Ulnar Nerve Entrapment at the Wrist. The ulnar nerve and artery course through Guyon's canal and may become entrapped there.[137] This canal is bounded by the volar and transverse carpal ligaments and palmaris brevis muscle, with the pisiform bone proximally and medially, and the hook of the hamate laterally and distally. Common causes of entrapment include local masses, such as ganglion formation, lipomas, and uremic tumoral calcinosis, or anatomic variants, such as the presence of abductor digit minimi within the canal.[138] Evaluation is typically based on physical examination and electrodiagnostic studies. MRI, when a dedicated wrist coil is utilized, offers noninvasive visualization of Guyon's canal.[139] Surgical decompression involves unroofing of the canal and removal of any masses.[140,141]

Entrapments of the Radial Nerve

Compression neuropathy of the radial nerve occurs at the radial tunnel, a 5-cm space extending from the capitulum of the humerus to the distal edge of the supinator muscle. It is bounded anteromedially by the brachialis muscle, anterolaterally by brachioradialis and extensor carpi radialis brevis, and posteriorly by the capitulum. Just distal to the lateral epicondyle, the radial nerve divides into a purely sensory superficial branch and a deep branch, the posterior interosseous nerve.

While the superficial branch passes superior to the supinator muscle, the posterior interosseous nerve courses in a plane between the two heads of the supinator muscle as they both continue into the forearm. Potential sources of compression at this level include the fibrous bands that anchor the radial nerve to the elbow, the recurrent radial artery and its associated vessels and branches (collectively known as the leash of Henry), and the arcade of Frohse at the fibrous origin of the supinator and other muscles.[140,142–144]

Radial Tunnel Syndrome and Posterior Interosseous Nerve Syndrome. Classically, there are two distinct clinical syndromes involving this pathology—one primarily involving pain and the other, motor dysfunction. Radial tunnel syndrome itself is a frequently-cited, yet somewhat controversial diagnosis, as some argue against its existence. It consists of pain symptoms including deep aching pain, often worse at night, in the extensor muscle mass at the lateral elbow. On physical examination, several particular maneuvers are suggestive of this diagnosis: (1) reproduction of pain by resisting extension of the third digit, with the elbow and wrist in full extension; (2) tenderness to palpation over the entry of the posterior interosseous nerve into the supinator muscle, approximately 5 cm distal to the radial head; and (3) reproduction of pain with the application of a tourniquet at this level.[145–148]

In contrast to radial tunnel syndrome, posterior interosseous nerve syndrome is defined primarily by motor symptoms, including progressive weakness of the wrist and digit extensor muscle group. Due to the relatively distal point of compression, innervation to the brachioradialis, extensor carpi radialis muscles, and supinator are typically unaffected. Weakness in wrist extension is incomplete, such that there is radial deviation. Pain, when present, is secondary in this constellation of symptoms.

Development of this entrapment syndrome is associated with repetitive forceful movements involving elbow extension and forearm pronation and supination.[149] Mass lesions, elbow dislocation, vascular malformations, and synovial inflammation are other potential etiologies of compression, and MRI or ultrasound may useful in the identification of compression. Electrodiagnostic studies are of limited utility for most patients. Hence, the diagnosis is typically clinical.

Operative release of entrapment includes an exploration of all the branches of the radial nerve, such that the posterior interosseous branch can be fully liberated.[150] Few large case series have been analyzed, and reported outcomes vary in the region of 70%. In some series, however, improved functional outcomes have been reported in over 90% of treated patients.[151–153]

Superficial Sensory Branch Entrapment. Entrapment of the superficial sensory branch of the radial nerve can occur through externally compressive apparel such as watch bands. Chronic intermittent compression tends to cause numbness and dysesthesias over the dorsal surface of the hand, whereas blunt injury at this location typically causes highly refractory pain. Operative neuroplasty has yielded significant improvement of symptoms in 74% to 86% of patients.[154–156] Of note, superficial sensory branch entrapment may be associated with De Quervain's tenosynovitis, and release of the extensor compartment is sometimes performed in combination with neuroplasty.

Entrapment of the Suprascapular Nerve

Suprascapular nerve entrapment presents with shoulder pain along the border of the trapezius muscle, and often denervation of the associated musculature.[157–160] On physical examination, it is exacerbated with abduction and external rotation of the arm. The suprascapular nerve passes through the suprascapular notch and beneath the suprascapular ligament before entering the supraspinatus fossa.[161] Compression at the suprascapular ligament is common, and thus, a palsy involving both supraspinatus and infraspinatus is more frequently seen than an isolated infraspinatus denervation on EMG. History of trauma such as shoulder dislocation or scapular fracture is usually present. When this is absent, suprascapular ligament compression, tumor, ganglion, or Parsonage-Turner neuritis should be considered. Reported pain relief and strength increase after surgery have been excellent, with improvement in over 90% of patients.[159,160,162–165] Early surgical treatment appears to yield better results than a delayed operation.[166]

Thoracic Outlet Syndrome

The term "thoracic outlet syndrome" (TOS) was coined by Peet to describe compression at the thoracic inlet of the neurovascular bundle comprised of the brachial plexus, subclavian vein, and subclavian artery.[166b] TOS is most commonly neurogenic in origin. In TOS, unlike other upper extremity entrapments, nerve conduction studies across the putative entrapment site are not feasible. The diagnosis is therefore typically based upon clinical criteria.

TOS has been subdivided into three syndromic zones, according to likelihood of entrapment of the brachial plexus, subclavian artery, and subclavian veins. Anterior scalene syndrome occurs with brachial plexus or subclavian artery compression in the interscalene triangle. Costoclavicular syndrome occurs with compression of any nearby structures in the space between the clavicle and the first rib. Retropectoralis minor syndrome can involve any adjacent structure as well, and compression occurs at the attachment site of pectoralis minor at the coracoid process (the subcoracoid tunnel).[167–170]

In cases of pure peripheral nerve compression, insidious onset of pain and paresthesias in the neck, shoulder, arm, or hand is typical, whereas motor weakness occurs in just 10% of patients. Nearly 90% of cases involve the ulnar nerve distribution.[171] Symptoms may be reproduced when assuming a spear-throwing position or with downward pressure on the shoulder. Tenderness (with or without Tinel's sign) over the anterior scalene muscle in the supraclavicular fossa may also be present.[172]

Diagnosis can be aided by imaging and electrodiagnostic studies. In particular, a radiograph demonstrating anomalous bony findings, such as a cervical rib, in the presence of corresponding symptoms is highly predictive of good surgical outcome. Comparing MRIs of the thoracic outlet in the standard anatomic position and following hyperabduction and external rotation of the arm may reveal significant narrowing of the costoclavicular space in patients with TOS compared to normal healthy subjects.[168]

With careful attention to patient selection and surgical technique, good results have been reported with surgical management. Surgery can involve first rib resection, anterior scalenectomy, resection of the costoclavicular ligament, or neuroplasty, depending upon suspected pathology.[172] The majority of surgeons employ a transaxillary or supraclavicular approach.

In general, immediate pain relief with surgery is good, although results often deteriorate over time. Numerous outcome studies for the transaxillary approach report greater than 90% of patients enjoy initial symptomatic relief. However, long-term follow-up has revealed that less than 50% of patients sustain relief at 5 years, and less than 10% of patients have relief persisting at 20 years.[170,171,173] While reported in fewer numbers and with shorter follow-up, outcomes for the supraclavicular approach appear to be equally good in terms of initial results.[174,175] Complications of surgery for TOS are unfortunately common and include vascular injury, brachial plexus injury, and thoracic wall injury.[176] The pathophysiology, diagnosis, and management of TOS is discussed in more detail in Chapter 39.

Entrapments of Lower Extremities

Of the entrapment syndromes seen in the lower extremities, meralgia paresthetica (symptoms along the lateral femoral cutaneous nerve) is the most common. Inciting factors are many, including trauma, weight gain, and clothing. Indeed, trauma is the foremost cause of peripheral nerve injury in the lower extremities, particularly around the pelvic, inguinal, and ankle regions, often involving the femoral, obturator, ilioinguinal, iliohypogastric, genitofemoral, and posterior tibial nerves. Described chronic compressive syndromes include entrapment of the lateral femoral cutaneous, sciatic, saphenous, posterior tibial, common peroneal, deep peroneal, and plantar digital nerves. Results from surgical management of meralgia paresthetica and Morton's neuroma (of a plantar digital nerve) are discussed with other pathologies treated by neurectomy, and will be omitted here.

Sciatic Nerve Entrapment. The posterior L4 to S3 sacral plexus nerve roots typically give rise to the sciatic nerve, which travels anterior to the piriformis muscle before passing beneath its inferior border to exit the pelvis through the greater sciatic foramen posterior to the piriformis muscle, along with the superior and inferior gluteal vessels and nerves. When the sciatic nerve instead travels above or even through the piriformis muscle, a syndrome of gluteal region pain, weakness in hip abduction resulting in a lurching gait, and tenderness to palpation just lateral to the greater sciatic notch can be induced.[177] Weakness in knee flexion in the absence of paraspinous muscle weakness can be suggestive of this peripheral injury as well, and there is often discrete tenderness between the greater trochanter and ischium.

This entrapment syndrome is six times more common in women than in men and often associated with repetitive trauma such as horseback riding, muscular hypertrophy or ossification, or with iatrogenic injury to the sciatic nerve.[178] It can closely mimic the sciatica caused by lumbar disc herniation or spinal

stenosis, and MRI is particularly helpful in determining the likelihood of a peripheral nerve entrapment in relation to the far more common spinal etiologies. Electrodiagnostic tests are very difficult to perform reliably in this region, and are generally of little utility. Focal tenderness directly over the piriformis muscle, together with normal MRI of lumbar spine, is suggestive of sciatic nerve entrapment.

Surgical management involves sectioning of the overlying piriformis muscle and has provided excellent relief in a limited number of reported cases.[179,180] A feared complication of this procedure is complete sectioning of one of the associated gluteal vessels, which can retract into the pelvis, necessitating laparotomy for hemostasis.[181] There have been case reports of spontaneous entrapment neuropathies involving the distal portions of the sciatic nerve in the thigh.[182,183]

Saphenous Nerve Entrapment. Iatrogenic saphenous nerve injury is commonly a result of saphenous vein harvesting. A similar syndrome that also presents as dysesthesias and pain involving the medial aspect of the knee and anterior tibial region has been treated successfully with surgical release in the subsartorial (Hunter's) canal.[32,184] A fascial band between the abductor magnus and vastus medialis muscles is the offending factor, and pain can typically be elicited on examination with palpation over the canal.

Tibial Nerve Entrapment. Tibial nerve entrapment at the popliteal fossa results from compression by the tendinous arch of the origin of the soleus muscle, as well as from nerve tumors, Baker's cyst, and trauma. As it crosses medially in the popliteal fossa, the tibial nerve travels superficially to the popliteus muscle, while passing under the tendinous arch of the soleus muscle before entering the space between the heads of the gastrocnemius and plantaris muscles.[185,186]

Symptoms of tarsal tunnel syndrome result from compression of the posterior tibial nerve at the medial malleolus. The tarsal tunnel itself refers to the deep posterior compartments of the distal leg as they pass beneath the flexor retinaculum, which is formed from the superficial and deep aponeuroses of the leg.[187] Symptoms typically include pain and dysesthesias involving the plantar surface of the foot and sometimes the heel, depending on whether the posterior tibial nerve trifurcates and gives rise to the medial calcaneus sensory branch proximal to the point of compression. Tinel's sign over the flexor retinaculum is quite sensitive and specific in the diagnosis of entrapment, particularly when combined with the dorsiflexion-eversion maneuver.[188] Both MRI and electrodiagnostic studies are extremely helpful in confirming and assessing severity of the pathology, particularly in recurrent cases and in those rare instances refractory to conservative management.[189–192] The differential diagnosis is wide and includes such common etiologies as complex regional pain syndrome, plantar fasciitis, and Achilles tendonitis.

Surgical sectioning of the flexor retinaculum and release of the nerve has demonstrated only moderate success, perhaps in part due to the success of conservative management in such a large proportion of cases.[193–195] Pfeiffer and Cracchiolo[196] reported 44% of patients received significant improvement after decompression, and two subsequent studies showed similar overall benefit. Sammarco and Chang[197] later reported significantly better surgical outcomes in patients with duration of symptoms lasting less than 1 year, compared with disease present for greater than 1 year. Still, Turan et al.[198] demonstrated that surgical management is still of benefit in those with longstanding symptoms, providing excellent results in 61% of patients who experienced symptoms for more than 5 years.

Peroneal Nerve Entrapments. Once the sciatic nerve reaches the popliteal fossa, it gives rise to the common peroneal nerve, which then wraps around the fibular head and passes into the peroneal tunnel alongside the peroneus longus tendon. There, it trifurcates, giving off superficial and deep peroneal nerve branches, as well as a sensory branch to the tibiofibular joint and knee.[199] Entrapment syndromes typically arise due to compression in the knee (due to fatty tissue deposition or Baker's cyst) or at the peroneal tunnel, but the superficial and deep branches can be compressed at the fascial exit of the superficial branch over the anterolateral aspect of the lower shin,[200] and at the anterior tarsal tunnel bounded by the fascial layers over the talus and the inferior extensor retinaculum, respectively. Several small series of patients undergoing decompression of the superficial and deep branches have shown the efficacy of surgical treatment, but large reports guiding decision-making in surgical decompression are lacking.[201–205]

The common peroneal nerve rests in a particularly superficial position at the fibular neck, and thus is susceptible to external compression as well as to traction injury. It is also a common site of intraneural ganglia.[199] Neuropathy is commonly found in women who habitually sit in a cross-legged position. Similarly, prolonged squatting or kneeling can cause compressive symptoms. Repetitive plantarflexion and inversion of the foot is often the mechanism of traction upon the nerve, and a constricting band at the level of the fibular head is often found at the time of operation. Symptoms most commonly include foot drop, weakness of ankle, dorsiflexion and eversion, and pain in the peroneal nerve dermatome along the lateral leg. The pain symptoms can be easily confused with such common ailments as shin splints or tibial stress fracture, as well as with an L5 radiculopathy or compartment syndrome. Electrodiagnostic studies are helpful in isolating the region of entrapment.[206]

Surgical decompression must not be delayed, although conservative management is successful in approximately one third of cases.[207] In one analysis, 87% of patients with motor dysfunction obtained good improvement, whereas only 54% of patients with purely sensory deficits experienced long-term relief.[208] However, the average time between onset of symptoms and operation was 14 months in this study. In another series, surgical intervention was shown to yield a 97% immediate success rate when performed within 2 months of onset of injury, whereas in cases lasting 4 to 8 months, only a 38% benefit was found.[209]

DORSAL RHIZOTOMY AND GANGLIONECTOMY

Basic Considerations

The Bell-Magendie model describes a dorsal root comprised solely of primary afferent fibers, while the ventral root contains only efferent fibers. Dorsal rhizotomy and ganglionectomy procedures seek to take advantage of this apparent physiologic segregation to halt the inflow of nociceptive signals to the spinal cord at particular levels, while sparing motor outputs. Injury to motor fibers in the ventral root is avoided (Fig. 102.3). No neuroma forms at the cut ends of the rootlets, as nerve fibers that enter the spinal cord are deprived of their cell body and hence degenerate.[210]

Theoretically an appealing treatment option for pain, rhizotomy in practice often fails to confer the lasting benefit that one might expect. Early surgeons performed dorsal rhizotomy for a broad range of conditions including stump pain, intercostal neuralgia, angina, visceral pain, and spastic hemiplegia. After comparing operative results for pain with those for spasticity in 1911, Groves remarked, "Strangely enough, the division of the posterior spinal roots has given the least satisfactory results in those very cases where we should have expected it to be the most efficient . . . the relief of pain."[211]

An important problem with rhizotomy is that the sensory afferents that arise from a region of the body may provide contributions to multiple spinal nerves. Conversely, fibers from a single

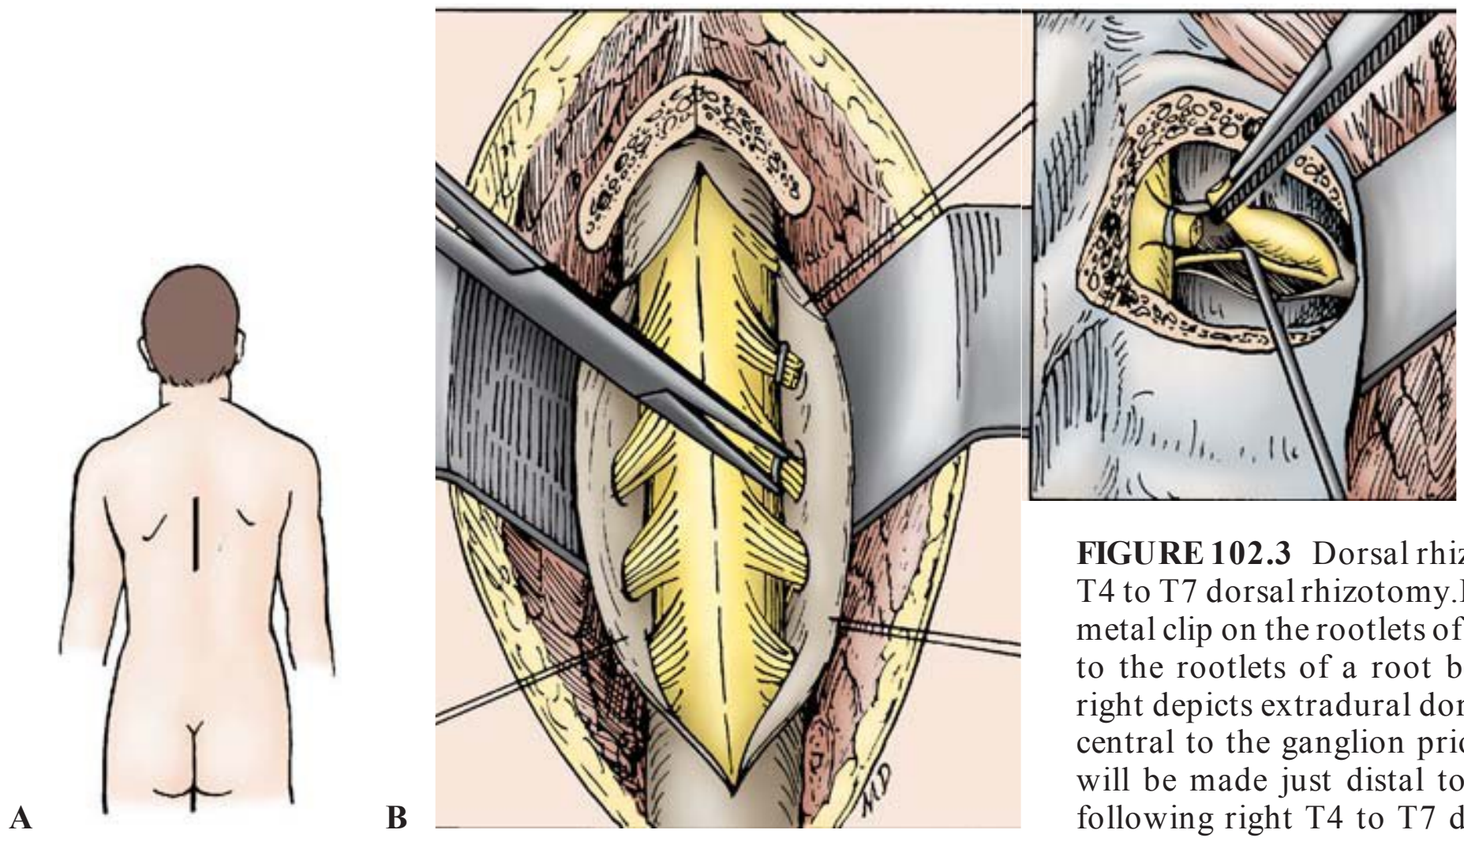

FIGURE 102.3 Dorsal rhizotomy. **A.** Location of midline dorsal incision for T4 to T7 dorsal rhizotomy. **B.** Intradural dorsal rhizotomy with application of metal clip on the rootlets of a root already transected above and being applied to the rootlets of a root below just prior to sectioning them. Inset on the right depicts extradural dorsal rhizotomy showing division of the dorsal root central to the ganglion prior to extirpation of the ganglion by a lesion that will be made just distal to the ganglion. **C.** Expected area of sensory loss following right T4 to T7 dorsal rhizotomy.

spinal nerve may innervate multiple segments of the spinal cord. As a result, sensory dermatomes overlap considerably, so that ablation of a single dorsal root produces little sensory deficit.[212] The earliest studies[213,214] of the dermatomes appreciated this complexity, and early surgeons performed rhizotomy at two to three levels or more to achieve pain control.[211] Extensive remodeling of sensory dermatomes, attributed to intraspinal sprouting of dorsal root axons,[215] functional reorganization of existing sensory pathways,[216] and other mechanisms, has since been described.

A second potential explanation of surgical failure involves the presence of unmyelinated sensory fibers in the ventral roots. In 1894, Sherrington[217] noted degeneration of fibers on the cord side of a transected ventral root.[218] He suggested that these fibers, which he presumed would double back and reenter the cord through the dorsal root, might provide a physiologic basis for the observation that stimulation of the ventral root results in pain. Microscopy has demonstrated that some fibers do, in fact, enter the cord through ventral roots, cross the ventral horn, and synapse within the dorsal horn or enter the dorsal columns.[219] Thus, dorsal rhizotomy may fail ultimately because of the presence of afferents that reach the spinal cord via the ventral root. However, the actual frequency of ventral root sensory nerves is not known.

To obviate this problem, consideration may be given to performance of a sensory ganglionectomy. The cell body for all primary afferents is believed to reside in the dorsal root ganglion, regardless of whether the fibers reach the spinal cord via the dorsal or ventral roots. One report cites a patient with recurrent pain following dorsal rhizotomy that experienced enduring pain relief following removal of the dorsal root ganglia at the same level,[220] providing further evidence that afferents concerned with pain may enter the spinal cord through ventral roots. Ganglionectomy has gained acceptance in the treatment of certain pain disorders.[221] However, including ganglionectomy in a dorsal rhizotomy has not been demonstrated to yield better long-term results, though late recurrence with ganglionectomy is also common.

Clinical Considerations

Preoperative Evaluation

Dorsal rhizotomy or sensory ganglionectomy may be attempted for treatment of both nociceptive and neuropathic pain, although in our experience, pain often recurs within a few years. Prediction of the potential effect of an operation can be fairly simple, if only a single level is affected. A number of confounding anatomic situations, such as root-to-root anastomosis or overlap of root innervation, must be considered.[222] Identification of the appropriate spinal level and roots or ganglia for ablation is accomplished through paravertebral local anesthetic nerve blocks. Spinal epidural or subarachnoid blocks can be used for screening purposes when considering sacral rhizotomy. For greater accuracy in diagnosis, these blocks should be performed at multiple levels, with placebo controls. There is a tendency for the anesthetic to leak into the epidural space, and this may lead to a false positive result.

Although rhizotomies are now done infrequently for pain, some patients do gain enduring pain relief from rhizotomy or ganglionectomy, with acceptable morbidity. The challenge is to select the patients most likely to benefit. Feasibility dictates the appropriate procedures, to some extent. If the clinical problem is limited to one root, ganglionectomy has appeal in order to avoid the problem of ventral root afferents. Unfortunately, surgical ganglionectomy involves destruction of a substantial portion of the facet, and therefore may not be practical if two or more roots are involved. Rhizotomy may be preferable in this instance; however, the problem of pain recurrence may be higher. No clinical studies directly compare rhizotomy and ganglionectomy, and differences in outcome between the two procedures are not well understood.

Dorsal rhizotomy and sensory ganglionectomy spare motor efferents and do not lead to the formation of neuromas. However, careful attention must be given to the potential complications of dorsal root surgery. Ablations of the dorsal roots attenuate not only pain, but also vibratory, temperature, and proprioceptive inputs. Loss of these sensory functions may be troublesome, particularly in the extremities. In addition, with the ablation of the highly vascularized dorsal roots, blood supply to the spinal cord can be jeopardized. Ablation of more than six dorsal roots increases this risk considerably.[212] Finally, dorsal rhizotomy and ganglionectomy, if unsuccessful, preclude the use of dorsal column stimulation as a means of pain treatment, because the primary afferents on which the stimulator acts undergo wallerian degeneration.

The following case presents evaluation and treatment of a patient with neuropathic pain, in an ideal setting for performance of a ganglionectomy, although with eventual pain recurrence:

> A 42-year-old woman underwent an anterior cervical discectomy and fusion with harvesting of a bone graft from the left iliac crest. An anterior abdominal wall hernia developed at the site of bone harvest.

This defect was repaired with mesh, and the patient developed severe pain at the repair site. Eventually the repair site was explored, and injury to the subcostal nerve (T12) was noted. The neuroma was resected back and relocated to a healthy muscular bed away from scar. Pain was relieved for several weeks and then returned. An additional attempt at neuroma relocation surgery met with the same fate. Opioid treatments as well as other pharmacologic approaches failed to provide satisfactory relief. Nerve root blocks of T12 but not of T11 or L1 led to complete pain relief. A ganglionectomy was performed at T12, and the patient had sustained pain relief for 2 years.

In this case, pain was limited to a single, clearly defined spinal level. The return of pain following neurectomy demonstrated the high likelihood of reformation of a painful neuroma. A single ganglionectomy both eliminated the pain and precluded the reformation of a painful neuroma. However, the pain recurred after 2 years. In our experience, peripheral nerve stimulation, spinal cord stimulation, and intrathecal pain pumps may be preferable and nondestructive first-line therapies for radicular pain prior to performance of sensory rhizotomy or ganglionectomy.

Operative Technique

Dorsal rhizotomy is performed using either an intradural or extradural approach, while ganglionectomy is by extradural approach. For intradural rhizotomy, a laminectomy is performed at the levels of interest and the dura is opened, where sensory rootlets are then identified at the intervertebral foramina, followed proximally, and divided. For extradural rhizotomy, the lateral facet is removed and the appropriate nerve roots are exposed laterally. The proximal spinal root is dissected free, and the dorsal rootlet is identified and divided. For ganglionectomy, the dorsal root ganglion is also dissected free and removed. In some cases, separation of the ganglion from the motor root is difficult and there may be resections of this structure as well, a factor to be borne in mind when selecting the ablative approach. Ganglionectomy can also be performed from a foraminal approach with minor disruption of the facet. Sacral rhizotomy may be accomplished though sacral laminectomy and division of the thecal sac between the S1 and S2 roots.[223]

Specific Indications and Outcomes

Indications for dorsal rhizotomy or ganglionectomy may be broadly divided into procedures for cancer and noncancer pain,[224] and are outlined by the Joint Section on Pain in its 1994 recommendations. In addition,[224b] dorsal rhizotomy can be a useful therapy in treatment of certain spasticity disorders, including spastic cerebral palsy. Barrash and Leavens[225] reported success in 70% (50 of 71) of patients with cancer, with 10.5-month average follow-up. By contrast, Onofrio and Campa[226] reported an overall success rate of 41% (46 of 112) in patients with localized idiopathic pain. Wilkinson[227] reported excellent pain reduction in 74% of patients with dorsal root ganglionectomy alone, with no adverse complications, for pain refractory to other treatments. The differences in success rate between cancer and noncancer pain could potentially result from earlier mortality among patients with cancer-related pain, given the significant incidence of late-recurring pain.

Cranial and Cervical Pain

Rhizotomy of C1 to C4 in combination with cranial nerves V, IX, and X may provide effective pain relief from extensive head and neck cancers.[228] In considering such a procedure, one would have to consider the morbidity of such an extensive operation in terms of sensory loss. In some cancer victims, however, sensory loss is already extensive. Dorsal cervical rhizotomy may also be combined with trigeminal tractotomy. Cancers of the lung or breast with brachial plexus involvement, with loss of function in the upper limb, may also benefit from cervical rhizotomy.

Occipital Neuralgia

The greater occipital nerve, formed by the posterior primary ramus of C2, and the lesser occipital nerve, formed by the C2 and C3 roots in the cervical plexus, jointly innervate the occipital region of the scalp. Occipital neuralgia is headache characterized by severe paroxysmal lancinating or continuous pain, localized to this innervated region.[229] Occipital neuralgia may be due to migraine, compression of the C2 root, entrapment of greater occipital nerve at the superior nuchal line, or nerve injury.[230]

C2 or C3 ganglionectomy, as well as upper intradural cervical rhizotomy, have been used successfully in treatment of occipital neuralgia. Stechison and Mullin[231] reported success in 4 of 4 patients with idiopathic greater occipital neuralgia, with 2-year average follow-up. Lozano et al.[232] reported that patients with occipital neuropathic pain due to trauma are more likely to experience significant pain reduction following C2 ganglionectomy than other patient groups with occipital pain. Onofrio and Campa[226] reported relief from occipital neuralgia in 64% (9 of 14) of patients immediately, and 50% (7 of 14) of patients after months to years following ablation of 1 to 3 cervical roots. Dubuisson[233] reported success in 71% (10 of 14) of patients, with 33-month average follow-up, following partial posterior rhizotomy at C1 to C3. Cervical nerve block has been shown to be useful for confirmation of occipital neuralgia, and possibly as a patient selection tool for rhizotomy.[234] In a recent study, Burchiel and colleagues[235] reported the return of pain within a year in 65% (13 of 20) of patients undergoing C2 or C3 ganglionectomy. Occipital nerve stimulation may be considered a favorable alternative to C2 or C3 ganglionectomy.[236]

Thoracic Pain

Pain associated with chest wall invasion of pleural-based or chest wall malignancies, as well as localized thoracic pain secondary to nerve invasion or compression, can be an indication for dorsal rhizotomy or ganglionectomy. Arbit et al.[237] reported complete pain relief in 64% (9 of 14) and 50% to 100% pain relief in an additional 29% (4 of 14) of patients with cancer pain, with 22-month median follow-up, following thoracic dorsal and ventral rhizotomy. Smith[238] reported success in 10 of 10 patients with intercostal pain due to thoracotomy,[7] herpes zoster,[2] and cancer,[1] following thoracic ganglionectomy.

Postsurgical Truncal Pain

Persistent pain following thoracotomy or laparotomy may be responsive to dorsal rhizotomy. White and Kjellberg[212] reported successful treatment of intercostal neuralgia in three of four patients, with 8-month median follow-up, following thoracic rhizotomy. Loeser[224] reported success in 33% (1 of 3) of patients at more than 3 months. By contrast, Onofrio and Campa[226] reported on 18 patients with postthoracotomy pain and 5 patients with postlaparotomy pain, none of whom obtained benefit. White and Kjellberg[212] also reported successful treatment of postherniorrhaphy neuralgia in 3 of 4 patients, with 2-year median follow-up, following thoracolumbar rhizotomy. There are no large series of patients upon which to base management decisions.

Sacral Pain

Cancers of the colon, rectum, urinary tract, cervix, and prostate may result in pain attributable to sacral roots. Unfortunately, ablation of the second and third sacral roots may affect bladder, sphincter, and sexual function. Thus, sacral root division is indicated in cases of pelvic cancer pain, where patients have already lost bladder and bowel function. It is a simple procedure that may confer striking benefit. Saris et al.[239] reported success in 47% (7 of 15) of patients with colorectal cancer presenting with perianal pain, with 1-year median follow-up, following bilateral S3 to S5 rhizotomy. Felsoory and Crue[223] reported satisfactory

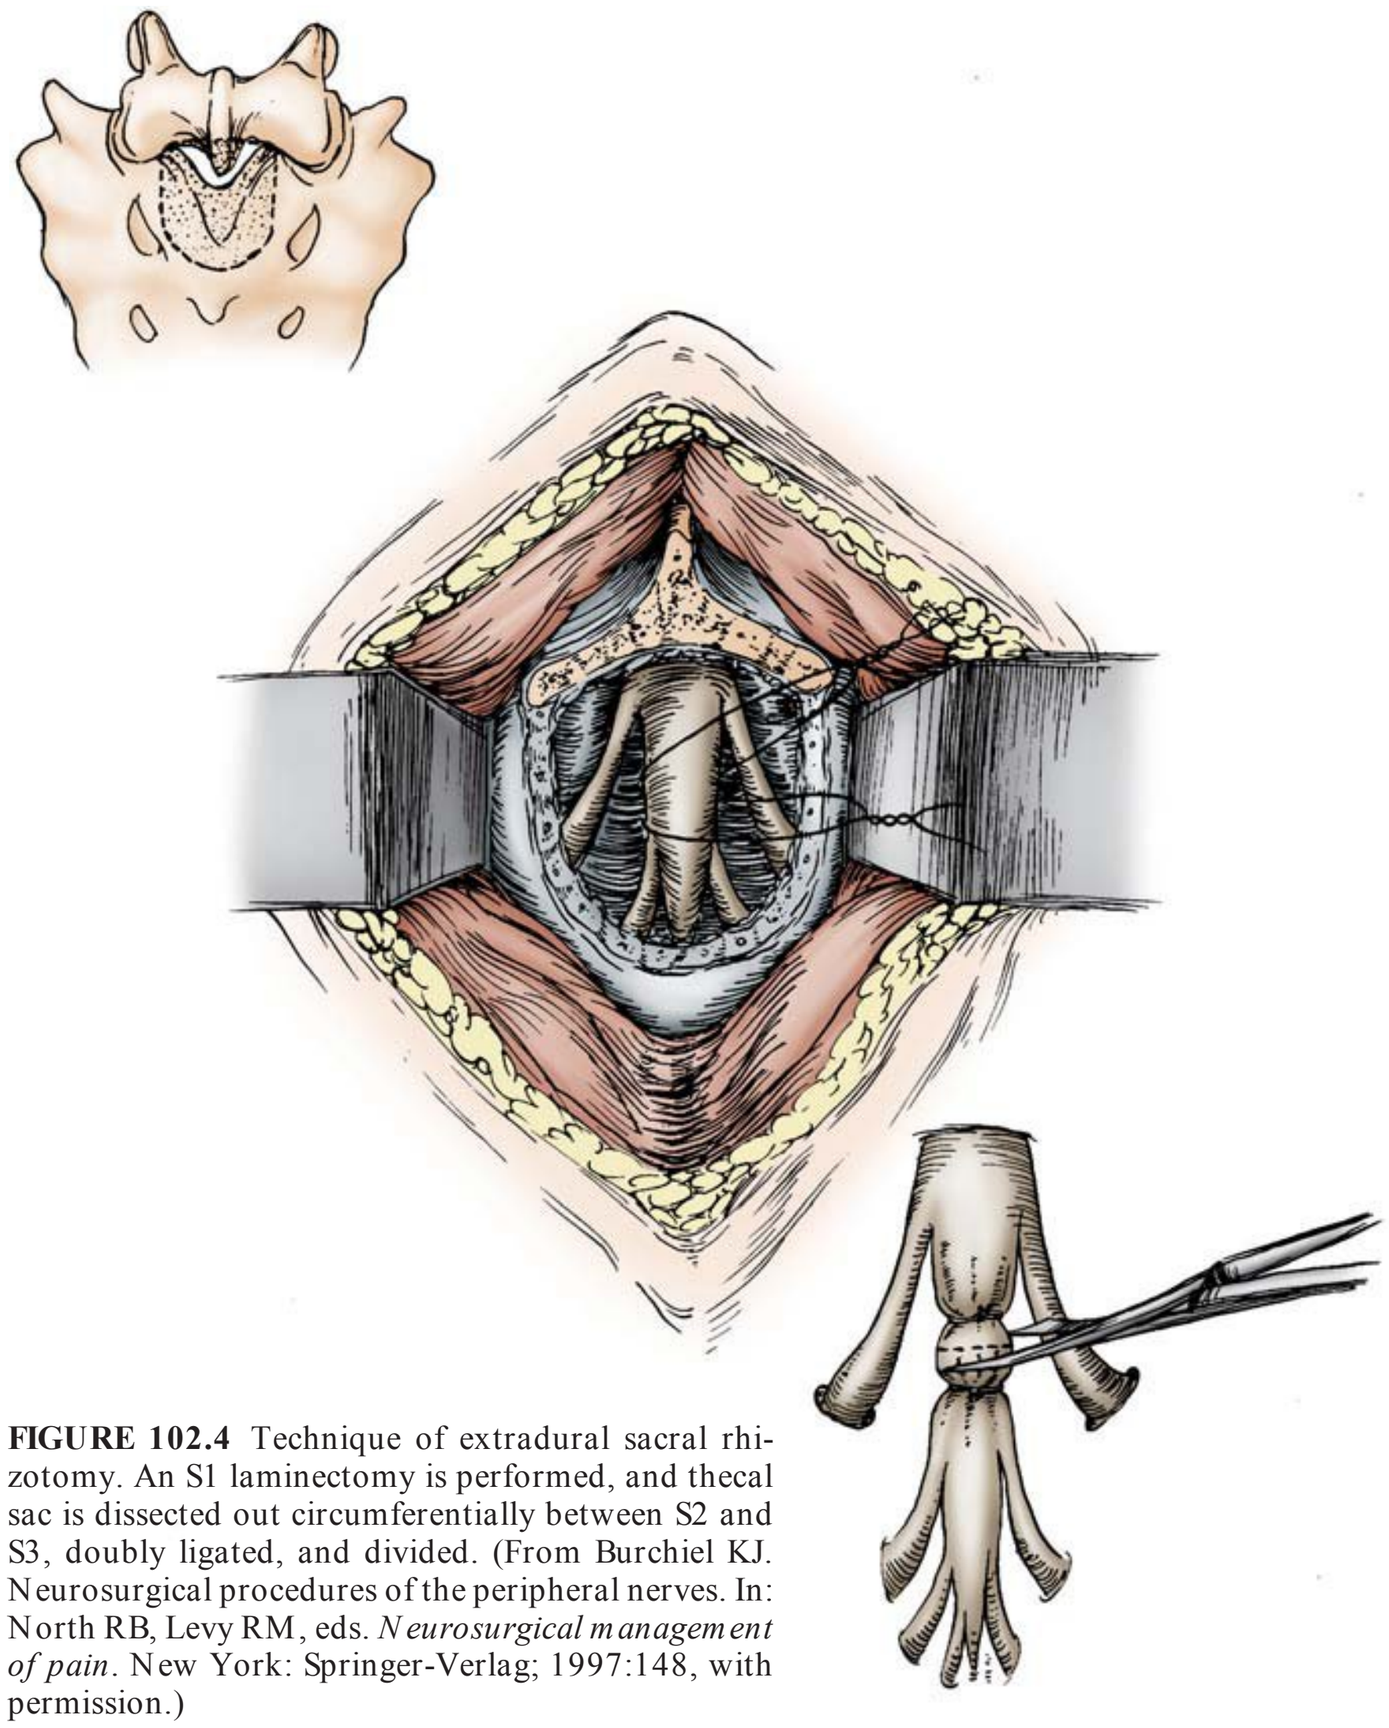

FIGURE 102.4 Technique of extradural sacral rhizotomy. An S1 laminectomy is performed, and thecal sac is dissected out circumferentially between S2 and S3, doubly ligated, and divided. (From Burchiel KJ. Neurosurgical procedures of the peripheral nerves. In: North RB, Levy RM, eds. *Neurosurgical management of pain*. New York: Springer-Verlag; 1997:148, with permission.)

results in 69% (20 of 28) of patients with colorectal,[17] cervical,[5] anal,[3] and other[3] cancers, with unstated follow-up duration, following transection of the cauda equina at L5-S1. The surgical anatomy is depicted in Figure 102.4.

Extremity Pain

Rhizotomy or ganglionectomy are indicated for denervation of a functionally useless limb. There are few other indications in the treatment of extremity pain. That multiple roots may be involved, the morbidity of sensory loss, and the problem of frequent pain recurrence, lead to infrequent use of these procedures for extremity pain. Ganglionectomy for monoradicular extremity pain has been proposed, but remains unproven.[240] North et al.[241] reported greater than 50% relief from failed back surgery syndrome in none of the 13 patients they studied, with 5.5-year average follow-up. By contrast, Taub et al.[242] reported success in 59% (36 of 61) of patients with intractable monoradicular sciatica following dorsal root ganglionectomy, with 5 to 9 years median follow-up. This unusually high rate of success likely reflects very careful patient selection.

The choice of rhizotomy or ganglionectomy for treatment of extremity pain requires a balance between compromise of function due to elimination of sensation and the elimination of pain. For the upper extremity, White and Kjellberg[212] reported successful treatment of diffuse upper extremity pain in 50% (7 of 14) of patients, with 3-year median follow-up, following rhizotomy at various levels. Following the procedure, none of the patients complained of unpleasant numbness or clumsiness of the hand, perhaps reflecting the seriousness of the preoperative condition. In the lower extremity, they reported successful treatment of lateral femoral cutaneous neuralgia in 67% (4 of 6) of patients, with 3-year median follow-up, following L2 to L3 rhizotomy. Spinal cord stimulation may offer a nondestructive alternative to rhizotomy or ganglionectomy for the treatment of extremity pain.[243]

Visceral Pain

Though rarely used today due to the advent of other techniques, dorsal rhizotomy has been reported to be highly effective in controlling visceral pain. White and Kjellberg[212] reported successful treatment of medically intractable angina in 75% (3 of 4) of patients, with 14-month median follow-up, following T1 to T4 rhizotomy. Success was 50% (3 of 6) for treatment of other forms of visceral pain.

Axial Spine Pain

Lumbar median branch rhizotomy via percutaneous radiofrequency ablation is indicated for treatment of facet arthropathy

pain and is discussed in detail in Chapter 101. Local and radicular pain due to lumbar spine disease is largely unresponsive, in the longer term, to dorsal rhizotomy. Loeser[224] reported success in 75% (12 of 16) at up to 3 months, but only 14% (2 of 14) at more than 3 months for patients with disk disease. Onofrio and Campa[226] reported improvement in 17% (11 of 64) of patients with lumbosacral pain following rhizotomy, with unstated follow-up. Wetzel et al.[244] reported success in 55% (28 of 51) at up to 6 months and 19% (7 of 37) at 2 years for patients with lumbar radiculopathy after lumbar surgery.

Postherpetic Neuralgia

Dermatomal pain following herpetic infection responds poorly to dorsal rhizotomy. Loeser[224] reported failure in two of two patients. Onofrio and Campa[226] reported success in only 20% (one of five) of patients, with 5-year follow up, following unilateral rhizotomy. The treatment of postherpetic neuralgia is discussed in Chapter 27.

