disadvantages, methadone is a valuable tool that helps carefully selected and monitored patients with refractory pain at a relatively low cost.

Safe Product Selection and Use of Opioids

Oxycodone and morphine are probably the best first-line opioid agents for an opioid naïve patient with acute pain. The adage, start low–go slow, would have the prudent clinician starting as low as 2.5 mg oxycodone, 5 mg oral morphine, or 1–2 mg parenteral morphine, and then basing adjustments on the individual response. Morphine can be titrated more quickly than other agents, but generally the short-acting opioids are titrated on a daily basis and long-acting formulations can be safely titrated once or twice a week.[109] Hydrocodone is another reasonable first-line option; however, it is available only in fixed-dose combinations with acetaminophen and has less than ideal pharmacokinetic properties for older adults. Tramadol is commonly chosen, but it has low potency and an association with seizures that requires cautious patient selection and attention to potential drug-drug interactions.[109]

In Europe, buprenorphine is emerging as a potential first-line opioid with desirable pharmacokinetic and pharmacodynamic properties in older adults. Labeling and prescribing restrictions in the United States preclude it from being used widely; however, it merits consideration for expanded use in the future. Buprenorphine is a potent opioid with partial mu-agonist and kappa-antagonist activity.[110] The absorption, distribution, metabolism, and excretion of buprenorphine, as well as the ceiling to its respiratory depressant effects, make it a good choice for older adults. The transdermal buprenorphine patch is ideally suited for older adults, although it is not yet commercially available in the United States.[111]

Safe, Effective Use of Adjuvants in the Older Person

Adjuvant analgesics include a variety of agents with analgesic activity whose primary use and indication is other than for pain. Many of these adjuvants are used "off-label" and have been found clinically useful for specific pain conditions.[112] These drugs may be used alone or in combination with analgesics to treat persistent pain conditions, particularly neuropathic pain. Amitriptyline is the best studied adjuvant for pain, but it should be avoided in the elderly due to its cardiac, anticholinergic, and sedative effects.[88] Nortriptyline or desipramine are better choices with a 75% lower incidence of side effects at comparable doses.[112] Duloxetine, a selective serotonin and norepinephrine reuptake inhibitor, has approved labeling for certain pains and appears to be a better tolerated antidepressant for older adults.

Antiepileptic drugs are first-line agents to treat neuropathic pain in older persons.[113,114] Gabapentin and pregabalin have labeled indications for specific neuropathic pain disorders. Lower toxicity and fewer drug-drug interactions increase these drugs' usefulness in the older population. Due to a risk of somnolence, mental clouding, and dizziness, dosing should be initiated as low as 100 mg at bedtime and cautiously titrated upward. Carbamazepine also has U.S. Food and Drug Administration-approved labeling for trigeminal neuralgia, but like many older antiepileptic agents, drug-drug interaction, liver, and hematologic toxicity make them less than ideal in older adults.

Many other adjuvant drugs can be used in the older adult for their coanalgesic effect or to offset side effects of pain relievers. They may be selected for their general ability to reduce pain, such as a local anesthetic, or based on targeted (e.g., alpha-2-adrenergic, GABA-B) receptors where they work.[113] Targets vary considerably based on the underlying pathology; however, for each agent selected, they must start at a low dose, with careful titration, and have frequent monitoring to establish their safety and efficacy before adding, subtracting, or adjusting other medications.

ADDITIONAL TREATMENTS FOR PAIN OF OLDER PERSONS

Pharmacologic management is the foundation of pain treatment in most settings; however, alone, medication(s) often fall short of providing optimal pain reduction and functional improvement. In addition to medical management, there are many other approaches to pain relief that add benefit to the treatment plan. In conventional medicine, there are physical or psychosocial (cognitive/behavioral) modalities often provided by a physical therapist, physiatrist, or psychologist. Additional complementary and alternative medicine (CAM) approaches are also utilized for the prevention and control of pain. Integrated, multidisciplinary pain treatment programs are likely the most beneficial in optimizing the outcomes when pain is complex and refractory to initial treatment attempts.

Physical Modalities

Physical approaches to pain control range from highly technical interventional approaches to simple applications of heat/cold, orthotics, electrical stimulation, or therapeutic exercise. Among modalities offered by physical therapists, active techniques, like therapeutic exercise and aquatic therapy, work better for older adults than passive approaches like superficial heat, transcutaneous electrical nerve stimulation, and acupuncture.[115] The dry and fragile skin of some older adults may contribute to discomfort, irritation, or even tearing of skin when removing pads. Therefore, good hydration, extra gel, or cream at the electrode site and caution when removing the pads from the skin may improve tolerance of that modality. Caution to protect the skin of older adults also comes into play with the topical application of heat and cold or during massage techniques.[116]

Interventional approaches can provide significant benefit to older adults whose severe, disabling pain is not responsive to less invasive measures. Proper selection and precise performance of the specific procedure is needed, as is vigilant monitoring of patient response. For many nerve blocks, the major life-threatening complication is intravascular injection, thus many providers will use fluoroscopic verification of needle placement before injections.[117] Older adults are more likely to have contraindications to certain injections, such as anticoagulation, uncontrolled diabetes, and progressive neurologic disorders. New innovations like the X-Stop (Medtronic Spine, LLC, Memphis, TN), kyphoplasty, and vertebroplasty interventions are providing less invasive options

for vertebral disorders (e.g., spinal stenosis, vertebral compression fractures) that are more common in older adults.[118]

Psychosocial Approaches to Pain Control

Psychosocial (cognitive/behavioral) modalities may focus on altering the patient's thoughts, feelings, or behaviors in a way that reduce pain, stress, and emotional distress. Specific techniques include education and counseling, distraction, coping skills training, and facilitating emotional disclosure. There are a variety of techniques such as relaxation, imagery, and hypnotherapy that help people. Although older adults are less likely to be referred for these forms of therapy, they benefit from cognitive-behavioral therapy,[119] relaxation, and biofeedback training.[120] Despite limited research, it appears that older patients with persistent pain benefit substantially from coping skills training.[121–123]

Older adults do better when interventions are tailored to meet their specific needs (multimodal presentation, addressing needs of visual or auditory impairment, involving spouses/caregivers, etc.).[119] Although these and other psychosocial modalities help many older persons, there are some who may be physically or mentally inappropriate candidates for specific techniques.[116]

Complementary and Alternative Medicine Approaches to Pain Control

A variety of CAM approaches are used by older adults to relieve pain. Patients may use the terms holistic, natural, home remedy, or "Eastern Medicine" to refer to these techniques. Given that more than 60% of persons over age 50 use CAM approaches, professionals need to ask patients about their use of these methods in a nonjudgmental manner that encourages honest, full disclosure. The National Center for Complementary and Alternative Medicine recognizes five categories[124] of approaches: Alternative Medical Systems, Mind-body Medicine, Biologically-based Therapy, Manipulative and Body-based Practices, and Energy-based Medicine. Back pain is the most common condition for which CAM approaches are used, with pain accounting for 6 out of the top 10 reasons people use these approaches.[125]

Perhaps some people turn to CAM to give them a greater sense of control or to feel less dependent on a doctor, a pill, or a procedure. Close to 40% of patients however, seek CAM therapies because of a failure to benefit from conventional medicine or a lack of access to medicine due to costs.[125] Many older persons have embraced the use of biological therapies such as glucosamine/chondroitin, S-adenosyl-L-methionine, and Devil's claw, which have potency comparable to NSAIDs with less toxicity. However, some herbal remedies have been tainted with drugs or heavy metals.[126,127] More commonly, interactions between medications and herbal remedies occur.[128]

Multidisciplinary Pain Treatments

Multidisciplinary pain treatment programs are underutilized for older adults with pain[129]; although studies have not found age-related differences in treatment expectations, acceptance, compliance, or drop-out rates.[130] Subtle, and likely unintentional, age biases prevent many qualifying older adults from being admitted to these programs.[130] Multidisciplinary pain clinics have better outcomes in terms of pain reduction, functional improvement, and lower health care utilization than those who receive only single-modality interventions.[131] Although the cost-benefit ratio has not clearly been delineated for older adults, there is no compelling evidence to suggest that they should be denied such treatment. In fact, the potential adverse effects of untreated pain and/or polypharmacy suggest that multidisciplinary treatment should be considered for all geriatric patients with significant pain complaints.

CONCLUSION

Certainly, there are risks when treating older adults with severe or persistent pain. In fact, the undertreatment of pain is an important risk that can contribute to physical harm, mental despair, and social isolation during what has been dubbed "the golden years." Although much remains to be learned, we currently have sufficient knowledge to improve the way pain is assessed and treated, while refining methods to further improve the safety and efficacy of pain relief efforts.

Clear consistent assessment methods are needed by choosing and using tools validated for older adults. The patient's understanding of the tool should be validated so that meaningful information is gathered and recorded. When planning interventions, a shared decision-making approach is appropriate, where patients and their loved ones are informed of the risks, benefits, and variable responses typical for particular treatment options. This shared decision-making engages the patient as an active participant in the treatment process and educates them about desired and undesired effects that may be encountered and need to be recorded.

Cautious drug and dose selection is needed for the older adult. Lower starting doses and longer dosing intervals are justified until the patient's response to analgesics is known. Monitoring the patient's response early in therapy for side effects, drug (or herbal) interactions, and toxicity is important, especially for those with comorbid conditions that add risks. Continued monitoring for older adults on sustained treatment is important as several late-onset toxicities (e.g., GI bleed, hypertension, liver/renal impairment, opioid-induced hyperalgesia) may not emerge until months or years of therapy have passed.

The prudent use of nonoperative interventions (e.g., nerve blocks) and nondrug or CAM therapies should be considered for older adults with persistent pain. Given the breadth of options available to treat pain, allowing it to go untreated in older adults is erroneous. Whereas not all treatments are good options for older adults, failing to treat pain is unacceptable, especially for those who are so vulnerable to the harmful effects of unrelieved pain.

CHAPTER 56 ■ OBSTETRIC PAIN

CYNTHIA A. WONG

HISTORICAL NOTES

Childbirth pain is arguably the most severe pain most women will endure in their lifetimes. The modern era of childbirth analgesia began in 1847 when Dr. James Young Simpson administered ether to a woman in childbirth and later, in the same year, chloroform. The use of analgesia for childbirth aroused violent opposition from some physicians, the public, and the clergy.[1] Simpson was labeled a heretic, blasphemer, and an agent of the devil. The furor died down somewhat in 1853, when John Snow successfully administered chloroform to Queen Victoria for the birth of her eighth child.

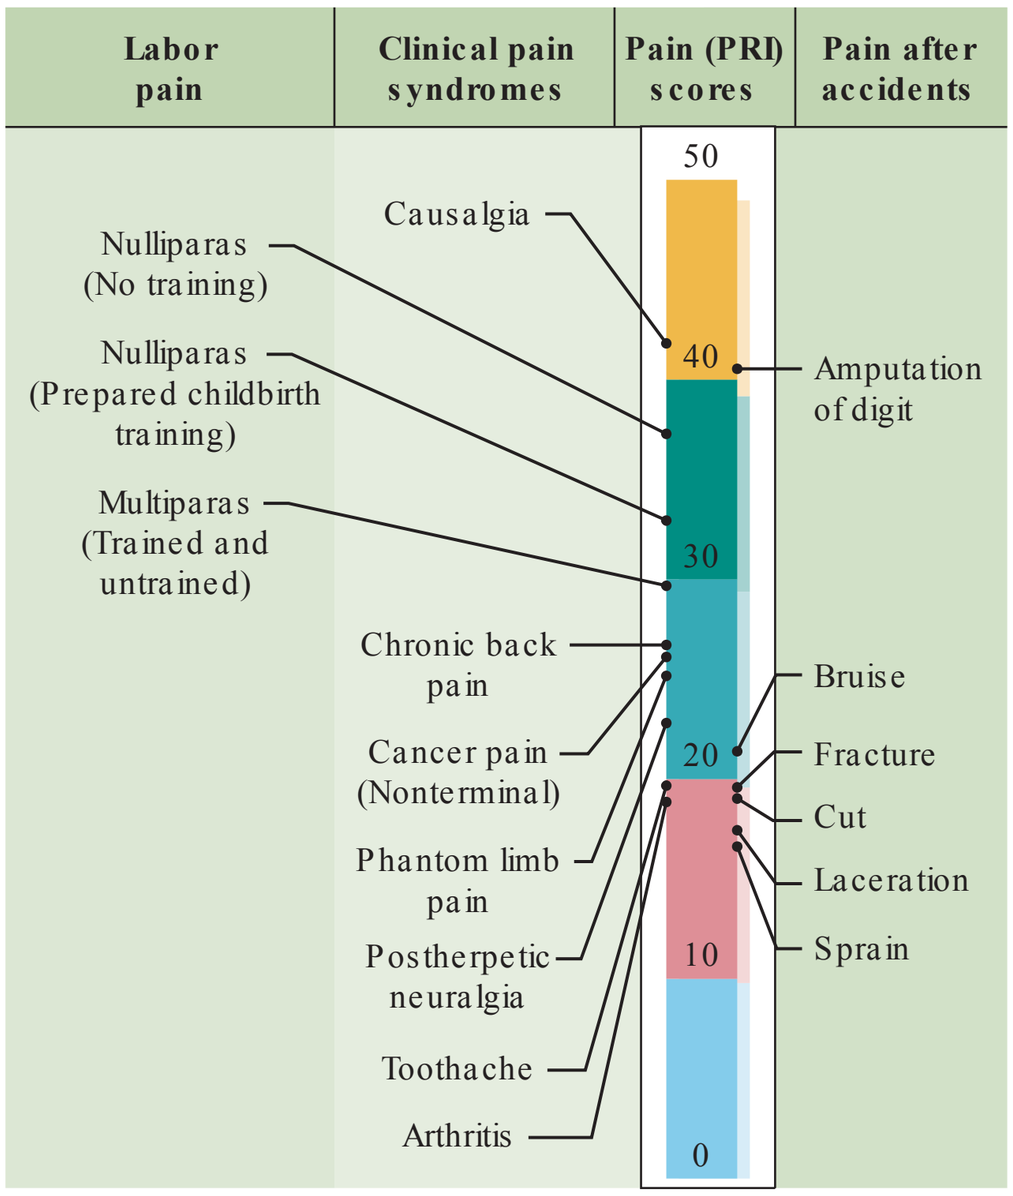
In the ensuing years, public opinion regarding obstetric analgesia began to change, thus forcing the medical community to offer analgesia. Women enthusiastically embraced labor analgesia. Fanny Longfellow, the wife of poet Henry Wadsworth Longfellow and the first woman in the United States to receive labor analgesia in the modern era, wrote that "This is certainly the greatest blessing of this age."[2] Pain began to lose its theological connections.[3] It was no longer considered punishment for sin or divine retribution. Instead, disease and pain were considered biologic processes that could be studied and treated.

Following this auspicious beginning in the 19th century, however, childbirth analgesia was largely neglected by the medical community. The next major step occurred in the early 20th century when *Dämmerschlaf*, or "twilight sleep," was introduced in Europe.[4] The combination of scopolamine and morphine was enthusiastically accepted by women, but not by the medical profession. Medical professionals expressed concern about the effect of childbirth analgesia on the progress of labor. In addition, with the advent of twilight sleep, physicians began to appreciate that anesthetics cross the placenta and had potentially adverse effects on the newborn. This was the stimulus for Virginia Apgar, an anesthesiologist, to develop an evaluation tool to assess neonatal well-being in 1953.[5] A salutary effect of the Apgar score was that scientific studies comparing the effects of different anesthetic techniques on neonatal outcome were now possible.

Regional anesthesia was first introduced in 1884, when Carl Koller described the use of cocaine to anesthetize the eye.[6] Descriptions of regional anesthesia, including spinal, lumbar epidural, caudal, paravertebral, and pudendal nerve blocks, were published in the obstetric literature between 1900 and 1930.[3] In the 1930s and 1940s, John G. P. Cleland contributed to our understanding of the innervation of the uterus and applied this knowledge to regional anesthesia in the care of the obstetric patient.[7] Continuous neuraxial analgesia, as it is practiced today, had its birth in 1943, when Robert A. Hingson and Waldo B. Edwards published the first report of continuous caudal analgesia for childbirth.[8] Flexible, disposable catheters replaced the original malleable needles, and refinements were made, and continue to be made, in technique, drugs, doses, and delivery techniques.

Although other regional nerve block and systemic analgesic techniques are often used for analgesia, women continue to request neuraxial labor analgesia for childbirth at ever increasing rates. In the most recent survey performed in 2001, over 60% of women in large maternity hospitals in the United States received neuraxial analgesia during labor.[9] Similarly, spinal or epidural anesthesia accounts for over 95% of the anesthetics for elective cesarean deliveries. Multimodal analgesic therapy, which often includes a regional technique component, is the norm for postcesarean analgesia. This chapter will summarize the physiology of childbirth pain, physiologic changes of pregnancy that influence the provision of analgesic and anesthetic care, specific labor analgesic techniques, the effects of analgesia on the mother and infant, and the treatment of nonobstetric pain during pregnancy and lactation.

PAIN OF CHILDBIRTH



Although it is a common observation that parturients vary in the amount of pain and suffering associated with labor and vaginal delivery, few well-designed studies on the prevalence, intensity, and quality of labor pain have been performed. Melzack et al.[10] used the McGill Pain Questionnaire to assess childbirth pain. The mean total pain rating index (PRI) was 34 for nulliparous and 30 for parous women. Significant differences were also found between nulliparas and parous women in the sensory qualities of pain. Labor pain scores were 8 to 10 points higher than those associated with cancer pain, phantom limb pain, and postherpetic neuralgia (Fig. 56.1A), although there was a wide range of scores ranging from mild to excruciating (Fig. 56.1B).

Childbirth Pain Mechanisms and Pathways

Most data support the concept that the pain of the first stage of labor originates predominantly in the cervix and the lower uterine segment, rather than the body of the uterus. Dilation of the cervix and lower uterine segment results in distension, stretching, and tearing of tissues. During the late first stage and second stage of labor, the descent of the fetus and intense stretching and tearing of the tissues of the vagina and perineum become additional sources of pain.

Based on animal and human studies, Cleland concluded that the sensory afferents from the uterus and cervix that transmit pain during the first stage of labor enter the spinal cord at T11 and T12 (Fig. 56.2).[7] He demonstrated that these visceral sensory afferents are intermingled with sympathetic efferents by demonstrating that bilateral paravertebral lumbar sympathetic blockade abolished the pain of the first stage of labor. Second stage pain from descent of the fetus in the birth canal is primarily somatic in nature and is transmitted through sacral nerves to the S2 through S4 segments of the spinal cord.

Bonica[11] used a series of discrete nerve blocks of various nociceptive pathways, including paracervical, segmental epidural, caudal, and transsacral blocks, to further refine our knowledge of the nerve pathways that transmit labor pain to the central nervous system. He demonstrated that the upper part of the cervix and lower uterine segment are supplied by afferents that accompany the sympathetic nerves through the uterine and cervical plexus, the inferior, middle, and superior hypogastric plexuses, and the aortic plexuses. The nociceptive afferents then pass to

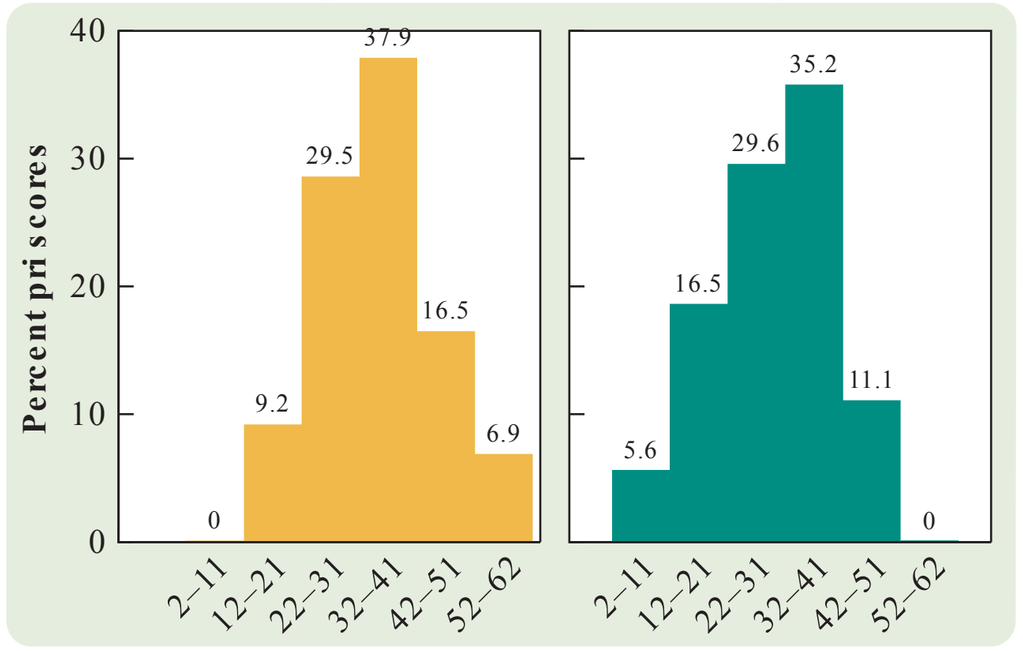


FIGURE 56.1 **A.** Comparison of pain scores using the McGill Pain Questionnaire obtained from women during labor and from patients in general hospital clinics and an emergency department. The PRI represents the sum of the rank values for all words chosen from 20 sets of pain descriptions. **B**. Distribution of PRI scores from nulliparous and parous women in six intervals of the total PRI range. (Redrawn after Melzack R. The myth of painless childbirth (the John J. Bonica lecture). *Pain* 1984;19(4): 321–337, with permission.)

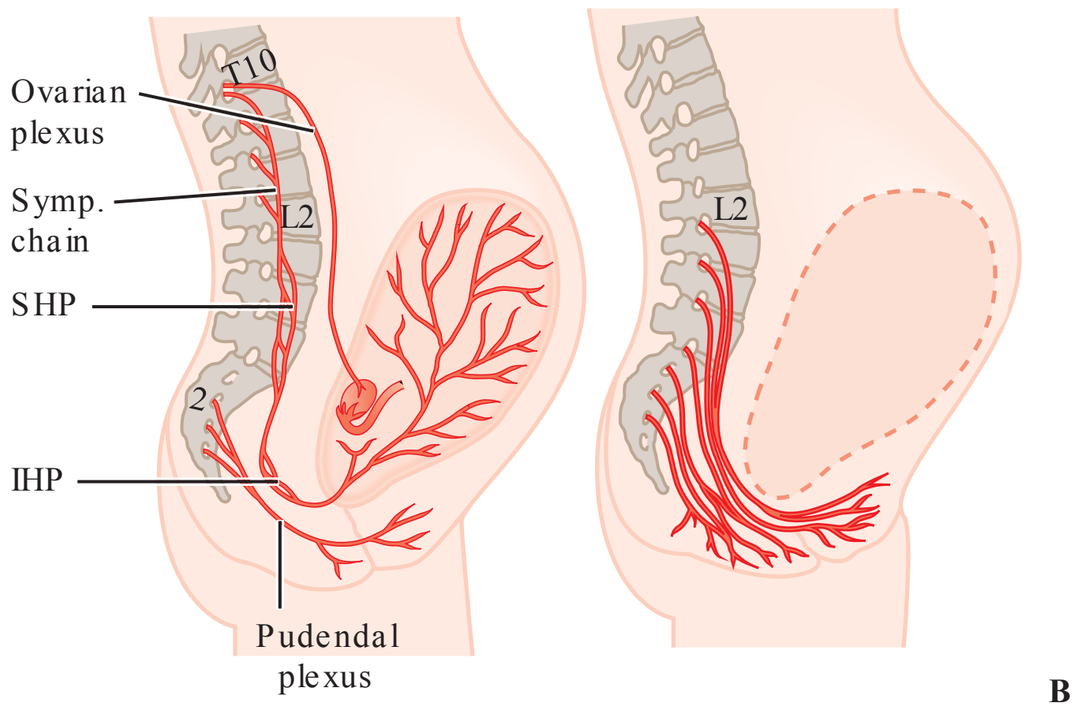

FIGURE 56.2 Schematic depiction of the peripheral nociceptive pathways involved in the pain of childbirth. **A**. The uterus, including the lower uterine segment and cervix, is supplied by afferents that pass from the uterus to the spinal cord by accompanying sympathetic nerves through the cervical plexus, the superior and inferior hypogastric plexuses (SHP, IHP), the lumbar and lower thoracic sympathetic chain, and to the T11, T12, and L1 nerve roots. The vagina and perineum are supplied by afferents that travel to the spinal cord via the pudendal nerve to the S2 through S4 nerve roots. **B**. The nerves involved in the transmission of nociceptive impulses are provoked by noxious stimulation of pelvic structures.

the lumbar sympathetic chain and course cephalad through the lower thoracic sympathetic chain via the rami communicantes of the T10, T11, T12, and L1 spinal segments. Finally, they pass through the dorsal roots of these nerves to make synaptic contact with the interneurons of the dorsal horn.

Typical of pain arising from viscera, the pain of the first stage of labor is often referred to the T10 through L1 dermatomes. Additionally, during the late first stage and second stage of labor, some parturients experience referred pain to the lower lumbar and sacral dermatomes as a result of stimulation of pain-sensitive structures within the pelvic cavity and pressure on one or more roots of the lumbosacral plexus. The pain may be severe if the fetus is in an abnormal position.

Visceral C-fibers transmitting pain during the first stage of labor terminate in the spinal cord in a loose network of synapses in the ipsilateral, superficial, and deep dorsal horn and the ventral horn, as well as crossing the midline to the contralateral dorsal horn with extensive rostrocaudal extension.[12] In contrast, somatic afferent fibers tend to terminate in the ipsilateral superficial laminae of the dorsal horn with minimal rostrocaudal fiber extension. This explains the diffuse localization of visceral first stage labor pain compared to somatic second stage labor pain. It may also explain why the neuraxial administration of lipid soluble opioids in early labor provides complete analgesia, as these drugs penetrate deeply into the spinal cord.

Understanding the anatomic basis of the transmission of labor pain underlies the current treatment of labor pain using regional anesthesia techniques. The visceral pain of the first stage of labor can be blocked with bilateral cervical plexus, lumbar sympathetic blocks, or central neuraxial blockade. The somatic pain caused by descent of the fetus in the birth canal can be blocked with bilateral pudendal nerve blocks or neuraxial blockade.

Our current understanding of the neurophysiologic basis of labor pain is superficial at best. Better understanding of the pain pathways, neurotransmitters, and receptors involved in labor pain will open up new avenues for the treatment of labor pain in the future.

Factors That Affect the Pain of Childbirth

In addition to physiologic factors such as intensity, duration, pattern of contractions, and descent of the fetus, the amount or degree of pain and suffering associated with childbirth is influenced by physical, psychologic, emotional, and motivational factors.

Physical factors that are associated with the severity and duration of childbirth pain include age, parity,[13] history of previous pain or dysmenorrhea, fatigue, the condition of the cervix at the onset of labor, and the relationship between the size and position of the fetus to the size of the birth canal. Generally, an older nullipara experiences longer and more painful labor than a

younger nullipara.[10] The cervix of parous women begins to soften even before the onset of labor and is less sensitive than that of the nullipara. The intensity of uterine contractions in early labor tends to be higher in nulliparous compared to parous women, whereas the reverse is true as labor advances. Pain is greater in the presence of dystocia caused by a contracted pelvis, a large baby, or abnormal presentation or position. Women who go on to require cesarean delivery following a period of labor have more breakthrough pain[14] and require more epidural[14] and systemic[15] analgesia during labor than women who deliver vaginally.

Psychologic factors, such as fear, apprehension, and anxiety, also influence the degree of pain and suffering during childbirth.[16] The presence of family members[17] or birthing companions[18] during labor and delivery may decrease anxiety and positively affect the progress of labor. Education, intense motivation, and cultural influences can influence the affective and behavioral dimensions of pain, although they probably minimally affect actual pain sensation. Bonica[19] observed women who had had predelivery training in psychoprophylaxis manifested little or no pain behavior during childbirth, although when questioned the next day, most of them indicated the process had been quite painful. Jewish health providers rated the labor pain of Jewish women higher than that of Bedouin women who were delivering in the same institution,[20] whereas the level of pain assessed by the women themselves was not different.

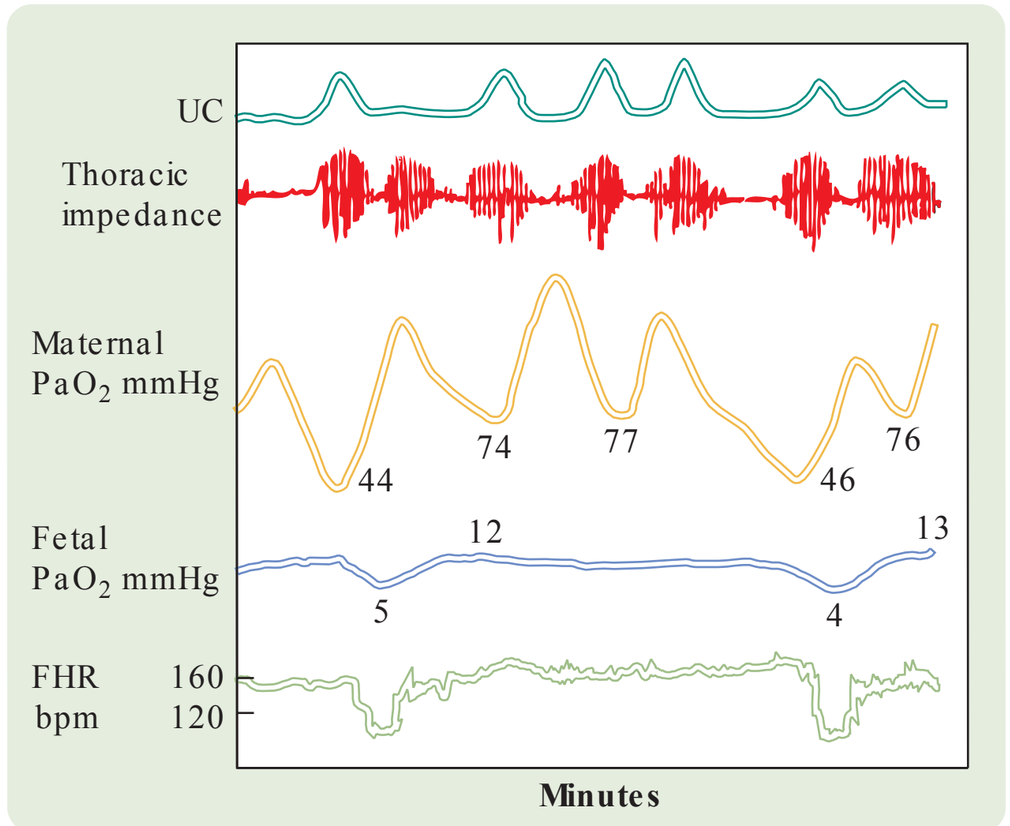

FIGURE 56.3 Continuous recording of uterine contractions (UC), maternal thoracic impedance, maternal transcutaneous oxygen tension (PaO_2), fetal oxygen tension, and fetal heart rate (FHR) in a nullipara breathing room air 120 minutes before spontaneous delivery. Marked hyperventilations during uterine contractions were followed by hypoventilation or apnea between contractions. After the first and fourth contractions, the maternal PaO_2 fell to 44 and 46 mm Hg, with a consequent decrease in fetal PaO_2, and variable decelerations, which reflect fetal hypoxemia. (Redrawn after Huch A, Huch R, Schneider H, et al. Continuous transcutaneous monitoring of fetal oxygen tension during labour. *Br J Obstet Gynaecol* 1977;84[Suppl 1]:1–39.)

Effects of Pain on the Mother and Fetus

Labor and vaginal delivery produce tissue damage and, similar to tissue injury from other causes, result in pain and local segmental, suprasegmental, and cortical responses. These responses include marked stimulation of the respiration and circulation, as well as the hypothalamic, autonomic centers of neuroendocrine function, limbic structures, and psychodynamic mechanisms of anxiety and apprehension. These may have a deleterious impact on the mother, fetus, and newborn. Many of these responses are mitigated by effective pain relief.

The pain of childbirth is a powerful respiratory stimulus, resulting in a marked increase in minute ventilation and oxygen consumption during contractions.[21] Compensatory periods of hypoventilation between contractions cause transient maternal hypoxemia and, potentially, fetal hypoxemia (Fig. 56.3). Maternal hyperventilation causes severe respiratory alkalosis and a left shift of the maternal oxyhemoglobin dissociation curve, thus diminishing oxygen transfer to the fetus. The pain and stress of labor activates the sympathetic nervous system, resulting in an increase in plasma catecholamine concentrations, cardiac output and blood pressure (Fig. 56.4). Epinephrine and norepinephrine levels increase by 200% to 600% during unmedicated labor,[22] and this increase is associated with a decrease in uterine blood flow. Pain and anxiety and the accompanying increased catecholamine levels may contribute to prolonged or dysfunctional labor.[23] Epinephrine is a tocolytic, and physicians have long observed that an apparent dysfunctional labor pattern can be corrected with effective analgesia.[24] Finally, unrelieved severe pain can produce serious mental health disturbances that may interfere with maternal–fetal bonding, future sexual relationships, and contribute to postpartum depression,[10] and, rarely, posttraumatic stress disorder.

The healthy parturient easily tolerates the large increase in cardiac work, but parturients with heart disease, severe preeclampsia, or pulmonary hypertension may not tolerate these changes without adverse outcome. Similarly, the healthy fetus tolerates the changes in uterine blood flow; however, these changes may be deleterious in the setting of uteroplacental insufficiency (e.g., preeclampsia, intrauterine growth retardation).

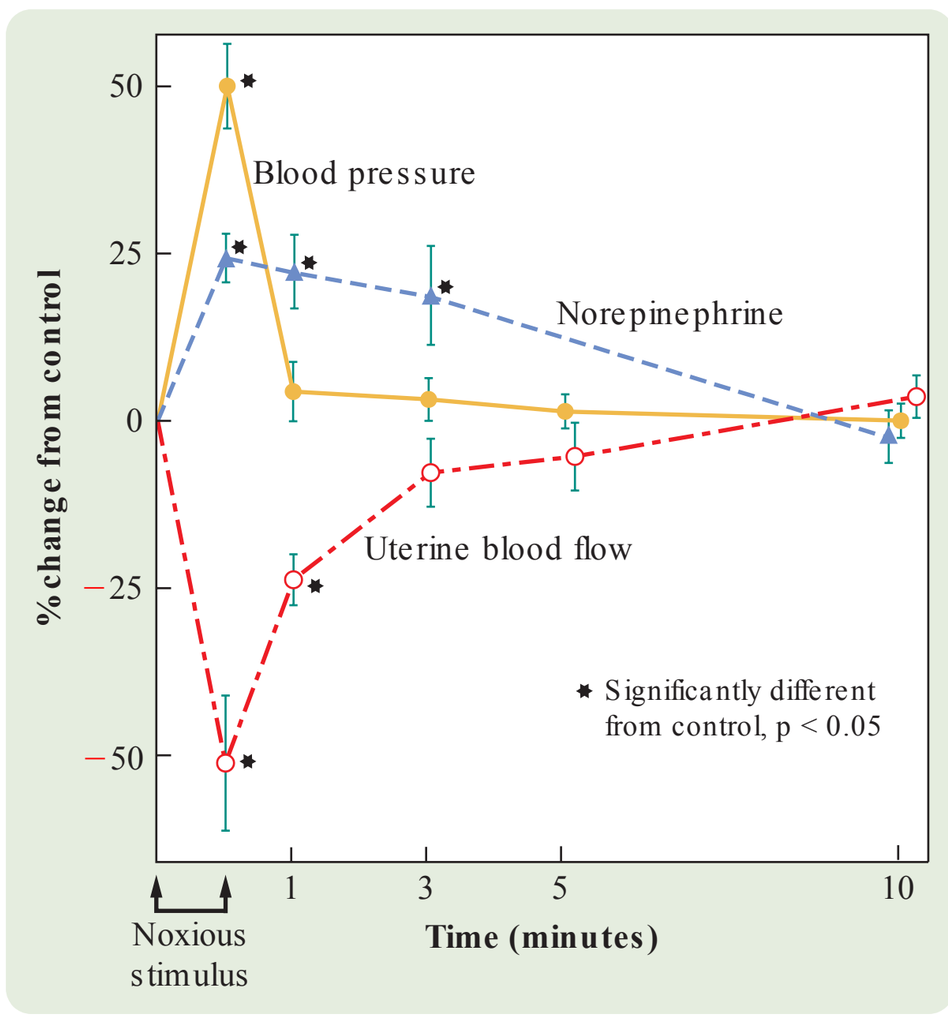

FIGURE 56.4 Effect of noxious stimulus (application of an electric current to the skin) on maternal arterial blood pressure, norepinephrine blood level, and uterine blood flow in a pregnant ewe. The increase in arterial pressure is transient and the decay in norepinephrine level is more protracted and is reflected by a mirror image decrease in uterine blood flow. (Redrawn after Shnider SM, Wright RG, Levinson G, et al. Uterine blood flow and plasma norepinephrine changes during maternal stress in the pregnant ewe. *Anesthesiology* 1979;50(6):524–527, with permission.)

In summary, there is large individual variation in how women experience childbirth pain and suffering. Pain associated responses to noxious stimuli during childbirth are net effects of highly complex interactions of various neural systems, modulating influences, and psychologic factors. These interactions are responsible for the complex physiologic, behavioral, and affective responses that characterize the pain of childbirth.

PHYSIOLOGIC CHANGES OF PREGNANCY

Pregnancy is associated with significant anatomic and physiologic changes. Many of these changes impact the treatment of pain during pregnancy, parturition, and the puerperium. Safe care of these women requires a thorough understanding of these changes and their impact on the treatment of pain. In addition, a thorough understanding of the fetal–placental complex is necessary for the safe care of the fetus and neonate. These changes and their anesthetic implications are summarized in Table 56.1 and discussed below.

Respiratory Changes

Pregnancy is associated with anatomic and physiologic changes involving the airway, lung volumes, ventilation, and the dynamics of breathing. Capillary engorgement, an increase in upper airway soft tissue mass, and enlargement of the breasts contribute to making endotracheal intubation more difficult in pregnant compared to nonpregnant women.[25] Failed intubation and pulmonary aspiration (often associated with difficult airway management) are the most common causes of anesthesia-related maternal mortality.[26] Therefore, in addition to the ability to provide complete analgesia, continuous neuraxial labor analgesia has the added benefit of avoiding the need for general anesthesia and endotracheal intubation should emergency cesarean delivery be required.

Oxygen consumption, carbon dioxide production, and minute ventilation increase during pregnancy.[27] Functional residual capacity (FRC) decreases[28] and closing capacity may exceed FRC in supine pregnant women at term. Obesity, recumbency, and anesthesia (neuraxial or general) further decrease FRC.

During parturition, minute ventilation and oxygen consumption increase markedly, and hyperventilation results in P_aCO_2

TABLE 56.1

PHYSIOLOGIC CHANGES OF PREGNANCY AND ANESTHETIC IMPLICATIONS

Physiologic change	Anesthetic implication
Respiratory	
Increase in O_2 requirement and CO_2 production	Greater risk of desaturation after induction of general anesthesia
Decrease in FRC	Greater risk of desaturation after induction of general anesthesia
Cardiovascular	
Hyperdynamic: increased reliance on sympathetic nervous system	Increase in incidence and severity of hypotension after neuraxial analgesia/anesthesia
Decreased responsiveness to vasoactive agents	Require higher doses of vasopressors to correct hypotension
Aortocaval compression	More profound hypotension with parturient in the supine position
Aortocaval compression and engorgement of azygous veins	Less epidural space and decreased egress of drugs from the epidural space result in lower requirement for epidural drugs
Central nervous system	
Increased lumbar lordosis and decreased thoracic kyphosis	Decreased size of lumbar interspinous space and altered movement of anesthetic agents within CSF
Rotation of pelvis	Tuffier's line more cephalad
Widening of the pelvis	Spine more "head-down" in lateral position
Decrease in CSF volume	Decrease in local anesthetic dose requirements
Decrease in CSF specific gravity	Altered baricity of spinal anesthetic solutions
Increase in CSF pH	Change in proportion of un-ionized drug
Increased susceptibility to all anesthetics	Decrease in anesthetic dose requirements
Increased progesterone levels	Increased pain threshold
Pharmacokinetics	
Altered volume of distribution	Change in drug pharmacokinetics
Altered protein binding of drugs	Change in drug pharmacokinetics
Increased renal blood flow	Change in drug elimination
Altered hepatic microsomal enzyme activity	Change in drug metabolism

values as low as 10 to 15 mm Hg.[29] Maternal aerobic oxygen requirements exceed oxygen consumption resulting in a progressive maternal lactic acidemia.[30]

Cardiovascular Changes

The cardiovascular system is hyperdynamic during pregnancy. Total blood volume increases by approximately 50% during pregnancy,[31] as does cardiac output (Fig. 56.5).[27] Plasma volume increases more than red cell mass, resulting in the physiologic anemia of pregnancy.[31] Organ perfusion is markedly increased, particularly perfusion of the uterus. Systolic blood pressure falls minimally, whereas diastolic pressure decreases by approximately 20%.[27] Both return to prepregnant levels at term. Hemodynamic stability is more highly dependent on sympathetic nervous system activity[32] and arterial responsiveness to vasopressors is reduced.[33]

Aortocaval Compression

At term, compression of the aorta and vena cava by the gravid uterus in the supine position results in decreased right ventricular preload and a 10% to 20% decrease in cardiac output compared to the standing position.[34] Vena cava compression begins as early as 13 to 16 weeks' gestation and is nearly complete at term (Fig. 56.6).[35] Partial aortic compression in the supine position results in decreased blood flow to the pelvis and lower extremities. Aortic compression is completely relieved by the lateral position,[36] whereas partial caval decompression is still present.[35] However, in the lateral position, collateral circulation through the azygous system maintains venous return and cardiac output.[37] The left lateral position is superior to the right lateral position for maintenance of venous return.[38]

During labor, cardiac output increases due to increased central blood volume secondary to autotransfusion during uterine systole and because of increased sympathetic nervous system activity. Due to the adverse effects of aortocaval compression, parameters of fetal well-being deteriorate when parturients labor in the supine compared to lateral position.[39] Adverse effects may be more profound in the parturient with neuraxial blockade induced sympathetic blockade.

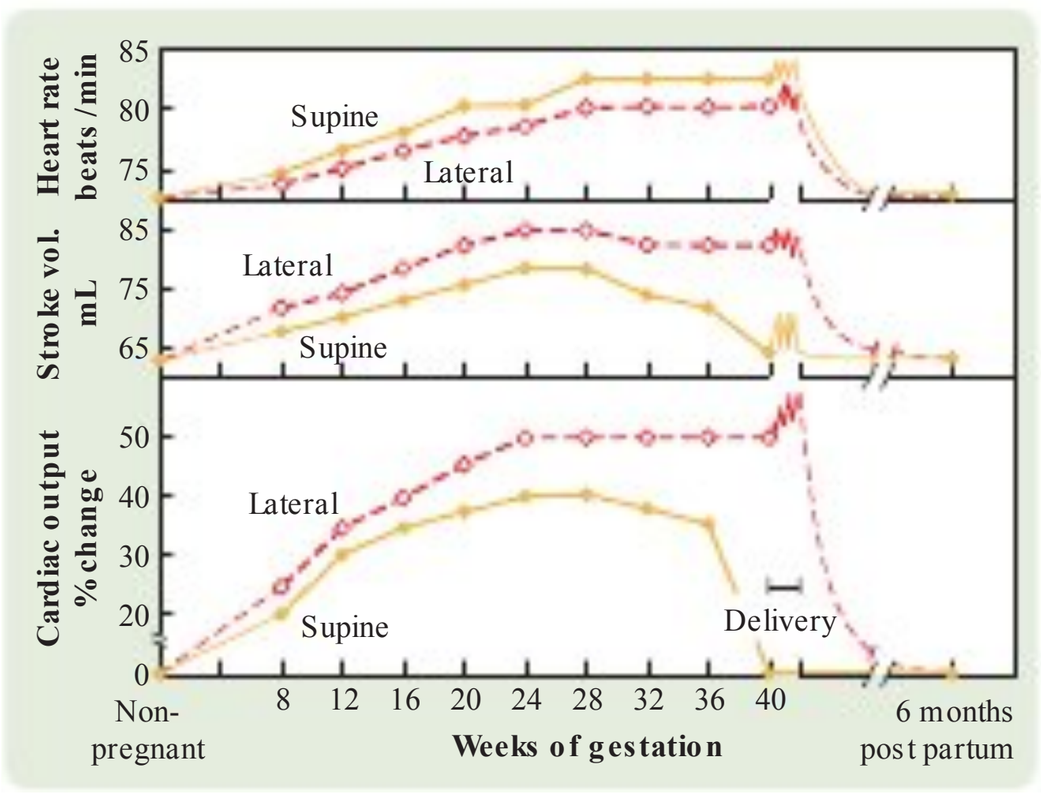

FIGURE 56.5 Changes in heart rate, stroke volume, and cardiac output during pregnancy and in the puerperium. (Redrawn after Bonica JJ. Obstetric analgesia and anesthesia, 2nd ed. Seattle: University of Washington Press; 1980:5, with permission.)

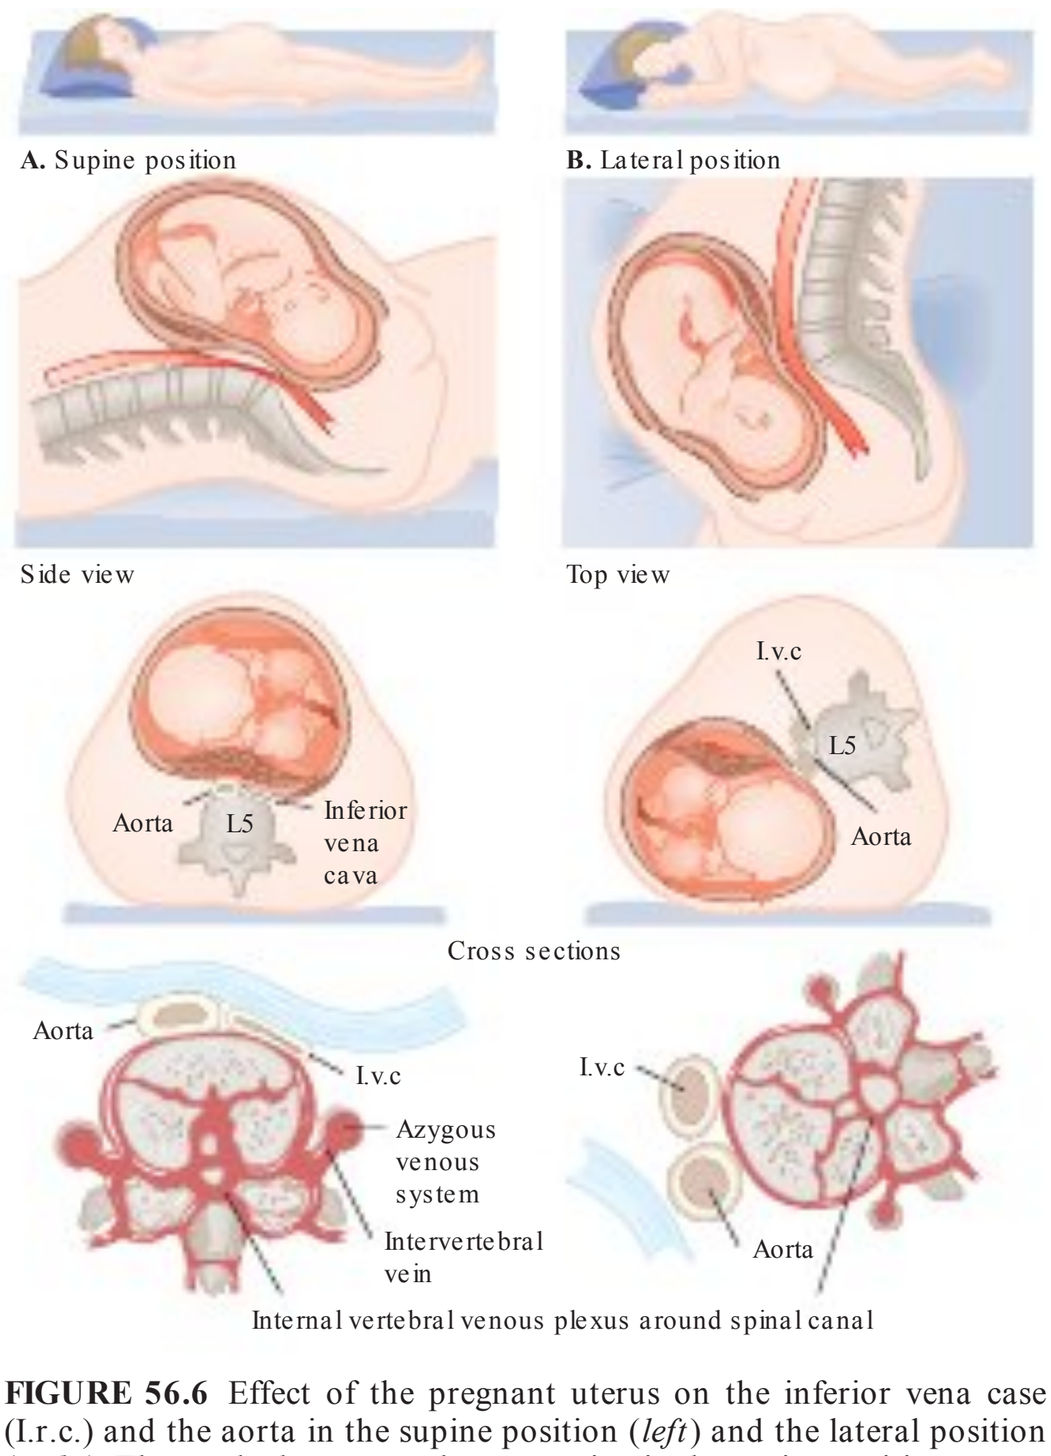

FIGURE 56.6 Effect of the pregnant uterus on the inferior vena case (I.r.c.) and the aorta in the supine position (*left*) and the lateral position (*right*). The marked aortocaval compression in the supine position causes venous blood to be diverted to and through the vertebral venous plexus, which becomes engorged and reduces the size of the epidural and subarachnoid spaces. (Redrawn after Bonica JJ. Obstetric analgesia and anesthesia, 2nd ed. Seattle: University of Washington Press; 1980:8, with permission.)

Implications for Labor Analgesia

Shunting of lower extremity blood through the azygous system results in venous engorgement in the epidural space. This functionally reduces the size of the epidural and subarachnoid spaces, thus reducing the amount of anesthetic necessary to produce neuroblockade. Sympathetic blockade in the term parturient (e.g., as a consequence of neuraxial analgesia/anesthesia) results in a marked decrease in blood pressure compared to nonpregnant control subjects.[40] Pregnant women may require higher doses of vasopressors compared to nonpregnant individuals to treat hypotension.[33]

Central Nervous System Changes

Anatomy of the Spinal Column and Analgesic Implications

Anatomic and physiologic changes in the nervous system alter responses to pain and susceptibility to both general and regional anesthesia. Specifically, anatomic changes in the spinal canal may affect neuraxial anesthesia techniques. The epidural and vertebral foraminal veins are enlarged, resulting in an increased risk of intravascular injection. Additionally, there is decreased nonvascular space in the spinal canal and decreased egress of epidural anesthetic agents from the epidural space. Engorged epidural veins[41] and increases in abdominal pressure[42] are associated with

a decrease cerebral lumbosacral cerebral spinal fluid (CSF) volume.

Anatomic changes also occur to the ligamentous and bony structures of the vertebral column. The hormonal changes of pregnancy may cause the ligamentum flavum to feel less dense and "softer" in pregnant women compared to nonpregnant patients; thus, it may be more difficult to feel the passage of the epidural needle through the ligamentum flavum. Progressive accentuation of lumbar lordosis during pregnancy alters the relationship of surface anatomy to the vertebral column. The line joining the iliac crests (Tuffier's line) assumes a more cephalad relationship to the vertebral column and accentuated lumbar lordosis results in less space between adjacent lumbar spinous processes. The apex of the lumbar lordosis is shifted caudad during pregnancy, and the typical thoracic kyphosis in women is reduced in pregnant women.[43] This may influence the spread of hypo- or hyperbaric intrathecal anesthetic solutions in supine patients.

Subarachnoid dose requirements may also be affected by the lower specific gravity of CSF in pregnant compared with nonpregnant women[44] and the higher CSF pH.[45] Widening of the pelvis may lead to a relative head-down position in women in the lateral position; thus, affecting movement of hypo- or hyperbaric anesthetic solutions in the CSF. Because of the gravid uterus, it may be more difficult for a pregnant woman to achieve flexion of the lumbar spine. Finally, labor pain may make it difficult for women to assume and maintain an ideal position while the anesthesiologist initiates neuraxial anesthesia.

Neurohormonal Changes and Analgesic Implications

Pregnancy-induced neurohumoral changes may alter responses to pain. Lower plasma substance P concentrations[46] and higher CSF progesterone levels[47] are found in pregnancy. In a rat model, the pregnancy-associated increased concentration of plasma β-endorphin was associated with an increased tolerance to visceral stimulation and this effect was reversed by naloxone.[48] Pain thresholds are increased during pregnancy[49] and labor.[50] Both peripheral and central nervous tissue from pregnant animals (including human) appears to be more susceptible to many different analgesic and anesthetic agents, including local anesthetics, volatile anesthetic agents, and thiopental. Possible mechanisms of enhanced neural blockade during pregnancy include potentiation of the analgesic effect of endogenous analgesic systems, hormone-related changes in the actions of spinal cord neurotransmitters, increased permeability of the neural sheath, or other pharmacodynamic or pharmacokinetic differences between pregnant and nonpregnant women.[51]

Together, these anatomic and physiologic changes result in a 25% reduction in the segmental dose requirement for spinal anesthesia,[47] and a similar segmental dose reduction for epidural anesthesia.[52]

Pharmacokinetic Changes

Pregnancy alters disposition of drugs by several mechanisms. Volume of distribution may be altered. For example, the elimination half-life of thiopental is markedly prolonged secondary to a large increase in the volume of distribution.[53] Plasma protein concentration decreases, leading to altered drug binding.[54] For example, lidocaine is less protein bound during pregnancy, resulting in a higher free fraction in the blood.[55] Increased renal blood flow and glomerular filtration and altered hepatic microsomal activity change renal and hepatic drug clearance.

Uteroplacental Unit

Blood flow to the uterus increases markedly during pregnancy, from 50 to 100 mL/minute before pregnancy, to 700 to 900 mL/minute at term. Uterine blood flow (UBF) is directly related to uterine perfusion pressure and indirectly related to uterine vascular resistance.

$$\text{UBF} = \frac{\text{uterine arterial} - \text{uterine venous pressure}}{\text{uterine vascular resistance}}$$

UBF is not autoregulated; therefore, decreases in uterine arterial pressure (systemic hypotension), increases in venous pressure (caval compression, uterine contraction or increase in uterine tone, Valsalva maneuver), or increases in uterine vascular resistance (increase in uterine vasoconstriction relative to systemic vasoconstriction) result in decreased UBF.

The net effect on UBF of any therapeutic intervention depends on relative changes in systemic and uterine vessels and effect on uterine tone. Labor analgesia may directly and indirectly affect UBF, both positively and negatively. For example, neuraxial analgesia may increase UBF as a result of decreased sympathetic outflow (secondary to both pain relief and direct sympathetic blockade), and decreased maternal hyperventilation. Conversely, neuraxial analgesia-induced maternal hypotension may decrease UBF. Additionally, neuraxial analgesia may be associated with transient uterine hypertonus secondary to an acute decrease in circulating epinephrine levels[56] and loss of its tocolytic effects.[57] Uterine hypertonus may also result from high concentrations of local anesthetic in uterine tissue, for example, after a paracervical block.[58]

Transfer of Drugs Across the Placenta

Most drugs administrated to the mother cross the placenta to the fetus to some degree. Placental transfer depends on a number of factors, including plasma drug concentration and electrochemical gradients across the placenta, molecular weight, lipid solubility, degree of ionization, membrane surface area and thickness (changes during pregnancy), maternal and fetal blood flow, placental binding and metabolism, and degree of maternal and fetal protein binding. Direct drug teratogenicity may manifest as death, structural abnormalities, growth restriction, and functional deficiencies. Teratogenic potential is influenced by the timing of exposure, drug dose, duration of exposure, and genetic predisposition.[59] The risk of structural teratogenicity is greatest during the period of organogenesis (day 31 to 71 after the first day of the last menstrual period). Functional or behavioral teratogenicity may result from drug exposure during pregnancy, and even after birth, as the central nervous system continues to develop during this period. Nondrug teratogens include hypoxia, hypercarbia, hyperthermia, hypoglycemia, and ionizing radiation.

NONPHARMACOLOGIC METHODS OF LABOR ANALGESIA

Nonpharmacologic methods to relieve the pain and suffering of childbirth include childbirth education, emotional support, massage, aromatherapy, audiotherapy, and therapeutic use of hot and cold. More specialized techniques that require specialized training or equipment include hydrotherapy, intradermal water injections, biofeedback, transcutaneous electrical nerve stimulation (TENS), acupuncture or acupressure, and hypnosis. Many of these techniques are inadequately studied in that study quality is poor and sample size is small,[60,61] and therefore, conclusions about efficacy are not possible.

Antenatal Childbirth Education

Childbirth education is widely practiced. Unfortunately, studies of childbirth education lack scientific rigor. Study results are inconsistent as to whether participation in childbirth education

classes influences outcomes, such as use of analgesia, duration of labor, mode of delivery, and incidence of nonreassuring fetal status.

Labor Support

Emotional support is commonly provided by the parturient's husband or a friend. "Continuous labor support" refers to the nonmedical support of the parturient by a trained person.[61] Prospective, controlled trials and several systematic analyses have concluded that women who receive continuous labor support have shorter labors, fewer operative deliveries, fewer analgesic interventions, and greater satisfaction.[62]

Hydrotherapy

Hydrotherapy is the immersion of the parturient in warm water (deep enough to cover the abdomen) during labor (not birth). Systematic reviews of randomized controlled trials have concluded that women experience less pain and use less analgesia without change in the duration of labor, rate of operative delivery, or neonatal outcome.[63]

Intradermal Water Injections

Intradermal water injection consists of the injection of 0.05 to 0.1 mL of sterile water, using an insulin or tuberculin syringe, at 4 sites on the lower back: over each posterior superior iliac crest, and 1 cm medial/3 cm caudad to these injections (Fig. 56.7). The technique is used to treat back pain during labor. The injections themselves are acutely painful for about 20 to 30 seconds, but as the injection pain fades, so does lower back pain.[61] Randomized controlled trials have found that the technique is effective in reducing severe back pain during labor without any known side effects to the mother and fetus, although the rate of use of other analgesic modalities does not appear different from control groups.[61]

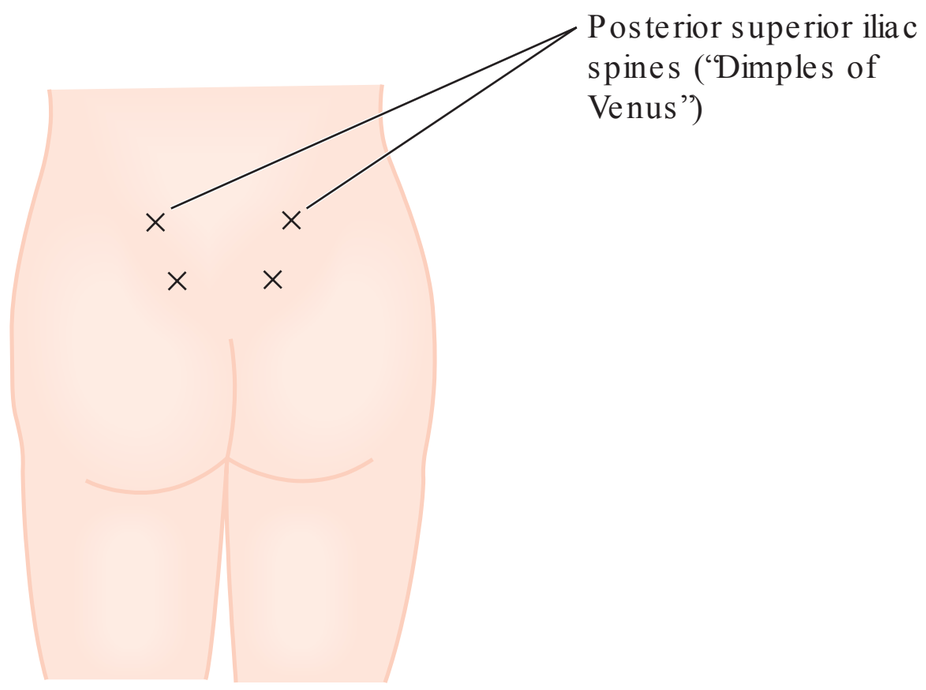

FIGURE 56.7 Placement of intradermal water blocks: four intradermal injections of 0.05 to 0.1 mL of sterile water to form four small blebs over each posterior superior iliac spine and 3 cm below and 1 cm medial to each spine. The exact locations of the injections do not appear to be critical to the block success. (Redrawn after Simkin P, Bolding A. Update on nonpharmacologic approaches to relieve labor pain and prevent suffering. *JMidwifery Womens Health* 2004;49(6):489–504, with permission.)

Hypnosis

Self-hypnosis for treatment of childbirth pain has been practiced for several centuries. Hypnosis requires prenatal training of the mother, and sometimes her partner, by a trained hypnotherapist. A meta-analysis of five randomized controlled trials that included 749 women found the use of pharmacologic analgesia methods was decreased in the hypnosis compared to control groups.[64] Data were inconclusive or limited regarding progress of labor and neonatal outcomes.

Transcutaneous Electrical Stimulation

TENS involves the application of low-intensity, high-frequency electrical impulses to the skin of the lower back. The buzzing, electrical current sensation caused by the TENS unit may reduce the mother's awareness of contraction pain. Studies of TENS are inconsistent, but in general, labor pain does not appear to be lessened, nor is the use of other analgesic modalities.[61]

Acupuncture and Acupressure

Acupuncture is a component of traditional Chinese medicine that has gained popularity in Western cultures in recent years. In three randomized controlled trials conducted in Scandinavian countries, women randomized to acupuncture versus control (no or "false" acupuncture) reported modestly lower pain scores and lower use of epidural and systemic opioid analgesia.[65,66] Whether these results can be replicated in other Western societies requires further study.

SYSTEMIC ANALGESIA

Inhalational Analgesia

Inhalation analgesia for labor and vaginal delivery is unusual in the United States, but is more common in other countries. The only inhaled anesthetic agent currently in common use is nitrous oxide. It is available in the United Kingdom as Entonox (The Linde Group, Munich, Germany), a mixture of 50% nitrous oxide and 50% oxygen. Special equipment is required to ensure the safe administration of the drug without contamination of the labor room. The mother must be taught to breathe the mixture correctly, so that peak brain nitrous oxide concentrations coincide with peak contraction pain. Studies are conflicting as to whether nitrous oxide provides benefit to the parturient.[67] The intermittent use of nitrous oxide, however, appears safe for the fetus and neonate, as there is negligible fetal accumulation and neonatal respiration or neurobehavioral scores are not depressed.[68] Concomitant use of nitrous oxide and systemic opioids, however, may increase the risk of maternal hypoxemia.

Volatile halogenated anesthetic agents have been used in the past for labor analgesia. Analgesia, however, is incomplete, as doses that provide significant analgesia are also associated with significant maternal sedation. Theoretically, the newer volatile agents, desflurane and sevoflurane, have an advantage compared to the older agents (e.g., methoxyflurane, halothane), because their lower blood–gas solubility coefficient results in more rapid onset and offset. In a small study, pain relief scores were significantly higher in women who received sevoflurane compared to nitrous oxide, and women preferred sevoflurane.[69] Sedation scores, however, were also higher with sevoflurane, and whether or not volatile agents interfere with the progress of labor (they inhibit uterine contractility) remains to be determined.

Parenteral Opioid Analgesia

Systemic opioid analgesia, administered by the subcutaneous, intramuscular, or intravenous route, is widely used around the world either as the sole analgesic modality or prior to the administration of regional labor analgesia. The use of systemic opioids for labor analgesia lacks rigorous scientific study. There is a high incidence of side effects (e.g., sedation, nausea, and vomiting), and analgesia is incomplete, at best, during active labor. In fact, existing data suggest that opioids provide little significant analgesia.[70,71] Meperidine is the most commonly used systemic opioid; however, there are few studies comparing opioids and little scientific evidence that any one opioid is better than another. All have similar, dose-related, maternal and fetal side effects. Maternal side effects include nausea, vomiting, delayed gastric emptying, dysphoria, and respiratory depression. All opioids cross the placenta. In utero, opioids may result in a slower fetal heart rate and decreased beat-to-beat variability.[72] The likelihood of neonatal respiratory depression depends on the dose and timing of administration.

Patient-Controlled Intravenous Analgesia

Patient-controlled intravenous analgesia (PCIA) has theoretical advantages to nurse-administered opioid analgesia, including superior analgesia with smaller drug doses, resulting in a lower incidence of side effects. PCIA studies have been reported using meperidine, nalbuphine, fentanyl, and more recently, remifentanil with and without a background infusion. Remifentanil has the theoretical advantage of rapid onset and offset compared to the other opioids. Bolus doses have ranged from 0.2 to 1 μg/kg with lock-out intervals from 1 to 5 minutes,[73–76] and infusion rates from 0.025 to 0.1 μg/kg/minute.[75] However, as with other systemic opioid techniques, it is unclear whether remifentanil PCIA can provide satisfactory analgesia without an unacceptably high incidence of side effects.[73,76]

NEURAXIAL ANALGESIA

Neuraxial labor analgesia is the most effective method of pain relief during childbirth and the only method that provides complete analgesia without maternal or fetal sedation. The use of neuraxial analgesia for childbirth has increased dramatically in the United States over the past 40 years.[9] The most common techniques are continuous lumbar epidural analgesia and combined spinal-epidural analgesia. Single-shot spinal, continuous spinal, and caudal analgesia are occasionally used.

Contraindications to neuraxial analgesia and anesthesia include patient refusal, infection at the puncture site, pre-existing coagulopathy, and lack of experienced anesthesia providers. Relative contraindications include hemorrhage or other causes of hypovolemia, untreated systemic infection, preload-dependent disease states, and lumbar spine pathology. The anesthesiologist should weigh the risk and benefits of a neuraxial procedure for each patient independently and the specific neuraxial analgesic technique should be tailored to individual patient needs. The risks and benefits of the procedure should be discussed with each parturient, preferably early in labor. The advantages and disadvantages of specific neuraxial techniques are listed in Table 56.2.

TABLE 56.2

ADVANTAGES AND DISADVANTAGES OF SPECIFIC NEURAXIAL TECHNIQUES FOR LABOR ANALGESIA

	Analgesia technique				
	Continuous epidural	**Combined spinal-epidural**	**Single-shot spinal**	**Continuous spinal**	**Caudal**
Advantages	• Continuous technique • No dural puncture • Ability to convert to epidural anesthesia	• Rapid onset • Early sacral block • Low dose of anesthetic • Complete early labor analgesia with opioid only†	• Rapid onset • Technically easier • Early sacral block	• Rapid onset • Early sacral block • Low dose of anesthetic • Continuous technique • Ability to convert to spinal anesthesia	• Ability to access epidural space in patient with lumbar epidural pathology
Disadvantages	• Slow onset • Requires greater mass of anesthetic* • Delayed sacral blockade/sacral sparing	• Requires dural puncture • Delayed diagnosis of malfunctioning epidural catheter	• Requires dural puncture • Limited duration of analgesia	• Requires dural puncture with large gauge needle‡ • Potential for accidental intrathecal injection of epidural dose of anesthetic agents	• Requires large volume/mass of anesthetic to block T10 dermatome†‡‡

*Greater vascular absorption of anesthetic agents and greater likelihood for accidental intravascular injection of a toxic amount of local anesthetic.
†Large doses of epidural opioid may provide near complete analgesia for early labor, but at the expense of significant systemic absorption and with accompanying side effects.
‡Increased risk of PDPH.
‡‡May not be able to achieve T4 sensory blockade necessary for cesarean delivery.

Epidural Analgesia

Lumbar epidural analgesia has been the mainstay of regional labor analgesia. Placement of an epidural catheter allows analgesia to be maintained until after delivery. Additionally, it allows conversion to epidural anesthesia should cesarean delivery be necessary. No dural puncture is required. Randomized studies consistently demonstrate that pain scores are lower and patients are more satisfied with epidural analgesia compared to nonneuraxial analgesia.[77,78] Injection of anesthetics in the lumbar epidural space allows spread of the anesthetic solution both cephalad and caudad. Neural blockade to the T10 dermatome is necessary to relieve uterine and cervical pain, whereas blockade of the sacral dermatomes is necessary to block the pain of vaginal and perineal distention.

Compared to spinal analgesic techniques, the onset of epidural analgesia is significantly slower (15–20 minutes compared to 2–5 minutes), particularly the onset of sacral analgesia. It may take several hours of lumbar epidural infusion, or several bolus injections of local anesthetic into the lumbar epidural space, to achieve sacral analgesia. This is particularly disadvantageous in a rapidly laboring parturient who requires rapid onset of sacral analgesia for the late first and second stages of labor. In addition, epidural compared to spinal analgesia requires significantly more drug(s) to attain comparable analgesia, thus increasing the risk of systemic toxicity. Finally, there is significantly more systemic absorption of anesthetic agents, and therefore, maternal and fetal plasma drug concentrations are higher with epidural compared to spinal analgesia.

Lumbar epidural analgesia is initiated in either the sitting or lateral position. The epidural space is identified with a 17- or 18-gauge epidural needle, usually using a loss-of-resistance to air of saline technique. A flexible catheter is passed through the needle approximately 4 to 5 cm into the epidural space, the epidural needle is removed, and the catheter is secured. A test dose is frequently administered to rule out intrathecal or intravascular catheter placement. The most common test dose is lidocaine 15 mg/mL with epinephrine 5 μg/mL, 3 mL. No matter whether a test dose is injected, drugs should be injected incrementally into the epidural space, as no test is 100% sensitive and catheters may migrate during use. Pregnant women are very difficult to resuscitate from local anesthetic cardiac toxicity.

Analgesia is initiated by bolus injection of anesthetic(s) through the epidural needle, catheter, or both. Analgesia is maintained with intermittent bolus injections or a continuous infusion. The catheter is removed after delivery when there is no further need for analgesia/anesthesia.

Drugs for Initiation of Epidural Analgesia

Drugs commonly used for epidural labor analgesia are listed in Table 56.3. Local anesthetics, primarily bupivacaine, have been the mainstay of epidural analgesia for many years. The amount of epidural local anesthetic required for satisfactory analgesia increases as labor progresses.[79] Low bupivacaine concentrations (≤1.25 mg/mL) provide excellent analgesia with minimal motor block. The ED_{50} of bupivacaine 1.25 mg/mL was lower than the ED_{50} of bupivacaine 2.5 mg/mL, suggesting that the use of low concentrations is associated with less overall drug requirement.[80] Bupivacaine is highly protein bound with minimal placental transfer,[81] and duration of analgesia is approximately 2 hours. Onset to peak effect is approximately 20 minutes. Lidocaine and 2-chloroprocaine have shorter latency, but their duration of analgesia is shorter, limiting their usefulness for routine labor analgesia. In addition, lidocaine is less protein bound than bupivacaine and therefore has a higher umbilical vein/maternal vein ratio.[82] Controlled studies, however, have found no difference in neonatal neurobehavioral scores between epidural lidocaine, bupivacaine, and 2-chloroprocaine.[83,84] 2-Chloroprocaine is most useful for rapidly converting epidural *analgesia* to epidural *anesthesia* for urgent operative delivery.

TABLE 56.3

TYPICAL DRUGS FOR INITIATION OF EPIDURAL LABOR ANALGESIA*

Drug	Concentration	
Local anesthetics†		**Dose (Volume)**
Bupivacaine	1.00–1.25 mg/mL	10–15 mL
Ropivacaine	1.0–2.0 mg/mL	10–15 mL
Opioids†		**Dose (Mass)**
Fentanyl	—	50–100 μg
Sufentanil	—	5–10 μg
Adjuvants		
Epinephrine	1.25–5.00 μg/mL	—
Clonidine‡	—	60–75 μg‡‡

*The actual drug dose will depend on the stage of labor (women in advanced labor require higher doses), the progress of labor (women with rapid progress of labor will require higher doses), and whether or not an anesthetic containing test dose has been administered.
†Local anesthetics and opioids are commonly administered together, in which case a lower dose of each is required.
‡Clonidine is not approved for use in obstetric patients in the United States.
‡‡This dose should be combined with local anesthetics, as higher doses used alone cause sedation and hypotension.

Ropivacaine is a homologue of bupivacaine, formulated as a single levorotatory enantiomer. Its onset and duration of action are similar to bupivacaine,[85] but it has less potential for cardiac toxicity. Although potency studies suggest that ropivacaine is approximately 40% less potent than bupivacaine,[86] clinical studies comparing low concentrations of ropivacaine and bupivacaine for labor analgesia suggest that they are equipotent in terms of sensory blockade for labor analgesia.[87,88] However, ropivacaine may be associated with less motor blockade than equipotent doses of bupivacaine.[89] Levobupivacaine, the S-enantiomer of bupivacaine, is not available in the United States. Similar to ropivacaine and bupivacaine in its onset and duration of action, it is less cardiotoxic than bupivacaine and is associated with less motor blockade compared to bupivacaine.[87,89]

Opioids, particularly the lipid-soluble opioids, fentanyl and sufentanil, are commonly added to local anesthetics for epidural analgesia. Epidural opioids and local anesthetics interact synergistically to provide analgesia.[90,91] The addition of opioids shortens latency, allows for decreased concentration of local anesthetic, thus decreasing motor block, and prolongs analgesia. While epidural opioids alone can provide moderate analgesia for early labor, analgesia is incomplete, and the necessary dose is accompanied by bothersome side effects (e.g., pruritus, nausea, vomiting, maternal sedation, neonatal respiratory depression). Combining local anesthetics with opioids allows for effective analgesia while minimizing the side effects of both drugs.

Fentanyl and sufentanil are ideal for labor analgesia because of their rapid onset (5 to 10 minutes). Their short duration of action (60 to 90 minutes) is overcome by maintaining analgesia with a continuous epidural infusion. Doses commonly used for epidural analgesia initiation and maintenance have been shown to be safe for both the mother and neonate.[92,93] Morphine has a much slower onset (30 to 60 minutes) and longer duration of action (12 to 24 hours) than fentanyl or sufentanil. The long

duration of action is not beneficial, as the bothersome side effects of morphine (pruritus, nausea, and vomiting) continue to be present after delivery.

Adjuvants for epidural labor analgesia include epinephrine and clonidine. Epidural epinephrine may contribute to analgesia by decreasing the uptake of local anesthetics and opioids from the epidural space secondary to vasoconstriction,[94] and by binding to spinal cord α_2-adrenergic receptors.[95] Clonidine also binds to α_2-adrenergic receptors and has been shown to supplement epidural labor analgesia. It is not approved for use in obstetric patients in the United States, however, because of the risks of sedation and hypotension.

Combined Spinal-Epidural Analgesia

Combined spinal-epidural (CSE) analgesia has become increasingly popular in the past decade. There are advantages and disadvantages to CSE compared to traditional epidural analgesia (see Table 56.2). Onset of analgesia is significantly faster compared to epidural analgesia.[96] Complete analgesia for early labor can be accomplished with the intrathecal injection of lipid soluble opioids without the addition of local anesthetics, thus avoiding motor blockade and decreasing the risk of hypotension. This is ideal for patients who wish to ambulate, or for those with preload dependent conditions such as stenotic heart lesions. The effective opioid dose is significantly less than for systemic or epidural administration. Therefore, systemic drug absorption is minimal, as are direct fetal effects. The addition of local anesthetic to a lipid soluble opioid results in sacral analgesia within several minutes. This is a decided advantage compared to lumbar epidural analgesia, as sacral analgesia is difficult to accomplish after a single lumbar epidural dose of local anesthetic. Therefore, CSE analgesia provides more complete analgesia for women in advanced stages of labor or women whose labor is progressing rapidly. Finally, use of the CSE technique may decrease the incidence of failed epidural analgesia (e.g., a nonfunctioning epidural catheter).[97,98]

There are several undesirable side effects of CSE analgesia. The incidence of pruritus is higher with intrathecal versus epidural opioids.[99] Dural puncture is required to initiate CSE analgesia. The risk of postdural puncture headache (PDPH) may be minimally higher with the CSE compared to pure epidural technique (estimated excess rate of 3 in 1000).[100] However, a more serious concern is that dural puncture in the obstetric patient may be a risk factor for postpartum neuraxial infection, a rare but potentially life-threatening complication.[101]

Another potential drawback of CSE analgesia is that it will be unclear for 1 to 2 hours after initiation of analgesia as to whether the epidural catheter is properly sited in the epidural space. Therefore, if a functioning epidural catheter is critical to the safe care of the patient (e.g., in the presence of a nonreassuring fetal heart rate pattern or an anticipated difficult airway), then CSE analgesia may not be the technique of choice.

Several techniques for CSE analgesia/anesthesia have been described, including using two skin punctures in two interspaces, two punctures in one interspace, and the needle-through-needle technique.[100] The most common CSE technique for labor analgesia is the needle-through-needle technique in a midlumbar interspinous space. The epidural space is identified with an epidural needle in the standard fashion. The epidural needle then functions as an introducer needle as a long spinal needle is passed through it until the dura is punctured. The intrathecal drug(s) is injected through the spinal needle, the spinal needle is withdrawn, and an epidural catheter is threaded through the epidural needle. Analgesia is maintained via the epidural catheter, as with traditional epidural analgesia.

Drugs for Initiation of Combined Spinal-Epidural Analgesia

CSE labor analgesia is usually initiated with a lipid soluble opioid (fentanyl or sufentanil) or a combination of opioid and local anesthetic (Table 56.4). Morphine is not commonly used because of its long latency and long duration of action (a disadvantage, as women usually deliver before regression of side effects). However, morphine has been successfully combined with intrathecal bupivacaine and fentanyl in order to shorten latency and increase duration of analgesia.[102] This combination of drugs may be particularly useful in settings where continuous epidural infusion techniques are impractical.[102] Meperidine is unique among the opioids in that it has weak local anesthetic properties. However, meperidine was associated with a significantly higher incidence of nausea and vomiting compared to combined fentanyl-bupivacaine.[103]

Intrathecal opioids can provide complete analgesia early in labor when the pain stimuli are primarily visceral. Onset of analgesia occurs within 5 minutes[96] and lasts 70 to 100 minutes.[104] The reported ED_{95} of intrathecal fentanyl varies from 14[105] to 23 μg.[106] The relative potency ratio of intrathecal sufentanil to fentanyl for labor analgesia is 4.4:1.[104] When administered at twice the ED_{50}, the duration of sufentanil analgesia was 25 minutes longer than fentanyl, although the incidence of side effects was not different.[104] The duration of action of intrathecal opioids is dose-related, although fentanyl doses greater than 25 μg do not increase duration of analgesia and are associated with a higher incidence of side effects.[105]

In the late first stage and second stage of labor, local anesthetic must be added to the opioid in order to block somatic stimuli from the vagina and perineum. The local anesthetic works synergistically with the opioid; thus, lower doses of both drugs can be used.[107,108] Bupivacaine is most commonly combined with fentanyl or sufentanil. The ED_{95} of bupivacaine combined with sufentanil 1.5 μg was 3.3 mg,[109] and was 1.66 mg when combined with fentanyl 15 μg.[110] Bupivacaine doses between 1.25 to 2.5 mg are commonly used. Levobupivacaine and ropivacaine are not approved for intrathecal use in the United States. They are less potent than bupivacaine for intrathecal labor analgesia.[109]

Bupivacaine without opioid is not commonly used for labor analgesia. Doses high enough to provide analgesia are associated

TABLE 56.4

DRUGS FOR THE INITIATION OF INTRATHECAL LABOR ANALGESIA

Drug(s)*	Opioid dose (μg)	Bupivacaine dose (mg)
Fentanyl	15–25	—
Sufentanil	5–7.5	—
Bupivacaine-fentanyl	10–15	1.25–2.5
Bupivacaine-sufentanil	1–2.5	1.25–2.5
Bupivacaine-fentanyl-morphine†	Fentanyl 12.5–25	2.0–2.5
	Morphine 200–250	

*Opioids alone provide complete analgesia for early labor, but the addition of local anesthetics is required for late first stage and second stage analgesia.

†The combination of bupivacaine-fentanyl-morphine may be advantageous in the settings where continuous epidural infusions for maintenance of analgesia are impractical and single-shot techniques are an alternative.

with significant motor blockade and lower doses either do not provide satisfactory analgesia or are associated with an unacceptably short duration of action.[108]

Maintenance of Epidural Analgesia

Epidural analgesia may be maintained with intermittent bolus injection, continuous epidural infusion, or patient controlled epidural analgesia (PCEA), with or without a background infusion. Continuous epidural infusions result in less need for bolus injections[111,112] and increased patient satisfaction,[113] but higher total drug dose[111,113] compared to intermittent injections. However, the infusion of lower concentration-bupivacaine at a higher rate may result in similar analgesia with less motor block and no increase in total dose.[113,114] Common infusion solutions and protocols are listed in Table 56.5.

PCEA allows for both a continuous epidural infusion and patient-titrated bolus injections. PCEA resulted in greater patient satisfaction[115,116] and a lower average hourly dose of bupivacaine (and therefore less motor block),[116,117] and less need for physician intervention.[117] The protocols for PCEA vary widely, and it is unclear whether this affects analgesia and outcome. At one extreme, most of the hourly dose is administered via a background infusion which the parturient may supplement with self-administered boluses. At the other extreme, there is no background infusion and the entire dose is self-administered via intermittent boluses. Bupivacaine consumption is higher with background infusions compared to a pure PCEA technique without a background infusion.[118] Although data are conflicting as to whether a background infusion improves analgesia, it may be helpful in selected parturients (e.g., nulliparas with long labors).[119] Solutions for PCEA generally mimic those used for continuous infusions (see Table 56.5). The parturient administered bolus dose is 5 to 10 mL, the lock-out interval is 10 to 20 minutes, and the background infusion varies from 0 to 15 mL. Commonly, 30% to 50% of the hourly dose is administered as a background infusion.

The bolus administration of epidural anesthetic solution appears to result in improved analgesia with a lower total drug dose. Investigators have recently demonstrated that timed (automated) intermittent boluses (5 to 10 mL every 30 to 60 minutes) administered via a programmable pump result in improved parturient satisfaction, less drug use, longer duration of analgesia, and less breakthrough pain compared to a continuous infusion of the same mass of drug per unit time.[120–122] There may be better distribution of anesthetic solution within the epidural space when large volumes are injected as a bolus compared to a slow infusion.

TABLE 56.5

DRUG SOLUTIONS FOR MAINTENANCE OF EPIDURAL LABOR ANALGESIA*

Drug solution	Local anesthetic concentration (mg/mL)	Opioid concentration (μg/mL)
Bupivacaine-fentanyl	0.625–1.25	2–4
Bupivacaine-sufentanil	0.625–1.25	0.20–0.33
Ropivacaine-fentanyl	0.8–1.5	2–4
Ropivacaine	2.0	—

*Continuous infusions rate: 10–15 mL/hour. PCEA parameters: PCEA bolus 5–10 mL, lockout interval 10–20 min, background infusion 0–15 mL/hour (commonly 30%–50% of hourly dose requirement).

Other Central Neuraxial Techniques

Single-Shot and Continuous Spinal Analgesia

In general, single-shot spinal analgesia is not useful for most laboring patients because of its limited duration of action. It may be indicated in parturients who require analgesia/analgesia shortly before anticipated delivery or in settings where continuous epidural analgesia is not possible. Drugs for single-shot spinal analgesia mimic those used for the initiation of CSE analgesia (see Table 56.4).

Continuous spinal analgesia is currently not practical for most parturients. The available catheters (essentially epidural catheters) require a large gauge introducer needle and are therefore associated with an unacceptably high incidence of PDPH. However, the placement of a continuous spinal catheter is a management option in patients with inadvertent dural puncture with an epidural needle or when rapid analgesia is necessary in an obese patient. Continuous spinal labor analgesia is commonly maintained with the same solution used for epidural analgesia, but at a rate of 1 to 2 mL/hour.

Caudal Analgesia

Continuous caudal epidural analgesia is used infrequently in the practice of modern obstetric anesthesia. Large volumes of local anesthetic are required for first stage analgesia and result in higher maternal plasma concentrations of drug. There is a risk of needle/catheter misplacement and direct injection into the fetus. However, this technique is an option in patients in whom access to the lumbar spinal canal is not possible (e.g., fused lumbar spine).

Side Effects of Neuraxial Analgesia

Common side effects of neuraxial labor analgesia include hypotension and pruritus. Other side effects include urinary retention, delayed gastric emptying (after opioid techniques, but not pure local anesthetic techniques), oral herpes simplex virus recrudescence, shivering, maternal hyperthermia, and fetal bradycardia.

Hypotension

Blockade of the sympathetic nervous system by local anesthetics causes vasodilation, increased venous capacitance, decreased preload, and decreased cardiac output. Hypotension may result in decreased uteroplacental perfusion and fetal heart rate decelerations or bradycardia. Therefore, maternal blood pressure and fetal heart rate should be monitored for 15 to 30 minutes after the induction of neuroblockade. Although intravenous volume expansion prior to initiating neuraxial analgesia has traditionally been used to reduce the incidence and degree of hypotension, it is not clear that this has any real benefit with modern low-dose neuraxial labor analgesia techniques.[123] The mother should be positioned in the full lateral position after initiation of neuraxial blockade and hypotension should be treated with small bolus doses of intravenous vasopressor.

Pruritus

Pruritus is common side effect of neuraxial opioid administration. It is more common after intrathecal (as high as 100%) compared to epidural administration, and the incidence and severity are dose related.[106,108] The cause is unknown, but it is not thought to be histamine-related. Pruritus may be generalized or localized to the nose, face, or chest and is typically self-limited. Concomitant local anesthetic administration decreased the incidence and severity of pruritus compared to fentanyl alone,[124] whereas the addition of epinephrine worsened the pruritus.[125] The one-time

administration of naloxone (40 to 80 μg) or nalbuphine (2.5 to 5 mg) is usually effective for the treatment of pruritus induced by fentanyl or sufentanil. A naloxone infusion may be required for the treatment of morphine-induced pruritus.

Fetal Bradycardia

Fetal bradycardia, not associated with maternal hypotension, occurs after initiation of both epidural and CSE analgesia. Clark and colleagues[57] hypothesized that this may be due to the acute decrease in plasma epinephrine levels following the initiation of neuraxial analgesia.[56] Epinephrine is a tocolytic, and the acute decrease in maternal plasma concentration may result in temporary imbalance of uterine tocolytic/tocodynamic forces, resulting in uterine hypertonus, decreased uterine perfusion, and ultimately, fetal bradycardia. Nitroglycerin has been used successfully to treat uterine hypertonus associated with the initiation of neuraxial analgesia.[126]

Maternal Hyperthermia

Epidural labor analgesia greater than 6 hours is associated with maternal fever.[127,128] The mechanism is unclear, but may be a result of increased heat production (e.g., shivering), decreased heat loss (inhibition of sweating in area of neuroblockade or less heat loss via respiratory tract because of lack of hyperventilation), or alterations in temperature regulation induced by epidural analgesia.

Complications of Neuraxial Analgesia

Complications of neuraxial labor analgesia include inadequate or failed analgesia, inadvertent dural puncture, subdural injection, respiratory depression, high- or total-spinal anesthesia, systemic local anesthetic toxicity, needle or catheter trauma to central nervous system tissue (spinal cord and nerve roots), direct tissue local anesthetic toxicity (cauda equina syndrome, arachnoiditis), pneumocephalus, spinal or epidural hematoma, spinal or epidural abscess, and meningitis.

Inadvertent Dural Puncture

Inadvertent dural puncture with an epidural needle occurs in 1.5% of obstetric patients receiving epidural analgesia or anesthesia, and 52% will develop a PDPH.[129] This is a particularly troublesome complication of epidural analgesia because women are usually quickly mobile after childbirth with the need to care for their newborn infants. A therapeutic epidural blood patch with autologous blood remains the gold standard treatment. Between 34% to 68% of women get complete relief,[130–132] whereas 7% to 16% of women get no relief. The volume of autologous blood that provides the best outcome with fewest side effects is not well studied, but anesthesiologists generally inject between 15 and 20 mL of autologous blood.

Other treatment modalities for the prevention and treatment of PDPH have not proven effective (e.g., epidural saline infusion, caffeine, prophylactic blood patch) or are inadequately studied (placement of an intrathecal catheter).

Respiratory Depression

Severe respiratory depression or arrest has been reported after the intrathecal injection of sufentanil in laboring women.[133] The risk appears to be increased when intrathecal opioids are administered before or after systemic opioids. Respiratory depression is opioid dose-dependent.[106] It generally occurs within 2 hours after the intrathecal administration of fentanyl and sufentanil. In contrast, respiratory depression after epidural and intrathecal morphine usually presents 6 to 12 hours after administration of drug.

OTHER REGIONAL ANALGESIC TECHNIQUES

Neuraxial analgesia is the most effective and flexible analgesic technique for labor and delivery. However, some parturients may not be candidates for neuraxial analgesia or may not want it. Other nerve blocks may provide acceptable, albeit less flexible, analgesia.

Paracervical Block

A paracervical block blocks transmission of visceral afferent nerve impulses from the uterus and cervix through the paracervical (Frankenhäuser's) ganglion. Advantages include excellent analgesia for the first stage of labor, before fetal descent, without somatic sensory or motor block. However, the block is not continuous, and it does not relieve somatic pain caused by distension of the pelvic floor, vagina, or perineum.

Serious maternal complications are unusual; however, serious fetal complications are not uncommon. Inadvertent direct fetal scalp injection can result in fetal systemic local anesthetic toxicity and may be more likely to occur with advanced cervical dilation (>8 cm). Fetal bradycardia is the most common fetal complication. The etiology is unclear. Recommendations to reduce complications include (1) perform the block only in parturients with no evidence of uteroplacental insufficiency, (2) perform the block when the cervix is dilated <8 cm, (3) monitor uterine activity and fetal heart rate continuously, (4) after injecting local anesthetic on one side, wait 5 to 10 minutes before injecting anesthetic on the second side, and (5) consider using 2-chloroprocaine.[134]

Lumbar Sympathetic Block

Paravertebral lumbar sympathetic blockade interferes with transmission of visceral afferent nerve impulses from the uterus and cervix at the level of the L2 to L3 sympathetic chain. Similar to a paracervical block, it provides analgesia for the first stage, but not the second stage of labor. Disadvantages include a technique that is not continuous and that it is technically difficult to learn and perform and requires bilateral injections. Advantages include that it is associated with less fetal bradycardia than a paracervical block, it provides first stage analgesia without any motor block, it is useful for patients with previous back surgery,[135] and the progress of labor is accelerated compared to epidural analgesia.[136]

Pudendal Block

A pudendal nerve block interrupts pain signals from vaginal, vulvar, and perineal distension. It provides satisfactory analgesia for spontaneous vaginal and low- or outlet-forceps delivery, but not mid-forceps delivery or exploration of the upper vagina, cervix, or uterine cavities. Bilateral success rate may be as low as 50%.[137] The pudendal nerve can be blocked via the transperineal or transvaginal route. Most obstetricians in the United States employ the transvaginal route immediately before delivery. However, earlier pudendal nerve blocks (just before or after complete cervical dilation) provide better analgesia, do not increase the incidence of instrumental delivery,[138] and allow for a repeat block should the initial block fail.

Maternal and fetal complications of pudendal nerve block are rare. Fetal complications include fetal trauma and/or direct fetal injection of local anesthetic.[139]

Perineal Infiltration

Perineal infiltration is often used immediately before delivery to provide anesthesia for an episiotomy or repair. It provides no motor relaxation. Five to 10 mL of local anesthetic are injected into the posterior fourchette. Perineal infiltration may be complicated by direct injection of local anesthetic into the fetal scalp resulting in neonatal local anesthetic toxicity.[140]

EFFECTS OF ANALGESIA ON THE PROGRESS OF LABOR

There has been much controversy concerning the effect of neuraxial labor analgesia on the progress of labor and mode of delivery. Early investigators noted that regional analgesia appeared to be an effective treatment for dysfunctional labor.[24,141] Observational studies, however, have uniformly found an association between neuraxial analgesia, prolonged labor, and operative delivery. A number of randomized controlled trials have compared neuraxial labor analgesia to systemic opioid analgesia and most found no difference in the rate of cesarean delivery between groups.[142,143] The probable explanation for observed association between epidural analgesia and cesarean delivery is that women who have more pain during labor (and thus more likely to request analgesia) have a higher risk of cesarean delivery.[14,15] Fetal macrosomia, malposition, and dysfunctional labor are associated with more painful labor and a higher rate of cesarean delivery.

Another concern is whether neuraxial analgesia adversely affects the first stage of labor, particularly when administered in the latent phase. Again, observational studies suggest that early labor initiation of neuraxial analgesia is associated with an increased rate of cesarean delivery. Randomized controlled trials, however, uniformly demonstrated that early labor initiation of neuraxial compared to systemic opioid analgesia does not adversely affect the outcome of labor,[77,144,145] and in fact, may result in faster labor.[144,145]

Randomized controlled trials comparing neuraxial to systemic opioid analgesia have assessed the risk of instrumental vaginal delivery and duration of labor as secondary outcomes. Systematic review of these trials have found that the duration of the first stage of labor may be prolonged by approximately 30 minutes, the duration of the second stage of labor may be prolonged by approximately 15 minutes, and the rate of instrumental forceps delivery may be increased.[142,143] Several groups of investigators have demonstrated that neuraxial analgesia with bupivacaine 2.5 mg/mL results in a higher instrumental vaginal delivery rate compared to low dose bupivacaine-opioid techniques.[99,146] Thus, it is the responsibility of the anesthesiologist to use a regional technique that minimizes motor block in order to decrease the risk of instrumental vaginal delivery.

NONOBSTETRIC DRUG THERAPY DURING PREGNANCY AND LACTATION

The management of pain during pregnancy is complicated by the need to limit the transfer of drugs across the placenta, particularly during the first trimester, as well as the necessity of limiting radiation exposure. Key management concepts (Table 56.6) include assessment of risk versus benefit. For example, withholding seizure medications at the risk of recurrent seizures is not sensible. In general, using older drugs with a longer history is advisable, as well as using the minimum effective dose. Drugs with an active metabolite should be avoided if possible, and nerve blocks are preferable to systemic analgesia.

TABLE 56.6

PRINCIPLES OF DRUG ADMINISTRATION DURING PREGNANCY AND LACTATION

Pregnancy
- Assess risk versus benefit
- Consider gestational age of fetus
- Use older drugs
- Use the minimum effective dose
- Avoid drugs with active metabolites
- Consider nerve blocks
- Consider nonpharmacologic therapies
- Use ultrasound and MRI for imaging

Lactation
- Assess risk versus benefit
- Choose the safest drug
- Use minimum effective dose
- Use drugs with no active metabolite
- If drug may present risk to neonate, measure neonatal drug concentration
- Give maternal dose just after feeding
- Consider age of infant (maturity of metabolic pathways)

Most drugs administered to the mother cross into breast milk, although neonatal drug exposure is much smaller than fetal exposure. Principles of drug administration during lactation are listed in Table 56.6. Drugs undergo first pass metabolism in the neonatal gut, and neonatal exposure is generally 1% to 2% of the maternal dose.[147] Determinants of drug transfer to milk and neonatal exposure include maternal plasma concentration, drug pKa (breast milk is slightly acidotic compared to plasma), volume of milk, and the maturity of neonatal drug metabolism and elimination pathways.[148] Hepatic drug-metabolizing enzymes appear to mature at different rates but are generally impaired in the neonate compared to the adult.[148] Glomerular filtration rate does not reach adult values until 2.5 to 5 months of age.

Drug Classification During Pregnancy and Lactation

The United States Food and Drug Administration introduced a 5-category pregnancy drug classification in 1979 (Categories A, B, C, D, X). This classification has some major limitations.[149] There are very few controlled studies in humans in which lack of fetal harm has been demonstrated. Animal studies do not translate well to humans, as teratogenicity is markedly species specific. Therefore, the safety status of most drugs is largely unknown. All new drugs are classified as Category C (either animal studies have revealed adverse effects but no controlled studies in women have been reported, or studies in women and animals are not available), and this does not help the practitioner or patient assess the drug's safety during pregnancy. Several Internet databases offer information on drug use during pregnancy and lactation,[149] as well as a well-known reference book.[59] Some drug companies maintain pregnancy registries for specific drugs.

The American Academy of Pediatrics has categorized drugs in terms of safety to the nursing infant.[150] Most drugs, including most analgesics, are listed as compatible with breastfeeding.

Analgesic Drugs During Pregnancy and Lactation

Acetaminophen is the first line analgesic during pregnancy for the treatment of mild pain. Low-dose aspirin is considered safe; however, higher doses should be avoided as they may be associ-

ated with an increased risk for placental abruption and other bleeding problems and fetal gastroschisis.[149] Nonsteroidal anti-inflammatory drugs (NSAIDs) may cause constriction of the ductus arteriosus and may have adverse effects on fetal renal function, leading to oligohydramnios. Therefore, indomethacin and ibuprofen are not recommended for use for more than 2 days beyond the first trimester.[149] Opioids are considered safe during pregnancy, although there is a potential for neonatal abstinence syndrome after delivery.

Acetaminophen is also considered safe for nursing infants, as are NSAIDs. However, aspirin should be used with caution during lactation because of the slow elimination of salicylates by neonates and resultant drug accumulation.[149,150] Opioids are considered safe during lactation.[150] However, meperidine should be avoided, as normeperidine has a markedly prolonged half-life in the newborn[151] and accumulation may result in neurobehavioral depression and seizures.

CHAPTER 57 ■ PAIN AND SICKLE CELL DISEASE

SAMIR K. BALLAS

INTRODUCTION

Historical Milestones

Historically, sickle cell disease (SCD) evolved through four periods: (1) the tribal medicine period in Africa, (2) the period of clinical recognition by Western medicine, (3) the period of biochemical/cellular research, and (4) the period of molecular characterization and treatment. Thus, this evolution progressed from bedside to bench, eventually returning to the bedside.

SCD was known in Africa before the twentieth century. Inhabitants of West Africa realized that the disease was hereditary and gave it specific names such as Chwechwechwe, Ahotutuo, Nwiiwii, and Nuidudui.[1] These names are characterized by alliteration of letters that seemingly signified the recurrent clinical manifestations of the disease and the crying sounds by children in pain.

Dr. James Herrick of Chicago[2] ushered in the clinical period with a report of SCD in 1910. He described a young black student from Grenada in the West Indies who presented with cough and fever. This case report is significant because it documented "peculiar elongated and sickle-shaped red blood corpuscles in a case of severe anemia," and this left no doubt that the patient had a severe variety of sickle cell syndrome, probably sickle cell anemia (SS).[2]

Between 1910 and 1949, there was a plethora of descriptions of the various clinical features of SCD by physicians, most notably by Mason[3] who coined the term SS and by Diggs[4] who noted that the hallmark of SS is recurrent and painful vascular occlusive crisis interspersed with periods of stable state with no signs or symptoms other than those due to chronic hemolytic anemia.

The biochemical/cellular period in the history of SCD was ushered in by Pauling and his associates[5] who introduced the concept of SS as a molecular disease. They demonstrated that hemoglobin isolated from red cells of patients with SCD differed electrophoretically from the hemoglobin of normal persons and that the hemoglobin of those with sickle cell trait was a mixture of normal and sickle hemoglobin. Neel[6] showed that the inheritance of SS followed simple Mendelian genetics. Ingram[7] reported that the only difference between normal and sickle hemoglobin was the replacement of glutamic acid by valine. The work of several groups established the subunit structure and primary sequences of the subunits ($\alpha\beta,\gamma,\delta$) of human hemoglobin and localized the sickle mutation to the sixth residue of the β-globin chain

($\beta 6^{Glu \rightarrow Val}$). The interaction of the sickle mutation with other hemoglobin abnormalities clarified the spectrum of sickle cell syndromes. The advent of DNA technology in the 1970s and the 1980s paved the way for the molecular period including the molecular diagnosis of sickle cell disorders, prenatal diagnosis, and the identification of α-genotypes and β^s haplotypes and their effect on the clinical picture of SCD. By the 1980s, it had become clear that SCD is a highly heterogeneous disorder not only at the clinical level but also at the cellular and molecular levels. The recent success of the human genome project initiated studies to determine epistatic genes that may modify the phenotypic expressions of SCD.[8]

Hematologic Aspects of Sickle Cell Disease

Hemoglobinopathies are inherited disorders of the structure and/or function of the hemoglobin molecule that have no established cure in adult patients. Cure has been achieved in selected children with SS by using allogeneic bone marrow transplantation, stem cells, or cord blood transplantation.[9–14] Hemoglobinopathies are broadly divided into two major groups: structural variants and thalassemias. Structural variants are, most commonly, the result of single base mutations in the globin genes. Thalassemias are characterized by decreased synthesis of globin chains.

Nature of the Sickle Mutation

The most common structural variant of normal hemoglobin is the sickle hemoglobin (Hb S) followed by hemoglobin C (Hb C). Both of these hemoglobins are the result of single base mutation in the sixth codon of exon l of the β-globin gene responsible for the synthesis of the β-globin chain of the hemoglobin molecule. In case of Hb S, the mutation is the result of a single base change (GAG $\rightarrow$ GTG) in the sixth codon of exon 1 of the β-globin gene responsible for the synthesis of the β-globin polypeptide of the Hb molecule ($\alpha_2\beta_2$). This change, in turn, results in replacement of the normal glutamic acid with valine at position 6 of the β-globin chain and the formation of sickle Hb.[7,15] In case of Hb C, the mutation is the result of a single base change (GAG $\rightarrow$ AAG) in the same codon as the Hb S; this change results in replacement of the normal glutamic acid with lysine at position 6 of the β-globin chain and the formation of Hb C. These mutations change the net charge of the variant hemoglobin thus allowing their separation by electrophoresis.

Structural variants of hemoglobin are inherited in an autosomal codominant manner according to Mendelian principles. Thus, if one parent is normal and the other has SS, then all children will have sickle cell trait.

Sickle cell syndromes, collectively referred to as SCD, comprise a group of clinically significant hemoglobinopathies in which the sickle gene is inherited from at least one parent. SS is the homozygous state where the sickle gene is inherited from both parents. Sickle cell syndromes also result from the coinheritance of the sickle gene with hemoglobin (Hb)C gene giving rise to HbSC diseases, with β-thalassemia genes (β^0 or β^+) giving rise to sickle -β^0-thalassaemia or sickle -β^+-thalassemia respectively or with other β-globin structural variants giving rise to other combinations such as HbSO Arab, HbSD disease, and so on. Tables 57.1 and 57.2 list major types of sickle cell syndromes commonly seen in the United States. Certain complications of SCD may be more common in one category than another. Thus, frequent painful crises, severe anemia that requires blood transfusion and acute chest syndrome (ACS), are more common in SS than other types of SCD. Sickle retinopathy, on the other hand, is more common in HbSC disease than in SS. It must be emphasized that the order of severity outlined in Table 57.2 is based

TABLE 57.2

MAJOR SICKLE CELL SYNDROMES ARRANGED IN ORDER OF DECREASING SEVERITY

Disease	Abbreviation
Sickle Cell Anemia	SS

Hb, Hemoglobin; MCV, Mean Corpuscular Volume; Retic, Reticuloyte Count.
*Hb A_2 and Hb C have the same electrophoretic mobility at alkaline pH and are not separable on routine analysis; they can be separated, however, by High Pressure Liquid Chromatography (HPLC).
(Note that all disorders may be associated with variable degrees of α-gene deletions.)

TABLE 57.3

UNIQUE FEATURES OF SICKLE-α-THALASSEMIA ($\beta^S/\beta^S - \alpha/-\alpha$) COMPARED WITH SS WITHOUT α-GENE DELETION (β^S/β^S; αα/αα)

Milder anemia
Increased HbA_2 level
Splenomegaly in adults
Increased prevalence of avascular necrosis
Increased prevalence of retinopathy
Decreased prevalence of cerebrovascular accidents
Decreased prevalence of leg ulcers
Less tissue damage

on population statistics. Thus, if one compares the overall clinical picture of 100 patients with SS, for example, with that of 100 patients with HbSC disease then the latter will be milder as far as frequency of painful episodes, morbidity, and mortality are concerned. On the individual basis, however, the scheme of Table 57.2 does not always apply. Thus, an individual patient with SS may have a mild disease whereas an occasional patient with S-β^+-thalassemia may have a severe disease.

Genotypes

Sickle cell syndromes can also be divided into subcategories depending on the α genotypes and β haplotypes.[16–18] About 65% of patients with SS have normal α genotypes ($\beta^s\beta^s$; αα/αα), 30% have one α gene deleted ($\beta^s\beta^s$; $-\alpha/\alpha\alpha$), and the remaining 5% have two α genes deleted ($\beta^s\beta^s$; $-\alpha/-\alpha$). The effect of α gene deletion on the clinical picture of sickle cell syndromes is controversial. Generally speaking, α gene deletion is associated with milder anemia[19] and less blood transfusion. The increased hemoglobin level associated with α gene deletion however, increases the blood viscosity, which is often accompanied by increased frequency of painful crises[20,21] and vaso-occlusive episodes such as avascular necrosis.[22,23] The effect of α gene deletion on the clinical picture is best illustrated in SS with two α gene deletions ($\beta^s\beta^s$; $-\alpha/-\alpha$). Table 57.3 lists the unique features of this type of SCD.[24,25] It is noteworthy that HbA_2 is elevated in SS with two α gene deletions, a finding that confuses this diagnosis with S-β^0-thalassemia that is, typically, also associated with elevated HbA_2 levels. The clinical picture, family history, hematologic data, and molecular diagnostics can differentiate the two diagnoses.[25]

β-Haplotypes refer to the nucleotide sequence 5′ and 3′ to the sickle gene. Three major types have been described in Africans and African Americans.[17] These are the Senegalese (Sen), Benin (Ben), and Central African Republic (CAR) haplotypes. The significance of these haplotypes pertains to their effect on HbF production. It has been established that the higher the HbF level, the milder is the SS.[21,26] Again, these conclusions are based on population data and may not apply to an individual patient.

Sickle cell syndromes are multisystem disorders that have protean clinical manifestations. Management of these syndromes includes the following approaches: (1) management of anemia and its sequelae; (2) management of painful episodes; (3) management of infections; (4) management of organ damage; and (5) management with experimental therapeutic modalities. This chapter will focus on the pathogenesis and management of acute and chronic sickle cell pain syndromes.

PATHOPHYSIOLOGY

SCD is a quadrumvirate of: (1) pain syndrome; (2) anemia and its sequelae; (3) organ failure including infection; and (4) comorbid conditions. Pain, however, is the insignia of SCD and dominates its clinical picture throughout the life of the patients (Fig. 57.1). Pain also may precipitate or be itself precipitated by the other three components of the quadrumvirate. Management of sickle pain must be within the framework of the disease as a whole and not in isolation. The pain associated with SCD is often perplexing to treat. There is no doubt as to the original pathology, yet because of the complex biopsychosocial accompaniments to SCD, opioid-seeking behavior can easily be misinterpreted as inappropriate. In order not to miss catastrophic complications, a complaint of pain should always be taken seriously. There are anecdotes of patients with SCD who were dismissed from certain programs only to be found dead at home within 24 hours or less after dismissal or to be admitted to other hospitals with serious complications.[27] Sickle pain could be the prodrome of a serious and potentially fatal complication of SCD in some patients.