SYMPATHECTOMY

Basic Considerations

Sympathetic Efferents

Sympathetic efferents reach their target structures in two steps. Preganglionic sympathetic efferents arise in the intermediolateral cell column of the spinal cord at T1 to L3. Thinly myelinated fibers emerge in the ventral roots and transit briefly through the spinal nerve before exiting to form the white rami communicantes, leading to the paravertebral sympathetic ganglia. Some preganglionic fibers form synapses in the sympathetic chain with postganglionic neurons, from which unmyelinated fibers return to the spinal nerves, forming the gray rami communicantes. These postganglionic efferents provide sympathetic innervation to blood vessels, sweat glands, and other structures. Other preganglionic fibers pass through the paravertebral sympathetic chain without forming synapses and continue to the prevertebral ganglia. In the prevertebral ganglia, these efferents synapse with postganglionic effector neurons. From the prevertebral ganglia, unmyelinated fibers innervate the abdominal and pelvic viscera. Sympathectomy has been used in the treatment of pain from the limbs, the heart, and abdominal viscera. Presacral neurectomy and thoracic sympathectomy for cardiac pain are discussed earlier in this chapter and are not further addressed here.

Sympathetically Maintained Pain

In some patients with chronic pain syndromes, the pain depends on the activity of sympathetic efferents in the painful area. This pain, termed SMP, is defined as that aspect of pain that is relieved by blockade of sympathetic efferents.[245] Pain that is unaffected by the activity of sympathetic efferents is termed sympathetically independent pain. The diagnosis of SMP is empiric; that is, it is made based on response to treatment. In any pain syndrome, a portion may be sympathetically maintained, while another part is sympathetically independent. Notably, complex regional pain syndrome and other neuropathic conditions may or may not be associated with SMP.

Traditionally, three distinct mechanisms have been considered as ways through which ablation of sympathetic nerves or ganglia may lead to pain relief:

1. The sympathetic efferents in T1 to L3 that pass through paravertebral sympathetic ganglia to abdominal and pelvic viscera do not travel alone. They are accompanied by afferents, with cell bodies in the dorsal root ganglia of T1 to L3, which convey sensory information about distension and inflammation of visceral organs to the central nervous system. As a result of this colocalization, ablation of prevertebral ganglia (or the nerves originating from them) interrupts the flow of nociceptive signals from visceral structures to brain, thereby producing pain relief. Hence, as a treatment for visceral pain, sympathectomy is a form of sensory neurectomy.
2. Sympathectomy may improve pain associated with ischemia. Sympathetic efferents maintain arterial tone. In vasospastic and vasoocclusive conditions, the vasodilation consequent to sympathectomy may ameliorate ischemia, thereby decreasing pain.[246]
3. Finally, sympathectomy may eliminate norepinephrine-mediated activation of nociceptors and thereby relieve SMP. In this section, we concentrate on this latter mechanism and extremity pain related to complex regional pain syndromes in which a component of pain has been demonstrated to be sympathetically maintained.

Understanding of the pathophysiologic mechanisms underlying SMP continues to increase. The involvement of both A and polymodal C nociceptors is evident, though incompletely elucidated.[247,248] Immunologically-mediated mechanisms involving prostaglandin, bradykinin, substance P, neuropeptide Y, and calcitonin gene-related peptide, have also been proposed in treatment-resistant patients.[249,250] Increased expression of class I and II human leukocyte antigen in patients diagnosed with reflex sympathetic dystrophy suggests a genetic predisposition to poor treatment response,[251] although a relationship to SMP has not been defined.

By definition, SMP is eliminated by blockade of sympathetic efferent innervation of the painful area. Thus, anesthetic blockade of the relevant sympathetic ganglia relieves pain in patients with SMP. Stimulation of the sympathetic chain evokes pain in patients with SMP but not in those without SMP.[25] Moreover, Walker and Nulson[252] noted that stimulation of the severed distal end of the sympathetic chain evokes pain in those diagnosed with SMP but not in other patients. Thus, the central connections of sympathetic efferent fibers are not required for stimulation of the sympathetic system to evoke pain. These observations establish that efferent sympathetic fibers, rather than afferent sensory fibers that may travel with sympathetic fibers, account for SMP in nonvisceral pain syndromes.

Several independent lines of pharmacologic evidence support the claim that norepinephrine released from sympathetic fibers is critical in SMP. First, regional infusion of guanethidine, which acts to deplete norepinephrine from sympathetic terminals, relieves pain in patients with SMP.[253] Second, in patients whose pain had been relieved by either sympathetic block or sympathectomy, a cutaneous injection of norepinephrine into the previously painful area rekindles the pain and hyperalgesia. However, norepinephrine injected intracutaneously into normal subjects induces less pain and less hyperalgesia.[254,255] Finally, administration of sympathetic β-adrenergic antagonists, such as prazosin, phenoxybenzamine, or phentolamine, relieves SMP.[256–259]

Following nerve injury, neuromas that form may acquire sensitivity to norepinephrine. Injection of pH-balanced norepinephrine solution into normal subcutaneous tissues causes little pain. However, injection of norepinephrine onto painful neuromas does induce pain.[260] Thus, nerve injury may be associated with the induction of SMP.

These observations suggest that an abnormal increase in the amount of norepinephrine released from sympathetic terminals is not likely to be the mechanism of SMP. Rather, it is the response to norepinephrine that appears to be critical. Studies continue to support this theory, demonstrating the benefit of perioperative pharmacologic sympathetic block in reducing recurrence.[261,262] Whether this change is due to an up-regulation of β-adrenergic receptors or increased receptor sensitivity is unknown.

Clinical Considerations

Preoperative Evaluation

SMP cannot be diagnosed purely from history and physical examination of the patient.[263] However, it must be differentiated from similar-appearing chronic pain syndromes, particularly peripheral nerve injury. A number of clinical features are helpful: (1) In general, SMP does not occur in places other than the extremities or face. As a rule, the likelihood of developing SMP parallels the density of sympathetic innervation of the skin. Hence, truncal pain is far less likely to be due to SMP than is extremity pain. (2) Signs that may be inferred to represent increased sympathetic activity in the painful area do not necessarily denote the presence of SMP.[264] For example, limbs associated with SMP may be warmer, cooler, or the same temperature as unaffected limbs. Similarly, differences in sweating, nail growth, and muscle tone do not reliably contribute to the diagnosis of SMP. Nonetheless, sweating abnormalities in particular, as well as temperature alterations in general, may have some diagnostic utility.[265] We have found that among patients with traumatic nerve or soft tissue injury with touch-evoked pain, all patients with SMP and 50% of patients with sympathetically independent pain have striking sensitivity to mild cooling stimuli.[7,266]

Due to adverse effects and lack of definitive supporting evidence, surgical sympathectomy is typically reserved for medically-refractory SMP. Careful patient selection is critical to success. Thus, preoperative evaluation is of great importance. Mechanical allodynia with temperature change and cooling hyperalgesia together form an indication for sympathetic blockade.[264] The effect of sympathetic blockade via regional blockade or systemic infusion, in turn, plays an important role in identifying patients who might benefit from sympathectomy. High rates of recurrence, either due to sympathetic chain regeneration or new-onset complex regional pain syndrome, as well as significant adverse effects of the operation, serve to further highlight the need for discriminating patient selection. Finally, early intervention is important to optimize patient outcomes.

Quantitative Sensory Testing. Essentially all patients with SMP have cooling hyperalgesia.[263,266] In fact, patients with SMP often spontaneously volunteer that the one stimulus that they most dread is cooling of the painful area. Cooling hyperalgesia occurs less frequently in patients with sympathetically independent pain. This suggests that cooling hyperalgesia is a highly sensitive, though not specific, indicator of SMP.

Local Anesthetic Sympathetic Ganglion Blocks. The traditional procedure to diagnose SMP is percutaneous injection of local anesthetic onto the sympathetic ganglia serving the painful region. In local anesthetic sympathetic ganglion blocks (LASB), ganglia are localized through anatomic landmarks, ideally under fluoroscopic guidance, and local anesthetic is injected into the region. The presence of local anesthetic at the ganglia prevents norepinephrine from being released into peripheral tissues. While frequently used to diagnose SMP, LASB results must be interpreted with care: (1) Incomplete block of individual ganglia may falsely underestimate the contribution of SMP to a painful condition. The extent of sympathetic block must be evaluated by assaying for effects of sympathetic block, such as changes in skin temperature; (2) Spread of local anesthetic onto somatic afferents in the nerve roots, or blockade of sensory afferents that accompany sympathetic efferents, may induce pain relief by way of somatic block rather than sympathetic block. Careful sensory examination must be performed to ensure that somatic afferents are not affected by injection of local anesthetic; (3) LASB may evoke a placebo response, causing overestimation of pain relief. In addition to these interpretive issues, LASB has some risk. Complications reported with LASB include pneumothorax, phrenic and laryngeal nerve block, cardiac arrhythmia, kidney injury, hemorrhage, and inadvertent intravascular or epidural injections (see Chapter 97 for a detailed discussion of the role of local anesthetic blocks in the diagnosis of SMP).

Systemic Phentolamine Infusion. An alternative strategy to assess the potential efficacy of sympathectomy involves intravenous infusion of phentolamine, a short-acting antagonist of β-adrenergic receptors.[257,259] There is good correlation between pain relief with LASB and that with systemic phentolamine infusion (SPI).[259,263] As a systemic infusion, phentolamine does not provide any information about anatomic localization, as is available with LASB. However, SPI has a number of advantages over LASB: (1) the test is painless in that the phentolamine is delivered systemically and does not require fluoroscopy or needles to be placed in the paravertebral space; (2) with SPI, a significant observation period can be used prior to the administration of the drug, and the patient can be blinded to the time of drug administration, allowing a placebo-control period in every trial; (3) SPI appears to be safer than LASB, with only nasal stuffiness and peripheral vasodilation reported as side effects.[267] Furthermore, because the activity of nearby sensory afferents is preserved, SPI appears to be a more specific diagnostic test for SMP.[259,263]

Intravenous Regional Block. A third method to detect SMP involves regional intravenous infusion of an agent that impedes peripheral release of norepinephrine,[253] known as a Bier block. Sympatholytic agents studied include bretylium, reserpine, and guanethidine.[266] To avoid systemic circulation of the sympatholytic agent, a tourniquet is applied to the limb during the test. The central advantage of intravenous regional block (IRB) is localization of sympathetic block to the limb of interest. However, there are shortcomings: (1) some patients poorly tolerate the required tourniquet application; (2) the dramatic release of sympathetic neurotransmitter accompanying infusion of guanethidine in SMP patients may be severely painful; (3) the blocking agent may leak beyond the tourniquet, in some instances with significant hemodynamic effects; (4) the need for a tourniquet makes IRB difficult to perform either in the trunk or in the lower extremity; (5) it is difficult to evaluate placebo responses with IRB. Though frequently mentioned as a means to diagnose and to treat SMP, we believe that IRB has few advantages. The same degree of β-receptor blockade can be achieved with systemic phentolamine.

Medical Treatment of SMP. Once the diagnosis of SMP is made, the mainstay of treatment is medical sympatholysis, with surgical intervention reserved for refractory cases. A remarkable feature of SMP is that extended sympathetic blockade may lead to long-term or permanent relief from the disorder. When the goal of blockade is diagnosis, the diagnostic technique should be specific to the sympathetic nervous system. By contrast, when the goal is treatment, there need not be specificity. There are several medical and interventional means by which to achieve sympatholysis. The choice of technique should be based on considerations of safety, comfort, and efficacy.

Multiple sympathetic ganglion blocks with local anesthetics have, in the past, served as the criterion standard for treatment. However, local anesthetic treatment of peripheral nerves may work as well by inducing similar blockade of the distal sympathetic fibers. For example, SMP in the upper extremity could be treated either by LASB of thoracic sympathetic ganglia or by local anesthetic application to the appropriate nerves.

Alternatively, while epidural administration of anesthetic may lack specificity as a means to diagnose SMP, it may provide an effective treatment regimen. Epidural clonidine, though limited by hemodynamic effects, provides extensive analgesia.[268] SPI has been used successfully to treat SMP in a patient with pain in all extremities due to Sjögren's associated polyneuropathy.[269]

When episodic treatments fail to provide adequate relief, chronic treatment with oral sympatholytics may reduce SMP. Both phenoxybenzamine and prazosin have been used in this manner.[256,258] However, the systemic hypotension that frequently accompanies the use of these agents may preclude adequate sympathetic blockade. Finally, topical clonidine, which is likely to inhibit local norepinephrine release, may be a low-morbidity treatment of SMP in some patients, albeit locally.[254,270] If well tolerated, this and other medical techniques could substantially reduce the need for surgical sympathectomy; indeed the role for surgical sympathectomy remains in question.

Operative Techniques

To achieve sympathectomy of the upper extremity, it is necessary to resect the T2, T3, and T4 sympathetic ganglia. Removal of less than all three ganglia risks inadequate sympathectomy for pain. One of our patients required extension of the sympathectomy to T5. This is best achieved through a thoracoendoscopic technique, although the data on this operation have been acquired through open supraclavicular transaxillary or posterior costotransversectomy approaches. By contrast, the lumbar sympathetic chain, most commonly involving L2 and L3 ganglia, is generally accessed through an anterolateral retroperitoneal surgical approach. Percutaneous approaches have been suggested, but these procedures often do not achieve enduring results. In addition, the scarring produced by these approaches makes later surgical treatment more difficult.

Many clinicians have reported limited success in the treatment of pain by surgical sympathectomy.[271,272] Failure of sympathectomy may reflect inadequacies either of the preoperative evaluation, as discussed above, or of the extent of the sympathectomy. For example, sympathetic outflow to the arm derives predominantly from the T2 and T3 ganglia and not from the stellate ganglion. Failure to remove the T2 ganglion, at a minimum, will result in continued sympathetic innervation of the hand. An important feature in the lower extremity is that sympathetic innervation is often bilateral. Bilateral lumbar sympathectomy of L2 to L4 is typically necessary (Fig. 102.5). A typical patient history is one of impressive relief of pain lasting several weeks following an ipsilateral lumbar sympathectomy. The pain then returns, and at that time the pain may be relieved by a contralateral block of the lumbar sympathetic ganglia. Patients will typically have enduring relief of pain following contralateral lumbar sympathectomy.[273,274] As in the upper extremity, complete sympathectomy is required for pain relief; the partial denervation that is successful for vascular diseases is not adequate as a treatment for pain.

Specific Indications and Outcomes

Ulmer and Mayfield[275] reported successful treatment of 96% (67 of 70) of soldiers with burning pain due to nerve injury by surgical sympathectomy of appropriate ganglia. In studies of a civilian population, Manart et al.[276] reported a "good" response to thoracic sympathectomy in 59% (13 of 22) of patients with burning posttraumatic pain, even when diagnostic blockades were not typically performed. For patients selected for preoperative diagnostic sympathetic block, Mockus et al.[277] reported improvement in 94% (29 of 31) of patients, with 3.4 years average follow-up. AbuRahma[278] reported 1-year satisfactory improvement of pain in 20 of 21 patients. Overall success rates of 90% or greater with surgical sympathectomy have been reported by several groups.[279] Thompson[280] reported successful surgical treatment in 46% (55 of 120) of patients with SMP following minor trauma, who were unresponsive to medical therapy. Overall, long-term successful outcomes in 70% to 85% of cases of thoracic, and slightly less in lumbar sympathectomy, can be expected.

As noted, results of sympathectomy largely depend upon careful patient selection.[258] Our experience has been that patients do extremely well if the pain responds dramatically to sympathetic ganglion block and systemic infusion of phentolamine, and there is provocation of pain with injection of norepinephrine when the patient is under the influence of a LASB. While our conclusions are preliminary, it appears that if one or more of these elements are missing, the patient does not fare as well. The modest response rates to sympathectomy in earlier series may reflect improper patient selection and inadequate sympathectomy (e.g., bilateral sympathectomy required for lower extremity pain) or more extensive unilateral ganglionectomy for total denervation of an extremity.

Postoperative Complications

Surgical sympathectomy may be associated with idiosyncratic complications. One frequent complication, affecting up to 20%

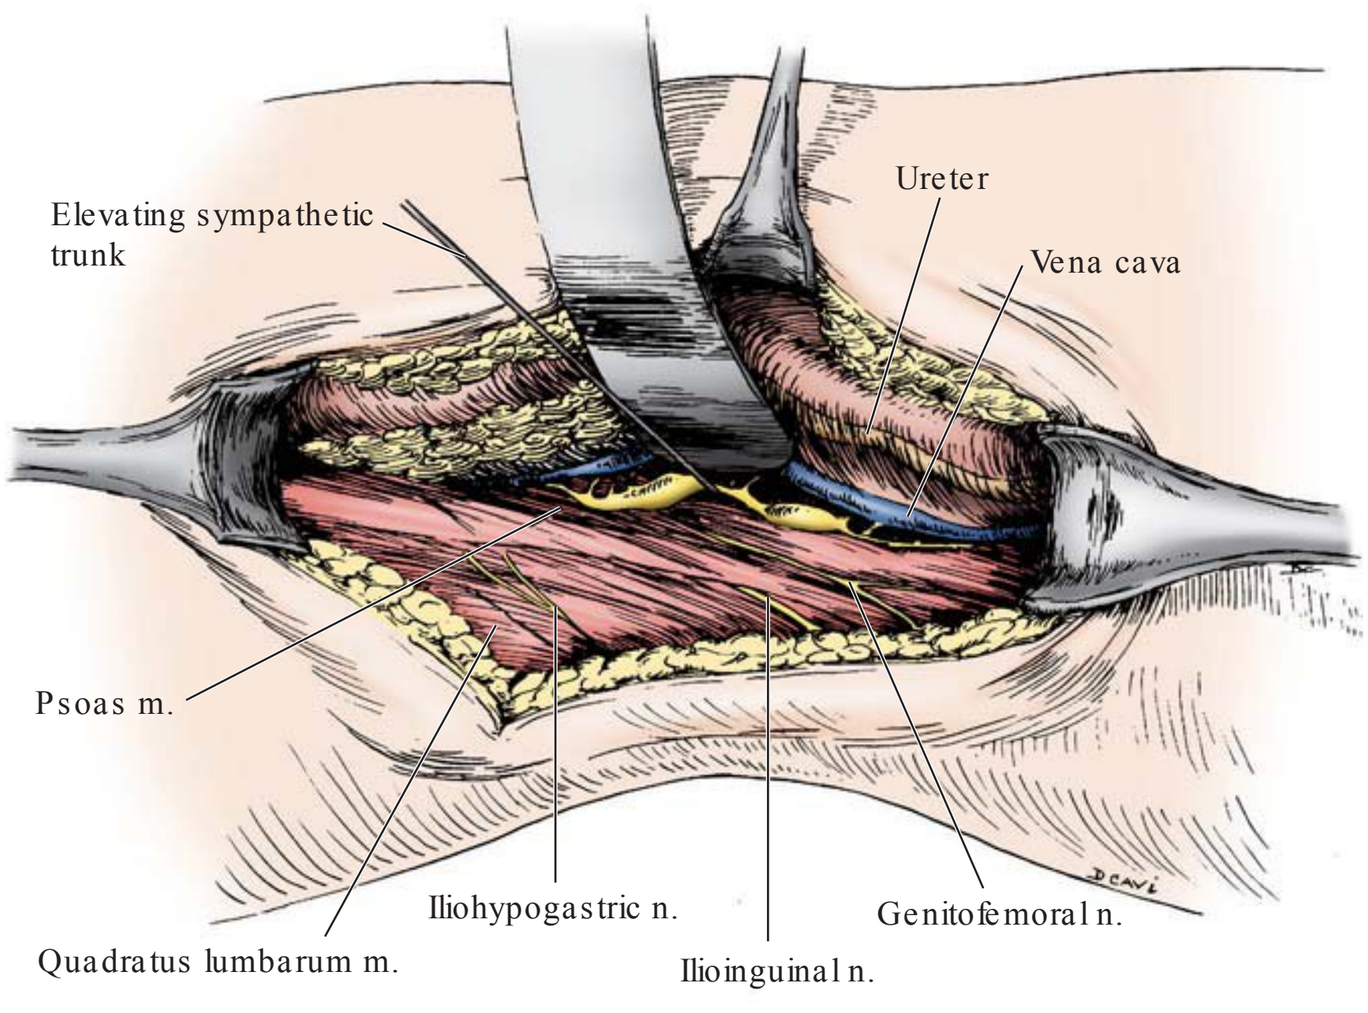

FIGURE 102.5 Open lumbar sympathectomy is done through retroperitoneal exposure of the sympathetic chain. (From Wilkinson HA. Neurosurgical procedures of the sympathetic nervous system. In: North RB, Levy RM, eds. *Neurosurgical management of pain*. New York: Springer-Verlag; 1997:170, with permission.)

to 50% of patients, is postsympathectomy pain.[277,281,282] This condition is characterized by the sudden onset, a few weeks after the procedure, of superficial burning pain, deep aching pain, and cutaneous hyperalgesia.[283] The pain arises in the proximal regions of limbs and the trunk, despite surgical ablation of sympathetic innervation to the distal limbs. Fortunately for the majority of patients, postsympathectomy pain resolves spontaneously in several weeks to a few months and no further surgical intervention is warranted.[281]

Ablation of sympathetic input to a region of skin results in sudomotor paralysis. In the upper extremity, the resultant dryness can be uncomfortable. In the lower extremity, dryness is better tolerated. Postural hypotension also can be a transient problem. However, even in patients with sympathectomy of all four extremities, this problem is usually not enduring. Compensatory hyperhidrosis, as well as pathologic gustatory sweating, may be found in patients following sympathectomy.[284] Two additional complications of sympathectomy include paradoxical vasoconstriction and ileus. Sympathetic fibers arising from the celiac and mesenteric ganglia modulate gastrointestinal motility. Both complications are generally transient.

CONCLUSION

The peripheral nervous system offers a number of attractive strategies for treatment of pain. Peripheral nerves may be transected or released from regions of entrapment. Where regional pain control is required, sensory roots or ganglia may be the targets of therapy. In cases where pain has a significant sympathetically maintained component, sympathectomy may offer significant and long-lasting pain relief.

As for all surgical procedures, careful patient selection and clear establishment of the etiology of the painful condition is critical to ensure successful analgesia. Enthusiasm for these surgical procedures must be tempered by a keen appreciation of potential complications.

Nerve transection may either produce or eliminate pain. This leaves the clinician with the sometimes daunting task of deciding if, when, and how to perform neurectomy. Each patient must be carefully evaluated. In the case of minor nerves previously transected, the clinician should not labor over the decision to relocate the neuroma to a protected, unscarred site. In this instance there is little to lose.

Pain due to mechanical compression may be relieved through release of nerve root entrapments. Carpal tunnel release and release of ulnar nerve entrapment at the elbow are among the most commonly performed peripheral nerve procedures. However, many less common forms of nerve root entrapment may be overlooked or misdiagnosed. A systematic understanding of peripheral neuroanatomy on the part of the pain clinician is essential to accurate diagnosis and treatment of these pain syndromes.

Dorsal rhizotomy is seldom used in modern practice, but a survey of the existing literature reveals that patients certainly exist in whom rhizotomy conferred long-term benefit. Today's pain clinician does well to keep this option in mind in properly selected cases. Ganglionectomy has certain theoretical advantages over rhizotomy and neurectomy and is still another technique that should be considered in certain cases. However, recurrence of pain several years after surgery may be quite common.

Sympathectomy is helpful in patients with persistent SMP who are refractory to medical management. Recognition of the clinical symptoms of SMP, such as cold allodynia, and appropriate selection of sympathetic blockade modalities are required to make the diagnosis and to provide a successful treatment strategy. Hence, the key to success with this procedure, as with most surgery, is meticulous patient selection and proper execution of the operation.

CHAPTER 103 ■ THE SURGICAL MANAGEMENT OF TRIGEMINAL NEURALGIA

WAEL F. ASAAD AND EMAD N. ESKANDAR

INTRODUCTION

Trigeminal neuralgia is the most common of a family of disorders caused by spontaneous (nontraumatic) injury to a cranial nerve. Most cases are believed to result from impingement on the nerve by a vascular structure, usually an artery, causing demyelination and subsequent pathologic electrical activity. Those suffering from this disease report intermittent bouts of sharp, lancinating pain in the distribution of the trigeminal nerve or its three main branches. Hemifacial spasm and glossopharyngeal neuralgia are among the other less common, spontaneous cranial nerve compression diseases, resulting from injury to the seventh and ninth cranial nerves, respectively.

HISTORY

Early descriptions of paroxysms of facial pain reminiscent of the modern conception of trigeminal neuralgia can be found in the works of Aretaeus of Cappadocia in the first century CE, Galen in the second, and Avicenna in the eleventh.[1,2] Although many of these descriptions may resemble toothache, dental caries were relatively rare in those times, and so the connection to trigeminal neuralgia is more plausible.[3] In a letter dated 1677, John Locke, the well-known empiricist philosopher and physician, gave one of the first detailed accounts of a case of trigeminal neuralgia in his patient, the Countess of Northumberland.[4] He described clearly certain features which today are considered classical for this disease: the sudden onset and offset of painful spasms confined to one side of the face, and the characteristic triggering of these symptoms by touch or facial movements.

The label *tic douloureaux* was first applied nearly a century later by Nicolas André,[5] though in retrospect only two of his five cases are likely to have been suffering from trigeminal neuralgia. Shortly thereafter, in 1773, John Fothergill presented a paper to the Medical Society of London entitled, "On a Painful Affliction of the Face." As did Locke before him, he described the key components of true trigeminal neuralgia, including short duration, intensely painful spells occurring at irregular intervals, and elicitation of these symptoms by touch to or motion of the face. His grandnephew, Samuel Fothergill, accurately identified the source of these symptoms as the trigeminal nerve, from whence trigeminal neuralgia was referred to as "Fothergill's Disease."[2]

At that time, the repertoire of available medicines was limited; opium and hemlock extracts were given to patients with inconsistent results. The need for better therapies led to the development of operative strategies. Neurectomy, or the sectioning of peripheral nerves, was the early procedure of choice.[6] However, once it became clear that peripheral nerve lesioning was rarely permanently successful, surgeons devised more invasive methods targeting the trigeminal, or the "Gasserian," ganglion itself for resection or destruction. William Rose[7] developed a procedure in which he approached the trigeminal ganglion by removing the overlying maxilla. As noted by Harvey Cushing,[8] the decision by patients to electively undergo such a disfiguring procedure spoke to the severity of the affliction. In the 1890s, Fedor Krause and Frank Hartley independently developed a transcranial (as opposed to transfacial) procedure for resecting the trigeminal ganglion, which was later adopted by W. W. Keen and refined by Harvey Cushing.[8,9] These operations, in contrast to the retromastoid route in use today, utilized a temporal approach. Before Cushing, uncontrolled bleeding was common, often requiring multiple operative attempts over several days with intervening periods of tamponade, and occasionally necessitating ligation of the carotid artery.[8] Mortality rates often approached 20%. Cushing's technique improved the safety of ganglionectomy substantially, though patients were nevertheless left with sensory loss.

Walter Dandy,[10] in 1925, described a more selective, retromastoid procedure which involved severing only a certain subgroup of the trigeminal nerve roots. This procedure had the advantage of reducing pain while preserving touch. Importantly, based upon his observations across 215 cases, he came to believe that vascular compression of the trigeminal nerve (most often by the superior cerebellar artery, but occasionally by veins) may represent the primary pathophysiology of trigeminal neuralgia.[11] Vilhelm Magnus,[12] a Norwegian surgeon, had made a similar observation in one case (in which a carotid artery aneurysm impinged upon the trigeminal ganglion) in 1927, but Dandy was perhaps the first to suggest that vascular compression was indeed a systematic cause of this disease. Nevertheless, it was not until 1959 that W. James Gardner published the first series of vascular decompression surgeries for trigeminal neuralgia.[13]

Although Gardner reported a 62% success rate (defined as a complete alleviation of pain without recurrence during the follow-up period, which was up to 6 years), just over a quarter of his 200 patients suffered from postoperative sensory loss. Given this and the other risks of surgery, as well as the development of more effective medical therapies, decompressive surgery fell out of favor, giving way to percutaneous ablative methods, which became the last resort of choice.[14]

Recently, microvascular decompression (MVD) has regained prominence as a first-line surgical intervention in those who have failed medical therapy and who are relatively younger, whereas the percutaneous methods are reserved for older or less healthy patients.[15] In addition, the option of radiosurgery has been increasingly utilized. More discussion about these issues is presented below.

PRESENTATION

Typical trigeminal neuralgia is characterized by the following features:

- Paroxysms of pain lasting a few seconds to at most a few minutes
- The pain is intense and usually described as sharp, stabbing, or electrical in nature
- The pain is often precipitated by tactile stimuli to specific and consistent trigger zones or by specific actions (such as chewing or talking)
- Unilateral or asynchronously bilateral
- Involves the V2 > V3 > V1 branches of the trigeminal nerve and does *not* extend behind the ear or into the neck
- If the V1 and V3 branches are affected, so will V2
- Subjective numbness is usually minimal or absent (though it may be a sequela of prior nonmedical treatment)
- The pattern of pain and its manner of elicitation is consistent within an individual, though it may evolve slowly
- Focal neurologic deficits are absent in classic trigeminal neuralgia, though typical symptoms may be elicited by lesions which are also associated with other neurologic findings
- Trigeminal neuralgia may coexist with glossopharyngeal neuralgia, in which case both etiologies require treatment to achieve pain relief

Trigeminal neuralgia typically presents in patients in their late 50s, and is slightly more prevalent in females[16,17]; the bouts of pain may become more frequent with increasing age, and a constant, background pain may appear and slowly worsen.[18] The incidence of trigeminal neuralgia is estimated to be about 3 to 5 persons per 100,000.[16] Risk factors are pre-existing contralateral trigeminal neuralgia and hypertension.[16] Apparent familial forms of this disease have been reported but are very rare.[19,20]

If the pain is described as "throbbing" or "aching" and is associated with a sensation of facial pressure or swelling, the diagnosis is more likely "atypical facial pain."[21] The absence of trigger zones and precipitating actions is characteristic, and subjective numbness may be prominent. This type of pain more often occurs in relatively younger females (<45 years of age), may coexist with a diagnosis of fibromyalgia, and often is associated with psychiatric and social disturbances such as depression, narcotic dependence, and inability to work.

ANATOMY AND PATHOPHYSIOLOGY

The etiology in most cases of trigeminal neuralgia is attributed primarily to compression of the trigeminal nerve by an artery (usually a superior cerebellar artery [SCA]), though in a minority of cases the compressing structure may be a vein.[11,22–24] Other arteries that occasionally seem to compress the nerve, in decreasing order of frequency, are the anterior inferior cerebellar artery, vertebral artery, posterior inferior cerebellar artery, and the basilar artery.[25]

The mechanism by which the pressure of a vascular structure impinging upon a nerve causes injury is likely to be demyelination, at least in part.[26–28] In particular, the root entry zone (REZ), where central oligodendrocytes rather than peripheral Schwann cells give rise to the myelin sheath, is often implicated as being the most vulnerable region of the nerve. Often, the length of the REZ is estimated to be about one-fourth to one-third of the distance along the nerve from its junction with the pons to its exit into Meckel's cave (the "cisternal" portion of the nerve). On histologic examination, this distance averages about 2.5 millimeters and represents usually less than 25% of the total length of the cisternal segment of the trigeminal nerve.[29] The observation that relieving vascular compression more distally along the nerve nevertheless results in the alleviation of pain may reflect abnormalities of the REZ which have been visualized in such cases[30]; these abnormalities may be a result of transmitted mechanical forces to the REZ from the site of distal compression. Therefore, a finding of distal rather than proximal compression of the trigeminal nerve is not generally regarded as a contraindication to decompression, and outcomes after decompressive surgery for distal sites of neurovascular contact do not differ significantly from cases with proximal pathology.[24]

The loss of myelin results in abnormally close apposition of neighboring axons without their proper insulation. Such a situation makes possible the phenomenon of "ephaptic" transmission,

whereby action potentials traveling along one axon induce action potentials in neighboring axons.[31,32] Therefore, action potentials within nerve fibers transmitting touch could, through this sort of cross-talk, generate activity in nearby fibers mediating pain.[33] Compounding this, trigeminal nerve injury and associated focal demyelination may lead to the production of ectopic action potentials,[34] further contributing to a sensation of pain.

However, if demyelination is the source of the pathology, how does decompressive surgery result in the often immediate cessation of pain? Two factors are thought to account for this. First, ephaptic conduction may be less effective when a compressive force is removed, allowing relatively more distance between axons. Second, mechanical compression alone can result in the ectopic generation of action potentials, so decompression may reduce the rate of spontaneous, aberrant activity.[35] A third factor, which has an unknown influence on the generation of pain but is likely also an immediate result of nerve decompression, is the release of mechanical conduction block, particularly in larger axons.[33] That some patients have a slower time-course of recovery after decompressive surgery likely reflects a relatively greater contribution of certain more slowly reversible factors over other immediately reversible factors in the etiology of their particular manifestations of the disease.

IMAGING

Imaging is performed in cases of suspected trigeminal neuralgia primarily to rule out multiple sclerosis and cerebello-pontine angle tumors and to assess for vascular malformations and aneurysms. Any of these lesions can mimic the symptoms of trigeminal neuralgia if they result in pressure on the nerve. Suspicion for one of these types of lesions should be especially high when focal neurologic deficits are found on physical exam.

Recently, advances in magnetic resonance (MR) imaging techniques have allowed the possibility that the primary pathology of trigeminal neuralgia, vascular compression, may be visible, thereby confirming the diagnosis. MR angiography (MRA) can demonstrate the presence of relatively larger arteries at the origin of the trigeminal nerve near the pons (Fig. 103.1). One study found that preoperative MRA was accurate in predicting operative findings in 18 of 21 consecutive cases of trigeminal neuralgia.[36] The three cases in which the offending vessel was not visualized included two petrosal veins and a smaller SCA.

In addition to MRA, constructive-interference steady state (CISS, pronounced "kiss") sequences may be useful because of their ability to show cranial nerves in high resolution and with good contrast. These images may suggest direct contact between the nerve and a vascular structure, as well as demonstrate "kinking" of the nerve (Fig. 103.2). A study examining the relationship between neurovascular proximity on CISS sequences and subsequent radiosurgery found that those with MRA evidence of direct contact had a significantly greater likelihood of responding to radiosurgery.[37] However, other groups are less certain of the relationship between perceived neurovascular contact and symptomatology.[38] Whether these differences are due to different imaging parameters or to differences in image interpretation remains to be clarified.

Another MR technique, diffusion tensor imaging (DTI) has been used to examine demyelinating diseases by measuring the fractional anisotropy (FA) of affected brain tissue. In essence, this technique measures the relative diffusibility of water along different dimensions; the presence of myelin restricts diffusion preferentially in the direction orthogonal to the length of nerve, thereby increasing anisotropy. Because vascular compression may promote a similar end-point, namely a decrease in the integrity of the nerve sheath, DTI has been proposed as a method to corroborate nerve damage in trigeminal neuralgia and other compressive cranial neuropathies by assessing for a decreased FA. So far, however, the sensitivity of this technique[39] is not adequate to recommend this imaging modality for the diagnosis of trigeminal neuralgia.

MEDICAL THERAPY

Anticonvulsant medications are a staple in the medical management of trigeminal neuralgia. Carbamazepine, phenytoin, and lamotrigine are known to be effective, while valproate, gabapentin, and benzodiazepines (among others) have less evidence to support their efficacy, though they may hold promise.[40] Antiepileptic medications such as carbamazepine and phenytoin work, in part, by selectively blocking high-frequency neuronal activity, which in the case of trigeminal neuralgia may limit the degree of ectopic firing.

Based upon current evidence,[41] carbamazepine is considered the first-line therapy. Lamotrigine and baclofen can be added if the pain is still uncontrolled. Oxcarbazine, a derivative of carbamazepine, may be substituted for carbamazepine if the latter is not well-tolerated.

Over time, the efficacy of these medications tends to wane.[42] If the pain becomes refractory to medications, or if the side effects of the medications are intolerable, referral to a surgeon or radiation oncologist is warranted. While MVD is the criterion standard, it is invasive and so requires a healthy and willing patient.

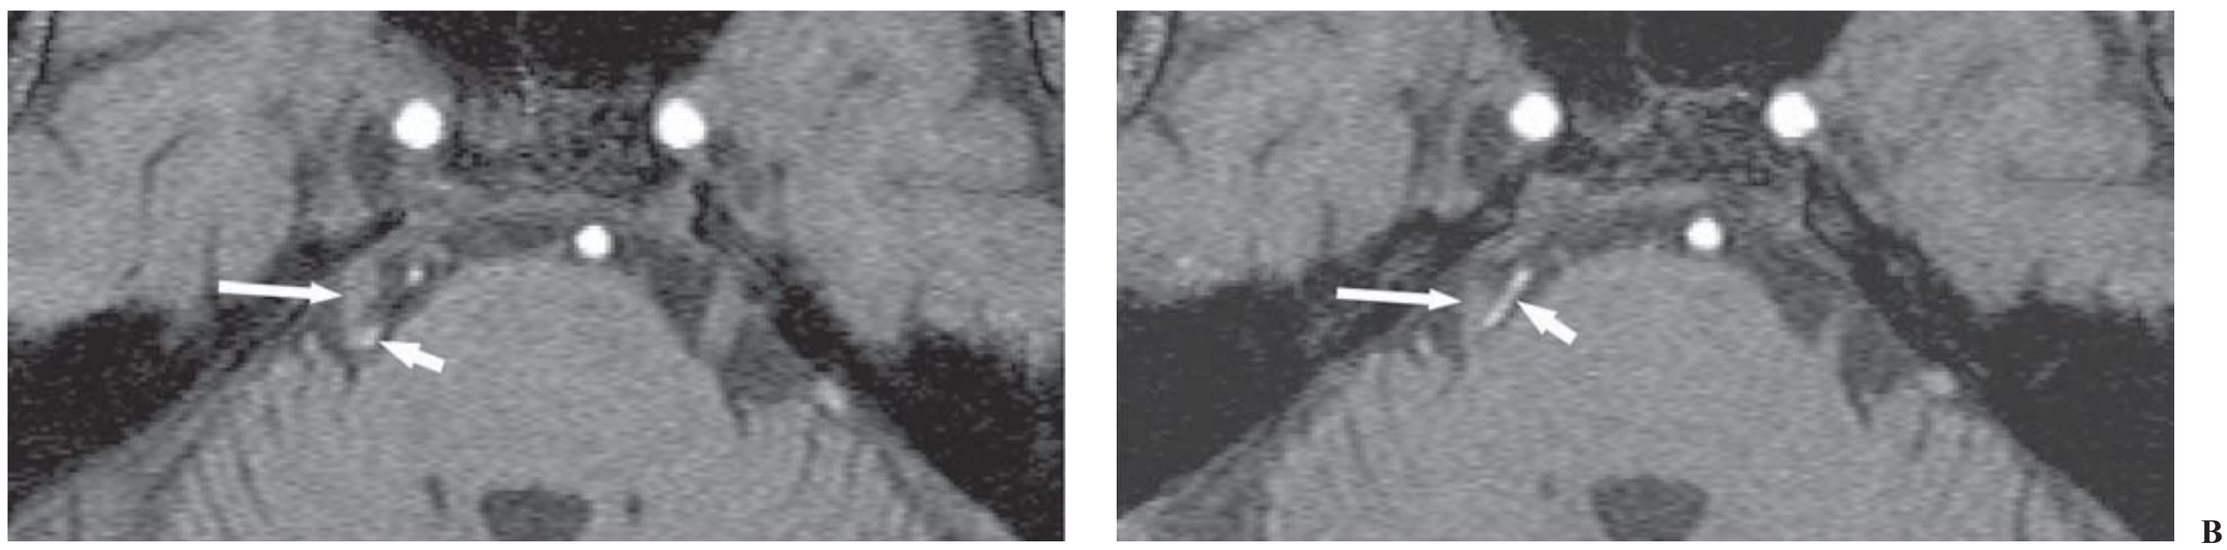

FIGURE 103.1 Images in a 63-year-old man with trigeminal neuralgia, with neurovascular compression caused by the superior cerebellar artery. Two adjacent transverse MRA images **(A,B)** (39/6.5, 20 degrees flip angle) show that the superior cerebellar artery (*short arrow*) has compressed the right trigeminal nerve (*long arrow*) at the medial site. (Reproduced with permission from Yoshino N, Akimoto H, Yamada I, et al. Trigeminal neuralgia: evaluation of neuralgic manifestation and site of neurovascular compression with 3D CISS MR imaging and MR angiography. *Radiology* 2003;228(2):539–545.)

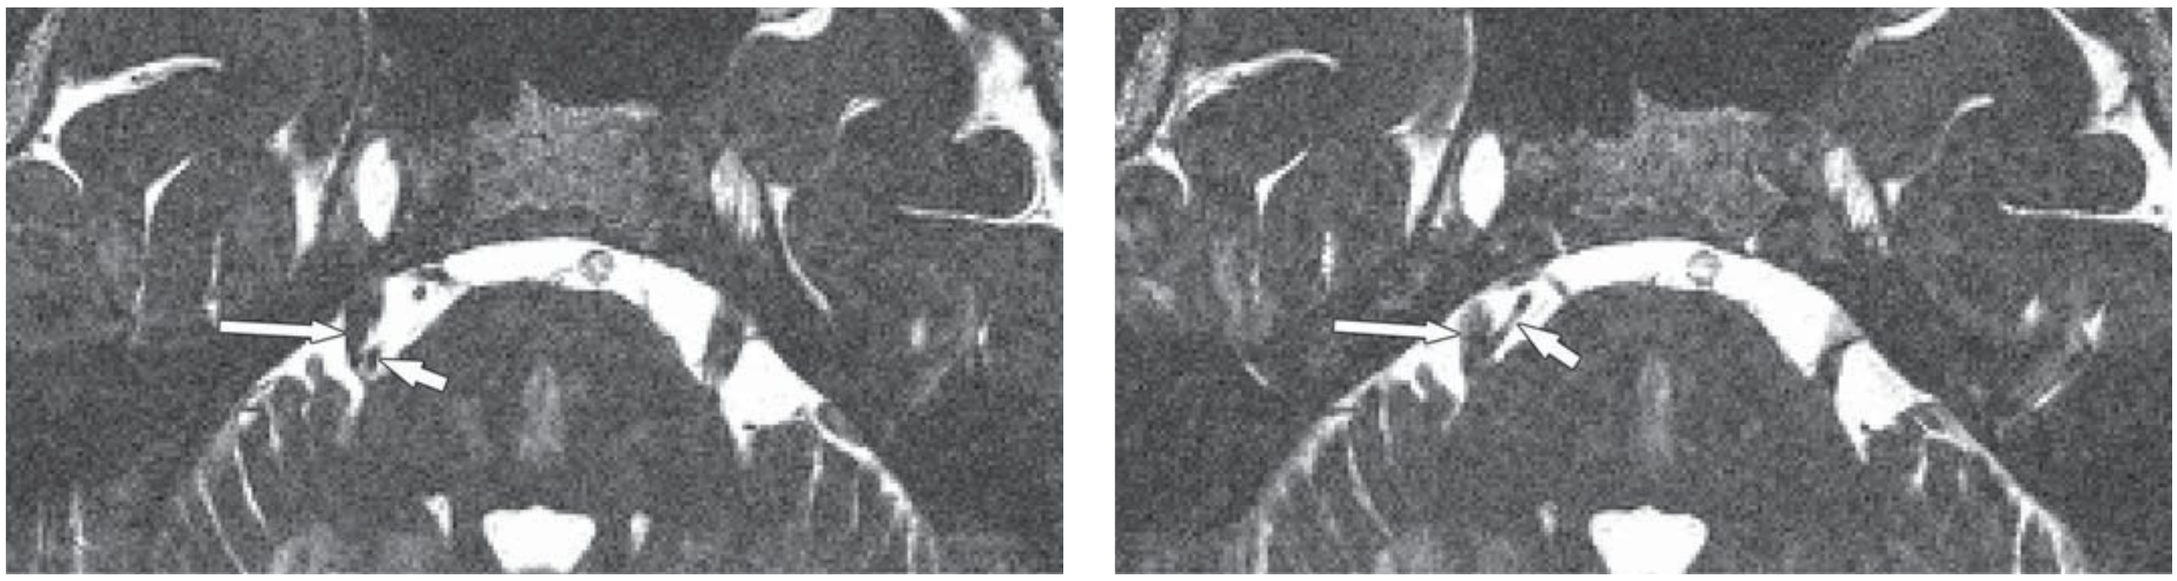

FIGURE 103.2 Images in a 63-year-old man with trigeminal neuralgia, with neurovascular compression caused by the superior cerebellar artery. Two adjacent transverse three-dimensional CISS MR images **(A,B)** (12.25/5.9, 70 degrees flip angle) show that the superior cerebellar artery (*short arrow*) has compressed the REZ of the right trigeminal nerve (*long arrow*) at the medial site. (Reproduced with permission from Yoshino N, Akimoto H, Yamada I, et al. Trigeminal neuralgia: evaluation of neuralgic manifestation and site of neurovascular compression with 3D CISS MR imaging and MR angiography. *Radiology* 2003;228(2):539–545.)