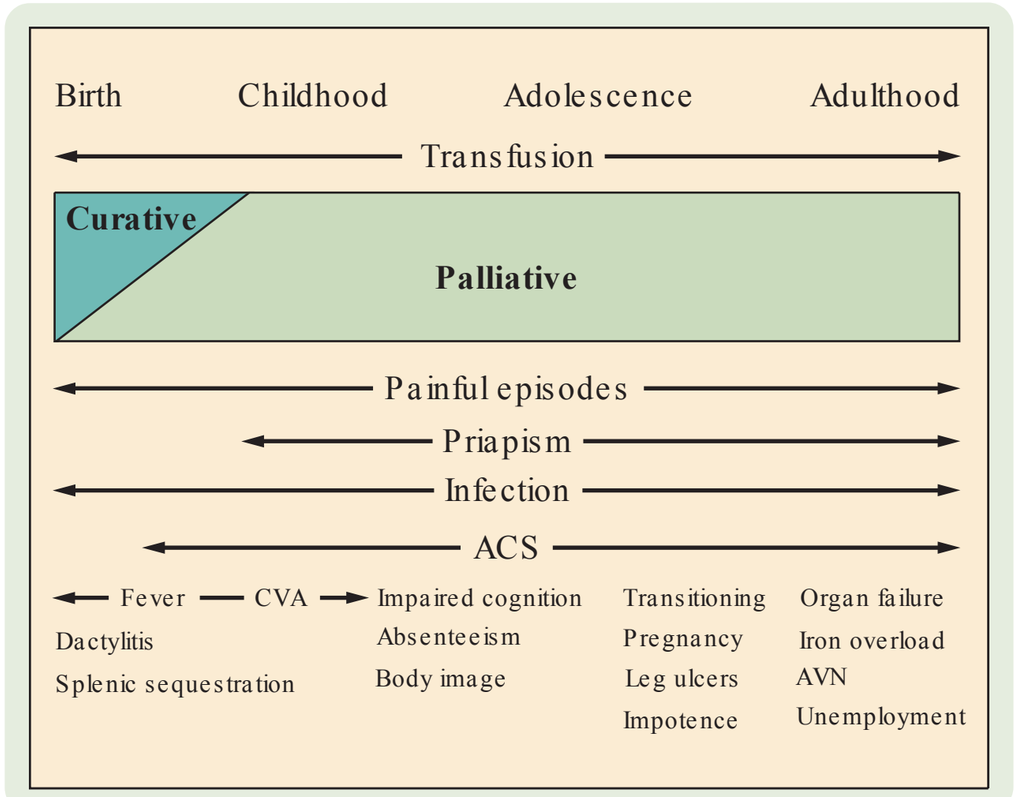

FIGURE 57.1 Sequence of complications of SS from birth through adult life. Cure is possible in selected children. The mainstay of management in most patients is palliative, with pain management being most important. ACS, acute chest syndrome; AVN, avascular necrosis; CVA, cerebrovascular accident. (Modified from Ballas SK. Sickle cell disease: current clinical management. *Semin Hematol* 2001;38:308, with permission.)

Vaso-occlusion

The most important pathophysiologic event in SS that explains most of its clinical manifestations is vaso-occlusion which may involve both the micro- and macrovasculature.[28–31] Factors that culminate in vaso-occlusion are listed in Table 57.4.[9,31–34] The primary process that leads to vascular occlusion is the polymerization of sickle Hb upon deoxygenation which, in turn, results in distortion of the shape of red blood cells (RBCs), cellular dehydration, and decreased deformability and stickiness of RBC that promotes their adhesion to vascular endothelium (Fig. 57.2). Progress in the pathogenesis of vascular occlusion pertains to cellular dehydration and adhesion to endothelial cells described below.

Red Blood Cell Dehydration

Cellular dehydration is secondary to loss of potassium (K^+) and water. Two major transport mechanisms seem to play a significant role in cellular dehydration. The first mechanism is the potassium chloride (KCl) cotransport pathway activated by acidifica-

TABLE 57.4

DETERMINANTS THAT CONTRIBUTE TO VASCULAR OCCLUSION IN SICKLE CELL DISEASE

- Microrheology

  - The environment

tion and cell swelling.[35–37] This pathway is most active in reticulocytes and is a feature of low-density sickle cells (reversibly sickled cells). Reticulocyte dehydration appears to contribute to the generation of dense sickle cells directly without going through repetitive cycles of oxygenation-deoxygenation.[38]

The second transport system that mediates cellular dehydration is the calcium (Ca^{2+}) activated K^+ channel or the Gardos pathway, which seems to be activated by Ca^{2+} reflux-induced deoxygenation.[35–37,39–41] Although much of the intracellular Ca^{2+} in sickle cells is sequestered in endocytic vesicles,[42–44] transient reflux of Ca^{2+} during deoxygenation-induced sickling seems to be responsible for stimulating the Gardos pathway. Unlike the KCI cotransport, the Gardos pathway seems to be most active in the dense fraction of sickle RBCs. However, in most patients, both transport systems are operative.

It should be noted, however, that the exact mechanism by which polymerization of sickle Hb leads to cellular dehydration is not fully delineated to date. Further research in this area may refine current approaches to molecular therapy.

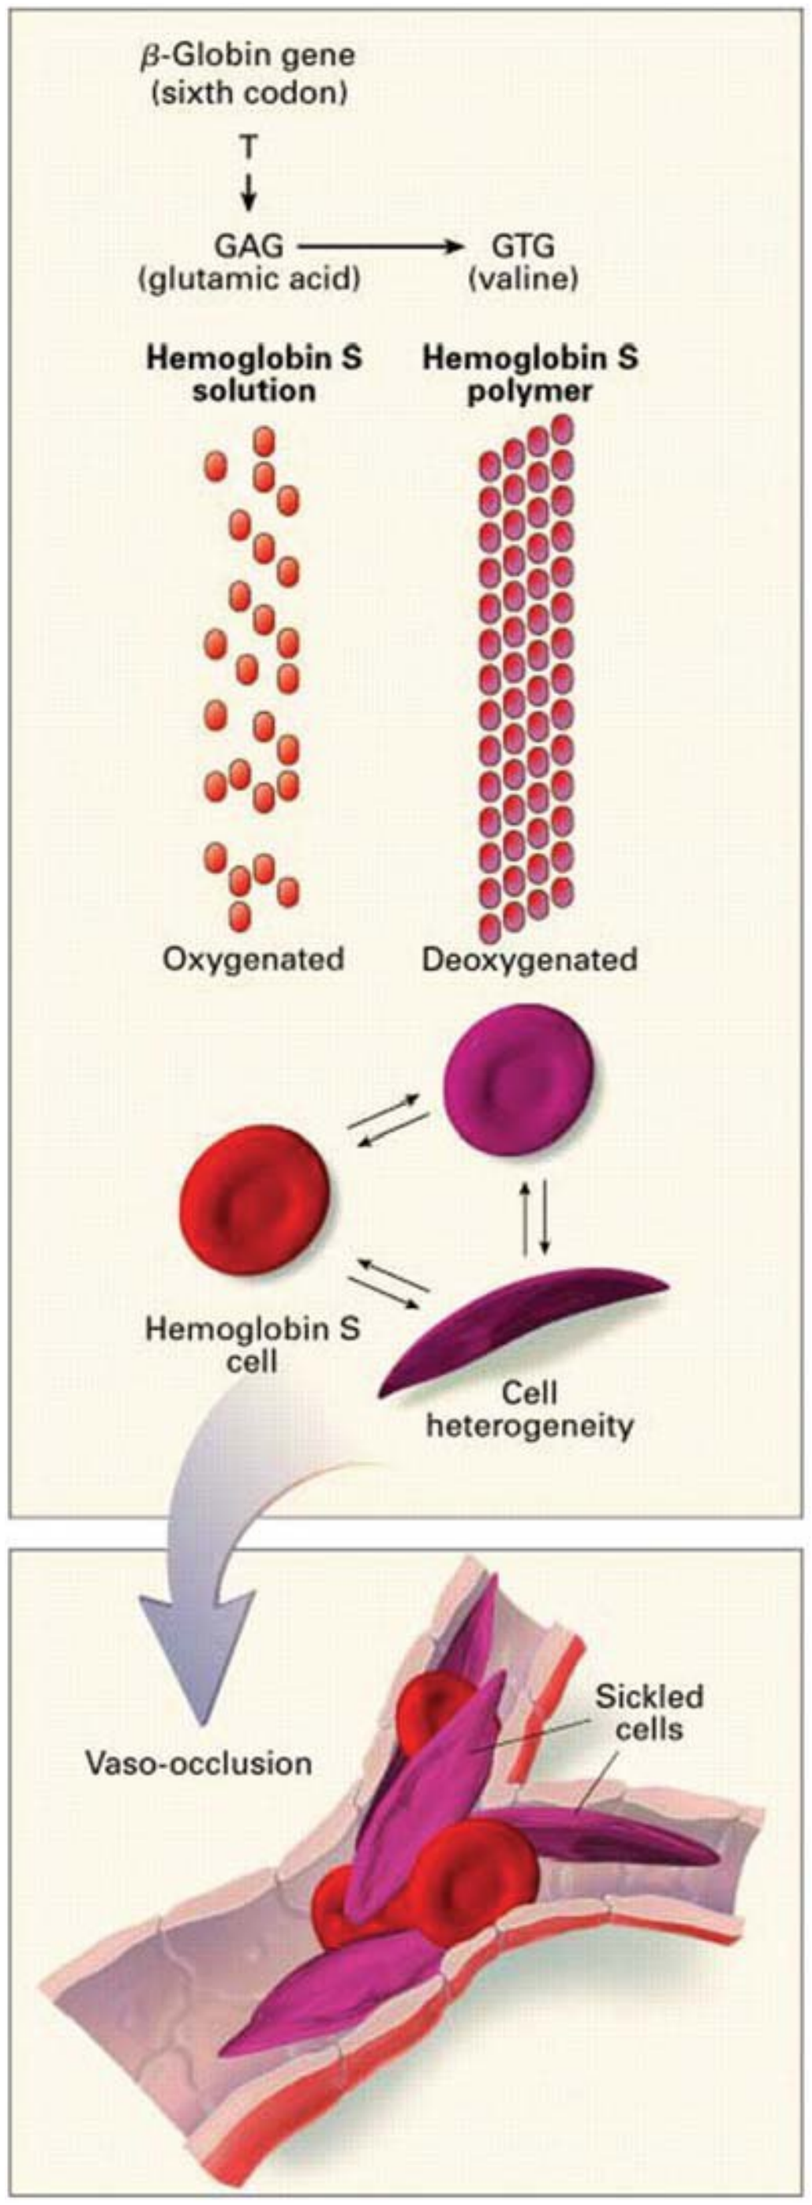

FIGURE 57.2 Pathophysiology of SCD. In hemoglobin S, a substitution of T for A in the sixth codon of the β-globin gene leads to the replacement of a glutamic acid residue by a valine residue. On deoxygenation, hemoglobin S polymers form, causing cell sickling and damage to the membrane. Some sickle cells adhere to endothelial cells, leading to vaso-occlusion. (Reproduced from Steinberg MH. Management of sickle cell disease. *New Engl J Med* 1999;340:1022, with permission.)

Adhesion to Vascular Endothelium

Adhesion of sickle RBCs to vascular endothelium appears to be a pathophysiologic contributor to vaso-occlusion. Sickle RBCs adhere to cultured endothelial cells in vitro under both static and dynamic conditions whereas normal cells do not.[45–48] These findings suggest that sickle RBCs have sticky surfaces that promote their attachment to monolayers of cultured endothelial cells. These in vitro observations have been documented to occur also in ex vivo perfusion studies in rats[49] and transgenic mice.[50] Both cellular and plasma factors have been reported to affect adhesion of sickle RBCs to vascular endothelium. Thus, young deformable sickle RBCs appear to be more adherent to vascular endothelium than are dense, rigid, irreversibly sickled cells.[48,51,52]

Adherence of sickle RBCs to vascular endothelium results in intimal hyperplasia in larger vessels that may lead to vascular occlusion and tissue infarction.[53,54] Hebbel et al.[45] reported strong correlation between the degree of adhesion of SS RBC to endothelial cells in vitro and the severity of the disease in patients with SS or other variants of SCD. Hypofibronectinemia seems also to be related to disease severity: the lower the level of plasma fibronectin, the more severe the disease.[55]

Tissue Damage

Recent in vivo studies in transgenic mice suggest that vaso-occlusion results in the creation of an inflammatory state.[56,57] The sequence of events seems to be as follows: (1) reticulocytes carrying the $\alpha_4\beta_1$ receptor adhere to endothelial cells; (2) this is followed by logjam where there is propagation of occlusion caused by the accumulation of rigid deoxygenated mature RBCs proximal to the site of adhesion; (3) the obstruction eventually clears leading to reperfusion and its associated injury; and (4) a new cycle of adhesion starts thus creating a vicious cycle of occlusion and reperfusion. Evidence of reperfusion injury includes: (1) inflammatory response in the vascular bed of the transgenic mouse with increased leukocyte rolling, adhesion, and emigration after 3 hours of mild hypoxia followed by reperfusion; (2) local production of free radicals; and (3) the complete inhibition of (1) and (2) after the infusion of monoclonal murine anti-P-selectin antibody, before reoxygenation.[56] Restoration of oxygen to ischemic tissue seems to result in the generation of free radicals associated with inflammatory endothelial and tissue damage.

Sickle RBCs from patients with a high level of Hb F seem to be less adherent to vascular endothelium than those from patients with low Hb F levels. Specifically, Setty et al.[58] found that pediatric SS patients with high levels of F cells had a concomitant decrease in the number of CD36+, very late antigen (VLA) 4+, and CD71+ erythrocytes, and hence, less adherent RBCs. Moreover, Hb F seems to affect the exposure of phosphatidylserine on the surface of RBCs and coagulation activation. In vivo cycles of sickling/unsickling with resulting membrane changes and microvesicle formation contribute to phosphatidylserine exposure.[59] Phosphatidylserine-exposing RBCs in the transgenic sickle mouse[60] were found to have shortened RBC survival. Children with SS and high HBF levels were reported to have less phosphatidylserine-exposing RBCs and, hence, milder hemolytic anemia suggesting a possibly milder clinical picture.[61]

Epistatic Genes

Other factors that may also affect the severity of SS include gene modifiers (epistatic genes) that may affect the phenotypic expression of the sickle mutation. Styles et al.[62] reported that specific human leucocyte antigen (HLA) alleles may influence the risk of stroke in SS. Adekile et al.[63] found that the 677 C→T mutation of the methyltetrahydrofolate reduction gene is relatively frequent among Kuwaiti patients with SS, but did not find any correlation with disease severity or prevalence of avascular necrosis. The role of epistatic genes in modifying the phenotypic expression is an active area of research. Genes that modulate the biochemical pathways of nitric oxide biology, oxidants, inflammation, cell adhesion, vasoregulation, and hemostasis may modulate SCD, and single-nucleotide polymorphisms in some of those genes have already been associated with sickle cell subphenotypes.[8] Future research may enable us to decipher the intricate pathophysiology of SS and its complications and usher in newer therapeutic venues.

In addition to the factors discussed above, there is growing evidence that psychosocial and environmental factors may precipitate vaso-occlusion and affect the frequency and severity of painful episodes. Physical stress, trauma, dehydration, and infections are known precipitating factors.

TYPES OF SICKLE PAIN

Sickle cell pain can be classified in a number of ways.[64–66] Pathophysiologically, sickle cell pain could be nociceptive or neuropathic; temporally, it could be acute or chronic; anatomically, it could be somatic, visceral, unilateral, bilateral, localized, or diffuse; pathologically, it could be mild, moderate, or severe; and etiologically, it could be due to the disease itself or secondary to therapy or to comorbid conditions. The etiologic classifications of sickle pain are listed in Table 57.5 and includes acute pain syndromes, chronic pain syndromes, neuropathic pain syndromes, pain secondary to therapy, and pain due to comorbid conditions.

TABLE 57.5

ETIOLOGIC CLASSIFICATION OF SICKLE CELL PAIN

- Acute pain syndromes
  - Acute painful sickle cell crises
  - ACS
  - Acute abdominal pain syndromes
    - Right upper quadrant syndrome
    - Left upper quadrant syndrome
  - Hand-Foot syndrome (dactylitis)
  - Priapism
  - AMF
- Chronic pain syndrome
  - With objective signs
    - Avascular (aseptic) necrosis
    - Arthropathies
    - Vertebral body collapse
    - Leg ulcers
    - Chronic osteomyelitis
  - Without objective signs
    - Intractable chronic pain
- Neuropathic pain syndromes unique/common in SCD
  - Mental nerve neuropathy
  - Ischemic optic neuropathy
  - Spinal cord infarction
  - Other neuropathies
- Pain syndromes secondary to therapy
  - Postoperative pain
  - Loose prosthesis (shoulders/hips)
- Pain syndromes due to comorbid conditions
  - Trauma
  - Peptic ulcer disease
  - Migraine headache
  - Arthritides (septic, rheumatoid, degenerative, collagen)
  - Other conditions

ACUTE SICKLE CELL PAIN SYNDROMES

The Acute Painful Sickle Cell Crises

Vaso-occlusion is the de facto prerequisite for the development of the acute sickle cell painful crises. Tissue damage consequent to vaso-occlusion initiates a number of complex biochemical, neurologic, electrochemical, and inflammatory events that incite nociception and pain. The inflammatory response to vaso-occlusion may enhance sympathetic activity via neuroendocrine pathways triggering release of norepinephine, which in the setting of tissue injury causes more tissue ischemia, thus creating a vicious cycle. It is the combination of ischemic tissue damage and secondary inflammatory response that accounts for the extreme severity of the pain in SCD (Fig. 57.3). Tissue injury generates several major pain mediators[67–70] including, but not limited to, interleukin-1, bradykinin, K^+, hydrogen (H^+), histamine, substance P, and calcitonin gene-related peptide (CGRP). Inter-

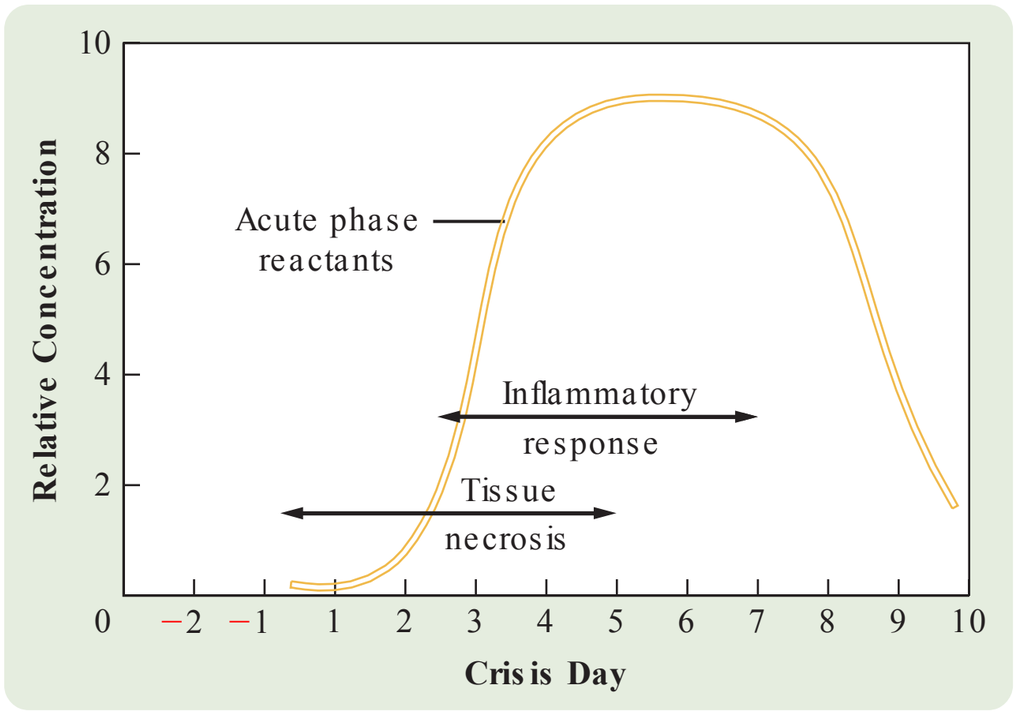

FIGURE 57.3 Sequence of events during the evolution of painful crisis. Tissue necrosis consequent to ischemia elicits an inflammatory response that is associated with an increase in the serum level of acute-phase reactants. (Modified from Ballas SK. Sickle cell disease: clinical management. *Baillieres Clinical Haematology* 1998;11:193, with permission.)

keukin-1 (IL-1) is an endogenous pyrogen and also upregulates the cyclooxygenase gene leading to synthesis of prostaglandins E_2 and I_2. Bradykinin, K^+, H^+, and histamine activate nociceptive afferent nerve fibers and evoke a pain response. Prostaglandins sensitize peripheral nerve endings and facilitate the transmission of painful stimuli along A-δ and C fibers that reach the cerebral cortex via the spinal cord and the thalamus. Moreover, activated nociceptors release stored substance P, which itself facilitates the transmission of painful stimuli. Bradykinin, substance P, and CGRP also cause vasodilatation and extravasations of fluids that can lead to local swelling and tenderness. The pathway for pain stimuli is subject not only to activators, sensitizers, and facilitators, but also to inhibitors. Serotonin, enkephalin, β-endorphin, and dynorphin are endogenous central pain inhibitors. Thus, in a given patient, the net outcome of tissue ischemia may be severe or mild pain, depending on the extent of tissue damage and the net balance of pain stimulators versus pain inhibitors. This may explain, in part, the considerable variation in the frequency and severity of painful sickle crises among patients, and longitudinally in the same patient.

Predisposing Factors

There are at least three sets of predisposing factors that predict the frequency and severity of the acute painful sickle cell crisis. These are genetic, cellular, and environmental (or epigenetic) factors. Genetic factors include Hb F level, the coexistence of α-gene deletion, β-thalassemia, β-haplotypes, and epistatic gene modifiers as was mentioned above. They also include gender, since males constitute about 60% to 66% of admissions to the hospital.[71,72] Females, however, have longer hospital stays per admission than males.[71] Cellular factors with decreased RBC deformability and increased number of dense cells in the steady state have a salutary effect, most likely because these are associated with more severe anemia and hence relatively decreased whole blood viscosity.[19,73] Patients with SS and relatively high hemoglobin level are more likely to experience more frequent crises than those patients with SS and lower Hb level. Decreased level of vitamin A (less than 30 ug/dL) and nocturnal hypoxia are environmental factors amenable to preventative therapy.[74,75]

Precipitating Factors

Like other acute episodes of illness, the acute sickle cell painful crisis has precipitating features. Major reported factors that seem to precipitate vaso-occlusive crises include dehydration, stress of any kind (physical, traumatic, physiologic, emotional), infection, acidosis, sleep apnea, and pregnancy.[64,65] Nevertheless, most painful episodes are not preceded by an obvious precipitating factor. Gill et al.[76] reported that daily mood and stress predict painful events, utilization of health care facilities, and work activity in adults with SCD. In a retrospective study, Smith et al.[77] found a complex relationship between temperature changes, temperature extremes, and their relationship to emergency department (ED) visits and hospital admissions for sickle cell painful crises in adults. The most relevant finding of this study was an inconsistent confirmation of a relationship between daily ambient temperature and ED visits or hospital admissions for sickle cell crises. Jones et al.[78] studied retrospectively the number of admissions with acute pain and SCD to King's College Hospital, London, together with daily meteorological records collected locally. Data from 1400 days and 1047 separate admissions were analyzed. Increased admissions were significantly associated with increased wind speed and low humidity, but showed no relationship to temperature, rainfall, or barometric pressure. The strongest effect was for maximum wind speed/humidity ratio with 464 admissions on days in the lowest two quartiles of this parameter and 582 in the highest quartiles. The effect of high wind and low humidity is likely to be related to skin cooling. Anecdotally, many patients report that sudden changes in temperature seem to precipitate acute painful episodes.

Phases of the Acute Painful Crisis

The clinical picture of sickle cell pain is protean in nature. Typically, acute painful episodes affect long bones and joints with the low back being the most frequently reported site of pain.[64,79] Other regions of the body, including the scalp, face, jaw, abdomen, and pelvis, may be involved. A severe acute sickle cell painful episode has been defined as one that requires treatment in a medical facility with parenteral opioids for 4 or more hours.[80,81] The occurrence of three or more such crises indicates that the affected patient has severe SCD. Descriptors most often used to characterize sickle cell pain include throbbing, sharp, dull, stabbing, and shooting in decreasing order of frequency.

The concept that the painful crisis evolves along phases was first introduced by Ballas and Smith[82] and Akinola et al.[83] who independently and almost simultaneously described the presence of two phases of the uncomplicated painful crisis in prospective longitudinal studies of adults with SCD. Akinola et al.[83] studied 20 patients over 16 months, and Ballas and Smith[82] studied 117 painful crises affecting 36 patients with SS over 6 years. In both studies, the initial phase was associated with increasing pain, decreased RBC deformability, increase in the number of dense cells, red cell distribution width (RDW), hemoglobin distribution width (HDW), reticulocyte count, leukocytosis, and decrease in the number of platelets. The second phase was characterized by established pain of maximum severity and gradual reversal of the abnormalities of the first phase. Later, Ballas[84] revised the description of the painful crisis and refined its evolution into four phases by including observations by several other investigators (Fig. 57.4, Table 57.6). The phases were called prodromal, initial, established, and resolving phases. Beyer et al.[85] found that the painful crisis also evolves along phases in children but the phases were broken down into seven and were labeled differently. Jacob et al.[86] studied 40 crises affecting 27 children over 9 months. Their findings supported previous observations related to changes during the evolution of painful episodes that may be occurring in phases. Although the phases were given different names, the concepts were similar.

The evolution of the uncomplicated painful crises along phases allows the observer to determine the presence of objective signs of its occurrence. To that end there are two extremely important prerequisites for finding objective signs. First, the availability of

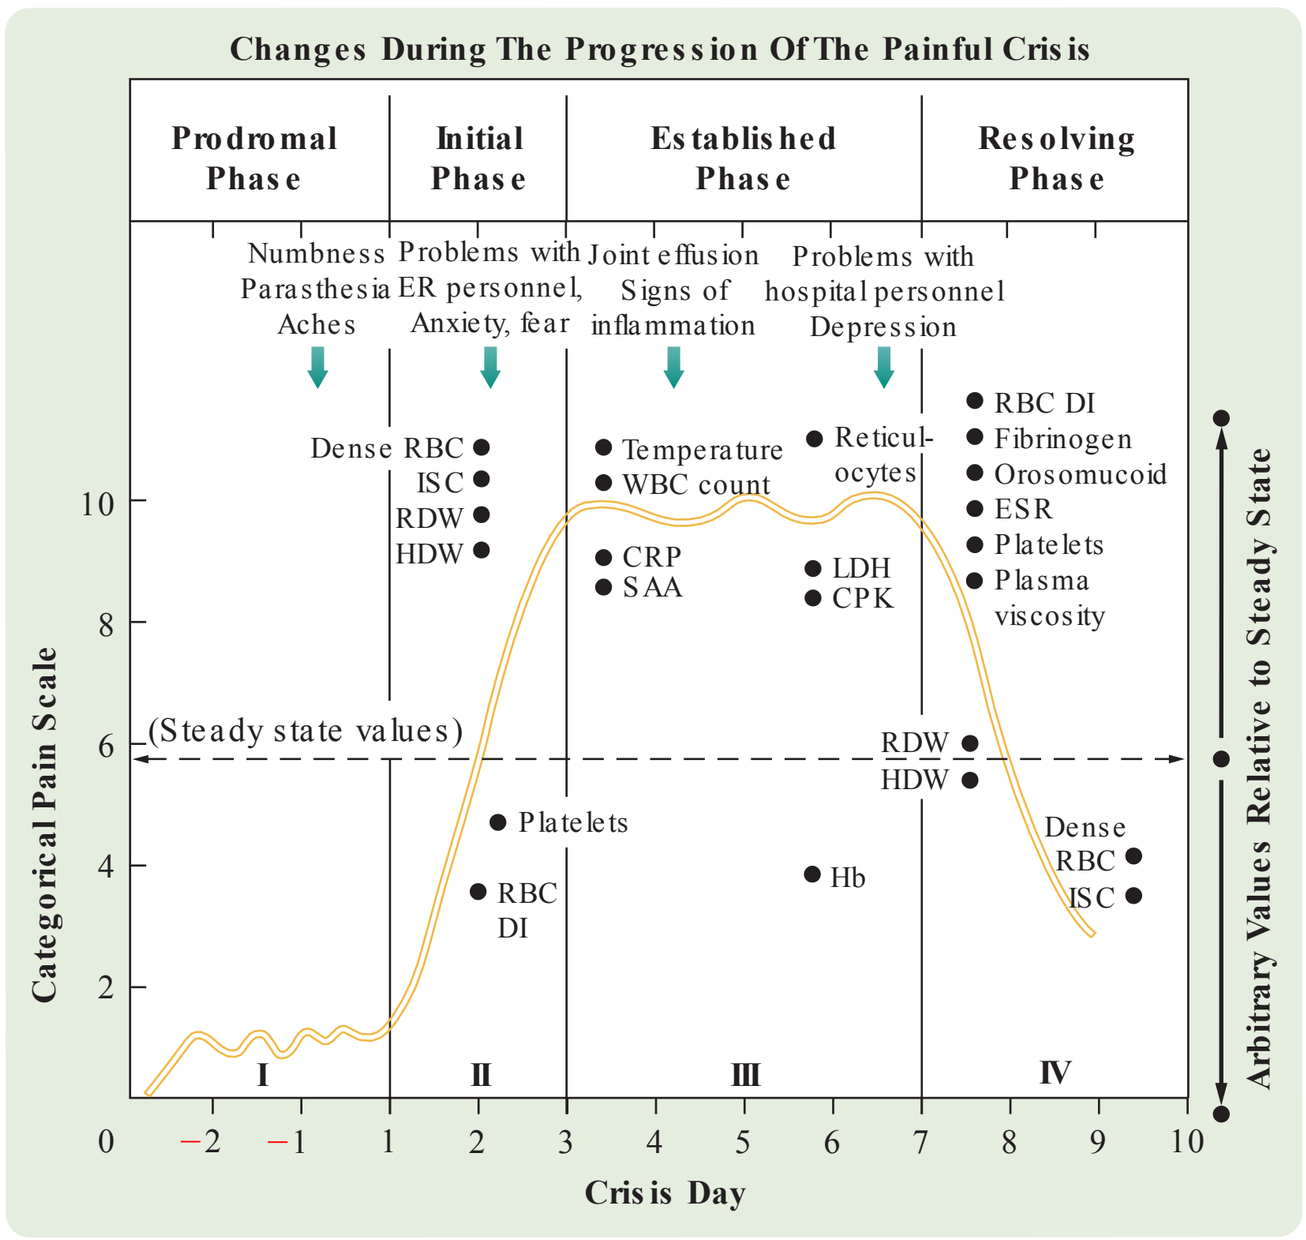

FIGURE 57.4 A typical profile of the events that develop during the evolution of a severe sickle cell painful crisis in an adult in the absence of overt infection or other complications. Such events are usually treated in the hospital with an average stay of 9–11 days. Pain becomes most severe by day 3 of the crisis and starts decreasing by day 6 or 7. The Roman numerals refer to the phase of the crisis: I, prodromal phase; II, initial phase; III, established phase; and IV, resolving phase. Dots on the X axis indicate the time when changes became apparent, and dots on the Y axis indicate the relative value of change in comparison to the steady state indicated by the horizontal dashed line. Arrows indicate the time when certain clinical signs and symptoms may become apparent. Values shown are those reported at least twice by different investigators; values that were anecdotal, unconfirmed, or that were not reported to occur on a specific day of the crisis are not shown. CPK, creatinine phosphokinase; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; Hb, hemoglobin; HDW, hemoglobin distribution width; ISC, irreversibly sickled cells; LDH, lactate dehydrogenase; RBC DI, red cell deformability index; RDW, red cell distribution width; SAA, serum amyloid A. (Modified from Ballas SK. The sickle cell painful crisis in adults: phases and objective signs. *Hemoglobin* 1995;19:327, with permission.)

steady state data. A steady state is best defined as a point in time in the history of a patient not preceded by an acute painful crisis or comorbid conditions for at least 1 month, not followed by a painful crisis within 2 days and in the absence of previous blood transfusion for at least 3 or, even better, 4 months. The second prerequisite to identify objective signs is to do serial lab determinations. Some parameters change at variable points in the progression of a painful crisis (see Fig. 57.4, Table 57.7). The presence of phases allows the provider to monitor the progress of the crisis and manage it rationally, thereby avoiding the conflicts that may arise between patients and providers about the authenticity of pain.

TABLE 57.6

PHASES OF THE ACUTE SICKLE CELL PAINFUL CRISIS

Phase	Possible synonym(s)	Duration
Prodromal	Precrisis	Up to 2 days before crisis
Initial	First Evolving Infarctive	Days 1 and 2 of the crisis
Established	Second Postinfarctive Inflammatory	Days 3–7 of crisis
Resolving	Last Healing Recovery Postcrisis	Post day 7 of crisis

From Ballas SK. Sickle cell pain. In: *Progress in Pain Research and Management*. Vol. 11. Seattle, WA: IASP Press; 1998, with permission.

Consequence of the Crisis

The decrease in Hb level with the concomitant increase in reticulocyte count seems likely to be due to the hyperhemolysis that sometimes occurs during uncomplicated painful crises. This has been confirmed[87] by the finding of decreased RBC survival during the evolution of the painful crisis in selected patients (Fig. 57.5). The increase in platelet count, fibrinogen, and blood viscosity as the crisis resolves indicates a hypercoagulable state that may cause recurrence of the crisis. This may explain, in part, why about 16% of patients are readmitted to the hospital with a painful crisis within 1 week after discharge.[71,82] Other possible causes of readmission include premature discharge or the development of an opioid withdrawal syndrome after discharge. More recently, Ballas and Lusardi[71] and Jacob et al.[88] reported a decrease in analgesic efficacy after the fourth to sixth hospital day in some patients. These patients continued to have relatively high pain scores by the time they were discharged and were most likely to be readmitted within 1 week after discharge. The reasons for loss of analgesic efficacy are not known. Possible etiologies include inadequate pain management, increase in the levels of acute phase reactants that bind to opioids and make them unavailable to induce pain relief, the development of tolerance to opioids, hyperalgesia, or adaptations at opioid receptor sites.[65,66] Patients with frequent painful crises that require hospital admission seem to have more morbidity and mortality than otherwise.

The above data suggest that special attention has to be paid at the resolving phase of the painful crises. Measures should be considered to avoid the possibility of hospital readmission soon after discharge. Providers should consider continuing aggressive pain therapy during hospitalization; if needed, rule out the possibility of tolerance and consider opioid rotation, designing discharge instructions that avoid causing withdrawal after discharge. To that end, the establishment of a postdischarge clinic to evaluate patients within a few days after discharge to ensure compliance with discharge instructions is recommended.

TABLE 57.7

MAJOR CHANGES IN OBJECTIVE SIGNS DURING THE EVOLUTION OF THE SICKLE CELL PAINFUL CRISIS

Acute Chest Syndrome

In 1979, Charache et al.[89] introduced the term ACS to define acute episodes of fever, chest pain, increased leukocytosis, and pulmonary infiltrates (Fig. 57.6) in adult patients with SS, most of whom probably had pulmonary infarction. More recently, the definition of ACS was expanded to include hypoxemia, cough, shortness of breath, wheezing, chills, and worsening anemia.[90] Moreover, the current definition of ACS stresses that the infiltrates must be "new," when compared with a previous chest ra-

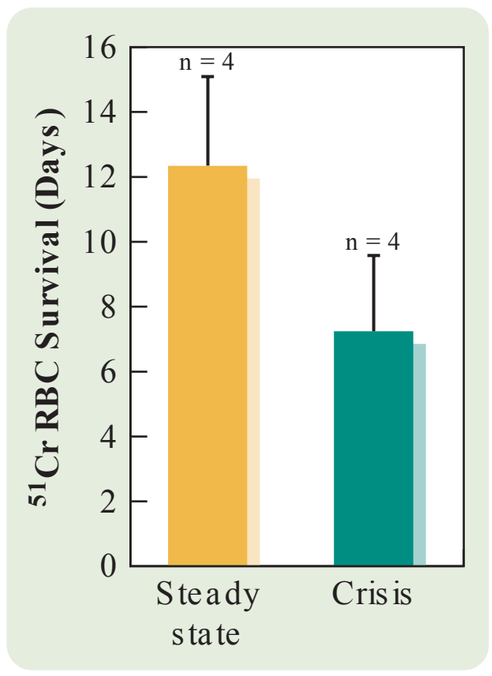

FIGURE 57.5 RBC survival decreases significantly during the evolution of the sickle cell painful crisis.

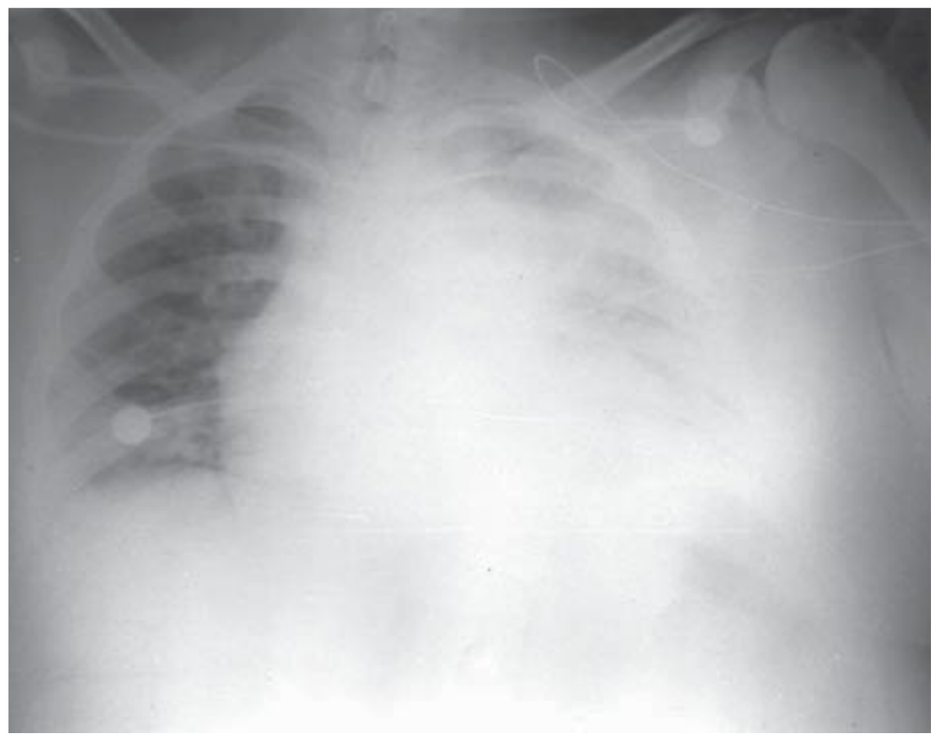

FIGURE 57.6 Chest radiograph showing diffuse pulmonary infiltrates of a patient with ACS.

diograph. If a previous radiograph is not available, the infiltrate should be considered as new and treated as such. The signs and symptoms of ACS vary from very mild to very severe and even life-threatening. Another feature of ACS that is not included in the definition is the presence of blister cells in peripheral blood.[91] ACS is second only to acute painful episodes as a cause of hospitalization of patients with SCD and also the most common complication of surgery and anesthesia.[92] ACS is the most common cause of death and is closely associated with acute painful episodes especially in adults.[93,94] Although ACS is usually self-limited and resolves with treatment, it can be associated with respiratory failure with a mortality rate of about 1.8% in children and 4.8% in adults.[95,96]

Risk factors for developing ACS are listed in Table 57.8.[97,98] The incidence of acute syndrome is highest in SS, followed by S-β^0-thalassemia, Hb SC disease and S-β^+-thalassemia in decreasing order of frequency. The single most important preventative factor is a high level of Hb F due either to endogenous genetic factors or to exogenous induction, for example with hydroxyurea.[80,97,99–101] The mean corpuscular volume (MCV) of RBCs, platelet count, and α-thalassemia bear no relation to ACS.[90,98] Known etiologies of ACS include infection, especially community-acquired pneumonia, pulmonary infarction as a result of in situ sickling, fat-bone marrow embolism, or pulmonary embolism. Infection is commonly caused by chlamydia, mycoplasma, respiratory syncytial virus, coagulase-positive *Staphylococcus aureus*, *S. pneumoniae*, *Mycoplasma hominis*, parvovirus, and rhinovirus in decreasing order of frequency.[95] Adhesion of sickled RBCs to endothelial cells of small- or medium-sized pulmonary vessels may result in occlusion of microvascular flow and consequent pulmonary infarction.[101–103] This sequence of events is supported by dynamic imaging studies but confirmatory clinical data are not available. Pulmonary thromboembolism is uncommon as a cause of ACS despite the presence of a hypercoagulable state in sickle cell disease.[104] It seems that this hypercoagulable state plays a more important role in stimulating cellular adhesion and activating the inflammatory system than in initiating the thrombotic cascade.[49,105] There is no definite evidence of the prevalence of pulmonary embolism (PE) in hospitalized patients with SCD. Stein et al.[106] determined the prevalence of deep vein thrombosis (DVT) and PE in hospitalized patients with and without SCD. They found high prevalence of PE in patients with SCD compared with non-SCD African American patients of the same age, although the prevalence of DVT was comparable in both groups. Stein et al.[106] suggested that their findings are compatible with the concept that thrombosis in situ mimics PE and might be present in many SCD patients. On the other hand, their data suggest that PE is not rare in patients with SCD, indicating that PE might be an etiologic factor in patients with SCD who develop respiratory symptoms. In such patients, imaging studies may clarify the exact diagnosis. Pulmonary fat-bone marrow embolism (Fig. 57.7) in patients with SS appears to be more common than previously thought.[98,104] The characteristic clinical picture is of severe bone pain, usually in long bones, followed by dyspnea, hypoxia, and fever. Tissue infarction of the bone marrow within the long bones seems to generate a source of fat and necrotic tissue that has been demonstrated on autopsy.

The exact mechanism by which fat or bone marrow reaches the lung during painful sickle cell crises is not well known. A probable cause is "retrograde embolization."[107] According to

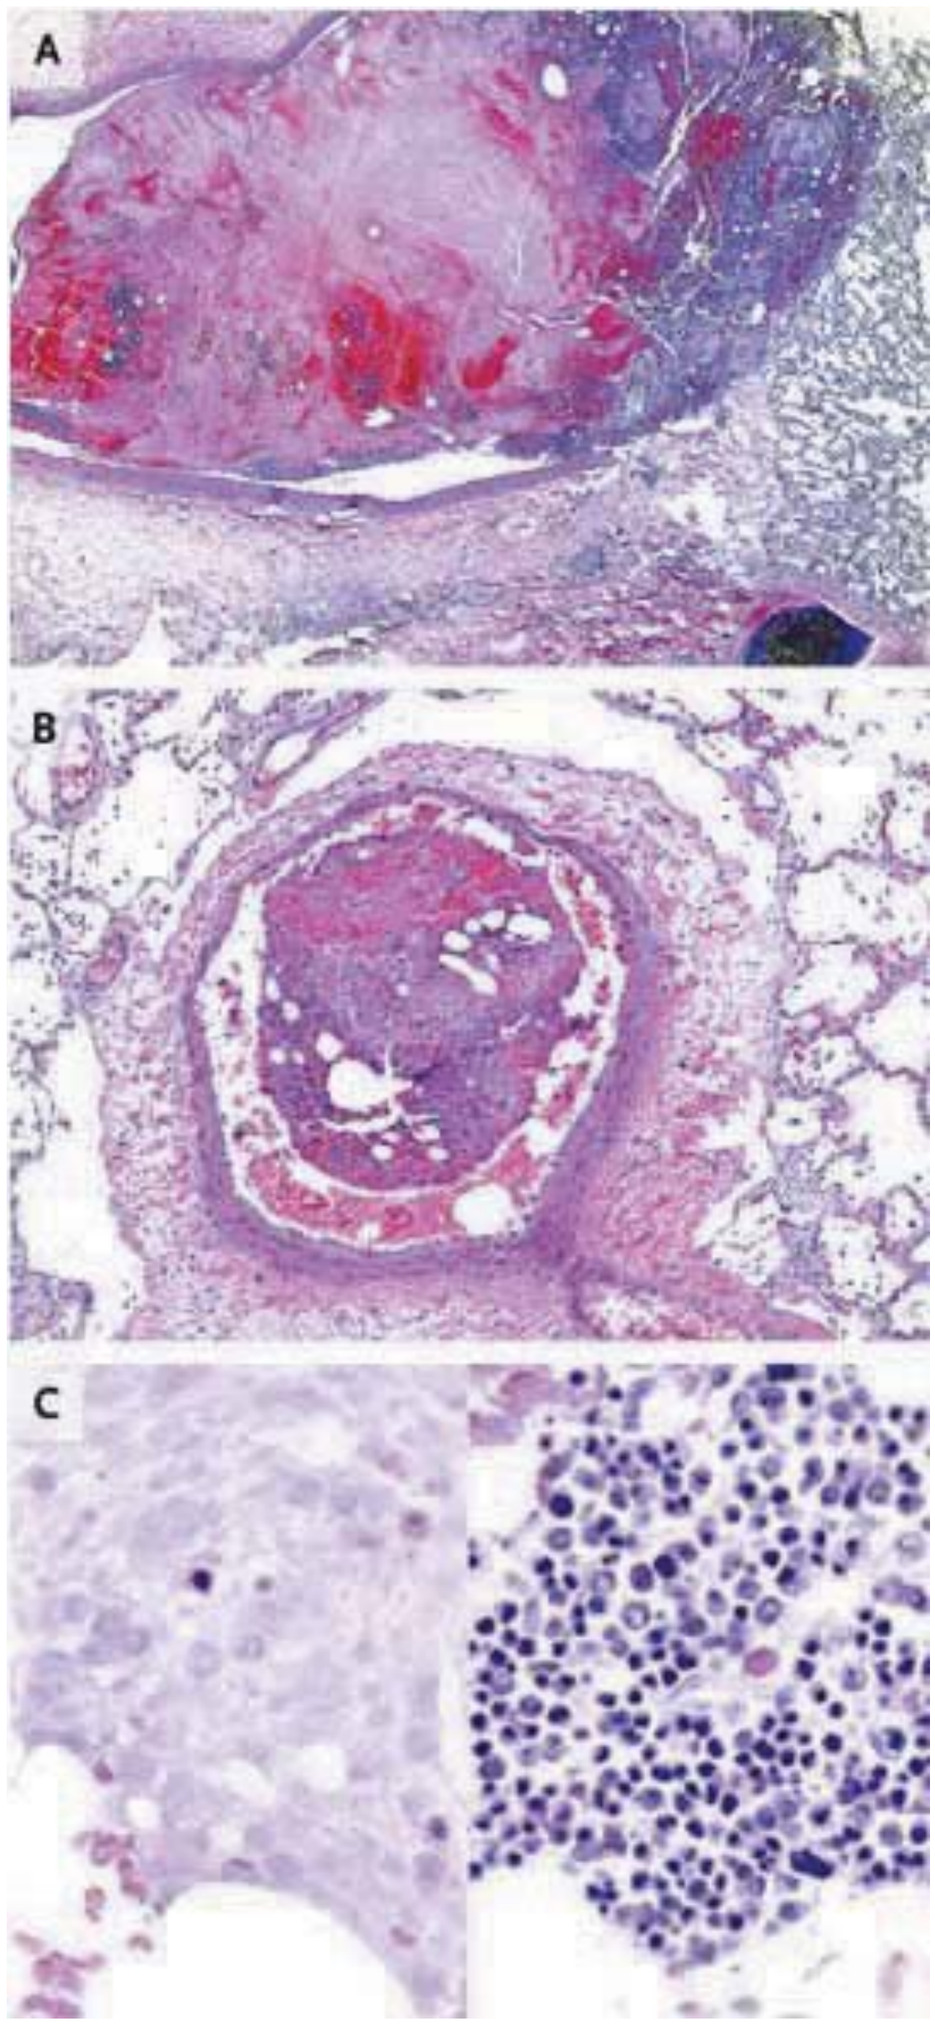

FIGURE 57.7 Photomicrographs of Lung and Bone Marrow (Hematoxylin and Eosin). Bone marrow emboli, consisting of particles of bone marrow surrounded by fibrin, are present in small pulmonary arteries (Panels A and B). In Panel C, a section of bone marrow shows the absence of cellular detail, indicating infarction (*left*), as compared with a section of normal bone marrow from the same patient (*right*). (Medoff BD, Shepard JA, Smith RN, et al. Case records of the Massachusetts General Hospital. Case 17-2005. this hypothesis, obstruction of vascular channels within the bone by conglomerates of sickled RBCs leads to bone marrow infarction and necrosis of the hematopoietic elements and fat. The increased intramedullary pressure disrupts the endothelium of the engorged vessels, thus allowing the retrograde movement of necrotic bone marrow and fat into adjacent intramedullary sinusoids which directly communicate with arterioles and veins, in turn spreading the necrotic material systemically. Concurrent with tissue damage, the secretary phospholipase A_2 ($sPLA_2$) is activated and cleaves membrane phospholipids to form several mediators of inflammation including free fatty acids.[108] The latter causes damage to pulmonary endothelium culminating in a leak syndrome which, if severe, may be similar to adult respiratory distress syndrome. Elevated levels of PLA_2 is both a marker and probably a predictor of ACS.[95,108]

Diagnostic work-up of ACS should include serial chest radiographs, induced deep sputum and blood cultures, monitoring arterial blood gases, monitoring hemoglobin level, ventilation, and perfusion scans, and ruling out thrombophlebitis in the pelvis or lower extremities. The diagnosis of fat embolism entails the identification of fat-laden macrophages in blood, urine, induced deep sputum, or better bronchoalveolar lavage fluid obtained by bronchoscopy.[96,104] Blister cells have been described in the peripheral blood of patients with SCD and ACS.[91]

Management of ACS includes oxygen, incentive spirometry, antibiotics, simple blood transfusion or exchange transfusion, judicious use of analgesics, careful hydration, and possibly vasodilators. Incentive spirometry prevents splinting and atelectasis, and may actually prevent ACS in patients who have rib infarction.[109] Intravenous (IV) antibiotics are indicated since it is difficult to rule out pneumonia or infected lung infarcts. A combination of a third generation cephalosporin and a macrolide or a fluoroquinolone should be used to cover typical and atypical pathogens. Simple transfusion or exchange transfusion is indicated in patients with worsening respiratory function. The beneficial effects of blood transfusion may not be due simply to decreasing the proportion of sickled RBCs and other mechanisms may be involved. These include: (1) an immunomodulatory mechanism by which inflammatory cytokines (IL-8, in particular) bind to the Duffy antigen present on transfused RBCs, but often absent on RBCs of African Americans,[110] and (2) the albumin that is present in transfused units or used in blood exchange may bind free fatty acids, thus neutralizing their damaging effect on the pulmonary endothelium.

Although IV corticosteroids in children with ACS may be beneficial,[111] their use in adults with ACS is controversial. Huang et al.[112] reported 2 adult patients with SCD whose clinical picture deteriorated and was complicated by worsening pain, fat embolism, and coma after corticosteroid therapy. Adults, unlike children, have more adipose tissue that may hypertrophy with corticosteroids, increasing the chances of fat embolization. Moreover, corticosteroids may induce or worsen avascular necrosis, which is more common in adults than in children.

Excessive use of opioid analgesics may precipitate ACS because of their depressive effects on respiration. Recent reports[95] recommend the use of nonsteroidal anti-inflammatory drugs (NSAIDs). This recommendation should be considered carefully. Opioids have a few systemic adverse effects, and careful monitoring of their use ensures their safety. They should be discontinued if the respiratory rate is less than 10 per minute, and their adverse effects can be quickly reversed with opioid antagonists. NSAIDs, on the other hand, have considerable systemic adverse effects that may not be readily obvious. NSAIDs decrease the level of prostaglandins and prostacyclin that are essential in modulating the vascular tone of smooth muscle and renal blood flow. Thus, NSAIDs may worsen the clinical picture of acute syndrome as a result of vasoconstrictive effects and bronchospasm.

Preliminary reports on the use of nitric oxide (NO), a vasodilator, in patients with SCD support a possible role of this agent in the management of ACS.[113] Another recent investigational approach to treat ACS includes the use of purified poloxamer 188, which is a nonionic surfactant. It is hypothesized that this agent reduces blood viscosity, prevents adhesion of RBCs to vascular endothelium, and improves microvascular blood flow.[114,115] Ballas et al.[116] performed a Phase I evaluation of purified poloxamer 188 in the management of ACS. Forty-three patients with SCD and ACS were treated with doses up to 2960 mg/day by continuous IV infusion. The maximum tolerated dose has not been identified. No evidence of renal toxicity or other limiting adverse events were found. One adult patient died due to sepsis and adult respiratory distress syndrome, which were unrelated to treatment. Poloxamer 188 seems to be safe in patients with ACS, and preliminary data suggest that it may shorten its duration and the length of hospitalization in a dose-related manner. Children appear to benefit more than adults. The data and safety profile justify further studies with purified poloxamer 188 in the treatment of ACS.

Because ACS is relatively frequent in hospitalized patients with SS and in view of the need to monitor arterial blood gases in its management, it is important to establish baseline blood gases and pulmonary function tests for all patients. These determinations will be of value in evaluating patients who present with acute onset of pulmonary signs and symptoms.

Acute Abdominal Pain Syndromes

The abdomen is the second most common site of pain in SCD after musculoskeletal pain (including chest wall). The cause may be intra-abdominal pathology or pain referred from the lungs with pneumonia or from the lower ribs and the femoral heads with avascular necrosis. Specific pain syndromes due to SCD are listed in Table 57.9.[64]

An acute abdominal sickle cell painful crisis is characterized by severe, usually generalized, abdominal pain and signs of peritoneal irritation. It may also be accompanied by fever, leukocytosis, and markedly elevated levels of lactate dehydrogenate (LDH). Clinically, a severe abdominal crisis may closely mimic an acute abdomen and may lead to an exploratory laparotomy in search of surgically correctable pathology. Patients with SCD who arrive at the ED with an acute abdominal crisis may be misdiagnosed with acute appendicitis or acute cholecystitis and undergo laparotomy and often "prophylactic" appendectomy and/or cholecystectomy.[64,84]

TABLE 57.9

DIFFERENTIAL DIAGNOSIS OF ABDOMINAL PAIN IN SICKLE CELL DISEASE

Left upper quadrant syndrome

Abdominal crisis (pseudo-acute surgical abdomen)
Bowel infarction
Girdle syndrome

From Ballas SK. Sickle cell pain. In: *Progress in Pain Research and Management*. Vol. 11. Seattle, WA: IASP Press; 1998, with permission.

The abdominal pain has been attributed to enlarged mesenteric and retroperitoneal lymph nodes, bone marrow hyperplasia, infarction of the vertebral bodies, hepatobiliary disease, splenic disease, or mesenteric arterial thrombosis.[117,118] The abdominal pain seen in crisis may persist for several days, although protracted episodes lasting longer than 5 days are not unusual.[119] Differentiation from other causes of acute abdominal pain may be difficult.

Pain in the trunk in association with abdominal distention has been referred to as girdle syndrome.[120,121] It is thought to result from sickling in the mesenteric blood supply. Fluid levels may be visible on radiographs of the abdomen. Mild cases are self-limiting over a 2- to 5-day period and are treated symptomatically with IV fluids since gut absorption is impaired. More severe cases have associated involvement of the liver and lungs, and in very severe cases multiorgan failure including ACS should be considered. Such patients may have markedly distended loops of bowel and require nasogastric suction and exchange transfusion. Infarction of segments of gut can occur, and surgical intervention may be required.

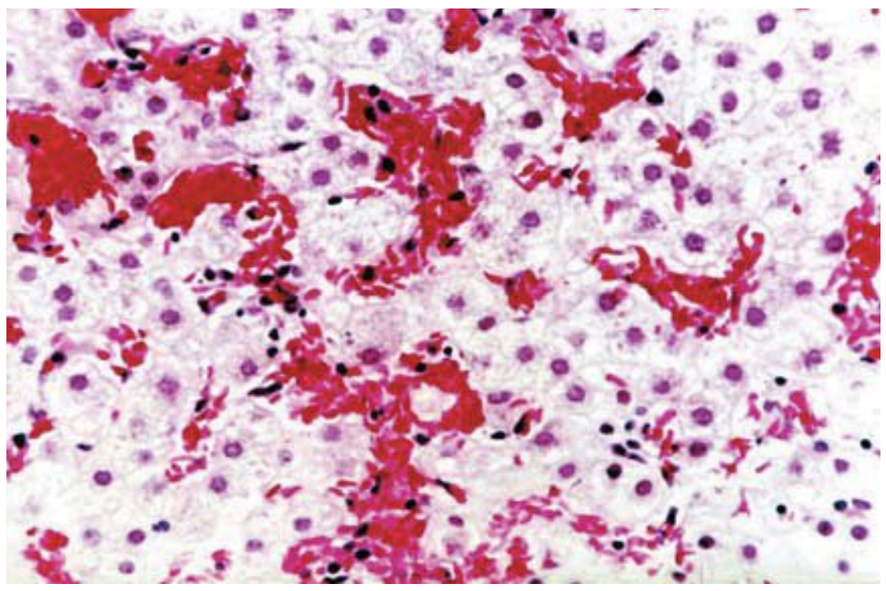

FIGURE 57.8 Liver biopsy from a patient with SS and hepatic crisis showing engorgement of hepatic sinusoids with sickled erythrocytes. (Ballas SK. Sickle cell pain. *Progress in Pain Research and Management*. Vol. 11. Seattle, WA: IASP Press; 1998, with permission.)

Right Upper Quadrant Syndrome

Chronic hyperbilirubinemia, cholelithiasis, and gallbladder disease are common in patients with SCD. At least two thirds of patients with SS have hepatomegaly and 75% have cholelithiasis. About 90% of patients with cholelithiasis undergo cholecystectomy either prophylactically or after an episode of acute calculus cholecystitis. Most cholecystectomies are currently performed by laparoscopy, a much simpler procedure than laparotomy, and are associated with less morbidity.[122,123]

A genetic basis for the hyperbilirubinemia pertains to mutations in UDP-glucuronyl transferase 1(UGT1A1), the enzyme that catalyses bilirubin glucuronidation. It seems that genetic polymorphism of the UGT 1A enzyme affects the metabolism of bilirubin. The bilirubin level as well as gallstone formation appear to be significantly higher in patients with the 7/7 genotype compared with the 6/6 genotype of the enzyme. Similar findings were reported in patients with Hb E-thalassemia.[124,125]

Vasavda et al.[126] determined the linear effects of α-thalassemia, the UGT1A1, and haem oxygenase (HMOXI) polymorphisms on bilirubin levels and cholelithiasis in 263 patients with SCD. Regression analysis showed that serum bilirubin levels and the incidence of gallstones were strongly associated with the number of UGT1A1 (TA) repeats in all subjects ($p < 0.0001$ and $p < 0.01$, respectively). While HMOXI genotype had no effect, coinheritance of α-thalassemia reduced serum bilirubin levels in all SCD patients independently of the number of UGT1A1 (TA) repeats. Each additional (TA) repeat was associated with an increase in mean serum bilirubin levels of 21% and cholerlithiasis risk of 87% in SCD.

Hepatic crisis (also called sickle cell intrahepatic cholestasis) is manifested by the sudden onset of right upper quadrant pain, progressive hepatomegaly, increasing bilirubin levels (mostly indirect), and prolongation of prothrombin and partial thromboplastin times.[127] The levels of liver enzymes (γ-glutamyl transpeptidase [γGT] and alanine amino transferase [ALT]) are also increased but not to those levels seen in acute viral hepatitis. Liver biopsy shows engorgement of hepatic sinusoids with sickled erythrocytes (Fig. 57.8). Hepatic crises vary in severity from minor episodes to sever life-threatening situations. Children and adults may suffer from either form; adults, however, have a higher frequency of the severe form. Total blood exchange is a recommended form of therapy. Blood exchange is indicated if the total bilirubin level increases progressively to values greater than 50 g/L. At that level, the prothrombin time values are usually prolonged. Blood exchange should be total in nature that is, remove whole blood and replace it with RBCs and fresh frozen plasma in order to correct the coagulation abnormality.[128]

Left Upper Quadrant Syndrome

Acute Splenic Sequestration Crisis. The spleen is the first organ to suffer from the destructive effects of sickle microvasculopathy that eventually lead to functional asplenia and autosplenectomy. During infancy, the spleen is enlarged in about 75% of patients with sickle anemia. Children between the ages of 5 months and 2 years are most vulnerable to splenic sequestration that varies in severity from mild to life-threatening episodes. In its full blown picture, acute splenic sequestration is characterized by a pentad of: (1) rapid fall in hemoglobin level, (2) rise in reticulocyte count, (3) fall in platelet count, (4) sudden increase in spleen size associated with acute pain and tenderness in the left upper quadrant, and (5) signs and symptoms of hypovolemia.[129,130] Minor episodes may resolve spontaneously but severe episodes can be fatal and may be mistaken for the sudden infant death syndrome. Fibrosis occurs by the age of 8 years and the risk for splenic sequestration decreases.[131,132] Nevertheless, older children and adults with persistent splenomegaly in certain sickle cell syndromes (SS with two a-gene deletions, Hb SC disease, and sickle -β-thalassemia) continue to be vulnerable for relatively milder episodes of splenic sequestration and for splenic infarction or splenic hemorrhage.[133] Severe splenic sequestration that could be life-threatening, however, has been described in adults with SS.[134–137]

The pathophysiologic mechanisms that lead to acute splenic sequestration are not well understood. One possible mechanism is acute obstruction of the venous flow from the spleen with a resultant damming effect associated with sudden enlargement of the spleen due to pooling of RBCs and platelets.[138,139] The acidotic environment of the spleen, due to its sluggish circulation, stimulates sickling, increases viscosity, and contributes to further obstruction of blood flow. Infection can cause more vascular engorgement in addition to rapid acceleration of sickling. Obstruction of venous flow may be related to abnormal rheologic properties of sickle erythrocytes.[140] Moreover, scanning electron microscopy has demonstrated trapping rigid sickle cells in the splenic cords of patients with SS.[141]

Treatment of acute splenic sequestration consists of rapid restoration of intravascular volume and oxygen-carrying capacity. This goal is achieved by the transfusion of sickle-negative RBCs at a rate of 15–20 mL/kg with careful monitoring to avoid sudden overexpansion of blood volume that may precipitate pulmonary edema. After successful treatment, the spleen usually shrinks within a few days and gradually regains its baseline size.

Acute episodes of splenic sequestration tend to recur within a few months to a year after the initial sequestration crisis. Splenectomy has been recommended for patients who survive the initial severe episode.[30] The onset of splenic sequestration corre-

lates with the increased risk for septicemia from *Streptococcus pneumoniae* and *Haemophilus influenza* type b, and it is recommended that all patients with sickle cell syndromes receive pneumococcal and *H. influenza* vaccines. It is important to educate the family about acute splenic sequestration so they can be alert for early symptoms and seek immediate medical intervention. The spleen is the major organ that produces immunoglobulin M (IgM). Patients with autosplenectomy typically have low levels of IgM, a finding that is similar to those patients with anatomic splenectomy.[142]

Hand–Foot Syndrome (Dactylitis)

This acute pain syndrome occurs most commonly in infants and young children between the ages of 6 months and 2 years with a few case reports up to 7 years. The clinical picture is characterized by acute painful swelling of one or more extremities. It is caused by inflammation due to ischemic infarction of the bone of the affected extremity resulting in swelling, redness, and pain in affected areas. Fever and leukocytosis may be present. The episode is usually self-limiting and resolves within 1 week, but recurrent attacks are common. Treatment is symptomatic and if the attack persists, acute osteomyelitis should be ruled out.[64,65]

Priapism

Priapism occurs when sickle cells congest the copra and prevent emptying of blood from the penis. It can result from tricorporal involvement (both of the corpora cavernosa and the corpus spongiosum) or bicorporal involvement (both corpora cavernosa). The latter is more common, especially in children, and is not usually associated with impotence. There are two major clinical presentations of priapism: acute and chronic.[143] The acute presentation is characterized by a prolonged painful erection that persists beyond several hours, responds poorly to exchange transfusion, and frequently requires surgical intervention. Acute priapism may be followed by complete or partial impotence. The chronic form of priapism is characterized by repetitive, reversible, painful erections called ‘‘stuttering’’ priapism. It usually occurs after intercourse or it may awaken patients early in the morning. Stuttering priapism responds well to diazepam or pseudoephedrine. Patients who become impotent may benefit from psychologic counseling and the insertion of penile implants. A practical and relatively simple approach to manage outpatients with priapism has been recently reported.[105] Specifically, aspiration of the corpora cavernosa followed by irrigation with a dilute epinephrine solution was effective in producing detumescence in most patients. Patients who do not respond to this approach are potential candidates for exchange transfusion and/or surgery.[128]

An association between priapism, leg ulceration, nitric oxide resistance, pulmonary hypertension, and death was reported by Kato et al.[144] The hallmark of this association seems to be an elevated level of LDH, a marker of hyperhemolysis.

Acute Multiorgan Failure

This is a catastrophic life-threatening complication of SCD in the context of acute sickle cell painful crisis that may even occur in patients with otherwise mild SCD.[145,146] Fever, rapid decrease in hemoglobin level and platelet count, nonfocal encephalopathy, and rhabdomyolysis are associated with acute multiorgan failure (AMF). Prompt and aggressive simple blood transfusion or blood exchange transfusion could be life saving with rapid recovery of organ failure in most cases. AMF may occur in patients with a history of relatively mild disease with little or no evidence of chronic organ damage and may be recurrent. High hemoglobin levels in the steady state may be a predisposing factor.

Differential diagnosis of AMF includes ACS and drug overdose. AMF is initially heralded by a rapid fall in hemoglobin and platelet counts from baseline. Aspartate aminotransferase (AST), ALT, total and direct bilirubin, serum creatinine, and creatine phosphokinase are elevated by the third or fourth day of an acute sickle cell painful crisis.

CHRONIC SICKLE CELL PAIN

There are two types of chronic sickle cell pain: chronic pain due to obvious pathology (leg ulcers and avascular necrosis) and intractable chronic pain with no obvious objective signs.

Avascular Necrosis

Avascular necrosis (also called ischemic necrosis or osteonecrosis) is the most commonly observed complication of SCD after the number of painful crises in adults. Although it tends to be most severe and disabling in the hip area, it is a generalized bone disorder in that the femoral and humeral heads as well as the vertebral bodies may be equally affected. Figure 57.9 shows a ‘‘fish mouth’’ or step-like depression seen in some patients with SCD and is probably caused by avascular necrosis or infarction of the central portion of the vertebral body and may lead to vertebral collapse.[64] The limited terminal arterial blood supply and the paucity of collateral circulation make these three areas especially vulnerable to sickling and subsequent bone damage. Patients with SS and α-gene deletion have a higher incidence of avascular necrosis because the relatively high hematocrit increases blood viscosity and thus, enhances microvasculopathy in the aforementioned an-

FIGURE 57.9 ‘‘Step-like’’ or ‘‘fish mouth’’ deformity of the lumbar vertebrae of a patient with SS. (Ballas SK. Sickle cell pain. *Progress in Pain Research and Management*. Vol. 11. Seattle, WA: IASP Press; 1998, with permission.)

FIGURE 57.10 Avascular necrosis of the femoral head in SCD. Sickle cell pain. (Ballas SK. Sickle cell pain. *Progress in Pain Research and Management*. Vol. 11. Seattle, WA: IASP Press; 1998, with permission.)

atomic sites.[147,148] The MCV and AST levels are negatively correlated with vascular necrosis.[148]

Figure 57.10 shows an example of the radiologic picture of avascular necrosis of the hips in sickle cell disease. Ficat et al.[149] proposed a four-stage radiographic classification as summarized in Table 57.10. Knowing the stage of the disease is important in choosing the most appropriate therapeutic approach. At the time of diagnosis of avascular necrosis, 47.4% of the patients showed stage II disease, 29.6% showed stage III, and 23% showed stage IV.[148]

Medical treatment of avascular necrosis is symptomatic and includes providing nonopioid and/or opioid analgesics for pain relief as well as physical therapy. Advanced forms of the disease (stage III or IV) require total bone replacement. Core decompression in the management of avascular necrosis appears to be effective if done in the early stages of avascular necrosis.[150] This, however, was not supported by a prospective randomized multicenter study comparing physical therapy alone with core decompression and physical therapy for femoral head avascular necrosis in 46 patients with SCD.[151] Physical therapy alone appeared to be as effective as hip core decompression followed by physical therapy in improving hip function and postponing the need for additional surgical intervention at a mean of 3 years of treatment. Results of hip arthroplasty in patients with SS are not as encouraging as results of arthroplasty performed for arthritic hip.[152] Placement of an internal prosthesis may be difficult owing to the presence of hard sclerotic bone in patients with SCD. Other problems associated with hip arthroplasty in these patients include an increased incidence of infection,[153,154] a failure rate of about 50%, and a high morbidity due to loosening of both cemented and uncemented prostheses. Recent techniques of arthroplasty may improve the life expectancy of hip prostheses.[155]

Leg Ulcers

Leg ulceration is a painful and sometimes disabling complication of SS that occurs in 5% to 10% of adult patients. The most common site for the appearance of leg ulcers is the distal third of the leg, especially on the inner area, just above the ankle and over the medial malleoli (Fig. 57.11). Ulceration involves the skin and underlying tissues of the involved areas. The deeper the ulcer, the more severe. Leg ulcers are classified into stages depending on their depth and net surface area (Table 57.11). Severe pain may necessitate the use of opioid analgesics. Leg ulcers are more common in males and older patients, and less common in patients with α-gene deletion, high total Hb level, or high levels of Hb F.[24] Leg ulcers seem to be more common in patients who are also carriers of the CAR β-gene cluster haplotype.[156] As was mentioned earlier, leg ulceration can be associated with priapism, pulmonary hypertension, and death in a subtype of SCD characterized by high levels of LDH as a marker of hyperhemolysis.

Treatment of leg ulcers includes wound care using wet to dry dressings soaked in saline or Burow's solution. With aggressive daily localized treatment, many ulcers heal within a few months. Leg ulcers that persist beyond 6 months may require blood transfusion or skin grafting, although results of the latter treatment have been disappointing. Because leg ulcers may recur after minimal trauma, protective stockings or leggings with nonelastic (special Velcro) lower-extremity orthoses with ankle straps, to be worn during working hours, appears to be an effective preventative measure.[157] Principles of management include education, protection, infection control, débridement, and compression bandages. Débridement may be achieved surgically or medically

TABLE 57.10

RADIOLOGICAL CLASSIFICATION OF AVASCULAR NECROSIS

Imaging findings		Clinical symptoms
Stage I	Normal plain radiograph Normal CT Abnormal MRI with marrow and bone necrosis	Usually no pain
Stage II	Sclerosis and lytic areas on radiography Necrosis on CT and MRI	Pain not always present
Stage III	Flattening of femoral head, widening of the joint space and cresent sign on radiograph. Cresent sign on MRI	Pain present especially with weight bearing, relieved with rest.
Stage IV	Collapse of the femoral head and narrowing of the joint space; osteoarthritis	Pain at rest, joint stiffness and weakness, secondary arthritis

A B

FIGURE 57.11 Leg ulcers in a patient with SS. (Ballas SK. Sickle cell pain. *Progress in Pain Research and Management*. Vol. 11. Seattle, WA: IASP Press; 1998, with permission.)

by using agents, such as a papain/urea/chlorophyllin ointment (Panafil), that facilitate débridement by enzymatic digestion of necrotic tissue. The efficacy of blood transfusion or exchange transfusion, hyperbaric oxygen, and skin grafting is anecdotal. Recent advances in management include the use of platelet-derived growth factor, prepared either autologously (Procuren), or by recombinant technology (Regranex) and the use of cultured skin grafts.

The relationship between leg ulcers in patients with SS and hydroxyurea is not clear. Early reports[158] suggested that hydroxyurea seems to have a salutary effect on leg ulcers. Recent reports[159] indicated that that hydroxyurea used in treatment of myeloproliferative disorders is associated with increased incidence of leg ulcers. To date, there is no evidence whether hydroxyurea is beneficial or harmful in the management of leg ulcers in patients with SS. Ferster and colleagues[160] recently reported their experience with a group of 93 children and young adults with SCD treated with hydroxyurea for a median follow-up of 3.5 years. Leg ulcers did not complicate the clinical picture of these patients.

TABLE 57.11

STAGES OF THE SEVERITY OF LEG ULCERATION

Stage 1: Nonblanchable erythema of intact skin; the heralding lesion of skin ulceration. In individuals with darker skin, discoloration of the skin, warmth, edema, induration, or hardness may also be indicators.

Stage 2: Partial thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.

Stage 3: Full thickness skin loss involving damage to or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.

Stage 4: Full thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendon, joint capsule). Undermining and sinus tracts may also be present.

Chronic Pain Without Objective Signs

The second type of chronic pain in SCD is intractable chronic pain without obvious pathology where the only complaint is the patient's self-report of unremitting pain. Failure to treat recurrent severe acute painful crises aggressively, extensive surgery, or severe emotional stress may all contribute to the development of an intractable chronic pain syndrome. The pathophysiology of this transition is not well understood. Possibilities include recruitment and activation of dormant afferent nerve fibers that transmit stimuli and result in "central sensitization" whereby the pain threshold is lowered to a degree that ambient innocuous events cause severe pain—a condition referred to as allodynia.[64,65,70] Moreover, central sensitization changes the way the brain and nervous system respond to pain; new pathways develop that can lead to the sensation of chronic pain.[70,161] Once chronic pain sets in, it usually becomes independent of the usual inciting events. Nevertheless, chronic pain syndrome continues to be punctuated with superimposed acute painful crises due to vaso-occlusion.

Neuropathic Pain

Neuropathic pain is characterized as burning, tingling, shooting, lancinating, and numbing. These symptoms may occur in the presence or absence of obvious central or peripheral nerve injury. A number of reported neuropathic pain syndromes seem to be associated with, and due to, the disease itself. These include mental nerve neuropathy,[162,163] trigeminal neuralgia,[164] acute proximal median mononeuropathy,[165] entrapment neuropathy,[166] acute demyelinating polyneuropathy,[166] ischemic optic neuropathy,[167] orbital infarction,[168] orbital apex syndrome,[169] and spinal cord infarction.[170]

MANAGEMENT OF SICKLE CELL PAIN

Effective management of sickle cell pain is complex and entails a thorough understanding of the issues that are associated with the treatment of pain in an incurable chronic disease.[64–66,171,172] Major prerequisites for an effective and rational management of sickle cell pain pertain to the patient, the pathophysiology of the disease, the pharmacology of analgesics, and the attitude of the

health care providers. A patient is a unique human entity. The more a provider knows the patient, the more effective pain management becomes. Knowledge of the patient should not be limited to age, sex, precise diagnosis, complications, and previous pain management methods. It should also take into consideration the biopsychosocial fabric of the patient's life, including his or her level of education, employment status, occupation, family structure, source of income, ethnicity, housing conditions, fears, religion, beliefs, habits, hobbies, and perception of the severity and prognosis of his or her disease. This approach allows the physician to individualize pain management and avoid unfounded generalizations about patients and their consumption of opioid analgesics. Such generalizations, for instance, may result in oversedation of a patient naïve to opioids, or in undertreatment of a patient too tolerant to them.

Sickle cell pain, like other types of pain, is a complex human experience that is strongly affected not only by pathophysiologic factors but also by psychologic, social, cultural, and spiritual ones. It is, however, consequent to tissue damage generated by the sickling process and occlusion of the microvasculature, as was described in the pathophysiology section. An important aspect of effective management of sickle cell pain is the intent of the care provider. Do the providers in question endeavor to treat patients in an empathetic manner by listening to, respecting, and believing them? Or do they stigmatize them as drug addicts demonstrating drug-seeking behavior and thereby justify the expulsion of some patients from their system?

Perhaps the difficulty of treating sickle cell pain can best be addressed with reference to a clinical anecdote. The patient is a young African American male who makes frequent visits to the ED for painful episodes and is labeled as an addict. The connection of the disease with race results in many ramifications that impact on care. Disparities in care arise because of the wide cultural gulf between health care providers who are predominantly white and the predominantly black patient group.[172–175] Communication and stereotyping complicate pain assessment and treatment. Frequent flyers in the ED often become labeled as drug seekers, regardless of their diagnosis or the chronicity of their disease. Concerns about addiction are justified in the SCD population since these patients carry many associated risks, including disease chronicity and dismal prognosis, comorbid psychiatric disease including depression and anxiety, young age, and unremitting pain. Yet the approach needs to be one not of avoiding opioids, but rather recognizing the risk while providing adequate pain management (with opioids if necessary) under controlled conditions that aim to minimize risk.

Nonpharmacologic Management of Pain

Nonpharmacologic management of pain includes cutaneous stimulation (transcutaneous electrical nerve stimulation), heat, cold, and vibration, distraction, relaxation, massage, music, guided imagery, self-hypnosis, self-motivation, acupuncture, and biofeedback. Although there are no well-controlled clinical trials of the efficacy of these methods in the management of sickle cell pain, there are many anecdotal reports of their efficacy in pain management, both by patients and providers.

Pharmacologic Management of Pain

Pharmacologic management of pain includes three major classes of compounds: nonopioids, opioids, and adjuvants.[64,65,171] Nonopioids include acetaminophen, NSAIDs, topical agents, and corticosteroids. Most clinically useful opioid analgesics are agonists at the mu-opioid receptor, although the mixed agonist/antagonist buprenorphine and the partial agonist pentazocine have achieved some popularity, especially in Europe. Adjuvants commonly used in the management of sickle cell pain include antihistamines, benzodiazepines, antidepressants, anticonvulsants, and phenothiazines. Aspects of these pharmacologic agents that pertain to SCD will be discussed here.

Nonopioids and Sickle Cell Disease

Acetaminophen. This drug has been implicated in papillary necrosis of the kidney and in hepatoxicity with a dose that exceeds 4 g/day or with the recommended dose in patients with liver disease.[176–178] Since patients with SCD are at risk for renal and hepatic complications, the dosage given to them and their renal and hepatic functions have to be monitored carefully.

NSAIDs. These drugs are well-tolerated by most patients. Care has to be taken if the patients are sensitive to them, if the renal function is impaired, and if the patient has pulmonary complications, especially ACS. NSAIDs should not be given to patients with impaired renal function. NSAIDs occasionally cause bronchospasm and may worsen or precipitate ACS.[178]

Opioids and Sickle Cell Disease

Depending on point of view, opioids may be considered first-line treatment for severe acute sickle cell pain. There is certainly no alternative to opioids for the treatment of severe pain, although nonopioid and nonmedical treatments should be added whenever possible as opioid-sparing adjuncts. Specific considerations for choice of opioid in SCD patients are outlined here.

Meperdine. This should be avoided whenever possible. If it has to be given, the dose has to be adjusted in the presence of abnormal renal function, and the patient has to be monitored for early signs of neurotoxicity such as myoclonus, tremors, and hyper-excitability.[64,65]

Morphine. The major metabolite of morphine (6-morphine glucuronide) is excreted in the kidney. Accordingly, the dose of morphine has to be monitored in the presence of renal failure. Other recently reported side effects of morphine include increased risk of ACS in patients with SCD,[179,180] acceleration of renal injury,[181] and retinopathy[182] in transgenic sickle mice. In a retrospective study of hospitalized children with SCD, Buchanan et al.[180] reported that patients on morphine were more likely to develop ACS and had longer hospital stays than patients receiving nalbuphine hydrochloride (Nubain).

Methadone. Methadone is associated with several potential toxicities, including cardiotoxicity due to prolongation of the QTc interval with arrhythmia that could be fatal. In treating sickle cell pain with methadone, the provider should follow the adage "start low and go slow." Most reported fatalities due to methadone are due to overaggressive introduction of methadone to patients who have never before received the drug. This is a reflection of the drug's unusual and unpredictable pharmacokinetics. Another important point in using methadone is to be aware of the side effects of other drugs used in combination with methadone. Patients with SCD often receive antibiotics or antidepressants which also prolong the QTc interval. The EKG of such patients should be carefully monitored.[70,161]

Adjuvants and Sickle Cell Disease

Antidepressants that are known to cause priapism should not be used in patients with history of priapism. These include trazodone, selective serotonin reuptake inhibitors, and tricyclic antidepressants in decreasing order of risk to cause priapism.[70,161]

Pain Management of Outpatients[64,65,171]

Management of patients with SCD as outpatients in the clinic or office is extremely important and is the basis on which future treatments and interventions are based. Patients should be followed by the same providers in order to maintain continuity of care. The most important aspect of outpatient management is in

the collection of baseline data that include detailed medical history, physical exam, known complications, medications, and comprehensive laboratory data. Management of exacerbations in the ED or in the hospital depends heavily on knowing the steady state parameters of the patient in question. As was mentioned earlier, a steady state is a point in time in the history of a patient that is not preceded by an acute painful episode or comorbid conditions for at least 1 month or more and that is not associated with blood transfusion within the previous 3–4 months. It is highly desirable that patients be seen and evaluated in the office or clinic by a social worker and a psychologist or psychiatrist. It is in the outpatient setup that details of care in general and in the ED, day unit, and hospital in particular are explained and discussed. The pros and cons of all medications the patient is taking will be reviewed. Prescriptions will be given as needed. Vaccines will be administered when required.

Treatment of sickle cell pain as a chronic pain condition using round the clock long-acting opioids has been advocated by some clinicians.[183,184] They claim that such regimens stabilize the disease, reduce the number and frequency of acute exacerbations and crises, reduce ED visits, and reduce length of hospital stay.

In the outpatient setting, patients should be empowered to cope with their disease and be authorities on its manifestations that apply to them individually. This includes education about SCD, its genetic basis, inheritance and family counseling; adherence to regular schedule of medical follow-up; avoidance of situations that exert an adverse effect on their disease and adoption of those activities of daily living that are beneficial to them; knowing their rights and responsibilities as patients with SCD when dealing with care providers, medical facilities, and the workplace; and participation in local support groups and communication with community leaders and advocates.

Management and follow-up of outpatients in the office and clinic should culminate in an individualized treatment plan for each patient. Such a plan should summarize pertinent aspects of the medical history, physical exam, laboratory data, complications, and treatment plans as outpatients, in the day unit, emergency room, and the hospital. In some places, the treatment plan may be transformed into an identification card to be carried by the patient and presented to case provider as needed.[185]

Pain Management in the Day Unit

The major advantage of treating sickle cell painful crisis in the day unit (or day hospital) is that the patients do not have to wait for a long time before they receive treatment.[186] In the day unit, analgesic therapy is usually initiated within 15–20 minutes after arrival to the unit. Adult patients are admitted to the day unit if they have an uncomplicated painful crisis based on inclusion and exclusion criteria protocol. After thorough assessment, treatment is initiated with IV hydration and a loading dose of opioid analgesic followed by assessment within 30 minutes. After the initial assessment, the patient may be medicated with 25% to 75% of the loading dose of opioid analgesic depending on the level of pain relief and sedation. The patient's vital signs are assessed every 30 minutes for the first 2 hours of treatment, and then hourly thereafter. If the respiratory rate falls below 10 breaths per minute, systolic blood pressure below 90 mm Hg, and/or sedation, the opioid is withheld and the patient is closely monitored. The duration of treatment usually lasts an average of 6 hours.

Pain Management in the Emergency Department[64,65,171]

Treatment of acute sickle cell painful episodes in the ED follows similar principles of thorough assessment, treatment with analgesics/adjuvants, coordination of cure, monitoring, outcome, and disposition.

The major problem in the ED is the length of waiting time to initial analgesia, which could be up to several hours. Needless to say, waiting while in pain constitutes a stressful situation that could worsen the painful crises and render it no longer amenable to resolution and discharge from the ED, but to hospital admission. Many EDs are in the process of determining and implementing strategies that could shorten the time to initial treatment.

Specific treatment in the ED should be based on the history or the computerized version of the treatment plan, if available. Usually, analgesics are given individually every 2 hours for a total of three doses. Adjuvants may also be given intravenously or orally as needed. If the pain is resolved or reduced to a level with which the patient is comfortable, the patient is discharged with instructions for follow-up by the primary care physician and/or hematologist. Otherwise, the patient will be admitted to the hospital.

Management of Sickle Cell Pain in the Hospital[64,65,171,187]

Prerequisites for rational management of the acute sickle cell painful crisis in the hospital include knowledge of the patient, knowledge of the nature of sickle cell pain, and knowledge of the pharmacology of analgesics in general and opioids in particular. To that end, it is desirable to have patients with crises admitted to the care of providers (preferably hematologists) who are familiar with these prerequisites and with the principles of pain management. Patient-controlled analgesia (PCA) is a useful method of delivering opioid analgesics in hospitalized patients.[187] Successful management of the acute painful crisis in the hospital should include the following steps:

- Multidimensional assessment to determine the location of pain, its intensity, its quality, precipitating factors, modifying factors, triggers, and to determine mood, relief, and sedation. A major component of assessment is to listen and believe the patient without a judgmental attitude.
- Choice of analgesics (opioids/nonopioids), adjuvants, and hydration, if needed; such choices are individualized based upon the past medical history and the assessment of the patient in question. If the acute painful episode is superimposed on chronic pain for which the patient is taking long-acting/controlled-release opioids with short-acting opioids for breakthrough pain, keep the long-acting/controlled-release opioids the same and discontinue the oral short-acting ones.
- Determination of the route and method of administration of short-acting analgesics. These, again, should be individualized; parenteral analgesics are usually administered either on a fixed schedule or via a PCA pump.
- Titration of the dose of analgesics to achieve relief with which the patient is comfortable.
- Maintenance of the dose that achieves adequate relief. Consider opioid rotation (i.e., change the opioid chosen) initially to an equianalgesic or lower dose of a different opioid if the first opioid does not achieve or maintain relief.
- Plan to treat breakthrough pain, neuropathic pain, and side effects of the crisis or the analgesics, if present.
- Tapering the dose of analgesics once the patient uses the PCA pump less frequently or the intensity of pain decreases by two or more points.
- Gradual switching to oral analgesics using tables of equianalgesic dose as an initial guide. One example would be to decrease the parenteral dose by 25% and replace it with an equianalgesic oral dose. The latter should be adjusted according to its effect to achieve pain relief with which the patient is comfortable.
- Prevention of withdrawal by using either clonidine patch or methadone.
- Plan for discharge and follow-up.

Details of these steps may vary among patients, providers, and institutions. It should be emphasized that desirable outcome of management of the acute painful crisis in the hospital depends on early and aggressive treatment of pain without delay, avoidance of hasty and premature discharge from the hospital, and having a plan for follow-up after discharge, preferably within a week or less.

Specific Approaches to Treatment

There are five approaches to the treatment of SCD: supportive therapy, symptomatic treatment, preventative therapy, abortive therapy, and curative therapy (Table 57.12). Most important among these that have the potential to ameliorate or cure the disease include Hb F induction, RBC rehydration, bone marrow/stem cell transplantation, and gene therapy.

It has been the hope of patients with SCD, their families, and providers that there will be therapy that will either cure or markedly alter the natural history of this disease. With better understanding of the pathology of SCD and coordination of multiple therapies that attack different pathologic mechanisms of the disease, this goal seems likely. Although the long-term safety and efficacy of these novel therapies have not been well studied, there is good potential for at least some of them to achieve the desired goal.

Induction of Hb F. High levels of Hb F have a beneficial effect in patients with SS. Platt et al.[21] has shown that there is a significant inverse correlation between the frequency of painful crises and Hb F levels greater than 4% (i.e., the higher the Hb F, the milder the disease). Hb F interferes with the polymerization of sickle Hb and the higher (and the more pancellular) it is, the lower the intracellular concentration of sickle Hb. However, there are exceptions to this rule in that there are patients with high Hb F levels and severe disease and vice versa.

Agents that have been shown to increase the level of Hb F in humans are listed in Table 57.13. Among these, hydroxyurea as monotherapy seems to be the least toxic and most effective.[80,81,188] Moreover, hydroxyurea is the only drug studied for efficacy in a relatively large scale, placebo-controlled, randomized clinical trial. All the other agents listed in Table 57.13 have been reported anecdotally to increase Hb F levels. None of the others was used in a controlled phase III clinical trial to date.

TABLE 57.12

CURRENT APPROACHES TO MANAGEMENT OF SICKLE CELL DISEASE

I. Supportive therapy
   - Folic acid
   - Immunization (Adults)
   - Psychologic support

II. Symptomatic treatment
   - Analgesia/adjuvants for pain
   - Blood transfusion
   - Antibiotics
   - Surgery

III. Preventative therapy
   - Prophylactic antibiotics (infants and children)
   - Immunizations (infants and children)
   - Avoidance of known precipitating factors
   - Hb F induction (Hydroxyurea)
     - Purified poloxamer 188
   - RBC rehydration (investigational)

IV. Abortive therapy
   - ? Nitric oxide

V. Curative therapy
   - Transplantation
   - Bone marrow, stem cells, cord blood
   - Gene therapy (experimental, transgenic mice)

Hydroxyurea is a cell-cycle specific cytotoxic agent that inhibits ribonucleotide reductase. The molecular mechanism(s) by which hydroxyurea increases the production of Hb F is (are) unknown. Possible mechanisms include perturbations in cellular kinetics and/or recovery from cytotoxicity, recruitment of early erythroid progenitors and recruitment of primitive erythroid progenitors (BFU-E) that lead to production of Hb F-containing reticulocytes (F-reticulocytes). Long-term hydroxyurea therapy with the maximum tolerated dose (mean dose 21.3 mg/kg) with respect to myelosuppression raises Hb F by as much as 15% to 20% (mean 14.9%, range 1.9% to 26.3%).

In the randomized, placebo-controlled, double blind multicenter study of hydroxyurea (MSH) study, among 299 adult patients with SS with three or more painful crises per year, hydroxyurea resulted in a significant ($p < 0.001$) reduction in the incidence of painful crises, ACS, and transfusion requirement.[80,81] Hydroxyurea improved the quality of life of the patients taking it.[189] There was no difference between the placebo and hydroxyurea arms in the incidence of death, stroke, or hepatic sequestration. Maximum tolerated doses of hydroxyurea were not required to reduce the incidence of painful episodes. Although an increase in Hb F seems to be the obvious and logical explanation for the salutary effects of hydroxyurea, other reasons for its beneficial effects include changes in RBC volume, cellular hydration, the cell membrane, and a direct effect on endothelial cells.

Follow-up of patients who continued to take hydroxyurea after the termination of the MSH study had less mortality than those who did not take hydroxyurea.[190] Adverse effects of hydroxyurea are listed in Table 57.14. Toxic effects are dose- and time-dependent. Careful monitoring of blood counts every 2 weeks after starting hydroxyurea can prevent these. Later, the frequency of monitoring of blood counts and blood chemistries can be decreased to once every 1 to 2 months once the patient is in a stable condition and receiving an acceptable maintenance dose. Anemia is a rare toxic effect of hydroxyurea; in fact, in the MSH study, most patients who took hydroxyurea experienced

an increase in their Hb levels. It is unfortunate to note that it seems that hydroxyurea is underutilized in the treatment of patients with SS. There may be many patients who meet the criteria for treatment with hydroxyurea but are not receiving it.[191] The idiosyncratic effects of hydroxyurea occur in some patients but not others. However, the incidence of these effects was similar between the placebo and hydroxyurea in the MSH study.[80] In animal studies, hydroxyurea had carcinogenic and teratogenic effects.[192–194] To date, however, no carcinogenic effect has been reported in patients with polycythemia vera and erythrocytosis due to congenital heart disease treated with hydroxyurea.[195,196]

The following limitations should be considered when using hydroxyurea to prevent painful crises in patients with SCD. Firstly, hydroxyurea was approved in the United States by the Food and Drug Administration for the prevention of crises in patients with SS and not in other types of SCD. Secondly, the long-term effects of hydroxyurea in patients with SCD are not known and, finally, some patients do not respond to hydroxyurea. Methods to identify these nonresponders are being studied in order to improve the selection process for hydroxyurea therapy. In some patients, combining hydroxyurea with other agents that augment Hb F production may be indicated.

Purified Poloxamer 188 (Flocor)

This is a nonionic surfactant that is thought to reduce blood viscosity and to prevent adhesion of RBCs to vascular endothelium, thus improving microvascular blood flow. It appeared to be a promising agent in preventing or reducing the frequency of acute sickle painful crises. A randomized, double-blind, placebo-controlled, intention-to-treat trial using purified poloxamer 188 (Flocor) was conducted between March 1998 and October 1999 in 40 medical centers in the United States.[197] Two-hundred and fifty-five patients with SCD (ages 9–53) who had a painful episode severe enough to require hospitalization and opioid analgesics for the treatment of pain were enrolled in the study. A decrease in the duration of painful episodes and an increase in the proportion of patients who achieved resolution of the symptoms were observed when the purified poloxamer 188-treated patients were compared with the patients receiving placebo. The difference between these groups was significant but relatively small. In subgroup analysis, a more significant effect on both parameters was observed in children and patients who were receiving concomitant hydroxyurea. It is important to confirm both of these observations in further prospective trials.

Red Blood Cell Rehydration

Polymerization of deoxy Hb results in cellular dehydration which, in turn, increases the intracellular concentration of sickle Hb that leads to further polymerization, thus creating a vicious cycle. Major mechanisms by which water is lost from sickle cells include the Ca^{2+}-activated K^+ channel (Gardos channel) and the KCI cotransport channel. Activation of these channels result in K^+ and water loss from sickle erythrocytes with consequent dehydration. A decrease in the intracellular concentration of sickle Hb, even small decreases, can slow the polymerization of sickle Hb to a point where RBCs can exit from the capillaries (decreased transit time) before the sickle Hb polymerizes (increased delay time for polymerization). Hydroxyurea achieves this goal by decreasing the effective concentration of sickle Hb and diluting it with Hb F, which does not participate in polymerization. Another approach to inhibit polymerization is to rehydrate sickle RBCs and restore their normal water content.[198,199]

A selective approach to specifically rehydrate sickle RBCs by inhibiting the Gardos pathway has been tried by using oral clotrimazole.[198] In 5 patients treated with 20 mg/kg/day of clotrimazole, the RBC Gardos channel was inhibited, cell K^+ content increased, RBCs were rehydrated, and a very modest increase in hemoglobin levels was noted. The effects of clotrimazole on cellular rehydration, however, were very modest compared with those seen in hydroxyurea. A phase III randomized, double-blind, placebo-controlled trial, however, failed to show that Gardos channel inhibitors decreased the frequency of acute sickle cell painful crisis (unpublished data). Oral magnesium pidolate also reduces RBC dehydration in patients with SCD by inhibiting the KCl cotransport channel.[199] Clinical trials using myasthenia gravis are underway at the present.

Bone Marrow/Stem Cell/Cord Blood Transplantation

Although transplantation therapy was initially limited for children,[9–12] the procedure has been extended to older adolescents and young adults in recent studies. Thus, Panepinto et al.[13] in the United States reported outcomes after myeloablative hematopoietic cell transplantation (HCT) from HLA-matched sibling donors in 67 patients with SCD transplanted between 1989 and 2002. The most common indications for transplantation were stroke and recurrent vaso-occlusive crisis in 38% and 37% of patients, respectively. The median age at transplantation was 10 years (range 2–27 years). Twenty-seven percent of patients had a poor performance score at transplantation. Ninety-four percent received busulfan and cyclophosphamide-containing conditioning regimens, and bone marrow was the predominant source of donor cells. Most patients achieved hematopoietic recovery, and no deaths occurred during the early posttransplant period. Rates of acute and chronic graft-versus-host disease (GVHD) were 10% and 22%, respectively. Sixty-four of 67 patients are alive with 5-year probabilities of disease-free and overall survival of 85% and 97%, respectively. Nine patients had graft failure with recovery of sickle erythropoiesis, 8 of whom had recurrent sickle-related events.

Similarly, Bermaudin et al.[14] from France reported outcomes of related myeloablative stem cell transplantation from HLA-matched sibling donors in 87 consecutive patients (2–27 years old) with severe SCD between November 1988 and December 2004. Cerebral vasculopathy was the principal indication for transplantation in 55 patients (63%). All the patients received grafts from a sibling donor after a myeloablative conditioning regimen (CR). The only change in the CR during the study period

was the introduction of antithymocyte globulin (ATG) in March 1992. The rejection rate was 22.6% before the use of ATG, but 3% thereafter. With a median follow-up of 6 years (range, 2.0 to 17.9 years), the overall and event free survival (EFS) rate were 93.1% and 86.1%, respectively. GVHD was the main cause of transplantation related mortality (TRM). Importantly, cord blood transplant recipients did not develop GVHD. No new ischemic lesions were detected after engraftment, and cerebral velocities were significantly reduced. The outcome improved significantly with time: the EFS rate among the 44 patients receiving transplants after January 2000 was 95.3%.

These studies confirm and extend earlier reports that HCT from HLA-matched related donors after myeloablative conditioning (especially with ATG) offer a very high survival rate, with few transplant-related complications and the elimination of sickle-related complications in the majority of patients who undergo this therapy.

Gene Therapy

Gene therapy, in simple terms, is the introduction of new genes into healthy or abnormal cells either in vitro or in vivo. Gene therapy in SS is limited at present to investigational laboratory procedures and the use of transgenic mouse models to determine the most effective and safest method of altering the genetic information in hematopoietic stem cells.[200] Research in this area has advanced at a faster rate than previously expected, and gene therapy may be available for trial in selected patients with sickle cell disease in the near future.

CONCLUSION

SCD is an inherited disorder of hemoglobin structure that has no established cure in adults at the present. Cure has been achieved in selected patients with bone marrow/stem cell/cord blood transplantation from HLA-matched donors in the majority of cases after myeloablative conditioning regimen.

SCD is almost synonymous with pain, and the acute sickle cell painful crisis is the insignia or hallmark and the number one cause of hospitalization. Advances in the pathophysiology of SCD focused on the sequence of events that occur between polymerization of deoxy of hemoglobin S and vaso-occlusion. Adhesion of sickle RBCs to endothelial cells, cellular dehydration, inflammatory response, reperfusion injury, and tissue damage appear to be important pathophysiologic events that culminate in the perception of pain.

The acute sickle cell painful crisis evolves along four phases: prodromal, initial, established, and resolving phases. Several clinical and laboratory changes occur during the painful crisis provided the findings are compared to well-established baseline data. The resolving acute painful crisis may culminate in a hypercoagulable state that could precipitate another crisis in some patients. Hospital readmission seems to occur within 1 week in about 16% of patients after discharge from the hospital.

Serious and potentially fatal complications of SCD such as ACS and AMF occur within 3 or 4 days after the onset of an acute crisis, Other types of acute sickle pain include priapism, dactylitis, hepatic crisis, and splenic sequestration.

Chronic pain and neuropathic pain do occur in SCD, and their pathophysiologic events and management are similar in other types of chronic pain. Although management of SS continues to be primarily palliative in nature, there have been promising preventative and curative approaches to therapy. Pain management should be individualized and coupled with the proper utilization of opioid and nonopioid analgesics in order to achieve adequate pain relief. Early recognition and treatment of organ failure minimizes morbidity and improves outcome. The use of hydroxyurea decreases the morbidity and mortality of SCD. Cure is possible in selected children and young adults with bone marrow or cord blood transplantation. Future research seems to focus on refining the molecular and cellular approaches to therapy including gene therapy and mechanisms that rehydrate sickle RBCs and/or prevent their adhesion to vascular endothelium.

CHAPTER 58 ■ PAIN IN HUMAN IMMUNODEFICIENCY VIRUS DISEASE

WILLIAM BREITBART AND ALBERTO CORTES-LADINO

INTRODUCTION

With the introduction of highly active antiretroviral therapies (i.e., combination therapies including protease inhibitors) the face of the acquired immunodeficiency syndrome (AIDS) epidemic, particularly for those who can avail themselves of and/or tolerate these new therapies, is indeed changing. Death rates from AIDS in the United States have dropped dramatically in the last several years, and rates of serious opportunistic infections and cancers are declining. Despite these hopeful developments, the future is still unclear, and millions of patients with human immunodeficiency virus (HIV) disease worldwide will continue to die of AIDS and suffer from the enormous burden of physical and psychologic symptoms. Even with advances in AIDS therapies, pain continues to be an important palliative care issue for patients with HIV disease. As the epidemiology of the AIDS epidemic changes in the United States, the challenge of managing pain in AIDS patients with a history of substance abuse is becoming an ever growing challenge. Studies conducted between 1990 and 1995 have documented that pain in individuals with HIV infection or AIDS is highly prevalent, diverse, and varied in syndromal presentation, associated with significant psychologic and functional morbidity, and alarmingly undertreated.[1–11] Pain management needs to be more integrated into the total care of patients with HIV disease. Responses from a self-referred sample of AIDS outpatients indicate that AIDS patients experience many distressing physical and psychologic symptoms along with a high level of distress.[12] This chapter describes the prevalence and types of pain syndromes encountered in patients with HIV disease and reviews the psychologic and functional impact of pain as well as the barriers to adequate pain treatment in this population. Finally, principles of pain management, with particular emphasis on the management of pain in HIV-infected patients with a history of substance abuse, are outlined.

PREVALENCE OF PAIN IN ACQUIRED IMMUNODEFICIENCY SYNDROME

Estimates of the prevalence of pain in HIV-infected individuals have been reported to range from 30% to over 90%, with the prevalence of pain increasing as disease progresses,[1,2,4,5,9,13–15] particularly in the latest stages of illness.

Studies suggest that approximately 30% of ambulatory HIV-infected patients in early stages of HIV disease (pre-AIDS; Category A or B disease) experience clinically significant pain, and as many as 56% have had episodic painful symptoms of less clear clinical significance.[1,4,7,9,16] In a prospective cross-sectional survey of 438 ambulatory AIDS patients in New York City, 63% reported frequent or persistent pain of at least 2 weeks duration at the time of assessment.[1] The prevalence of pain in this large sample increased significantly as HIV disease progressed, with 45% of AIDS patients with Category A3 disease, 55% of those with Category B3, and 67% of those with Category C1, 2, or 3 disease reporting pain. Patients in this sample of ambulatory AIDS patients also were more likely to report pain if they had other concurrent HIV-related symptoms (e.g., fatigue, wasting), had received treatment for an AIDS-related opportunistic infection, or if they had not been receiving antiretroviral medications (e.g., AZT, ddI, ddC, d4t).

In a study of pain in hospitalized patients with AIDS in a public hospital in New York City, over 50% of patients required treatment for pain, with pain being the presenting complaint in 30% and the second most common presenting problem after fever.[5] In a French multicenter study, 62% of hospitalized patients with HIV disease had clinically significant pain.[4] Schofferman and Brody[17] reported that 53% of patients with far-advanced AIDS cared for in a hospice setting had pain, while Kimball and McCormack[14] reported that up to 93% of AIDS patients in their hospice experienced at least one 48-hour period of pain during the last 2 weeks of life.

Larue and colleagues[18] demonstrated that patients with AIDS being cared for by hospice at home had prevalence rates and intensity ratings for pain that were comparable to, and even exceeded, those of cancer patients. Breitbart and colleagues[2] reported that ambulatory AIDS patients in their New York City sample reported a mean pain intensity on average of 5.4 (on the 0–10 numerical rating scale of the Brief pain Inventory) and a mean pain at its worst of 7.4. In addition, as with pain prevalence, the intensity of pain experienced by patients with HIV disease increases significantly as disease progresses. AIDS patients with pain, like their counterparts with cancer pain, typically describe an average of 2.5 to 3 concurrent pains at a time.[2,3]

Frich and Borgbjerg[19] concluded that the incidence of disturbing pain in AIDS is high, specifically in the extremities, gastrointestinal (GI) tract, and head. In a study of 95 AIDS patients, the overall incidence of pain was 88%, and 69% of the patients suffered from pain which interfered with daily activity to a degree described as moderate to severe. In AIDS patients approaching end of life, 93% of patients reported experiencing pain and discomfort at some time during the last 2 weeks of life. This percentage may be even higher if some pain and discomfort went unrecognized. Most patients experienced at least one 48-hour period of pain and discomfort during the last 2 weeks of life; furthermore, 88% received some sort of opioid analgesia with the majority experiencing some relief.[14]

IMPACT OF HIGHLY ACTIVE ANTIRETROVIRAL THERAPY ON MEDICAL CARE, PALLIATIVE CARE, AND QUALITY OF LIFE

Brechtl and colleagues[20] assessed the impact of highly active antiretroviral therapy (HAART) on a wide range of clinical outcomes and psychologic variables in patients with advanced HIV/AIDS. Data on 70 patients with CD4+ cell counts below 300 cc and a projected survival greater that 1 month was collected at baseline and after 1 and 3 months. In addition to standard clinical and laboratory markers, a series of observer-rated and self-report instruments were used to measure pain and symptom distress, psychologic well-being, depression, and physical functioning abilities. The only psychosocial measure that improved significantly with treatment was depression. Ratings of pain intensity, physical and psychologic symptom distress, and overall quality of life did not change. These results suggest that despite the improvements in CD4+ cell count and HIV viral load, body weight, albumin, and ferritin, the benefits of HAART treatment on pain and symptom distress and psychosocial well-being are less clear.[20]

PAIN SYNDROMES IN HUMAN IMMUNODEFICIENCY VIRUS/ ACQUIRED IMMUNODEFICIENCY SYNDROME—OVERVIEW

Pain syndromes encountered in AIDS are diverse in nature and etiology. The most common pain syndromes reported in studies to date include painful sensory peripheral neuropathy, pain due to extensive Kaposi's sarcoma (KS), headache, oral and pharyngeal pain, abdominal pain, chest pain, arthralgias and myalgias, as well as painful dermatologic conditions.[1,3,5,7,9,13,17,18,21,22] In a sample of 151 ambulatory AIDS patients who underwent a research assessment which included a clinical interview, neurologic examination, and review of medical records,[3] the most common pain diagnoses included headaches (46% of patients, 17% of all pains), joint pains (arthritis, arthralgias, etc., 31% of patients, 12% of all pains), painful polyneuropathy (distal symmetrical polyneuropathy, 28% of patients, 10% of all pains), and muscle pains (myalgia, myositis, 27% of patients, 12% of all pains). Other common pain diagnoses included skin pain (KS, infections, 25% of patients; 30% of homosexual males in the sample had pain from extensive KS lesions), bone pain (20% of patients), abdominal pain (17% of patients), chest pain (13%), and painful radiculopathy (12%). Patients in this sample had a total of 405 pains (averaging three concurrent pains), with 46% of patients diagnosed with neuropathic type pain, 71% with somatic pain, 29% with visceral pain, and 46% with headache (classified separately because of controversy as to pathophysiology). When pain type was classified by pains (as opposed to patients), 25% were neuropathic pains, 44% were nociceptive-somatic, 14% were nociceptive-visceral, and 17% were idiopathic type pains. Patients in this study with lower CD4+ cell counts were significantly more likely to be diagnosed with polyneuropathy and headache. Hewitt and colleagues[3] demonstrated that while pains of a neuropathic nature (e.g., polyneuropathies, radiculopathies) certainly comprise a large proportion of pain syndromes encountered in AIDS patients, pains of a somatic and/or visceral nature are also extremely common clinical problems. A review performed by O'Neill and Sherrard[7] showed that HIV therapies including didanosine, stavudine, and zalcitabine have become a major cause of neuropathic pain, which influences the high prevalence of pain among HIV patients.

Pain syndromes seen in HIV disease can be categorized into three types (Table 58.1): (1) those directly related to HIV infection or consequences of immunosuppression; (2) those due to AIDS therapies; and (3) those unrelated to AIDS or AIDS therapies.[3,11] In studies to date, approximately 45% of pain syndromes encountered are directly related to HIV infection or consequences of immunosuppression; 15% to 30% are due to therapies for HIV- or AIDS-related conditions, as well as diagnostic procedures; and the remaining 25% to 40% are unrelated to HIV or its therapies.[3]

TABLE 58.1

PAIN SYNDROMES IN AIDS PATIENTS

I PAIN RELATED TO HIV/AIDS
- HIV Neuropathy
- HIV Myelopathy
- Kaposi's Sarcoma
- Secondary Infections (intestines, skin)
- Organomegaly
- Arthritis/Vasculitis
- Myopathy/Myositis

II PAIN RELATED TO HIV/AIDS THERAPY
- Antiretrovirals, Antivirals
- Antimycobacterials, PCP Prophylaxis
- Chemotherapy (Vincristine)
- Radiation
- Surgery
- Procedures (bronchoscopy, biopsies)

III PAIN UNRELATED TO AIDS
- Disc Disease
- Diabetic Neuropathy

In three reviews of the literature, Breitbart,[23] Douaihy et al.,[24] and Markus and Fincham[25] discussed the assessment and management of HIV-/AIDS-related pain and its impact on quality of life and presented a multidisciplinary approach with specific recommendations to treat psychosocial issues associated with HIV and the pain syndromes related.