Less invasive options are available, though their efficacies fall short of the long-term, pain-free ideal often achievable with MVD.

MICROVASCULAR DECOMPRESSION SURGERY

MVD is a procedure in which the compressing artery or vein is mobilized away from the nerve. In the case of trigeminal neuralgia, a retrosigmoid craniotomy is performed in order to expose the cisternal portion of the trigeminal nerve, which extends from the pons to the entrance of Meckel's Cave. The patient may be placed in a prone, lateral decubitus, supine and head-tilted, or sitting position, depending on the experience and preference of the surgeon. A short linear or curvilinear incision is made behind the mastoid process such that a small (about 2.5 cm diameter) craniectomy may be performed within the angle of the junction of the sigmoid and transverse sinuses. In order to minimize retraction yet allow proper visualization of the nerve, cerebrospinal fluid is drained from the cisterna magna, thereby relaxing the cerebellum; aggressive retraction can cause potentially serious complications (e.g., venous occlusion, stroke). In addition, auditory evoked potentials can be monitored in order detect early signs of excessive brainstem manipulation or cerebellar retraction.[43]

Once the nerve is exposed, the offending vessel is usually apparent. If so, carefully separating the nerve from this vessel generally requires gentle, blunt spreading with occasional sharp scissoring to break the arachnoid sheets and strands which connect them. A small piece of Teflon may then be interposed between the nerve and vessel to prevent spontaneous reattachment. Rarely, in cases where the problematic vessel was long and ectatic, some surgeons have employed a fenestrated aneurysm clip closed around this vessel and then sutured to the dura, as a means to separate the two structures.[44]

If no compressing vessel is found, some surgeons have advocated dissecting away the possibly thickened arachnoid around the nerve, perhaps placing a small piece of Teflon between the nerve and brainstem, and creating mild neurapraxia by gently squeezing the trigeminal nerve between the tips of the bipolar cautery.[45] At least one group has suggested that the use of a rigid endoscope (tilted at 30 degrees, in their case) may increase the prospect of detecting a compressing vessel.[46]

Overall, MVD has excellent success rates. In one landmark study, nearly three-quarters of patients undergoing MVD were pain-free and off medication after 5 years, and about two-thirds of those followed for 20 years were still pain-free without medication.[25] Comparable results on long-term pain-free outcomes have been reported by others.[47,48] Despite the initial costs associated with an inpatient neurosurgical procedure, MVD is nevertheless the most cost-effective therapy when considered in light of these long-term benefits.[49] The comparative effectiveness of MVD and percutaneous techniques for treatment of trigeminal neuralgia is shown in Table 103-1.

Several factors are predictive of a good outcome, namely immediate relief of pain postoperatively, male sex, arterial rather than venous compression (at the REZ), and relatively shorter duration of symptoms preoperatively (<8 years).[25,50] In addition, as is the case with other complex surgical procedures, the safety of MVD is dependent to a significant extent on the experience of the surgeon (and the institution at which the procedure is performed); the rates of neurologic complications including stroke, hemorrhage, facial weakness, and the need for ventriculostomy were higher among low-volume surgeons.[51]

The recurrence of facial pain after MVD has been attributed to recurrent vascular compression as well as perhaps granuloma formation around the Teflon[52]; one study found that five of ten MVD reoperations led to the discovery of this condition.[53] The particular techniques best suited to avoid this complication are still a matter of speculation.

RADIOSURGERY

Radiosurgery and its potential for the treatment of a multitude of neurologic disorders have attracted increasing attention over the past several years, though the first radiosurgical procedure for trigeminal neuralgia occurred as far back as 1951.[54] The prospect of a noninvasive and (hopefully) one-time treatment for the affliction of trigeminal neuralgia has obvious appeal to those who suffer from inadequate medical control or unacceptable medication side effects. In general, those who are not satisfied with medical therapy and who refuse or fail MVD (or cannot safely undergo general anesthesia) may be candidates for radiosurgery.

The technical goal of radiosurgery is to impart a focused dose of radiation to the trigeminal nerve or ganglion in such a manner as to create a functional lesion of the pain-mediating structure. The source of radiation is either a gamma knife or a stereotactic radiosurgery system. A gamma knife uses 201 fixed radiation sources that are placed at the ends of collimators which, arranged in a hemisphere, target their energy to a single focal point. Stereotactic radiosurgery systems, by contrast, use a linear accelerator to generate high-energy particles that are then delivered through

TABLE 103.1

RESULTS OF PERCUTANEOUS TECHNIQUES AND POSTERIOR FOSSA EXPLORATION FOR PATIENTS TREATED FOR TRIGEMINAL NEURALGIA

	Patients (%)				
	Percutaneous Techniques			Posterior Fossa Exploration	
	Radiofrequency Rhizotomy (n = 6205)	Glycerol Rhizotomy (n = 1217)	Balloon Compression (n = 759)	Microvascular Decompression (n = 1417)	Partial Trigeminal Rhizotomy (n = 250)

*Combined values for microvascular decompression and partial trigeminal rhizotomy.
(Adapted from Taha JM, Tew JM Jr. Comparison of surgical treatments for trigeminal neuralgia: reevaluation of radiofrequency rhizotomy. *Neurosurgery* 1996;38(5):865–871.)

a single source that rotates around the focal point. Both types of radiosurgery have been applied to the treatment of trigeminal neuralgia, and neither appears to hold a significant advantage over the other in terms of efficacy.

The exact target of radiosurgery for trigeminal neuralgia has evolved over time.[55] Currently, the REZ of the trigeminal nerve is considered to be the site which yields the best pain relief.[56,57] Delivering an additional dose to the cisternal portion of the nerve yielded more numbness, but no difference in pain alleviation.[58,59] Similarly, a meta-analysis of recent studies shows that higher doses, while yielding better pain relief, are also associated with increased numbness.[55]

Though radiosurgery does offer the clear benefit of some pain-relief, its application is limited by three main factors: (1) delayed onset of pain-relief; (2) lack of complete pain relief; and (3) poor long-term efficacy.

Radiosurgery has a delayed onset of effect in most patients. One study showed that about 20% of patients responded immediately, but 30 days elapsed before 80% of patients were pain-free. This may be too long for a small number of patients in the midst of a pain crisis, and who therefore require more immediate results.

The lack of consistent, complete, long-term pain relief is a shortcoming which radiosurgery shares with all of the ablative (nondecompressive) techniques. While some initial pain relief is reported by the vast majority of those undergoing these procedures,[60] the percentage of those who are truly pain-free appears to be significantly lower.[61,62] Importantly, the percentage of those who are pain-free and off medications 2 years after radiosurgery has been reported to be 16%,[61] 30%,[63] 50%,[64] ~58%,[65] and just under 60%.[60] In all except the last of these studies, a longer follow-up interval beyond 2 years resulted in finding an increasing proportion of patients relapsing into pain.

Those whose pain is not relieved by radiosurgery are still candidates for MVD. One group reported on six patients who had previously undergone one or two rounds of radiosurgery and then elected to undergo open decompression.[66] They found that prior irradiation did not technically hamper the operation and that five of these six patients were subsequently pain-free and off medication at last follow-up (about 2 years on average).

PERCUTANEOUS PROCEDURES

A variety of percutaneous options exist for the treatment of trigeminal neuralgia. These procedures typically have the goal of ablating the trigeminal ganglion in order to relieve pain. In general, the degree to which these procedures relieve pain is directly related to the degree of sensory loss observed,[67] reflecting the nonselective methods employed. While immediate pain relief is typical and its frequency may be comparable to that of MVD,[68] the long-term success of these procedures is limited; a meta-analysis of these procedures found that more than 1 in 3 patients will have a recurrence of pain within 3 years, and more time generally yields more recurrurences.[69] Nevertheless, these procedures have a role in the operative management of trigeminal neuralgia because the minimally invasive, outpatient nature of the operation makes it suitable for patients who are either unwilling or unable to undergo a craniotomy (i.e., MVD).[15]

The mechanism of ablation is usually radiofrequency thermocoagulation, glycerol rhizolysis, or balloon compression. No single method has been convincingly demonstrated to out-perform the others in terms of either initial pain relief or length of effect.[69] Therefore, the method selected is determined by the experience and comfort of the surgeon. Only one of these procedures (balloon compression) is usually performed under general anesthesia, and all are performed in a day-surgery (outpatient) setting. For radiofrequency gangliolysis and glycerol rhizolysis, a combination of mild to moderate sedation and local anesthesia is employed. In all cases, fluoroscopy is used to guide a needle through the foramen ovale to the trigeminal ganglion (Fig. 103.3). The

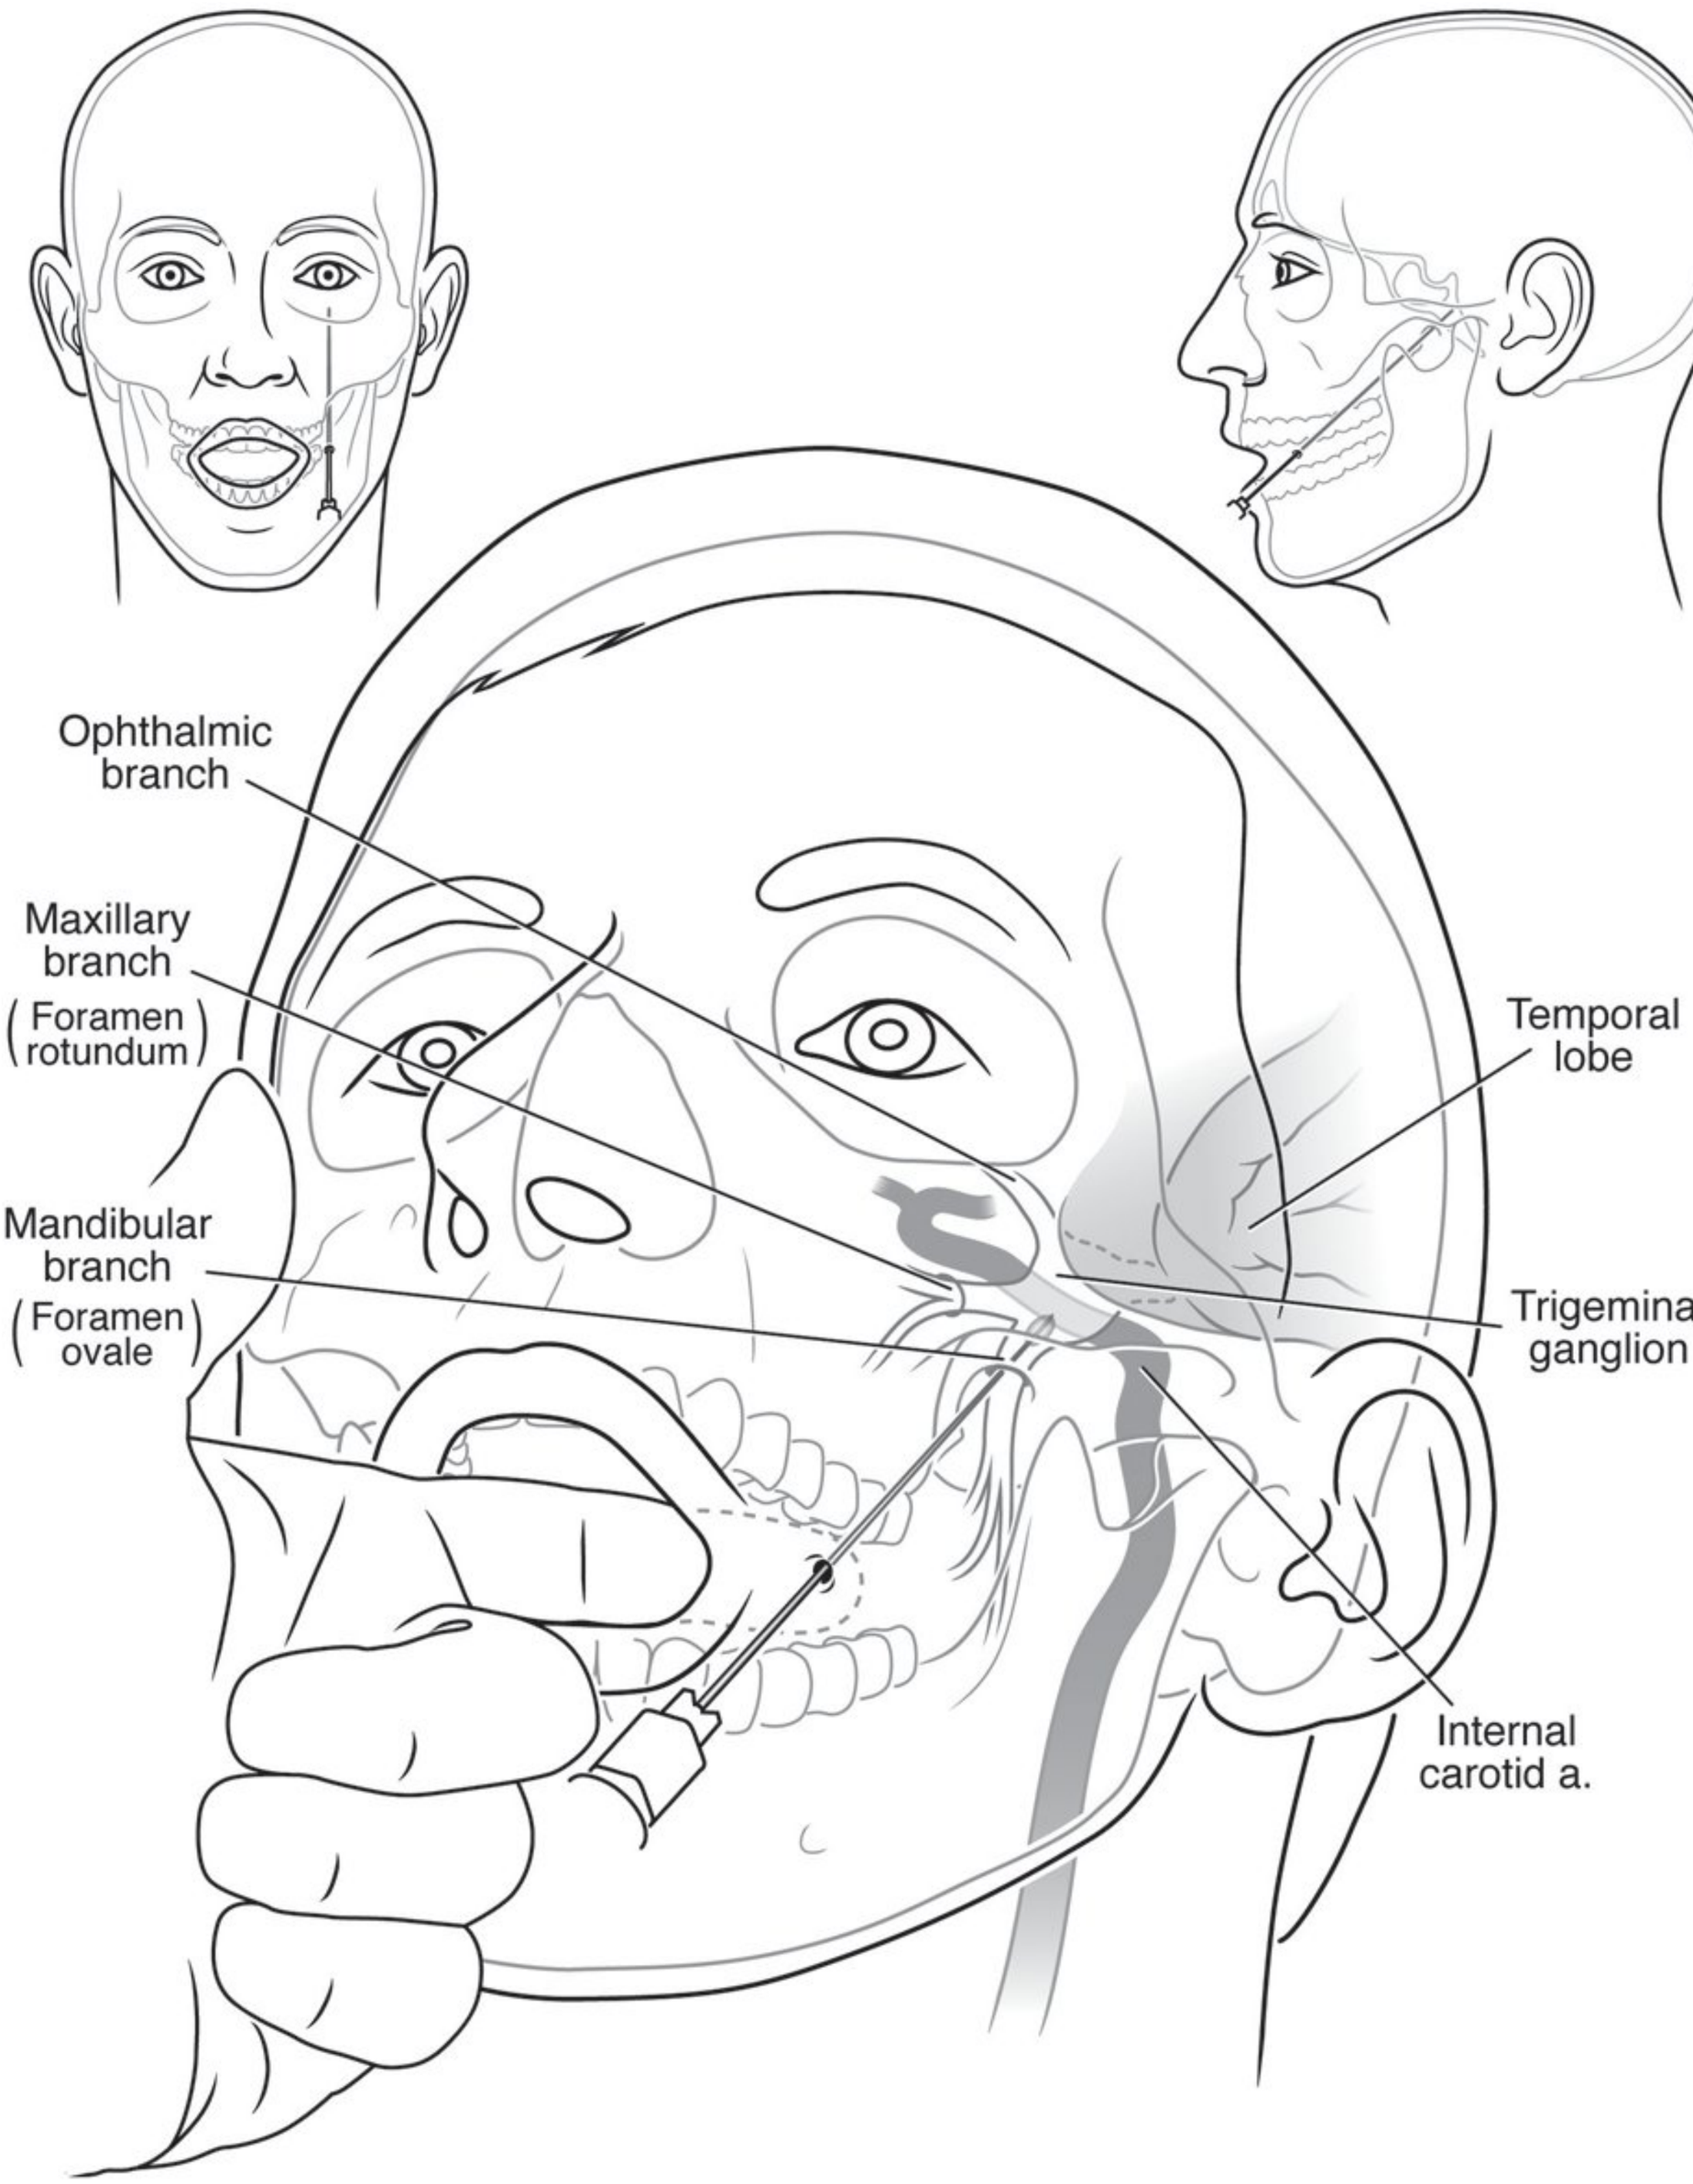

FIGURE 103.3 Radiofrequency treatment of the trigeminal ganglion. The radiofrequency cannula is inserted just lateral to the lateral margin of the lips and advanced medial to the mandible and lateral to the oral mucosa. The index finger of the operator is placed in the patient's mouth to ensure that the tip of the cannula does not penetrate the oral mucosa en route to the foramen ovale. Note the close proximity of the carotid artery, the temporal lobe, and the brainstem to the final position of the cannula. **(Insets)** The proper trajectory of the needle and final needle position are shown in the frontal and axial planes. (Redrawn with permission from Rathmell JP, Borgoy J. Complications associated with radiofrequency treatment for chronic pain. Neal JM, Rathmell JP (eds). Complications in regional anesthesia and pain medicine. Elsevier, Philadelphia; 2007; Figure 29-2, p. 292.)

entry point for the needle should be about 2.5 cm lateral to the angle of the mouth and about 1 cm inferior to the occlusal plane formed by the opposed teeth. The three main branches of the trigeminal nerve are arranged somatotopically such that V1 fibers are the most medial and superior and V3 fibers are the most lateral and inferior. This arrangement means that V3 fibers are encountered first upon entering Meckel's Cave through the foramen ovale and the subsequent divisions are encountered at about 5 mm intervals; as a general guide, on a lateral radiograph, V3 fibers should be encountered at about 5 mm proximal to the clival plane.[70] Advancing more than 7 mm beyond the clival plane may damage the abducens nerve.[71]

Radiofrequency thermocoagulation, or percutaneous radiofrequency trigeminal gangliolysis, replaced electrocoagulation in the 1970s because it allowed a greater degree of control over the heat generated and therefore the size of the lesion.[72] Once the target is located and entered, a temperature of 75° to 85° Celsius for 60 to 90 seconds is used to create the lesion. Short-duration, ~40° stimulation is often first delivered as a test to confirm the correct probe positioning. Because the generation of the lesion can be very painful and result in a profound vagal response, atropine or glycopyrrolate should be on hand to respond to potentially significant drops in heart rate and blood pressure.

Glycerol rhizolysis, meanwhile, entails the injection of a small amount (typically 0.3 mL) of anhydrous glycerol into the cisternal space just posterior to the ganglion[73]; glycerol produces a dose-dependent conduction blockade, inhibiting transmission through C-fibers at lower doses than A-fibers.[74] To aide localization, the same injection needle can be used first to inject contrast, filling the cistern in order to outline the trigeminal ganglion. After the procedure, the patient must remain seated with his or her head tilted forward for about 2 hours in order to minimize the leakage of any excess glycerol toward the brainstem; some have suggested that altering head tilt might bias the lesion toward a particular division. However, because this procedure relies on the use of a fluid which may track through spaces and along nerves and vessels, preferential targeting of individual trigeminal divisions may be difficult to obtain, especially in inexperienced hands.

Balloon compression is a variation of older techniques that applied mechanical force to the trigeminal ganglion in order to produce a functional lesion.[75,76] This technique has been advocated as the preferred method for V1 ablation. Because severe bradycardia and hypotension may follow balloon inflation, general anesthesia is usually employed. The balloon opening pressure may be monitored, and higher values are reported inside Meckel's Cave (~300 cm Hg) as compared with more proximally outside the foramen ovale or more distally into the posterior fossa.[77] The balloon is inflated by the injection of 0.5 to 2.0 mL of radiocontrast, and the visualization of a "pear-shape" formed by the balloon (on lateral radiographs) within trigeminal cistern is typically described.

All ablative techniques (including radiosurgery) entail the possible complication of anesthesia dolorosa (though with radiosurgery the frequency may be less). There are no truly adequate medical therapies for this dreaded condition. Attempted surgical remedies have over the years included a wide variety of procedures from cingulotomy to thalamotomy to REZ lesioning to motor cortex stimulators; the best is yet to be definitively shown.

OTHER PROCEDURES

The ability of subdermal injections of botulinum toxin to achieve adequate, though very temporary (2 to 4 months), relief from the pain of trigeminal neuralgia has been reported.[78,79] Multiple injections are made into the area of pain, and the analgesic effect is observed within 10 to 20 days. Because botulinum toxin has neuromuscular blocking effects as well as antinociceptive effects, many patients will experience some degree of motor palsy. Thus, while this approach has the advantage of being perhaps the least invasive of the nonmedical options (with the exception of radiosurgery), its disadvantages include short duration of effect and facial weakness.

An even more transient analgesic effect (only about 4 hours) has been reported for the use of intranasal lidocaine spray for second division (V2) trigeminal neuralgia.[80] This strategy succeeds because V2 passes through the sphenopalatine ganglion just behind the middle turbinate. The success of this approach may open the door to longer-lasting medications delivered in the same manner, though its utilization may be limited to the relatively fewer number of patients whose symptoms are restricted to V2.

CONCLUSION

MVD is currently the preferred mode of treatment for medication-refractory patients with typical trigeminal neuralgia and who are able to tolerate a craniotomy. Most patients are pain-free for decades following this procedure. When performed by an experienced surgeon at a capable institution, the risks are relatively low and the treatment will be cost-effective over the long-term. Percutaneous procedures and radiosurgery are preferable for those who may be older or who have significant comorbidities that increase the risk of open surgery under general anesthesia.

CHAPTER 104 ■ ABLATIVE NEUROSURGICAL PROCEDURES FOR CHRONIC PAIN

DONALD C. SHIELDS AND EMAD N. ESKANDAR

INTRODUCTION

Chronic pain management often requires pharmacological and/or surgical approaches for effective symptomatic relief. Neurosurgical interventions have become more efficacious as pain transmission pathways are better understood. In most instances, pharmacological therapies are attempted initially, but invasive approaches are subsequently considered, with appropriate patient selection, if other options are exhausted. Surgical options include anatomic, neuroaugmentative, and ablative approaches which are tailored to the patient's specific needs and comorbidities. Anatomic procedures are designed to alleviate or modify the structural source of pain such as performed in microdiscectomies, laminectomies, or instrumented fusion procedures for metastatic spine disease. Neuroaugmentative techniques include the use of high frequency stimulation or placement of local analgesic administration devices for symptomatic relief. However, in specific patients for whom sequelae such as numbness are acceptable, ablative procedures can be considered in order to interrupt pain signal transmission. Some ablative procedures such as cordotomy have provided initial pain relief with subsequent reemergence of a deafferentation pain. Thus, ablative procedures are often reserved for patients with shortened life expectancies, while more reversible anatomic/neuroaugmentative methods are considered initially in chronic pain patients who require surgical intervention. In recent years, with the emergence of improved pharmacological therapies and high frequency stimulation, the use of stereotactic lesioning for pain has declined considerably. Medial thalamotomy and anterior cingulotomy procedures remain in use by many functional neurosurgeons while mesencephalic tractotomy, trigeminal tractotomy, and hypophysectomy may be occasionally employed by some practitioners.

POSTCENTRAL GYRECTOMY

Resection of sensory cortex was attempted in the 1930s and 1940s for patients with intractable pain.[1,2] Since lateral thalamic nuclei related to spinothalamic tract inputs project directly to primary and secondary sensory cortices, portions of Brodmann's areas 1, 2, and 3 were excised. Procedures performed under local anesthetic for intraoperative cortical mapping resulted in fewer unexpected postoperative deficits. Relatively large craniotomies were required for exposure of the primary motor and sensory cortices. Results from these procedures often demonstrated initial pain relief, but a relapse of the original symptoms upon long-term follow-up.[3] More extensive resections including the postcentral and corresponding precentral gyri resulted in significant pain relief; however, insufficient data is available for a complete assessment of these procedures.[4] As precise sensory and motor functions among different patients vary in these gyri, the resection of cortical grey matter has not emerged as a practical method for pain relief due to the potential for postoperative functional deficits.

CINGULOTOMY

Cingulotomy remains an intracranial ablative procedure in relatively common use. Originally developed to avoid the neurocognitive complications related to frontal lobotomy, anterior cingulotomies have been devised for multiple conditions with generally safe, but variable symptomatic results. Since the 1950s, anterior cingulotomies have been performed in patients with obsessive compulsive disorder, anxiety, depression, chronic pain, and, more recently, acute cancer pain.[5–12] In 1962, Foltz and White employed this technique to uncouple the noxious component of pain from cortical integration.[9] The later anterior bilateral stereotactic "cingulumotomy" was reported in patients with "psychogenic," "organic," or cancer-related pain.[13] With a reported follow-up period from 1 to 9 years, approximately two-thirds of patients with chronic "organic" pain demonstrated significant improvement (Table 104.1). Many lesions (0.2 cm in diameter) were placed 1 to 3 cm posterior to the genu of the corpus callosum.[9,14] Subsequent radiofrequency generated cingulate lesions were reported by Pillay and Hassenbusch with magnetic resonance imaging guidance.[12,15] Favorable results were reported in these studies in patients with chronic pain and Dejerine-Roussy syndrome.

Anatomy and Physiology

The anterior cingulate cortex is a mesocortical structure with crucial roles in affective experience and emotional expression (Fig. 104.1). With multiple connections to limbic structures, nucleus accumbens, thalamus, septum, basal ganglia, and other cortical structures, the anterior cingulate region has been implicated in motor response selection, attention, error detection, and emotional responses.[16–19] Various animal studies have demonstrated the production of complex motor behaviors, vocalization, and

autonomic responses with cingulate stimulation, although lesions in this area result in impaired problem solving skills and blunted reward responses.[20–26] Human studies have suggested nociceptive stimuli are involved in activation of bilateral anterior cingulate gyri.[27–32] Cutaneous laser stimulation evokes both pain and cerebral potentials although contralateral potentials are more robust than those of the ipsilateral anterior cingulate.[33] Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies suggest that cingulate activation is proportional to the demand for attentional focus and information processing.[34–38] Anterior cingulate activation was most pronounced when patients were required to inhibit competing responses or establish new stimulus–response associations. In studies of patients with bilateral anterior cingulotomies, changes in emotional experience with concomitant derangements in attentional functioning were evident. Focus, persistence, and executive function skills were impaired in tasks requiring sustained attention.[39] Thus, some investigators have proposed the anterior cingulate cortex participates in the integration of sensory inputs, motivational signals, and task demands—such that the subject's attention is focused on the most relevant stimuli for a specific task.[39] As such, the anterior cingulate may reinforce or sustain the perception of pain by amplifying the tendency of patients to emotionally respond to pain or associated inputs.[40,41] Many postcingulotomy patients continue to report pain; however, they are less concerned with or affected by it.

Techniques

Stereotactic frame application and target localization require attachment of the frame on the morning of surgery with subsequent computed tomography (CT) or MRI images prior to the surgical procedure. The frame is typically held in place by four pins tightened against the patient's skull under local anesthesia. After scanning, the projected target can be calculated directly from the imaging data and/or through assessment of the x, y, and z coordinates in relation to the patient's anterior commissure–posterior commissure (AC-PC) line. For the latter, the center point of the frame is compared to the Cartesian coordinates (x, y, and z) of the subject's anterior/posterior commissures and specific anatomical target. The AC and PC coordinates are entered into a computer program for adjustment of a preloaded Schaltenbrand-Wahren atlas by either shortening or elongating the preset AC-PC distance to accommodate that of the patient. Once adjusted, the projected target coordinates are determined. These coordinates can be compared with coordinates calculated from the MRI and averaged to arrive at the final projected target.

Stereotactic anterior cingulotomies may be performed with local or general anesthesia. MRI localization of the anterior cingulate target approximately 25 mm posterior to the anterior extent of the lateral ventricles is determined. Following attachment of the stereotactic frame to the operating room table, bilateral scalp incisions and burr holes are placed along, or slightly anterior to, the coronal suture 1.5 to 2 cm lateral to the midline. With the coordinates entered on the stereotactic frame, burr holes can be accurately positioned by passing the twist drill through the drill guides set on the frame.

Before the final lesion target is determined, many practitioners employ physiological localization via microelectrode recordings. This technique further confirms the correct target, as discrepancies can often exist between the projected target site from imaging data and that obtained via microelectrode recordings. To begin, a cannula is attached to the arc and aligned to the burr holes. After the cannula passes through the dural opening and into the brain, microelectrodes are inserted into the shaft of the cannula for recording. Many surgeons begin recording 10 to 25 mm above the projected target. Continuous extracellular recordings of single-unit and multiunit neuronal discharges are amplified, displayed on a monitor, and fed into an audio monitor. Neuronal firing/bursting patterns, action potential characteristics, quiet intervals, and background activity provide the surgeon valuable information about anatomical target localization in relation to the measured depth of the microelectrode. One to six electrode tracts, each separated by 2 mm, can be used for target localization. High-frequency stimulation at these sites may also provide information regarding nearby structures. For example, stimulation of lemniscal fibers often results in paresthesias, and that of the internal capsule can cause muscle contractions. Thus, with a

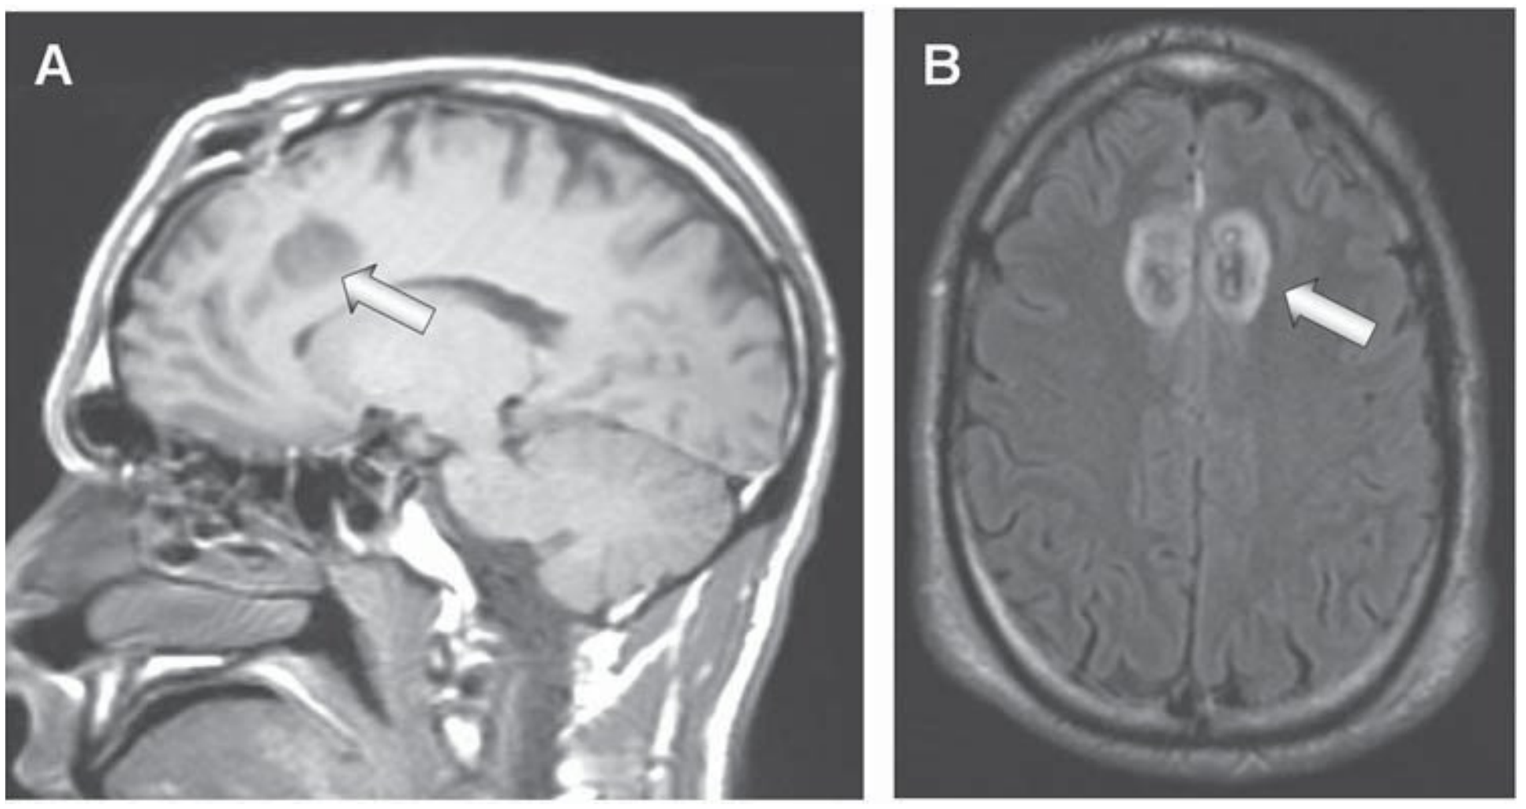

FIGURE 104.2 Representative postoperative ablative lesions. Sagittal **(A)** and axial **(B)** MR images of stereotactic anterior cingulotomy lesions (*arrows*). Three radiofrequency ablations were performed in each cingulate gyrus to form the lesions as shown.

combination of image guidance and physiological localization, lesion targets can often be established with considerable accuracy.

For anterior cingulotomies, lesions are usually positioned in the center of each cingulate gyrus in the medial-lateral plane using a 1 to 2 mm radiofrequency probe (10 mm exposed tip) inserted at the same trajectory as that of the microelectrode. The probe is connected to a radiofrequency generator which monitors tip temperature and electrode impedance during electrical current application. Each lesion can be created in approximately 60 seconds at 85°C. This minimally invasive technique enables the surgeon to reduce the risks of dural bleeding or significant brain shift secondary to cerebrospinal fluid loss. A postoperative MRI before removal of the stereotactic frame allows the surgeon to confirm lesion placement and rule out intracranial hemorrhage (Fig. 104.2).

Results

Patients have reported improvements in their pain scores following cingulotomies from 25% to 80% (average 49%).[10,14,42,43] However, questions remain regarding actual reduction of the sensation of pain or diminution of the patient's emotional and behavioral reactivity to pain.[40,41] In some instances, a bimodal pattern developed wherein patients with mild confusion did not complain of pain and discontinued their use of analgesics without noticeable withdrawal symptoms.[6] Over the ensuing weeks to months, some patients again noted similar but progressively improved pain symptoms as their confusion waned. Some investigators have suggested this alteration of the habituation process deterred patients from fixation on their pain following the procedure.[44]

Complications associated with cingulotomies have been highly variable, but are often self-limited and/or easily treated. Although often transient, seizure onset following this procedure has been reported between 0% to 50% in various series.[8,10,13,14,43,45] Urinary incontinence, short-term hypotension, hemiparesis, aphasia, disorientation, or hemiplegia following hemorrhage have also been described.[8,11–13,43] No operative deaths have been reported; however, postoperative suicide has occurred on occasion. Some series demonstrated improved Wechsler Adult Intelligence Scale scores following cingulotomies, but deficits in the nonverbal sequential tapping test were also observed.[42] Across more recent series, no significant long-term neurological or behavioral changes were reported following bilateral stereotactic cingulotomies.

PREFRONTAL LEUKOTOMY

Cingulotomy procedures were progressively adapted from frontal lobe operations such as the prefrontal leukotomy, designed to treat psychiatric disorders.[46] White matter tracts from thalamic and cingulate structures, representing the rostral extent of the reticular activating system, pass anterior to the lateral ventricular frontal horns. Initial reports of improved pain symptoms in psychiatric patients who underwent resection of these fiber tracts, led to the use of prefrontal leukotomies for chronic pain patients.[47,48] These procedures were largely supplanted by resection of the medial frontal white matter only.[49] Typically, resection of frontal lobe white matter tracts was accomplished via suction under direct vision, injection of sclerosing solutions, or radiofrequency ablation procedures. Results from these procedures varied with regard to pain relief. Of note, noticeable personality changes were often observed in patients with extensive resections who nonetheless received improved pain control. As a result of various cognitive side effects, smaller resections which evolved into the current cingulotomy procedure largely replaced the traditional prefrontal leukotomy.

THALAMOTOMY

As various thalamic nuclei are involved in processing painful stimuli en route to the cingulate gyrus and other cortical structures, the thalamus has historically been targeted in patients with chronic pain.[50,51] Original results with lesions in the ventrocaudal thalamic nucleus were marked by a high incidence of unwanted sensory deficits such as proprioceptive changes and neuropathic pain symptoms.[52,53] Thus, medial thalamotomies which had significantly fewer side effects were considered. Originally, many cancer patients received consideration for medial thalamic lesioning until more advanced pharmacological delivery techniques were adopted. Although less common, patients with tumors which respond poorly to opiate administration, such as head and neck carcinomas, have demonstrated substantial pain reduction from stereotactic thalamotomy procedures. In addition, patients

with chronic pain from peripheral deafferentation, stroke, spinal cord injury, arthritis, and Parkinson disease-related neurogenic pain have been treated with thalamotomy procedures.[54–56] Chronic pain patients have also benefited from lesions placed in the pulvinar and anterior thalamus without affecting normal sensation.