PAIN IN WOMEN WITH HUMAN IMMUNODEFICIENCY VIRUS/ ACQUIRED IMMUNODEFICIENCY SYNDROME

The Memorial Sloan Kettering group has reported on the experience of pain in women with AIDS.[3,26] While preliminary in nature, these studies suggest that women with HIV disease experience pain more frequently than men with HIV disease and report somewhat higher levels of pain intensity. This may in part be a reflection of the fact that women with AIDS-related pain are twice as likely to be undertreated for their pain compared to men.[2] Women with HIV disease have unique pain syndromes of a gynecologic nature specifically related to opportunistic infectious processes and cancers of the pelvis and genitourinary tract.[27] Women with AIDS were significantly more likely to be diagnosed with radiculopathy and headache in one survey.[3] In a pilot survey of aberrant drug-taking attitudes and behaviors of a mixed group of 52 cancer patients and a group of 111 women with HIV/AIDS, Passik et al.[28] reported that patients would consider engaging in aberrant behaviors, or would possibly excuse them in others, if pain or symptom management were inadequate.

PAIN IN CHILDREN WITH HUMAN IMMUNODEFICIENCY VIRUS/ ACQUIRED IMMUNODEFICIENCY SYNDROME

Children with HIV infection also experience pain.[29] HIV-related conditions in children that are observed to cause pain include meningitis and sinusitis (headaches), otitis media, shingles, cellulitis and abscesses, severe candida dermatitis, dental caries, intestinal infections, such as *Mycobacterium avium intracellulare* (MAI) and cryptosporidium, hepatosplenomegaly, oral and esophageal candidiasis, and spasticity associated with encephalopathy that causes painful muscle spasms. Oleske and colleagues[30] have reported that pain in HIV-infected children carries an increased mortality.

SPECIFIC PAIN SYNDROMES ENCOUNTERED IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS DISEASE

The following section reviews, in detail, the various painful manifestations of HIV disease. The authors acknowledge the important review by O'Neill and Sherrard[7] that formed the basis of this section on specific pain syndromes in HIV disease.

Gastrointestinal Pain Syndromes

Many of the opportunistic infections and HIV-associated neoplasms may present as pain referable to the GI tract. Generally, the pain will be alleviated by specific treatment of the causative diseases. Adequate analgesia should be provided during diagnostic assessment.[7]

Oropharyngeal Pain

Oral cavity and throat pain is very common, accounting for approximately 20% of the pain syndromes encountered in one study.[5] The sources of oral cavity pain have been well described.[7,31,32] Oropharyngeal candidiasis occurs in up to 75% of HIV-positive individuals and, although frequently asymptomatic, it is the most common cause of oral cavity pain. Bacterial infections are mainly seen as necrotizing gingivitis and can arise in HIV-positive patients in spite of maintaining a good standard of oral hygiene.[7] Dental abscesses occur more commonly in HIV-infected individuals than in the general population. Oral ulcerations are extremely common and can be the result of herpes simplex virus (HSV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), atypical and typical mycobacterial infection (MAI), cryptococcal infection, or histoplasmosis. Frequently, no infectious agent can be identified, and these painful aphthous ulcers are a clinically challenging problem.[7] Up to 75% of patients with cutaneous KS also have intraoral lesions, most commonly on the palate, although these seldom cause pain.[7]

Esophageal Pain

About one third of patients with HIV disease experience esophageal symptoms such as dysphagia or pain upon swallowing (odynophagia) often due to esophageal candidiasis. Esophageal candidiasis occurs in between 25% and 75% of patients with HIV disease[33–35] and may present as dysphagia or odynophagia. Ulcerative esophagitis, which can be quite painful, is usually a result of CMV infection but can be idiopathic. Infectious causes of esophagitis include HSV, EBV, Mycobacteria, Cryptosporidium, and *Pneumocystis carinii*.[33,34,36–39] KS and lymphoma both have been reported to invade the esophagus resulting in dysphagia, pain, and ulceration.[7] Zidovudine has also been reported to be a cause of esophageal ulceration.[40]

Abdominal Pain

Abdominal pain is the primary site of pain in 12%–25% of patients with HIV disease.[3,5,41] Infectious causes of abdominal pain predominate and include cryptosporidiosis, shigella, salmonella and Campylobacter enteritis, CMV, ileitis, and MAI. Perforation of the small and large intestine secondary to CMV infection has been described.[41] Repeated intussusception of the small intestine has been seen in association with Campylobacter infection.[42] Lymphoma in the GI tract can present with abdominal pain and intestinal obstruction.[43] KS spreads to the GI tract of 40% to 50% of AIDS patients with cutaneous lesions.[44] Rarely, intestinal KS may cause obstruction, bleeding, perforation, and diarrhea.[45] Other causes of abdominal pain in HIV positive patients[7] include ileus, organomegaly, spontaneous aseptic peritonitis, toxic shock, herpes zoster, and Fitzhugh-Curtis syndrome (perihepatitis in association with tubal gonococcal or chlamydia infection).

Biliary Tract and Pancreatic Pain

Cholecystitis may occur in HIV-infected patients as a result of opportunistic infection; CMV and cryptosporidiosis are the most common infectious agents. Extrahepatic biliary tract obstruction secondary to KS or MAI infection has been reported.[7] Sclerosing cholangitis (CMV, cryptosporidiosis), also known as AIDS cholangiopathy, is another cause of right upper quadrant or epigastric pain.[46] Opportunistic liver infections (CMV, MAI, fungal infections) as well as drug-induced hepatic toxicities (ddI, pentamidine) are sources of hepatitis and abdominal or right upper quadrant pain.[47]

Pancreatitis is often related to adverse effects of HIV-related therapies, in particular the antiretroviral agents didanosine (ddI) and dideoxycytidine (ddC). Between 7% to 10% of patients on ddI develop pancreatitis, and lower rates are reported with other antiretrovirals. Intravenous pentamidine is also associated with pancreatitis. Infectious causes of pancreatitis include CMV, MAI, and cryptococcal infection.[48] Rarely, lymphoma or KS may involve the pancreas resulting in pancreatitis.

Anorectal Pain

Painful anorectal diseases are common, occurring in about one third of homosexual men with HIV disease.[49] Infectious causes of anorectal pain include perirectal abscesses, CMV proctitis, fissure-in-ano, and HSV infection. A small increase has been noted in anal/anorectal carcinoma in HIV-positive homosexual men.[50]

Chest Pain Syndromes

Chest pain is a common complaint in patients with HIV disease, comprising approximately 13% of the pain syndromes encountered in a sample of ambulatory AIDS patients.[3] Sources of chest pain in patients with HIV disease are similar to those encountered in the general population (i.e., cardiac, esophageal, lung and pleura, and chest wall); the etiologies may be somewhat unique (i.e., opportunistic infections) cancers. In immunosuppressed patients, infectious causes of chest pain should be considered, particularly in the presence of fever and some localizing sign such as dysphagia, dyspnea, or cough. Infectious causes of chest pain include Pneumocystis pneumonia (with or without a pneumothorax), esophagitis (CMV, candidiasis, HSV), pleuritis/pericarditis (viral, bacterial, tuberculous), and postherpetic neuralgia. Opportunistic cancers (KS, lymphoma) invading the esophagus, pericardium, chest wall, lung, and pleura may be sources of chest pain. Rarely, pulmonary embolus or bacterial endocarditis may be the cause of chest pain.

NEUROLOGIC PAIN SYNDROMES IN ACQUIRED IMMUNODEFICIENCY SYNDROME

Pain syndromes originating in the nervous system include headache, painful peripheral neuropathies, radiculopathies, and myelopathies. The HIV virus is highly neurotropic, invading central nervous system (CNS) and peripheral nervous system structures early in the course of HIV disease. As many as 40% to 75% of patients with late-stage AIDS have a neurologic complication[51–54] either directly due to HIV itself (e.g., AIDS dementia, HIV peripheral neuropathy, HIV myelopathy), or secondary to opportunistic infection (e.g., CNS toxoplasmosis, CMV neuropathy), cancer (e.g., CNS lymphoma), or medication side effects (toxic neuropathies due to ddI, ddC [zalcitabine], D_4T [stavudine], or AZT [zidovudine]-induced headache). Headache is a frequent symptom in HIV-infected patients and may be an important indication of disease of the CNS including opportunistic infections and cancers. Rarely, cerebrovascular events (e.g., thalamic stroke) occurring in hypercoagulable states can result in central pain syndromes.

Headache

Headache is extremely common, reported by approximately 40% to 50% of patients with HIV disease, particularly in later stages of illness.[3,55] Headache poses a diagnostic dilemma for physicians in that the underlying cause may range from benign stress and tension to life threatening CNS infection.[7] The differential diagnosis of headache in patients with HIV disease includes HIV encephalitis and atypical aseptic meningitis, opportunistic infections of the nervous system, AIDS-related CNS neoplasms, sinusitis, tension, migraine, and AZT-induced headache.[56] Toxoplasmosis and cryptococcal meningitis are the two most commonly encountered opportunistic infections of the CNS in patients with HIV disease.[53] Cerebral toxoplasmosis usually presents with persistent headache, sometimes associated with focal signs, change in mental status, or seizures. Diagnosis is based on radiologic imaging (magnetic resonance imaging is more sensitive than computed tomography) with a characteristic appearance of multiple deep ring-enhancing lesions and a clinical response to a trial of empiric treatment for toxoplasmosis. A brain biopsy is sometimes necessary to establish a definitive diagnosis and to differentiate cerebral toxoplasmosis from cerebral lymphoma. Cryptococcal meningitis usually presents with symptoms of headache, neck stiffness, and recurring fever, although focal neurologic signs may occur. Other opportunistic infections of the CNS that can present as headache in the AIDS patient include CMV, HSV and herpes zoster, progressive multifocal leukoencephalopathy (papovavirus), *Candida albicans*, mycobacterium tuberculosis, *Mycobacterium avium intracellulare*, and neurosyphilis. Headache related to sinus infection is common in immunocompetent patients with HIV disease who present with headache but have no focal neurologic signs. Opportunistic cancers of the CNS include CNS lymphoma, metastatic systemic lymphoma, and metastatic intracranial KS. These can present, particularly in the immunocompromised patient with HIV disease, with signs of increased intracranial pressure with or without focal neurologic signs, as well as fever and meningismus. More benign causes of headache in the patient with HIV disease include AZT-induced headache, occurring in 15% to 30% of patients, tension headache, migraine with or without aura, and unclassifiable or idiopathic headache.[57] Evers and colleagues[58] concluded that the pro-

gressing immunologic deficiency of HIV-infected patients seems to influence the pain processing of headache in different ways. During that natural course of infection, the migraine frequency significantly decreased, while the frequency of tension type headaches increased.[58]

NEUROPATHIES ENCOUNTERED IN HUMAN IMMUNODEFICIENCY VIRUS-INFECTED PATIENTS

Pain syndromes of a neuropathic nature occur in approximately 40% of AIDS patients with pain.[3] While several types of peripheral neuropathy have been described in patients with HIV/AIDS (Table 58.2), the most common painful neuropathy encountered is the predominantly sensory neuropathy of AIDS, affecting up to 30% of people with HIV infection.[51,54,59,60] Other potentially painful neuropathies encountered in HIV/AIDS patients, however, can be caused by viral and nonviral infectious processes (mononeuritis multiplex, including polyneuritis cranialis, polyradiculopathy of the lower limbs-cauda equina syndrome, and plexopathies caused by CMV, HZV, and MAI), immune mediated inflammatory demyelination (acute and chronic Guillain-Barré syndrome), a variety of medical conditions (diabetic neuropathy, postherpetic neuralgia, entrapment neuropathies), nutritional deficiencies (B6, B12), toxins (alcohol), and HIV-related therapies (e.g., ddI, ddC). Several antiretroviral drugs, such as ddI, ddC, and D_4T, and chemotherapy agents used to treat KS (vincristine), as well as a number of medications used in the treatment of *Pneumocystis carinii* pneumonia (PCP), mycobacterial infection, and other HIV-associated infections can cause painful toxic neuropathy.[7,61,62]

TABLE 58.2

NEUROPATHIES ENCOUNTERED IN HIV/AIDS INFECTED PATIENTS

I PREDOMINANTLY SENSORY NEUROPATHY OF AIDS

II IMMUNE-MEDIATED
- Inflammatory demyelinating polyneuropathies (IDPs)
  - Acute (Guillain-Barré syndrome)
  - Chronic (CIDP)

III INFECTIOUS
- Cytomegalovirus polyradiculopathy
- Cytomegalovirus multiple mononeuropathy
- Herpes Zoster
- MAI

IV TOXIC/NUTRITIONAL
- Alcohol, Vitamin deficiencies (B6, B12)
- Antiretrovirals:
  - ddI (didanosine), ddC (zalcitabine), D4T (stavudine)
- Antivirals:
  - Foscarnet
- PCP prophylaxis:
  - Dapsone
- Antibacterial:
  - Metronidazole
- Antimycobacterials:
  - INH (isoniazid), rifampin, ethionamide
- Antineoplastics:
  - Vincristine, vinblastine

V OTHER MEDICAL CONDITIONS:
- Diabetic neuropathy
- Postherpetic neuralgia

Predominantly Sensory Neuropathy of Acquired Immunodeficiency Syndrome

The most frequently encountered neuropathy is a symmetrical predominantly sensory painful peripheral neuropathy. This is a late manifestation, occurring most often in patients with an AIDS-defining illness but has been reported earlier in the course of the disease.[51] Prevalence in hospice populations ranges from 19% to 26%.[17,63,64] It is the only peripheral sensory neuropathy which has been postulated to be a direct result of HIV infection of the peripheral nervous system.[51] It has been reported by Zhou and colleagues[65] that in subjects with advanced HIV-1 infection, epidermal nerve fiber density assessment correlates with the clinical and electrophysiologic severity of distal sensory polyneuropathy. The predominant symptom in about 60% of patients is pain in the soles of the feet. Paraesthesia is frequent and usually involves the dorsum of the feet in addition to the soles. Most patients have signs of peripheral neuropathy (most commonly, absent or reduced ankle jerks and elevated thresholds to pain and vibration sense), and while the signs progress, the symptoms often remain confined to the feet.[51,66,67] Although the patient's complaints are predominantly sensory, electrophysiologic studies demonstrate both sensory and motor involvement.

A qualitative study of 19 patients using a grounded-theory approach was designed to assess the impact distal symmetrical peripheral neuropathy has on persons with AIDS. Themes in the debilitation continuum included isolating the symptom cluster, inventing and testing interventions, and assimilating the annoyance. Their results suggested that only individualized interventions presented favorable results.[68]

Immune-Mediated Neuropathies

Acute Guillain-Barré syndrome has been described in association with seroconversion (group-I infection) but may occur at any time. Both acute and chronic inflammatory demyelinating polyneuropathies are predominantly motor, and sensory abnormalities are rare.[60] Mononeuritis multiplex presents with sensory or motor deficits in the distribution of multiple spinal, cranial, or peripheral nerves[52] and may progress into a chronic inflammatory demyelinating polyneuropathy.[60]

Infectious Neuropathies

Polyradiculopathies (associated with CMV infection) often present with radicular pain and follow a distinct course.[69] The onset is usually subacute and the deficit initially confined to sacral and lumbar nerve roots. Both sensory and motor functions are involved, and there is usually early involvement of sphincters. Progression is relentless.[60] An analysis by Harrison and colleagues[70] of pain related to herpes zoster identified three variables related to pain: extent of lesion healing, extension of lesion crusting, and the number of new vesicles. Harrison et al.,[70] showed that the significance of baseline pain due to herpes zoster was a predictor of return to daily life functioning. Furthermore, the significance of pain at presentation and at 1 month were significant predictors of chronic pain.[70]

Toxic/Nutritional Neuropathies

Toxic and nutritional neuropathies in patients with HIV disease have been reported with the following: alcohol, vitamin deficiencies (B6, B12), antiretroviral drugs such as ddI, ddC, and D_4T, antivirals such as foscarnet, PCP prophylaxis such as dapsone, antibacterial drugs such as metronidazole, antimycobacterial

drugs such as isoniazid, rifampin, and ethionamide, and antineoplastics such as vincristine and vinblastine.[61,67]

Painful Neuropathies According to Stage of Human Immunodeficiency Virus Infection

The type of neuropathy varies with the stage of infection. The acute or seroconversion phase of HIV disease is associated with mononeuritides, brachial plexopathy, and acute demyelinating polyneuropathy. The latent or asymptomatic phase (CD4+ T lymphocytes >500/mm^3) is characterized by acute and chronic demyelinating polyneuropathies. The transition phase (200–500 CD4+ cells) is characterized by herpes zoster (shingles) and mononeuritis multiplex. The late phase of HIV disease (<200 CD4+ cells) is characterized by HIV predominantly sensory polyneuropathy, CMV polyneuropathy, mononeuritis multiplex, autonomic neuropathy, mononeuropathies secondary to meningeal disease, and antiretroviral induced toxic neuropathies.[61]

RHEUMATOLOGIC PAIN SYNDROMES

In studies conducted by the Memorial Sloan-Kettering group,[3] over 50% of pain syndromes were classified as rheumatologic in nature including various forms of arthritis, arthropathy, arthralgia, myopathy, myositis, and myalgias. In another study, 72% of patients with different stages of HIV infection had painful symptoms involving the musculoskeletal system.[71]

Arthritis and Arthropathies

HIV disease has been associated with several types of painful arthritis and arthropathies including nonspecific arthralgias, reactive arthritis, psoriatic arthritis, HIV-associated arthritis, and, rarely, aseptic arthritis.[72,73] The most frequently reported arthritis is a reactive arthritis or Reiter's syndrome.[72–74] Acute HIV infection may present with a polyarthralgia in association with a mononucleosis-like illness. There is also a syndrome of acute severe and intermittent articular pain, often referred to as HIV-associated painful articular syndrome, which commonly affects the large joints of the lower limbs and shoulders. Psoriasis and psoriatic arthritis have been reported in patients with HIV infection.[75,76] The arthritis is typically seen in conjunction with the skin changes of psoriasis, and authors suggest it may follow a disease course that proves refractory to conventional therapy.[7] An HIV-associated arthritis has also been described,[77] which typically presents as an oligoarthritis affecting the joints of the lower limbs. Synovial fluid is noninflammatory, and biopsy shows a mild chronic synovitis. There is no associated infection to suggest a reactive arthritis, and the patients reported have been HLA-B27 negative. It appears that this arthritis is caused by the HIV virus itself.[72] Septic arthritis has been reported in patients with HIV disease, including arthritis due to bacterial infections and infections with *Cryptococcus neoformans* and *Sporothrix schenckii*.[72,73]

Myopathy and Myositis

Muscle pain is very common in patients with HIV disease. Several types of myopathy and myositis have been described in HIV-infected patients including HIV-associated myopathy or polymyositis, necrotizing noninflammatory myopathy in association with zidovudine and without zidovudine, pyomyositis, and microsporidiosis myositis.[78–84] Polymyositis may occur at any stage of HIV infection, is thought to be the result of direct viral infection of muscle cells,[73] and may present with a subacute onset of proximal muscle weakness and myalgia.[78] Electromyographic evidence of myopathy, a raised serum creatinine kinase, and biopsy evidence of polymyositis are common in symptomatic patients. Drugs used in the treatment of HIV disease may also be associated with the development of myalgia[56] and myositis.[79,85] Zidovudine has been particularly implicated. In these patients, symptoms frequently improve following discontinuation of zidovudine therapy.[7]

THE IMPACT OF PAIN ON QUALITY OF LIFE

Pain, in patients with HIV disease, has a profound negative impact on physical and psychologic functioning, as well as overall quality of life.[4,8] In a study of the impact of pain on psychologic functioning and quality of life in ambulatory AIDS patients,[4,8] depression was significantly correlated with the presence of pain. In addition to being significantly more distressed, depressed, and hopeless, those with pain were twice as likely to have suicidal ideation (40%) as those without pain (20%). HIV-infected patients with pain were more functionally impaired.[8] Such functional interference was highly correlated to levels of pain intensity and depression. Patients with pain were more likely to be unemployed or disabled and reported less social support. Larue and colleagues[4] reported that HIV-infected patients with pain intensities greater than 5 (on a 0–10 NRS) reported significantly poorer quality of life during the week preceding their survey than patients without pain. Pain intensity had an independent negative impact on HIV patients' quality of life, even after adjustment for treatment setting, stage of disease, fatigue, sadness, and depression. Singer and colleagues[9] also reported an association between the frequency of multiple pains, increased disability, and higher levels of depression. Psychologic variables, such as the amount of control people believe they have over pain, emotional associations, and memories of pain, fears of death, depression, anxiety, and hopelessness, contribute to the experience of pain in people with AIDS and can increase suffering.[8,86] The Memorial group also reported that negative thoughts related to pain were associated with greater pain intensity, psychologic distress, and disability in ambulatory patients with AIDS.[87] Those AIDS patients who felt that pain represented a progression of their HIV disease reported more intense pain than those who did not see pain as a threat. Vogel and colleagues[88] assessed 504 ambulatory AIDS patients in order to measure symptom distress, physical and psychosocial functioning, and demographic and disease-related factors. As opposed to those who reported sexual contact as a means of transmission, patients who reported intravenous drug use as HIV transmission indicated higher levels of distress as well as physical symptom distress.[12] Furthermore, Vogel and colleagues[88] showed that both the number of symptoms and symptom distress were highly associated with psychologic distress and poorer quality of life.

Rosenfeld, Breitbart, and colleagues assessed hastened death, its prevalence, and predictors in more than 370 patients with advanced AIDS, and measures for depression, hopelessness, spiritual well-being, social support, pain, and physical symptoms were administered. The most significant variables associated with high desire of death were hopelessness and depression.[88b]

MANAGEMENT OF PAIN IN ACQUIRED IMMUNODEFICIENCY SYNDROME

Assessment Issues

The initial step in pain management is a comprehensive assessment of pain symptoms. The health professional working in the AIDS setting must have a working knowledge of the etiology and

treatment of pain in AIDS. This would include an understanding of the different types of AIDS pain syndromes discussed above, as well as a familiarity with the parameters of appropriate pharmacologic treatment. A close collaboration of the entire health care team is optimal when attempting to adequately manage pain in the AIDS patient. A careful history and physical examination may disclose an identifiable syndrome (e.g., herpes zoster, bacterial infection, or neuropathy) that can be treated in a standard fashion.[89,90] A standard pain history[91,92] may provide valuable clues to the nature of the underlying process and indeed may disclose other treatable disorders. A description of the qualitative features of the pain, its time course, and any maneuvers that increase or decrease pain intensity should be obtained. Pain intensity (current, average, at best, at worst) should be assessed to determine the need for weak versus potent analgesics and as a means to serially evaluate the effectiveness of ongoing treatment. Pain descriptors (e.g., burning, shooting, dull, or sharp) will help determine the mechanism of pain (somatic, nociceptive, visceral nociceptive, or neuropathic) and may suggest the likelihood of response to various classes of traditional and adjuvant analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs], opioids, antidepressants, anticonvulsants, oral local anesthetics, corticosteroids, etc.).[93–95] Additionally, detailed medical, neurologic, and psychosocial assessments (including a history of substance use or abuse) must be conducted. Where possible, family members or partners should be interviewed and included in the pain management treatment plan. Patient and family education pamphlets on the management of HIV/AIDS pain are available. During the assessment phase, pain should be aggressively treated while pain complaints and psychosocial issues are subject to an ongoing process of re-evaluation.[92]

PAIN MEASUREMENT AND ASSESSMENT TOOLS

An important element in assessment of pain is the concept that assessment is continuous and needs to be repeated over the course of pain treatment. The use of readily available, simple, and clinically validated pain self-report measures or tools can make this process simpler and more reliable. There are essentially four aspects of pain experience in AIDS that require ongoing assessment and evaluation which can be aided by these tools: (1) pain intensity; (2) pain relief; (3) pain-related functional interference (e.g., mood state, general, and specific activities); and (4) monitoring of intervention effects.

Three commonly used self-report pain intensity assessment tools include: (1) a simple descriptive pain intensity scale; (2) a 0–10 numeric pain intensity scale; and (3) the Visual Analog Scale (VAS) for Pain Intensity. A Pain Faces scale is used in children and in non-English speaking or illiterate populations. The Memorial Pain Assessment Card (MPAC)[96] is a helpful clinical tool that allows patients to report their pain experience. The MPAC consists of visual analog scales that measure pain intensity, pain relief, and mood. The Brief Pain Inventory (BPI)[97] is another pain assessment tool that has been widely used in cancer and AIDS pain research and clinical settings. The BPI has a useful Pain Interference Subscale that assesses pain's interference in seven domains of quality of life and function. There are many other pain assessment tools available for adults and children.

Joint Commission on Accreditation of Healthcare Organization Pain Standards

Effective January 1, 2001, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) established new pain management standards for accreditation.[98] These new standards state that: (1) individuals served have the right to appropriate assessment and referral for a provision of management of pain and (2) that pain must be assessed in all individuals. The pain standards are available at www.jointcommission.org/standards/. Some key concepts of the JCAHO standards are listed in Table 58.3. The pain assessment tools and measures described above can be useful in helping organizations and practitioners comply with these standards. General principles of assessment and management described in this chapter may also be helpful. Other sources for help in meeting the pain standards include such resources as Building an Institutional Commitment to Pain Management: The Mayday Resource Manual for Improvement.[99] This resource is an excellent compilation of resource material to promote institutional support of pain management; all of the sample resource tools are available on a disc.

TABLE 58.3

JOINT COMMISSION ON ACCREDITATION OF HEALTHCARE ORGANIZATION'S PAIN STANDARDS

- Recognize the right of patients to appropriate assessment and management of pain;
- Assess the existence and, if so, the nature and intensity of pain in all patients;
- Record the results of the assessment in a way that facilitates regular reassessment and follow-up;
- Determine and assure staff competency in pain assessment and management, and address pain assessment and management in the orientation of all new staff;
- Establish policies and procedures which support the appropriate prescription or ordering of effective pain medications;
- Educate patients and their families about effective pain management; and address patient needs for symptom management in the discharge planning process.

Multimodal Approach

Federal guidelines developed by the Agency for Health Care Policy and Research (AHCPR) for the management of cancer pain also address the issue of management of pain in AIDS and state that, "The principles of pain assessment and treatment in the patient with HIV positive/AIDS are not fundamentally different from those in the patient with cancer and should be followed for patients with HIV-positive/AIDS."[93] In contrast to pain in cancer, pain in HIV disease may more commonly have an underlying treatable cause.[7]

Optimal management of pain in AIDS is multimodal and requires pharmacologic, psychotherapeutic, cognitive-behavioral, anesthetic, neurosurgical, and rehabilitative approaches. A multidimensional model of AIDS pain, which recognizes the interaction of cognitive, emotional, socioenvironmental, and nociceptive aspects of pain suggests a model for multimodal intervention.

Pharmacotherapies for Pain in Acquired Immunodeficiency Syndrome

The World Health Organization (WHO)[95] has devised guidelines for analgesic management of cancer pain that the AHCPR has endorsed for the management of pain related to cancer or AIDS.[92] These guidelines, also known widely as the "WHO Analgesic Ladder," have been well validated.[100] This approach advocates

selection of analgesics based on severity of pain, as well as the type of pain (i.e., neuropathic versus non-neuropathic pain). For mild-to-moderate severity pain, nonopioid analgesics such as NSAIDs and acetaminophen are recommended. For pain that is persistent and moderate to severe in intensity, opioid analgesics of increasing potency should be utilized. Adjuvant agents, such as laxatives and psychostimulants, are useful in preventing as well as treating opioid side effects such as constipation or sedation, respectively. Adjuvant analgesic drugs, such as the antidepressant analgesics, are suggested for considered use, along with opioids and NSAIDs, in all stages of the analgesic ladder (mild, moderate, or severe pain), but have their most important clinical application in the management of neuropathic pain.

This WHO approach, while not yet validated in AIDS, has been recommended by the AHCPR and clinical authorities in the field of pain management and AIDS.[5,7,9,17,62,93,101] Clinical reports describing the successful application of the principles of the WHO Analgesic Ladder to the management of pain in AIDS, with particular emphasis on the use of opioids, have also recently appeared in the literature.[6,14,17,102–105]

Nonopioid Analgesics

The nonopioid analgesics (Table 58.4) are prescribed principally for mild-to-moderate pain or to augment the analgesic effects of opioid analgesics in the treatment of severe pain. The use of NSAIDs in patients with AIDS must be accompanied by heightened awareness of toxicity and adverse effects. NSAIDs are highly protein-bound, and the free fraction of available drug is increased in AIDS patients who are cachectic, wasted, and hypoalbuminic, often resulting in toxicities and adverse effects. Patients with AIDS are frequently hypovolemic, on concurrent nephrotoxic drugs, and experiencing HIV nephropathy and so are at increased risk for renal toxicity related to NSAIDs. The antipyretic effects of the NSAIDs may also interfere with early detection of infection in patients with AIDS.

The major adverse effects associated with NSAIDs include gastric ulceration, renal failure, hepatic dysfunction, and bleeding. The nonacetylated salicylates, such as salsalate, sodium salicylate, and choline magnesium salicylate, theoretically have fewer GI side effects and might be considered in cases where GI distress is an issue. Prophylaxis for NSAID-associated GI symptoms include H2 antagonist drugs (cimetidine 300 mg three or four times a day or ranitidine 150 mg twice a day), misoprostol 200 mg four times a day, omeprazole 20 mg once a day, or an antacid. Patients should be informed of these symptoms, issued guaiac cards with reagent, and taught to check their stool weekly. NSAIDs effect kidney function and should be used with caution. NSAIDs can cause a decrease in glomerular filtration, acute and chronic renal failure, interstitial nephritis, papillary necrosis, and hyperkalemia.[106] In patients with renal impairment, NSAIDs should be used with caution, since many (i.e., ketoprofen, fenoprofen, naproxen, and carprofen) are highly dependent on renal function for clearance. The risk of renal dysfunction is greatest in patients with advanced age, pre-existing renal impairment, hypovolemia, concomitant therapy with nephrotoxic drugs, and heart failure. Prostaglandins modulate vascular tone, and their

TABLE 58.4

ORAL ANALGESICS FOR MILD TO MODERATE PAIN IN AIDS

	Starting		Plasma	
Analgesic (by class)	**Dose (mg)**	**Duration (hrs)**	**Half-life (hrs)**	**Comments**
NONSTEROIDAL				
Aspirin	650	4–6	4–6	The standard for comparison among nonopioid analgesics
Ibuprofen	400–600	—	—	Like aspirin, can inhibit platelet function
Choline magnesium trisalicylate	700–1500	—	—	Essentially no hematologic or GI side effects
Celecoxib	100–200	11	11	Decrease dose by 50% in moderate hepatic impairment
WEAKER OPIOIDS				
Codeine	32–65	3–4	—	Metabolized to morphine, often used to suppress cough in patients at risk of pulmonary bleed
Oxycodone	5–10	3–4	—	Available as a single agent and in combination with aspirin or acetaminophen
Proxyphene	65–13	4–6	—	Toxic metabolite norpropoxy accumulates with repeated dosing

inhibition by the NSAIDs can cause hypertension as well as interference with the pharmacologic control of hypertension.[107] Caution should be used in patients receiving B-adrenergic antagonists, diuretics, or angiotensin-converting enzyme inhibitors. Several studies have suggested that there is substantial biliary excretion of several NSAIDs, including indomethacin and sulindac. In patients with hepatic dysfunction, these drugs should be used with caution. NSAIDs, with the exception of the nonacetylated salicylates (e.g., sodium salicylate, choline magnesium trisalicylate), produce inhibition of platelet aggregation (usually reversible, but irreversible with aspirin). NSAIDs should be used with extreme caution, or avoided, in patients who are thrombocytopenic or who have clotting impairment. The role of cyclooxygenases (COX)-2 antagonists, such as celecoxib, play in T-cell proliferation in HIV patients on combination antiretroviral therapy has been well described, suggesting these types of medications as potential therapeutic targets in HIV infection.[108,109] The overexpression of COX has been linked to the development and progression of several types of cancer including astrocytomas, breast, ovarian, and colorectal, and it has been reported that the inhibition of COX-2 suppresses growth and induces apoptosis in human esophageal adenocarcinoma cells.[110]

COX-2 inhibitors have an analgesic action equal to that of conventional NSAIDs, but with fewer GI complications and have been widely used for rheumatic diseases.[111] COX-2 inhibitors are associated with an increased risk of adverse cardiovascular events, including myocardial infarction, stroke, and new onset or worsening of pre-existing hypertension, GI irritation, ulceration, bleeding, and perforation, and are contraindicated for the treatment of perioperative pain in the setting of coronary artery bypass graft.[112]

OPIOID ANALGESICS

Opioid analgesics are the mainstay of pharmacotherapy of moderate to severe intensity pain in the patient with HIV disease (Table 58.5). Several reports describing the safe and effective use of opioid drugs in the management of moderate to severe pain in populations of patients with HIV disease (including patients with a history of injection drug use (IDU) as their HIV transmission factor) have begun to appear in the literature.[14,102–105,113] Kaplan and colleagues[113] conducted a multicenter study in which 44 patients with moderate to severe AIDS-related pain were treated with sustained release oral morphine in an open-label prospective study of patients treated for up to 18 days. Pain intensity decreased by 65% in the completed patients, quality of life was good in 80%, acceptability of therapy was 96% in the com-

TABLE 58.5

OPIOID ANALGESICS FOR MODERATE TO SEVERE PAIN IN AIDS

Analgesic	Equi-analgesic route	Dose (mg)	Analgesic onset (hrs)	Duration (hrs)	Plasma half-life (hrs)	Comments
Morphine	PO IM, IV, SC	30–60* 10	1–1.5 0.5–1	4–6 3–6	2–3	Standard of comparison for the narcotic analgesics. *30 mg for repeat around-the-clock dosing; 60 mg for single dose or intermittent dosing.
Morphine	PO	90–120	1–1.5	8–12	—	Now available in long acting sustained release forms.
Oxycodone	PO PO	20–30 20–40	1 1	3–6 8–12	2–3 2–3	In combination with aspirin or acetaminophen it is considered a weaker opioid, as a single agent it is comparable to the strong opioids, like morphine. Available in immediate release and sustained release preparation.
Hydromorphone	PO IM, IV	7.5 1.5	0.5–1 0.25–.05	3–4 3–4	2–3 2–3	Short half-life; ideal for elderly patients. Comes in suppository and injectable forms.
Methadone	PO IM, IV	20 10	2–1 0.5–1	4–8 —	15–30 15–30	Long half-life; tends to accumulate with initial dosing, requires careful titration. Good oral potency.
Levorphanol	PO IM	4 2	0.5–1.5 0.5–1	3–6	12–16 12–16	Long half-life; requires careful dose titration in first week. Note that analgesic duration is only 4 hours.
Meperidine	PO IM	300 75	0.5–1.5 0.5–1	3–6 3–4	3–4 3–4	Active toxic metabolite, or meperidine, tends to accumulate (plasma half-life is 12–16 hours), especially with renal impairment and in elderly patients causing delirium, myoclonus and seizures.
Fentanyl transdermal system	TD IV	0.1 0.01	12–18	48–72 —	20–22 —	Transdermal patch is convenient, bypassing GI analgesia until depot is formed. Not suitable for rapid titration

IM, intramuscular; IV, intravenous; PO, per oral; SC, subcutaneous; TD, transdermal.

pleted patients, 92% of side effects were resolved, and total morphine dose remained stable through the course of the study. In a pilot study, Lefkowitz and Newshan[103] reported similar findings on the effectiveness and safety of the transdermal fentanyl patch in a small sample of patient with AIDS-related pain. With transdermal fentanyl, pain severity scores decreased, mean pain relief scores increased, and daily functioning measures improved significantly.[103] Furthermore, Lefkowitz and Newshan[103] reported transdermal fentanyl was effective for chronic pain in chemically dependent and nonchemical dependent AIDS patients. In persons with AIDS near the end of life, the use of opioid analgesia remains common practice. The medical records of 185 adult AIDS patients receiving hospice care were reviewed by Kimball and McCormick.[14] Most patients (93%) experienced at least one 48-hour period of discomfort during the last two weeks of life; the majority (88%) received some form of opioid analgesia. Of these patients, 62% experienced some relief of pain thereafter.[14]

Principles that are useful in guiding the appropriate use of opioid analgesics for pain[94,100,114] include the following: (1) choose an appropriate drug; (2) start with lowest dose possible; (3) titrate dose; (4) use "as needed" doses selectively; (5) use an appropriate route of administration; (6) be aware of equivalent analgesic doses; (7) use a combination of opioid, nonopioid, and adjuvant drugs; (8) be aware of tolerance; and (9) understand physical and psychologic dependence. Rotate opioids to restore analgesic efficacy when necessary. In choosing the appropriate opioid analgesic for cancer pain, Portenoy[94] highlights the following important considerations: (1) opioid class; (2) "weak" versus "strong" opioids; (3) pharmacokinetic characteristics; (4) duration of analgesic effect; (5) favorable prior response; and (6) opioid side effects.

Opioid analgesics are divided into two classes, the agonists and the agonist-antagonists, based on their affinity to opioid receptors. Pentazocine, butorphanol, and nalbuphine are examples of opioid analgesics with mixed agonist-antagonist properties. These drugs can reverse opioid effects and precipitate an opioid withdrawal syndrome in patients who are opioid-tolerant or dependent. They are of limited use in the management of chronic pain in AIDS. Oxycodone (in combination with either aspirin or acetaminophen), hydrocodone, and codeine are the so-called "weaker" opioid analgesics and are indicated for use in Step 2 of the WHO ladder for mild-to-moderate intensity pain. More severe pain is best managed with morphine or another of the stronger opioid analgesics, such as hydromorphone, methadone, levorphanol, or fentanyl. Oxycodone, as a single agent without aspirin or acetaminophen, is available in immediate and sustained-release forms and is considered a "stronger" opioid in these forms.

The oral route has often been described as the preferred route of administration of opioid analgesics from the perspectives of convenience and cost. However, the transdermal route of administration has gained rapid acceptance among clinicians and patients. Patients with HIV infection are burdened with the task of taking anywhere from 20–40 tablets of medication per day and often need to follow complicated regimens where medication has to be taken on an empty stomach, etc. In a study on patient-related barriers to pain management in AIDS patients,[115] the vast majority of AIDS patients endorse a preference to utilize a pain intervention that required a minimal number of additional pills (e.g., sustained-release preparations of oral opioids) or interventions that did not require taking pills at all (i.e., transdermal opioid system). Immediate release oral morphine or hydromorphone preparations require that the drug be taken every 3 to 4 hours. Longer-acting, sustained-release oral morphine preparations and oxycodone preparations are available that provide up to 8–12 hours or more of analgesia, minimizing the number of daily doses required for the control of persistent pain. Rescue doses of immediate-release, short-acting opioid are often necessary to supplement the use of sustained-release morphine or oxycodone, particularly during periods of titration or pain escalation. The transdermal fentanyl patch system (Duragesic, Ortho-McNeil Inc., Raritan, NJ) also has applications in the management of severe pain in AIDS.[103,105] Each transdermal fentanyl patch contains a 48–72 hour supply of fentanyl, which is absorbed from a depot in the skin. Levels in the plasma rise slowly over 12–18 hours after patch placement, so dosage forms are available. As with sustained-release morphine preparations, all patients should be provided with oral or parenteral rapidly acting short duration opioids to manage breakthrough pain. The transdermal system is convenient and can minimize the reminders of pain associated with repeated oral dosing of analgesics. In AIDS patients, it should be noted that the absorption of transdermal fentanyl could be increased with fever, resulting in increased plasma levels and shorter duration of analgesia from the patch.

It is important to note that opioids can be administered through a variety of routes: oral, rectal, transdermal, intravenous, subcutaneous, intraspinal, and even intraventricularly.[105] There are advantages and disadvantages as well as indications for use of these various routes. Further discussion of such alternative delivery routes as the intraspinal route, etc., are beyond the scope of this chapter; however, interested readers are directed to Chapter 45 and the Agency for Health Care Policy and Research Clinical Practice Guideline: Management of Cancer Pain.[93]

Opioid Side Effects

While the opioids are extremely effective analgesics, their side effects are common and can be minimized if anticipated in advance. Sedation is a common CNS side effect, especially during the initiation of treatment. Sedation usually resolves after the patient has been maintained on a steady dosage. Persistent sedation can be alleviated with a psychostimulant, such as dextroamphetamine, pemoline, or methylphenidate. All are prescribed in divided doses in early morning and at noon. Additionally, psychostimulants can improve depressed mood and enhance analgesia.[116,117] Delirium, of an either agitated or somnolent variety, can also occur while on opioid analgesics and is usually accompanied by attentional deficits, disorientation, and perceptual disturbances (visual hallucinations and more commonly illusions). Myoclonus and asterixis are often early signs of neurotoxicity that accompany the course of opioid induced delirium. Meperidine, when administered chronically in patients with renal impairment, can lead to a delirium due to accumulation of the neuroexcitatory metabolite normeperidine.[118] Opioid-induced delirium can be alleviated through the implementation of three possible strategies: (1) lowering the dose of the opioid drug presently in use; (2) changing to a different opioid; or (3) treating the delirium with low doses of high potency neuroleptics, such as haloperidol. The third strategy is especially useful for agitation and clears the sensorium.[119] For agitated states, intravenous haloperidol in doses starting at between 1 mg and 2 mg is useful, with rapid escalation of dose if no effect is noted. GI side effects of opioid analgesics are common. The most prevalent are nausea, vomiting, and constipation.[94] Concomitant therapy with prochlorperazine for nausea is sometimes effective. Since all opioid analgesics are not tolerated in the same manner, switching to another narcotic can be helpful if an antiemetic regimen fails to control nausea. Constipation caused by narcotic effects on gut receptors is a problem frequently encountered, and it tends to be responsive to the regular use of senna derivatives. A careful review of medications is imperative, since anticholinergic drugs such as the tricyclic antidepressants can worsen opioid-induced constipation and can cause bowel obstruction. Respiratory depression is a worrisome but rare side effect of the opioid analgesics. Respiratory difficulties can almost always be avoided if two general principles are adhered to: (1) start opioid analgesics in low doses in opioid-naive patients; and (2) be cognizant of relative potencies

when switching opioid analgesics, routes of administration, or both.

Opioid rotation is a useful strategy to improve pain management especially in long-term treatment. Accumulation of toxic metabolites can lead to the development of symptoms that include hallucinations, myoclonus, nausea and vomiting, and persisting pain. Several strategies of opioid rotation using equianalgesic doses have been reported to be useful in managing pain while decreasing the tolerance as well as the frequency and severity of opioid toxicity.[120–122]

Adjuvant Analgesics

Adjuvant analgesics are the third class of medications frequently prescribed for the treatment of chronic pain and have important applications in the management of pain in AIDS (Table 58.6). Adjuvant analgesic drugs are used to enhance the analgesic efficacy of opioids, treat concurrent symptoms that exacerbate pain, and provide independent analgesia. They may be used in all stages of the analgesic ladder. Commonly used adjuvant drugs include antidepressants, neuroleptics, psychostimulants, anticonvulsants, corticosteroids, and oral anesthetics.[93,120,121]

Antidepressants

The current literature supports the use of antidepressants as adjuvant analgesic agents in the management of a wide variety of chronic pain syndromes, including cancer pain, postherpetic neuralgia, diabetic neuropathy, fibromyalgia, headache, and low back pain.[122–127] The antidepressants are analgesic through a number of mechanisms that include antidepressant activity,[123] potentiation or enhancement of opioid analgesia,[128–130] and direct analgesic effects.[131] The leading hypothesis suggests that both serotonergic and noradrenergic properties of the antidepressants are probably important and that variations among individuals in pain (as to the status of their own neurotransmitter systems) is an important variable.[90] Other possible mechanisms of antidepressant analgesic activity that have been proposed include adrenergic and serotonin receptor effects,[132] adenosinergic effects,[133] antihistaminic effects,[132] and direct neuronal effects, such as inhibition of paroxysmal neuronal discharge and decreasing sensitivity of adrenergic receptors on injured nerve sprouts.[134]

There is substantial evidence that the tricyclic antidepressants in particular are analgesic and useful in the management of chronic neuropathic and non-neuropathic pain syndromes. Amitriptyline is the tricyclic antidepressant most studied and has been

TABLE 58.6

PSYCHOTROPIC ADJUVANT ANALGESIC DRUGS FOR AIDS PAIN

Generic name	Approximate daily dosage range (mg)	Route
TRICYCLIC ANTIDEPRESSANTS		
Amitriptyline	10–150	PO,IM
Nortriptyline	10–150	PO
Imipramine	15.5–150	PO,IM
Desipramine	10–150	PO
Clomipramine	10–150	PO
Doxepin	12–150	PO,IM
HETEROCYCLIC AND NONCYCLIC ANTIDEPRESSANTS		
Trazodone	125–300	PO
Maprotiline	50–300	PO
SEROTONIN REUPTAKE INHIBITORS		
Fluoxetine	20–80	PO
Paroxetine	10–60	PO
Sertraline	50–200	PO
Citalopram	10–60	PO
Escitalopram	10–60	PO
NEWER AGENTS		
Nefazodone	300–600*	PO
Venlafaxine	75–225†	PO
Duloxetine	60‡	PO
PSYCHOSTIMULANTS		
Methylphenidate	2.5–20 BID	PO
Dextroamphetamine	2.5–20 BID	PO
Pemoline	13.75–75 BID	PO
Modafinil	100–400	PO
PHENOTHIAZINES		
Fluphenazine	1–3	PO,IM
Methotrimeprazine	10–20 q6h	IM,IV
BUTYROPHENONES		
Haloperidol	1–3 PO	PO,IV
Pimozide	2–6 BID	PO
ANTIHISTAMINES		
Hydroxyzine	50 q4h–q6h	PO
ANTICONVULSANTS		
Carbamazepine	200 tid–400 TID	PO
Phenytoin	300–400	PO
Valproate	500 tid–1000 TID	PO
Oxcarbazepine	300 bid–1800 daily‡‡	PO
Pregabalin	50 tid–150 BID‡‡	PO
Gabepentin	1800–3600 daily‡‡	PO
Felbamate	1200–3600 daily‡‡	PO
Lamotrigine	100–400 daily‡‡	PO
ORAL LOCAL ANESTHETICS		
Mexiletine	600–900	PO
CORTICOSTEROIDS		
Dexamethasone	4–16	PO,IV
BENZODIAZEPINES		
Alprazolam	0.25–2.0 TID	PO
Clonazepam	0.5–4 BIC	PO

BID, twice a day; IM, intramuscular; IV, intravenous; PO, per oral; q6h, every 6 hours; QID, four times a day; TID, three times a day.
*Monitor liver function; if AST, ALT increase by 3x, discontinue and do not reintroduce.
†Adjust dose for renal impairment.
‡Adjust for renal impairment. Not recommended in hepatic impairment.
‡‡Adjust dose for renal impairment.

proved effective as an analgesic in a large number of clinical trials addressing a wide variety of chronic pain syndromes, including neuropathy, cancer pain, fibromyalgia, and others.[90,123,126,135–137] Other tricyclics that have been shown to have efficacy as analgesics include imipramine,[138,139] desipramine,[89,140] nortriptyline,[141] clomipramine,[142,143] and doxepin.[144]

The heterocyclic and noncyclic antidepressant drugs, such as trazodone, mianserin, maprotiline, and the newer serotonin-specific reuptake inhibitors (SSRIs), fluoxetine and paroxetine, may also be useful as adjuvant analgesics for chronic pain syndromes.[90,116,126,131,138,140,145–150] Fluoxetine, a potent antidepressant with specific serotonin reuptake inhibition activity,[148] has been shown to have analgesic properties in experimental animal pain models[149] but failed to show analgesic effects in a clinical trial for neuropathy.[140] Several case reports suggest fluoxetine may be a useful adjuvant analgesic in the management of headache[150] and fibrositis.[151] Paroxetine, a newer SSRI, is the first antidepressant of this class shown to be a highly effective analgesic in a controlled trial for the treatment of diabetic neuropathy.[138] Newer antidepressants such as sertraline, venlafaxine, and nefazodone may also eventually prove to be clinically useful as adjuvant analgesics. Nefazodone, for instance, has been demonstrated to potentiate opioid analgesics in an animal model.[152] Based on the post hoc result of three multicenter randomized, double-blind, placebo-controlled, parallel-group studies, the serotonin-norepinephrine reuptake inhibitor duloxetine appears to be well tolerated in the treatment of diabetic peripheral neuropathic pain.[93]

Given the diversity of clinical syndromes in which the antidepressants have been demonstrated to be analgesic, trials of these drugs can be justified in the treatment of virtually every type of chronic pain.[121] The established benefit of several of the antidepressants in patients with neuropathic pains,[135,138] however, suggests these drugs may be particularly useful in populations such as cancer and AIDS patients, where an underlying neuropathic component to the pain(s) often exists.[121] While studies of the analgesic efficacy of these drugs in HIV-related painful neuropathies have not yet been conducted, they are widely applied clinically using the model of diabetic and postherpetic neuropathies.

While antidepressant drugs are analgesic in both neuropathic and non-neuropathic pain models, their clinical use is most commonly in combination with opioid drugs, particularly for moderate to severe pain. Antidepressant adjuvant analgesics have their most broad application as "coanalgesics," potentiating the analgesic effects of opioid drugs.[93] The "opioid sparing" effects of antidepressant analgesics has been demonstrated in a number of trials, especially in cancer populations with neuropathic as well as non-neuropathic pain syndromes.[126,127]

The dose and time course of onset of analgesia for antidepressants when used as analgesics appears to be similar to their use as antidepressants.

There is compelling evidence that the therapeutic analgesic effects of amitriptyline are correlated with serum levels, as are the antidepressant effects, and that analgesic treatment failure is due to low serum levels.[135] A high-dose regimen of up to 150 mg of amitriptyline or higher is suggested.[135] The proper analgesic dose for paroxetine is likely in the 40–60 mg range, with the major analgesic trial utilizing a fixed dose of 40 mg.[138] There is anecdotal evidence to suggest that the debilitated medically ill (cancer and AIDS patients) often respond (for depression or pain) to lower doses of antidepressant than are usually required in the physically healthy, probably because of impaired metabolism of these drugs.[120] As to the time-course of onset of analgesia, a biphasic process appears to occur. There are immediate or early analgesic effects that occur within hours or days, and these are probably mediated through inhibition of synaptic reuptake of catecholamines. In addition, there are later, longer analgesic effects that peak over a 2 to 4 week period that are probably due to receptor effects of the antidepressants.[135,136]

Neuroleptics and Benzodiazepines

Neuroleptic drugs, such as methotrimeprazine, fluphenazine, haloperidol, and pimozide, may play a role as adjuvant analgesics[141,153–155] in AIDS patients with pain; however, their use must be weighed against what appears to be an increased sensitivity to the extrapyramidal side effects of these drugs in AIDS patients with neurologic complications.[156] Anxiolytics, such as alprazolam and clonazepam, may also be useful as adjuvant analgesics, particularly in the management of neuropathic pains.[157–159]

Psychostimulants

Psychostimulants, such as dextroamphetamine, methylphenidate, pemoline, and modafinil, may be useful antidepressants in patients with HIV infection or AIDS who are cognitively impaired.[117,158] Psychostimulants also enhance the analgesic effects of the opioid drugs.[160] Psychostimulants are also useful in diminishing sedation secondary to narcotic analgesics, and they are potent adjuvant analgesics. Bruera et al.[117] demonstrated that a regimen of 10 mg methylphenidate with breakfast and 5 mg with lunch significantly decreased sedation and potentiated the effect of narcotics in patients with cancer pain. Methylphenidate has also been demonstrated to improve functioning on a number neuropsychologic tests, including tests of memory, speed, and concentration, in patients receiving continuous infusions of opioids for cancer pain.[117] Dextroamphetamine has also been reported to have additive analgesic effects when used with morphine in postoperative pain.[161] In relatively low doses, psychostimulants stimulate appetite, promote a sense of well-being, and improve feelings of weakness and fatigue in cancer patients.

Pemoline is a unique alternative psychostimulant that is chemically unrelated to amphetamine but may have similar usefulness as an antidepressant and adjuvant analgesic in AIDS patients.[117] Advantages of pemoline as a psychostimulant in AIDS pain patients include the lack of abuse potential, the lack of federal regulation through special triplicate prescriptions, the mild sympathomimetic effects, and the fact that it comes in a chewable tablet form that can be absorbed through the buccal mucosa and thus can be used by AIDS patients who have difficulty swallowing or who have intestinal obstruction. Clinically, pemoline is as effective as methylphenidate or dextroamphetamine in the treatment of depressive symptoms and in countering the sedating effects of opioid analgesics. There are no studies of the capacity of pemoline to potentiate the analgesic properties of opioids. Pemoline should be used with caution in patients with liver impairment, and liver function tests should be monitored periodically with longer-term treatment. The U.S. Food and Drug Administration (FDA) suggests that patients sign an informed consent document which outlines the potential liver toxicities of pemoline when pemoline is prescribed.

Modafinil, a novel psychostimulant that has shown efficacy in treating excessive daytime sleepiness associated with narcolepsy, has recently demonstrated potential for the treatment of depression and fatigue.[162] Modafinil needs further study; however, it appears to be a promising alternative to other psychostimulants in patients who cannot tolerate or have contraindications to the use of other stimulants. Modafinil has minimal cardiovascular effects, does not cause tolerance or dependence, has a low abuse potential, and does not require a special triplicate prescription.

Anticonvulsant Drugs

Selected anticonvulsant drugs appear to be analgesic for the lancinating dysesthesias that characterize diverse types of neuropathic

pain.[122] Clinical experience also supports the use of these agents in patients with paroxysmal neuropathic pains that may not be lancinating, and to a far lesser extent, in those with neuropathic pains characterized solely by continuous dysesthesias. Although most practitioners prefer to begin with carbamazepine because of the extraordinarily good response rate observed in trigeminal neuralgia, this drug must be used cautiously in AIDS patients with thrombocytopenia, those at risk for marrow failure, and those whose blood counts must be monitored to determine disease status. If carbamazepine is used, a complete blood count should be obtained prior to the start of therapy, after 2 and 4 weeks, and then every 3–4 months thereafter. A leukocyte count below 4000 is usually considered to be a contraindication to treatment, and a decline to less than 3000, or an absolute neutrophil count of less than 1500 during therapy, should prompt discontinuation of the drug. Other anticonvulsant drugs may be useful for managing neuropathic pain in AIDS patients, including phenytoin, clonazepam, valproate, and gabapentin.[121] Several newer anticonvulsants have been used in the treatment of neuropathic pain. These drugs can be rapidly titrated and well tolerated and include gabapentin, pregabalin, oxcarbazepine, lamotrigine, and felbamate.

Although not fully understood, anticonvulsant medications are commonly used in the treatment of several chronic pain states. Pregabalin is FDA-approved for neuropathic pain associated with diabetic neuropathy. A randomized placebo-controlled trial reported by Dworkin et al.[163] demonstrated that pregabalin at doses of 300 mg or 600 mg daily significantly reduced pain by 30% after 8 weeks of treatment. It has also been used for pain in patients with fibromyalgia.[164] Gabapentin is also FDA-approved for the treatment of postherpetic neuralgia. In a multicenter, double-blind, randomized, placebo-controlled 7-week trial, gabapentin at doses of 1800 mg and 2400 mg daily was superior to placebo in postherpetic neuralgia patients.[165] Oxcarbazepine has shown in small clinical trials to be effective in the management of trigeminal neuralgia and diabetic neuropathy.[166,167] There is evidence that lamotrigine can be used to treat effectively HIV neuropathy, trigeminal neuralgia, spinal cord injury pain, and poststroke pain.[168–170]

Corticosteroids

Corticosteroid drugs have analgesic potential in a variety of chronic pain syndromes, including neuropathic pains and pain syndromes resulting from inflammatory processes.[92] Like other adjuvant analgesics, corticosteroids are usually added to an opioid regimen. In patients with advanced disease, these drugs may also improve appetite, nausea, malaise, and overall quality of life. Adverse effects include neuropsychiatric syndromes, GI disturbances, and immunosuppression.

Baclofen

Baclofen is a GABA-agonist that has proven efficacy in the treatment of trigeminal neuralgia.[171] On this basis, a trial of this drug is commonly employed in the management of paroxysmal neuropathic pains of any type. Dosing is generally undertaken in a manner similar to the use of the drug for its primary indication: spasticity. A starting dose of 5 mg two to three times per day is gradually escalated to 30–90 mg per day, and sometimes higher if side effects do not occur. The most common adverse effects are sedation and confusion.

Oral Local Anesthetics

Local anesthetic drugs may be useful in the management of neuropathic pains characterized by either continuous or lancinating dysesthesias. Controlled trials have demonstrated the efficacy of tocainide[172] and mexiletine,[173] and there is clinical evidence that suggests similar effects from flecainide[174] and subcutaneous lidocaine.[175] It is reasonable to undertake a trial with oral local anesthetics in patients with continuous dysesthesias who fail to respond adequately to, or who cannot tolerate, the tricyclic antidepressants and with patients with lancinating pains refractory to trials of anticonvulsant drugs and baclofen. Mexiletine is preferred in the United States.[92] Paice and colleagues[176] studied 26 subjects in order to test the efficacy of topical capsaicin in the management of HIV-associated pain. Results suggest that capsaicin is ineffective in relieving pain with HIV-associated distal symmetrical peripheral neuropathy; however, capsaicin has been shown to be effective in relieving pain associated with other neuropathic pain syndromes.[176]

DRUG INTERACTIONS: ANALGESICS AND ANTIHUMAN IMMUNODEFICIENCY VIRUS DRUG THERAPIES

Many of the available anti-HIV drugs have the potential to interact with other medications prescribed for pain, depression, anxiety, or other medical conditions. These drug interactions can be dangerous, resulting in drug toxicities due to elevated levels of medication or drug ineffectiveness because of the lowering of drug levels in the serum. Opioid analgesics can interact with certain anti-HIV drug therapies, and these interactions should be kept in mind when prescribing opioids. The protease inhibitor ritonavir can increase the levels of several opioid drugs including codeine, hydrocodone, oxycodone, methadone, and fentanyl. Patients on ritonavir should not be prescribed meperidine or propoxyphene because of increased risk of serious toxicity. Antidepressant and anticonvulsant analgesics can also interact primarily with ritonavir. Ritonavir can increase the serum levels of bupropion (bupropion, bupropion hydrochloride, fluoxetine, trazodone, and desipramine), resulting in increased drug toxicities (e.g., seizures with bupropion). Both ritonavir and saquinavir may increase levels of anticonvulsants such as phenobarbital, phenytoin, carbamazepine, and clonazepam.

NONPHARMACOLOGIC INTERVENTIONS

A variety of physical and psychologic therapies may also prove useful in the management of HIV-related pain (Table 58.7). Phys-

Cordotomy

TABLE 58.8

EXERCISE 1: SLOW RHYTHMIC BREATHING FOR RELAXATION

1. Breathe in slowly and deeply.
2. As you breathe out slowly, feel yourself beginning to relax; feel the tension leaving your body.
3. Now breathe in and out slowly and regularly, at whatever rate is comfortable for you. You may wish to try abdominal breathing.
4. To help you focus on your breathing and breathe slowly and rhythmically: (1) breathe in as you say silently to yourself, "in, two, three"; (2) breathe out as you say silently to yourself, "out, two, three."
   Or
   Each time you breathe out, say silently to yourself a word such as "peace" or "relax."
5. Do steps 1 through 4 only once or repeat steps 3 and 4 for up to 20 minutes.
6. End with a slow deep breath. As you breathe out say to yourself, "I feel alert and relaxed."

Adapted from McCaffery and Beebe, 1989.[193]

ical interventions range from bedrest and simple exercise programs to the application of cold-packs or heat to affected sites. Other nonpharmacologic interventions include whirlpool baths, massage, the application of ultrasound, and transcutaneous electrical nerve stimulation. Increasing numbers of AIDS patients have resorted to acupuncture to relieve their pain, with anecdotal reports of efficacy.

Several psychologic interventions have demonstrated potential efficacy in alleviating HIV-related pain, including hypnosis, relaxation, and distraction techniques such as biofeedback and imagery and cognitive-behavioral techniques (see Tables 58.8 and 58.9 for sample relaxation and distraction exercises). Where non-

TABLE 58.9

EXERCISE 2: PEACEFUL DISTRACTION

Something may have happened to you a while ago that brought you peace and comfort. You may be able to draw on that past experience to bring you peace or comfort now. Think about these questions.

1. Can you remember any situation, even when you were a child, when you felt calm, peaceful, secure, hopeful, or comfortable?
2. Have you ever daydreamed about something peaceful? What were you thinking of?
3. Do you get a dreamy feeling when you listen to music? Do you have any favorite music?
4. Do you have any favorite poetry that you find uplifting or reassuring?
5. Have you ever been religiously active? Do you have favorite readings, hymns, or prayers? Even if you haven't heard or thought of them for many years, childhood religious experiences may still be very soothing.

Additional points: Very likely some of the things you think of in answer to these questions can be recorded for you, such as your favorite music or a prayer. Then, you can listen to the tape whenever you wish. Or, if your memory is strong, you may simply close your eyes and recall the events or words.

Adapted from McCaffery and Beebe, 1989.[193]

pharmacologic and standard pharmacologic treatments fail, anesthetic and even neurosurgical procedures (such as nerve block, cordotomy, and epidural delivery of analgesics) are additional options available to the patient who appreciates the risks and limitations of these procedures.

UNDERTREATMENT OF PAIN IN ACQUIRED IMMUNODEFICIENCY SYNDROME

Reports of dramatic undertreatment of pain in AIDS patients have appeared in the literature.[2,4–6] These studies suggest that all classes of analgesics, particularly opioid analgesics, are underutilized in the treatment of pain in AIDS. The Memorial Group[2] has reported that less than 8% of ambulatory AIDS patients reporting pain in the severe range (8–10 on a NRS of pain intensity) received a strong opioid, such as morphine, as recommended by published guidelines (i.e., the WHO Analgesic Ladder). In addition, 18% of patients with "severe" pain were prescribed no analgesics whatsoever, 40% were prescribed a nonopioid analgesic (e.g., NSAID), and only 22% were prescribed a "weak" opioid (e.g., acetaminophen in combination with oxycodone). Utilizing the Pain Management Index (PMI),[177] a measure of adequacy of analgesic therapy derived from the Brief Pain Inventory's record of pain intensity and strength of analgesia prescribed, these investigators further examined adequacy of pain treatment. Only 15% of the sample received adequate analgesic therapy based on the PMI. This degree of undermedication of pain in AIDS (85%) far exceeds published reports of undermedication of pain (using the PMI) in cancer populations of 40%.[178] Larue and colleagues[4] report that in France, 57% of patients with HIV disease reporting moderate to severe pain did not receive any analgesic treatment at all, and only 22% received a "weak" opioid.

While opioid analgesics are underutilized, it is also clear that adjuvant analgesic agents, such as the antidepressants, are also dramatically underutilized.[2,4–6] Breitbart and colleagues[2] report that less than 10% of AIDS patients reporting pain received an adjuvant analgesic drug (e.g., antidepressants, anticonvulsants) despite the fact that approximately 40% of the sample had neuropathic type pain. This class of analgesic agents is a critical component of the WHO Analgesic Ladder, particularly in managing neuropathic pain, and is vastly underutilized in the management of HIV-related pain.

BARRIERS TO PAIN MANAGEMENT IN ACQUIRED IMMUNODEFICIENCY SYNDROME

A number of different factors have been proposed as potential influences on the widespread undertreatment of pain in AIDS, including patient, clinician, and health care system related barriers.[2,115,179] Sociodemographic factors, which have been reported to be associated with undertreatment of pain in AIDS, include gender, education, and substance abuse history.[1] Women, less educated patients, and patients who reported IDU as their HIV risk transmission factor are significantly more likely to receive inadequate analgesic therapy for HIV-related pain.

Breitbart and colleagues[115] surveyed 200 ambulatory AIDS patients utilizing a modified version of the Barriers Questionnaire (BQ),[180] which assesses a variety of patient-related barriers to pain management (resulting in patient reluctance to report pain or take opioid analgesics). Results of this study demonstrated that patient-related barriers (as measured by BQ scores) were significantly correlated with undertreatment of pain (as measured by the PMI) in AIDS patients with pain. Additionally, BQ scores

were significantly correlated with higher levels of psychologic distress and depression, indicating that patient-related barriers contributed to undertreatment for pain and poorer quality of life. The most frequently endorsed BQ items were those concerning the addiction potential of opioids, side effects and discomfort related to opioid administration, and misconceptions about tolerance. While there were no age, gender, or HIV risk transmission factor associations with BQ scores, nonwhite and less educated patients scored higher on the BQ. Several additional AIDS specific patient-related barriers examined[115,179] reveal that 66% of patients are trying to limit their overall intake of medications (i.e., pills) or utilize nonpharmacologic interventions for pain, 50% of patients cannot afford to fill a prescription for analgesics or have no access to pain specialists, and about 50% are reluctant to take opioids for pain out of a concern that family/friends/physicians will assume they are misusing or abusing these drugs.

In a survey of approximately 500 AIDS care providers,[181] clinicians (primarily physicians and nurses) rated the barriers to AIDS pain management they perceived to be the most important in the care of AIDS patients. The most frequently endorsed barriers were those regarding lack of knowledge about pain management or access to pain specialists and concerns regarding the use and addiction potential of opioid drugs in the AIDS population. The top five barriers endorsed by AIDS clinicians included: lack of knowledge regarding pain management (51.8%); reluctance to prescribe opioids (51.5%); lack of access to pain specialists (50.9%); concern regarding drug addiction and/or abuse (50.5%); and lack of psychologic support/drug treatment services (43%). Patient reluctance to report pain and patient reluctance to take opioids were less commonly endorsed barriers, with about 24% of respondents endorsing those barriers. In contrast, past surveys of oncologists rated patient reluctance to report pain or take opioids as two of the top four barriers. Like AIDS care providers, oncologists also endorsed highly a reluctance to prescribe opioids, even to a population of cancer patients with a significantly lower prevalence of past or present substance abuse disorders. Both oncologists and AIDS care providers report they have inadequate knowledge of pain management and pain assessment skills.

Pain Management and Substance Abuse in Acquired Immunodeficiency Syndrome

Individuals who inject drugs are among the AIDS exposure categories with the highest rate of increase over the past 5 years, especially in large urban centers. Pain management in the substance-abusing AIDS patient is perhaps the most challenging of clinical goals. Fears of addiction and concerns regarding drug abuse affect both patient compliance and physician management of pain and use of narcotic analgesics, often leading to the undermedication of HIV-infected patients with pain.

Studies of patterns of chronic narcotic analgesic use in patients with cancer, burns, and postoperative pain, however, have demonstrated that, although tolerance and physical dependence commonly occur, addiction (i.e., psychological dependence and drug abuse) is rare and almost never occurs in individuals who do not have histories of drug abuse.[182–184] More relevant to the clinical problem of pain management in AIDS patients, however, is the issue of managing pain in the growing segment of HIV-infected patients who have a history of substance abuse or who are actively abusing drugs. The use, specifically of opioids for pain control in patients with HIV infection and a history of substance abuse, raises several difficult pain treatment questions, including how to treat pain in people who have a high tolerance to narcotic analgesics, how to mitigate this population's drug-seeking and potentially manipulative behavior, how to deal with patients who may offer unreliable medical histories or who may not comply with treatment recommendations, and how to counter the risk of patients spreading HIV while high and disinhibited.

Perhaps of greatest concern to clinicians is the possibility that they are being lied to by a substance abusing AIDS patient complaining of pain. Clinicians must rely on a patient's subjective report, which is often the best or only indication of the presence and intensity of pain, as well as the degree of pain relief achieved by an intervention. Physicians who believe they are being manipulated by drug-seeking patients often hesitate to use an appropriate opioid regimen. The fear is that the clinician is being "duped" into prescribing narcotic analgesics which will then be abused or sold. Clinicians do not want to contribute to or help sustain addiction. This leads to an immediate defensiveness on the part of the clinician and an impulse to avoid prescribing opioids and even to avoid full assessment of a pain complaint. Because concerns are often raised regarding the credibility of AIDS patients' report of pain, particularly where there is a history of IDU, Breitbart and colleagues[184b] conducted a study of 516 ambulatory AIDS patients in which they compared the report of pain experience and the adequacy of pain management among patients with and without a history of substance abuse. This study found that there were no significant differences in the report of pain experience (i.e., pain prevalence, pain intensity, and pain-related functional interference) among patients who reported IDU as their HIV transmission risk factor and those who reported other transmission factors (non-IDU). Furthermore, there were no differences in the report of pain experience among patients who acknowledged current substance abuse, those in methadone maintenance, and those who were in drug free recovery. The description of HIV-related pain was comparable among IDU and non-IDU groups. What was different was the treatment received by these two groups. Patients in the IDU group were significantly more undermedicated for pain compared to the non-IDU group. A survey of 211 HIV-infected patients was conducted in order to assess pain reporting in HIV-infected patients with and without intravenous drug use.[185] It was demonstrated by Martin and colleagues[185] that non-IDU patients showed a strong correlation between pain and disease stage, CD4+ levels, and mortality rates. Intravenous drug users, however, did not display the same correlation between pain and disease parameters. Finally, Martin et al.[185] concluded that pain was more prominent in IDU compared to non-IDU, suggesting the need to differentiate risk groups in pain-related studies. Unfortunately, the existence or severity of pain cannot be objectively proven. The clinician must accept and respect the report of pain in spite of the possibility of being duped and proceed in the evaluation, assessment, and management of pain.

Experience from the cancer pain literature suggests that it is possible to adequately manage pain in substance abusers with life-threatening illness and to do so safely and responsibly utilizing opioid analgesics and several sound principles of pain management outlined here (Table 58.10).[101,186–188] Most clinicians experienced in working with this population of patients recommend that practitioners set clear and direct limits. While this is an important aspect of the care of intravenous drug-using people with HIV disease, it is by no means the whole answer. As much as possible, clinicians should attempt to eliminate the issue of drug abuse as an obstacle to pain management by dealing directly with the problems of opiate withdrawal and drug treatment. Clinicians should err on the side of believing patients when they complain of pain and should utilize knowledge of specific HIV-related pain syndromes to corroborate the report of a patient perceived as being unreliable. Messiah and colleagues[189] sought to demonstrate whether physicians were able to accurately identify IDUs and treat them appropriately. The results suggest that identification of active IDU may be partially based on incorrect interpretations of subjective cues.[189]

The clinician must be familiar with and understand the current terminology relevant to substance abuse and addiction. It is important to distinguish between the terms *tolerance*, *physical de-*

TABLE 58.10

AN APPROACH TO PAIN MANAGEMENT IN SUBSTANCE ABUSERS WITH HIV DISEASE

1. Substance abusers with HIV disease deserve pain control; we have an obligation to treat pain and suffering in all of our patients.
2. Accept and respect the report of pain.
3. Be careful about the label *substance abuse*; distinguish between tolerance, physical dependence, and addiction (psychological dependence or drug abuse).
4. Not all *substance abusers* are the same; distinguish between active users, individuals in methadone maintenance, and those in recovery.
5. Individualize pain treatment.
6. Utilize the principles of pain management outlined for all patients with HIV disease and pain (WHO Analgesic Ladder).
7. Set clear goals and conditions for opioid therapy: set limits, recognize drug abuse behaviors, make consequences clear, use written contracts, and establish a single prescriber.
8. Use a multidimensional approach: pharmacologic and nonpharmacologic interventions, attention to psychosocial issues, team approach.

pendence, and *addiction* or *abuse* (psychologic dependence). Tolerance is a pharmacologic property of opioid drugs defined by the need for increasing doses to maintain an (analgesic) effect. Physical dependence is characterized by the onset of signs and symptoms of withdrawal if narcotic analgesics are abruptly stopped or a narcotic antagonist is administered. Tolerance usually occurs in association with physical dependence. Addiction or abuse (also often termed psychologic dependence) is a psychologic and behavioral syndrome in which there is drug craving, compulsive use (despite physical, psychologic, or social harm to user), other aberrant drug-related behaviors, and relapse after abstinence.[101] The term "pseudoaddiction" has been coined to describe the patient who exhibits behavior that clinicians associate with addiction, such as requests for higher doses of opioids, but in fact is due to uncontrolled pain and inadequate pain management.[190]

The clinician must also distinguish between the "former" addict who has been drug free for years, the addict in a methadone maintenance program, and the addict who is actively abusing illicit and/or prescription drugs. Actively using addicts and those on methadone maintenance with pain must be assumed to have some tolerance to opioids and may require higher starting and maintenance doses of opioids. Preventing withdrawal is an essential first step in managing pain in this population. In addition, "active" addicts with AIDS will understandably require more in the way of psychosocial support and services to adequately deal with the distress of their pain and illness. Former addicts may pose the challenge of refusing opioids for pain because of fears of relapse. Such patients can be assured that opioids, when prescribed and monitored responsibly, may be an essential part of pain management, and the use of the drug for pain is quite different from its use when they were abusing similar drugs. Some authorities emphasize the importance of conducting a comprehensive pain assessment in order to define the pain syndrome. Specific pain syndromes often respond best to specific interventions (i.e., neuropathic pains respond well to antidepressants or anticonvulsants). Adequate assessment of the cause of pain is essential in all AIDS patients and particularly in the substance abuser. It is critical that adequate analgesia be provided while diagnostic studies are underway. Often, treatments directed at the underlying disorder causing pain are very effective as well. For example, headache from CNS toxoplasmosis responds well to primary treatments and steroids.

When deciding on an appropriate pharmacologic intervention in the substance abuser, it is advisable to follow the WHO Analgesic Ladder. This approach advocates selection of analgesics based on severity of pain; however, clinicians also often take into account the nature of the pain syndrome in selecting analgesics. For mild to moderate pain, NSAIDs are indicated. The NSAIDs are continued with adjuvant analgesics (antidepressants, anticonvulsants, neuroleptics, steroids) if a specific indication exists. Patients with moderate to severe pain, or those who do not achieve relief from NSAIDs, are treated with a "weak" opioid, often in combination with NSAIDs and adjuvant drugs, if indicated.

It has been pointed out that it is critical to apply appropriate pharmacologic principles for opioid use. Data by Kaplan et al.[191] suggest that AIDS patients with prior drug use history benefited from opioid analgesia but required substantially more morphine than nonusers. One should avoid using agonist-antagonist opioid drugs. The use of as needed dosing often leads to excessive drug-centered interactions with staff that are not productive. While patients should not necessarily be given the specific drug or route they want, every effort should be made to give patients more of a sense of control and a sense of collaboration with the clinician. Often, a patient's report of beneficial or adverse effects of a specific agent are useful to the clinician.

The management of pain in substance abusing AIDS patients requires a team approach. Early involvement of pain specialists, psychiatric clinicians, and substance abuse specialists is critical. Nonpharmacologic pain interventions should be appropriately applied, not as a substitute for opioids but as an important adjunct. Realistic goals for treatment must be set, and problems related to inappropriate behavior around the handling of prescriptions and interactions with staff should be anticipated.

Hospital staff must be educated and made aware that such difficult patients evoke feelings that if acted on could interfere with providing good care. Clear limit setting is helpful for both the patient and treating staff. Sometimes, written rules about what behaviors are expected and what behaviors are not tolerated and the consequence should be provided. The use of urine toxicology monitoring, restrictions of visitors, and strict limits on amount of drug per prescription can all be very useful. It is important to also remember that rehabilitation or detoxification from opioids is not appropriate during an acute medical crisis and should not be attempted at that time. Once more stable medical conditions exist, referral to a drug rehabilitation program may be very useful. Constant assessment and re-evaluation of the effects of pain interventions must also take place in order to optimize care. Special attention should be given to points in treatment where routes of administration are changed or where opioids are being tapered. It must be made clear to patients what drugs and/or regimen would be introduced to control pain when opioids are tapered or withdrawn, and what options are available if that nonopioid regimen is ineffective.[192]

Finally, it is important to recognize that substance abusers with AIDS are quite likely to have comorbid psychiatric symptoms as well as multiple other physical symptoms which can all contribute to increased pain and suffering. Adequate attention must be paid to these physical and psychologic symptoms for pain management to be optimized.

CONCLUSION

Pain in AIDS, even in this era of protease inhibitors and decreased AIDS death rates, is a clinically significant problem contributing greatly to psychologic and functional morbidity. Pain can be adequately treated and so must be a focus of palliative care in the AIDS patient.

Substance abusers and women are particularly undertreated segments of the AIDS pain population and need special attention. Managing pain in AIDS patients with a history of substance abuse is a particularly challenging problem which AIDS care providers will be facing with increasing frequency.

CHAPTER 59 ■ THE TREATMENT OF CHRONIC PAIN IN PATIENTS WITH HISTORY OF SUBSTANCE ABUSE

HOWARD A. HEIT AND DOUGLAS L. GOURLAY

INTRODUCTION

Chronic pain has no positive physiologic value, while acute pain is an adaptive, beneficial response necessary for the preservation of tissue integrity.[1] Recurrent migraine headache, painful peripheral neuropathy, or metastatic bone cancer serves no useful physiologic purpose. In addition, pain is the most common complaint presenting to the primary health care professional and should be treated in all populations.[2]

The U.S. Census Bureau reported in July 2007 that the nation's population had reached 301 million. Approximately 16% to 23% (50 to 70 million) of the population suffers pain which is under-treated or not treated at all.[2] Three percent to 16% of the American population may have the disease of addiction.[3] This incidence and percentage of chronic pain and addiction is most likely representative of most developed countries. Furthermore, in certain subsets of the general population, the incidence of pain may be considerably greater as has been reported in methadone maintenance treatment programs.[4] Opioids may be indicated in a small percentage of these patients with moderate to severe pain. However, this population may be at increased risk for relapse even in the context of a comprehensive treatment plan that includes "rational pharmacotherapy." In addition, regulatory scrutiny often leaves the health care professional in a position of real or perceived vulnerability when prescribing a controlled substance (CS). This may put both health care professionals and their patients at risk of a suboptimal outcome for an often treatable medical condition.

The use of controlled substances including opioids in persons who may suffer from concurrent substance use disorders presents challenges to the health care professional. Success in the treatment of either condition requires an approach that encompasses the biopsychosocial needs of the patient. Pain management necessitates the need for appropriate boundary setting within the doctor-patient relationship. Unfortunately, it is impossible to determine beforehand, with any degree of certainty, who will become problematic users of prescription medications. By recognizing the need to carefully assess all patients, in a biopsychosocial model, stigma can be reduced, patient care improved, and overall risk contained.[5]

The goals of this chapter are to address the complex issues associated with the treatment of pain in persons with problematic behavior and to offer the health care professional an approach that may reduce risk and, hopefully, improve outcome.

PRINCIPLE OF BALANCE

Health care professionals who treat patients at the interface of pain and addiction and officials who formulate and enforce regulations must understand the central principle of "balance" as it relates to the use of any CS including opioids.

That principle provides for a system of controls to reduce the risk of diversion, abuse, or trafficking of opioids, balanced against the assurance of the availability of opioids for legitimate medical and scientific purposes and accessibility of opioids to all who need them for the relief of pain.[6] Health care professionals must embrace this principle as should our patients, dispensing pharmacists, and community.

By applying the principle of balance, it stands to reason that health care professionals should be able to treat pain in patients with the disease of addiction who are willing to simultaneously address both conditions. One can successfully treat acute pain in the face of an active addiction, but one will not achieve the stated goals in chronic pain management with an untreated substance use disorder.[7] Mutual support programs such as Alcoholics Anonymous and Narcotics Anonymous are quite clear in terms of their position on the management of any medical condition: these are side issues and should not interfere with the 12 steps and traditions of their respective programs. Inappropriate use of prescription medications, even when legitimately prescribed by a licensed professional, can interfere in the recovery process. For this reason, patients "in recovery" from drug or alcohol misuse need to ensure that their physicians are knowledgeable in the recovery process or have guidance from someone with such knowledge involved in their care.

The Importance of the Definitions

Using precise definitions at the interface of pain and addiction medicine will allow health care providers to improve their clinical practice of pain management (Table 59.1).[8–10]

Confusion between physical dependence and addiction may contribute to the under-treatment of chronic pain. Ballantyne et al. have expressed concern over the apparent separation of physical and psychological dependence in the diagnosis of addiction as if to suggest that these are entirely separable phenomena.[11] Although the following definitions share many elements in common, "continued use despite harm" remains the behavioral marker in the chronic pain patient that will define, over time, an addictive disorder, if present.[12] Physical dependence does not mean addiction,[12a] nor is it necessarily devoid of psychological components. Physical dependence and addiction can coincide, but physical dependence is neither necessary nor sufficient to make a diagnosis of addiction. Physical dependence is an expected, neuropharmacological adaptation that occurs as a result of chronic exposure to an agonist class of drug. Addiction is a much more complex biobehavioral phenomenon.[8–10]

Physical dependence is a natural, expected neuroadaptive response that can occur with opioids, alcohol, benzodiazepines, corticosteroids, antidepressants, diabetic agents, cardiac medications, and many other medications used in clinical medicine. Abrupt cessation of these medications can produce a withdrawal syndrome that can include, but is not limited to, nausea, vomiting,

TABLE 59.1

DEFINITIONS

1. Addiction is a primary, chronic, neurobiologic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, and continued use despite harm and craving.*
2. Physical dependence is a state of adaptation that is manifested by a drug-class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.*
3. Tolerance is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drugs' effects over time.*
4. Pseudoaddiction is a syndrome that causes patients to seek additional medications due to inadequate pharmacotherapy being prescribed. Typically when the pain is treated appropriately, the inappropriate behavior ceases.†
5. Pseudotolerance is the need to increase medication such as opioids for pain when other factor(s) are present, such as disease progression, new disease, increased physical activity, lack of compliance, change in medication formulation, drug interaction, addiction, and/or deviant behavior.‡
6. Iatrogenic addiction occurs when a patient, with a negative personal or family history for alcohol or drug addiction or abuse, is appropriately prescribed a controlled substance and subsequently in the therapeutic course meets the diagnostic criteria for addiction to that substance.**
7. Misuse is use of a medication (for a medical purpose) other than as directed or as indicated, whether willful or unintentional, and whether harm results or not.§
8. Abuse is any use of an illicit drug with the intentional self-administration of a medication for nonmedical purpose such as altering one's state of consciousness (e.g., getting high). Note that licit substances (e.g., alcohol) can also be abused.§
9. Diversion is the intentional removal of a medication from legitimate distribution and dispensing channels.§
10. Aberrant behavior is when the patient steps outside the boundaries of the agreed upon treatment plan which is established as early as possible in the doctor-patient relationship.¶

diaphoresis, diarrhea, abdominal cramps, seizures, anhedonia, dysphoria, and in some cases even death.[8–10] For example, a heroin addict may be both physically dependent and addicted to the narcotic, while the pain patient taking opioids is physically dependent, but not addicted. Both will experience some degree of withdrawal if the drug is abruptly stopped. In the pain patient, physical dependence with withdrawal may also be associated with withdrawal-mediated hyperalgesia.[13]

Iatrogenic addiction is not clearly defined in the literature.[14] The true incidence of iatrogenic addiction to opioids is not known.[14] It is therefore important to set limits and boundaries for all patients before writing the first prescription.[5]

It is only by careful evaluation and rational pharmacotherapeutic management of the pain that concurrent diagnoses such as addiction or pseudoaddiction can be confirmed. While a diagnosis of addiction is made prospectively over time, a diagnosis of pseudoaddiction is usually made retrospectively.[7] When reasonable limits and boundaries are placed on a patient and they continue to step out of bounds, addiction or pseudoaddiction should be considered.

Health care professionals with improved understanding of the definitions on the basic scientific and clinical levels will be better able to evaluate and treat chronic pain patients with or without the disease of addiction.

BASIC SCIENCE OF THE DISEASE OF ADDICTION

Drugs of misuse act at local cellular and membrane sites that are within a neurochemical system that is called the reward and withdrawal pathway (Fig. 59.1).[15] This pathway is in the mesolimbic dopamine system, and it involves, among other structures, the ventral tegmental area, nucleus accumbens, amygdala, and prefrontal cortex of the primitive brain. Addiction is a neurobiological disease that causes disruption of this pathway. This disruption is mediated via receptor sites and neurotransmitters. Central to this reward and withdrawal pathway is the neurotransmitter dopamine, which has been shown to be relevant not only to drug reward, but to food, drink, sex, and social reward.[16,17] Disruption of this neurochemical pathway by drugs of abuse may lead to addiction. Drug withdrawal can intensify with repeated drug use and can persist during prolonged periods of drug abstinence, a symptom complex known as the protracted abstinence syndrome.[18] This sensitization of a neural process related to drug cravings or to environmental stimuli such as sights, smells, and sounds associated with drugs (referred to as cues) leads to the progressive increase in drug-seeking behavior that characterizes addiction. Such sensitization appears to increase the attractiveness of the drug taking and that of the drug-associated stimuli.[19]

One of the most common reasons for relapse is stress.[15] It stands to reason that if a chronic pain patient is in recovery from drug or alcohol use and his or her pain is inadequately treated, he or she may turn to the inappropriate use of licit or illicit drugs.

The health care professional must recognize addiction as a treatable albeit irreversible brain disease[20,21]; it is a distinct medical condition that may or may not be associated with the patient's pain syndrome.

Opioids can cause physical dependence and, upon abrupt discontinuation, withdrawal as a result of up regulation of the cyclic aminophosphorase (cAMP) pathway at the locus ceruleus.[18] This is a normal physiologic response to this class of medications. It should be noted that most of the medications capable of producing physical dependence are not associated with the disease of addiction.

Tolerance is also a natural, expected physiologic response that can occur with exposure to certain classes of drugs, especially alcohol and opioids. The *key* to this definition is that all other factors remain stable so that just the physiologic response to the drug can be evaluated.[8] In fact, tolerance is neither good nor bad. It occurs at different rates, to different effects, in different patients, over time. So while there is relatively rapid tolerance to the cognitive blunting effects of the opioid class of drug, tolerance to the constipating effects of opioids rarely occurs. Unappreciated disease progress that is associated with dose escalation is termed pseudotolerance and is a term that was coined to describe the apparent loss of analgesic effect in cancer patients with unrecog-

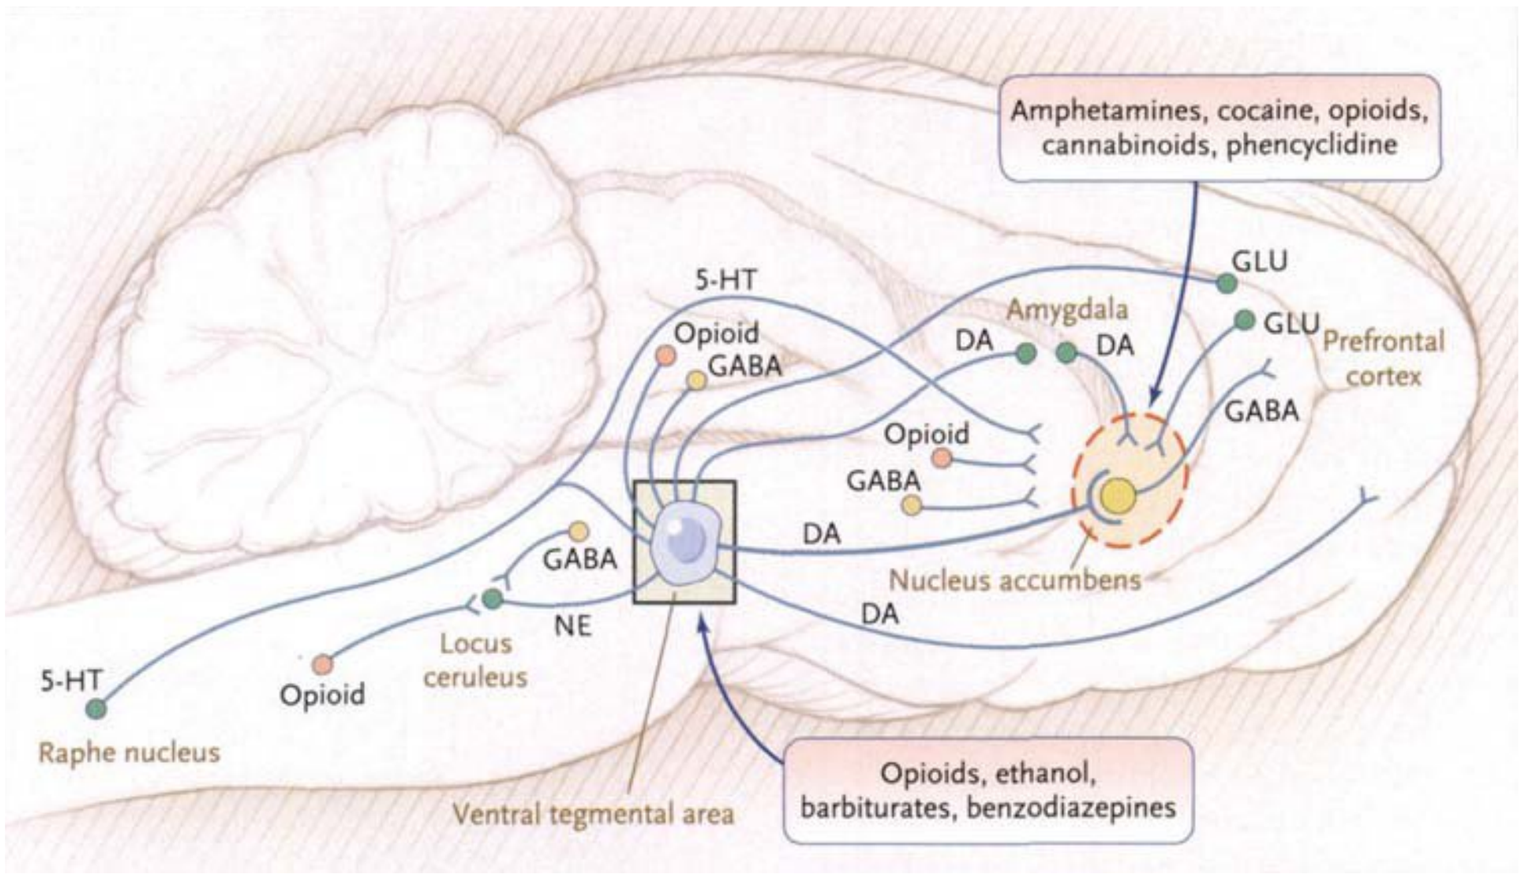

FIGURE 59.1 Common reward pathway: mesocorticolimbic dopamine (DA) system. (Reproduced from Cami J, Farre M. Drug addiction. *N Engl J Med* 2003; 349(10):975–986, with permission.)

nized increases in tumor burden.[22] Pharmacodynamic tolerance involves adaptations that occur at both the site of the drug action (e.g., receptor and ion channel), as well as in related systems more distal to it. For example, pharmacodynamic tolerance to opioids is evident at both the level of the opioid receptor in the locus ceruleus (primary) and in the dopaminergic reward pathways afferent to the site of this discrete drug action (secondary).[19] Both persons addicted to heroin and chronic pain patients taking opioids can exhibit tolerance to the drug.

Binary Concept of Pain and Addiction

In the past, the literature has suggested that pain conditions and addictive disorders might be dichotomous phenomena.[5,7,23] It has been said that in the context of a "legitimate" pain diagnosis, which usually meant a condition that made sense to the assessing health care professional, the likelihood of there being an addictive disorder was so small as to not even merit investigation. Unfortunately, if the patient had an obvious substance use disorder, very real and treatable pain conditions were often ignored. With time, this thinking was tempered somewhat to suggest that in the absence of a current or past personal or family history of a substance use disorder, the risk of addiction was very low indeed.[5] This dichotomous approach to pain and addiction has not served patients, health care professionals, or society well.

In reality, there is nothing about a genuine pain condition that is protective against having a concurrent substance use disorder; however, untreated pain, as a stressor, should be considered in the assessment of relapse risk.[15] While there are some data in the animal literature to suggest that acute pain may blunt the euphoric reward of some drugs including opioids,[24,25] the ability to generalize this phenomenon to the human population and more importantly, the sustainability of this "protection" has yet to be established. Patients with a substance use disorder are often disproportionate consumers of health care resources, especially in the context of trauma.[26,27] The presence of a preexisting substance use disorder is not mitigated by a concurrent pain problem; it is complicated by it.

While there is no evidence in the literature to suggest that those patients without past histories or increased risk of substance use disorders become addicted as a result of rational pharmacotherapy for the treatment of any medical condition, including chronic pain, there is little credible evidence to the contrary either. Perhaps more relevant questions to ask are whether rational pharmacotherapeutic management of acute or chronic pain can reactivate a previously dormant substance use disorder or express an as yet unidentified genetic predisposition toward substance misuse or addiction. In the authors' opinion, the answer to both questions is very likely, "Yes."[7]

Risk, of course, varies with circumstance. For example, the prevalence of alcoholism in the hospitalized general medical population is estimated at 19% to 26%,[28] while in the trauma subset, the prevalence rises to 40% to 62%.[27] Regardless of what the actual risk is, it is clear that no one specific marker can reliably identify the at-risk pain patient, so careful boundary setting for all patients is strongly recommended.[5]

Not all aberrant behavior reflects drug misuse or addiction. Some individuals who do not meet the diagnostic criteria for addiction may also use medications and other drugs problematically. This group is sometimes referred to as "chemical copers."[29] These individuals lack the skills commonly acquired during childhood and adolescence and tend to turn to external sources for support in dealing with life's problems. More often than not, however, these patients suffer from complex, multidimensional problems that may only be partially responsive to even optimum pharmacotherapy in the absence of a biopsychosocial treatment plan. Unidimensional problems may respond to unidimensional pharmacologic solutions. Multidimensional problems, however, may transiently respond to pharmacologic interventions, but rarely in a sustainable fashion.[7]

It is only by aggressive investigation and rational pharmacotherapeutic management of the pain that this diagnosis can be made. The diagnosis of addiction is often made prospectively over time. When the patient's behavior remains aberrant despite the appropriate management of the underlying painful condition with reasonably set limits, substance misuse or addiction should be considered. In contrast, the diagnosis of pseudoaddiction is made retrospectively in that with appropriate management of pain, aberrant behavior is reduced or eliminated.[5,7] When reasonable limits and boundaries are placed on a patient and yet the patient continues to step out beyond these limits, addiction and pseudoaddiction should be in the differential diagnosis.

Boundary setting may include interval dispensing and contingency prescribing. Interval dispensing requires the patient to see other members of the health care team, such as a staff member of the prescriber or the pharmacist on a more frequent basis than the actual prescriber. Thus, interval dispensing can be a simple and effective means to help patients keep from "borrowing from tomorrow to pay for today," thereby reducing the risk of running

out of medications early. With contingency prescribing, receiving the next prescription is contingent on something such as bringing bottles in for "pill counts" or mandatory attendance at all appointments.

Pain and Opioid Addiction—A Continuum Approach

While pain and addiction can and sometimes do exist as comorbid conditions, they may also be present as part of a dynamic continuum with pain at one end of the spectrum and addiction at the other (Fig. 59.2).[7,23] In cases where the identified substance of misuse is one in which there can be no doubt about the medical appropriateness of its use, such as with alcohol or cocaine, a comorbid pain and substance use disorder should be considered. However, when the drug in question can arguably be both the problem and the solution, depending on the health care professionals' training and perspective, a continuum model may better apply.[7,23] With chronic pain, appropriateness of ongoing opioid use should be periodically evaluated, especially when there is little or no objective evidence of improvement in pain relief or function.

In cases in which pain and addiction coexist either as a continuum or comorbid condition, it is important to identify which aspect of the illness is dominant. Failure to treat both conditions, when present, will undoubtedly lead to frustration and poor outcomes in both domains. It is equally important to realize that this continuum is dynamic, with substance use disorder symptoms becoming dominant during periods of stress even after years of stable recovery.[7,23]

Separating the "Motive" from "Behavior" when Dealing with Pain and Addiction

One of the greatest challenges facing practitioners treating complex pain patients is dealing with the patient who explains his or her aberrant behavior in terms of his or her chronic pain. Not infrequently, the health care professional will hear the patient say, "But I'm not an addict, I'm a pain patient" when challenged with explaining why he has run out of medication early, yet again. Of course, interpreting such behavior can be challenging.[30] The differential diagnosis is long and includes dependence, pseudoaddiction, true addiction, comorbid psychopathology, "chemical coping,"[29] and even criminal behavior such as diversion.[7] More often than not, the patient and/or patient's family can identify and are willing to discuss the aberrant behavior in the context of a "problem," rather than as evidence of a possible substance use disorder.

Take for example the patient who has unilaterally escalated his or her daily dose of medication, necessitating an early return for prescription renewal. While this may occur occasionally for quite legitimate reasons, repeated unilateral dose increases reflect behavior that must be carefully evaluated. In such a case, it may be more useful to focus on the problematic behavior (running out early) rather than the motive behind the behavior (i.e., addiction/abuse, chemical coping, etc.) when exploring this with the patient. Once the problematic behavior is identified and a remedial course of action selected, the ease with which the patient adheres to this "solution" will help to identify which aspect of the aberrant behavior differential is likely at work. Patients whose problematic behavior remains unchanged despite conservative efforts likely suffer from more complex problems that would best be referred to a substance-use-disorder professional or other clinician with greater experience and resources to assess and manage these more challenging cases. Non-forensic, patient-centered urine drug testing (UDT), which is discussed in Chapter 60, can be a very useful tool in these cases.[5,31,32]

In the case of criminal behavior, such as diversion of the prescribed medications, the behavior and motive behind it are clearly unacceptable. In the authors' opinion, this is cause to sever the doctor-patient relationship and dismiss the patient from the practice. Dismissing patients for such criminal behavior is unlikely to be construed as abandonment in most jurisdictions.

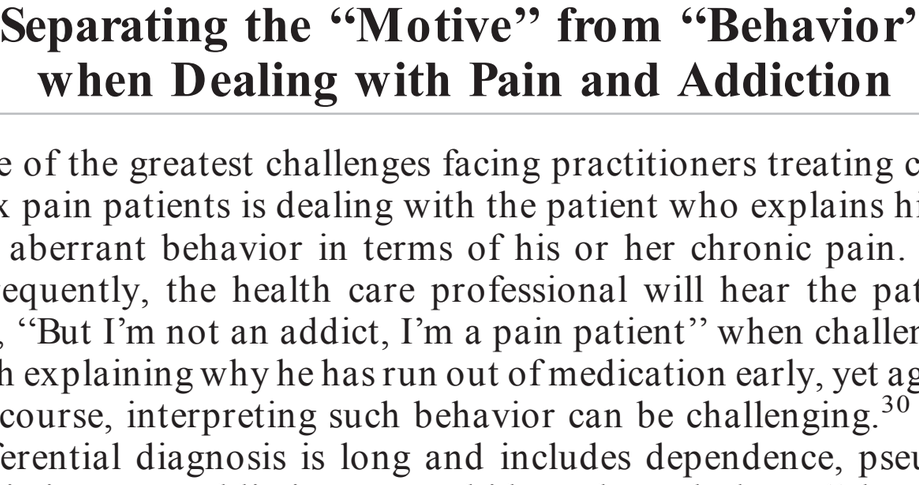

FIGURE 59.2 Pain and addiction continuum. (Adapted from Heit HA, Gourlay D. Chronic pain and addiction. In: Pasricha PJ, Willis WD, Gebhart GF, eds. *Chronic Abdominal and Visceral Pain: Theory and Practice*. New York: Taylor and Francis, 2006:231–244, with permission.)

Opioids for Analgesia or Opioid-Stabilizing Effect?

Not all pain syndromes are equally responsive to opioids.[33] Neuropathic pain may be less opioid responsive, often requiring higher doses.[34] In cases in which a patient is physically dependent on opioids, as one would expect with prolonged use of this class of drug, it can sometimes be useful to consider the appropriateness of continuation of opioid therapy, especially when treatment goals of improved function and decreased pain remain unmet.

Most pain is, to some degree, opioid responsive. Yet, despite years of experience with opioid therapy, it remains unclear who in advance will achieve a sustained response.

When the patient and clinician define the need to remain on opioid therapy not by how well the patient is doing but rather by how poorly things go when they try to reduce or discontinue the drug, it is time to reexamine the therapeutic role of opioids. When opioid levels in a physically dependent pain patient become inadequate, early withdrawal may occur. In the context of opioid-abstinence-induced hyperalgesia, it would be expected that the pain complaint might worsen.[13] It is something of a myth that patients who no longer need opioids always come off them easily. In any trial of therapy, including opioid pharmacotherapy, there must be a clear exit strategy in addition to an entrance, stabilization, and maintenance strategy before writing the first prescription.[7,35] This is not to say that those patients who are clearly benefiting from opioid pharmacotherapy should be weaned from these medications on the assumption that they "may no longer need them," but rather that not all persons who have inadequate pain relief or function while on opioids should remain on this class of drugs. In fact, some persons with poorly controlled pain while on opioid therapy may improve with a carefully executed opioid taper. The term taper is used here rather than detoxification, which is a term more commonly associated with the disease of addiction. Pain patients are "tapered," and addiction patients are "detoxed." In some jurisdictions, this can be a critical distinction in medicolegal terminology.

Recommendations for Terminating Opioid Therapy

A trial of opioid therapy is just that: a trial. In some cases, a decision to discontinue opioids is made. While the optimum case is one in which both the clinician and the patient feel this is the appropriate course to take, not infrequently it is the clinician

TABLE 59.2

CAGE-AID (ALCOHOL INCLUDING DRUGS) QUESTIONNAIRE[40]

- Have you tried to Cut down or Change your pattern of drinking or drug use?
- Have you been Annoyed or Angry by others' concern about your drinking or drug use?
- Have you felt Guilty about the consequences of your drinking or drug use?
- Have you had a drink or used a drug in the morning (Eye-opener) to decrease hangover or withdrawal symptoms?

alone who has made this decision. Discontinuation of the opioid class of drugs should, when possible, be done respecting that the patient may have become physically dependent. While no one taper schedule should be considered the criterion standard, it is important to bear the following in mind. The speed with which the dose can be reduced at the beginning of the taper does not necessarily predict the speed with which the patient will be able to finish. As a general rule, a taper that most patients will tolerate well is to drop the dose 10% every 1 to 2 weeks until the patient reaches the bottom third, and then reduce the dose by 5% every 2 to 4 weeks until completed. During the taper, worsening pain scores, especially in the morning, may indicate too rapid a dose reduction, frustrating the efforts at tapering the drug. It is important to remember that opioid termination should not be synonymous with termination of care, although for some patients, the net effect is that they will seek care elsewhere if opioids are not being prescribed.

The purpose of effective pain management in any patient population, including those suffering from substance use disorders, is to reduce pain while improving function. When a drug appears to do more harm than good and yet continues to be used, an active addictive disorder must be considered. While risk can never be eliminated, it can usually be managed. Failure to identify pain and addiction, where they exist, can render even the most ardent efforts at pain management ineffective and frustrating.

ASSESSMENT TOOLS

There are multiple assessment tools that are available for health care professionals to stratify the risk of drug/alcohol abuse or addiction.[36a] These tools may be used in pain management, especially if one is considering the use of controlled substances. The following tools have been proposed to help the clinician identify the "at risk" patient for aberrant behavior, including the Alcohol Use Disorders Identification Test (AUDIT),[36] the Screener and Opioid Assessment for Patients with Pain (SOAPP),[37,38] the CAGE-AID (Alcohol Including Drugs) (Table 59.2),[39,40] and the Opioid Risk Tool (ORT).[41] The CAGE Questionnaire has a sensitivity and specificity such that if the patient answers two out of four questions positively on it there is a current diagnosis of alcohol misuse or drug dependency with a sensitivity of 77% to 94% and a specificity of 79% to 97%.[40]

ORT is a five-question clinical interview or patient questionnaire to assess patients at risk for aberrant behavior with prescription opioids prior to treatment initiation. It quantifies the level of risk for patients in an easy-to-use format. Its scoring is based on gender, family history of substance abuse, personal history of substance abuse, age, history of sexual abuse, and psychological disease (Table 59.3).[41]

An increased risk does not mean that any given patient will behave aberrantly, and for those that do, not all behavior is equally important in terms of meaning. However, for those patients at increased risk, the need for closer monitoring should be evident. It is also important to note that on initial evaluation of all patients, the health care professional should always ask respectfully and in a nonjudgmental manner about a history of drug or alcohol abuse/addiction, physical or sexual abuse, or any current or past history of mental disorders. This information allows the treating health care professional to formulate the appropriate treatment plan with boundary settings. It also offers the opportunity to bring another member(s) into the treatment team

TABLE 59.3

STRATIFYING RISK: OPIOID RISK TOOL

to begin to address the biopsychosocial issues of the patient. This increases the chances of the patient reaching his or her goals of pain management.

UNIVERSAL PRECAUTIONS IN PAIN MEDICINE

The heightened interest in pain management is making the need for appropriate boundary setting within the clinician-patient relationship even more apparent. Unfortunately, it is impossible to determine beforehand, with any degree of certainty, who will become problematic users of prescription medications. With this in mind, a parallel can be drawn between the chronic pain management paradigm and our past experience with problems identifying the "at-risk" individuals from an infectious disease model.

The term "universal precautions," as it applies to infectious disease, came out of the realization that it was impossible for a health care professional to reliably assess risk of infectivity during an initial assessment of a patient.[42] Lifestyle, history, and even aberrant behavior such as injection drug use were unreliable indicators that led to patient stigmatization and increased health care professional risk. It was only after research into the prevalence of such diseases as hepatitis B, hepatitis C, and HIV that we realized the safest and most reasonable approach to take was to apply an appropriate minimum level of precaution to *all* patients to reduce the risk of transmission of potentially life threatening infectious disease to health care professionals. Fear was replaced by knowledge and with knowledge came the practice we now know as Universal Precautions (UP) in infectious disease.

UP, in pain medicine, is a risk management term introduced in 2005 which proposes adopting a minimum level of inquiry and care applicable to *all* patients presenting with chronic pain. UP offers an assessment and ongoing management scheme for all chronic pain patients.[5] It recognizes the need to carefully assess all patients within a multidimensional biopsychosocial model, including history of and present aberrant behaviors that might be associated with drug or alcohol use. By applying careful and reasonably set limits in the clinician-patient relationship, it is possible to triage chronic pain patients into three categories according to risk as presented later in this chapter.[7]

UP were introduced as a means to open up a dialogue between the pain management and addiction communities around the assessment and management of risk. They were not proposed as complete but rather as a good starting point for those treating chronic pain. It is important to note that UP are not simply about opioid therapy, but rather stress the importance of assessing and, where necessary, managing treatable comorbid conditions including substance use disorders.[43] As with UP in infectious disease, by applying the following recommendations, patient care may be improved, stigma reduced, and overall risk contained.[5]

The Ten Principles of Universal Precautions in Pain Medicine

The ten principles of UP are listed in Table 59.4. Treatable causes for pain should be identified where they exist and therapy directed toward the pain generator. In the absence of specific objective findings, pain can and should be treated. Any comorbid conditions, including substance use disorders and other psychiatric illness, must also be identified and addressed. A complete inquiry into personal and family history of substance misuse is essential to adequately assess and treat any patient. A sensitive and respectful assessment of risk should not be seen in any way as diminishing a patient's complaint of pain. Patient-centered urine drug testing (UDT) should be discussed with all patients regardless of what medications they are currently taking. In the authors' opinion, the prescription of controlled substances to patients who are "philosophically opposed" to UDT is relatively contraindicated.