Anatomy and Physiology

Medial thalamic structures such as the dorsomedial (DM), centromedian (CM), parafascicular (PF), and centrolateral (CL) nuclei are involved in processing painful stimuli. Axonal projections from the spinothalamic tract ascend in the ventral and ventrolateral spinal cord white matter following decussation. Many of these axons from paleospinothalamic and dorsal spinothalamic tracts terminate in the intralaminar thalamic nuclei such as the CL nucleus. Medial thalamic neurons then project to the cingulate gyrus for further processing.[57] Previous studies have suggested thalamic nociceptive neurons have extensive receptive fields with little discernible somatotopic organization.[58,59] Thus, these cells may play a limited role in localization of painful stimuli; however, they appear to respond to varying stimulus intensities and emotional characterizations of pain.[60] Human studies have demonstrated prolonged thalamic neuronal bursting patterns in subjects with deafferentation pain; lesions colocalized with these patterns in the medial thalamus are reported to substantially improve pain relief.[61]

Neospinothalamic tract axons terminate in the ventral posterolateral thalamic (VPL) nucleus as the corresponding trigeminal fibers project to the ventral posteromedial (VPM) nuclei. Thus, in contradistinction to intralaminar/medial thalamic nuclei, stereotactic lesions in the VPL/VPM (Fig. 104.1) often result in decreased pain and temperature sensation along the contralateral hemibody. In addition, lesions placed in the anterior thalamic nuclei and pulvinar resulted in pain relief in some patients. Since anterior thalamic nuclei project largely to frontal lobe cortical structures, anterior thalamotomies were postulated to play a role in motivational and affective pain components.[62] Pulvinotomy is also rarely performed as exact target sites and electrophysiological data are poorly defined. Although the precise mechanism for pain reduction is not currently understood, previous studies reported long-term pain relief in approximately 25% of patients without evidence of sensory loss.[63]

Techniques

Stereotactic medial thalamotomy procedures are performed after the patient is immobilized in a stereotactic frame with local anesthesia as described previously. MRI sequences are often employed to localize the projected thalamic target and evaluate the anatomical structures unique to each patient. Burr holes can be directed via the stereotactic frame drill guides near the coronal suture approximately 3 cm on each side of the midline. Microelectrode recordings are then commonly used to provide detailed electrophysiological data regarding specific thalamic nuclei, although medial nuclei provide a relatively large target without significant somatotopic arrangement. Thus, without pathognomonic electrophysiological findings, intraoperative testing may not provide definite positioning data in all patients, but deafferentation pain associated with sustained neuronal bursting patterns often responds well to lesioning.[61] Radiofrequency lesions created in or near the dorsomedial nucleus, intralaminar zone, and centromedian nucleus are often most efficacious in relief of chronic pain symptoms. Coordinates from 6 to 10 mm lateral to the AC-PC plane, 7 to 11 mm posterior to the AC-PC midpoint, and from 1 mm below to 2 mm above the AC-PC line have been used in stereotactic thalamotomies[64,65] (Fig. 104.3). Following frame

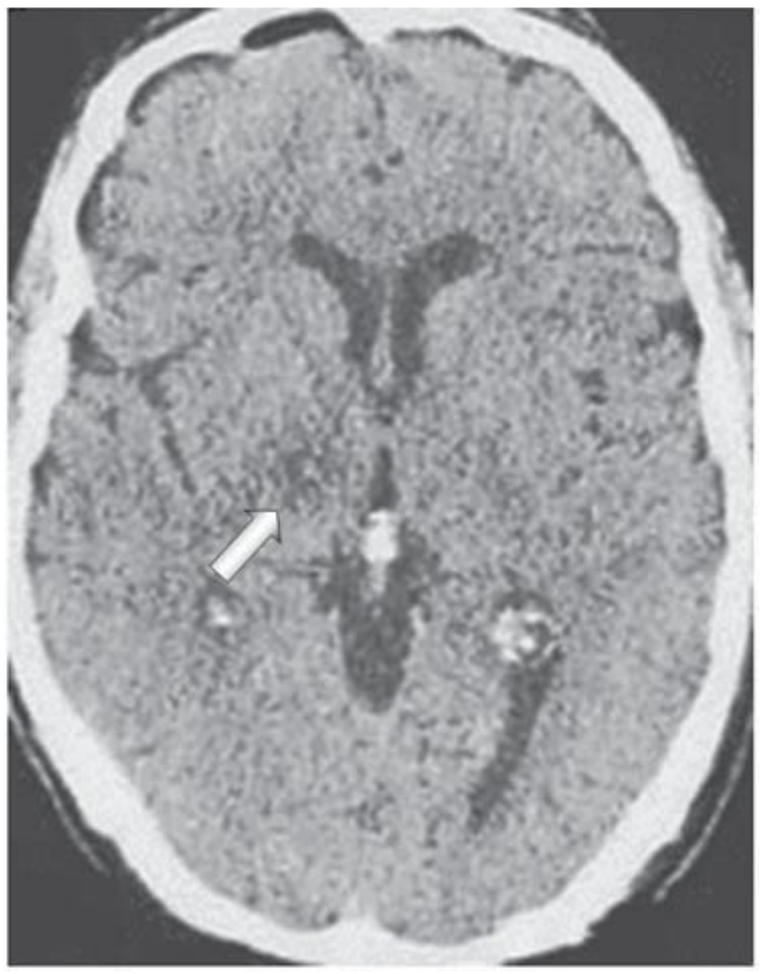

FIGURE 104.3 Postoperative axial CT image following right-sided stereotactic thalamic lesion (*arrow*).

removal, a postoperative MRI can provide the practitioner information regarding the lesion size/position and evidence of intracranial hemorrhage.

Results

Stereotactic medial thalamotomy procedures have been associated with substantial reduction in pain immediately after treatment. Since several medial thalamic nuclei (CM, PF, and CL) are involved in nociceptive pain transmission, an established consensus has not yet emerged regarding a specific nucleus or region to lesion. Nociceptive pain symptoms often respond more favorably than neuropathic pain symptoms to thalamic lesioning. However, long-term follow-up studies have shown recurrence of chronic pain symptoms in many patients.[50] Tasker demonstrated a reduction in nociceptive pain in 46% of subjects while 29% noted neuropathic pain relief[66] (Table 104.2). Frank and colleagues found 60% of patients described pain relief with medial thalamotomies while Jeanmonod et al. reported from 50% to 100% pain relief in approximately two-thirds of patients without production of iatrogenic neurological deficits.[67,68]

RADIOSURGICAL THALAMOTOMIES

Radiosurgical lesions have been documented using both the Leksell gamma knife and linear accelerator systems. With CT and

TABLE 104.2

RESULTS OF THALAMOTOMY FOR CHRONIC PAIN

Study	Year	Initial pain relief (% of patients)
Tasker[66]	198	46
Frank et al.[68]	1987	60
Jeanmonod et al.[67]	1994	67
Young et al.[64]	1995	67

MRI localization techniques, lesion accuracy has been substantially improved in recent years. Some studies demonstrate similar efficacy of radiosurgical and stereotactic thalamotomies.[69] However, pain relief is initially noted by the patient 2 to 3 months after radiosurgical lesioning with stable results 4 to 6 months post-procedure. Thus, radiosurgical thalamotomies may be less efficacious for cancer related pain in patients with shortened life expectancies. In lieu of microelectrode recordings in radiosurgical procedures, fMRI studies may provide anatomical/functional data which can be coregistered with the MRI to provide the investigator more information regarding target size and location.

Using the Leksell stereotaxic system and Cobalt^{60} Gamma Unit, Steiner and colleagues described radiosurgical lesioning of the ventromedial thalamus using 160 to 180 Gy. In 24 patients with unilateral lesions placed contralateral to the pain and 26 patients with bilateral lesions, approximately two-thirds of patients noted short-term pain relief.[70] However, with time, only 8 of 52 patients described good pain relief. Later studies by Young et al. found approximately 60% of chronic pain patients with MRI-guided gamma knife lesions retained long-term pain relief using similar radiation dosages.[64] Of note, the latter study used MRI guidance with lesions designed to include intralaminar nuclei, such as the CL nucleus, which project to the cingulate cortex. Frighetto and colleagues reported a smaller population of chronic pain patients who underwent linear accelerator radiosurgical ablation using a 5 mm diameter collimator with 5 to 8 evenly distributed noncoplanar arcs.[71] Maximal radiation dosages varied from 150 to 200 Gy. All of the patients received substantial pain relief, although one patient noted pain recurrence approximately 4 months after treatment. Thus, radiosurgical thalamotomies with MRI target localization may improve safety for patients, although results are delayed by several months.

MESENCEPHALIC TRACTOTOMY

The mesencephalon was considered as a site for lesioning in chronic pain patients in the 1940s (Fig. 104.1).[72] Originally used to treat cancer-related pain, mesencephalic tractotomy was found to be most effective in reducing nociceptive pain of the head, neck, and upper extremities rostral to the C5 dermatome. The lateral spinothalamic and spinoreticular tracts, which lie just beneath the pial surface, are transected at the level of the colliculi while the medial lemniscus is preserved. The lateral spinothalamic tract is more superficial than the spinoreticular tract. These pathways transmit pain information from the contralateral hemibody along with affective and motivational aspects of pain. The procedure has been considered in some patients with partial diaphragm paralysis secondary to lung cancer in which a high cervical cordotomy might result in further diaphragmatic dysfunction. Neuropathic pain related to phantom limb symptoms, postcordotomy dysesthesias, and brachial plexus/lumbosacral plexus avulsion has also been considered for treatment via mesencephalic tractotomy.[73–80]

Techniques

Stereotactic lesioning procedures have described insertion of radiofrequency electrodes through frontal skull burr holes as described previously.[76] This can be achieved under local anesthesia for evaluation of the patient's symptoms intraoperatively. The spinothalamic tracts can be localized with MRI approximately 7to 9 mm lateral to the midline, 4 to 5 mm inferior to, and 5 mm posterior to the PC. Microelectrode recording data can be used to describe surrounding structures such as the periaqueductal grey or medial lemniscus. Stimulation of the periaqueductal grey region may produce sensations of anxiety, fear, blushing, or piloerection.[81,82] Medial lemniscus stimulation (approximately 9–12 mm lateral to the midline) can result in contralateral paresthesias while spinothalamic tract stimulation usually results in cold or burning sensations.[82] Once the spinothalamic tract is localized, a radiofrequency lesion is created with a radiofrequency electrode. The patient is preferably awake during this period so extraocular movements and sensation can be tested. Once the electrode temperature is above 48°C, the lesion gradually is enlarged over the next 30 to 45 seconds. Typically small lesions are generated initially; after testing the patient's symptoms, the lesion size can be expanded. Practitioners often note a loss of sharp pain sensation which indicates appropriate analgesia, but transient deficits in light touch sensation over the contralateral hemibody have also been described.

Results

Nociceptive pain relief has been described in 60% to 70% of patients, but neuropathic pain results are less favorable.[81] Consistent pain relief has been historically limited by side effects. Because of the close approximation of surrounding structures, it is difficult to create a lesion large enough to encompass the spinothalamic and spinoreticular tracts without encroaching on the medial longitudinal fasciculus, medial lemniscus, and oculomotor nucleus. Thus, ocular motility deficits, sensory loss due to medial lemniscus damage, and dysesthesias can result. Lesions adjacent to the superior colliculus may result in pain relief in 75% of patients, but oculomotor deficits may be present in 87%. Lesions at the level of the inferior colliculus achieve significant pain relief in less than 60% of patients, but oculomotor defects are reduced to around 20%.[80,83]

MEDULLARY AND PONTINE SPINOTHALAMIC TRACTOTOMY

Lesions of the lateral spinothalmic tract at either the pontine or medullary levels (Fig. 104.1) were introduced in 1941 to achieve a more rostral level of analgesia compared to cervical cordotomies.[84,85] At these levels, the lateral spinothalamic tract ascends in the anterolateral white matter. Investigators found painful dysesthesias may develop over time with inconsistent pain relief beyond one year. Resulting sensory loss may also result in tissue injury (i.e., burns) in patients unaware of painful stimuli. Thus, these lesions are typically employed for cancer-related pain in the neck or shoulder in patients with shortened life spans. In addition, lesions in this region can cause interruption of respiratory drive.

Although stereotactic techniques with this procedure have been reported, many medullary and pontine spinothalamic tractotomies were performed with a craniotomy under general anesthesia. The prone or lateral decubitus positions have been employed for creation of a posterior fossa craniotomy and upper cervical laminectomies. Exposure of the medulla allows for tractotomies in the region above or below the obex. Few of these procedures are presently performed due to possible side effects (ipsilateral ataxia or motor deficits) and frequent failure to relieve deep burning/aching pain experienced by many cancer patients.

TRIGEMINAL TRACTOTOMY

Trigeminal tractotomy was developed to disrupt nociceptive pain of the orofacial structures transmitted via the descending trigeminal tract.[86] The most caudal subdivision of the spinal trigeminal nucleus, the nucleus caudalis, is analogous to the spinal cord dorsal horn. This subdivision was selected because it was believed to transmit nociceptive trigeminal inputs, while nonnociceptive sensory information was directed through the rostral subdivisions

of the spinal trigeminal nucleus or principal sensory nucleus. More recent studies have refuted this hypothesis, demonstrating nociceptive inputs in the rostral subdivisions as well.[87–89] However, trigeminal tractotomy avoids complete resection of the trigeminal sensory root—leaving tactile and proprioceptive afferents intact. The corneal reflex for instance is lost with complete trigeminal rhizotomy while it is often preserved following a tractotomy.

Trigeminal tractotomy has been considered for relief of cancer-related orofacial pain. The procedure has been combined with cervical rhizotomies for treatment of pain due to head and neck tumors, and has been reported for use in refractory trigeminal neuralgia cases.[90–97] Patients with anesthesia dolorosa or various other types of neuropathic orofacial pain typically have not reported pain relief with this procedure. Both open and stereotactic trigeminal tractotomies have been described for sectioning of the trigeminal tract. In the open procedure, 3–5 mm incisions of the nucleus caudalis have been described. Possible complications include restiform body injury with ipsilateral arm ataxia, dorsal column nuclei injury with ipsilateral proprioception loss, or spinothalamic tract disruption with contralateral pain/temperature loss of the trunk and extremities. Stereotactic trigeminal tractotomy has not gained wide acceptance because target localization in the posterior fossa with most systems is difficult to confirm. Hitchcock reported insertion of an electrode at a 30-degree angle approximately 6 mm from the midline.[98,99] Verification of positioning was confirmed by stimulation at 50 Hz to evaluate for production of facial sensations. Four of five patients with cancer-related pain reported relief of their symptoms.

HYPOTHALAMOTOMY AND HYPOPHYSECTOMY

Patients with violent behavior associated with mental retardation or epilepsy were considered for posterior hypothalamic lesioning in the 1960s.[100] The procedure was also employed with some success in patients with cancer-related pain of the face and postherpetic neuralgia.[101–102] Under local anesthesia, a radiofrequency electrode can be stereotactically placed 2 mm inferior to the AC-PC line and 3 mm lateral to the AC-PC plane in the posterior hypothalamus. Electrical stimulation in this region can cause papillary dilation, hypertension, tachycardia, and a subjective sense of fear or horror. The use of stereotactic hypothalamotomy has not been widely employed since there is no distinct anatomic target, and no clear advantage has been demonstrated versus stereotactic thalamotomy procedures.

Radiosurgical ablation of the pituitary gland has also been effective in treatment of otherwise refractory cancer-related pain.[103] Nine patients in this study with bone metastases underwent Gamma knife radiosurgery with a maximum radiation dose of 160 Gy. The target included the pituitary gland and stalk with either one or two isocenters, 8 mm in total diameter. The optic nerve received a dose no higher than 8 Gy with no resulting visual side effects. Pain relief was reported within several days of treatment, and 1 to 24 month follow-up data revealed no hormonal dysfunction or recurrence of pain. Despite these results, more prospective studies should be completed before radiosurgical ablation of the pituitary can be fully assessed for pain relief.

CONCLUSION

Although deep brain stimulation techniques have supplanted many ablative procedures, the latter provide more cost effective results. Ablative procedures also provide therapy in medically refractory patients such as those with brittle diabetes and others with increased infection risks. Hardware malfunction and skin erosion by stimulator electrodes are also avoided. However, the effects of stereotactic ablative lesions cannot be modulated or reversed as is the case with high frequency stimulation. Thus, ablative procedures for chronic pain have been largely replaced in developed countries by improved pharmacotherapy, intrathecal delivery systems, and high frequency stimulation techniques in patients without contraindications due to underlying medical conditions.

CHAPTER 105 ■ INTERDISCIPLINARY CHRONIC PAIN MANAGEMENT: PERSPECTIVES ON HISTORY, CURRENT STATUS, AND FUTURE VIABILITY

MICHAEL E. SCHATMAN

HISTORY OF INTERDISCIPLINARY CHRONIC PAIN MANAGEMENT

The interdisciplinary approach to chronic pain as it is practiced today represents a relatively new science. In the 1940s, John J. Bonica became the first physician to recognize the complexity of chronic pain syndromes, understanding that they affect patients not only physically but across myriad dimensions of their lives. As chronic pain of nonmalignant origin has been noted to be the most unpredictable type of pain (as compared to acute and chronic pain due to malignancy), it is the most difficult type of pain to treat.[1] Meldrum[2] notes that Bonica found himself frustrated by his inability to effectively treat these patients on his own at Madigan Army Hospital in Washington during World War II and found that consultation with his colleagues seemed to benefit all who were involved. Immediately following the war, Bonica developed the first formal interdisciplinary pain management team at Tacoma General Hospital, with members including an anesthesiologist, orthopedist, neurosurgeon, internist, psychiatrist, and radiation therapist. This team treated all types of pain syndromes, not limiting its practice to patients with chronic pain of nonmalignant origin. Interestingly, unbeknownst to Bonica, F.A.D Alexander was simultaneously developing a similar interdisciplinary pain diagnostic and therapeutic program at a Texas Veterans Administration hospital.[3] Another interdisciplinary program developed in Portland, Oregon, as well as several others in Canada and Europe.[3]

Despite the success achieved by these programs and efforts to promulgate them spearheaded by Bonica, the field of interdisciplinary chronic pain management (ICPM) remained stagnant during the 1950s and the first half of the following decade. Due to a lack of acceptance of the interdisciplinary approach by the medical community, Bonica was "about to give up," and later wrote, "Despite my persistent drum beating, consisting of several hundred lectures and the publication of numerous articles in various parts of the world, the multidisciplinary concept was ignored by the medical profession for two decades."[4] Meldrum[5] has recently suggested that Wilbert Fordyce's integration of a strong behavioral component into Bonica's team in the late 1960s was instrumental in the development of the modern interdisciplinary pain treatment team. With the introduction of this behavioral approach to assessment and treatment, the focus of pain clinics shifted from the eradication of pain to teaching patients how to *manage* their symptoms and restore a positive quality of life.[6] Due to the fact that the purely behavioral approaches to chronic pain were found to be time-consuming and expensive to implement, they were soon replaced in interdisciplinary treatment programs by cognitive-behavioral approaches, which emphasize the patient as an *active participant* in his or her rehabilitation who is able to develop the coping skills necessary to restore independence.[2]

In the 1970s and 1980s, ICPM programs proliferated rapidly to the extent that these clinics were described as "medicine's new growth industry."[7] In addition to providing chronic pain management services, numerous postdoctoral fellowships in pain management developed during this period of time, typically in university-based facilities. Among the most active and prestigious of these facilities was that developed by Bonica at the University of Washington in 1960, where he was succeeded in directorship by the neurosurgeon, John Loeser. Loeser instituted a highly structured inpatient program at the University of Washington that was developed around Fordyce's operant conditioning approach. According to Loeser, the great success of his program was due to the interaction between the various disciplines of the treatment team members rather than to any specific intervention that was applied.[8] By the early 1980s, Aronoff and colleagues[9] suggested that approximately 1000 interdisciplinary treatment centers were in operation in the United States and were becoming more numerous in other parts of the world as well. In 1999, Anooshian and colleagues[10] reported that there were approximately 2000 pain treatment facilities in the United States, with the majority considered multidisciplinary. However, it has been noted that while third party payers were initially enthusiastic regarding these programs, they soon became skeptical. Aronoff states, "By the early 1990s the pain clinic movement was experiencing image problems so serious that some pain programs closed while others changed their names to functional restoration or work-conditioning programs to avoid using the word *pain* as a descriptor."[11] Because of strategic changes in nomenclature, it is difficult to specifically determine the point at which the number of interdisciplinary treatment programs and the availability of this type of pain management began to decline. However, Schatman[12,13] has noted that the number of programs in the United States accredited by the Committee on Accreditation of Rehabilitation Facilities (CARF) declined from 210 in 1998 to 84 in 2005, with a similar but less dramatic decline noted in the number of programs accredited by either CARF, the Joint Commission on Accreditation of Healthcare Organizations, or the American Academy of Pain Management reported between 1997 and 2003. Later in this chapter, the paradox of this decrease in the availability of ICPM programs will be discussed in greater detail.

Theoretical Basis of Interdisciplinary Chronic Pain Management

ICPM, as it is practiced today, is based on the biopsychosocial approach that initially achieved prominence through the work of Engel.[14,15] This model emphasizes the complex and dynamic interaction between physiologic, psychologic, and social factors that serve to perpetuate and potentially worsen pain experience.[16] While considered a relatively new development in medicine, Gilbert[17] notes that the biopsychosocial model was practiced by ancient Greek physicians over 2000 years ago. Certainly, the addition of Wilbert Fordyce to Bonica's treatment team was instrumental in the evolution of the interdisciplinary approach, as it

resulted in the consideration of the emotional and behavioral sequelae of chronic pain as well as nociceptive experience. Turk and Melzack[18] suggest that the measurement of pain should involve the motivational-affective and cognitive-evaluative contributions, not just the nociceptive. Undoubtedly, this holds true for the *treatment* of chronic pain as well. Steen and Haugli[19] note that while the biomedical model may be an effective approach to disease states in which the cause is clearly defined, it is not appropriate for conditions such as chronic musculoskeletal pain. Chronic pain is a disease of the *person*, and the person is often obscured by the traditional biomedical approach.[20] The interdisciplinary approach is based on the premise that no one individual can "cure" the patient of all of the ills associated with his or her pain condition. At the time that Bonica was developing his method of treating pain, medicine was becoming progressively more specialized. While specialization serves to enhance expertise, specialization without diversification results in limitations to what the medical field can offer to patients whose conditions are as complex as is chronic pain. This, perhaps, was the greatest wisdom that Bonica contributed to the pain treatment community,

Loeser[8] and numerous others[21–26] have written of the importance of communication between treatment team members. While the terms "multidisciplinary" and "interdisciplinary" are often used interchangeably, it is important to note that "multidisciplinary" suggests only the involvement of multiple disciplines, while "interdisciplinary" suggests the involvement of multiple disciplines *working in concert* to help patients with pain overcome not only nociceptive phenomena, but the emotional and behavioral implications of persistent pain as well. ICPM can be considered the most collaborative approach along the continuum of multidisciplinary models. Because this type of chronic pain treatment requires such close communication among team members, interdisciplinary programs ideally involve treatment teams working in a single setting. In the early days of the discipline, programs were frequently operated in inpatient settings, as the practitioners who developed them believed that inpatient treatment allowed for a higher level of control over contingencies than would outpatient programs. Inpatient treatment, however, was expensive, incurring the criticism of the health insurance industry. In 1990, Peters and Large[27] published a study that found little difference in outcomes between inpatient and outpatient chronic pain management programs. The release of this study coincided with the conversion of many programs from inpatient to outpatient treatment. Currently, there are very few inpatient ICPM programs in the United States, with CARF reporting that as of June of 2007, only 6 of its accredited 83 ICPM programs are inpatient.[28]

The interdisciplinary approach recognizes the bidirectionality of pain and psychosocial factors, considering that emotions and maladaptive behavioral patterns can perpetuate as well as result from persistent physical discomfort. Myriad investigators have made an effort to answer the "chicken-or-the-egg" issue of nociceptive and psychologic factors contributing to the chronic pain experience, with no clear results emerging. In the interdisciplinary model of chronic pain management, this issue is of minimal importance, as patients improve on *multiple* dimensions if they are provided with appropriate guidance and exert maximal effort. As noted earlier in this chapter, the goal of chronic pain management has evolved from "pain elimination" to genuine "pain management," with an emphasis on restoring the patient's independence and overall quality of life. This emphasis is crucial, as a recent analysis[29] suggests that there is little difference in pain relief between common approaches to chronic pain, including medication therapy, surgery, spinal cord stimulation, intrathecal drug delivery, and ICPM programs.

The approaches of ICPM programs vary to a certain degree. However, Okifuji and colleagues[30] suggest that the typical treatment provided includes 3 common elements: (1) medication management, (2) graded physical exercise, and (3) cognitive and behavioral techniques for pain and stress management. The degree to which each of these elements is emphasized should vary based upon the needs of the specific patient, although is probably more contingent upon the personality of the program and the individual clinicians. While the importance of the cohesiveness and communication between treatment team members cannot be overemphasized, it should be recognized that each team member brings very specific and necessary expertise to the program. Baszanger[31] describes the professionals who treat chronic pain from a team approach as "pluridisciplinary"; each of the disciplines has its own unique training methods and clinical experiences and accordingly is likely to approach the same patient with different assumptions and treatment methods.

Composition of the Interdisciplinary Chronic Pain Management Team and Roles of Members

Authors who have described the composition of treatment teams and the specific roles of their members have tended to rely on the programs that they directed to provide such description.[16,26,32] For the purpose of this chapter, the composition of ICPM treatment teams and the functions that the individual members provide will be described more generically. It is important to note that ICPM treatment team composition varies based on program philosophy and economic factors, although certain "core" members are essential if patients are to be treated through a biopsychosocial model.

- **Medical Director/Physician:** The ICPM program medical director provides medical leadership, and, to a considerable extent, accepts responsibility for the physical well-being of the patients that are treated. While it is important that the physician possesses expertise in the rehabilitation of pain disorders, a survey of programs yields wide variance in the training experience and practice specialties of their medical directors. These specialties include physical medicine and rehabilitation, anesthesiology, neurology, rheumatology, occupational medicine, orthopaedic surgery, neurosurgery, psychiatry, and internal medicine. The physician on an interdisciplinary treatment team is responsible for taking a medical history, evaluating the patient for purposes of providing or confirming a diagnosis, managing medications (which may include detoxification), providing patient education, and guiding other team members in regard to the physical treatment that they provide. Additionally, in some programs, the physician provides interventions such as trigger point injections to patients. While such interventions are not known as a "cure" for chronic pain, Hatzakis and Schatman[33] have advocated for their use in certain situations in order to promote adherence with the physical reconditioning component of an ICPM program. The physician needs to be able to effectively communicate the patient's physical status to other team members. While some medical directors tend to "rule the team with an iron fist," the physician who is seen as warmer and less directive is likely to foster greater team cohesiveness, which is consistent with the literature on small group process.[34] Spoonhour and Schatman[35] have suggested that selflessness is a positive attribute in an ICPM leader, as the most effective medical directors are those who are willing to allow the team member with certain expertise to function in a manner maximizing the benefit of that expertise.
- **Nurse Case Manager:** Nurses on ICPM treatment teams often assume diverse responsibilities and are accordingly invaluable. Because of their medical backgrounds, they can potentially serve as extensions of the physician, obtaining medical histories, monitoring medications, encouraging healthy life-

styles, and providing education to patients and their families. In a role delineation study, Pellino and colleagues[36] determined that assessing, evaluating, and monitoring pain were nurses' most common activities. Nurses are also the multidisciplinary team members that spend the greatest amount of time with patients.[37] Additionally, as many nurses are trained and experienced in case management, a nurse is often the team member responsible for the day-to-day management of the program. Duties may include triaging referred patients, confirming insurance sponsorship, development of policies and procedures, quality assurance, collection and maintenance of patient data, and correspondence with referral sources, employers, attorneys, health insurance providers, and other health care professionals treating a patient.

- **Psychologist:** Pain psychologists on interdisciplinary treatment teams are responsible for the psychosocial aspects and status of patients' care. As patients become more chronic, their development of maladaptive emotional and behavioral patterns increases, necessitating expert psychologic care if they are to become more functional in their lifestyles. Initially, the psychologist provides a comprehensive psychosocial evaluation, with this evaluation serving multiple purposes. First, the psychologist must determine whether a patient is appropriate for an ICPM program. Psychologic testing routinely used in assessing chronic pain patients can identify conditions such as thought disorders and dramatic personality disorders that would make certain patients inappropriate for admission to a program.[38,39] Through a thorough evaluation, the psychologist can reduce the likelihood that a dramatically disturbed patient will experience yet another failure, while simultaneously protecting the emotional well-being of the rest of the treatment team as well as the therapeutic milieu. The second purpose of the psychosocial evaluation is to identify the specific maladaptive emotional and behavioral patterns that are perpetuating the patient's chronic pain, thereby leading to a treatment plan of cognitive and behavioral interventions that will address these patterns. Like the physician and the nurse, the psychologist is also an educator, although the education that he or she provides is generally focused on psychosocial factors. Typically, the pain psychologist will work with patients on both an individual and group basis, with an emphasis on unlearning maladaptive responses to pain, problem-solving techniques, stress management training, decreasing catastrophization, and enhancing self-efficacy. Through these approaches, reductions in depression and anxiety along with more adaptive behavioral responses to pain are typically evidenced. A pain psychologist will also often work with a patient's family during the course of a program, as the family may unwittingly be reinforcing the "patient role," thereby enabling the patient. Finally, as psychologists are trained as scientist-practitioners, they are likely to coordinate outcomes research for the ICPM team. Such research is of great importance, not only in terms of identifying potential weaknesses of a program, but for marketing purposes as well.
- **Physical Therapist:** The physical therapist on a pain treatment team is responsible for assessing patients' levels of functioning, and then designing and monitoring programs of graded therapeutic exercise that will safely increase these levels. Areas of focus may include increasing flexibility and range of motion, restoring appropriate posture and body mechanics, ambulation and gait training, development of core strength and stability, cardiovascular fitness, and increasing upper and lower extremity strength and endurance. Treatment is typically provided on both an individual and group basis. Passive modalities such as ultrasound, electrical stimulation, and massage are generally avoided, as the focus of ICPM is on teaching patients *independent* management of their pain. Stretching and strengthening are emphasized, as these exercises have been empirically supported through systematic reviews as being among the most effective treatments for a number of types of chronic pain.[40–45] It is critical that the treatment team's physical therapist has received specialized training in chronic pain management, and that he or she is *interested* in treating patients with chronic pain. As is true for physicians,[46–48] many physical therapists lack the training and interest necessary to treat patients with chronic pain effectively. Typically, physical therapists are trained in an acute pain model, with an emphasis on passive modalities. The physical therapist who works as a member of an ICPM team must function as a *behaviorist*, demonstrating recognition that the patients have developed emotional sequelae of their pain as well as maladaptive behavioral patterns that must be modified in order to achieve successful outcomes. Training and ongoing supervision of the physical therapist by the treatment team's psychologists is ideal. Rotating potentially disinterested therapists from a hospital's physical therapy department through an ICPM clinic will invariably result in poor outcomes and negatively impact treatment team cohesiveness.
- **Occupational Therapist:** On many ICPM teams, there is considerable overlap between the duties of physical therapists and occupational therapists. Areas that are considered primarily within the domain of occupational therapist include ergonomic training, upper extremity activities of daily living, work activities, leisure activities, and any other activities that are meaningful and purposeful to the individual patient. Some occupational therapists perform work-site analyses, visiting the work place to which the patient intends to return, observing the specific job-related tasks that he or she will need to perform, and then developing a work simulation component of the ICPM program. Helping patients problem-solve pain management strategies that can be applied in the work place is another critical role of the occupational therapist. As for physical therapists, occupational therapists should have training and experience in applying behavioral interventions as well as traditional occupational therapy training in order to optimize outcomes. Emotional interference with restoration of function should be understood as well, particularly as it relates to return-to-work issues. In some ICPM programs, the occupational therapist serves as the vocational counselor as well.
- **Vocational Counselor:** The vocational counselor on the treatment team is responsible for a number of important functions, with these functions dictated by the specific goals of the program and the needs of the individual patient. Returning patients to gainful employment is considered a primary goal of many ICPM programs, particularly those that take a *functional restoration* approach.[49] As a large percentage of patients in interdisciplinary treatment programs suffer from pain secondary to work-related injuries,[50,51] vocational issues can become extremely complicated. In such instances, the vocational counselor is responsible for helping the patient understand the benefits of returning to the work force, while simultaneously serving as a case manager who contacts employers, obtains and analyzes job descriptions, and "greases the wheels" to facilitate return to previous employment. In situations in which the previously-held position is no longer available, the vocational counselor may provide a patient with interest and aptitude testing in order to help him or her identify new employment situations that may be realistic given the patient's educational and work histories, economic realities, and any given physical limitations anticipated at the completion of the program. Additionally, there are situations in which a vocational counselor provides testing and counseling in order to prepare a patient for vocational retraining. Like other team members, the vocational counselor needs to be psychologically-minded, understanding issues such as primary and secondary gain as well as the role of psychologic factors in perpetuating perceived disability. Vocational coun-

selors in ICPM programs typically work with patients on both an individual and group basis. At times, the team's vocational specialist will accompany the occupational therapist on a work-site analysis, serving as a "second set of eyes and ears" in order to help understand potential obstacles that may impede efforts to return a patient to the work force.

- **Biofeedback Therapist:** The biofeedback therapist on the ICPM team is primarily responsible for reducing patients' psychophysiologic reactivity to stress, although also often participates in neuromuscular re-education. Of all the self-management techniques that are taught to a patient through an interdisciplinary program, perhaps those taught by the biofeedback therapist are most important, as they can help shift a patient toward internal locus of control[52] and restore a patient's sense of self-efficacy,[53,54] as well as reduce tension and pain. Biofeedback equipment is utilized to help patients recognize how their bodies respond to stress, as awareness of stress among chronic pain sufferers is often limited.[55] Biofeedback technology provides a patient with visual and/or auditory feedback regarding physiologic functions including muscle tension levels, perspiration, extremity temperature, and brain wave patterns. Once patients gain awareness of how their bodies responds to stress, the biofeedback therapist can teach them to alter these functions through a variety of relaxation techniques, including progressive muscle relaxation, imagery, diaphragmatic breathing, and autogenic techniques. In some ICPM programs, biofeedback training is provided by psychologists, who are often trained in the discipline. However, it is often more cost-efficient to have another team member serve as the biofeedback therapist, with supervision provided by the psychologist. States do not license therapists in biofeedback, although they are eligible for certification through the Biofeedback Certification Institute of America (BCIA). Some physical and occupational therapists are trained in biofeedback, particularly neuromuscular re-education. In certain situations, a physical therapist or occupational therapist will work in tandem with a biofeedback therapist, helping a patient recognize through muscle tension readings the impact of his or her bracing and guarding on levels of function and pain. Biofeedback/relaxation training is generally provided on both an individual and a group basis during the course of an ICPM program. It should be noted that there are some ICPM programs that do not include biofeedback therapy as a core aspect of treatment. However, given the literature on the benefits of biofeedback in the treatment of chronic pain,[52–54] it is likely that this omission relates to reimbursement issues. For example, while the ICPM programs in Pennsylvania (where biofeedback is routinely covered by third party payers) include biofeedback as a central aspect of treatment, biofeedback therapy is *not* reimbursed by third party payers in the state of Washington, thereby essentially precluding its utilization.
- **Other ICPM team members:** While the "core" treatment team is composed of physicians, psychologists, nurses, physical and occupational therapists, vocational counselors, and biofeedback therapists, some ICPM teams include other disciplines as well. These include therapeutic recreation specialists, social workers, chaplains, dieticians, and non-nurse case managers. However, the functions that these specialized treatment team members fulfill are often performed by other core team members. Although ICPM programs tend to follow a common philosophy of treatment and goals, no two programs are identical. Accordingly, a degree of variance in the composition of the treatment team is to be expected.

The Process of Interdisciplinary Chronic Pain Management

ICPM begins with a referral to the program, which is generally handled by the team member in charge of case management. Referrals may come from a wide variety of sources, including other physicians and health care providers, attorneys, employers, and insurance carriers. Some ICPM programs are a part of a broader pain management system, in which case triage may be necessary. Due to economic realities, insurance coverage is generally confirmed prior to proceeding. Once this is accomplished, medical records are requested and reviewed in order to ascertain the patient's appropriateness for evaluation.

As ICPM entails comprehensive treatment, the initial evaluation of the patient must be comprehensive as well. Prospective patients are typically evaluated by the physician, psychologist, physical and occupational therapist, biofeedback therapist, and vocational counselor. Following these evaluations, the treatment team members ideally meet in order to discuss the patient's appropriateness for admission, prognosis, and other issues that may have an impact on treatment. As important as the patient's ability to benefit from the *individual components* of the program is the patient's acceptance of and willingness to comply with the program philosophy. For example, a program that emphasizes functional restoration as a means of returning the patient to the work force and closing a disability claim ought not admit a patient who is determined to lack vocational motivation, unless the treatment team is confident that the program will result in a change in this attitude.

One of the biggest mistakes that an ICPM program can make is to simply reject a patient deemed inappropriate for admission and return him or her to the referral source without recommendations. Some patients may be considered physically appropriate for admission, although are not immediately admitted due to psychosocial factors. If the treatment team believes that these factors can be mitigated, delaying admission until the patient has received appropriate psychologic treatment may be in the best interest of the patient and the program. When a patient is determined to never be likely to meet the admission criteria, it behooves the patient and the program to return the patient to the referral source with recommendations for alternative treatment(s). An ICPM clinic is often seen as a "last resort" by referral sources that have a limited understanding of the complexities of chronic pain, and these referral sources may be grateful for ideas regarding managing challenging patients, even if they are not admitted to the program.

ICPM programs tend to be intensive, often requiring patients to participate up to 40 hours per week. While often daunted by the prospect of such a commitment, patients are informed that their day-to-day activities will be varied and that they will not be asked to perform physical tasks that are beyond their functional capacities. Distinguishing between "hurt" and "harm" and assuring patients that the treatment team considers their physical and emotional safety to be of the greatest importance helps build therapeutic trust, thereby enhancing adherence.[33] ICPM programs that are less intensive tend to be of longer duration. A study by Rose and colleagues[56] suggests that outcomes do not relate to program length, and accordingly, the level of intensity of treatment may be based on the personal preferences of the program developers. This is consistent with a more recent study[57] in which the frequency of aggressive spine therapy was determined not to influence clinical outcomes.

Similarly, the specific "mix of services" that patients receive between *and within* programs will vary. Consistency of treatment is considered important,[35] although a "one size fits all" approach is not appropriate given that each patient's circumstances and phenomenologic experience of pain is unique. Typically, patients spend most of their time in the gym engaging in activities that will increase their flexibility, strength, and functional capacities. Early in their programs, patients are likely to require considerable hands-on training by the physical and occupational therapists, as the ineffectiveness of their previous exercise programs is likely the catalyst for referral to an ICPM program. As patients progress, however, they tend to require less of the therapists'

attention, with this independence in pain management representing an important milestone in treatment. Patients whose emotional status and behavioral responses to their pain are less dysfunctional will likely require less time with the psychologist than will those patients who are struggling psychosocially. Similarly, patients demonstrating limited psychophysiologic reactivity to stress will require less intensive biofeedback training, and those whose vocational issues are less complex will require less concentrated vocational counseling services. All patients require group education on chronic pain management, and the presenters of the education should make an effort to tailor presented material to the needs and competencies of the group as a whole. The frequency with which a patient sees the physician on an individual basis will vary depending on the specific philosophy of the program. Frequent individual physician appointments are discouraged, particularly as the program progresses, as a goal of ICPM is typically reduction of medical services in lieu of enhanced independent self-management of pain.

The patient-centered nature of ICPM is substantiated by a weekly team conference in which each patient has the opportunity to meet with the entire treatment team in order to discuss his or her progress, any issues that are potentially limiting gains, and goals for the coming week. Feedback should be consistent and coherent. In situations in which patients' adherence is considered good and they are making progress, team conference provides a forum in which they are able to receive much-needed positive reinforcement regarding their attitude and effort. Patients with chronic pain are often unjustifiably blamed for the failures of the primary and secondary care systems to help them recover, making appropriate positive reinforcement even more important. Conversely, in cases in which adherence and progress are considered by the team to be inadequate, the conference provides an opportunity for the treatment team to present a united front in addressing the relevant issues and work with the patients to remedy any problematic aspects of their programs. Numerous studies[58–67] have indicated that characterologically-disturbed patients (i.e., those suffering from personality disorders) are grossly overrepresented in the chronic pain population, and problems associated with treating these patients in ICPM programs have been discussed.[38,39] "Splitting" of treatment team members is not uncommon, particularly in situations in which the patient's agenda is not consistent with that of the team (e.g., a patient in a functional restoration program who would rather continue to collect disability payments than return to active employment may sabotage the efforts of the vocational counselor). Because passively or actively noncompliant patients must face the entire treatment team at the weekly conference, their ability to manipulate the treatment team or individual team members is substantially compromised. While those who treat patients with chronic pain from an ICPM model work to facilitate success for *all* patients, there are those whose inability to make progress necessitates early discharge. Stanos[26] has recently suggested that such premature discharge can potentially encourage enhanced compliance or efforts among other patients in the group. Team conference also provides an excellent opportunity to engage in discharge planning, which should be a holistic process that takes multiple aspects of the patient's long-term pain management planning into consideration. A weekly multidisciplinary progress reported is generated from team conference, with this report sent to the relevant parties. While the attendance of the patient and the core treatment team are mandatory, there are cases in which the presence of other interested parties such as family members, attorneys, insurance company representatives, and employers is also desirable.

Once a patient has completed an ICPM program, he or she can be neither forgotten nor abandoned. Although programs are typically close-ended, follow-up should continue on a quarterly basis for at least a year. For the sake of cost-efficiency, selected measures of patients' emotional and behavioral responses to their pain that are administered at initial evaluation can be sent to them, with the data then analyzed for several purposes. First, if a patient is demonstrating deterioration of pain management skills following discharge, a meeting with the most appropriate team member can be scheduled in order to assess the problem. In effective ICPM programs, such deterioration is uncommon, as patients must meet benchmarks throughout the course of the program indicating assimilation of the central concepts of chronic pain management. However, for example, there are instances in which patients can benefit from adjustment of their home exercise programs. Second, follow-up allows for additional data collection. Outcomes data is of great importance, as even the best ICPM program should consider itself less than perfect and in a process of perpetual evolution. Data from program patients should be analyzed quarterly in order to help the treatment team recognize which elements of the program are succeeding and which need to be reassessed for effectiveness. Positive outcomes data should also be considered a powerful marketing tool, as it is difficult to argue with success. Potential referring physicians may be uninformed regarding the wide range of benefits of interdisciplinary treatment for their patients, and well-organized data may help them understand how a program can make their own lives easier as well as helping their more challenging patients. Additionally, while some health insurance programs may argue against the efficacy of ICPM, data that invalidates their arguments will ideally help convince them of the legitimacy of this treatment approach.

Empirical Support for Interdisciplinary Chronic Pain Management: Clinical Efficacy and Cost-Effectiveness

The methodologically-robust studies supporting not only the clinical efficacy but the cost-effectiveness of ICPM are too numerous to discuss individually. Accordingly, this section of the chapter will focus on the meta-analyses and systematic reviews that provide the discipline with unequivocal empirical support.

The first meta-analysis of ICPM was that performed by Flor and her colleagues[68] in 1992. While their review of 65 studies identified an average pain reduction of only 20%, interdisciplinary treatment programs were found to be effective in reducing medication use, reducing emotional distress, reducing health care utilization, reducing iatrogenic consequences, increasing return to work and physical activity levels, and closing disability claims. Not surprisingly, ICPM programs were determined to be superior to unimodal treatments as well as to no treatment and waiting list controls. The authors also determined that the beneficial effects of the programs appeared to be stable over time. Despite the significance of these findings, Flor and colleagues[68] recommended that they be interpreted with some caution due to inconsistencies in their methodologies and the marginal quality of their research designs and descriptions.

In 1998, Turk and Okifuji[69] performed a comparative analysis of ICPM programs in order to assess their cost-effectiveness as compared to surgery, chronic opioid therapy, and implantable devices. Differences in use of health care services and pain medication along with disability payments were calculated, with the results supporting the strong relative cost-effectiveness of the interdisciplinary approach. Most striking was the finding that ICPM programs were up to 21 times more cost-effective than alternative treatments for chronic pain such as surgery.

Okifuji and colleagues[30] performed a review of the literature on various treatment approaches to chronic pain, analyzing the cost-effectiveness of ICPM in comparison to surgery or conventional medical treatment. ICPM compared favorably to other treatments in terms of pain reduction, management of opioid analgesics, restoration of function as measured by activity levels and return to work, health care utilization, and closure of disabil-

ity claims. Additionally, the authors dispelled the myth of ICPM representing an expensive approach to pain management, calculating that its use in lieu of the traditional approaches could result in a cost savings of $5 billion per year in the United States. This finding becomes particularly relevant as medicine moves toward "pay for performance" and the controversy regarding the allocation of limited medical resources intensifies.

Turk[70] obtained similar findings in a 2002 review, noting not only that ICPM is comparable to oral medications, surgery, spinal cord stimulation, and intrathecal drug delivery in terms of pain relief, but that interdisciplinary treatment can provide considerable savings in costs for medications and additional health care utilization. The author also noted that the non-ICPM approaches are associated with iatrogenic complications and adverse events, ascertaining the superiority of ICPM in terms of physical functioning, return-to-work rates, and closure of disability claims. Turk's data on cost-effectiveness are dramatic, as he determined that interdisciplinary care is 6.29 times more cost-effective than surgery, 15 times more so than conventional care, and 25 times more cost-effective than spinal cord stimulation.

Hoffman et al.[71] recently performed a meta-analysis of interdisciplinary approaches to chronic pain within the larger context of a meta-analysis of psychologic approaches to chronic low back pain, considering randomized controlled trials from 1982 to 2003. Interdisciplinary treatment was compared to active controls as opposed to passive controls such as waiting lists. Unfortunately, only a small number of outcome measurements were analyzed in this study, although a strength of the meta-analysis was its consideration of posttreatment follow-up (3 to 12 month), and long-term follow-up (more than 12 month) data. Differences between work status of ICPM and active control group patients were statistically significant at follow-up and long-term follow-up, and while pain interference was significantly lower at program completion for patients treated through broad-based approaches, the statistical significance of this difference did not persist through follow-up. Unfortunately, the meta-analysis failed to assess between group differences in work interference at long-term follow-up, which would have been useful given the long-term differences in vocational status that were identified. As a whole, however, this meta-analysis supports the increased function associated with ICPM.

Most recently, Turk and Swanson[29] performed an "analysis and evidence-based synthesis" of the efficacy and cost-effectiveness of medications, surgery, spinal cord stimulation, intrathecal drug delivery systems, and ICPM in the treatment of chronic pain. As was the case in previous reviews, the authors found that all of these approaches resulted in roughly the same amount of pain relief, with only ICPM determined to be essentially free of iatrogenic complications and adverse events, and superior in terms of reducing health care utilization, restoring physical functioning, returning workers to employment, and closing disability claims. Again, ICPM was determined to be numerous times more cost-effective than the other treatments considered in achieving each of these goals.

Perhaps the most compelling empirical support for ICPM is provided by the 2001 and 2002 systematic[72] and Cochrane[73] reviews by Guzman and colleagues and the 2003 Cochrane Review by Schonstein et al.,[74] as these studies involved careful analysis of trial quality. In each of these reviews, the authors determined that ICPM improves pain and function, which was not determined to be the case for less intensive treatments. Not surprisingly, the Cochrane Review by Schonstein and colleagues[74] did not find strong evidence for the efficacy of interdisciplinary treatment for *acute* pain, which is less biopsychosocially-mediated than is chronic pain. Given the complexity of chronic pain, it follows that its treatment requires a more complex, interdisciplinary approach than is necessary for acute pain.[75]

In addition to the meta-analyses and reviews discussed in this section, mention should be made of several individual studies that provide strong support for the efficacy of ICPM, with these investigations examining patients' maintenance of gains achieved through interdisciplinary treatment. Establishment of the long-term efficacy of ICPM is of particular importance given that the duration of the longest randomized controlled trial evaluating chronic opioid therapy is 32 weeks,[76] with the weighted mean duration of such randomized controlled trials determined to be approximately 5 weeks.[70] Reviews of the long-term efficacies of spinal surgery,[77–81] spinal cord stimulation,[82] and intrathecal drug delivery systems[83] have also not been particularly encouraging.

In a 1980 study,[84] severely disabled patients who were treated in an ICPM program were followed for periods ranging from 1 to 8 years. Seventy-seven percent of the treated patients were leading "normal lives" without medication for pain as compared to only 3% of the untreated control groups. Roberts and colleagues[85] performed follow-ups at 8 years on patients treated in an ICPM program. They found that program completers reported significant reductions in pain and higher levels of function at work and at home than those who dropped out of treatment. Lanes et al.[86] followed-up patients with chronic low back pain who were treated in an ICPM at an average of 3.1 years after program completion. They found that 62% of their patients achieved either a good or a fair vocational outcome, and that the majority reported either better or much better general well-being at follow-up than prior to treatment. More recently, Patrick and colleagues[87] performed a 13-year follow up of patients who had been treated at an ICPM program and determined that treatment gains were maintained in all areas assessed (i.e., pain intensity, pain interference, and mood). Additionally, the patients in this study demonstrated levels of general health on most dimensions comparable to peers of similar ages who did not suffer from chronic pain. As a whole, this body of literature suggests that most patients who are treated through an interdisciplinary approach are able to convert short-term learning into long-term lifestyle modification. While the quality of ICPM programs varies, those that strongly emphasize psychoeducational intervention are perhaps more likely to avoid what Turk and Rudy[88] referred to as potential "decay of effect" following completion of treatment.

The Threat to the Viability of Interdisciplinary Chronic Pain Management

As mentioned earlier in this chapter, the number of ICPM programs in the United States has decreased dramatically over the past decade,[28] thereby severely limiting the availability of the treatment for chronic pain for which overall clinical efficacy and cost-efficiency have been most rigorously validated. The demise of the ICPM program is a particularly curious and disturbing phenomenon, particularly given the cost of chronic pain—not only to the individual sufferer, but to society as a whole. In addition to the staggering health care costs associated with chronic pain (estimated at $125 billion annually in 1999),[30] indirect costs such as lost productivity (estimated at $61.2 billion annually in 2003),[89] lost wages, disability compensation, disruption in the work place, and lost productivity of spouses and other caretakers of chronic pain sufferers are also bewildering. For example, it has recently been suggested that disability payments relating to chronic pain may exceed medical costs by a factor of five.[29] Turk[70] estimated that the treatment of chronic pain through ICPM programs in the United States resulted in health care savings of $45 billion annually. As he also noted that only 6% of patients who are treated by pain specialists are fortunate enough to be treated through an interdisciplinary approach, and only 2.5% to 5% of patients with chronic pain are ever treated by a pain specialist,[90] the wholesale development and appropriate utilization of ICPM programs theoretically has the potential to produce savings to society in the *trillions* of dollars annually!

Why would a treatment approach to chronic pain that has been empirically established to be so clinically effective and cost-efficient and that has the potential to help ameliorate suffering on an individual basis and save society as a whole profound sums of money become inaccessible? Schatman[12,13] has examined this paradox from an ethical perspective and identified several potential causes for the demise of the ICPM program.

First, health insurance carriers tend to be "penny wise, pound foolish" in their efforts to contain costs and generate profits. This tendency is somewhat paradoxical, as the insurance industry is certainly aware of the copious body of literature supporting the cost-efficiency of ICPM that has been discussed in this chapter. Aggravating this nonsensical approach is the practice of "carving out" basic treatment components from interdisciplinary programs in an effort to contain costs. Of this practice, Gatchel has recently noted, "This has paradoxically produced the effect of steering patients away from multidisciplinary treatments that demonstrably reduce health-care utilization, and toward more expensive unimodal therapies associated with poorer outcomes."[91] Gatchel and his colleagues[92,93] have performed empirical studies demonstrating the compromised efficacy associated with the carve-out phenomenon. Their research has indicated that physical and psychological functioning as well as vocational outcomes are adversely affected by carve-outs, both at program's completion and at 1-year follow-up. In another study, Gatchel and colleagues[94] conducted a cost-utility analysis of carving-out services from ICPM programs. The authors determined that this "cost-saving" practice of insurers actually resulted in compromised emotional and physical gains, lower reductions in pain, and inferior health-related quality of life, and actually costs more than the intact ICPM program.

Second, it has been noted that, "there is a tendency of third-party payers to expect pain treatment centers to solve all of their (patients') social problems,"[95] not recognizing that even the most effective ICPM program cannot control all outcomes, just as they cannot control all patient and social variables. For example, workers compensation carriers are typically invested in ICPM program patients returning to the work force. In 2000, when the national unemployment rate was below 4%, it was easier to return injured workers to active employment than it was in 2003, when unemployment reached 6%.[96] An example of a patient variable that cannot necessarily be controlled is characterological disturbance. As mentioned earlier in this chapter, a number of studies have identified the overrepresentation of characterologically disturbed patients in the chronic pain population.[58–67] While Schatman[38,39] has elucidated the potential problems associated with treating dramatically characterologically disturbed patients in ICPM programs, the lack of high quality outcome research on the ability of these patients to benefit from interdisciplinary treatment makes their perfunctory exclusion a violation of the bioethical principle of justice. However, experience suggests that personality-disordered chronic pain patients are more likely to experience failure in an ICPM program. Unfortunately, third party payers unrealistically expect interdisciplinary programs to "fix" their patients, regardless of how irreparably "broken" they may be.

Third, pharmaceutical companies have historically marketed medications such as opioids, nonsteroidal anti-inflammatory drugs, and anticonvulsants to health insurance companies as "quick fixes" for chronic pain, despite the lack of empirical evidence supporting monotherapy with medications as more cost-efficient in the long run than ICPM. Similarly, implantable device manufacturers are well-known to market aggressively, despite their lack of an evidence basis for the efficacy and cost-efficiency of their products.

Fourth, the possibility that interventional pain management specialists are becoming progressively less anxious to relinquish control of their patients should be considered. Given decreases in reimbursement for the relatively time-consuming ICPM approach in conjunction with a pattern of higher levels of reimbursement for procedures used to treat chronic pain,[97–99] there exists an increasing fiscal disincentive to refer patients to ICPM programs. Chapman states, "Concurrent with the decline of intensive programs is the rise of procedural interventions and medication, which receives a great deal of support from medical technology and pharmaceutical companies."[100]

Finally, ICPM programs are extremely labor intensive and can only treat a finite number of patients. Accordingly, hospitals in which they are housed do not consider them "cash cows," and accordingly are choosing to discontinue their operation. This is sadly true even in academic medical centers, in which so many of the great ICPM programs once operated. Even "not-for-profit" medical centers have shifted from a professional ethic in which the ethos is amelioration of suffering to the business ethic of cost-containment and profitability. Sadly, it is the patient suffering from chronic pain that is caught between these two "ethical foundations" as ICPM programs continue to close. Schatman[12,13] has addressed the demise of ICPM programs in considerable detail, questioning this unfortunate development from both principle-based and virtue ethics perspectives.

Future Directions: Reviving the Discipline

The quandary with which the field of ICPM is faced is a disturbing and distressing one. In response to perceived helplessness, a number of the top chronic pain management specialists in the United States have chosen to abandon the discipline, while others have chosen to become expatriates, practicing in interdisciplinary settings in the United Kingdom and Canada. Despite criticism regarding these countries' nationalized health care systems, ICPM continues to flourish in these nations, particularly as compared to in the United States. For example, a 2006 study by the British Pain Society[101] indicated that there are 92 ICPM programs in the United Kingdom, serving approximately 60 million inhabitants,[102] thereby producing a ratio of one interdisciplinary clinic for roughly every 650,000 inhabitants. A 2007 study of pain clinics in Canada[103] indicated that there are currently 120 ICPM programs in that country, serving approximately 33 million inhabitants,[104] thereby yielding a ratio of one clinic for every 275,000 inhabitants. While none of the major American pain organizations (e.g., the American Pain Society, the American Academy of Pain Management, the American Society of Pain Educators, the American Academy of Pain Medicine, the American Pain Foundation) was able to provide an estimate in the number of ICPM programs still operating in the United States, a 2005 report aired on ABC's *World News Tonight* claimed that there were only 200 interdisciplinary clinics in the United States.[105] Based on this number of clinics serving 303 million inhabitants of the United States,[106] the number of inhabitants served by the average ICPM clinic in the United States is approximately 1,500,000. This suggests that access to ICPM in the United States is more than twice as limited as in the United Kingdom, and more than five times as limited as in Canada. Fortifying the argument for superior access to interdisciplinary treatment abroad is the fact that while the number of ICPM clinics in the United States is decreasing rapidly, the number of clinics in the United Kingdom actually increased from 70 in 2001[107] to its 2006 level of 92 such facilities.[101]

Symbolic and specious efforts have been made to improve the quality of pain care in the United States in recent years. For example, the National Pain Care Policy Act[108] was introduced in March of 2005. This bill calls for making adequate treatment, education, and research relating to pain management a national public health priority. One of the bill's provisions is for the development of six government-funded regional pain treatment and research centers. Seemingly, such a program would enhance access to high-quality ICPM. Unfortunately, however, this is not

likely to come to fruition. First, the creation of merely six treatment centers when thousands are needed is insufficient. It is true that the National Pain Care Policy Act calls for the development of centers for research as well as for treatment. However, millions of dollars are already being spent at hundreds of institutions across the United States for chronic pain research. Unfortunately, research in the absence of facilities that actually provide treatment that has already been empirically-established as clinically effective and cost-efficient does not serve to solve the chronic pain crisis in the United States. Second, investigation indicates that the bill was referred to the Committees on Energy and Commerce, Ways and Means, Armed Services, and Veterans Affairs, where no action was taken. The National Health Care Policy Act was reintroduced in 2007 as H.R. 2994,[109] and has been referred again to the House Committee on Energy and Commerce. No subsequent action on the bill has been taken, and there is no evidence that this legislation is the top priority of the current (or any) Congress. In an American Pain Society newsletter, Turk[110] suggested that the bill "faces a long and arduous trek through Congress," which is perhaps an understatement. Another spurious and symbolic effort to improve pain care policy in the United States is Congress's declaration of the first decade of the new millennium as the "Decade of Pain Control and Research."[111] It is unlikely that the wholesale closure of ICPM clinics in the United States during this decade represents the most effective effort at pain control. Finally, the campaign to treat pain as "the fifth vital sign" in the current decade by the Joint Commission on Accreditation of Healthcare Organizations has been applied primarily to palliative care, and it is difficult to draw a link between this symptom monitoring practice and the availability of ICPM. Despite these symbolic efforts, the most clinically effective and cost-efficient method for the treatment of chronic pain of benign origin continues to march toward obsolescence.

Accordingly, Schatman[12,13] has suggested that it is the ethical obligation of the federal government to assure that this highest-quality treatment for chronic pain becomes accessible once again—much as the governments of the other "civilized" nations of the world are making efforts to do so. As noted earlier, the cost to society as a whole, as well as to the individual sufferer, is overwhelming. Under the Obama administration, providers of chronic pain care (as well as health care considered more broadly) are hopeful that steps toward nationalized health care will serve to increase the availability of interdisciplinary chronic pain treatment to Americans. Pellegrino[112] has suggested that the moral answer to our health care crisis would be a "mixed economy" in which medical care is removed from the competitive marketplace. He states, "freedom from acute or chronic pain, disability, or disease, is a condition of human flourishing. Human beings cannot attain their fullest potential without some significant measure of health. A good society is one in which each citizen is enabled to flourish, grow, and develop as a human being."[112] Perhaps more so than any other condition, chronic pain robs its victims of the ability to flourish, grow, and develop. ICPM is an approach that cannot become extinct, as it represents the most powerful method that we have to enhance quality of life among those who suffer from chronic pain.

CONCLUSION

The history of ICPM is a rich and distinguished one, as countless patients have experienced relief of their suffering and reclaimed their quality of life through interdisciplinary treatment. Despite substantial and unequivocal empirical support for its clinical utility and cost-efficiency, the number of once abundant programs in the United States has dwindled, resulting in patients being forced to resort to less effective and more expensive treatment options which tend to focus on body parts as opposed to the person in need. It has been suggested that ICPM needs to be streamlined in order to become consistent with economic realities if the discipline is to survive, with managed care organizations most guilty of advocating "carve-outs."[91] However, practitioners who have seen the dramatic beneficial effects of ICPM programs that are intact question the need to fix a model that is really not broken, as doing so adversely impacts the integrity of the interdisciplinary approach.

Unfortunately, pure capitalism does not necessarily solve every societal problem, and chronic pain is certainly one such example. Despite the opposition to nationalized health care within the medical community,[113–116] no one has offered a realistic proposal other than nationalized health care to solve the growing chronic pain crisis. Government financing and management of ICPM would clearly not be unprecedented, as millions of Americans are treated through Medicare, Medicaid, and the Veteran's Administration systems. It is not surprising that some of the leading ICPM programs in the United States are found within the Veteran's Administration system, which continues to embrace interdisciplinary approaches to medicine.[117–119]

In a presentation at the Eighth World Congress of the International Society for the Study of Pain,[120] the original pioneer of ICPM, John Bonica, was referred to as the "world champion of pain." As chronic pain practitioners, we recognize our fiduciary obligation to advocate on behalf of our individual patients. Unfortunately, doing so in and by itself is no longer necessarily sufficient. Perhaps all of the noble practitioners of the interdisciplinary approach need to become "champions" by sacrificing our time and other available resources to advocate for the preservation of the closest thing to a "cure" for chronic pain that is available to our patients.

CHAPTER 106 ■ SPINE CLINICS

RALPH F. RASHBAUM, ANDREW R. BLOCK, AND DONNA D. OHNMEISS

INTRODUCTION

Back pain has many different dimensions and is a complex problem. Anatomically, the human spine is a structure of tremendous intricacy, serving functions which, at times, can be contradictory. Consider, for example, the primary roles of the spine—support and flexibility. The spine must be strong enough to keep the body upright. At the same time, the spine must have elastic properties, allowing for broad motion through flexion, extension, and rotation. Further, the spine has a protective function, surrounding and cushioning the delicate structures of the spinal cord and nerve roots from damage. The spine is capable of accomplishing these tasks through a conglomeration of bones, joints, tendons, ligaments, discs, nerve tissue, and assorted other structures. Spinal anatomy is complicated by the number of mobile segments, the proximity of the nerve roots, the intricate motions of multiple small joints, and the natural changes that occur with aging. The biomechanics are complex and allow us to perform demanding combined motions such as bending forward and twisting. Also

involved in movement are the large muscle groups of the spine. Knowledge of the intricate biochemistry of the intervertebral disc and the role of inflammatory mediators in back pain continues to expand. There is also a significant psychologic component that impacts the behaviors of patients with back pain and their recovery from injury. Considering the complexity of the spine, it is understandable that definitively diagnosing the exact source or sources of symptoms is often difficult or impossible.[1] This task is made even more difficult by the strong impact of personality in reporting and dealing with pain, particularly work-related low back pain.[2]

The spine is continually beset by physical stresses, and, once an individual reaches adulthood, it is in a constant state of degeneration and decline. The very complexity of the human spine creates the conditions that make it so difficult to resolve spine pain. With so many complex and interacting structures, pain can arise from individual structures, multiple structures, or their dynamic interaction. As noted by Jerome Groopman in his best-selling text, *How Doctors Think*,[3] "given all of these structures, the source of the chronic . . . back pain is often a mystery. Doctors can be hard-pressed to identify why a patient is uncomfortable."

Despite its complexity, back pain is a very common problem that severely impacts the lives of many. Using data from the 2002 National Health Interview Survey, Strine and Hootman[4] reported that the 3-month prevalence of back and/or neck pain among adults in the United States was 31%. These subjects generally had more comorbid conditions and greater psychologic distress than did subjects without back or neck pain. As discussed by Fanuele et al.[5] using the SF-36 general health status questionnaire, back pain patients were significantly impaired, even when compared to a variety of other health conditions. In order to effectively treat such patients, one must understand the severity of the problems and appreciate that back pain may often be accompanied by a variety of comorbidities. Chronic back pain is an extremely expensive problem. Many of the patients have failed to gain adequate relief from surgery, and some have suffered injury during the surgery itself. In some patients, the physiologic origin of their pain cannot be definitively determined.

The patient with chronic spine pain is often passed from practitioner to practitioner, often of widely-varying expertise, training, and experience, and each subjecting the patient to their own preferred techniques for palliation. As the patient drifts farther into disability, pain, and medication use, desperation increases, and the cost of single-modality treatments increases in parallel, while the probability of overcoming the pain and of improving function, diminish. It is, according to Groopman, "as though each approach to diagnosis and treatment is essentially a 'franchise' and that too many franchises are battling for control."[3] Such a state of affairs leads to treatments that are increasingly expensive, unfocused, unsubstantiated, and ineffective.

Thus is the complexity of chronic spine pain, and the costly, untenable nature of many treatments. All point to the need for a different approach to chronic spinal pain. The desired approach is no different now from that developed for general chronic pain by Dr. Bonica, and aptly described by Loeser, Turk, and Chapman in the third edition of *Bonica's Management of Pain*.[6] They state that Dr. Bonica:

> . . . brought clinical psychologists, pharmacists and other non-physician providers to the conference table with anesthesiologists, neurologists, physiatrists, neurosurgeons, orthopedic surgeons, psychiatrists and others. This blend of perspectives kept each specialist from exercising specialty-specific tunnel vision, and in conferences a group understanding often emerged that greatly exceeded the understanding that the record would yield after a series of serial consultations.

This is an apt description of the multidisciplinary approach to care. Of course, a multidisciplinary approach alone does not guarantee either efficiency or effectiveness. In order to provide maximally effective and efficient treatment, and to limit treatment costs, a spine treatment facility must include practitioners with the highest levels of training and experience, who follow treatment guidelines that are scientifically-validated yet flexible enough to address the idiosyncrasies of individual patient problems. The care needs to be carefully coordinated to avoid duplication, unnecessary expense, and use of treatments with limited possibility of success. A number of specific principles should guide the multidisciplinary spine facility:

1. Specific algorithms for evaluation and treatment
2. Ongoing multidisciplinary case management and case discussion
3. Active process of continuous quality improvement including outcome measurement, assessment of patient satisfaction, and use of results to improve treatment algorithms
4. Professional education of treatment team members
5. Participation in active research programs

In this chapter, we discuss in the key elements needed to establish and maintain an effective multidisciplinary spine facility.

TREATMENT COMPONENTS

The three major components that comprise the clinical aspects of a multidisciplinary spine center are (1) a group of dedicated, highly-trained physicians and allied health providers with expertise in spine care; (2) a set of treatment algorithms guiding assessment and intervention; and (3) active and aggressive case management, especially when patients fall outside of established treatment algorithms. One of the keys of a successful center is building a team that understands and respects the role and skills of all the other team members.

TREATMENT PROVIDERS

Conservative Care Gatekeepers

Of the many individuals who experience back pain, only about 1% ever undergo spine surgery.[7] It is therefore logical that the initial evaluation of patients presenting to a spine treatment center should be conducted by a "conservative care" physician—one who is specially-trained in the assessment and treatment of spinal disorders. These physicians should be able to triage patients and place them into appropriate assessment and treatment algorithms. Complicated cases and those requiring urgent or emergent intervention can be rapidly identified and referred for appropriate diagnostic procedures and appropriate intervention. However, the majority of cases will be best handled using standard treatment algorithms in which resolution of the injury is expected with minimal intervention. Such physicians may include specialists in anesthesiology, physical medicine and rehabilitation, occupational medicine, or even appropriately-trained and experienced chiropractors.

Pain Management

The most ubiquitous and bothersome indication of spine injury is pain. Unremitting pain, often fluctuating randomly, can decimate both emotional stability and physical capability. As the patient proceeds through treatment at a spine center, it is for pain that the patient most urgently seeks treatment, and it is pain that is most immediately mitigated. Physicians now have a diverse armamentarium of oral and injectable medications that may pro-

vide immediate, and at times prolonged, relief. The oral medications are most often opioid analgesics and, even in recently-developed time-release preparations, carry with them both the potential for physical dependence and addiction in up to 40% of chronic pain patients.[8] Targeted injections are of some value in specific conditions (see Chapters 97 and 98 for a detailed discussion), but their use requires sophisticated equipment and advanced training in order to be used safely and effectively. Pain management physicians, often specially-trained anesthesiologists, can effectively use injection therapy, but these treatments must be used in coordination with the other evaluation and treatment efforts, including physical therapy (PT).

Psychology

Patients suffering with spinal injuries and pain experience dramatic emotional and social changes. Up to 80% of patients with persistent spinal pain are diagnosable with clinical depression,[9] and many will express anger as the most common emotion they experience.[10] Fear and avoidance of pain often drive patients into unnecessary functional decline. Marriages and relationships can shatter, and spine injuries often leave economic devastation in their wake. For these reasons, specifically trained psychologists often play a pivotal role within the spine center. Numerous studies have shown that psychosocial factors can complicate recovery from spine surgery (see Block et al.[11] for a review). Thus, one of the major functions played by psychologists is to perform presurgical psychologic screening, providing information to surgeons about the level of psychosocial risk found in patients who are being considered for spine surgery. Such a process allows the surgeon to individualize treatment protocols. In patients who have a high level of identified psychosocial risk, alternatives to spine surgery can be considered. Psychologists often see nonsurgical patients as well, helping them deal with the emotional sequelae of spinal injury and to help them learn new means of coping with pain and its limitations.

Physical Therapy

Many back pain sufferers require little intervention from a physician. Their problems are related to body mechanics and deconditioning. One aspect to PT is that patients often continue the activities they learned during therapy. Many clinics provide patients a home exercise program as their formal treatment period ends. Also, getting into the habit of exercise during PT may encourage patients to continue a more active lifestyle, improving their general health as well as potentially decreasing their back pain.

A conservative approach to the treatment of spine injuries often incorporates PT as a first-line treatment. Frequently, therapists provide the combination of strengthening, stretching, palliative modalities (such as heat or electrical stimulation), and hands-on muscle activation that provide pain relief of such benefit that more intense or even invasive interventions may be avoided. For example, Fritz et al.[12] found that patients with acute spine pain who have high adherence rates to active physical therapy-based exercise programs achieve excellent reductions in disability and pain.

Occupational Therapy

One of the most challenging and costly aspects of back pain is dealing with workplace-related back pain. In many settings, physical therapists take on part of the role of occupational therapists. They can perform structured functional evaluations to determine the patient's current level of performance compared to their job demands.

Spine Surgery

Spine surgery is the topic of many publications, much discussion, and inspiration for developing new implants and operative techniques. Only about 10% of patients seeking care for back pain go on to have surgery. The risks involved, as well as the costs, mandate that surgery is used sparingly and when nonoperative options have failed to provide adequate relief. A spine center of excellence needs a group of well-trained spine specialty surgeons. Although not frequently addressed in the literature, there has been some investigation into the relationship of surgeon experience and complications associated with spine surgery. Wiese et al.[13] found that the complication rate following lumbar microdiscectomy was significantly less among surgeons with a greater level of experience (2.2% vs. 10.7%). In results from a multicenter total disc replacement study, it was reported that among the high-enrolling surgeons and/or centers, the length of hospital stay, operating time, and complication rates were significantly less than among low-enrolling sites.[14] Results of the studies suggest that established spine centers that make use of a team of specialists with varying expertise have an advantage over individual physicians with respect to complication rates. In addition to the spine specialty surgeons, spine specialty operating room staff also contribute to the operative procedure by their familiarity with spinal procedures and instrumentation.

While surgery is sometimes viewed as the "end of the road" in treatment, this should not really be the case. While surgery is a dramatic event, it is only one step in a continuum of care. Treatment does not end with surgery. Most patients who undergo spinal surgery will not have been engaging in typical activities due to pain. Although the surgery may address the structural component of their problem, it cannot address the deconditioning that has occurred. In a spine clinic, there are postoperative rehabilitation protocols for the various types of surgery performed. In this day of escalating surgical options and approaches, physical therapists must gain a clear understanding of each operative intervention and lend their expertise to developing safe and effective rehabilitation protocols that will maximize functional recovery after surgery. For example, a therapist not working closely with spine surgeons may have a difficult time devising the most appropriate and safe program for a patient who has undergone surgery using a nontraditional approach such as the trans-sacral approach to the L5-S1 disc space or extreme lateral interbody fusion for other lumbar discs. Some new procedures require avoidance of specific motions early after surgery with guided progression back to full activity.[15] Without an understanding of the goals and functions of new implants, it is unlikely that a physical therapist working in isolation will be able to design an optimally safe and effective rehabilitation regimen.

One of the advantages of a spine specialty center is the enhanced opportunity for surgeons to participate in clinical trials evaluating new technologies. These centers are often preferred sites due to the expertise of the surgeons and the ability to have a large enough patient population to meet enrollment needs. The benefit to the surgeons is that they can offer patients interventions that would otherwise be unavailable outside of an investigational setting for many years to come. Patients have the benefit of possibly participating in clinical trials if they meet the selection criteria and elect to participate. The multidisciplinary nature of an established spine center offers the optimal atmosphere for testing new and emerging technologies for treating spinal disorders.

Chronic Pain Management Program

The multifaceted nature of spine injuries points to the importance of approaching spine treatment in a multidisciplinary fashion.

After treatment, patients must often resume a life where the very assumptions and boundaries have been greatly distorted, all too often by ongoing pain or marked functional limitations that were not present before illness or injury. With or without surgery for spinal disorders, pain and concomitant limitations often linger and, without proper treatment and planning, these can magnify. The chronic pain management program (CPMP) thus becomes a truly integral component of treatment in most spine centers. Such programs, involving many disciplines (most often physical medicine, physical and occupational therapy, psychology, and others), rely on therapeutic group milieu to assist patients in learning (and helping each other to learn) new ways to deal with pain, minimize its impact on their lives, and to overcome psychosocial barriers. Research on the CPMP approach indicates that patients achieve an average pain reduction of approximately 50%, about 75% are able to get off narcotic medications, and the return to work rate from such programs is approximately 67%.[16] Of course, CPMPs vary widely in terms of their composition and effectiveness. The spine center should, at a minimum, be certified by and adhere to the standards set by the Commission on Accreditation of Rehabilitation Facilities (CARF).

Potential Benefits of a Spine Specialty Clinic

Many components of treating chronic pain of other origins and back pain are similar. What, then, is the advantage of having a spine specialty clinic? Focusing solely on back pain has several potential advantages.

While in the past there may have been more separation between nonsurgical care providers and surgeons, the two can be blended into a comprehensive system. As reported by Rasmussen et al.,[17] the initiation of multidisciplinary "nonsurgical" spine clinics significantly reduced the number of lumbar discectomy surgeries performed. One of the factors that was felt most likely to account for this decline was an improved diagnostic evaluation process.

Considering the wide range of potential pain origins as well as the potential and varying roles of personality factors related to back pain, it is not surprising that patients cover a very broad spectrum of problems and needs. This gives rise to the need for true multidisciplinary care. But also considering these same factors, it is imperative that the care providers have, and maintain, a strong and specific knowledge base regarding spinal disorders. Such skills can only be developed and continually honed by ongoing interaction with back pain patients, continuing professional education, and the cross-training provided by the frequent interaction of professionals from various disciplines caring for similar patients. This is true not only for the physicians involved in the clinic, but also for the physical therapists and other members of the treatment team. By building a strong knowledge base in one area, providers can equip patients with a greater level of education in discussing their spinal problems. With the rapidly increasing knowledge base related to the chemical and biomechanical aspects of back pain, the pain system in chronic pain patients, advances in imaging, the rapid growth of spine surgery treatment options, and the role of diagnostic/therapeutic injections, it will become more and more difficult to keep pace with the current information. As evidenced by the large number of spine-related publications coming into print every month, it may be practically impossible to stay up-to-date if trying to achieve this in a variety of nonspine areas as well.

Specialized spine centers require a large patient population to support all the facets required for the multidisciplinary approach to care. While some painful conditions are relatively rare, back pain is a very common problem. Considering that 80% of people have back pain at some point during their lives and that about 10% go on to develop chronic pain, there are likely to be large enough patient populations in most communities to make a spine center a viable undertaking.

The term "Center of Excellence" is a determination used in several specialties to provide quality assurance for new procedures or technologies or for those surgeries not widely performed, such as video-assisted thoracic surgery.[18] A number of centers of excellence in spine care have emerged in recent years, but there is no uniform set of criteria used to define a spine center of excellence. Such centers have a multidisciplinary treatment philosophy and are committed to providing the highest quality of care. It is these centers of excellence that should be the lead sites in developing treatment guidelines, participating in registries, performing research, and providing education. Implementation of a structured quality assurance program is a critical element of developing a spine center of excellence. Designing and implementing guidelines, assessing outcomes, and implementing changes for improvement may be more manageable in a spine clinic than in a center dealing with multiple problems or in a the setting of an individual practitioner's office. This type of program is becoming increasingly needed in this age of increasing demands for ongoing quality assessment and reimbursement initiatives such as pay for performance.

Within the spine clinic, subspecialization will naturally take place. Based on the interests and skills of the professionals involved with patient care, various physicians will gravitate toward treatment of specific spinal disorders. For example, one may take the majority of patients with unusually challenging cervical spine problems, another may be a leader in one or more areas of spine arthroplasty, and there should be at least one surgeon adept at diagnosing the multiply operated failed back patient who eventually arrives at a spine specialty facility. Some physicians may elect to perform injections while others do not. There is a need for advanced interventions such as spinal cord stimulation for pain management. This type of subspecialization within a spine clinic further provides the care provider the opportunity to hone highly specialized skills as well as allowing them to pursue the interventions they are most interested in providing.

The presence of professionals from multiple disciplines in a spine clinic will also increase awareness about alternate pain mechanisms and approaches to treatment. For example, the addition of chiropractic care providers will increase the awareness of all the care providers of problems arising from the sacroiliac joint and the role of manipulative therapy in treating this group of patients with low back pain.

Coordination of Care

Working one's way through most health care systems can be daunting for patients. A comprehensive spine clinic can reduce confusion and anxiety. Patients can receive a wide variety of services as needed within a single facility. Patients receiving treatment in a single center will become familiar with employees, and they will find less redundant paperwork required for insurance and providing basic history and health data. The best spine centers provide close coordination of care from one provider to another through close communication.

Research and Education

If practicing in a university setting, education and research are built into the framework and environment of patient care. However, the success of programs still depends strongly on the commitment made by the individuals involved. While this is also true in private practice, the challenges are greater. There is no institutional framework or incentive built into the practice that pro-

motes involvement in either research or education. To create a research environment outside the university setting requires a commitment of time and financial resources. However, a practice cannot hope to become a spine care center of excellence without incorporating research and education. The implementation of a research program is becoming easier with the growing use of electronic medical records and registry systems in spine care facilities. Establishing an infrastructure for data collection compliments the current demands for evidence-based medicine and cost-effectiveness information for back pain interventions. Considering the societal costs associated with back pain, these demands may be even greater for spine care specialists than for other disciplines. While in the past, care providers may have been able to be successful without engaging in organized data collection, this is likely to change. Research also provides a venue to gain recognition in the peer group. This is more easily accomplished in a specialty clinic than in one spread across multiple specialties, unless focused efforts can be made in multiple areas.

The increasing use of electronic medical records and national study registries in spine has greatly facilitated tracking treatment outcomes. Although these mechanisms are far superior to traditional paper data collection, they still require time to harvest the data, address unanticipated scenarios, download, analyze, and prepare reports of the data, and write abstracts and manuscripts. One of the greatest advantages of the registries is that some are programmed to contact patients by e-mail up to 24 months after treatment and have patients complete self-assessment forms online without returning to the clinic. Although radiographic follow-up cannot be achieved, the patient's clinical condition can be evaluated.

Another opportunity to become active in spine research is through participation in clinical trials. To do so is a great responsibility for the investigator to ensure that the trials are being conducted in accordance to federal regulations and study protocols. Staff should be hired with experience in conducting clinical trials, regulatory requirements, and experience interacting with institutional review boards or human experimentation ethics committees. Many such trials are financially self-sustaining, as industry sponsors will provide the funding to cover the cost of conducting the trial. Participation in such studies provides the framework for rigorous data collection.

Research is a vital part of quality patient care. Although all care providers want to take the best care of their patients, without measuring and being willing to critically appraise their own outcomes it is impossible for the individual practitioner to assess and improve the quality of care they are delivering. Through the collection of data and ongoing assessment of results, problems, such as spikes in particular complication rates, can be identified and addressed. This is particularly important in a multiple physician group to assess the complications and clinical outcomes of all the care providers in the practice and to ensure that problems are addressed as soon as they are identified.

Accepting the role of serving as faculty for a residency program or establishing a fellowship program can also enhance the intellectual environment of a spine clinic. Such programs often lead to creating lecture series such as grand rounds and journal clubs, which are relatively inexpensive. Creating forums for discussion among all care providers in the group can strengthen the bonds of the practice, allow more insight into what the other team members' discipline offer to overall care, and can enhance care by getting the right patient to the right provider more quickly.

Spine specialty centers have the potential to step to the forefront in shaping the future of spine care on a large-scale basis. Being specialized and focused in one area makes it easier to participate in registry networks and other quality improvement initiatives.

CONCLUSION

The spine is a very complex structure that presents a diagnostic and treatment challenge. The complexity is compounded by the frequent and profound psychologic impact of chronic spinal disorders. A spine center of excellence must be designed to address the complexity of these challenges. One of the primary needs is an organized, deliberately planned approach to the evaluation and treatment of the broad spectrum of back pain patients. The multidisciplinary team must be trained and focused on quality spine care. The use of electronic medical records greatly enhances the ability to track patients and events related to their care. The team of providers must understand the role of the other team members and respect what each has to offer in providing quality care to patients. There must be strong leadership to keep the team focused and functioning well.

Part of developing a center of excellence is incorporating research and education. Research efforts can provide patients and practitioners with the opportunity to participate in clinical trials which can enhance the reputation of the center in the community while at the same time providing a means to assess outcomes of various treatments provided in the clinic. Only through incorporating research can providers have access to the latest technology. Everyone benefits from education. This can take on many forms including lectures, journal clubs, fellowship programs, and conducting research.

CHAPTER 107 ■ PAIN MANAGEMENT IN PRIMARY CARE

BILL MCCARBERG

INTRODUCTION

Prevalence of Pain in the United States

Pain is the most common reason cited for patients seeking medical care. Statistics reveal that pain accounts for up to 80% of total visits to physicians' offices.[1,2] In most cases, the patient understands the underlying disease process (e.g., pharyngitis, gastroenteritis, migraine headache). Pain associated with these disorders causes the patient to seek help from his or her physician. Although it is difficult to determine the prevalence of pain in exact numbers, recent surveys suggest that 75–105 million Americans experience pain daily or intermittently.[3–5] Pain management remains an elusive and frustrating goal despite a growing knowledge about the pathophysiology of pain. Taken together, the management of persistent pain in primary care is a complex enterprise.

Financial Implications of Chronic Pain

In 1992, Fishman and colleagues[6] studied a large managed care organization in the Pacific Northwest and followed the costs of medical care for 18 of the most common conditions seen in primary care. Of these 18 conditions, four were described as painful: neck pain, back pain, facial pain, and headache (excluding arthritis). The analysis found stroke to have the highest annual cost at $13,139 per diagnosis, followed by human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDs) ($10,246), dementia ($9824), and cancer ($8992).

Individually, the painful conditions were associated with relatively low annual costs: back and neck pain at $4226, facial pain at $4088, and headache at $4989. Despite these relatively low costs, the group of conditions described as painful were highly prevalent. Taking into account cost and prevalence, pain was the most costly of the 18 conditions with total annual health care costs of $198 million, followed by heart disease ($170 million), hypertension ($112 million), respiratory disease ($90 million), diabetes ($86 million), cancer ($55 million), stroke ($38 million), and HIV/AIDs ($4 million). More than 15 years later, the frequency of these disorders may be similar but the cost is almost certainly much higher.

Care management plans and disease management programs are abundant for other chronic conditions, such as asthma, hypertension, hyperlipidemia, and diabetes mellitus. Treatment strategies include case management, treatment algorithms, provider education, and patient support groups. In contrast, very little emphasis has been placed on studying and developing such initiatives for the group of conditions described as painful. Given the large allocation of U.S. health care dollars for treating patients with these conditions, it is time for the provider, payer, and policy maker communities to take notice.

Chronic Pain Management: The Status Quo

With the onset of pain, most patients attempt self-care with over-the-counter products and/or self-help techniques (e.g., distracting activities, rest). When these methods fail to afford adequate relief, the patient generally seeks help from a medical professional. In many cases, and particularly in health care systems with limited access to specialty care, the gatekeeping primary care provider is the first medical contact. The primary care provider recommends treatment and refers the patient for appropriate specialty care, such as a physical medicine assessment for low back pain.

When pain becomes chronic and specialty care is ineffective in improving the underlying condition, care management becomes more difficult. In a recent survey, only 34% of internists reported that they felt comfortable with their abilities to manage patients with chronic pain.[7] In a related article, Ballantyne wrote that the most difficult issue now facing physicians is, "whether and how to prescribe opioid therapy for chronic pain that is not associated with terminal disease, including pain experienced by the increasing number of patients with cancer in remission."[8] In part, physicians are hesitant to prescribe opioids because they lack both the understanding of how to accurately assess pain and the knowledge of available pain therapies.