TABLE 59.4

THE TEN PRINCIPLES OF UNIVERSAL PRECAUTIONS

1. Diagnosis with appropriate differential
2. Psychological assessment including risk of addictive disorders
3. Informed consent (verbal or written/signed)
4. Treatment agreement (verbal or written/signed)
5. Pre/post intervention assessment of pain level and function
6. Appropriate trial of opioid therapy +/− adjunctive medication
7. Reassessment of pain score and level of function
8. Regularly assess the "Four A's" of pain medicine *Analgesia, Activity, Adverse reactions, and Aberrant behavior*[47]
9. Periodically review pain and comorbidity diagnoses, including addictive disorders
10. Documentation

Adapted from Gourlay D, Heit H, Almarhezi A. Universal Precautions in Pain Medicine: A rational approach to the management of chronic pain. *Pain Med* 2005;6(2)107–112.

Informed consent is part of an initial evaluation. Health care professionals must discuss with and answer any questions about the proposed treatment plan including anticipated benefits and foreseeable risks. The specific issues of addiction, physical dependence, and tolerance should be explored at a level appropriate to the patient's understanding.

Written opioid agreements facilitate the documentation of informed consent, patient education, and compliance in the management of chronic pain.[44] A well-written agreement establishes the responsibilities of clinician to patient and vice versa. It outlines the treatment plan and documents informed consent. The opioid agreement establishes boundaries and consequences for nonadherence. Noncompliance with the agreement can aid in the diagnosis of the disease of addiction or substance misuse, which would often require a change in the treatment plan.

Opioid agreements have the potential to improve the therapeutic relationship.[44–46] The agreement, whether written and signed or informal, must be part of an environment of care that emphasizes honest and open communication. A practice policy for all patients prescribed opioids to sign a medication management agreement is often a simple and effective way to approach this sometimes uncomfortable issue. In the authors' opinion, the agreement should be reasonable, readable and flexible. Sometimes such agreements are called opioid contracts. However, these rarely reach the level of legally binding contracts, and as such are better referred to as medication management agreements. Where written agreements are used, both the patient and clinicians should sign two copies. The patient should be offered a copy to share with whomever he or she thinks appropriate. Effective agreements clearly define both the clinician's and patient's responsibilities (Table 59.5).[44–46]

Pre- and post-intervention assessment of pain level and function must emphasize that any treatment plan begins with a "trial of therapy." This is particularly true when controlled substances are contemplated or used. Without a documented assessment of preintervention pain scores and level of function, it may be difficult to demonstrate success in any medication trial. The ongoing assessment and documentation of goals met will support the continuation of any mode of therapy. Failure to meet these goals should necessitate reevaluation and possible change in the treatment plan.

An appropriate trial of opioid therapy, generally with adjunctive medication, may be warranted in moderate to severe pain. Although opioids should not routinely be thought of as treatment of first choice, they must also not be considered as agents of last

TABLE 59.5

TREATMENT AGREEMENT FOR OPIOID MAINTENANCE THERAPY FOR NONCANCER/CANCER PAIN

- Goals of therapy
- Single prescriber if possible
- Informed consent on all opioid risks
- Definition of addiction, tolerance, and physical dependence
- Need for patient disclosure of substance abuse history, psychiatric history including history of sexual, physical or emotional abuse, and medications currently prescribed
- Need for complete, honest self-report of pain relief, side effects, and function at each medical visit
- Establishment of regular medical visits
- Requirement for prescription renewal only during regular office hours
- Conditions of noncompliance (for example, evidence of drug hoarding or use of any illegal drug may cause termination of the clinician-patient relationship)
- Use of the word ''may'' instead of ''will'' in the agreement, so clinical judgment can be used in each situation
- Patient consent to random urine drug tests and pill counts
- Permission for the practice to contact appropriate sources to obtain or provide information about the patient's care or actions
- Where appropriate recovery program for substance misuse or addiction (patients must agree to concurrent assessment and treatment of their substance use disorder)

Adapted from Heit H. Creating and Implementing Opioid Agreements. *Disease Management Digest* 2003;7(1):2–3.

TABLE 59.6

TRIAGE OF THE CHRONIC PAIN PATIENT

Group I—primary care patients
This group has no past or current history of substance use disorders. They have a noncontributory family history with respect to substance use disorders and lack major or untreated psychopathology. This group clearly represents the majority of patients who will present to the primary care practitioner.

Group II—primary care patients with specialist support
In this group, there may be a past history of a treated substance use disorder or a significant family history of problematic drug use. They may also have a past or concurrent psychiatric disorder. These patients, however, are not actively addicted but do represent increased risk which may be managed in consultation with appropriate specialist support. This consultation may be formal and ongoing (comanaged) or simply with the option for referral back for reassessment should the need arise.

Group III—specialty pain management
This group of patients represents the most complex cases to manage due to an active substance use disorder or major, untreated psychopathology. These patients are actively addicted and pose significant risk to both themselves and to the practitioners who often lack the resources or experience to manage them. The prescription of controlled substances should generally be left to those persons with the experience and resources to manage the active addict.

Adapted from Gourlay D, Heit H, Almarhezi A. Universal Precautions in Pain Medicine: A rational approach to the management of chronic pain. *Pain Med* 2005;6(2):107–112.

resort. Pharmacologic regimens must be individualized based on subjective as well as objective clinical findings. The appropriate combination of agents, including opioids and adjunctive medications, may be seen as ''rational pharmacotherapy'' and provide a stable therapeutic platform from which to base treatment changes.

Regular reassessment of the patient's pain score and level of function, combined with corroborative support from family or other knowledgeable third parties, will help document the rationale to continue or modify the current therapeutic trial. The routine assessment of the ''Four A's'' of pain medicine, Analgesia, Activity, Adverse effects, and Aberrant behavior, will help to direct therapy and support pharmacologic options taken.[47] It may also be useful to document a fifth A: Affect (Personal communication, E. Covington, November 23, 2005). The prescriber should periodically review pain diagnosis and comorbid conditions, including substance use disorders. Underlying illnesses evolve. Diagnostic tests change with time. In the pain and addiction continuum, it is not uncommon for a patient to move from a dominance of one disorder to the other. As a result, treatment focus may need to change over the course of time. If an addictive disorder predominates, aggressive treatment of an underlying pain problem will likely fail if not coordinated with treatment for the concurrent addictive disorder.

Careful and complete documentation of the initial evaluation and at each follow up is both medicolegally indicated and in the best interest of all parties. Thorough documentation, combined with an appropriate doctor-patient relationship, will reduce medicolegal exposure and risk of regulatory sanction. If you do not document it, it did not happen.

Patient Triage

One of the goals in the initial assessment of a pain patient is to obtain a reasonable assessment of risk of a concurrent substance use disorder or major psychopathology. In this context, patients can be stratified into three basic groups. The UP triage scheme offers a practical framework to help determine which patients they may safely manage in the primary care setting, those comanaged with specialist support, and those who should be referred on for management of their chronic pain condition in a specialist setting (Table 59.6).[5]

It is important to remember that Groups II and III can be dynamic; Group II becoming Group III with relapse to active addiction, while Group III patients can move to Group II with appropriate treatment. In some cases, as more information becomes available to the practitioner, the patient who was originally thought to be low risk (Group I) may become Group II or even Group III. It is important to continually reassess risk over time.

TREATING THE PAIN PATIENT ON OPIOID AGONIST TREATMENT

The treatment of pain in a patient on opioid agonist treatment (OAT) with methadone or sublinguinal (S/L) buprenorphine for the disease of opioid addiction can be particularly challenging. In some cases, the controlled substance prescribed for pain can be the solution, the problem, or both.[7]

Methadone and S/L buprenorphine (with or without naloxone) can be used for the dual purpose of treating the disease of addiction and pain, but they pose an interesting challenge for the prescriber. For appropriate prescribing of these medications, their unique pharmacokinetic and pharmacodynamic properties must be understood. This allows for proper patient selection and evaluation in order to optimize outcomes in the treatment of pain, addiction, or the comorbid conditions of pain and addiction.

In the disease of addiction, the dose of methadone or S/L buprenorphine is usually given once a day. In the clinical experience of the authors, methadone and buprenorphine are best dosed every 6–8 hours for the most effective treatment of opioid responsive pain.[48] However, it should be noted that this dosing schedule for S/L buprenorphine for analgesia is not documented in the peer review literature.[48]

Buprenorphine's high receptor affinity may interfere with effectiveness of other full mu analgesics. As with other partial mu-agonists, buprenorphine is contraindicated in opioid-dependent patients since it may precipitate severe withdrawal.[49,50]

Pain management for patients who are using S/L buprenorphine for the disease of addiction requires a specialized approach. The literature suggests that to treat pain in a patient on OAT with S/L buprenorphine, one must discontinue the S/L buprenorphine and do a reinduction of the drug after the acute pain syndrome resolves.[51] This may not be necessary in some instances. In certain circumstances, the patient may be spared the discomfort of having to go into withdrawal as the full mu-agonist is discontinued and he or she is rotated back to S/L buprenorphine. In most cases, the pain can simply be managed by titrating the S/L dose upward to effect with a 6–8 hour dosing regimen up to maximum dose of 32 mg/day.[48] If breakthrough medication is needed, consider using one with high potency such as fentanyl or hydromorphone because of their high affinity to the opioid receptor.[48] In the authors' opinion, rapid onset opioid formulations should be used with caution in this population and primarily for acute pain (with tightly set boundaries as per UP with limited "pill load"[35] prescribed between evaluations of the acute pain) (see Chapter 60). It is important to remember that it is always possible to add a full mu-agonist to a patient who is maintained on buprenorphine without fear of precipitating withdrawal. The reverse is, however, not true.

The patient who is on OAT and requires chronic pain management should agree to the principles of UP and be placed in the appropriate group for risk stratification (Group II or Group III) and monitored accordingly.

THE TREATMENT OF PAIN AND SUFFERING IN OUR SOCIETY

There is a debate over whether opioids are "good" or "bad" and whether or not they should be available. Of course, opioids are "good" when used appropriately and "bad" when they are misused. They should be made available to the patients who need them, but only with appropriate monitoring and oversight individualized to each case.[52] The chronic pain population is incredibly heterogeneous and varies tremendously in terms of vulnerability to addiction and misuse. The best way to accomplish the goal of keeping opioids available to those who need them is for all stakeholders involved in legitimate opioid therapy to openly address the complexity of the issue and to do so in a collaborative fashion.[52]

Major stakeholders in achieving an appropriate balance in the treatment of pain and the prevention of drug abuse and diversion are health care professionals, patients, third-party payers, regulatory bodies, law enforcement, pharmaceutical industry, and the media. If these groups reconcile themselves to the need for thoughtful and unemotional dialogue, opioid treatment can remain a viable option while efforts are made to stem the tide of prescription drug misuse and addiction. Everyone has a stake in this complex issue. We are all aging and many of us will have pain. Societal solutions are needed now so that we can all enjoy the comfort of knowing that safe and effective pain treatment will be there for us if we need it. It is the responsibility of all to make this a reality.[52]

One wonders if pain patients are being held to a higher standard regarding compliance with their treatment plan. For example, in the treatment of any chronic illness such as diabetes mellitus, 100% adherence to the treatment plan, while desirable, is obviously not achieved in the majority of patients. In fact, a recent review indicates that approximately 20% to 50% of patients are not adherent to recommended medical therapy.[53] The failure to comply is a complex interplay of a multitude of biopsychosocial factors including but not limited to patient motivation. To expect 100% compliance with any pharmacotherapeutic agent, including CS, is to ignore this fact.

CONCLUSION

The purpose of effective pain management in any patient population, including those suffering from substance use disorders, is to reduce pain while improving function. While achieving this goal may be more difficult in patients with substance use disorders, it is not impossible. Risk can never be eliminated, but it can usually be managed. By approaching these patients within a biopsychosocial model using the information presented in this chapter, the health care professional can give the patient the best quality of life possible given the reality of his or her clinical situation.

CHAPTER 60 ■ COMPLIANCE MONITORING IN CHRONIC PAIN MANAGEMENT

DOUGLAS L. GOURLAY AND HOWARD A. HEIT

INTRODUCTION

The pain management practitioner faces several challenges in the safe and effective management of chronic pain. One of these relates to the important issue of monitoring compliance with a previously agreed upon course of therapy. Unfortunately, in today's medicolegal climate, the need for pain practitioners to take steps to reduce the risk of diversion and misuse of controlled substances (CS) has become apparent. While the debate continues as to what degree prescribers contribute to the overall source of CS that reaches the street,[1–3] there should be no debate about the prescriber's responsibility to ensure a decreased need for these drugs by addressing demand reduction strategies in all susceptible individuals. All pain patients are not potential diverters; all aberrant behavior does not represent drug addiction or misuse.[4] However, we tend to adopt a more casual attitude toward prescription drugs, including opioids, despite the fact that there is a disturbing trend toward prescription drug abuse by adolescents and others who have found their family medicine chests a ready supply of abuseable drugs.[5] Whether this is because of an implicit sense of safety associated with prescription products or due to a simple comparison with typical illicit drugs of abuse found on the street is unclear. What is clear is that once the prescription medication is no longer used for its original therapeutic indication, it may become available for the growing prescription drug abuse problem.[5] Only recently have we begun to formally examine strategies to deal with this problem.[5]

A considerable effort has been expended in teaching clinicians how to initiate pharmacotherapy ("entrance strategy") but, unfortunately, there has not been an equal effort expended in teaching the technique of terminating these medications ("exit strategy"), some of which may have considerable withdrawal syndromes associated with their rapid taper or abrupt discontinuation.

The challenge today is not identifying aberrant behavior; it is in interpreting what it means.[4] More importantly, there has been

little written in the literature to guide prescribers in the appropriate steps to take once such behavior is identified. This chapter will explore some of these issues and offer suggestions as to their management.

For the purposes of this chapter, compliance monitoring may be defined as those steps taken by a prescriber to ensure that treatment plans are adhered to and prescribed medications are appropriately used. Many factors contribute to a patient's failure to adhere to an agreed upon treatment plan.[6] To expect 100% adherence, even when controlled substances are involved, is to ignore this fact.[6]

Compliance monitoring should begin with an individual assessment of risk. As outlined in Chapter 59, it is unwise to assume that you can assess risk, with any degree of certainty, at the first visit. Risk assessment and management is best performed over time. Treatment agreements, interval and contingency prescribing, pill counts, and urine drug testing can all play important parts in helping to manage risk and improve outcomes.[7–12]

Urine drug testing (UDT), which is a tool providing objective evidence of clinical stability in an otherwise largely subjective branch of medicine, should play a key role in any practitioner's patient care plan. As with the diabetic patient who self reports optimum glycemic control at a follow-up visit, the clinician still performs a $HgBA_1C$ test (which is a measure of glycemic control over time) as an objective measure of treatment success. Since hyperglycemia is not illegal, there is little prejudice created in the clinician's mind when the objective test is at odds with the patient's self report. Just as with $HgBA_1C$, the clinician can use a discordant urine drug test result to motivate change on the part of the patient and to monitor healthy changes already made. This chapter will discuss the basics of clinical urine drug testing.

Compliance monitoring should be based on the initial visit then subsequent assessments of risk over time. A variety of tools have been developed to help the clinician with this important task.[13–18] Regardless of the tool used, the result is only an estimate of the risk of the patient engaging in aberrant behavior. It is not a contraindication for the prescribing of controlled substances but might cause a prudent clinician to seek formal consultation with or referral to other appropriate health care professionals who have sufficient experience and resources to manage these often challenging cases.[7]

INTERPRETING ABERRANT BEHAVIOR

Even with the most reasonable treatment plan, a patient's ability to comply is based on a multitude of potentially conflicting factors. When a patient fails to comply with recommendations in a previously agreed upon treatment plan, the treating clinician needs to have an approach that allows the patient and prescriber to adequately address these issues. Not all aberrant behavior represents abuse, addiction, or criminal intent. Similarly, what may seem like reasonable treatment goals for any given patient may be more difficult for some patients to comply with than others, even in the context of a previously signed treatment agreement. When a patient steps out of previously defined limits and boundaries, the clinician should examine this behavior in the context of a "Golden Moment" where the patient may actually begin to see things for the way they are, rather than the way he or she wished they were.[18a] In this way, both clinician and patient can improve their level of communication that is inherent in all positive therapeutic relationships. Rather than simply dismissing the patient for breaking the treatment agreement, which can perpetuate the patient's revolving-door approach to health care, both parties become better educated to move forward in a strengthened therapeutic relationship based on mutual trust and honesty. This approach best serves the mutual interests of patient, practitioner, and the community in which they live.

Some patients however are not ready to undertake this level of personal growth; they may need to seek care elsewhere. It is important to remember that it is generally better for a patient to abandon a reasonable and prudent course of therapy than it is for that patient to be dismissed from the practice. While it may be necessary and appropriate to discontinue the prescription of controlled substances such as the opioid class of medication, this should rarely be seen as equivalent to dismissal from care, although a drug-seeking patient may interpret the two as being the same.

Potential Treatment Traps in Compliance Monitoring

Borrowing from Tomorrow to Pay for Today

For most patients, problematic prescription drug use does not involve parenteral misuse or diversion. For those patients who do exhibit aberrant behavior such as running out of medications early, the most common problem relates to simply taking more than prescribed. The concept of *borrowing from tomorrow to pay for today* is something that many patients can relate to.[4] In these circumstances, prescribing smaller quantities of medications, to be dispensed by the pharmacist on an interval basis, can assist the patient with treatment adherence. Patients who need more oversight than weekly medication pickup should likely be referred on for more formal assessment of potential comorbid conditions such as substance use disorders or other significant psychopathology.

Avoiding Excessive Pill Loads

In the management of chronic pain, medications must be carefully titrated to their optimum dose. Traditional teaching for a trial of opioid therapy suggests using immediate-release medications to establish drug responsiveness followed by conversion to modified-release medication, typically in a two or three times daily dosing schedule with a suitable amount of immediate-release medication for breakthrough pain management. While the literature continues to suggest that patients do better on modified-release opioids for the baseline treatment of chronic pain, there are no long-term perspective studies in the literature to confirm this most important clinical point.[19–22] By definition, a successful trial is one in which the patient is clearly improved either in terms of pain relief, functional restoration, or ideally both. Properly chosen patients often do well with this approach. Some, however, improve initially but lack the sustainable relief seen with opioid-responsive pain. In these cases, there is often seen a gradual dose escalation with diminishing returns as the side effect profile begins to overtake the therapeutic effect. For some patients, efficacy is measured by the subtle cognitive effects transiently seen with a new drug or drug dose rather than the marked reduction in pain scores and improved function typically seen with treatment-responsive pain. Unfortunately, tolerance to these effects can develop quickly, leading to significant dose escalation. Sometimes, in an effort to reduce drug use, the prescriber provides the patient with smaller dose tablets in the hopes the patient will be able to titrate the dose down, thereby reducing the overall dose taken and the adverse effects often seen with higher medication levels.

For example, a patient who is using 80 mg of controlled-release oxycodone in an every 8-hour dosing schedule may request 20 mg tablets rather than the 80 mg tablets, indicating that they often feel they don't need to take the entire dose to keep their pain under control. In an effort to reduce the total daily dose, the 80 mg tablets are changed to 20 mg tablets. In this case

now, instead of receiving 3 tablets per day, 21 tablets per week, the patient receives 12 tablets per day (to be used "as directed" in a 3 times daily divided dose). This is a total of 84 tablets per week. In a monthly prescription, this amounts to 336 tablets. While some patients may achieve the desired goal of dose reduction, others will ultimately begin to redistribute the controlled-release drug, often taking the medication more frequently during the day than the agreed upon 8-hour interval. With such large quantities of tablets available, *borrowing from tomorrow to pay for today* can become a problem.[4] In such cases when patients have asked for smaller unit doses as just described, it can be revealing to ask the patient to bring in their extra medications at the next visit. It is a minority of patients who are able to comply with this request, indicating that they use the medication up eventually! In these cases, closer inquiry may show that the duration of action for the modified-release drug is really only 3 or 4 hours, necessitating 6 or more dosing intervals per day to achieve "stability." Clearly the use of a modified-release medication in the same fashion as an immediate-release preparation is inappropriate. In a sense, the patient can be legitimately advised that the "clever delivery system" has failed them. In these cases, the answer is not to dose more frequently with the controlled-release preparation but, rather, to consider rotating to another modified-release system or to a truly long-acting medication such as methadone.

URINE DRUG TESTING IN PAIN MEDICINE

Urine drug testing (UDT) is a useful tool in pain management that provides valuable objective information to assist in diagnostic and therapeutic decision making.[11] Results of UDT provide confirmation of the agreed upon treatment plan (adherence/compliance); UDT can diagnose relapse or drug misuse as early as possible and, finally, can be used to advocate for the patient with third party interests.[12]

To assess compliance, the clinician may look for the presence of prescribed medications as evidence of their use. Not finding the prescribed drug or finding unprescribed or illicit drugs in the urine merits further discussion with the patient while recognizing that laboratory error and test insensitivity can result in misleading data. Bingeing by the patient can result in unexpected negative urine reports if the patient runs out of medication prior to sample collection. Therefore, these results by themselves cannot be relied on to prove drug diversion and may be consistent with addiction, pseudoaddiction, or the use of an opioid for nonalgesic purposes—so-called chemical coping.[23] The purpose of UDT should be explained to the patient at the initial evaluation. UDT should be used, like all other diagnostic tests, to improve patient care. UDT can also enhance the relationship between clinicians and patients by providing documentation of adherence to mutually agreed upon treatment plans.[11,12]

Reports of unprescribed or illicit substances in the urine aid in the assessment and diagnosis of drug misuse or addiction. UDT results can be used to encourage change to more functional behaviors, while supporting the positive changes previously made. Thus, the appropriate use of a UDT result requires documentation in the medical record and an understanding on the part of both the patient and the clinician of how these results are to be used.[24]

In the pain management setting, the presence of an illicit or unprescribed drug does not necessarily negate the legitimacy of the patient's pain complaints, but it may suggest a concurrent disorder such as drug abuse or addiction. While acute pain can be treated in a patient with an active addictive disorder, it is improbable that one can successfully treat chronic pain in a patient with untreated addiction. The patient must be willing to accept assessment and treatment of both disorders to receive adequate outcomes in either.[25] Thus the diagnosis of a concurrent addictive disorder, when it exists, does nothing to negate a legitimate pain disorder but rather, it complicates it. In some cases, the very nature of the patient's diagnosis may change as a result of information gained through drug testing.

Specimen Choice

Urine has been the preferred biologic specimen for determining the presence or absence of most drugs since the 1970s.[26] This is in part due to the increased window of detection of 1 to 3 days for most drugs and/or their metabolites.[27] When compared to serum samples, the relatively noninvasive nature of sample collection, ease of storage, and low cost of testing favor urine as the specimen of choice.

Whom to Test

The question of whom to test is made easier by having a uniform practice policy that helps reduce individual stigma. Beyond this, any risk of patient profiling based on racial, cultural, or other physical appearances is eliminated. Careful explanation of the purpose of testing normally allays patient concerns.[11]

Frequency of Testing

Testing frequency is a function of many factors, some of which are patient based and others are a function of the practice. For example, in a pain practice where the patient referral base is typically more complex, a policy of testing all patients on admission and thereafter to be determined by clinical assessment of risk is recommended. On the other hand, in the average primary care setting, where the prevalence of substance-use-disordered individuals should be no greater than the population as a whole, it may be sufficient to discuss urine drug testing with all patients and reserve actual testing to a behaviorally triggered paradigm. Unfortunately, this latter approach does subject the patient and practitioner to the risk of missing a potentially treatable comorbid disorder (substance misuse/addiction).[2,28,29] As time moves forward, the use of urine drug testing is fast becoming a standard of care. What is becoming clear is that the risk to the patient and practitioner alike is a function of what is done with the data thus obtained and not fundamentally in the data itself.[29]

Testing Strategies

The literature is clear that there is often a disconnect between the reason a urine drug test was ordered, the results obtained, and, most importantly, the clinical consequences to the patient as a results of these tests. The fundamental problem is a lack of testing strategy or plan for the clinician to use in response to results obtained. So, for the cocaine-misusing, chronic noncancer pain patient who refuses to give up the use of this drug, the clinical course correction necessary may, for the sake of safety, simply involve the termination of the use of controlled substances such as the opioid class of drug. On the other hand, in the palliative care case where there may be a moral imperative to the continued use of controlled substances for pain management, the decision to move this person into a more supervised setting for medication management might be made based on this new information.

The clinician must know the drugs for which to test, appropriate methods to use, and the expected use of the results obtained.[30a] If the purpose of testing is to find unprescribed or illicit drug use, Gas Chromatography/Mass Spectroscopy (GC/MS) and Liquid Chromatograph/Mass Spectroscopy (LC/MS) or similar

TABLE 60.1

RETENTION TIMES AND DETECTION WINDOWS OF COMMON ANALYTES

Drug	Approximate retention time
Amphetamines	48 hours
Barbiturates	Short acting (e.g., secobarbital) 24 hours Long acting (e.g., phenobarbital) 2–3 weeks
Benzodiazepines	3 days if therapeutic dose ingested Up to 4–6 weeks after extended dosage (i.e., one or more years)
Cocaine	
Metabolite	2–4 days
Ethanol	2–4 hours
Methadone	Approximately 3 days
Opiates	2 days
Propoxyphene	6–48 hours
Cannabinoids	Moderate smoker (4 times/week) 5 days Heavy smoker (smoking daily) 10 days Retention time for chronic smokers may be 20–28 days
Phencyclidine	Approximately 8 days Up to 30 days in chronic users (mean value = 14 days)

Interpretation of retention time must take into account variability of urine specimens, drug metabolism and half-life, patient's physical condition, fluid intake, and method and frequency of ingestion. These are general guidelines only.

technologies are the most specific for identifying individual drugs or their metabolites.[30] Caution must be exercised when interpreting UDT results in a pain practice. True negative urine results for prescribed medication may indicate a pattern of bingeing rather than drug diversion. Time of last use of the drug(s) can be helpful in the interpretation of negative UDT results. Table 60.1 lists retention times/detection windows of common analytes.

A routine UDT screening panel should test for the following drugs/drug classes:

- cocaine
- amphetamines/methamphetamine
- opioids
- methadone
- marijuana
- benzodiazepines

To reduce the risk of an undetected substituted or adulterated test sample, random urinary creatinine, pH, and temperature should be included in the test panel to assist with interpretation and to increase specimen reliability. The temperature of a urine sample within 4 minutes of voiding should be between 90°F and 100°F.[31] Urinary pH undergoes physiologic fluctuations throughout the day, but should remain within the range of 4.5 to 8.0.[31] Urinary creatinine varies with daily water intake and hydration; normal human urine has a creatinine concentration greater than 20 mg/dL. Values lower than 20 mg/dL indicate dilution and findings lower than 5 mg/dL are inconsistent with human urine.[31,32] Test results outside of these ranges should be discussed with the patient and/or the laboratory, as necessary.[11]

The detection time of most drugs or their metabolites in urine is usually 1 to 3 days, which is influenced by several factors including but not limited to dose, route of administration, metabolism, urine concentration, and pH.[30,33] Chronic use of a lipid-soluble drug such as marijuana may extend the window of detection to a week or more.[31,34] Benzodiazepines and their metabolites differ widely in their elimination half-lives, which affect their clinical effect, excretion, and detection.[35] See Table 60.1.

The method chosen to detect a particular drug will depend on the reason for undertaking the test. Immunoassay drug tests are most commonly used. They are designed to classify substances as either present or absent and are generally highly sensitive. In pain management, specific drug identification using more sophisticated identification tests is often needed. Combined techniques such as GC/MS make accurate identification of a specific drug and/or its metabolites possible. When the patient is being prescribed drugs from several different classes of compounds, such as is often the case with many pain patients, specific drug identification is strongly recommended.

Immunoassay drug tests for natural opioids are very responsive to morphine and codeine, but do not distinguish between the two. UDT by immunoassay also shows a low sensitivity for semisynthetic/synthetic opioids such as oxycodone and fentanyl.[35,36] A negative result does not exclude their use. Even though an immunoassay may be negative for consumed oxycodone, it should be positive on GC/MS if the drug was used within the window of detection. The clinical importance of this fact with urine drug testing cannot be overstated, since compliant patients may have been dismissed from pain management practices secondary to false-negative immunoassay test when looking specifically for prescribed medication. More recently, drug-specific immunoassay tests have been developed for such drugs as oxycodone or methadone, which are semisynthetic and synthetic drugs, respectively. The previous detection of an analyte, especially semisynthetic drugs, does not ensure future detection, even when dose and dosing interval have not changed.[11] This is especially true when the drug concentration is "peri-threshold" as would be the case when the concentration is 302 ng/mL and the cutoff is 300 ng/mL. Small changes in the state of hydration could easily make the sample "negative" one day and positive another.

The presence of a prescribed drug in the urine sample makes monitoring of that class of drugs impossible by immunoassay technique alone. Specific drug identification by chromatographic testing (i.e., GC/MS, LC/MS) is also necessary to identify which member of the detected class is responsible for the positive screen.[11]

The clinician also must understand the basic metabolism of commonly prescribed drugs, especially opioids, so he or she will be able to appropriately interpret a urine drug test result that is positive for the prescribed medication and/or its metabolite(s). For example, codeine is a prodrug that has no intrinsic analgesic activity but is metabolized to morphine and other compounds for its analgesic properties. See Figure 60.1 for basic opioid metabolic pathways.

The amount of drug and/or metabolite(s) (i.e., ng/dL) within a urine sample should not be used to extrapolate backward and make specific determinations regarding compliance with prescribed medication. Software and laboratory products have not been scientifically validated and reported in the peer review literature to give this information at this time. Interpreting UDT beyond the current scientific knowledge may possibly put clinicians and patients at medical and/or legal risk.[36b,37,37a] In addtion, UDT can not diagnose addiction, physical dependence, or diversion and should always be verified and correlated with the clinical picture. Health care professionals should use UDT results in conjunction with other clinical information when deciding to continue with or adjust the established boundaries of the treatment plan.

Dealing with Unexpected Urine Toxicology Results

Unlike drug testing that is forensically based, such as workplace testing, drug testing in clinical practice must be used to improve

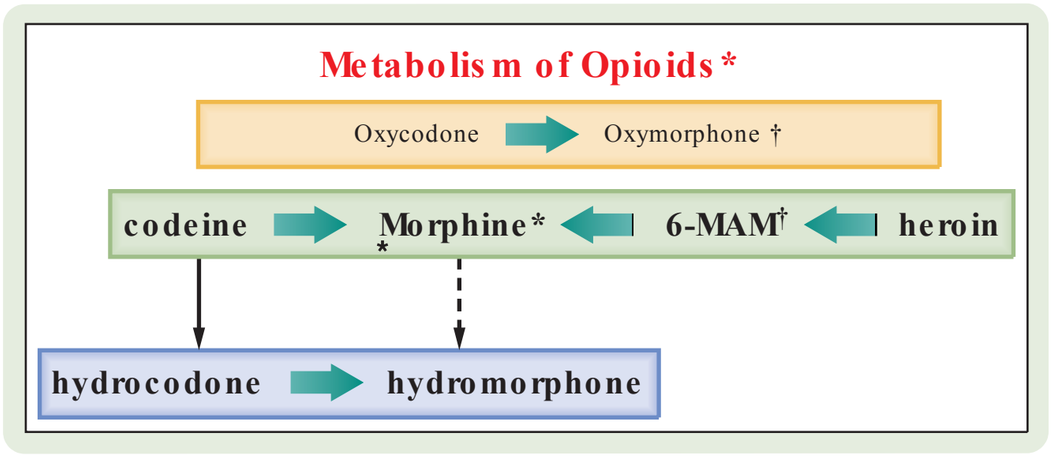

FIGURE 60.1 Basic opioid metabolic pathways. *Not comprehensive pathways, but may explain the presence of apparently unprescribed drugs; †6-MAM: 6-monoacetylmorphine; an intermediate metabolite. (From *D Gourlay, HA Heit, Y Caplan. *Urine Drug Testing in Clinical Practice: Dispelling the Myths & Designing Strategies*. 3rd ed.; †Sloan PA, Barkin RL. patient care. Unfortunately, these test results may come back unexpectedly negative for a prescribed drug or positive for an unprescribed one. The first step in interpreting contested results is to contact the lab to ensure that no clerical errors have been made. Occasionally, a negative urine is falsely reported as positive either due to a simple clerical error (i.e., lab wrote positive when they meant negative) or the patient has taken some other product or medication that is causing an unexpected result. In some cases, more definitive testing recommended by the lab will give answers to these questions, but they should never be ignored. There must be a process to follow that ultimately includes discussing the unexpected result with the patient.[11,12]

Unfortunately, drug tests may yield results that appear to be at odds with the patient's apparent level of clinical stability. Once confirmed as accurate, it is important to speak with the patient, carefully documenting the results and ensuing discussion in the medical record. When the patient acknowledges recreational use of prohibited substances, he or she should at least be advised of the clinical consequences of continued use including referral on to a specialist in substance use disorders or, if the patient indicates an unwillingness to stop using, discontinuation of the prescription of any controlled substances. When the patient indicates that he or she will no longer use, the patient should be tested more frequently and, when possible, randomly in order to ensure that this drug use has indeed stopped.[11,12] There are far more illicit/unprescribed drug users who *think* they are recreational users than actually *are* recreational users.

Decision to Terminate Opioid Therapy

The decision to change therapeutic direction should ideally be one made through mutual consultation and agreement between the patient and the physician. Unfortunately, occasions arise when the decision to discontinue a particular therapeutic agent or class of drugs must be made unilaterally. When it is clear that mutually agreed upon therapeutic goals have not been met, the trial of therapy should be considered a failure and an exit strategy implemented. One commonly held myth is that those patients who no longer need opioid therapy come off these agents easily. This is often untrue. In fact, many articles have been written about pharmacologic efforts at attenuating the withdrawal symptoms associated with opioid withdrawal.[38–41] Unfortunately, most of these articles are contained in the addiction medicine literature: The pain management literature has been surprisingly quiet on this issue. Interestingly, many medications other than the opioid class of drugs can pose significant challenges to the prescriber and patient alike when the decision is made to discontinue a course of therapy.[42–47]

As a general rule, it is better to taper a drug than to abruptly discontinue it. Furthermore, the ease with which a patient is able to reduce a large dose to a smaller one may not predict the ease with which the patient ultimately discontinues the drug altogether. For this reason, a reasonable taper schedule for drugs with a known discontinuation syndrome is to reduce the agent by ~10% every 1 to 2 weeks until the last one-third of the dose is reached, at which point the agent should be reduced by ~5% every 2 to 4 weeks until the agent is stopped. When withdrawal symptoms present themselves, it may be helpful to temporarily suspend the taper until these symptoms resolve. In some cases, certain therapeutic agents can be used to blunt the withdrawal process, especially toward the end of the taper. In the case of opioid withdrawal, the alpha-agonist clonidine can be useful to offset the hyperadrenergic symptoms associated with opioid withdrawal.[48]

When the decision is made to discontinue a certain class of medication, it is important to remember that this should not be misinterpreted as discontinuation of treatment. Unfortunately for some patients, discontinuation of a certain drug may result in their abandoning the practitioner who has made the decision to no longer provide this medication. From a medicolegal perspective, it is easier to defend against an assertion of "patient-abandonment" by a patient who has fired a practitioner who has made a patient-centered decision to alter treatment based on sound medical judgement, than it is to formally discharge the patient from your practice.

In conclusion, it is important to remember that a patient's failure to adhere rigorously to a previously agreed upon treatment protocol should not be interpreted as definitive evidence of a substance use disorder or worse, criminal intent. Patients fail to comply for a complex variety of reasons that must be assessed on an individual basis. Remember, aberrant behavior is much easier to identify than it is to interpret. By separating the motive from the behavior in assessing and interpreting departures from the agreed upon treatment plan, a patient-centered approach to problem solving can be implemented.[4]

CHAPTER 61 ■ HEADACHE

PETER J. GOADSBY

INTRODUCTION

Headache is a remarkably common problem even in general medicine or neurology and, by definition, has a substantial pain component. Books are devoted to the topic and interested readers are directed to recent editions for more detail on the subjects covered here.[1–5] The headache disorders are classified by the International Classification of Headache disorders,[6] now in its second edition, as being either primary, where the headache syndrome is itself the problem, or secondary, where the headache syndrome is driven by other pathological processes. This chapter is designed to cover the primary headaches with a broad view. Facial neuralgias and facial pain syndromes are covered elsewhere in this book. Where a primary headache causes face pain, and most primary headaches can do this, it will be included here for completeness. The chapter will cover the broad principles, the generic anatomy and physiology of head pain, and then discuss in turn the currently defined primary headache syndromes. There is much opportunity in headache to make patients significantly better and much research advancement in this very exciting area of medicine.

GENERAL PRINCIPLES

A general system for headache nosology is outlined in Table 61.1. The clinical challenge remains that while life-threatening headache is relatively uncommon in Western society, it occurs and its detection requires suitable awareness by the doctors of its clinical markers (Table 61.2). Primary headache, in contrast, often confers considerable disability over time and while not life-threatening, certainly robs patients of a decent quality of life.

Primary Headache Syndromes

The primary headaches are a group of remarkable disorders in which headache and associated features are seen in the absence of any exogenous cause. First, the general anatomy and physiology will be described as it applies to most of the syndromes. Then, the primary headache syndromes will be addressed and finally the chronic daily headache (CDH) syndromes will be explicitly mentioned as they drive so much disability.

Anatomy and Physiology

The most common *disabling* primary headaches, migraine and cluster headache, have been studied extensively in recent times and they are now relatively well understood insofar as neurological disorders that involve the brain are concerned. The word disabling is emphasized as the author takes the view that there are not sufficient, clear data to imply that tension-type headache provides a substantial and disabling community problem.[7] This is largely due to the probable inclusion of patients with migraine in many cohorts that have studied tension-type headache. In experimental animals, the detailed anatomy of the connections of the pain-producing intracranial extracerebral vessels and the dura mater has built on the classical human observations of Wolff,[8] and Feindel, Penfield, and McNaughton.[9,10] It is these structures, and not the brain itself, that primarily generate, or are perceived to generate, head pain.

The key structures involved are:

- The large intracranial vessels and dura mater
- The peripheral terminals of the trigeminal nerve that innervate these structures
- The central terminals and second order neurons of the caudal trigeminal nucleus and dorsal horns of C_1 and C_2 (trigeminocervical complex)
- Higher center processing in the thalamus, ventroposteromedial and posterior thalamus, and cortex
- Modulatory centers in the diencephalon and brainstem, such as periaqueductal grey matter, locus coeruleus and parts of the hypothalamus

The innervation of the large intracranial vessels and dura mater by the trigeminal nerve is known as the trigeminovascular system. The cranial parasympathetic autonomic innervation provides the basis for symptoms such as lacrimation and nasal stuffiness, which are prominent in the trigeminal autonomic cephalalgias,[11,12] although they may also be seen in migraine. It is clear from human functional imaging studies that vascular changes in migraine and cluster headache are driven by these neural vasodilator systems so that these headaches should be regarded as *neurovascular*.[13] The concept of a primary *vascular* headache should be abandoned since it neither explains the pathogenesis of what are complex central nervous system disorders, nor does it necessarily predict treatment outcomes. The term *vascular headache*

TABLE 61.1

COMMON CAUSES OF HEADACHE

Primary headache		Secondary headache	
Type	**Prevalence (%)**	**Type**	**Prevalence (%)**
Migraine	16	Systemic infection	63
Tension-type	69	Head injury	4
Cluster headache	0.1	Subarachnoid hemorrhage	<1

TABLE 61.2

WARNING SIGNS IN HEAD PAIN

- Sudden onset pain
- Fever
- Marked change in pain character or timing of attacks
- Neck stiffness
- Pain associated with higher center complaints
- Pain associated with neurological disturbance, such as clumsiness or weakness
- Pain associated with local tenderness, such as of the temporal artery

has no place in modern medical practice when referring to primary headache.

Migraine is an episodic syndrome of headache with sensory sensitivity, such as to light, sound, and head movement, probably due to dysfunction of aminergic brainstem/diencephalic sensory control systems (Fig. 61.1). The first of the migraine genes has been identified for familial hemiplegic migraine, and includes mutations in the *CACNA1A* gene for the $Ca_V2.1$ (α_{1A}) subunit of the neuronal P/Q voltage-gated calcium channel,[14] the Na/K ATP pump α_2 subunit gene *ATP1A2*,[15] and the voltage-gated sodium channel *SCN1A*.[16] These findings and the clinical features of migraine suggest it might be part of the spectrum of diseases known as channelopathies, or now ionopathies: disorders involving dysfunction of ion channel fluxes.[17] Functional neuroimaging has suggested that brainstem regions in migraine (Fig. 61.2), and the posterior hypothalamic region, in cluster headache (Fig. 61.3), are good candidates for specific involvement in primary headache.[13]

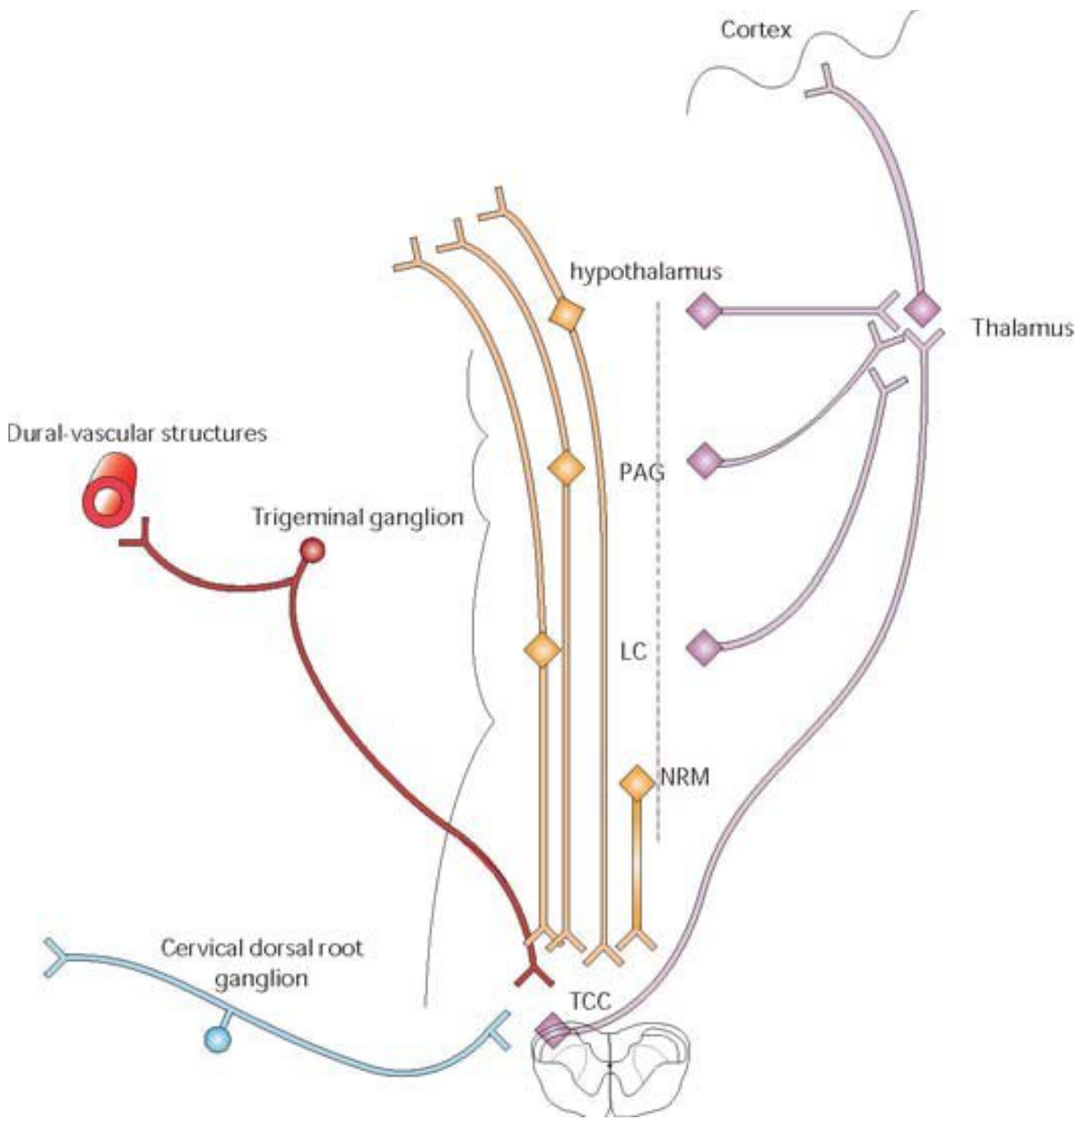

FIGURE 61.1 Pathophysiology of Migraine. Diagram of some structures involved in the transmission of trigeminovascular nociceptive input and the modulation of that input that form the basis of a model of the pathophysiology of migraine.[102] Afferents from dural-vascular structures innervated predominantly by branches of the first (ophthalmic division) of the trigeminal nerve whose cell bodies are found in the trigeminal ganglion (Vg) project to second order neurons in the trigeminocervical complex (TCC). The TCC extends from trigeminal nucleus caudalis to the caudal portion of the dorsal horn of the C_2 spinal cord. Input from cervical structures, such as joints or muscles, project through cell bodes in the upper cervical dorsal root ganglia (DRGs) to the TCC. TCC neurons project to ventrobasal thalamus (thalamus) and then to cortex. Sensory modulation can occur by descending influences onto the TCC that largely respect the midline (*dashed line*), such as those from hypothalamus, midbrain periaqueductal grey (PAG), pontine locus coeruleus (LC), and nucleus raphe magnus (RVM). These influences are cartooned as being direct but both direct and indirect projections are recognized. In addition, sensory modulation can occur from at least LC; PAG and hypothalamic projects to thalamus nuclei as ascending systems again that largely respect the midline.

Secondary Headache

It is imperative to establish in the patient presenting with any form of head pain whether there is an important secondary headache. Perhaps the most crucial clinical feature to elicit is the length of the history. Patients with a short history require prompt attention and may require prompt investigation and management. Patients with a longer history generally require time and patience rather than alacrity. There are some important general features, including associated fever or sudden onset of pain (see Table 61.2). Patients with a history of recent onset headache or neurological signs need a positive diagnosis of a benign disorder or require brain imaging with computed tomography (CT) or magnetic resonance imaging (MRI). Patients with a history of recurrent headache over a period of 1 year or more, fulfilling IHS criteria for migraine (Table 61.3) and with a normal physical examination, have positive brain imaging findings in only about 1/1000 images.[18] In general, it should be noted that brain tumor is a rare cause of headache, and rarely a cause of isolated long-term histories of headache. A notable exception to the general rules about secondary headache is pituitary tumor, which can trigger underlying primary headache biologies, and should always be considered, especially in the differential diagnosis of trigeminal autonomic cephalalgias.[19]

The management of secondary headache is generally self-evident: treatment of the underlying condition, such as an infection or mass lesion. One notable exception is the condition of chronic posttraumatic headache in which pain persists for long periods after head injury. This is an interesting problem that may be seen after central nervous system infection, both blunt and surgical trauma, intracranial bleeds, and other precipitants, using the term "trauma" in its broader context to mean a biological insult. While the syndrome is generally self-limiting up to 3–5 years after the event, treatment of the headache may be required if it is disabling (see CDH discussion below).

Migraine

Clinical Features

Migraine is an episodic brain disorder that affects about 12% to 15% of the population,[20,21] and can be highly disabling.[22] It has been estimated to be the most costly neurological disorder in the European community at more than €27 billion per year,[23] and its cost to the U.S. economy is a staggering $19.6 billion per year.[24] Migraine presents with headache generally accompanied by features, such as sensitivity to light, sound, or movement, and often with nausea, or less often vomiting (see Table 61.3). None of the features is compulsory, and indeed given that the migraine aura, visual disturbances with flashing lights or zig-zag lines moving across the fields or other neurological symptoms, is reported in only about 25% of patients, a high index of suspicion is required to diagnose migraine. In a controlled study of patients presenting to primary care physicians with a main complaint of headache

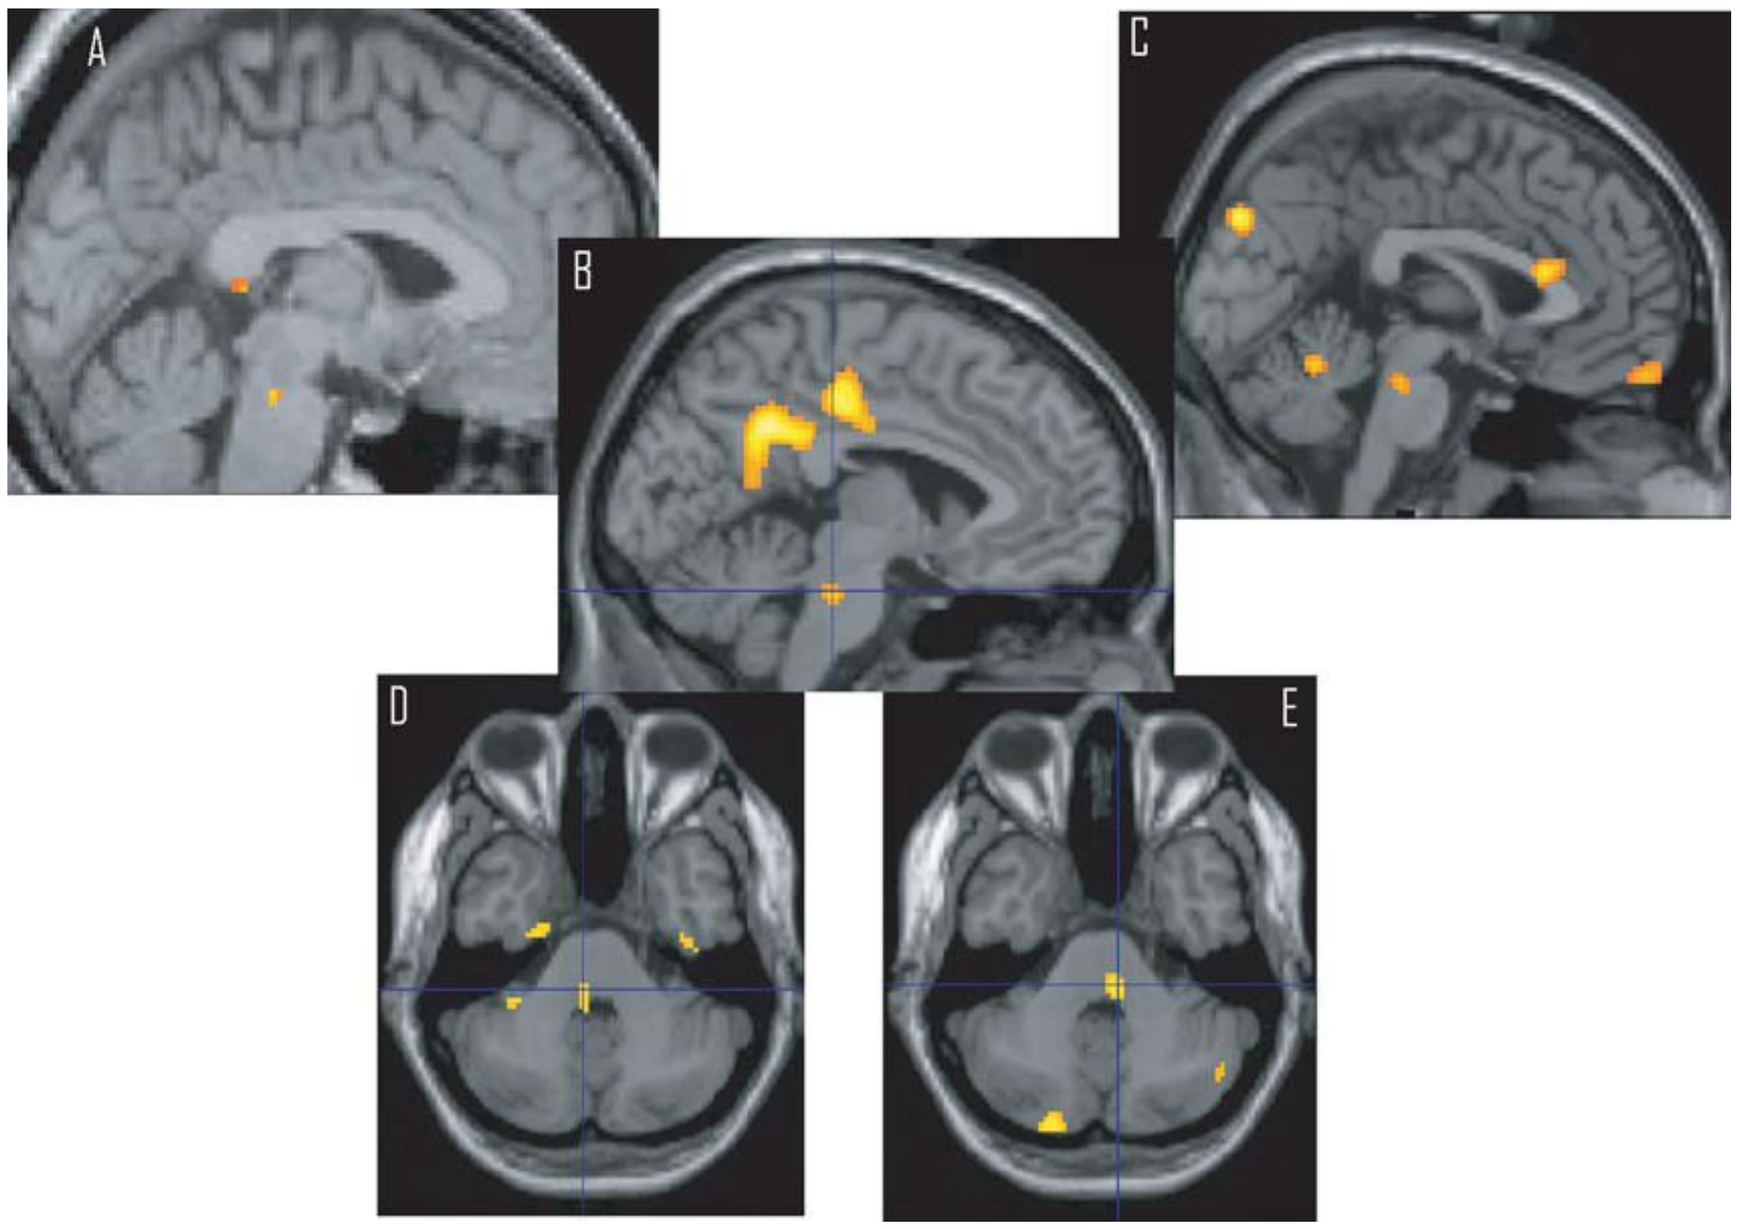

FIGURE 61.2 Activations identified on positron emission tomography in migraine. Consistently, there is dorsolateral pons activation in episodic migraine without aura, triggered by nitroglycerin (**A**)[103] or spontaneously studied (**B**),[104] and in chronic migraine (**C**).[25] Moreover, there is lateralization to the right (**D**) and left (**E**) in this structure that parallels the unilateral presentation of the pain.[105]

over the previous 3 months, migraine was the diagnosis on more than 90% of occasions,[7] thus a high index of suspicion is well rewarded. A headache diary can often be helpful in making the diagnosis; although, in reality the diary usually helps more in assessing disability or recording how often patients use acute attack treatments. Phenotyping remains an essentially clinical art mixing experience and an understanding of the problems likely to present—*good headache histories are taken not given*. In differentiating the two main primary headache syndromes seen in clinical practice, *migraine at its most simple level is headache with associated features, and tension-type headache is headache that is featureless*; furthermore *most disabling headache presentations in primary care are probably migrainous in biology*. By features here is meant throbbing pain, sensitivity to sensory stimuli (visual, auditory, olfactory), or to head movement itself.