Primary care physicians struggle with unexplained variability among pain patients. Physical abnormalities are not predictive of pain severity or dysfunction.[9] Large numbers of patients experience pain that may be constant, over long periods of time, and yet their life functioning is not changed in major ways. Conversely, there are other patients with similar structural abnormalities who suffer substantially more and cannot maintain their usual levels of activity.[10] Patients whose lives are significantly disrupted by pain engage in behaviors that are maladaptive, anticipate more distress, amplify sensations associated with pain, spend more time resting, and complain of less ability to control pain.[11,12]

At the same time, surveys evaluating the adequacy of pain treatment demonstrate that the current system is broken.[13] Patients report that they are not asked about pain, that they are afraid to report pain to their primary care providers, and that they are often not offered treatment. In one recent survey, 22% of pain patients reported being uncomfortable discussing pain with their personal physicians, 13% said they were denied pain medication or referrals to pain specialists, and 70% reported experiencing continued pain despite treatment.[14] Much of this system failure can be attributed to the treatment at the primary care level.

Searching for Solutions

There have been tremendous advances in the knowledge of pain pathophysiology, the understanding of treatments for pain, and recognition of the value in an interdisciplinary approach to pain management. On the scientific front, there has been an explosion

in pain research, and new pharmaceutical agents have become available for treating different types of pain. Complementary and alternative therapies for pain management have gained recognition. Novel interventional techniques and surgeries have been introduced. Professional pain societies have sprung up and training is now available to provide physicians and other health care professionals with expertise in pain management. Despite this unprecedented progress, pain care remains grossly inadequate and undertreatment of pain is still considered pandemic. The reasons for this continuing failure are varied, but it is clear that new solutions must focus on primary care.

A NEW APPROACH TO CHRONIC PAIN MANAGEMENT

Primary care is distinguished by familiarity with a wide variety of medical conditions yet proficiency in very few, if any. There are so many different types of pain that it is difficult for a nonexpert provider to become familiar with and comfortable treating pain. Current categories for classifying pain include nociceptive versus neuropathic, acute versus persistent, cancer versus noncancer, and area of the body (headache, abdominal pain, chest pain). These categories are simplistic and helpful only in a general way.

It is also difficult to assess the adequacy of treatment for pain in primary care. We are accustomed to accepted, well-defined, objective measurements. For many other chronic conditions, there are standardized outcome measures. In the diabetic, we can measure hemoglobin A_1C levels. In asthmatics, peak flow and the use of inhaled β agonists guide care. Treatment outcomes for pain are often subjective and confusing. If a patient's pain is better but function is not, is this outcome adequate? If the patient is satisfied with treatment but pain levels remain at 8–9/10, is this treatment sufficient? If the patient returns to work but is on high doses of opioids, is this acceptable? All of these questions, common in a specialty practice, complicate treatment in primary care.

Who Treats Chronic Illness?

When pain becomes chronic, a behavioral syndrome often emerges including depression, anxiety, helplessness, insomnia, deconditioning, and increased reliance on the health care system. At this point, chronic pain becomes a disease process that is amenable to disease management.[15] Chronic back pain is not a diagnosis but rather a description of duration and location. In many cases, it is not possible to be more precise in the diagnosis of low back pain since even experts disagree on the underlying etiology.[16]

Failure to be more precise in the diagnosis should not delay treatment or impede medical management. Treatment in primary care often involves uncertainty, as most of the conditions encountered cannot be diagnosed precisely: viral illness, rash, or headaches are common. Chronic pain falls into the group of conditions that defies definitive diagnosis and is suited to the primary care practice. A patient's suffering can be ameliorated by well-documented, nonpharmacologic interventions including patient education and self-help skills as well as nonspecific analgesics such as nonsteroidal anti-inflammatories and opioids.

All primary care physicians must treat patients with a variety of chronic diseases. In fact, most chronic illness is principally managed at the primary care level (Table 107.1).[17] Improvements in the medical management of asthma, hypertension, and diabetes have arisen from interventions implemented at primary care. Despite lack of expertise, the use of practice guidelines, treatment recommendations, chart reviews, shared experience, and expert assistance, primary care provides excellent medical supervision. Management of persistent pain lends itself to the same paradigm.

TABLE 107.1

CHRONIC CONDITIONS TREATED BY PRIMARY CARE PHYSICIANS VERSUS OTHER SPECIALISTS

Condition	Treated by primary care physicians	Treated by other specialists
Arteriosclerotic Cardiovascular Disease	86%	14%
Stroke	91%	9%
Hypertension	92%	8%
Diabetes Mellitus	90%	10%
Chronic Obstructive Pulmonary Disease	89%	11%
Asthma	94%	6%

A survey of 74 administrators who control the decisions in a variety of health plans representing 2200 to 2.5 million covered lives[18] reflected the widely held belief that chronic pain patients are best treated using a model similar to those used for other chronic conditions. These administrators also felt that primary care was best suited to deal with the majority of patients with chronic pain.

Why Primary Care is Involved

Primary care is based on the elements of trust, advocacy, and quality of life/lifestyle issues. In the primary care setting, patient nonadherence is common and expected. Persuading patients to strive for better health through exercise, diet, stress management, medication adherence, and disease monitoring is a common role for the primary care provider—a role that requires the provider to adopt and maintain a nonjudgmental attitude.

Primary care is uniquely positioned to provide care for patients with chronic pain. Of all specialties, primary care providers have the largest geographic distribution. Rather than clustering around medical centers in the largest cities, they are broadly distributed over diverse communities—from urban clinics to suburban medical centers to private practices in small towns and rural areas.

By its very nature, primary care entails developing a longitudinal experience with patients. Each office visit enables the provider to achieve greater understanding of how individual patients are dealing with their persistent pain. Primary care providers are experienced in providing comfort and disease management for conditions that have no cure. When clinicians are challenged to broaden their definition of pain as a symptom and begin to view it as an illness,[11] primary care is equipped to deal with all aspects of that illness.

When a patient's pain becomes persistent and specialty care becomes less effective as a treatment option, the providers can continue to play a key role by coordinating care, intervening when symptoms change, and constantly encouraging patients on lifestyle choices as they do in all other chronic diseases: weight loss, sleep hygiene, career change, anxiety/depression/anger management, conditioning, acceptance, and judicious use of medications.[19]

From a cost and utilization perspective, primary care is the appropriate setting for chronic pain management. Most types of health insurance, as well as Medicare and Medicaid, cover primary care visits yet may not cover long-term psychosocial treatment or interventional treatment. A 1995 low back pain study looked at 1555 patients cared for by chiropractors, orthopaedic surgeons, or primary care providers. Cost, work status, and time to restoration of baseline status were monitored. All groups achieved similar outcomes yet primary care was the least costly.[20]

Risks of polypharmacy are better managed within the primary care structure since it is accustomed to dealing with multiple diseases in a single patient.

Treating Chronic Pain in the Primary Care Setting—Why a Challenge?

Training in Pain

Much of formal medical training occurs in hospitals where acute symptoms and life-threatening conditions are studied. Very little practice is offered in the management of chronic pain in the outpatient setting. Training in pain management is generally limited to a brief session in a pharmacology or neuroanatomy course.

Medical school and residency fail to include practical pain management (e.g., use of opioids, polypharmacy, behavioral issues) which is essential for effective chronic pain supervision. Many of the issues that are critical to pain management differ from other chronic diseases. These issues—informed consent, nonadherence concerning analgesics, documentation, practice protection—are also not included in most medical curricula. Practical discussions about opioids does occur in the emergency room or on the hospital wards but this is often by word of mouth from supervising physicians, nurses, or other students. Myths and dogma arise from traditions handed down from resident to intern.

As a consequence of this lack in training, most graduating primary care providers are ill-equipped and therefore uncomfortable treating patients with persistent pain.[21] This often leads to undertreatment of the patient's pain.

Disagreement Among Experts—To Treat and Not to Treat

In recognition of the need to improve pain management, the Federation of State Medical Boards issued guidelines on the appropriate work up and treatment of persistent pain.[22] Most states have adopted the Federation recommendations in the form of Intractable Pain Acts. The safe and proper use of opioids is the cornerstone of these acts, encouraging providers to ask patients about pain and use medication when necessary. Increasingly, adequate pain relief is being viewed as a patient's right—and a physician's obligation—sometimes to the point of allowing the patient or family to take legal action against doctors for undertreatment of pain. On the other hand, opioids are now the most prescribed drug in the United States and the most common new drug of abuse.[23] This has led to a rise in new cautions in treating pain.

Despite medical board encouragement and Intractable Pain Acts, providers may be faulted for prescribing opioids. Doctors feel uncertain and uncomfortable caring for persistent pain since underprescribing and overprescribing can lead to legal consequences. The appropriate use of medication is not understood and felt to be risky for all patients.

Barriers to Treating Pain

Many barriers to the management of pain have been well documented in this text and others.[24] These obstacles include relating to the medical system, providers, patients, and regulatory and governmental agencies (Table 107.2).

All of these barriers are operant in primary care practices. At the same time, other obstacles are unique to primary care, making pain management more difficult even for the well-trained, conscientious provider.

Time Constraints. Primary care providers are under constant pressure to do more in less time. With cuts in reimbursement (Medicare, Medicaid, and other types of commercial insurance), a primary care provider's income is only maintained by increasing his or her work load. The 15-minute office visit must include other activities: telephone calls, add-on appointments, emergencies, hospital admissions, serving as preceptor for students or midlevel providers (i.e., interns, residents, nurse practitioners), and reviewing laboratory and x-ray reports.

Patients present with multiple medical complaints at each visit and expect the primary care provider to deal with each one. These complaints range from chronic conditions (diabetes, hypertension, and hypercholesterolemia), situational issues (insomnia, stress at work, menopausal symptoms), preventive care (immunizations, ordering a mammogram), procedures (skin tag removal, knee injections), and other issues (medication refills, disability forms, jury excuses, handicapped parking).

Comprehensive assessment and documentation would be difficult in this setting even if the entire 15 minutes were available for the visit. Because of the need for more documentation as part of the assessment and treatment, effective pain management requires more time than any other chronic disease process.

Lack of Adequate Guidelines. A variety of well-recognized treatment algorithms and evidence-based guidelines exist for treating other chronic conditions encountered by primary care physicians (e.g., cancer,[25] neuropathy,[26] fibromyalgia syndrome[27]). Although guidelines have been developed for some pain problems, there are relatively few specific recommendations for the treatment of persistent pain.

Even when guidelines are available, studies show that often they are not followed.[28] This can be explained in part by the nature of chronic pain. When a patient's chronic pain worsens,

TABLE 107.2

BARRIERS TO MANAGEMENT OF PAIN

Medical System	Access to medical care	Access to specialists	Denied coverage of medication or procedures	Denied coverage of CAM therapy*	Preauthorization requirements
Patients	Poor lifestyle choices	Fear to accept proven treatment	Expectation of cure	Stigma of psychiatric care	Beliefs about aging
Providers	Lack of Knowledge	Bias toward treatment	Failure to refer	Nialistic care	Beliefs about aging
Regulatory and Governmental Agencies	Lack of Medicare reimbursement	Oversight of opioid prescribing			

*CAM, complementary and alternative medicine.

the cause is frequently undiscoverable, making it difficult to apply a guideline or to decide on a different treatment when so many therapeutic options have been ineffective.

Patient Nonadherence to Treatment. In other diseases, the consequences of nonadherence are not apparent to the patient. Patients with worsening atherosclerosis, hypertension, or diabetes are very often asymptomatic. In contrast, nonadherence to medical management has serious implications for patients with persistent pain and their physicians. These include:

- Conflict—Nonadherence to recommended therapy may lead to increases in a patient's need for opioid medication. Conflicts also arise from patients requesting their physician's assistance in such matters as handicapped parking permits, disability claims, and failure to return to work.
- Risk—A physician's practice may become the target for investigation if patients are identified as overusing or abusing opioid drugs. Physicians are also at risk for enabling patients with persistent pain—facilitating the illness-related behavior rather than consistently encouraging a return to healthy behavior. On the flip side, physicians are not immune to the common suspicion/assumption that an individual's pain complaints are driven by secondary gain (e.g., substance abuse, disability, lawsuits, withdrawal from society, sympathy).

Specialty Referrals. Referrals for patients with persistent pain are unlike any others in primary care practice. A typical referral returns the patient to the primary care provider after the medical issue has resolved or the chronic illness has an understood treatment course. Dysfunctional uterine bleeding is diagnosed and treated before referral back to primary care. The fractured bone is set and stabilized, rehabilitation is arranged, and the patient presents back to primary care with restored function. The congestive heart failure patient has further testing, medication adjustments, and returns to primary care when symptoms have improved and the patient is stable.

The work up and treatment of the persistent pain patient, on the other hand, is very different and varies widely. The acupuncturist diagnoses an imbalance of energy and treats with needles and herbs. The physiatrist may focus on muscle tightness, nerve injury, and offers rehabilitative therapies. The interventionalist uses injections. The chiropractor focuses on structural imbalance of the skeleton and offers manipulation therapy.

Often the diagnoses and procedures for chronic pain are foreign to the primary care provider (e.g., disc disruption, discogram, vertebroplasty, facet arthritis, radiofrequency ablation), instilling a sense that primary care is less than competent in dealing with future patients. Unfamiliar drugs and drug combinations are awkward for physicians to prescribe and monitor. These may include polypharmacy with four or five drugs, combinations of multiple anticonvulsants, multiple opioids, and/or other analgesics, drugs rarely prescribed (e.g., methadone), and doses not used (e.g., high dose opioids or gabapentin).

After referral, patients return to primary care with unclear parameters on what constitutes success. Too often, the patient's pain level is as high as when first referred for specialty care. Psychosocial issues such as depression and anxiety have not been addressed. Monitoring patient behavior associated with opioid use is not well defined. Decisions regarding patient demands for early refills, when to do urine drug testing, how to interpret urine drug test results, and how frequently to schedule follow-up visits can be difficult and uncomfortable.

Comorbid Conditions. The most commonly occurring comorbid conditions in patients with persistent pain are depression, anxiety, insomnia, and substance abuse.[29] These comorbidities complicate care. Patients may resist psychiatric care for many reasons including the perceived stigma, the additional cost, or the belief that their pain is unrelated to the comorbidities.

Pain makes depression worse and depression makes pain worse, both independently.[30] Patients seeking relief from the pain and comorbid conditions may self-medicate with alcohol and other substances such as marijuana, which compounds the problem. They may take prescribed pain medications to treat the comorbid condition, which makes them feel worse.

Failure to address underlying anxiety, depression, insomnia, and substance abuse makes pain treatment more difficult. These comorbid conditions are difficult to treat in stable patients. When persistent pain or a chronic illness is also present, the treatment is even more complicated. It is not likely that a simple, single drug regimen or series of epidural steroid injections will be the long-term solution.

Adversarial Relationship. Medical practice in primary care is built on trust, respect, and advocacy for the patient. The doctor-patient relationship develops over years of providing preventive care, treating acute conditions, and supporting the patient through life transitions such as the birth of a child, the loss of employment, and the death of a close family member. This long-term relationship enables the primary care physician to acquire an understanding of the patient as an individual and allows the physician to better guide the patient through the complexities of medical care.

Persistent pain disrupts the normal pattern and creates an unusual relationship that is not seen in other chronic diseases. The primary care provider may at times feel forced into an uncomfortable adversarial position that he or she is not well trained to manage. Patients with chronic pain ask for many things that at times the physician must argue against or deny. The doctor-patient relationship can become tumultuous on many levels:

- The patient asks to go on disability and the doctor knows that the longer the patient is out of work the less likely it is that he or she will ever return to gainful employment.
- The patient asks for a medical excuse from jury duty. The doctor knows that the patient is not working, sitting at home, and is capable of fulfilling his or her civic responsibility.
- The patient wants to solve his or her problem by getting permanent handicapped license plates. The doctor knows that it is in the patient's best interest to be more active. Parking farther away from the store and walking may provide needed exercise.
- The patient wants the doctor to order additional or repeated expensive procedures (e.g., magnetic resonance imaging [MRI]) when his or her pain worsens. The doctor refuses because it will not change the treatment or lead to a cure for the persistent pain, and it is disallowed by the patient's health insurance plan.
- The patient demands more expensive, nonformulary drugs, often the latest new drug being advertised directly to consumers. The doctor argues that the drug is unlikely to be more effective than many generic alternatives and would not be approved by the patient's health insurance.
- The patient researches "miracle" treatments and cures on the Internet and presents the doctor with printed testimonials. The doctor knows that a majority of these treatments are unproven or perhaps dangerous.

In each of the scenarios described above, the doctor's role is to argue against the patient's wishes. When the doctor is unable to be supportive, the patient begins to question whether his or her "advocate" still wants to help. Often, the patient-doctor relationship becomes strained and the patient may resist potentially beneficial treatment options.

ADDRESSING BARRIERS TO CARE

As mentioned earlier in this chapter, primary care physicians are often uncomfortable treating patients with persistent pain. In ad-

dition to a relative lack of knowledge, there are a number of other underlying reasons for this.

Myths and Biases

Patients—Without conscious intention, people attach meaning to all sensory experiences. The smell of a rose may hold a special meaning to someone who received her first bouquet for the high school prom. The sound of the musical tune "Jingle Bells" may signify happiness, family gatherings, and holiday gifts. Pain, especially when it is persistent, often conveys a sense that the person is being punished for some real or perceived infraction. The common idioms associated with pain seem to confirm this understanding: "no pain, no gain," "you need to feel this," and "offer it up."

Too often, patients with chronic pain believe that they suffer because of some mistake they made (i.e., "I had a hard life, Doc. Of course I have pain.") or that pain is to be expected as a part of aging. There is so much meaning attached to pain, sometimes of a religious nature, that it is difficult to convince the patient otherwise. These beliefs about "needing pain" or "deserving pain" complicate treatment.

Providers—Primary care providers are suspicious of patients who complain of pain. Physicians understand certain types of pain—cancer pain, end of life pain, or acute trauma/illness pain—but are less accepting of the persistent pain that has few objective signs of defined conditions. We ask, "Why do some patients complain while others, with the same pathology or anatomy, do not complain?" "What is the secondary gain?" "Is this pain real?"

When pain is not easily explained, bias leads the primary care provider to suspect psychiatric causes. In addition, psychiatric comorbidities are common with persistent pain. Although specialists are more likely to understand the connection between anatomy and psychiatry, the primary care provider may believe that the persistence of the pain relates directly to the depression or anxiety thereby depreciating the pain complaint. Patients perceive this attitude as devaluing their experience.

Patient Resistance

The dichotomy of physical pain versus psychiatric pain is understood by patients. The patient reasons, "If my doctor cannot find anything wrong with me and if there is no fix for my situation, he or she will assume that I must be crazy." For this reason, feelings such as, "You think this is all in my head," are often expressed in patient encounters.

Physical and emotional pain cannot be separated. They coexist and feed on each other. For instance, the most balanced, rational, and accepting patients can still experience high pain levels from fibromyalgia syndrome even when anatomic pathology is lacking. On the other hand, those with extreme mental illness may not complain of pain at all. The best surgeon doing optimal surgery on a patient with low back and leg pain concordant with MRI findings may have surgery fail if an underlying psychiatric comorbid disease is not identified.

Despite wide recognition of the behavioral health comorbidities, patients often resist the suggestion that anxiety and depression may be exacerbating their pain. They equate these diagnoses with hysteria or hypochondria and feel that the physician is depreciating their pain experience. Treating comorbidities is difficult in this setting especially for the nonexpert primary care provider.

Regulatory Scrutiny

Fear of regulatory scrutiny is common in primary care settings although, in reality, very few primary care physician practices are ever monitored. Even fewer practices have had their licensure suspended. These few cases and those covered in the media often involve high profile providers or illegal and immoral activities. Despite this fact, reality does not mitigate perception and regulatory scrutiny, as noted in a previous chapter by Gilson in this text, continues to impede more aggressive pain management in many primary care practices.

Patient Expectations

The paternalistic relationship commonly seen in medical practice is being challenged by consumer activism. Patients have more access to health information than ever before. They have more time and motivation to research their conditions on the Internet, and sometimes know more about treatment options and a particular disease process than their primary care physician. As is often the case, this is a mixed blessing. On the one hand, an informed patient is much more amenable to self-management. On the other hand, an informed patient can present barriers to care.

Most patients with persistent pain do best with self-management skills. Acceptance of their chronic condition, developing strategies including conditioning exercises, and making changes in work or hobbies leads to the best results. However, when information-seeking patients are confronted with "miraculous cures" and daily news articles touting advancements in pain treatment, adapting to pain is difficult for the physician to sell. Too often, patients find themselves on a constant search for the next cure, only to be disappointed when it fails, then moving on to the next "harmless, 100% effective" treatment. As this pattern repeats over and over, the best treatment—acceptance, adaptation, and conditioning—is delayed. The expectations of desperate patients seeking miracle cures create significant barriers to optimum care.

PAIN PRACTITIONER: A PRIMARY CARE MODEL

Training

As in other disciplines, much of the training received by primary care physicians quickly becomes outdated as new knowledge is accumulated and scientific advancements are achieved. Education in all areas of medicine must be lifelong and constantly updated. Medical training provides a knowledge base with courses in neuroanatomy, pathophysiology, and pharmacokinetics. This serves primarily as a foundation and a method for learning and applying new knowledge.

The process of learning and reapplying new knowledge is well accepted in medicine. Despite all the practice management issues and the multilevel barriers to pain care, primary care providers continue to learn and apply new information in their daily clinical practice.

Collaboration with Pain Specialists

Education can occur at formal symposia, professional association meetings, dinner education, through journals, online education, and even the brief encounters with drug representatives. One of the strongest sources of knowledge for primary care is through associations with respected, education-oriented pain specialists.

As primary care physicians, we do not have to know how to operate on a compound fracture, place a cast, or teach the exercises for rehabilitation in order to provide competent aftercare for the patient. In most cases, specialists treat the chief or acute problem until the patient is cured or the condition or is stabilized

before referring the patient back to his or her primary care physician. Primary care's task is to understand the treatment provided and continue following the patient's condition to ensure optimal recovery.

Chronic problems rarely result in cure, as the name suggests. Congestive heart failure is not curable and the outpatient care is superbly handled in the primary care setting. Clear understanding of the role of primary care in managing persistent pain as a chronic condition will lead to greater competence in delivering this care.

For their part, pain specialists can greatly improve their communication with primary care. Among the topics which would be helpful are guiding primary care physicians through learning new skills and providing direction regarding when to refer patients back for further specialty care. Such constructive communication can lead to greater self-assurance and competence among primary care physicians as they manage complex pain patients in their practices.

New Focus

Persistent pain patients have similarities and differences from patients with other chronic illnesses. They are both chronic conditions where cure is unlikely. Self-management is the key to success. Denial about the disease and nonadherence to treatment recommendations are common and expected challenges for the provider.

On the other hand, psychiatric issues are more common in persistent pain and interfere with treatment. Patients resist psychosocial diagnosis and interventions. Opioid management that only occurs in persistent pain problems is challenging for the patient and the provider. Nonadherence to treatment recommendations increases morbidity and mortality in diabetes, hypertension, and congestive heart failure. In chronic pain, nonadherence increases the clinicians work stress, thereby requiring more office visits, documentation, and medication surveillance. Although regulatory scrutiny does not occur often, the perception of legal difficulties increases practice discomfort.

In managing pain, it is important for the physician to understand that pain scores are highly subjective and that the focus must be on function. Although measuring pain is important and mandated in a variety of settings,[31] the physician must not lose sight of the twin goals of treatment: function and adaptation.

A new pain complaint or worsening symptoms do not necessarily mandate more medication. In treating diabetes, a worsening $HgbA_1C$ leads the physician to recommend adjustments in diet, exercise, and medication. Similarly, in treating chronic pain, recommendations should take into consideration life stressors, pacing daily activities, depression, anxiety, and worsening of underlying pathology as well as medication. When the primary care provider understands that an increase in pain does not necessarily mean increasing the patient's opioid drug, treatment issues may become easier.

Assessment and Evaluation During Short Visits

Given the typically short office visit and the many pressures on the physician's time, chronic illness management is becoming more difficult. In the typical 15-minute appointment, the patient with low back pain must be evaluated, but he or she may have other conditions requiring assessment, such as hypertension, diabetes, a sleep disorder, and fatigue. Given an hour for the evaluation and adequate support staff, primary care physicians would all be better pain managers. But given a short time, stressed and overworked support staff, and patients with veritable shopping lists of complaints that must be addressed, this is not the case.

Despite the reality of a busy office schedule, primary care is uniquely positioned to take care of the chronic pain patients. We know our patients through associations developed over years of repeated exposure at routine medical care. We understand our patient's coping strategies, family dynamics, and work stresses. The solution to the dilemma lies in making the typical short office visit more effective for patients needing chronic pain management.

The 15-Minute Office Visit

Validating the Patient

Validation is straightforward when a patient presents with an ankle sprain or a sore back. The injury is easily identified by the history and the diagnosis is easily confirmed by physical examination. Diagnostic imaging and/or laboratory reports further support the physician's initial impression, and the patient's chief complaint and the associated pain improve steadily with a short course of uncomplicated therapies—a nonsteroidal anti-inflammatory drug, muscle relaxant, application of cold or heat, and rest.

Validation poses problems for primary care when the patient suffers from chronic pain. We are concerned that the patient will request something we cannot deliver, such as total pain relief, additional MRI studies, or more opioid drugs. The evidence shows that this is not usually the case. In a study of patients with fibromyalgia syndrome, providing the patient with a diagnosis resulted in the patient making fewer visits to the physician's office and becoming more empowered and proactive.[32]

Have you ever asked your patients, "What do you think I can do to help your pain?" Many of us are reluctant to ask because we fear a response that includes a request for long-term disability and opioids. Nonetheless, asking the patient opens a dialogue about expectations and responsibilities perhaps streamlining the office visit.

Once the patient understands that we believe their pain is real, more time can be spent dealing with symptom control, exercise, and other important management issues. At each office visit, make sure that the following steps have been taken:

- Ask about the pain and record the level using a pain score
- Determine the functional status of the patient and whether the treatment is improving function
- Modify the treatment according the patient's response
- Use nonpharmacologic and pharmacologic methods for pain control
- Explain the available options and foster a positive attitude in the patient toward dealing with the pain

Having a set routine with these key goals in mind sets the agenda and can streamline even a difficult, complicated visit.

Assessment Tools

Chronic pain usually starts as an acute pain episode. In most cases, the acute episode resolves and the patient returns to normal function. Even fibromyalgia syndrome, defined as widespread pain for months to years, has a beginning. The work-up and treatment can take months before the correct diagnosis is discovered and the physician becomes aware that the problem is long-term and likely to present problems in management.

At this point, the physician's attention should focus on disease management (i.e., symptom improvement rather than multiple interventions and cure). How can the physician best do this evaluation in a short office visit? Referral may or may not be an option as specialty referral may not be available, too expensive, and time consuming for many patients. Evaluation needs to be focused on the desired outcome of pain reduction, functional improvement, and identification and management of comorbidities. Because

such an evaluation can easily take up several visits, handouts and questionnaires can be very useful (i.e., The Initial Pain Assessment Tool, Pain Disability Index, Quality of Life Scale, Zung Self-Rating Depression Scale, and Function and Goal Setting).

Try giving the patient self-assessment forms that measure pain, function, depression, and anxiety, and allow the patient to complete the assignment at home. Patients tend to like these questionnaires since they permit patients to describe in detail issues that the physician may not have the time to elicit during the office visit.

A follow-up visit is designed to review the results with the patient. The handouts direct the follow-up visit to the important outcome variables: pain and function. They are helpful in that they let the patient know which outcomes are most important and what each subsequent office visit will address. The patient who demonstrates anxiety or depression on the self-reported questionnaire is more likely to accept treatment, making discussion and treatment of such comorbidities less time consuming. Assessment is covered in detail elsewhere in this text.

Substance Abuse Screening

Primary care physicians are often hesitant to prescribe opioids. When treating patients with chronic pain, such caution is justified. Substance abuse, particularly involving opioids, is an important comorbidity in chronic pain management. Fortunately, there are multiple questionnaires available to help assess this risk. Commonly used screening tools practical in primary care include The Screener and Opioid Assessment for Patients with Pain,[33] Opioid Risk Tool,[34] and Drug Abuse Screening Test.[35] Patients who score high on any of these scales are more likely to be difficult to manage when treated with opioids. If referral to a pain management specialist is an option, the primary care physician might consider this. Such screening is also covered fully elsewhere in this text.

Goal Setting and Plan of Action

Like other chronic illnesses, patient participation and adherence to treatment recommendations predicts better outcomes. Chronic pain affects many life activities and, in turn, quality of life. Goal-setting discussions direct the patient to improved activity and a targeted outcome. For example, if the patient wants and agrees to spend more time out of bed, walk 10 minutes a day, or work in the garden, any of these might serve as a goal that can be tracked with each visit. As patients begin to anticipate the questions the physician will ask about their goals, visits become more streamlined and focused on a functional outcome.

After the patient has been evaluated and treatment has been initiated, adequate follow-up of a patient with chronic pain can be difficult to accomplish in a 15-minute visit. Follow-up does not take as much time when the physician stays focused on the desired outcome. Consider a routine follow-up for a patient with diabetes. We begin by asking about diet, exercise, foot numbness, vision, and home glucose monitoring. We review the self-monitoring results, then do a physical exam focused on the blood pressure, eyes, heart, and monofilament exam of the feet. We review the $HgbA_1C$, microalbumin, and low-density lipoprotein. We insure that the patient is taking aspirin, a statin, and an ACE inhibitor. We change treatment based on all the information received. All of this is done every day with our diabetics and at each visit; all of this can be accomplished in 15 minutes.

The difference in following chronic pain, and the reason that visits consume more time, is that often it is unclear what to follow, what to ask, and what variables to track at each visit. Too often, the appointment becomes a session wherein the patient complains about pain, disability, and poor quality of life. It is vital that each follow-up session remains focused on symptom management and functional improvement. A patient's pain diary or journal can be helpful in focusing follow-up visits. Pain diaries, available in paper and electronic form, are similar to regular diaries except that the entries focus on pain. Patients record pain-related elements such as the time pain was felt, the type of pain (e.g., burning, stabbing, aching), the location of the pain, what he or she did to alleviate the pain, and whether what they did helped. The patient brings the pain diary to each follow-up session, focusing the visit on a particular pain score and whether the recommended treatment was effective.

Activity and sleep questionnaires are also helpful in concentrating the appointment on these quality of life issues. In a mutual goal-setting discussion with the patient, the questions can revolve around previously agreed upon and previously documented functional outcomes such as the amount of time spent out of bed, the 10-minute walk, or the time spent working in the garden.

Charts reviewed of primary care visits in pain patients frequently demonstrate a failure of adequate documentation.[36] Have the pain score, functional outcome, abuse risk, and side effects been recorded? Given the time pressures, it is no wonder that documentation often is low on our list of priorities. Handouts and questionnaires filed in the patient's chart enhance this record keeping and save time.

Pharmacologic Treatment

There are many pharmacologic treatment options for persistent pain. Pharmacology in primary care is difficult because of the many treatment choices and the lack of agreement among experts. How and why a particular medication is used in a pain patient varies based on pain severity, diagnosis, and many other factors. U.S. Food and Drug Administration-approved drugs or randomized trial results could guide prescribing. Experts are more likely to prescribe based on medical literature and new trends in treatment. Primary care often uses past experience even when this experience is inaccurate or inappropriate. An example of this is the common use of ineffective nonsteroidal anti-inflammatory medications in neuropathic pain treatment in the primary care office.[37] Another example is the use of short-acting hydrocodone compounds by primary care, even though most experts suggest that long-acting opioids are best for persistent pain.[38]

Access to medication is also a major force in pharmacologic options in the primary care setting. Nonformulary drugs or third tier medications requiring high patient copays are a significant factor in prescribing. If the primary care provider has to obtain a preauthorization or justify a prescription, the medication will not be prescribed since this extra step requires excessive time.

As the Ballantyne[8] article points out, opioid prescribing is one of the most difficult decisions facing primary care in managing persistent pain. When prescribing opioids for pain management, physicians are often faced with scenarios that mirror those we associate with addiction: early refills, lost or stolen medication, borrowed medication, and failed urine drug tests. In these cases, documentation is critical. Strategies such as the 4 As of treatment success enable the primary care physician to concentrate on the outcomes that are essential to the patient's overall quality of life (Table 107.3).[39]

Referral to an Addiction Specialist

When to refer a patient to specialty care is always a question and is highly variable among different practitioners. Some providers refer whenever chronic opioid management begins. Others refer only when intervention or surgery is needed. When behavior around the use of an opioid becomes problematic as in the example above, referral is often prudent. At a minimum, documentation of the behavior and an understanding between patient and provider is necessary. The 4 As allow the physician to address the issue and have a treatment strategy. Once the patient learns that early refills will not be tolerated, these requests will stop. It

TABLE 107.3

THE 4 As OF TREATMENT SUCCESS

A-1 = **A**nalgesia or pain score.

A variety of pain scales are available in multiple languages. Pain measurement is the first element in evaluating successful treatment.

A-2 = **A**ctivities of daily living or functional outcome that is meaningful to the patient.

At the initial and subsequent visits, work activities, household duties, social activities, hobbies, and physical exercise target are recorded and goal setting is discussed. One important caveat—when treating any chronic condition, a follow-up visit is necessary to evaluate the effectiveness of the treatment.

A-3 = **A**dverse events.

Anticipating and soliciting feedback from the patient regarding side effects from treatment allows the physician to manage adverse events rather than discontinue otherwise effective pain treatment. Since function is the most important treatment outcome, persistent sleepiness or a cognitive impairment from the opioid must be managed.

A-4 = **A**berrant behavior.

If a patient is being treated with opioid analgesics, most primary care physicians worry about the potential for dependence and addiction. Patients on long-term opioid therapy may display behaviors that raise concerns, including early refills, demands for additional medication, and using analgesic medication with other psychoactive drugs such as alcohol.

When such patient behavior occurs, interpretation is difficult. Document the behavior in the patient's chart, discuss it with the patient, and come to a mutual understanding of what action will be taken if the behavior occurs again. With requests for early refills, often the easiest (and least confrontational) response is to refill the medication; however, repeatedly doing what is easiest may lead to repeated requests for refills in the future.

One tactic for dealing with a repeat request for an early refill is to document the request and refuse to refill the medication until the appropriate refill interval. This will prompt a call from the patient at which time the physician can review the agreement about refills, express sympathy, and offer other medication to help the withdrawal. The early refill requests will usually stop. Documenting the behavior helps the physician to focus on setting limits and emphasizing the seriousness of opioid therapy.

is important for the physician to recognize the risk and recommend a corrective action (i.e., an abnormal urine drug test may trigger a referral to an addiction medicine provider). The addicted patient will argue and dismiss the risk. If you refuse refills without consultation, the patient looking for access to drugs for diversion or to get high will leave your practice. The patient in need of pain control will comply with the requested consultation.

Motivating Behavior Change in Patients with Chronic Pain

The key message in managing chronic pain is that the way to improve is through changes in lifestyle rather than solely through medication or surgical procedures. It is not an easy message for primary care to deliver because patients expect their physician to give them something to cure their problem. Lifestyle and behavior changes are never easy.

Successful management of chronic pain is much more dependent on what the patient does than on what the physician does to the patient. The issue becomes one of the patient's readiness to accept responsibility and to adopt a self-management approach. This represents a role reversal for the physician whose task is not to treat but to understand and motivate patients for self-management. On occasion, this may include convincing the patient not to look for another doctor or another procedure.

Because of their unique relationships with patients, primary care physicians are well suited in motivating patients to change. We are motivating patients to lose weight, stop smoking, take their medication, and get flu shots. A patient-centered approach, emphasizing the importance of considering the patient's perspective when making treatment recommendations, has been shown to be a valuable technique.[40] The goals of a patient-centered approach are to:

- Address the patient's concerns
- Enhance a collaborative relationship
- Provide information that the patient is ready to hear
- Refocus the visit from making treatment recommendations to supporting the patient's self-care
- Foster increased patient control of decision-making and responsibility for self-care

It is immediately evident that this technique requires a reorientation of the traditional patient-physician relationship. The physician must learn to view the patient as an autonomous and equal member of the health care team, whose self-knowledge is pivotal to the management of his or her condition (persistent pain).

Reflective listening is a technique that involves making statements that demonstrate the physician's understanding of what the patient has said. There are ways of making reflective statements, including

- Restating what the patient has said
- Paraphrasing what the patient has said
- Anticipating and continuing the patient's thought (i.e., saying what you believe the patient will say next rather than repeating)
- Reflecting the patient's feelings

The patient's readiness to change is the basis of a motivational approach. According to one well-regarded model,[41] patients who strongly believe that their pain only requires a medical or surgical intervention are not ready to accept and adopt self-management. On the other hand, patients who believe that medical and surgical interventions can provide only limited relief from pain are more likely to perceive benefits from self-management techniques. Readiness to self-manage should be assessed on a continuum, and interventions should be tailored to the particular patient's level of readiness to change.

The physician can help the patient to understand the importance of behavior change by guiding him or her through a discussion of the pros and cons, including whether a given change is attainable, how much effort it will take, and how much time it will take given the known obstacles. Motivating the patient involves eliciting the patient's feelings about and reasons for pain self-management, and reflecting back statements that support the premise that self-management is possible. Although time-pressed physicians may balk at the prospect of such a dialogue, the consultation time is usually more efficient (e.g., fewer arguments, less resistance) when a patient is encouraged to speak in a focused manner about a specific problem.

Goals for Pain Self Management. In general, primary care physicians are in agreement about health care goals such as encouraging smoking cessation, maintaining blood pressure within normal limits, and controlling blood sugar. Although the goals for pain self-management are not as clear cut, most pain specialists would advise primary care physicians to consider the following as important when motivating a patient:

1. Beginning or maintaining a regular exercise regimen
2. Using medications as prescribed
3. Returning to normal daily activities given the pain condition
4. Practicing appropriate pain and stress coping strategies (e.g., relaxation techniques, reassuring "self-talk")
5. Returning to or maintaining normal work activities
6. Pacing activities appropriately
7. Monitoring, managing, and/or reporting symptoms of depression as appropriate
8. Practicing good eating habits (e.g., reducing or maintaining an appropriate weight)
9. Engaging in other healthy lifestyle behaviors as necessary (e.g., reducing alcohol consumption, stop smoking)

Importance and Confidence Scales. Patients will change behavior only when they are convinced that it is important and when they have confidence that the change is possible. Assessing patient perceptions of importance and confidence can be helpful when evaluating motivation. For example, patients who give a low rating to the importance of exercise but a high rating to the belief that exercise could be done would need help to change their views of the importance of exercise before adherence could be expected. On the other hand, brainstorming for solutions may be helpful for those who rate importance high and confidence low.

Strategies for Helping Patients Understand the Importance of Change. Information and advice presented in a lecturing style often leads to patient responses of, "Yes, but. . ." and the already too brief visit is taken up with the patient expressing reasons why a recommended change will not work. Social psychology research has shown that, in general, people are more likely to believe what they have said over what others have said to them. It follows that a didactic approach may undermine the physician's attempts to motivate the patient.

Primary care providers are invested in behavior change and motivation. Four strategies have been shown to be effective in helping patients understand the importance of change and increase their confidence to make that change.[42] These uncomplicated strategies are effective because they enable patients to talk themselves into using pain self-management techniques.

1. **Always elicit positive statements from the patient.** Use the "why so high" technique. For example, ask the patient with chronic pain to rate the importance of daily exercise on a scale of 0 (low) to 10 (high). If the patient's answer is 5, ask "Why so high? Why not a 1?" Most patients understand the importance of conditioning and exercise in pain rehabilitation. By asking "why so high," the patient provides the evidence for an exercise program. Once you know the patient's thought process, you can use this to motive a change of behavior.
   "You think it is very important for you to make your muscles stronger to make your pain better" (restating what the patient has expressed).
2. **Examine the pros and cons of behavior change.** Patients will feel ambivalent about self-management. This allows the patient to explore feelings and think through self-management in a judgment-free environment. Bear in mind that although this technique is easy to understand, it can be difficult for the physician to do. He or she must listen, encourage, and provide a summary at the end of the visit.
   "What do you think will happen if you continue to stay in bed?" The patient may steer the conversation back to you: "unless you make me better, I cannot get out of bed" or "unless you give me more pain medication, I will not be able to get out of bed." Be persistent and keep to the same question. The patient has stated earlier that conditioning and exercise are important.
   "Your mother was sick all the time. How did that affect you?" Patients may have an environmental background for pain in another family member which impacted them when growing up. Patients may also express concern about the impact of their pain on the other members of the family. The desire to have their pain not have an impact may motivate the patient to different behavior.
3. **Elicit patient concerns about the status quo.** Patients who rate the importance of pain self-management as low may be concerned about their current situation. Ask the patient to talk about the consequences of not making the behavior change. Once the patient has listed as many concerns as he or she can think of, summarize these, using the patient's words if possible. This may help to increase the patient's perception of the importance of the change.
   "If things do not change, what will happen?" The patient may try to guide the discussion back to you and the medical profession, disability, or legal issues. Be persistent about "what will happen with your spouse or children; how will you pay the bills?"
4. **Brainstorm for solutions.** Without giving specific advice, remind the patient that there are usually many ways to achieve self-management. Guide the patient in conceptualizing a number of possibilities. Help the patient to decide which possibilities might work best for him or her. Guide the patient to develop of plan for achieving his or her goal.
   "You spend 16 hours of your day in bed. Any activity makes your pain worse. The last time you tried to exercise, your pain was at a 9/10 and you wanted to go to the hospital. How are you going to get to exercise?" Keep the focus on what the patient can do, or what solutions the patient has. Add suggestions and advice related to the patient's solutions.

Once the patient has adopted a self-management plan with specific goals, the physician can use open-ended questions to encourage the patient to talk about his or her progress. The questions should communicate the physician's interest in the patient's perspective. For instance, "At your last visit, you were thinking about making some changes in pacing your work. I'd be interested in hearing how this is going and whether you've noticed any change in your ability to manage your pain." Such questions enable the physician to conduct an informal assessment of the patient's readiness and also enhance rapport with the patient.

CONCLUSION

Persistent pain, a highly prevalent condition in the United States, has a significant impact on our health and productivity as a society as well as on our medical and financial resources. Primary care is the most appropriate setting for the management of patients with chronic pain because of the mutual understanding that results from a long standing physician-patient relationship. The barriers to managing chronic pain are significant but not insurmountable. Persistent pain is similar to other chronic illness but also has many differences, making management complicated and difficult in the busy primary care office. A new skill set is required by the provider to help the deplorable undertreatment of pain. Available tools (e.g., questionnaires, pain diaries, pain scales) and techniques (e.g., reflective listening, goal setting) make it possible for the primary care physician to provide management for patients with chronic pain in a 15-minute office visit. Diabetes, chronic obstruction pulmonary disease, and other chronic, complicated illnesses require other skills yet have been handled brilliantly in the primary care setting.

Some of the most appreciative patients are those who have a sympathetic provider to help them with chronic pain. Yet treating chronic pain patients is rarely met with enthusiasm in primary

care. Patients with chronic pain are complicated and rarely cured. They may have previously made little progress toward normal life functioning, and often have complex psychosocial issues that a physician cannot address. There is never sufficient time to adequately follow-up patients with pain. The primary care provider is accustomed to dealing with chronic problems through short, focused visits and a longitudinal experience. A treatment plan and mutually agreed upon goals allow the physician to conduct a follow-up visit in 15 minutes by focusing discussions on the treatment success that both the physician and patient desire.

CHAPTER 108 ■ PAIN MANAGEMENT AT THE END OF LIFE

JUDITH A. PAICE

Adequate relief of pain at the end of life is an ethical imperative. Studies suggest that although pain may not be the most prevalent symptom during the final days or weeks of life, it is frequently the most distressing.[1–8] In addition to the negative consequences pain has on the patient, inadequate pain control adversely affects the ongoing emotional well-being of family and friends at the bedside. To witness unrelieved pain during the final hours of life leaves long-lasting negative memories of the dying process that can hamper bereavement. The setting of care can dictate whether patients will receive adequate relief during the dying process, and significant change in our systems of care is needed. The majority of end-of-life care is currently provided in institutions, with more than two thirds of individuals dying in hospitals or nursing homes. In a large survey of surviving family members, more than 25% reported that their loved one received inadequate relief of pain in these settings.[9] The challenge for our health care system is to ensure that regardless of setting, pain management at end of life is provided by skilled professionals who understand the special needs of the dying. These skills include assessment of pain in those who might not be able to verbally describe their pain, awareness of pain syndromes common at end of life, as well as familiarity with the pharmacologic and nonpharmacologic management of pain in the dying. Furthermore, clinicians must be aware of the role of suffering and existential distress, as well as management of intractable symptoms.

INTRODUCTION

Currently, death in developed countries is more likely to occur after a long chronic illness. This is in contrast to a century ago when people died a more rapid death, often due to infection. Currently, the most common causes of death in high income countries include ischemic cardiac disease, cerebrovascular disease, and cancer.[10] Globally, 60% of deaths are due to chronic diseases, principally cardiovascular diseases and diabetes, cancers, and chronic respiratory diseases.[11] Thus, people are more likely to die after a long, protracted illness, and pain is a common comorbidity of these illnesses. Several care delivery models exist to address the specialized pain and symptom needs of those with life-threatening illnesses, including palliative care and hospice. Both of these care models focus attention on the patient and family, not unlike the structure of care delivered in truly interdisciplinary pain treatment programs.

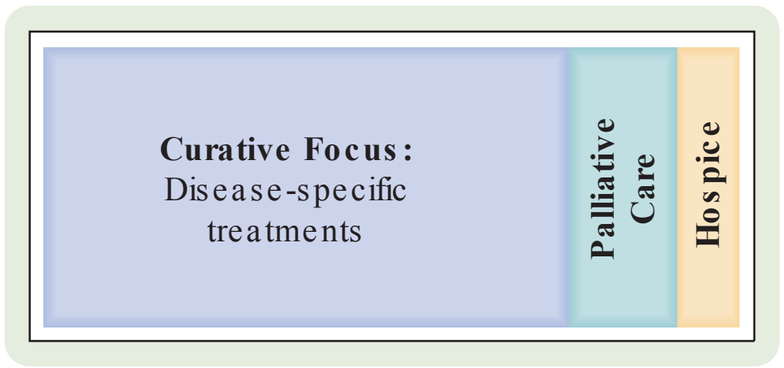
Palliative Care

Palliative care strives to relieve suffering and improve the quality of life of those individuals with a life-threatening illness.[12] The palliative care movement in the United States originated in academic medical centers but has moved into community hospitals, outpatient clinics, and other centers of care. In fact, palliative care programs now exist in 31% of hospitals in the United States.[13] Commitment to early identification, thorough assessment, and effective treatment of pain are key components of palliative care, as is attention to other physical, psychosocial, and spiritual concerns. The goal is to neither hasten nor prolong death, but rather affirm life by offering a support system to patients and families. To that end, palliative care is optimally provided by an interdisciplinary group of professionals, including physicians, nurses, social workers, chaplains, and others.

Confusion persists regarding the timing of appropriate referral to palliative care. Previous models of care incorporated palliative care during the final phases of life, once all curative therapy was completed (Fig. 108.1). It is clear that patients and families benefit greatly when palliative care is integrated into the plan of care early during the course of illness (Fig. 108.2). Effective pain management provided during cancer treatment, for example, can allow patients to complete potentially curative or life-prolonging therapies. Attention to other symptoms associated with the underlying illness, including distressing complications of treatment, can provide improved quality of life during this time. Recent research supports the feasibility of integrating palliative and oncology care in ambulatory patients. A study of patients with advanced nonsmall cell lung cancer receiving cancer treatment and palliative care in an outpatient clinic confirmed the high symptom burden experienced by these individuals, despite their newly diagnosed status, and the benefits of early attention to symptom management.[14]

Hospice

The modern concept of hospice care developed from the work of Dame Cicely Saunders and others in the United Kingdom during the 1960s. In this model, free-standing centers of care were developed where patients spent their final days receiving pain and symptom management, along with attention to the emotional and spiritual aspects of the individual's life. A decade later, hospice began in the United States with the same goals of care, but a home-based model quickly took root. In 1982, the Medicare Hospice Benefit was passed to provide reimbursement for these services. A Medicare Part A beneficiary is eligible for this benefit if she or he is determined to have a life expectancy of 6 months or less if the life-limiting disease or combination of comorbid conditions runs its normal course. Studies reveal that patients at end of life and their family members prefer care provided in the home with the support of hospice. Family members of patients receiving hospice services report significantly greater satisfaction with the overall quality of care compared with those dying in institutional settings: 70.7% rated care as "excellent" compared with less than 50%, respectively.[9] Both of these models, palliative care and hospice, provide support to patients and loved ones. As pain is so prevalent, all health care professionals working with people at this time of life must be exceptionally knowledgeable about common pain syndromes as well as appropriate assessment and management.



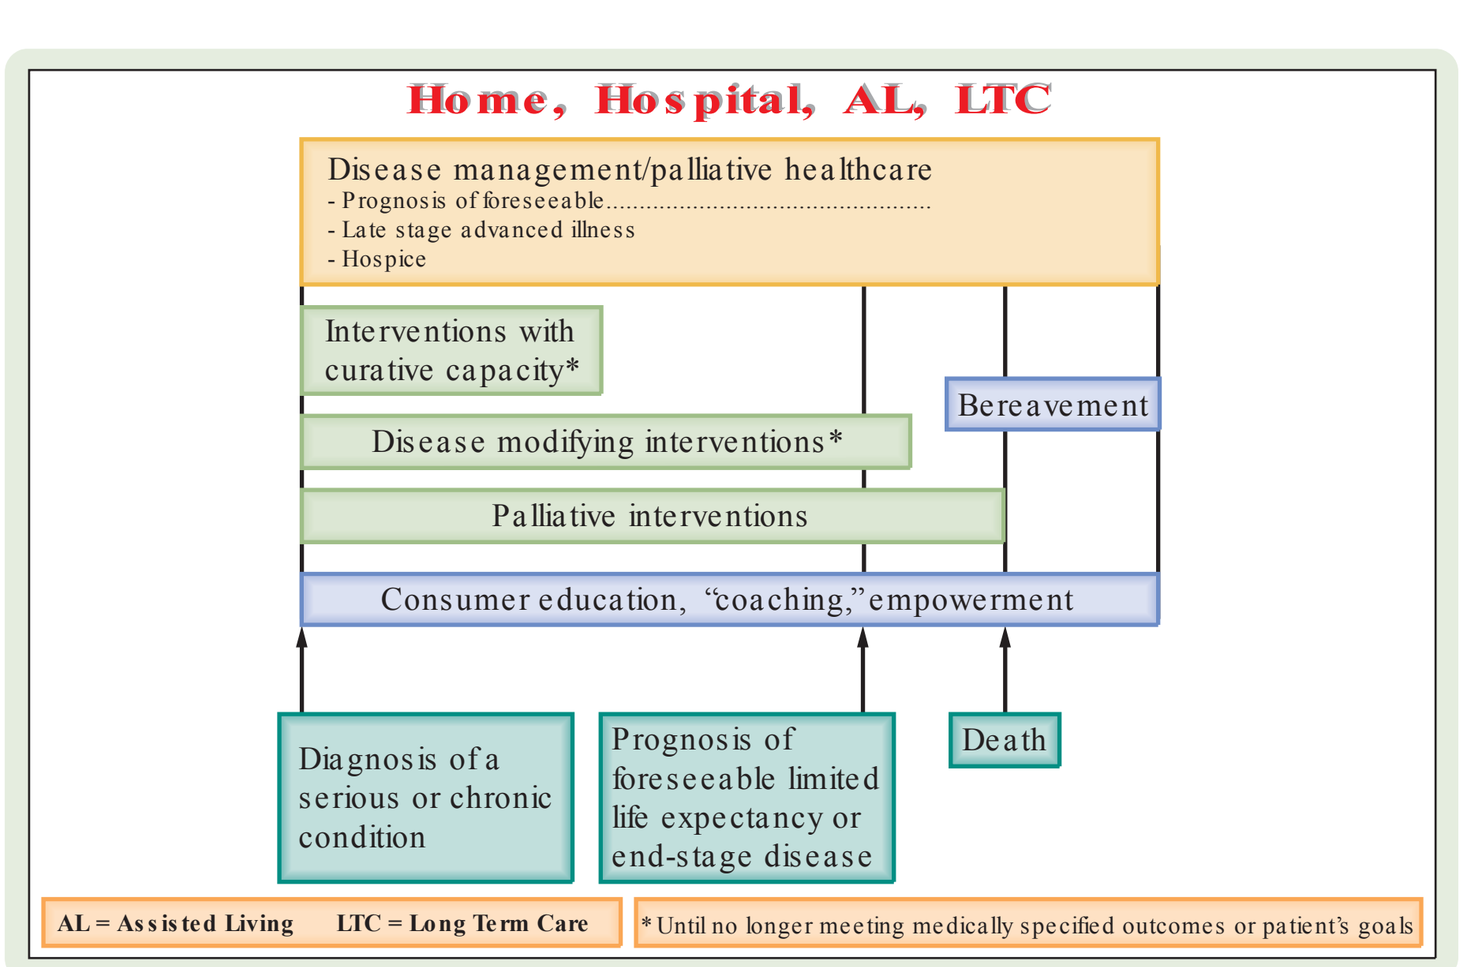


FIGURE 108.1 Previous models of palliative care and hospice.

PAIN SYNDROMES COMMON AT THE END OF LIFE

Pain syndromes specific to cancer have been well characterized, yet much research is needed to describe pain associated with other life-threatening illnesses. Furthermore, greater attention is needed to identify pain syndromes most common at the very end of life along with appropriate treatment strategies (Table 108.1).

Cancer

Prevalence rates of pain in advanced cancer vary based upon the settings of care in which the studies were conducted, the instruments used to measure pain and other symptoms, as well as the methods employed in data collection. In general, approximately two thirds of patients with advanced malignant disease experience pain.[2,15–17] Cancer patients referred to palliative care or hospice commonly have a greater prevalence of pain and other symptoms. For example, one study of lung cancer outpatients revealed that 27% had pain, compared with 76% in those referred to palliative care.[18] Regarding the pain trajectory in cancer patients very near the end of life, pain occurred in 54% and 34% at 4 weeks and 1 week prior to death, respectively.[19] Children dying of cancer also are at risk for pain and suffering, yet few studies detail the prevalence and characteristics of pain in this population.[20] The result of unrelieved pain and associated interference may include increased desire for hastened death.[21]

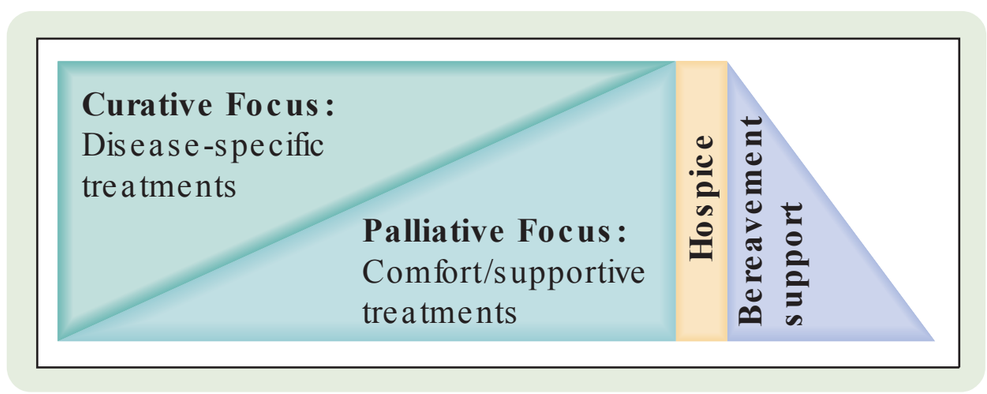

FIGURE 108.2 Proposed model for integration of palliative care.[12]

Noncancer Diagnoses

Many life-threatening illnesses are known to cause pain, including human immunodeficiency virus,[22] multiple sclerosis,[23,24] amyotrophic lateral sclerosis,[25] other neurologic disorders,[26] end-stage renal disease,[27] and heart failure.[28–31] At the end of life, it is apparent that many of the pre-existing pain syndromes associated with these disorders can escalate, particularly pain related to progression of disease, immobility, or comorbid complications. Furthermore, many patients with advanced disease are elderly and more likely to have existing chronic pain syndromes, such as osteoarthritis or low back pain.[32] Regrettably, there have been few studies characterizing the prevalence of pain or the types of pain experienced by these individuals with noncancer diagnoses. Greater awareness of the risk and types of pain seen will lead to improved detection, assessment, and treatment.

PAIN ASSESSMENT AT THE END OF LIFE

Challenges in Pain Assessment

Comprehensive assessment of pain at the end of life is imperative. As with all pain, assessment must be conducted upon initial pre-

TABLE 108.1

PAIN SYNDROMES IN PALLIATIVE CARE

Pain Related to Underlying Disease
- Tumor related pain due to pressure or compression
- Chest pain due to end stage cardiac disease
- Ischemia caused by atherosclerotic disease
- Abdominal pain with referral to thorax and shoulder due to liver failure, cirrhosis
- Abdominal pain due to ascites
- Extremity skin pain due to edema
- Back pain and skin discomfort/pruritus due to end-stage renal disease
- Chest pain due to pulmonary fibrosis, emphysema, other advanced lung disorders
- Central nervous system infection (meningitis, cryptosporidium) leading to headache
- Central pain after stroke, particularly affecting thalamus
- Trigeminal neuralgia in multiple sclerosis
- Vaso-occlusion leading to bone, muscle, and visceral pain in sickle cell disease
- Rapid onset of cachexia leading to peripheral neuropathy
- Spasticity due to neuromuscular disorders

Pain Related to Treatment
- Peripheral neuropathy due to chemotherapy, HAART
- Arthralgias and myalgias due to aromatase inhibitors
- Surgically induced phantom pain, chronic neuropathy
- Immunocompromise leading to postherpetic neuropathy
- Aseptic necrosis due to prolonged corticosteroid use

Pain Unrelated to Disease or its Treatment
- Pressure ulcers
- Reduced muscle and fat padding at bony prominences
- Muscle atrophy leading to myalgia
- Immobility leading to joint pain
- Contractures

From Von Roenn JH, Paice JA, Preodor ME. Pain management in palliative care. In: Von Roenn JH, Paice JA, Preodor ME. *Current Diagnosis & Treatment of Pain*. New York: Lange; 2006, with permission.

sentation, regularly throughout the course of care, and during any changes in the patient's pain state.[33] Documentation of and communication about these findings are crucial. Assessment in patients who are cognitively intact and able to verbalize can incorporate standard intensity tools such as the numeric rating scale (NRS), the verbal descriptor scale (VDS), the visual analogue scale (VAS), or the Brief Pain Inventory (BPI) for more comprehensive evaluation. A recent panel of international experts in palliative care rated essential components of pain assessment to include intensity, temporal pattern, treatment and exacerbating/relieving factors, location, and interference with health-related quality of life as essential dimensions.[34] In their content evaluation of more than 64 pain assessment tools, none were found to satisfactorily incorporate all of these domains.

Tools exist that measure multiple symptoms seen in life-threatening illness, and the majority include pain.[35] One study demonstrated that using systematic assessment of symptoms in palliative care yielded a 10-fold greater number than when volunteered by the patient. The investigators conclude that specific detailed symptom investigation is necessary.[36] Examples of tools include the Edmonton Symptom Assessment Scale,[37] the M.D. Anderson Symptom Inventory,[38] the Memorial Symptom Assessment Scale,[39,40] the Rotterdam Symptom Checklist,[41] the Symptom Distress Scale, and others. A limitation is that most of these instruments were developed to assess symptom prevalence and/or intensity in cancer populations and may not accurately reflect the experience of those with noncancer diagnoses. One exception is the Memorial Symptom Assessment Scale, which has undergone testing in seriously ill cancer and noncancer inpatients.[42] Although symptoms varied between the two groups, there was no significant difference in symptom distress scores, a global measure of symptom burden.[42] Another constraint of these scales for clinical care at end of life is the length of most of these tools, leading to respondent fatigue.[43] The Brief Hospice Inventory[44] was developed specifically to evaluate symptoms, including pain, and satisfaction with hospice care. Initial testing revealed that patients at end of life could complete the instrument.

A wide range of health-related quality of life instruments, such as the European Organization for the Research and Treatment of Cancer QLQ-C30 and the Functional Assessment of Cancer Therapy-General, include symptoms such as pain, but the burden to complete these tools preclude their use in those with advanced disease.[45] Two tools target patients at the end of life: The Hospice Quality of Life Index[46] and McGill Quality of Life Questionnaire.[3] Both instruments include symptoms and can be useful in assessing the global needs of dying patients. Although these tools are appropriate for patients who are cognitively intact, many patients at the end of life develop delirium, some have dementia, and others have limited ability to communicate due to intubation or neurologic disorders.

Pain Assessment in the Cognitively Impaired

Several excellent reviews thoroughly describe tools used to assess pain in cognitively impaired older adults, primarily those with dementia (Table 108.2).[47–50] Although many of these tools may be adapted to assess pain in the dying person with delirium or other disorders, none have undergone extensive testing in these populations. One exception is the Doloplus 2, which has undergone testing in palliative care patients, but investigators found the tool lacked validity and was challenging to use.[51]

Pain Assessment in Those Unable to Communicate

One in five people who die in hospitals have used intensive care unit (ICU) services during their final hospitalization.[52] In a large

multicenter study of patients with serious illness, half of those who died during hospitalization had received ICU care.[53] Thus, significant percentages of people with life-threatening illness will be admitted to the ICU prior to death. Yet, one in five patients in ICU lack decision-making capacity and are likely unable to accurately describe their pain.[54] Furthermore, although a number of these patients may be cognitively intact, the use of mechanical ventilation often complicates pain assessment. Some patients may be able to use a NRS, VDS, or VAS, either by pointing to a chart with numbers or a line representing pain or by nodding "yes" when asked sequentially if pain is "mild," "moderate," or "severe." For those patients who cannot use these techniques, several pain assessment tools have been developed to assess pain in the ICU, including the Behavioral Pain Scale[55] and the Critical-Care Pain Observation Tool.[56] For children, several tools exist, including the Faces, Legs, Activity, Cry, Consolability Observational Tool (validated in children 2 months to 7 years and tested in the ICU),[57] Distress Scale for Ventilated Newborn Infants (tested in ventilated newborns), and the COMFORT Behavior Scale (tested in neonates to 3 years of age in ICU).[58]

Although standardized instruments to measure pain at the end of life are needed, several principles can guide clinicians when patients are cognitively impaired and unable to report pain.[50] Behaviors suggestive of pain should be evaluated, including the furrowed brow, guarding, or vocalizing on movement. Consider causes of pain, including the underlying disease and treatments, as well as new complications such as pressure ulcers, constipation, urinary retention, or infection. Ask family members or others who have known the patient if they observe changes in behaviors that might imply discomfort. If any of these indicators suggest that the patient may be in pain, initiate an analgesic trial and reassess. Resolution of the behaviors provides suggestive evidence that pain exists. Regular administration of the analgesic should then be included in the treatment plan.

Pain Measurement in Research Conducted at End of Life

Research in pain at the end of life is hampered by lack of consistency in the use of valid and reliable pain measurement tools. An expert working group convened by the European Association of Palliative Care recommended standardized methods be applied in clinical trials and other pain studies in those with life-threatening illnesses. They recommended unidimensional tools such as the numerical rating scale, VAS or verbal rating scales, or when indicated, multidimensional tools such as the BPI-Short Form or the McGill Pain Questionnaire.[59]

PAIN MANAGEMENT STRATEGIES AT END OF LIFE

The principles employed in treating other patients in pain should be applied to the dying. These include the use of multimodal therapies based upon the underlying pain mechanisms as determined by comprehensive assessment. Of particular challenge at the end of life is the need for alternate routes of administration and a plan of care when pain becomes intractable to standard therapies or adverse effects to the treatment become unmanageable.

Routes of Drug Delivery

Many patients can use the oral route until death. In one study, 43% and 20% of cancer patients were able to take oral opioids at 1 week and 24 hours before death, respectively.[19] When oral delivery is no longer feasible, alternate routes of administration are available. Oral routes, including sublingual, transmucosal, and buccal delivery, as well as enteral, rectal, nasal, parenteral, spinal, topical, and transdermal routes, have all been employed.

Oral, Sublingual, Transmucosal, and Buccal Routes

When patients have difficulty swallowing pills but can take soft food, microsphere formulations of long-acting morphine provide sustained release when the capsule is broken open and the "sprinkles" are placed in applesauce or other soft food. Oral opioid solutions (e.g., morphine, oxycodone, hydromorphone, or methadone) can be swallowed or small volumes (0.5 to 1 mL) of a concentrated solution can be placed sublingually or buccally in patients whose swallowing abilities are limited. Nevertheless, buccal and sublingual uptake of these opioids is slow and not very predictable, particularly with more hydrophilic compounds such as morphine.[60,61] Small studies suggest that most of the analgesic effect of morphine administered in this manner is due to drug dripping down the oropharynx and into the gastrointestinal tract.[62] Conversely, absorption with the use of more lipophilic drugs, such as methadone and fentanyl, is relatively high.[60] Topical morphine mouthwash has been reported to treat chemotherapy-induced oral mucositis and might be useful for other pain syndromes associated with oral lesions.[63,64]

Transmucosal Fentanyl. Oral transmucosal fentanyl citrate (OTFC) is a lipid soluble (lipophilic) synthetic opioid formulation that consists of a lozenge on a stick. Patients must actively rub the fentanyl-containing lozenge against the oral mucosa to provide rapid absorption of the drug, usually experiencing some relief in 5–15 minutes, with a peak effect of 30 minutes.[65,66] This is particularly useful for breakthrough pain that is quick in onset. Unlike other breakthrough pain drugs, the dose of long-acting opioid does not predict the effective dose of OTFC.[67,68] Too rapid application, usually less than 15 minutes, will result in more of the agent being swallowed rather than being absorbed transmucosally. Some patients develop oral candida due to the high sugar content of the compound and others complain of the sweet taste and lack of variety in flavor, particularly with prolonged use.

Buccal Fentanyl. Rapidly dissolving fentanyl buccal tablets (FBT) provide faster onset of effect when compared with oral morphine administration. As with OTFC, peak effect is reported to be 30 minutes.[69] An important difference when comparing FBT with OTFC is that patients do not have to actively rub the applicator within the oral mucosa with buccal administration. This is appreciated by fatigued patients, those with musculoskeletal disorders that make this movement difficult, as well as individuals with oral lesions and those who are embarrassed by public use of the "lollipop"-appearing OTFC formulation. As with OTFC, the dose of long-acting opioid does not predict the effective dose of buccal fentanyl, and one cannot reliably convert from OTFC to FBT since the latter has a greater bioavailability. The rate and extent of fentanyl absorption were greater following FBT compared to OTFC, such that approximately 30% less drug was required when administering FBT to achieve similar OTFC systemic drug levels.[70]

Enteral and Rectal

Pre-existing enteral feeding tubes can be used to deliver medications when patients cannot swallow at the end of life. It is rare that circumstances would require placement of a tube at this time, and doing so may send a contradictory message about the need for enteral nutrition and hydration. The size of the tube and volume of fluid used to mix the "sprinkles" formulation of morphine must be considered when delivering this form long-acting morphine to avoid obstruction of the tube.

Opioids can be delivered via the rectal route using commer-

cially prepared suppositories, compounded suppositories, or microenemas. Studies suggest a larger area under the curve when morphine suppositories are used when compared with oral sustained-release morphine.[71] Sustained-release morphine tablets have also been used rectally, with resultant delayed time to peak plasma level and approximately 90% of the bioavailability achieved by oral administration.[72] Rectal methadone can be used safely and has bioavailability approximately equal to oral methadone.[73,74] Neutropenia and thrombocytopenia are generally considered contraindications to rectal drug administration, but clinicians must consider the goals of care for delivering these drugs as well as the risks and benefits at this time of life. Painful rectal lesions, such as hemorrhoids or fissures, preclude the use of these routes. Attempting to place agents rectally at home may be difficult for family members when caring for loved ones who cannot move or reposition without significant assistance. Case reports of stomal or vaginal administration suggest that these routes can provide effective delivery when other routes are not feasible.[75]

Nasal

Currently, the only commercially available opioid in nasal formulation is the mixed agonist-antagonist butorphanol. This category of opioid is not recommended in end of life care as combining these agents with a pure agonist opioid can result in symptoms of withdrawal or abstinence. Nasal fentanyl, hydromorphone, and morphine have undergone initial investigation, primarily in healthy volunteers.[76–78] Additional research is needed to establish feasibility, tolerability, and efficacy in a population with pain at end of life.

Parenteral

Parenteral administration includes intravenous and subcutaneous delivery of drug. Intramuscular opioid delivery is inappropriate in the palliative care setting due to the pain associated with this route and the variability in systemic uptake of the drug.[33] Intravenous administration of drugs is often used when patients are hospitalized at end of life, as this route provides rapid and predictable drug delivery. For patients being cared for at home, the need for vascular access may be cumbersome. Subcutaneous infusions, including morphine, hydromorphone, and fentanyl, provide an effective and safe alternative.[79] Methadone has been reported to cause local site irritation, although small case reports suggest that lower doses given intermittently are less likely to cause pain.[80] Subcutaneous boluses of morphine have a slower onset and lower peak effect when compared with intravenous boluses, although with continuous infusions they provide similar blood levels and resultant pain relief.[33,81] Subcutaneous infusions may include up to 10 mL/hour, although most patients absorb 2 to 3 mL/hour with the least difficulty. Volumes greater than 10 mL/hour are often poorly absorbed and can lead to pain or leakage of fluid. Hyaluronidase has been reported to speed absorption of subcutaneously administered fluids, although a recent randomized trial yielded no difference in pain or edema between treatment and placebo groups.[82] Despite these findings, these investigators and others suggest that hyaluronidase may have utility when subcutaneous absorption is not well tolerated.

Spinal (Epidural/Intrathecal)

Intraspinal routes, including epidural or intrathecal delivery, allow administration of drugs such as opioids, local anesthetics, and/or alpha-adrenergic agonists more proximate to their respective effector sites.[83,84] A randomized controlled trial demonstrated benefit for ambulatory cancer patients with a life expectancy of at least 3–6 months experiencing pain.[85] However, initiating this therapy during the final hours of life requires the availability of experts to place an external catheter, as well as caregivers with specialized knowledge to safely and effectively provide care. As with all therapies, the potential risks, including greater caregiver burden, need to be weighed against the benefits. Intraspinal delivery may be considered when patients do not obtain adequate relief from aggressive titration of systemic opioids and other analgesics or they experience intolerable adverse effects.[86] More information regarding the use of intraspinal drug delivery is available in Chapter 99.

Topical

Topical morphine administration to open areas, such as pressure ulcers, burns, malignant skin lesions, and ulcers associated with venous stasis or sickle cell disease, has been reported to be effective in case reports and open label trials.[87–90] However, a recent randomized controlled trial of topical morphine used to treat painful skin ulcers found no benefit when compared with placebo.[91] An analysis of the bioavailability of morphine when delivered to open ulcers found little systemic uptake, a possible explanation for the lack of efficacy.[92] Topical morphine applied to the wrist in a pluronic lecithin organogel (PLO) base for systemic delivery is being used in many hospice settings, yet evidence of its efficacy is lacking. A recent bioavailability study of topical morphine in healthy volunteers revealed that morphine was seldom detected in plasma samples after topical administration, and when values were detected, they were below the level of quantification.[93] These results suggest that topical administration of morphine compounded in a PLO base for topical drug delivery is unlikely to provide relief of pain.

Transdermal

Transdermal fentanyl has been used extensively and a wide range of dosing options (12, 12.5, 25, 50, 75, and 100 mcg/hour patches) makes this route particularly useful in palliative care.[94] Most individuals experience relief for 3 days, although approximately 25% of patients will consistently report increased pain on the third day, despite adequate use of breakthrough medications. These patients benefit from changing the patch more frequently (every 48 hours). Fentanyl is another option when considering opioid rotation, and several reports suggest the resolution of delirium when patients are converted from other opioids to transdermal or intravenous fentanyl.[95,96] Fever, diaphoresis, cachexia, morbid obesity, and ascites may have a significant impact on the absorption, predictability of blood levels, and clinical effects of transdermal fentanyl, although studies are lacking.[97] There is some suggestion in open-label and retrospective studies that transdermal fentanyl may produce less constipation than long-acting morphine. This may be a moot point in patients in palliative care since they are often using significant amounts of supplemental opioids for breakthrough pain.[98–101] A small subset of patients will develop skin irritation due to the adhesive in any patch. Because most topical antihistamines consist of an oil base which would prevent patch adherence, the use of an aqueous based steroid inhaler (intended for the management of asthma) applied prior to patch administration can preclude skin reactions and allows the patch to remain in place.

Intractable Pain or Unmanageable Adverse Effects of Treatment

Although most pain at end of life can be well-managed with available therapies, intractable pain or unmanageable adverse effects can occur that can lead to incredible suffering. In some cases, pain escalates due to rapidly increasing disease burden. At other times, pharmacokinetics of the opioids and other analgesics are altered by organ dysfunction associated with the dying process, leading to inadequate relief.

Effect of Organ Dysfunction on Pharmacokinetics

Organ dysfunction at the end of life will alter the absorption, distribution, metabolism and elimination of analgesic agents, thereby influencing the efficacy of the drug. People with advanced malignancy or other life-threatening illness may undergo changes in any of these phases as a result of extensive disease. Little is known about the alterations in absorption of opioids that occur when people are dying. Factors such as shortened gastrointestinal transit time may delay absorption of oral opioids, particularly long-acting or sustained-release compounds.

Distribution of the drug is in part dependent upon plasma proteins within the vasculature, body fat stories, and total body water.[102] These can all be significantly altered in patients who are cachectic and dehydrated at the end of life. Aging patients are known to have decreased volume of distribution of morphine and fentanyl. Additionally, methadone binds avidly to alpha$_1$ glycoprotein, which is increased in advanced cancer. This leads to decreasing amounts of unbound methadone and a delayed onset of analgesic effect.

Metabolism of drugs can be changed by advanced age, liver dysfunction, and other factors that are widespread in palliative care. Excretion can be altered as renal failure occurs, particularly since most opioids, with the exception being methadone, are mostly excreted by the kidneys. Patients with renal failure or those receiving dialysis might benefit from the use of agents that are more readily dialyzable, such as fentanyl, as opposed to morphine or codeine.[103] Research is needed regarding the effect of advanced disease and the dying process on the pharmacokinetics of analgesics, particularly opioids.

Myoclonus

One consequence of altered pharmacokinetics at the end of life is the development of myoclonus. Myoclonus is a sudden, uncontrollable, nonrhythmic jerking of the extremities. This can be extremely distressing, causing fatigue and sleep disruption, and exacerbating the patient's pain. Furthermore, myoclonus can progress to the development of uncontrolled seizures.[104] Myoclonus has been reported to occur after surgery to the brain,[105] in acquired immunodeficiency syndrome,[106] after hypoxia,[107] and after chlorambucil administration.[108] However, myoclonus at end-of-life care is most commonly associated with opioids. Controversy exists regarding whether this is dose dependent and how much of this effect is from parent drug versus metabolites. Most reports of opioid related myoclonus implicate higher doses, although it has been reported to occur in patients receiving low doses of opioids, particularly hydromorphone.[109,110] Other opioids that have been implicated include methadone[111] and fentanyl.[112] Myoclonus has also been reported during withdrawal from transdermal fentanyl.[113,114]

The underlying mechanism of opioid-induced myoclonus is poorly understood. Myoclonus and seizures have been reported to occur in patients receiving high-dose morphine or hydromorphone administration.[115,116] However, Fainsinger and colleagues[116] describe a case of myoclonus occurring with stable hydromorphone dosing in the face of acute renal failure. A retrospective chart review found that in terminally ill patients receiving parenteral hydromorphone, the dose and duration of drug were associated with the development of myoclonus, while age, gender, and diagnosis were not.[117] These findings point to the role of accumulating neuroexcitatory metabolites that are poorly excreted, either due to prolonged dosing, high doses, or concomitant renal failure. The 3-glucuronide metabolites are implicated as contributing to these neuroexcitatory effects.[118] Both morphine-3-glucuronide (M3G) and hydromorphone-3-glucuronide (H3G) are believed to produce excitatory behaviors, including myoclonus, allodynia, and seizures. In a study of cancer patients who developed allodynia and myoclonus during morphine infusions, M3G levels were elevated.[115] Case reports suggest that M3G and H3G plasma levels are greatly increased in the presence of renal failure, with the ratio of metabolite to parent compound four times higher than the ratio seen in patients with normal renal function.[119,120] However, one prospective study found no relationship between myoclonus and renal function.[121] In rodent models, H3G has more potent neuroexcitatory effects when compared with M3G.[122]

Regardless of the underlying cause, treatment is imperative. The goal is to significantly reduce the dose of the opioid, and this is usually accomplished by rotation to an alternate opioid.[123,124] Methadone has been used as an alternative agent with success, although other opioids may be easier to titrate and methadone also has been found to produce myoclonus.[111] Other strategies include adding adjuvant analgesics and using interventional techniques (e.g., spinal drug administration, nerve blocks) to potentially reduce the amount of total systemic opioid. Little research is available regarding agents used to reduce myoclonic jerking. Benzodiazepines, including clonazepam, diazepam, and midazolam, have been recommended.[123,125] The mechanism of action of benzodiazepines is through binding to γ-aminobutyric acid type A ($GABA_A$) receptors within the central nervous system, leading to central nervous system depression. At higher doses, benzodiazepines may also limit repetitive neuronal firing, similar to several anticonvulsant compounds. Clonazepam may be useful in patients who can swallow, with doses starting at 0.5 to 1 mg by mouth every 6 or 8 hours, with upward titration as needed. Lorazepam tablets or solution can be placed sublingually if the patient is unable to swallow. Lorazepam and midazolam can be administered parenterally and are often indicated during the final hours of life.

Intractable Pain at End of Life

When pain is poorly managed despite aggressive titration of available therapies, several other options can be employed.[126] First, thorough assessment is needed to rule out potentially reversible etiologies. Because the pain demands immediate attention, titration of the opioid therapy must be aggressive while carefully preventing and treating adverse effects. Additional therapies should be considered, such as corticosteroids, local anesthetics, ketamine, and other therapies. Bringing in a team approach is crucial, including experts in pain and palliative care, as well as chaplains, social workers, psychologists, and others, to address patient and family suffering. When these interventions are unsuccessful, palliative sedation may be considered.

Intravenous Lidocaine. Systemic administration of local anesthetics, such as lidocaine, has been used to treat chronic pain.[127–129] At subanesthetic doses, lidocaine blocks neuronal function in active or depolarized neurons without interfering with the normal function of other sensory or motor neurons. Although historically used as a monthly infusion in chronic pain clinics, similar protocols have been adapted for use in patients at end of life with intractable pain. The dosage is generally 1–3 mg/kg administered intravenously over 20–30 minutes.[130] During the bolus infusion, pain intensity scores often decline significantly. If effective, a continuous infusion of 1–3 mg/kg/hour will be initiated. Immediate signs of toxicity include numbness around the lips or a sensation of thickness of the tongue. Due to the short half-life of lidocaine, the symptoms of toxicity are transient and easily reversible by lowering the infusion rate. However, toxicity has been reported at very low doses of lidocaine.[131]

In concert with the goals of care at this time of life, cardiac monitoring is not usually performed nor are plasma levels of lidocaine obtained. If subcutaneous administration is indicated due to lack of venous access, the initial loading dose is administered over a longer time period (30 minutes to an hour) and the response may be delayed by a few minutes. If subcutaneous infusion is elected, more concentrated lidocaine solutions allow

for lower volumes to be infused. If the bolus dose is ineffective or toxicity is unmanageable, the lidocaine challenge is discontinued and other pain relief modalities must be selected.

The lidocaine infusion technique has been reported to be effective in a child with cancer, using 35 mcg/kg per minute initially, with an increase to 50 mcg/kg per minute after several days.[132] The only randomized controlled trial of intravenous lidocaine for neuropathic pain from cancer using 5 mg/kg over 30 minutes found no difference in analgesia.[133] Much more research in this particular area is needed.

Ketamine. Ketamine is an *N*-methyl-D-aspartate antagonist that can be given by a variety of routes: oral, intravenous, subcutaneous, intranasal, sublingual, epidural, intrathecal, and topical. It has been reported to improve pain relief and reduce opioid requirements in a variety of pain syndromes associated with cancer and other life-threatening illnesses.[134–138] Although it can be used earlier in the course of the disease trajectory, ketamine is most commonly trialed in the face of intractable pain at the end of life.

In a small (n = 10) study of cancer patients who reported pain unrelieved with morphine, a slow bolus of ketamine (0.25 mg/kg or 0.50 mg/kg) was evaluated using a randomized, double-blind, crossover, double-dose design. Ketamine, but not saline solution, significantly reduced the pain intensity in almost all the patients at both doses, with the greatest effect being in those treated with higher doses. Adverse effects included hallucinations in 4 patients and an unpleasant cognitive sensation in 2 patients. These adverse effects responded to diazepam 1 mg intravenously. Drowsiness was also significantly more likely to occur, particularly with the higher dose. The investigators concluded that ketamine improved morphine analgesia in a variety of difficult pain syndromes, yet central adverse effects can limit the use of this therapy.[139]

A study in young children and adolescents who were on high doses of opioids and had uncontrolled cancer pain examined the effect of adding a low-dose ketamine infusion. In 8 of 11 patients, ketamine infusions used as an adjuvant to opioid analgesia provided improvement in pain and was associated with opioid-sparing effects. This allowed reduction in opioid dose that ultimately improved social interaction during this important time.[140]

The usual oral dose of ketamine is 10 to 15 mg every 6 hours. Because oral preparations are not commercially available in the United States, the solution used for injection is administered orally, usually mixed with juice or cola to hide the unpleasant taste. Parenteral dosing is typically 0.04 mg/kg/hour with titration to a maximum of 0.3 mg/kg/hour. When given parenterally or orally, the onset of analgesia is 15–30 minutes with a duration of effect ranging between 15 minutes to 2 hours. A general recommendation is to reduce the opioid dose by approximately 25% when starting ketamine to avoid sedation. Severe side effects are generally associated with doses of parenteral ketamine above 0.5 mg/kg and include psychotomimetic phenomena such as dysphoria, nightmares, hallucinations, excessive salivation, and tachycardia.

Because of the lack of high quality, randomized controlled clinical trials, a recent Cochrane review concluded that there was insufficient evidence to conclude that ketamine improves the effectiveness of opioid treatment in cancer pain.[141,142] Clearly, more research in this area is needed.

Fears of Hastening Death

Pain at the end of life may be poorly managed due to fears of causing respiratory depression. This is particularly true when family members administering opioids at home express fear about causing their loved one's death. It can also occur in institutional settings where clinicians are uncomfortable ordering or administering therapeutic doses of drug. Clinicians and family members also fear "giving the last dose" of an opioid. Education is desperately needed. Respiratory depression is rare in palliative care as most patients are opioid-tolerant. A recent study of cancer patients undergoing parenteral opioid titration for severe pain revealed no change in end-tidal carbon dioxide, oxygen saturation, or respiratory rate.[143] Sykes and Thorns[144] evaluated 17 studies that examined the use of opioids at end of life. None of the five studies that explored opioid use and survival found any relationship. Their own earlier study also found no relationship between the dose or the timing of the opioid administration and the time of death.[145] These authors conclude that the doctrine of double effect, which suggests it is ethical to employ a treatment intending to obtain its beneficial effect (e.g., analgesia) but at the same time recognizing that it may also have harmful effects (e.g., respiratory depression or death), is not relevant. They also argue that it is potentially harmful to invoke this doctrine as it potentiates a myth: one that can lead to greater fear and unrelieved pain. A recent study from the National Hospice Database reported similar results; that the dose of opioid had no appreciable impact on the timing of death in patients with far-advanced disease.[146]

Suffering and Existential Distress

It may be very difficult to distinguish pain from other causes of suffering in dying patients. Although the trend toward greater attention to pain is positive, there is frequently little attention to the role loss, burden, sadness, fear, isolation, and other existential concerns that can play at this time of life.[147] Several studies support the need for more useful definitions and distinctions and to address the role of suffering in the individual's life. For example, one study asked hospice patients about suffering in an open-ended interview, revealing that in the views of the 100 patients included in this study, relief of pain and relief of suffering are not the same.[148] Another study of health care professionals revealed that suffering was viewed quite differently by chaplains, who defined this in spiritual terms, versus pain professionals, who placed existential issues in the context of pain.[149]

Using semistructured interviews, 381 patients with advanced cancer were asked if they felt they were suffering and were also asked about physical symptoms, social concerns, psychologic problems, and existential issues. Approximately 25% reported they were suffering at a moderate-to-extreme level. This suffering was strongly correlated with general malaise, weakness, pain, and depression. Thus, although many patients with advanced cancer do not consider themselves to be suffering, for those who are suffering, it is a multidimensional experience related most strongly to physical symptoms, but with contributions from psychologic distress, existential concerns, and social-relational worries as well.[150] The consequences of unresolved suffering are great, including a wish for hastened death. In a study of 96 terminally ill elders, 15 acknowledged significant suffering that resulted in a wish for a hastened death, and several had even considered strategies to accelerate the dying process. In analyses of the interviews of these individuals, four critical themes emerged: perceived insensitive and uncaring communication of a terminal diagnosis by their health care professional, experiencing unbearable physical pain, unacknowledged feelings regarding undergoing chemotherapy or radiation treatment, and dying in a distressing environment.[151]

Assessment of the whole person should be multidimensional, and an interdisciplinary team is best equipped to address these broad issues. In addition to a thorough pain and symptom assessment, patients should be asked about the meaning of their lives, their sense of hope, the goals they have for this time of their lives, and whether they are suffering. Suffering is a deeply personal experience, accompanied by a wide range of emotions and meanings. Inadequate assessment that only equates pain with suffering can lead to inappropriate increases in opioids, without benefiting their existential concerns, while leading to increased toxicity.[152]

When patients are identified as experiencing suffering, several

interventions can be useful. Life review allows the individual to reminisce about life experiences, often leading to self-discovery of meaning in the contributions they have made. Some people benefit by developing letters or videotapes to loved ones, to be read at a later date during anticipated landmark events in the loved one's life, such as college graduation, marriage, or the birth of a child. One novel model to address psychosocial and existential distress in the dying is called dignity therapy.[153] This brief, individualized approach to end-of-life care allows patients to discuss issues that are most important to them and to describe the things they would most want remembered as death draws near. These discussions are recorded, transcribed, and developed into a document, which can be given to family or loved ones. In one study of people with advanced cancer, 76% reported a heightened sense of dignity, 68% reported an increased sense of purpose, 67% reported a heightened sense of meaning, and 47% reported an increased will to live.[154] Family perceptions were also positive, with the majority stating that the document developed by the dying loved one helped during the grieving process and that the document would continue to be a source of comfort for their families and themselves.[155] Those who are suffering often feel voiceless and having professionals witness and listen to their concerns in an empathic manner can be extraordinarily therapeutic.