Frequent Migraine

If headache with associated features describes migraine attacks, then *headachy* describes the migraine sufferer over their lifetime. It is important to realize that the word migraine can both describe the attacks using standard criteria (see Table 61.3), and describe the disorder itself, which is more than just the attacks. The migraine sufferer inherits a tendency to have headache that is amplified at various times by their interaction with their environment, the much-discussed triggers. The brain of the migraineur seems more sensitive to sensory stimuli and to change, and this tendency is notably amplified in females during their menstrual cycle. Migraine sufferers may have headache when they oversleep, when tired, when they skip meals, when they overexert, when stressed, or when they relax from a stressor. They are less tolerant to change

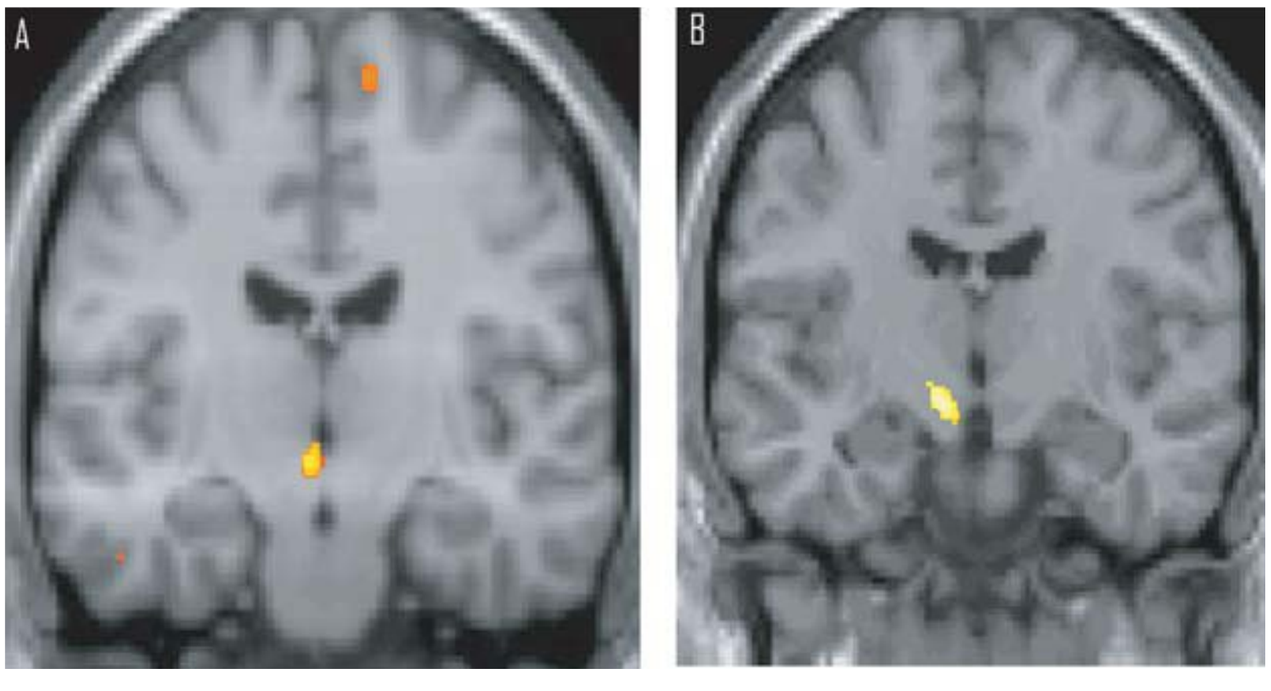

FIGURE 61.3 Activations on positron emission tomography in the posterior hypothalamic grey matter in patients with acute cluster headache (**A**). The activation demonstrated is lateralized to the side of the pain.[42] When comparing the brains of patients with cluster headache with a control population using an automatic anatomical technique known as voxel-based morphometry (VBM) that employs high-resolution T1 weighted MRI, a similar region is demonstrated (**B**) and has increased grey matter.[43]

TABLE 61.3

SIMPLIFIED DIAGNOSTIC CRITERIA FOR MIGRAINE

Repeated attacks of headache lasting 4–72 hours that have these features, normal physical examination and no other reasonable cause for the headache

At least 2 of:	At least 1 of:
• unilateral pain • throbbing pain • aggravation by movement • moderate or severe intensity	• nausea/vomiting • photophobia and phonophobia

Adapted from the IHS Classification[6]

and part of successful management is to advise them to maintain regularity in their lives in the knowledge of this fluctuating biology. It is this biology that marks migraine and in clinical practice must override the phenotype of individual headaches. It has been said that migraine can never occur daily; this is simply not correct. Chronic migraine very definitely occurs and is probably the largest part of the group of headaches known collectively as CDH that presents to doctors (see below). After making a diagnosis, the second step in the clinical process is to be sure that the disease burden has been captured: how much headache does the patient have and more important, what can the patient not do? What is their degree of disability? One can ask the patient directly to get a flavor for this, keep a diary, or get a quick but accurate estimate using the Migraine Disability Assessment Scale (MIDAS), which is well-validated and very easy to use in practice (Fig. 61.4).

Principles of Management of Migraine

After diagnosis, the management of migraine begins with an explanation of some aspects of the disorder to the patient.

- Migraine is an inherited tendency to have headache; this is caused by the patient's genes, therefore it cannot be cured *but*;
- Migraine can be modified and controlled by lifestyle adjustment and the use of medicines;
- Migraine is not life-threatening or associated with serious illness with the exception of females who smoke and use estrogenic oral contraceptives, but migraine can make life a misery;
- Migraine management takes time and cooperation when, for example, a headache diary has to be collected, or inquiry made concerning the disability.

INSTRUCTIONS: Please answer the following questions about ALL your headaches you have had over the last 3 months. Write your answer in the box next to each question. Write zero if you did not do the activity in the last 3 months (Please refer to the calendar below, if necessary)

1. On how many days in the last 3 months did you miss work or school because of your headaches? ……. |__|__| days
2. How many days in the last 3 months was your productivity at work or school reduced by half or more because of your headaches (Do not include days you counted in question 1 where you missed work or school)? …… |__|__| days
3. On how many days in the last 3 months did you not do household work because of your headaches? ……. |__|__| days
4. How many days in the last 3 months was your productivity in household work reduced by half or more because of your headaches (Do not include days you counted in question 3 where you did not do household work)? …… |__|__| days
5. On how many days in the last 3 months did you miss family, social, or leisure activities because of your headaches? …… |__|__| days

A. On how many days in the last 3 months did you have a headache? (If a headache lasted more than one day, count each day) …… |__|__| days

B. On a scale of 0 - 10, on average how painful were these headaches?

(where 0 = no pain at all, and 10 = pain as bad as it can be) …….. |__|__|

FIGURE 61.4 Migraine Disability Assessment Score (MIDAS) Questionnaire.

Nonpharmacological Management of Migraine

This approach aims to help the migrainous patient identify things making the problem worse and encourage them to modify these. Patients need to know that the brain sensitivity to triggers in migraine varies. Patient associations are often very helpful in supporting migraineurs to identify triggers. The knowledge that there is variability will remove considerable frustration on the patient's part, and will ring true to most as they have had the experience. The crucial lifestyle advice is to explain to the patient that migraine is a state of brain sensitivity to change. This implies that the migraine sufferer needs to regulate their lives: healthy diet, regular exercise, regular sleep patterns, avoiding excess caffeine and alcohol and, as far as practical, modifying or minimizing changes in stress. The balanced life with less highs and lows will benefit most migraine sufferers.

Preventive Treatments of Migraine

The patient needs to understand they have an inherited, incurable, but manageable problem. To start a preventive, they need to have sufficient disability to wish to take a medicine to reduce the affects of the disease on their life. The basis of considering preventive treatment from a medical viewpoint is a combination of acute attack frequency and attack tractability that is conferring an unacceptable degree of disability. Patients with attacks unresponsive to abortive medications are easily considered for prevention, while patients with simply treated attacks may be less obvious candidates. Another important consideration is disease progress. If a patient diary shows a clear trend of an increasing frequency of attacks it is better to initiate a preventive than wait for the problem to worsen.

A simple rule for frequency might be that for 1–2 headaches a month there is usually no need to start a preventive, for 3–4 it may be needed but not necessary, and for 5 or more per month prevention should definitely be considered. Options available for treatment are covered in detail in Table 61.4 and vary somewhat by country. One problem with preventives is that they have fallen into use for migraine from other indications and often bring unwanted or intolerable side effects. It is not clear how preventives work although it seems likely that they modify the brain sensitivity that underlies migraine. Another key clinical point is that generally each drug should be started at a low dose and gradually increased to a reasonable maximum if there is going to be a clinical effect.

Little has been done in terms of systematic study of patients with more intractable forms of migraine. Neuromodulation or neurostimulation approaches are promising, including stimulation of the occipital nerve, and functional imaging studies show that central processing of pain signals in migraine in the thalamus may be modified by such therapies.[25] This is an exciting and developing area.[26]

Acute Attack Therapies of Migraine

Acute attack treatments for migraine can be usefully divided into disease nonspecific treatments, analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs), and disease specific treatments, ergot-related compounds, and triptans (Table 61.5). It is important to be aware that most acute attack medications seem to have a propensity to aggravate headache frequency and can induce a state of refractory daily, near-daily, or medication-overuse headache. As evidence is gathered, this seems to occur in patients with migraine: either a previous clear history or a family or personal history of headacheyness.[27] Codeine-containing compound analgesics are particularly troublesome when available in over-the-counter (OTC) preparations. One should advise patients with migraine to avoid taking acute attack medicines on more than two days a week. A proportion of patients who stop taking regular analgesics will have substantial improvement in their headache with a reduction in frequency; however, for some it will not make any difference. It is crucial to emphasize to the patient that standard preventive medications often simply do not work in the presence of regular analgesic use.

Treatment strategies: Given the array of options to control an acute attack of migraine, how does one start? The simplest approach to treatment has been described as *Stepped Care*. In this model, all patients are treated, assuming no contraindications, with the simplest treatment, such as aspirin 900 mg or paracetamol (acetaminophen) 1000 mg with an antiemetic. Aspirin is an effective strategy, has been proven so in double-blind controlled clinical trials, and is best used in its most soluble formulations. The alternative would be a strategy known as *Stratified Care*, by which the physician determines, or stratifies, treatment at the start based on likelihood of response to levels of care. An intermediate option may be described as stratified care by attack. The latter is what many headache authorities suggest and what patients often do when they have the options.[28] Patients use simpler options for their less severe attacks relying on more potent options when their attacks or circumstances demand them.

Nonspecific Acute Migraine Attack Treatments. Simple drugs, such as aspirin and acetaminophen, are cheap and can be effective. Dosages should be adequate and the addition of domperidone (10 mg orally) or metoclopramide (10 mg orally) can be very helpful. NSAIDs can very useful when tolerated. Their success is often limited by inappropriate dosing, and adequate doses of naproxen (500–1000 mg orally or rectally, with an antiemetic), ibuprofen (400–800 mg orally[29]), or tolfenamic acid (200 mg orally[30]) can be extremely effective.

Specific Acute Migraine Attack Treatments. When simple analgesic measures fail or more aggressive treatment is required, the specific antimigraine treatments are required (Table 61.6). While ergotamine remains a useful treatment, it can no longer be considered the treatment of choice in acute migraine.[31] There are particular situations in which ergotamine is very helpful, but its use must be carefully controlled as ergotamine overuse produces dreadful headache in addition to a host of vascular problems. The triptans, serotonin 5-$HT_{1B/1D}$ receptor agonists, have revolutionized the life of many patients with migraine and are clearly the most powerful option available to stop a migraine attack. They can be rationally applied by considering their pharmacological, physicochemical, and pharmacokinetic features,[32] as well as the formulations that are available.[28] Recent data suggests that combining a triptan with an NSAID can improve efficacy and reduce headache recurrence.[33]

Tension-Type Headache

Clinical Features

As its name suggests, tension-type headache (TTH) is the headache form most seeking of understanding. TTH is diagnosed often, and while the phenotype is common, much of the disabling headache that goes under the name TTH is likely to be chronic migraine in terms of its biology. TTH has two forms: episodic TTH, where attacks occur on less than 15 days a month, and chronic TTH, where attacks, on average over time, are seen on 15 days or more a month. The International Headache Society (IHS) seeks to subdivide episodic tension-type headache into an infrequent variety, arguably of little impact on the patient's life, and a more frequent but nonchronic version. Patients with the chronic form are part of the broader clinical syndrome of CDH, but chronic tension-type headache and CDH are not equal concepts.

TTH has been defined by the IHS both for its episodic and chronic forms, although the admixture of symptoms allowed has

TABLE 61.4

PREVENTIVE TREATMENTS IN MIGRAINE*

Drug	Dose	Selected side effects
Pizotifen	0.5 mg to 2 mg daily	Weight gain Drowsiness
β-Blocker		
propranolol	40 mg to 120 mg b.d.	Reduced energy Tiredness Postural symptoms *Contraindicated in asthma*
Tricyclics		
• amitriptyline	25 mg to 75 mg nocte	Drowsiness
• dosulepin (dothiepin)		*note*: some patients are very sensitive and may only need a total dose of 10 mg, although generally 1–1.5 mg/kg body weight is required
• nortriptyline		
Anticonvulsants		
• Valproate	400–600 mg twice daily	Drowsiness Weight gain Tremor Hair loss Fetal abnormalities Hematological or liver abnormalities Paraesthesia Cognitive dysfunction Weight loss Care with a family history of glaucoma Nephrolithiasis Dizziness Sedation
• Topiramate	50–200 mg/day	
• Gabapentin	900–3600 mg daily	
Methysergide	1–6 mg daily	Drowsiness Leg cramps Hair loss Retroperitoneal fibrosis (1 month drug holiday is required every 6 months)
Flunarizine	5–15 mg daily	Drowsiness Weight gain Depression Parkinsonism
Single studies†		
• Lisinopril	20 mg daily	Cough
• Candesartan	16 mg daily	Dizziness
Nutraceuticals‡		
• Riboflavin	400 mg daily	GI upset
• Coenzyme Q10	100 mg three times daily	
• Butterbur	75 mg twice daily	
• Feverfew	6.25 mg three times daily	
No Convincing Controlled Evidence		
• Verapamil		
Controlled Trials to demonstrate no effect		
• Nimodipine

consistency problems. A useful clinical approach is to diagnose TTH when the headache is completely featureless: no nausea, no vomiting, no photophobia, no phonophobia, no osmophobia, no throbbing, and no aggravation with movement. Such an approach neatly divides migraine, which has one or more of these features and is the main differential diagnosis, from TTH.

Pathophysiology

The pathophysiology of TTH is poorly understood. This results from the fact that the name implies to most that it is a product of *nervous tension*, for which there is no clear evidence, and the definitions employed have undoubtedly admitted patients with migraine to the studies. Moreover, the concept that TTH in some way involves muscle contraction is incorrect since the evidence is that muscle contraction is no more likely than it is in migraine.[34] It seems likely that TTH is due to a primary disorder of central nervous system pain modulation alone in contrast with migraine, which is a more generalized disturbance of sensory modulation.

Management

Adopting the clinical approach to TTH outlined above results in diagnosing a headache form that is usually less disabling, more often described by patients as irritating. Its episodic form is generally amenable to simple analgesics, paracetamol (acetaminophen), aspirin, or other NSAIDs, which can be purchased OTC. There are clear clinical studies to demonstrate that triptans in TTH alone are not helpful, although germane to the above discussion, triptans are effective in TTH where the patient also has migraine.[35] For chronic TTH, amitriptyline is the only treatment with clear evidence of efficacy[36–38]; the other tricyclics, selective serotonin reuptake inhibitors, or the benzodiazepines have not been shown in controlled trials to be effective. Similarly, there is no controlled evidence for the use of electromyograph biofeedback, relaxation therapy, or acupuncture. Botulinum toxin has been shown reasonably clearly to be ineffective.[39] Stress management has been shown to be an effective approach in a controlled trial.[38]

Trigeminal-Autonomic Cephalalgias

Cluster Headache

Cluster headache is a rare form of primary headache with a population frequency of approximately 0.1%.[40] As a clinical anchor, it is about as common as multiple sclerosis in the United Kingdom,[41] and must be regarded as a disorder best managed by neurologists or headache specialists. It is perhaps the most painful condition of humans; in the cohort of more than 10 patients seen by the author, not a single one has had a more painful experience, including childbirth, multiple fractures of the limbs, or renal stones. It is one of a group of conditions known now as trigeminal-autonomic cephalalgias (TACs), and thus needs to be differentiated from other TACs[11] and the short lasting headaches without cranial autonomic symptoms, such as lacrimation or conjunctival injection (Table 61.7).

The core feature of cluster headache is periodicity, be it circadian or in terms of active and inactive bouts over weeks and months (Table 61.8). The typical cluster headache patient is male, with a 3:1 predominance, with bouts of one to two attacks of relatively short duration unilateral pain every day for eight to ten weeks a year. They are generally perfectly well between attacks. Patients with cluster headache tend to move about during attacks, pacing, rocking, or even rubbing their head for relief. The pain is usually retro-orbital boring and very severe. It is associated with ipsilateral symptoms of cranial (parasympathetic) autonomic activation: a red or watering eye, the nose running or

blocking, or cranial sympathetic dysfunction (eyelid droop). Cluster headache is likely to be a disorder involving central pacemaker regions of the posterior hypothalamus and perhaps other neurons of this region (see Fig. 61.2).[42,43]

The TACs (cluster headache, paroxysmal hemicrania, and SUNCT syndrome) present a distinct group to be differentiated from short-lasting headaches that do not have prominent cranial autonomic syndromes, notably trigeminal neuralgia, idiopathic (primary) stabbing headache, and hypnic headache.[44] By determining the cycling pattern, length of attack, frequency of attack, and timing of the attacks, most patients can be usefully classified. The importance of clinical classification of this group is threefold. First, the clinical phenotype determines the likely secondary causes that must be considered and appropriate investigations ordered. Secondly, the appropriate classification gives clarity to the patient with a clear diagnosis and allows the physician to draw on available literature to comment on natural history. Thirdly, the correct diagnosis determines therapy that can be very different in these conditions, being very good if the diagnosis is correct but largely ineffective if it is not (Table 61.9).

TABLE 61.8

DIAGNOSTIC CRITERIA FOR CLUSTER HEADACHE

3.1 Diagnostic criteria:
- A. At least 5 attacks fulfilling B–D
- B. Severe or very severe unilateral orbital, supraorbital and/or temporal pain lasting 15 to 180 minutes if untreated
- C. Headache is accompanied by at least one of the following:
  1. Ipsilateral conjunctival injection and/or lacrimation
  2. Ipsilateral nasal congestion and/or rhinorrhea
  3. Forehead and facial sweating
  4. Ipsilateral eyelid edema
  5. Ipsilateral forehead and facial sweating
  6. Ipsilateral miosis and/or ptosis
  7. A sense of restlessness or agitation
- D. Attacks have a frequency from 1 every other day to 8 per day
- E. Not attributed to another disorder

3.1.1 *Episodic cluster headache*
Description: Occurs in periods lasting 7 days to 1 year separated by pain-free periods lasting 1 month or more
Diagnostic criteria:
- A. All fulfilling criteria A–E of 3.1.
- B. At least 2 cluster periods lasting from 7–365 days and separated by pain-free remissions of ≥1 month

3.1.2 *Chronic cluster headache*
Description: Attacks occur for more than 1 year without remission or with remissions lasting less than 1 month
Diagnostic criteria:
- A. All alphabetical headings of 3.1
- B. Attacks recur over >1 year without remission periods or with remission periods <1 month

Headache Classification Committee of The International Headache Society. The International Classification of Headache Disorders: second edition. *Cephalalgia* 2004;24(Suppl 1):1–160.

Managing Cluster Headache

Cluster headache is managed using acute attack treatments and preventive agents. Acute attack treatments are usually required by all cluster headache patients at some time, while preventives can seem almost life-saving for the patients with chronic cluster headache and are often needed to shorten the active periods in patients with the episodic form of the disorder.

Preventive Treatments. The options for preventive treatment in cluster headache depend on the bout length (Table 61.10). Patients with short bouts require medicines that act quickly but will not necessarily be taken for long periods, whereas those with long bouts or those with chronic cluster headache require safe, effective medicines that can be taken for long periods. Verapamil is now widely considered as the first-line preventive treatment when the bout is prolonged or in chronic cluster headache. By contrast, limited courses of oral corticosteroids or methysergide can be very useful strategies when the bout is relatively short.

Verapamil has been suggested as a useful option for the last decade and compares favorably with lithium. What has clearly emerged from clinical practice is the need to use higher doses than had initially been considered and certainly higher than those used in cardiological indications. Although most patients will start on doses as low as 40–80 mg twice daily, doses up to 960 mg daily are often required. Side effects, such as gingival hyperplasia, constipation, and leg swelling, are recognized as are cardiac dysrhythmias. Verapamil can cause heart block by slowing conduction in the atrioventricular (AV) node, monitored clinically by the PR interval on the electrocardiogram (EKG). Given that the effects on the AV node take up to 10 days to manifest, 2 week intervals are recommended between dose changes on the first exposure, with EKGs prior to the next escalation, and routine 6 monthly EKGs after the dose is established.[45]

Acute Attack Treatment. Cluster headache attacks often peak rapidly and thus require a treatment with quick onset. Many patients with acute cluster headache respond very well to treatment with oxygen inhalation. This should be given as 100% oxygen at 10–12 L/minutes for 15–20 minutes.[46] It is important to have a high flow and high oxygen content. Injectable sumatriptan 6 mg is effective, rapid in onset,[47] and has no evidence of tachyphylaxis.[48] Sumatriptan 20 mg[49] and zolmitriptan 5 mg[50,51] nasal sprays are effective in acute cluster headache in controlled trials, and offer a useful option. Sumatriptan is not effective when given preemptively as 100 mg orally three times daily,[52] and there is no evidence that it is useful when used orally in the acute treatment of cluster headache; indeed, it can be associated with medication overuse headache problems.[53]

Surgical Treatment. The surgical treatment of cluster headache has been completely transformed by the introduction of neurostimulation therapies. Surgical treatment of cluster headache is reserved for the most refractory patients, typically with chronic cluster headache. Destructive procedures, such as pterygopalati-

*SUNCT/SUNA generally has no refractory period to trigger additional attacks, while this is a very common feature of trigeminal neuralgia.

nectomy or radiofrequency lesions of the trigeminal ganglion, have been used. The former is without clear effects and the latter is helpful but often at significant cost, including ocular complications or anesthesia dolorosa. Trigeminal rhizotomy has also been employed, with all the complications of radiofrequency lesions and the occasional death.[54] Set against this, the functional imaging work describing activations in the posterior hypothalamic region[42] directly lead to deep brain stimulation approaches in the same region that seem highly effective.[55] Occipital nerve stimulation is a further very promising and a largely noninvasive approach to the management of intractable chronic cluster headache,[56,57] which may become the surgical treatment of choice in this setting over the next 5 to 10 years.

Paroxysmal Hemicrania

Sjaastad and Dale[58] first reported eight cases of a frequent unilateral severe but short-lasting headache without remission, coining the term chronic paroxysmal hemicrania (CPH). The mean daily frequency of attacks varied from 7 to 22 with the pain persisting from 5 to 45 minutes on each occasion. The site and associated autonomic phenomena were similar to cluster headache, but the attacks of CPH were suppressed completely by indomethacin.

The essential features of paroxysmal hemicrania that we have seen from a substantial cohort of patients are[59]:

- unilateral very severe pain;
- short-lasting attacks typically 20 minutes in length;
- very frequent attacks (usually more than 5 a day);
- marked autonomic features ipsilateral to the pain;
- robust, quick (less than 72 hours), and excellent response to indomethacin.

The pathophysiology of paroxysmal hemicrania is marked by activations on positron emission tomography (PET) in the contralateral posterior hypothalamus and contralateral ventral midbrain.[60] The posterior hypothalamic activity is shared with cluster headache, short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT), and hemicrania continua, while the ventral midbrain activity is only seen in hemicrania continua, which remarkably is also an indomethacin-sensitive primary headache.[13]

The therapy of paroxysmal hemicrania (PH) may be complicated by gastrointestinal side effects seen with indomethacin, in which topiramate may be helpful.[61] Secondary PH is more likely if the patient requires high doses (>200 mg/day) of indomethacin and raised cerebrospinal fluid (CSF) pressure should be suspected in apparent bilateral PH. It is worth noting that indomethacin reduces CSF pressure by an unknown mechanism.[62] It is appropriate to image patients, with MRI if practical, when a diagnosis of PH is being considered.

?, unproven but promising.

Short-Lasting Unilateral Neuralgiform Headache Attacks with Conjunctival Injection and Tearing or Cranial Autonomic Activation (SUNCT/SUNA)

Sjaastad and colleagues[63] reported three male patients whose brief attacks of pain in and around one eye were associated with

sudden conjunctival injection and other autonomic features of cluster headache. The attacks lasted only 15–60 seconds and recurred 5–30 times per hour, and could be precipitated by chewing or eating certain foods, such as citrus fruits. They were not abolished by indomethacin. Brain imaging has suggested that they share with cluster headache and paroxysmal hemicrania the feature on activation studies of involvement of the posterior hypothalamic region.[64] Of the patients recognized with this problem, males dominate slightly and the paroxysms of pain may last between 5 and 300 seconds, although longer duller interictal pains are recognized, as are longer attacks with a saw-tooth pattern.[65] The conjunctival injection seen with SUNCT is often the most prominent autonomic feature and tearing may be very obvious. If one of either conjunctival injection or tearing are absent, or neither are present but another cranial autonomic symptom is seen, the term SUNA is used. The two key clinical features of SUNCT/SUNA are the attacks being triggerable with no refractory period to triggering. The latter serves as a very useful distinction between SUNCT/SUNA and trigeminal neuralgia. SUNCT/SUNA can be treated very often with lamotrigine and, if that is unhelpful, topiramate or gabapentin.[66] Carbamazepine often has a useful but incomplete effect. Given what has been reported, cranial MRI with pituitary and posterior fossa views is highly recommended when SUNCT/SUNA is considered as a diagnosis.

Other Primary Headaches

Primary Stabbing Headache

Short-lived jabs of pain, defined by the Headache Classification Committee of the IHS as primary stabbing headache,[6] are well documented in association with most types of primary headache.

The essential clinical features are:

- Pain confined to the head, although rarely is it facial;
- Stabbing pain lasting from 1 to many seconds and occurring as a single stab or a series of stabs;
- Recurring at irregular intervals (hours to days).

These pains have been called ice-pick pains or jabs and jolts. They generally respond to indomethacin (25–50 mg, two to three times daily). The symptoms tend to wax and wane and, after a period of control on indomethacin, it is appropriate to withdraw treatment and observe the outcome. Most patients will not want treatment when the nature of the problem is explained and they are reassured that the attacks are not sinister in any way.

Primary Cough Headache

Sharp pain in the head on coughing, sneezing, straining, laughing, or stooping has long been regarded as a symptom of organic intracranial disease, commonly associated with obstruction of the CSF pathways. The presence of an Arnold-Chiari malformation or any lesion causing obstruction of CSF pathways or displacing cerebral structures must be excluded before cough headache is assumed to be benign. Cerebral aneurysm, carotid stenosis, and vertebrobasilar disease may also present with cough or exertional headache as the initial symptom. The term "Benign Valsalva's maneuver-related headache" covers the headaches provoked by coughing, straining, or stooping but *cough headache* is more succinct and so widely used it is unlikely to be displaced.

The essential clinical features of primary cough headache are:

- Bilateral headache of sudden onset, lasting minutes, precipitated by coughing;
- May be prevented by avoiding coughing;
- Diagnosed only after structural lesions, such as posterior fossa tumor, have been excluded by neuroimaging.

Indomethacin is the medical treatment of choice in cough headache. Raskin[67] followed up an observation of Sir Charles Symonds, reporting that some patients with cough headache are relieved by lumbar puncture.[68] This is a simple option when compared to prolonged use of indomethacin. The mechanism of this response remains unclear.

Primary Exertional Headache

The relationship of this form of headache to cough headache is unclear and certainly much is shared. Indeed the relationship to migraine also requires delineation.

The clinical features are:

- Pain specifically brought on by physical exercise;
- Bilateral and throbbing in nature at onset and may develop migrainous features in those patients susceptible to migraine;
- Lasts from 5 minutes to 24 hours;
- Prevented by avoiding excessive exertion, particularly in hot weather or at high altitude.

The acute onset of headache with straining and breath holding, as in weightlifter's headache, may be explained by acute venous distension. The development of headache after sustained exertion, particularly on a hot day, is more difficult to understand. Anginal pain may be referred to the head, probably by central connections of vagal afferents and may present as exertional headache, so-called cardiac cephalgia.[69] The link to exercise is the important clinical clue. Pheochromocytoma may occasionally be responsible for exertional headache. Intracranial lesions or stenosis of the carotid arteries may have to be excluded as discussed for benign cough headache. Headache may be precipitated by any form of exercise and often has the pulsatile quality of migraine. The most obvious form of treatment is to take exercise gradually and progressively whenever possible. Indomethacin at daily doses varying from 25 to 150 mg is generally very effective in benign exertional headache. Indomethacin 50 mg, ergotamine 1–2 mg orally, dihydroergotamine by nasal spray, or methysergide 1–2 mg orally given 30–45 minutes before exercise are useful prophylactic measures.

Primary Sex Headache

Sex headache may be precipitated by masturbation or coitus and usually starts as a dull bilateral ache while sexual excitement increases, suddenly becoming intense at orgasm. The term orgasmic cephalagia is not accurate since not all sex headaches require orgasm. Two types of primary sex headache are recognized: a dull ache in the head and neck that intensifies as sexual excitement increases, and a sudden severe ("explosive") headache occurring at orgasm. Low CSF volume headache may also be precipitated by a sexual activity and is considered as a form of new daily persistent headache (see below).

The essential clinical features of sex headache are:

- Precipitation by sexual excitement;
- Bilateral at onset;
- Prevented or eased by ceasing sexual activity before orgasm.

Headaches developing at the time of orgasm are not always benign and consideration of a diagnosis of subarachnoid headache is essential. Sex headache affects men more often than women and may occur at any time during the years of sexual activity. It may develop on several occasions in succession and then not trouble the patient again, despite any obvious change in sexual technique. In patients who stop sexual activity when headache is first noticed, it may subside within a period of five minutes to two hours, and it is recognized that more frequent orgasm can aggravate established sex headache. About one-third of the patients with sex headache have a history of exertional headaches, but there is no excess of cough headache in patients with sex headache. In about 50% of patients, sex headache will

settle in 6 months. Migraine is reported in about 25% of patients with sex headache.

Primary sex headaches are usually irregular and infrequent in occurrence, so management can often be limited to reassurance and advice about ceasing sexual activity if a milder, warning headache develops. When the condition recurs regularly or frequently, it can be prevented by the administration of propranolol; the dosage required varies from 40–200 mg daily. An alternative is the calcium channel blocking agent diltiazem 60 mg three times daily, which this author finds particularly useful in such patients. Ergotamine (1–2 mg) or indomethacin (25–50 mg) taken about 30–45 minutes prior to sexual activity can also be helpful.

Hypnic Headache

This syndrome was first described by Raskin in patients aged 67 to 84 who had headache of a moderately severe nature that typically came on a few hours after going to sleep.[70] These headaches last from 15 to 30 minutes, are typically generalized, although may be unilateral, and can be throbbing. Patients may report falling back to sleep only to be awoken by a further attack a few hours later with up to three repetitions of this pattern over the night. In Dodick's series of 19 patients, 16 (84%) were female and the mean age at onset was 61, ±9 years.[71] Headaches were bilateral in two-thirds and unilateral in one-third and in 80% of cases mild or moderate. Three patients reported similar headaches when falling asleep during the day. None had photophobia or phonophobia, and nausea is unusual.

Patients with this form of headache generally respond to a bedtime dose of lithium carbonate (200–600 mg) and in those that do not tolerate this verapamil or methysergide at bedtime may be alternative strategies. Dodick and colleagues[71] reported that one to two cups of coffee or caffeine 60 mg orally at bedtime was helpful. This is a simple approach that is effective in about one-third of patients. An important secondary cause of hypnic headache is hypertension which should be carefully pursued and appropriately investigated as treatment of the blood pressure will arrest the headache problem.[72]

Primary Thunderclap Headache

Sudden onset severe headache may occur in the absence of sexual activity and the differential diagnosis includes the sentinel bleed of an intracranial aneurysm, cervicocephalic arterial dissection, and cerebral venous thrombosis. Headaches of explosive onset may also be caused by the ingestion of sympathomimetic drugs or tyramine-containing foods in a patient who is taking monoamine oxidase inhibitors, and can also be a symptom of pheochromocytoma. Whether thunderclap headache can be the presentation of an unruptured cerebral aneurysm is unclear. Day and Raskin[73] reported a woman with three episodes of sudden onset very severe headache who was found to have an unruptured aneurysm of the internal carotid artery, with adjacent areas of segmental vasospasm. In the absence of CT scan or CSF evidence of subarachnoid hemorrhage, studies indicate that such patients do very well, and there indeed seems to be a form of benign or primary thunderclap headache.

Wijdicks, Kerkhoff, and van Gijn[74] followed up 71 patients whose CT scans and CSF findings were negative for an average of 3.3 years. Twelve patients had further such headache, and 31 (44%) later had regular episodes of migraine or tension-type headache. Factors identified as precipitating the headache were sexual intercourse in 3 cases, coughing in 4, and exertion in 12, while the remainder had no obvious cause. A history of hypertension was found in 11 and of previous headache in 22. Markus[75] compared the presentation of 37 patients with subarachnoid hemorrhage and 189 with a similar thunderclap headache and normal CSF examination and could not discern any characteristic to distinguish the two conditions.

Investigation of any sudden onset severe headache, be it in the context of sexual excitement or isolated thunderclap headache, should be driven by the clinical context. The first presentation should be vigorously investigated with radiograph, CT, and CSF examination, and where possible MRI, magnetic resonance venography, or magnetic resonance angiography. Formal cerebral angiography should be reserved for when no primary diagnosis is forthcoming, and the clinical situation is particularly suggestive of intracranial aneurysm. Bearing in mind the entity of diffuse multifocal reversible cerebral vasospasm,[76] which may be seen in apparent primary thunderclap headache without there being an intracranial aneurysm, caution in interpretation of findings is crucial.

Hemicrania Continua

Two patients were initially reported with this syndrome, a woman aged 63 years and a man of 53, who developed unilateral headache without obvious cause. Both patients were relieved completely by indomethacin while other NSAIDs were of little or no benefit. Newman and colleagues[77] reviewed the 24 previously reported cases and added 10 of their own, including some with pronounced autonomic features resembling cluster headache. They divided their case histories into remitting and unremitting forms. Of the 34 patients reviewed, 22 were women and 12 men with the age of onset ranging from 11 to 58 years. The symptoms were controlled by indomethacin 75–150 mg daily. The essential features of hemicrania continua are:

- Unilateral pain;
- Pain is continuous but with exacerbations that may be severe;
- Complete resolution of pain with indomethacin;
- Exacerbations may be associated with autonomic features.

Apart from analgesic overuse as an aggravating factor, and a report in a human immunodeficiency virus-infected patient, the status of secondary hemicrania continua is unclear. Antonaci and colleagues[78] proposed the "indotest" by which the intramuscular injection of indomethacin 50 mg could be used as a diagnostic tool. In hemicrania continua, pain was relieved in 73 ±66 minutes and the pain-free period was 13 ±8 hours. A placebo-controlled modification of this test is preferred where possible to the open-label version. Using the latter method in conjunction with PET, it has been shown that there is activation of the contralateral posterior hypothalamus and ipsilateral dorsal rostral pons in association with the headache of hemicrania continua, as well as activation of the ipsilateral ventrolateral midbrain.[79] The alternative is a trial of oral indomethacin, initially 25 mg three times daily, then 50 mg three times daily, and then 75 mg three times daily. One should allow up to 2 weeks for any dose to have a useful effect. Acute treatment with sumatriptan has been employed and reported to be of no benefit. Cyclo-oxygenase II (COX-II) antagonists seem effective, although undesirable now, and topiramate is helpful in some patients, as is greater occipital nerve injection.

Chronic Daily Headache

Each of the above primary headache forms can occur very frequently. When a patient experiences headache on 15 days or more a month, one can apply the broad diagnosis of CDH. CDH is not one thing, but a collection of very different problems with different management strategies.[5] Crucially, not all daily headache is simply tension-type headache (Table 61.11). This is a very common clinical misconception in headache, confusing the clinical phenotype with the headache *biotype*. Population-based estimates of daily headache are remarkable, demonstrating that about 5% of Western populations have daily or near daily headache.[80] Daily headache may again be primary or secondary, and it seems clinically useful to consider the possibilities in this way when making management decisions (see Table 61.11). It should

TABLE 61.11

CLASSIFICATION OF CHRONIC DAILY HEADACHE

Primary		
>4 hr daily	<4 hr daily	Secondary
Chronic migraine*	Chronic cluster headache†	Posttraumatic • head injury • iatrogenic • postinfectious
CTTH*	Chronic paroxysmal hemicrania	Inflammatory, such as • Giant cell arteritis • Sarcoidosis • Behçet's syndrome
Hemicrania continua*	SUNCT	Chronic cerebrospinal fluid infection
NDPH*	Hypnic headache	Substance abuse headache

*May be complicated by analgesic overuse. In the case of substance abuse headache, the headache is completely resolved after the substance abuse is controlled.[6] Clinical experience suggests that many patients continue to have headache even after cessation of analgesic use. The residual headache probably represents the underlying headache biology.
†Chronic cluster headache patients may have more than 4 hours per day of headache. The inclusion of the syndrome here is to emphasize that, by and large, the attacks themselves are less than 4 hours in duration.

be said that population-based studies bear out clinical practice in that a large group of refractory daily headache patients overuse various OTC preparations.

Chronic Migraine

While it is widely accepted that some of the primary headaches (tension-type headache, cluster headache, and paroxysmal hemicrania) have chronic varieties, this question seems to have become unnecessarily troublesome for migraine. Few headache authorities would argue that migraine can never be chronic in terms of frequency, but the issue of whether patients with frequent headache, some of which fulfils standard criteria for migraine and some for tension-type headache, have a single migrainous biology is a very vexed one. Given that tension-type headache describes a phenomenology that is indistinct at best, it seems unlikely that all its phenotypes will have a single biological generator.

The concept behind chronic migraine is that some patients who inherit a migrainous biology end up with CDH. The typical patient will have daily headache of a dull, nonspecific type, punctuated by more severe attacks that would often, in isolation, fulfil standard criteria for migraine. In headache speciality clinics, this group is dominant, with about 90% of patients in referral headache clinics having chronic migraine usually with analgesic overuse. It could be suggested that they have a biologically more difficult problem and this is the basis for their overrepresentation in referral centers.

If one applies the concepts outlined for tension-type headache (see above) then the diagnosis of chronic tension-type headache (CTTH) is made when the patient has 15 days or more a month of entirely featureless generalized dull or pressure-like pain. When *any* of the attacks on *some* days have migrainous features: nausea, photophobia, phonophobia, throbbing, or aggravation with movement, then chronic migraine is more likely to be the diagnosis. Clearly both chronic migraine and CTTH exist. Moreover, some patients must simply have CTTH and episodic migraine coexisting; however, it is simply impossible on clinical or other grounds to determine who they are. The approach outlined overdiagnoses chronic migraine, taking that to be a biological entity, and underdiagnoses the coexistence of CTTH and episodic migraine. The converse would be true; if one diagnoses them all as CTTH and episodic migraine, then chronic migraine is missed. In clinical practice, the concept of chronic migraine is particularly helpful. Given that the lifestyle advice is identical for both CTTH and migraine, and that the range of therapeutic options for preventive treatment in migraine is so much greater, the clinician loses absolutely nothing diagnosing chronic migraine, and the patient has much to gain. For research there are other imperatives.

Management

The management of CDH can be very rewarding. Most patients overusing analgesics respond very sensibly when the problem is explained.

The keys to managing CDH are:

- Exclude treatable causes (see Table 61.11)
- Obtain a clear analgesic history
- Make a diagnosis of the primary headache type involved

Medication Overuse

Medication overuse is defined as consuming an acute attack therapy on 10 days or more per month. It is essential that analgesic overuse be reduced and eliminated if one is to see the underlying headache phenotype and commence to manage the problem. Patients can reduce their use either by, as an example, 10% every week or two, depending on their circumstances, or if they wish, and there is no contraindication, by immediate cessation of use. Either approach can be facilitated by first keeping a careful diary over a month or two to be sure of the size of the problem. A small dose of an NSAID, such as naproxen 500 mg twice daily if tolerated, will take the edge off the pain as the analgesic use is reduced, as does a greater occipital nerve injection. It is a useful aside that NSAID overuse does not seem to be a common issue in daily headache when they are dosed once or twice daily, whereas with more frequent dosing problems may develop. When the patient has reduced their analgesic use substantially, a preventive should be introduced. It must be emphasized that preventive therapies most often simply do not work in the presence of analgesic overuse. Thus, the patient must reduce the analgesics or the entire attempt to use the preventive is largely wasted, although this helpful rule must have some limitations that require study. The most common cause of intractability to treatment is the use of a preventive when analgesics continue to be used regularly. For some patients, this is very difficult and often one must be blunt that some degree of pain is inevitable in the first instance if the problem is to be controlled.

Some patients with medication overuse will require admission for detoxification. Broadly, this consists of two groups: those who fail outpatient withdrawal or those who have a significant complicating medical indication, such as brittle diabetes mellitus, or complicating medicines, such as opioids or barbiturates, where withdrawal may be problematic as an outpatient. When such patients are admitted, acute medications are withdrawn completely on the first day, unless there is some contraindication. Antiemetics, such as domperidone oral or suppositories, and fluids are administered as required, as well as clonidine for opioid withdrawal symptoms. For acute intolerable pain during the waking hours, aspirin (1 g intravenously) is useful and at night chlorpromazine by injection, after ensuring adequate hydration. If the patient does not settle over 3–5 days, a course of intravenous dihydroergotamine (DHE) can be employed as Raskin described.[81] As time goes by, one feels that DHE is indispensable in this setting. Often 5-HT_3 receptor antagonists, such as ondansetron or granisetron, will be required with DHE as it is essential to ensure that the patient does not have significant nausea.

Preventive Treatments

Tricylics, amitriptyline, doselupin (dothiepin), or nortriptyline, at doses up to 1 mg/kg, are very useful in patients with chronic migraine. Tricyclics are started in low dose (10–25 mg) daily and best given 12 hours prior to when the patient wishes to wake up to avoid excess morning sleepiness. The other very useful medications for these patients are the anticonvulsants, such as valproate, topiramate, and gabapentin. For valproate, doses up to 1500 mg daily are used, starting at 200 mg twice daily increasing to 400 mg or 600 mg twice daily as tolerated over 2 to 4 week intervals. The blood count and liver enzymes should be checked at baseline and the various side effects explained to patients, especially the fetal abnormalities to females. The efficacy of topiramate in chronic migraine is now established by placebo-controlled studies.[82,83] One can start at 25 mg nightly and increase by 25 mg every 10–14 days to aim for 50 mg twice daily. For gabapentin, the dose is 1800 to 3600 mg daily; it is very well tolerated, although probably less effective from a population viewpoint.

New Daily Persistent Headache

New daily persistent headache (NDPH) is a clinically useful concept with a range of important possible causes because some are very treatable (Table 61.12). From a nosological point of view, all that is mentioned here could be placed within various categories of the IHS classification,[6] and indeed the IHS refers to primary NDPH. However, the term as employed here serves both patients and clinicians by highlighting a group of conditions, some of which are curable, and encompasses the IHS term under the primary featureless form of NDPH.[84]

The patient with NDPH presents with a history of headache on most, if not all, days. The onset of headache is abrupt, often moment-to-moment, but at least in less than a few days where three is suggested as an upper limit. The typical history is for the patient to recall the exact day and circumstances, so from one moment to the next a headache develops that never leaves them. This presentation triggers certain key questions about the onset and behavior of the pain. The pressing issues arise from considering the secondary headache possibilities. Although subarachnoid hemorrhage is listed for some logical consistency, as the headache may certainly come on from one moment to the next, it is not likely to produce diagnostic confusion in this group of patients. Suffice it to say that subarachnoid hemorrhage is so important that it must always be considered if only to be excluded, either by history or appropriate investigation.

Primary New Daily Persistent Headache. Case series of primary NDPH showed it to occur in both males and females.[85] Migrainous features are common, with unilateral headache in about one-third and throbbing pain in about one-third. Nausea was reported in about half the patients, as was photophobia and phonophobia observed. A number of these patients have a previous history of migraine but not more than one might expect given the population prevalence of migraine.[85,86] It is remarkable that the initial report noted that 86% of patients were headache-free at 24 months. It is general experience amongst those interested in headache management that primary NDPH is perhaps the most intractable and least therapeutically rewarding form of headache. In general, one can classify the dominant phenotype, migraine, or tension-type headache, and treat with preventives according to that subclassification.

Secondary New Daily Persistent Headache. The secondary causes of the syndrome of NDPH are worthy of consideration, as they have distinctive clinical pictures that can guide investigation (see Table 61.12).

Low Cerebrospinal Fluid Volume Headache

The syndrome of persistent, low CSF volume headache is an important diagnosis not to miss. The more immediately obvious version of this problem is encountered commonly after lumbar puncture. In that situation, the headache usually settles rapidly with bedrest. In the chronic situation, the patient typically presents with a history of headache from one day to the next. The pain is generally not present on waking, worsens during the day, and is relieved by lying down. Recumbency usually improves the headache in minutes, and it takes only minutes to an hour for the pain to return when the patient is upright again. The patient may give a history of an index event: lumbar puncture, epidural injection, or a vigorous Valsalva, such as with lifting, straining, coughing, clearing the Eustachian tubes in an aeroplane, or multiple orgasms. Patients may volunteer, or a history may be obtained, that soft drinks with caffeine provide temporary respite. Spontaneous leaks are recognized, and the clinician should not be put off the diagnosis if the headache history is typical when there is no obvious index event. As time passes from the index event, the postural nature may be less obvious; certainly cases whose index event was several years prior to the eventual diagnosis are recognized. The term low volume rather than low pressure is used, since there is no clear evidence at which point the pressure can be called low. While low pressures, such as 0 to 5 cm, are often identified, a pressure of 16 cm CSF has been recorded with a documented leak. One should be aware of the possibility of the development of subdural collections in patients with low CSF volume headaches, which makes imaging before any invasive studies all the more important.

The investigation of choice is MRI with gadolinium (Fig. 61.5), which produces a striking pattern of diffuse pachymeningeal enhancement,[87] although in about 10% of cases a leak can be documented without enhancement.[88] The finding of diffuse meningeal enhancement is so typical that in clinical context, immediate treatment is appropriate. It is also common to see Chiari malformations on MRI with some degree of descent of the cerebellar tonsils. This is important since surgery in such settings simply worsens the headache problem. It seems appropriate that any patient being considered for such surgery for a headache indication should be reviewed by a neurologist first. To investigate further, CSF pressure may be determined, or preferably a leak sought with indium-labeled CSF. In CSF studies that can demonstrate the site, early emptying of tracer into the bladder or lack of progression of tracer over the cerebral convexities.

Treatment is bedrest in the first instance. False positive transient improvement in persistent low CSF volume headache with chiropractic and other similar therapies is recognized where the treatment necessitates the patient lying down for a prolonged period for the therapy. Intravenous caffeine (500 mg in 500 mL saline administered over two hours) is the standard and often very efficacious treatment. The ECG should be checked for any

arrhythmia prior to administration. A reasonable practice is to carry out at least two infusions separated by 4 weeks after obtaining the suggestive clinical history and MRI with enhancement. Since intravenous caffeine is safe, and can be curative by an unknown mechanism, it spares many patients the need for further tests. If that is unsuccessful, an abdominal binder may be helpful. If a leak can be identified, either by the radioisotope study, CT myelogram, or spinal T2-weighted MRI, an autologous blood patch is usually curative. In more intractable situations, theophylline is a useful alternative that offers outpatient management, although its onset of action is rather slow. An important phenotypically identical headache can be seen in the Postural Orthostatic Tachycardia Syndrome (POTS)[89] and should be considered when investigating this group of patients.

Raised Cerebrospinal Fluid Pressure Headache

As is the case for low CSF pressure states, raised CSF pressure as a cause of headache is well recognized by neurologists. Brain imaging can often reveal the cause, such as raised pressure due to a space-occupying lesion. The particular setting in which patients enter the spectrum of NDPH are those with idiopathic intracranial hypertension who present with headache without visual problems, particularly with normal fundi. It is recognized that intractable chronic migraine can be triggered by persistently raised intracranial pressure.[90] These patients typically give a history of generalized headache that is present on waking, and gets better as the day goes on. It is generally worse with recumbency. Visual obscurations are frequently reported. Fundal changes on raised intracranial pressure would make the diagnosis relatively straightforward but it is in those without such changes that the history must drive investigation. Patients often report a curious whooshing sensation in the occipital region.

Brain imaging is mandatory if raised pressure is suspected, and it is most simple in the long run to obtain an MRI and include MRV. The CSF pressure should be measured by lumbar puncture taking care to do so when the patient is symptomatic, so that both the pressure and response to removal of CSF can be determined. A raised pressure and improvement in headache with removal of CSF is diagnostic of the problem. The fields should be formally documented even in the absence of overt ophthalmic involvement. Initial treatment can be with acetazolamide (250 to 500 mg twice daily). The patient may respond in weeks with improvement in headache. If this is not effective, topiramate has many actions that may be useful in this setting: carbonic anhydrase inhibition, weight loss, and neuronal membrane stabilization probably through actions on phosphorylation pathways. A small number of severely disabled patients who do not respond to medical treatment will come to intracranial pressure monitoring and even shunting. This is exceptional and not undertaken without careful work-up.

Posttraumatic Headache

The issue of posttraumatic headache is vexing. The Headache Classification Committee accepts the existence of such a syndrome.[6] Much of the scientific discussion becomes marred by the often-quoted medico-legal morass concerning delayed effects of head injury. The term is used here to indicate trauma in a very broad way. NDPH may be seen after a blow to the head but more commonly after an infective episode, typically viral, or even malarial meningitis. A recent series identified one-third of all patients with NDPH reported the headache starting after a flu-like illness. The patient may note a period in which they had a significant infection: fever, neck stiffness, photophobia, and marked malaise. The headache starts during that period and never stops. Investigation reveals no current cause for the headache. It has been suggested that some patients with this syndrome have a persistent Epstein-Barr infection,[91] but this syndrome is anything but clearly delineated. A complicating factor will often be that the patient had a lumbar puncture during that illness, so a persistent low CSF volume headache needs to be considered first. Posttraumatic headache may be seen after carotid artery dissection, subarachnoid hemorrhage, and following intracranial surgery for a benign mass. The underlying theme seems to be that a traumatic event involving the dura mater can trigger a headache process that lasts for many years after that event.

The treatment of this form of NDPH is substantially empirical. Tricyclics, notably amitriptyline, and anticonvulsants, valproate, topiramate, and gabapentin, have been used with good effects. The monoamine oxidase inhibitor phenelzine may also be useful in carefully selected patients. On the positive side, the headache seems to run a limited course of 3 to 5 years in most patients, so will eventually settle.

Other Important Forms of Secondary Headache (Table 61.13)

Giant Cell Arteritis

This is an important cause of headache because delay in steroid treatment may result in blindness due to retinal artery ischemia.

TABLE 61.13

OTHER SECONDARY HEADACHES

- Giant cell arteritis
- Cervicogenic headache
- Raeder's paratrigeminal neuralgia[97]
- Tolosa-Hunt syndrome[98,99]
- Headache as a presentation of cervical dystonia[5]
- Headache in temporomandibular dysfunction
- Cardiac cephalalgia[69]
- Headache with endocrine disturbance, particularly pituitary tumor[19]
- Neck-tongue syndrome[100]
- Red-Ear syndrome[101]

It is also known as temporal arteritis or cranial arteritis. Patients are usually elderly with focal tenderness of the scalp, which may be provoked markedly by resting the head on the pillow. Jaw claudication provoked by chewing is a characteristic but relatively uncommon feature. Constitutional symptoms are common, particularly weight loss, malaise, or polymyalgia rheumatica. An elevated erythrocyte sedimentation rate is a strong pointer to the diagnosis. The temporal artery may be tenderly inflamed, swollen, or pulseless. On suspicion of this diagnosis, steroid treatment should be started pending the result of temporal artery biopsy. Treatment is very often long-term and requires careful monitoring for reactivation and the side effects of corticosteroids.

Cervicogenic Headache