Nonpharmacologic Techniques

Nonpharmacologic therapies can be particularly useful during the final hours of life. Cognitive-behavioral techniques, physical measures, and education can be used as part of the multimodal treatment plan to reduce pain and suffering. The patient's and caregivers' abilities to participate must be considered when selecting any of these therapies, including their fatigue level, interest, cognition, and other factors.[156] Cognitive-behavioral techniques include guided imagery,[157] meditation,[158] hypnosis,[159] music[160] and art therapy,[161] and other complementary therapies.[162]

Physical measures, including massage,[163,164] reflexology,[165] heat, and other techniques,[166] can produce relaxation and relieve pain. In a small study of massage in hospice patients, reductions in blood pressure, heart rate, and skin temperature were noted, suggestive of a relaxation effect.[167] A potential benefit of all of these therapies is the ability to include family members who are often seeking methods to provide comfort to their loved one.

Family involvement in all aspects of care is crucial. Family caregivers who rate their self-efficacy, or their ability to care for their loved one, as high report much lower levels of strain, as well as decreased negative mood and increased positive mood. Ultimately, the caregiver's self-efficacy in managing the patient's pain related to the patient's physical well-being. In dyads where the family caregiver perceived higher self-efficacy, the patient reported having more energy, feeling less ill, and spending less time in bed.[168] As a result of these findings, Keefe and colleagues[169] developed a partner-guided pain management training intervention that they tested in 78 advanced cancer patients who met criteria for hospice eligibility. Patients and their partners were randomly assigned to the intervention or to usual care as the control condition. The partner-guided pain management training protocol consisted of educational information about cancer pain with systematic training of patients and partners in cognitive and behavioral pain coping skills delivered in the patients' homes over three sessions. The partner-guided pain management protocol significantly increased partners' ratings of their self-efficacy for helping the patient control pain and other symptoms. These family caregivers also showed a trend toward reduced levels of caregiver strain.[169]

Although case reports and open label trials of cognitive-behavioral, physical measures, and educational interventions are reported to be very effective in relieving symptoms, more research is needed.[170] Furthermore, most existing research has been conducted in patients early in the disease trajectory, so more research is needed to determine the potential value, no less the feasibility, of these interventions in the final days and hours of life.

PALLIATIVE SEDATION

Although the majority of individuals with pain at the end of life can obtain relief with available therapies, some dying patients experience distressing symptoms that cannot be controlled. In these cases, palliative sedation may be considered. Several steps are crucial when implementing palliative sedation. First, the team must be confident that all other reasonable options have been explored, the disease is irreversible, and that death would be expected in hours to days.[171] Second, the patient and family should be carefully informed about the risks and benefits of sedation and they should agree with these plans. The entire team (physicians, nurses, respiratory therapy, chaplains, social workers, and others involved in the patient's care) must have the opportunity to discuss this option and agree as a team about the justification for the use of sedation and the details of the care to be provided.[172] These are generally complex cases that are emotionally stressful. All involved can benefit from talking about the complex medical, ethical, and emotional issues they raise.[172–174] Decisions about hydration and nutrition as well as resuscitation status (most centers require that the patient has do not resuscitate orders) should be made prior to initiating sedation. Sedation may be delayed if the patient is awaiting the arrival of a family member from out of town. In some cases, light sedation may be used and reversed once the relative arrives, then restarted and increased once the patient and loved one have had time to say good-bye.[175]

The agent most commonly employed is midazolam, although other benzodiazepines, propofol, or barbiturates can be administered (Table 108.3).[172,176] Benzodiazepines have anxiolytic, muscle relaxant, sedative-hypnotic, anticonvulsant, antiemetic, and amnesic effects. Their mechanism of action is through binding to GABA receptors within the central nervous system leading to central nervous system depression. Midazolam is the shortest acting agent within this class, with an onset of action within 3–5 minutes after intravenous injection and a half life of 1 to 4 hours. These attributes, rapid onset and relatively short duration, as well as the ability to administer it either intravenously or subcutaneously makes this a useful drug in instituting palliative sedation. Furthermore, it is stable with most other agents, but incompatible with corticosteroids such as dexamethasone, betamethasone, or methylprednisolone.

Propofol is an intravenous nonbarbiturate thought to enhance the activity of GABA. The advantages of propofol include rapid onset and short half-life. Although studies are lacking, the recommended dose of propofol to treat refractory pain/suffering is 1–2 mg/kg via intravenous injection over 5 minutes.[177] The bolus may need to be repeated if the first injection ineffective. Bolus doses are followed by a maintenance intravenous infusion of 2–10 mg/kg per hour, using the lowest dose needed to suppress symptoms. Propofol is recommended for intravenous administration; subcutaneous delivery has not been studied. Propofol contains soybean oil and egg yolk phospholipid, and therefore is contraindicated for use in patients with egg hypersensitivity or soya lecithin hypersensitivity.[178]

Family members must be provided sufficient information and support during this time. In a multicenter study conducted in Japan, bereaved family members of cancer patients who received sedation in seven palliative care units were surveyed.[179] The families reported that 69% of the patients were considerably or very distressed before sedation. Although the majority of families were satisfied with the treatment, 25% expressed a high level of emotional distress. The factors associated with high levels of family distress were poor symptom control after sedation, feeling the burden of responsibility for the decision, feeling unprepared for changes in the patient's condition, feeling that the physicians and

TABLE 108.3

DOSES OF AGENTS USED IN PALLIATIVE SEDATION[172,176]

Drug	Route	Bolus dose	Continuous infusion
Midazolam	IV, SQ	5 mg	Starting dose 1 mg/hour; usual maintenance dose 20–120 mg/hour
Lorazepam	IV,SQ, SL, PO	0.5–2 mg PO, SL every 1–2 hours; 2–5 mg SQ or IV	Starting dose 0.5–1.0 mg/hour; usual maintenance dose 4–40 mg/hour
Chlorpromazine	PO, IV, PR	10–25 mg every 2–4 hours	
Haloperidol	PO, IV, SQ	0.5–5 mg PO every 2–4 hours; 1–5 mg IV/SQ bolus	Starting dose 0.2 mg/hour; maintenance 0.2–0.6 mg/hour
Thiopental	IV	5–7 mg/kg/hour	20–80 mg/hour
Pentobarbital	IV	2–3 mg/kg	Starting dose 1 mg/kg/hour; titrate upward as needed
Phenobarbital	IV, SQ	200 mg, can repeat every 10–15 minutes	25 mg/hour; maintenance dose 25–66 mg/hour
Propofol	IV	20–50 mg bolus; may repeat	5–10 mg/hour; may increase dose by 10 mg/hour every 15–20 minutes

IV, intravenous; PO, oral; PR, rectal; SL, sublingual; SQ, subcutaneous.

nurses were not sufficiently compassionate, and a shorter time to their loved one's death. Regular monitoring of patient distress with timely modification of the sedation protocol is vital, as is providing sufficient information and sharing the responsibility for the decision. Family members require emotional support to assist with their anticipatory and ongoing grief.[179] As the use of palliative sedation increases, guidelines should be developed across settings and disciplines to ensure consistency. These guidelines must articulate that this therapy is not euthanasia, but is rather directed toward treatment of symptoms.[180]

CONCLUSION

The relief of pain during the final phase of life is vital for both the patient who is experiencing this pain and for those at the bedside witnessing this distress. All clinicians have the responsibility to learn how to assess pain in the cognitively impaired and how to employ effective pharmacologic and nonpharmacologic treatments. Empathic listening with attention to suffering and existential distress will help improve the quality of life of the dying. When pain remains severe, despite aggressive use of all appropriate options, the team must carefully consider the use of palliative sedation, along with the patient and their loved ones. All of this care involves the skills of a well-functioning interdisciplinary team, combining the expertise of each individual to provide optimal care to the most vulnerable of all of our patients.

CHAPTER 109 ■ TRAINING PAIN SPECIALISTS

JAMES P. RATHMELL, MICHAEL ZENZ, ROLLIN M. GALLAGHER, AND DAVID L. BROWN

THE EVOLUTION OF PAIN MEDICINE AS A SUBSPECIALTY

It has become impossible for any physician to become an expert in every field. As knowledge expands and the need for detailed skills arises, the natural progression is for specialization to ensue. There has long been a discomfort with specialization despite an unflagging progression in that direction. The urge to both specialize and remain unspecialized dates back to the earliest recorded history of medicine. The first specializations were between the barber-surgeons and the internists, and a rivalry of sorts remains to this day. Writing about Ambrose Paré, the 16th century physician who elevated the role of the barber-surgeons to that of other physicians, the present-day surgeon and historian Sherwin Nuland reflects on the ongoing distinction between internist and surgeon:

> Surgery is an exercise in the use of the intellect. Heckling internists, with tongues barely in check, would prefer that surgical specialists be viewed merely as dexterous craftsman who carry out the routing errands assigned to them by their more cerebrally endowed medical overseers. I attribute this teasing raillery to a kind of good-natured fraternal envy, not so much of our celebrity status, but rather of the visibility of the cures we surgeons achieve and the particular personal gratification we have while doing it.[1]

In the United States, anesthesiology has progressed toward further specialization, first with the establishment of critical care, then pain management (now pain medicine), and more recently pediatric anesthesiology and cardiothoracic anesthesiology. The addition of pain medicine as a subspecialty of anesthesiology is just one recent example of the growth of medical specialties. With specialization comes a conscious effort to focus practice to become intricately familiar with a more limited realm. The obvious result is a loss of the skills and knowledge needed to practice in the broader parent specialty. In pain medicine, many now view this as a full-time vocation. The scientific meetings and journals that keep pain medicine specialists up-to-date have little overlap with those that are designed to serve anesthesiologists practicing in the operating room. The only common thread between the

technical skills needed in the pain clinic and those required for anesthesiology in the operating room is expertise with neural blockade, which is one of several important skill sets needed in pain medicine. The rapid expansion of knowledge in the causes and complications of acute and chronic pain, particularly in the neurobehavioral sciences, has led to a growing recognition that the pain medicine practitioner must acquire a vastly different skill set than those practicing anesthesiology, including expanding their skills as diagnosticians.

Much has been written about the origins of pain medicine as a distinct discipline and anesthesiologists have played a primary role since the start,[2] as have specialists in neurology, psychiatry, neurosurgery, and physical medicine and rehabilitation.[3] Anesthesiology really started with the introduction of effective general anesthetics in the mid-nineteenth century, when surgical pain could be separated from operation. Almost 100 years later, the late John Bonica, an anesthesiologist and recognized father of the specialty we now call pain medicine, developed his career promoting multidisciplinary pain care and formal training of specialists. From his life's work, we now have extensive ongoing efforts to recognize and treat pain effectively, to train subspecialists, and to conduct basic and clinical research to further our understanding of pain and its treatment. The International Association for the Study of Pain (IASP) founded in 1974, its U.S. chapter, the American Pain Society, and the journal *Pain* are legacies left by Dr. Bonica for our patients. Dr. Bonica, beginning his practice with a focus on developing regional anesthesia techniques, soon came to realize that these techniques were inadequate to meet the needs of his patients and that he could not incorporate growing epidemiologic, basic, and clinical scientific evidence of the salience of neurobehavioral factors. This realization evolved to the belief that developing the field of pain as a separate clinical discipline and treating chronic pain competently required the intellectual input and clinical skills of several other specialties. Consequently, he published the first edition of this seminal textbook, *The Management of Pain*, to that end in 1953.[4] It is noteworthy that IASP presidents have backgrounds from anesthesiology, dentistry, neurology, neurophysiology, neurosurgery, psychiatry, and psychology. All share a common intellectual passion and achievement, as well as clinical dedication, to developing pain research, teaching, and clinical care in pain medicine.

Accredited fellowship training in pain medicine is a relatively recent development. Prior to 1992, training was frequently obtained in academic anesthesiology departments, including those of John Bonica, Philip Bridenbaugh, Harold Carron, Daniel Moore, Prithvi Raj, Alon Winnie, and others, and subsequently in programs run by their trainees. These unaccredited programs advanced the specialty, widened interest in pain medicine as a career, and propagated anesthesiology-based pain care in smaller and smaller communities across the country. Other specialists also contributed to the development of the practice model of pain care. Many of the early leaders of pain medicine were from other specialties, and they trained fellows in unaccredited programs as well. Multispecialty entrance into pain medicine training became a tradition in several cities, including Boston, under Daniel Carr (Harvard, Massachusetts General) and Carol Warfield (Harvard, Beth Israel), New York under Kathy Foley, Russ Portenoy, and Bob Breitbart (Sloan-Kettering), and in Seattle under John Loeser, John Bonica's successor (University of Washington), amongst others. For example, one of the authors (Rollin M. Gallagher), provided fellowship training in chronic pain rehabilitation at SUNY Stony Brook and Drexel College of Medicine to doctors with residency backgrounds in neurology, psychiatry, physiatry, and family practice before accreditation was possible. Outside of the United States, with the notable exception of Australia, this type of informal training remains the rule for those seeking expertise in pain medicine. In the United States, the American Board of Anesthesiology (ABA) developed interest in certifying pain medicine training. The failure of coalition of the boards of Anesthesiology, Psychiatry and Neurology, Physical Medicine and Rehabilitation, and Neurosurgery in 1990 to form a conjoint American Board of Medical Specialties (ABMS) board led the ABA, under the leadership of Bill Owens in his roles on both the ABA and the Residency Review Committee (RRC), and through his representations of the subspecialty to the ABMS, to begin accrediting formal training programs and certifying physicians in 1992 through the Accreditation Council for Graduate Medical Education (ACGME). Steve Abram and John Rowlingson were both key members of the group that assisted Dr. Owens in moving the new subspecialty forward.

The number of ACGME-accredited programs (Fig. 109.1) and the number of trainees in accredited programs has grown steadily over the past decade, reaching just under 100 training programs by 1999 that turn out about 250 new pain specialists each year (Fig. 109.2). The ABA working in parallel with the ACGME developed a subspecialty certification examination in pain medicine, first named the "Certificate of Added Qualifications in Pain Management," now titled "Subspecialty Certification in Pain Medicine." The first exam was given in 1993. The number of candidates sitting for the examination has steadily grown since the first exam was given.

Dr. Bonica's original push to develop multidisciplinary pain care recently evolved into collaboration between four specialties agreeing to a single and unified set of program requirements for all ACGME-accredited pain fellowships, regardless of sponsoring specialty. Consequently, in 1999, the ABA invited representatives of the American Board of Psychiatry and Neurology (ABPN) and the American Board of Physical Medicine & Rehabilitation (ABPMR) to join the ABA's Pain Management Examination Committee to broaden the examination beyond its prior focus on

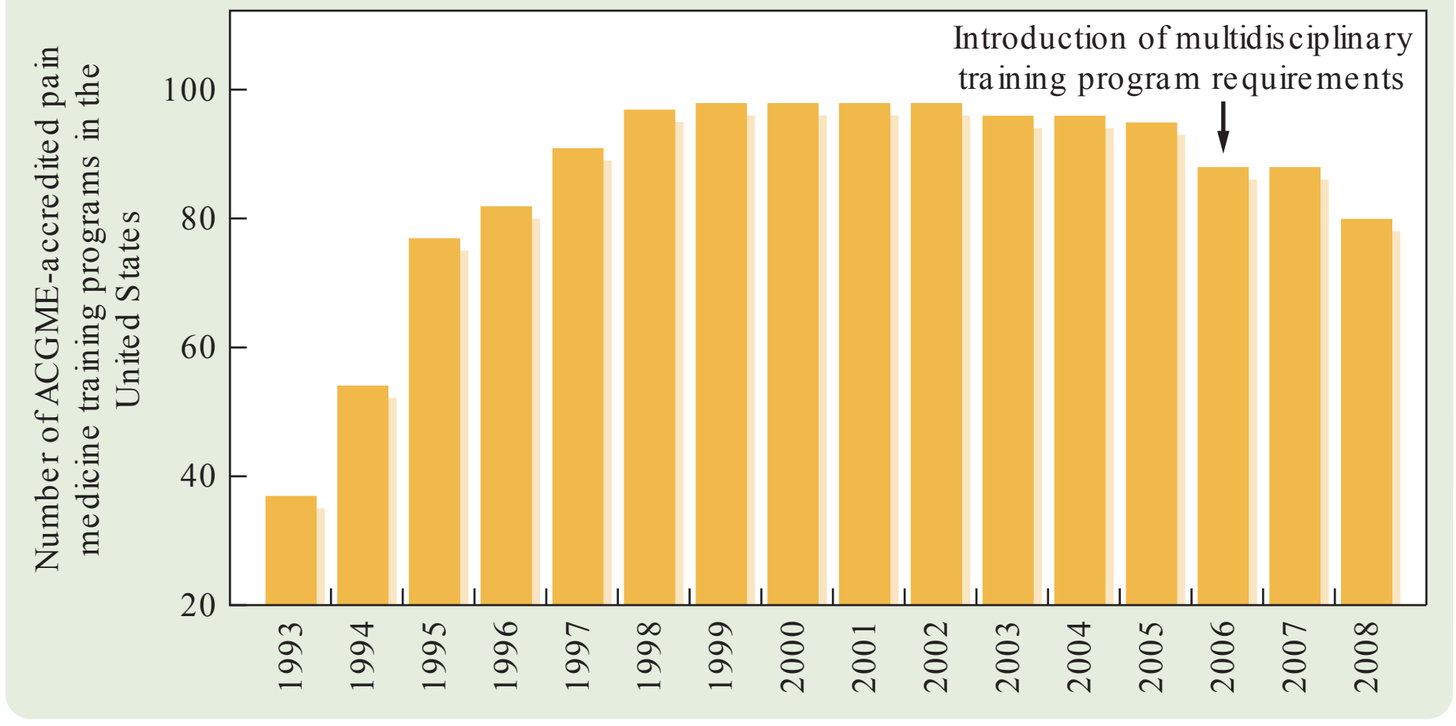

FIGURE 109.1 The number of pain medicine training programs accredited by the ACGME in the United States. The first pain medicine fellowships were accredited in 1993 and the number of programs rose to nearly 100 by 1999; with the introduction of new and more rigorous accreditation standards in the form of Multidisciplinary Training Program Requirements in 2006, the number of programs maintaining accreditation has declined by nearly 20%. (All data were provided by the ABA and are current as of August 2008.)

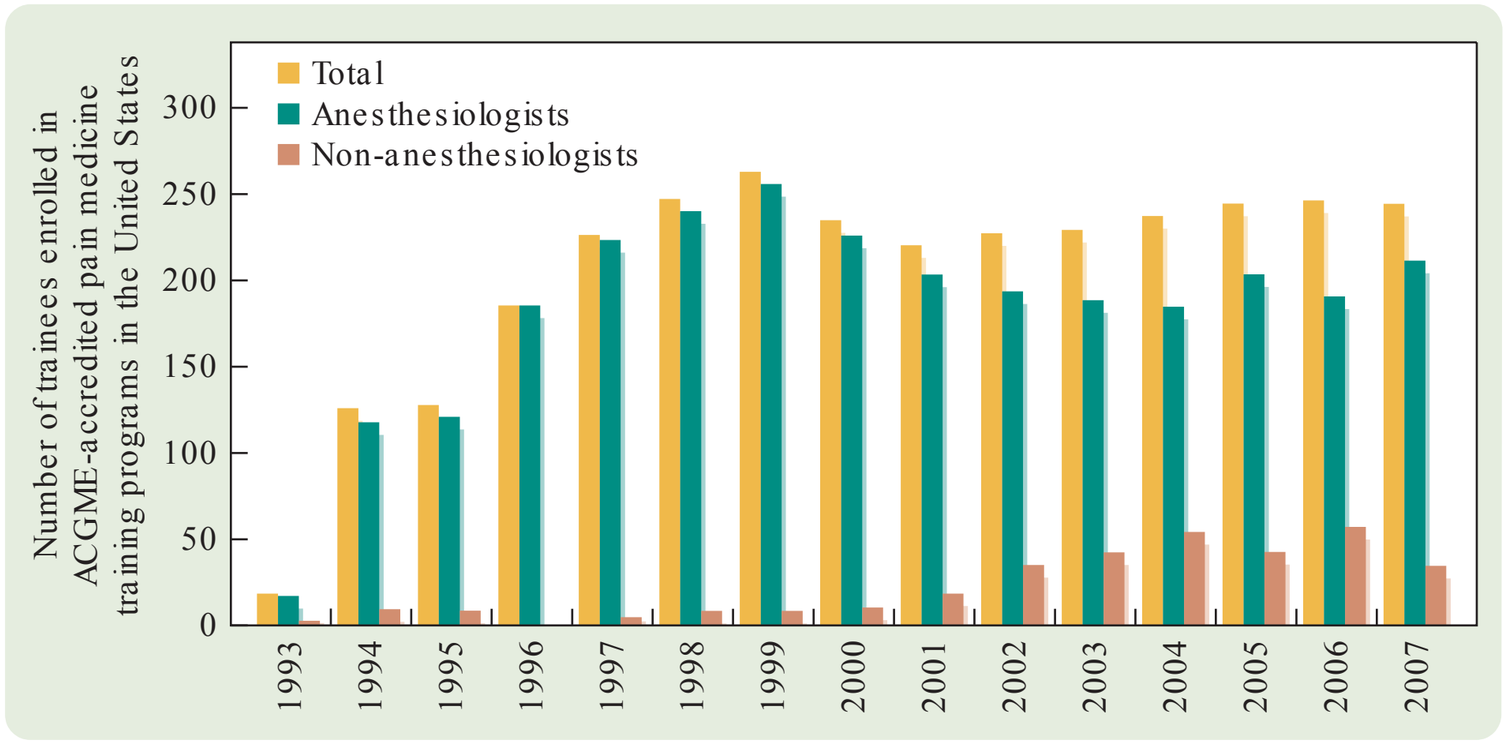

FIGURE 109.2 The number of trainees enrolled in pain medicine training programs accredited by the ACGME in the United States. The first pain medicine fellowships were accredited in 1993 and the number of trainees rose steadily through 1998, leveling off at about 250 trainees each year for the past decade. The number of physicians entering subspecialty training in pain medicine from disciplines other than anesthesiology has risen and these trainees now account for nearly 20% of all trainees. These nonanesthesiologists are primarily from the disciplines of neurology and physical medicine and rehabilitation. (All data were provided by the ABA and are current as of August 2008.)

regional anesthesia, and in 2000, the ABPN and ABPMR began issuing certificates of subspecialty certification in pain management to those diplomates who passed the expanded ABA examination. Between 2002 and 2006, the ACGME working in collaboration with the ABA, ABPN, and ABPMR developed new program requirements for pain fellowship training programs aimed at improving the quality of education in pain medicine and promoting a multidisciplinary approach to care. The new program requirements were adopted in 2006 and the number of programs achieving ongoing accreditation under these broader and more rigorous requirements has declined by nearly 20% (see Fig. 109.2). Equally important in the evolution of the discipline is the creation of academic physicians within the fellowships who undertake research programs to add new knowledge to this needed field of medical practice.

Pain and its consequences draw on resources from all medical disciplines. Dr. Bonica's experiences during World War II suggested that each medical specialist had unique expertise to bring to patients suffering in pain; hence his consistent and effective promotion of a multidisciplinary process for pain care. Also thanks largely to Dr. Bonica, anesthesiology has led the development of formal training programs. Indeed, the majority of currently accredited programs reside within academic anesthesiology departments and most program directors are anesthesiologists. Specialists from other disciplines have also focused their clinical and research efforts on pain. The most obvious example is neurology where the majority of clinical treatment and research about headache and peripheral neuropathy has arisen. Physical medicine and rehabilitation has also long had a focus and expertise in functional restoration, and physiatrists lead many chronic pain rehabilitation programs. And, of course, psychiatrists have been closely involved where pain, illness behavior, stress, depression, anxiety, and substance abuse overlap. During the last decade, specialists from these other disciplines have been seeking subspecialty training in pain medicine with increasing regularity.

The range of practitioners declaring themselves as pain medicine specialists is extraordinary; from clinics that provide largely or solely cognitive-behavioral approaches to chronic pain through functional restoration programs all the way to the type of clinic that offers nothing more than injections of various sorts. "Interventional Pain Medicine" is a term that has been coined for those techniques that involve minimally invasive treatments and minor surgery as part of their application, including neural blockade and implantable analgesic devices. Despite the paucity of scientific evidence to guide pain practitioners, particularly evidence to support the use of many interventional modalities, many techniques appear to have efficacy based on limited observational data and have been adopted into widespread use. As practitioners, we are left to choose among available treatment modalities, often with only anecdote and personal experience to guide us in treating a group of desperate patients with intractable pain who are willing to accept almost any treatment, even those which remain unproven. There is no single practice pattern that any pain specialist can point toward as the correct way to treat patients with chronic pain. Training programs vary widely in the scope of what they train practitioners to do. The best pain medicine practitioners strike a reasonable balance between interventional and noninterventional management. This practice pattern is sustainable and those adopting a balanced style of practice will be able to adapt to evolving scientific evidence that appears in support of pain treatment, regardless of the type of treatment. A balance between treatment modalities also allows practitioners to switch from one mode to another or incorporate multiple treatment approaches simultaneously. Use of these interventional modalities is just a small part of the armamentarium of the skilled pain medicine practitioner.

PAIN MEDICINE AS A PRIMARY MEDICAL SCPECIALTY

Dr. Bonica developed his multidisciplinary clinic with the understanding that the expertise of several specialties was necessary to successfully manage chronic pain. A detailed history of the intellectual background of pain medicine, and particularly Bonica's work in the early development of the field can be found in Baszanger's 1998 book, *Inventing Pain Medicine*.[5] Following this trajectory, in 1983, responding to the need to organize the diversity of specialists interested in and practicing pain medicine, and to obtain recognition and representation amongst other established specialists, a multispecialty group of physicians started the American Academy of Algology, whose name was changed in 1986 to American Academy of Pain Medicine (AAPM). These physicians initially worked with their parent ABMS specialty boards to develop a conjoint ABMS Board of Pain Medicine. When this coalition failed in 1989, the ABA took responsibility for developing subspecialty certification in pain management, later changing to the term pain medicine. From 1992–2000, nonanesthesiologists were generally excluded from taking fellowships and were also excluded from taking the ABA-certifying examination. Thus, the large majority of pain specialists formally trained in these fellowships obtained 3 years of anesthesiology residency and then were trained in pain management for 1 year, primarily by anesthesia faculty. As a result, many new pain specialists were intellectually or clinically unprepared by their formal training to assimilate the burden of managing chronic pain com-

prehensively and longitudinally in a biopsychosocial, chronic disease management model. Accordingly, they focused their efforts on developing interventional pain medicine practices, although many may have learned the additional core skills while managing pain in their practices over years, similar to the experience of the first generation of pain specialists with no formal training. The pattern of regional anesthesia practice was reinforced by the economic structure of health care, which then, and still now, created large incentives for doing procedures rather than emphasizing chronic disease management and functional rehabilitation. Due to these constraints, in 1991, the ABPM was incorporated to provide ABMS-equivalent credentialing for physicians from the primary specialties who were already practicing pain management, and to enable physicians from these other "parent" specialties to enter the practice of pain medicine. The ABPM required a credentialing process that included ABMS certification in anesthesiology, neurology, psychiatry, neurosurgery, or physiatry; documentation of a primary pain medicine practice that was broadly based; valid medical licensure; peer recommendations; and passing of an 8-hour examination in pain medicine that was designed and psychometrically-validated to reflect broadly the multispecialty origins of pain medicine as practiced in the field by experienced pain medicine practitioners, not by specialists or subspecialists in a parent specialty. The ABPM was formed as only a temporary solution to the lack of a credentialing process that was more representative of pain medicine as practiced in the community. The intent of the ABPM since its inception was ultimately to facilitate a separate ABMS Board in Pain Medicine; consequently, it has made two such applications to the ABMS, both which were rejected. Since 1993, the ABPM has credentialed over 2200 physicians as pain medicine specialists from these five specialties and the ABPM is recognized as ABMS equivalent in California, Texas, and Florida.

The rationale for a separate specialty in pain medicine involves the documentation of many factors: public health need[6–8]; a growing consensus of pain treatment as a human right[9]; ethical difficulties that are at the heart of pain medicine practice[10,11]; inadequate education[12] and knowledge[13] and a rapidly growing scientific and practice base[14]; and the need to promote integrated pain medicine with primary care.[15,16] The high costs of inadequately-managed pain reverberate in our society's health care crisis and are well documented. Emblematic of the same, it has been our citizens, the victims of inadequate pain management, who have decried this problem and demanded change through legislation at both a state and national level when organized medicine, itself beset by competition amongst established specialties, cannot act. The rationale is scientific as well. Since the publication of John Bonica's first edition of *Pain Management* in 1953, the problem of pain has challenged some of the best minds in science and medicine. In 1965, Melzack and Wall's[17] seminal paper in *Science* describing the Gate Theory of Pain created a conceptual framework resulting in a relative explosion of science in the physiology, molecular biology, and pharmacology of acute pain and the epidemiology, neurobiology, pathophysiology, genetics, and treatment of chronic pain conditions and diseases at the levels of soma, spinal cord, and brain. For example, a Medline search for titles with the key terms "pain" and "nociception" increased from 30,138 (pain) and 45(nociception) in the decade from 1970–1979 to 146,654 (pain) and 2417(nociception) in the 8 years from 2000–2007. Today's pain medicine physician is potentially armed with this tremendous knowledge base as a foundation for the myriad of effective medications, behavioral therapies, physical therapies, neural blockades, neuromodulatory devices, and cross-cultural complementary and alternative treatments such as acupuncture and meditation. The ABPM, AAPM, and a growing number of pain medicine and other specialists in organized medicine believe that longer training, either a 2-year fellowship or a separate 3-year residency, is needed to learn how, when, and in what combination these tools can be cost-effectively utilized to competently treat patients with chronic pain, to establish standards for training all physicians, and to lead the development of clinical research and health policy.[18] Although each traditional medical specialty contributes to this knowledge base and skill set, their respective specialists are not trained to manage the entirety of the spectrum of chronic pain contributing to fragmentation not unification of care and failed public health. Table 109.1 outlines the special skills contributed by traditional specialties that converge to define the pain medicine specialist. This specialized knowledge, education, training, and multidisciplinary nature suggest that pain medicine's evolution as a specialty is paralleling that of other disciplines, such as emergency medicine or physical medicine and rehabilitation. Knowledge and skills of the latter disciplines, initially fragmented, later coalesced into primary medical specialties because of the inability of multiple specialties to offer an integrated approach that would best serve patients, medical science, and public health.

Today, the momentum to establish standards for pain medicine as a specialty is now global. For example, in 1998 the government of Australia formally recognized pain medicine as a specialty and endorsed training and credentialing requirements recommended by the newly formed Faculty of Pain Medicine of the Australia New Zealand College of Anaesthetists.[19] In 2007, the Section and Board of Anaesthesiology of the European Union of Medical Specialists (EUMS/UEMS) initiated the establishment of the Multidisciplinary Joint Committee on Pain Medicine of the EUMS/UEMS, which has created a certification examination in pain medicine (see further discussion of training in the European Union later in this chapter). Also in 2007, the Ministry of Health of the People's Republic of China announced the designation of pain medicine as a separate specialty and that there will be a Department of Pain Medicine in all major hospitals in China.[20] In the United States, the ABPM and AAPM have applied jointly to the ACGME for establishing residency training programs in pain medicine under a new residency review committee. The simple rationale is that training for 1 year has proven to be inadequate. Similar to a cardiologist learning the science and clinical practice related to the cardiovascular system, starting with primary prevention of heart disease, by identification and early intervention of risk, and primary and secondary treatment of actual heart disease, the pain medicine specialist will learn about the pain perception and modulation system, from the relatively simple peripheral nociceptor to the system's complex neurobehavioral networks and about the pathophysiologies of this system.[21,22]

TRAINING IN PAIN MEDICINE IN EUROPE

In Europe, there is no systematic training in pain medicine for medical students. The lack of obligatory training leads to later deficiencies in clinical care. Some countries (e.g., Germany) have made efforts in establishing a core curriculum for medical students. However, the worldwide need for a thorough basic education in pain medicine is underestimated by most health care officials.

The postgraduate training varies widely within Europe. This led to guidelines for anesthesiologist specialist training in pain medicine.[23] In these guidelines approved by the EUMS/UEMS, pain medicine is considered to be an area of expertise in anesthesiology. However, simultaneously it is mentioned that pain medicine is not claimed for anesthesiology alone. It is clearly stated that pain medicine is included in anesthesia specialist training on the one side. On the other side, an additional qualification following basic anesthesia training is recommended. The multidisciplinary approach to pain is mentioned and an initiative to set up a multidisciplinary joint committee on pain medicine within the EUMS/UEMS has begun.

The proposed duration of pain medicine training is 3 months during the 5 years of basic anesthetic training required in the European Union. In contrast to this relation representing only

TABLE 109.1

EXAMPLES OF DISEASE AND TREATMENT CONTRIBUTIONS TO PAIN MEDICINE FROM TRADITIONAL SPECIALTIES

Specialty	Illness/Disease Knowledge Contribution	Medical Skill/ Treatment Contribution
Anesthesiology	Acute pain Chronic pain Cancer pain	Regional anesthesia (including neurolytic) Spinal anesthesia Operative anesthesia
Neurology	Peripheral neuropathy Neuropathic pain Central pain Headache	Assessment of neuropathic pain Neuropathic pain analgesia Headache medication
Neurosurgery	Spine disease Central pain	Implantable medication pumps Neurostimulation Spine evaluation and surgery
Orthopaedic Surgery	Low back pain Physical Disability	Spine evaluation and surgery Joint surgery
Palliative Care	Cancer pain	End-of-life symptom management Bioethics
Primary Care	Chronic diseases	Chronic disease management Biopsychosocial medicine
Psychiatry, Behavioral Medicine	Psychiatric comorbidity; Stress, behavior and emotions Fibromyalgia Personality and coping	Antidepressant analgesia Behavioral rehabilitation Biofeedback and relaxation Biopsychosocial formulation Psychotherapies (dynamic, cognitive-behavioral, group, family, hypnosis) Psychiatric diagnosis Psychological and psychometric evaluation Psychopharmacology
Radiological Medicine		Diagnostic imaging Procedure imaging Radiotherapy
Rehabilitation Medicine, Physical Therapy	Musculoskeletal medicine Myofascial pain Physical disability	Physical therapy Physical rehabilitation Transcutaneous electrical nerve stimulation Trigger point therapy
Rheumatology	Joint diseases Fibromyalgia	Joint injections Peripheral nociceptive analgesia (nonsteroidal anti-inflammatory drugs)
Complementary and Alternative Medicine		Acupuncture Massage Meditation Tai Chi

5% of the total time of training, it is recommended to occupy a minimum of 10% of the multiple choice questions in the diploma of the European Academy of Anaesthesia.

Some years ago, the Scandinavian Society of Anaesthesiology and Intensive Care established the Nordic education in advanced pain medicine. The clinical part lasts at least 3 months. The education includes, and this is unique in Europe, a scientific part.[24]

In April 2007, the Royal College of Anaesthetists established a faculty of pain medicine and stressed this as a major way point in the last 50 years.[25] However, the question is rasied: should pain medicine should strive to be a "stand alone speciality" or should it be linked to parent specialties like anesthesiology? Additionally, education is also required for the public and the patients? Both the British and the Irish curriculum in pain medicine require similar training and examination. The candidate has to complete a total of 6 months training in pain medicine before ending up with a 2-day written and oral examination with patient investigation and practical examination. The majority of treatment modalities, where the candidate should have an understanding and experience in the practice, are invasive procedures.

As early as 1992, the German Society of Anaesthesiology started a curriculum and specialist training in pain medicine. This included a 2-week theoretical course and a 1-year practical training requirement in a pain clinic. From this first example, a specialty open for all clinical disciplines has been developed. Since 1996, a specialty called "Specialised Pain Therapy" has been established by the German Medical Assembly. A curriculum has been developed by the German Pain Society and approved by the German Medical Assembly. Similarly to the Society of Anaesthetists, the specialization demands 1 year of clinical training in a certified institution and an 80-hour theoretical course. Additionally, to maintain specialty certification, physicians must attend multidisciplinary pain conferences regularly, where patients are presented and discussed between several disciplines, including at least one psychological discipline. In 2008, Austria introduced a similar specialty, and the German training is approved by the Austrian Medical Assembly.

The dramatic effect of a thorough education and programmatic work has been demonstrated in Catalonia in Spain within a project sponsored by the World Health Organization. Symptom control and patient satisfaction were both improved, and a striking cost savings of many million Euros per year has been demonstrated as compared to the rest of Spain.[26] Europe has lagged behind the United States in developing formal training for pain medicine specialists. In the European Union, training is not uniform, and there remains a long way still to go for a clear and consistent path to specialization and qualification in pain medicine.

TRAINING AND CREDENTIALING IN INTERVENTIONAL PAIN MEDICINE

In our rapidly changing world of modern health care, new technologies are appearing at a dizzying rate. Many of these new treatments require physicians to acquire detailed new knowledge and technical skills. The introduction of new techniques typically extends from centers in the public or private sector, where the ideas are conceived and tested in a limited realm among innovators. From there, anecdote can often take over, and many techniques in pain medicine have blossomed into widespread use with nothing more than word-of-mouth to propagate their use. The use of pulsed radiofrequency treatment for pain is one such example where clinical application has preceded detailed clinical testing.[27]

In the United States and Europe, industry often leads innovation by testing and leading the introduction of new devices. When the innovation appears to have merit in limited trials, many devices have been introduced to the market with approval through the U.S. Food and Drug Administration's (FDA) 510K "substantially similar device" process with little or no data regarding efficacy. Once on the market, the means by which practitioners decide to adopt new technologies, the speed of progression of these new techniques, and—of great importance—the means by which practitioners gain enough expertise to introduce new techniques into their own practices, are all highly variable and seemingly without any rational or consistent approach.

Interventional pain medicine is evolving as a distinct discipline that requires detailed new knowledge and expertise. Familiarity with radiographic anatomy for the conduct of image-guided injection and the minor surgical skills needed to place implanted devices such as spinal cord stimulators and implanted drug delivery systems are just a few of the techniques that practitioners must master. As we set out to introduce new interventional techniques to our own pain practices, we must assure that we have been properly trained to conduct these techniques to ensure safety and success.

Adequate exposure during the fellowship-training period to these newer treatment alternatives is necessary to assure appropriate application and optimize patient outcomes. While we do not have scientific data that define the average minimum level of experience that will be necessary to achieve competence, especially for complex procedures that are associated with significant risks, logic dictates that there are a minimum number of these procedures that trainees should be exposed to during a fellowship. The ACGME has established requirements for average minimal numbers of epidural, spinal, and peripheral nerve blocks necessary for accreditation of anesthesiology residency programs. Other medical subspecialties also require a minimum number of specified procedures to achieve and maintain competence: subspecialty training in gastroenterology has a requirement of performing a minimum of 100 esophagogastro-duodenoscopies and 100 colonoscopies with polyp removal[28] during formal training, and subspecialty training in cardiovascular disease requires 100 cardiac catheterizations to demonstrate minimum proficiency.[29] Indeed, the ACGME's RRC for Anesthesiology has accepted revised program requirements for pain medicine training programs that specify minimum exposure of trainees for various techniques, including image-guided spinal injection techniques in the cervical and lumbar spine; sympathetic blockade; neurolytic block, including radiofrequency treatment for pain; intradiscal procedures, including discography; spinal cord stimulation; and placement of permanent spinal drug delivery system. For those techniques that are now widely accepted as a core part of pain practice, we must assure that our trainees gain enough experience to conduct these procedures independently. One key element of the ACGME deliberations about unified pain training is to acknowledge that not all pain fellows will have experience in the wide variety of interventional techniques. Rather, it is hoped that these fellows will gain an understanding of all available options for patients with pain, and yet demonstrate and have competence documented in only those techniques for which formal training is made available during fellowship training.

It is difficult to define the techniques that are core for a pain practitioner, but it does seem that detailed knowledge of radiographic anatomy of the spine and the minor surgical skills required to implant spinal cord stimulators and place permanent spinal drug delivery systems are among those skills most practicing pain physicians would expect a new graduate from a pain fellowship to emerge with. New techniques are appearing at a staggering rate, and we cannot rely on pain fellowship programs to provide all of the technical training that is needed. Stronger standards for minimal training following fellowship are also urgently needed. Some pain practitioners believe that all too many of their colleagues find it perfectly acceptable to attend a brief weekend course and then introduce a highly technical new treatment into practice without additional study, training, or oversight.[30] Intradiscal electrothermal therapy, nucleoplasty, and radiofrequency treatment are among the many techniques that are showing promise and each requires a set of unique knowledge and skills to be used safely and effectively. Practitioners themselves must take the lead in obtaining adequate training *before* proceeding with any new and unfamiliar technique. The weekend workshop is just a start, often a good start—the best will give practitioners a detailed understanding of anatomy, pathophysiology of disease related to the use of the new technique, patient selection, conduct of the procedure, outcomes, and avoidance, management, and recognition of complications. Here we would like to suggest a method for practitioners[31] (Table 109.2): (1) *study the new technique*, the published literature, and gain a detailed knowledge of all aspects of the technique; (2) *attend a workshop*, preferably a hands-on cadaver-based workshop that allows introduction to the technique in as realistic a setting that can be assembled; (3) *plan* adequate time for your initial procedures; (4) *get help* at the bedside during initial conduct of new procedures—perhaps another experienced practitioner at your institution, an invited expert to assist, or team up with a colleague in a related discipline; (5) *inform your patients* that you are intro-

TABLE 109.2

SUGGESTED TRAINING AND EXPERIENCE WHEN INTRODUCING A NEW TECHNIQUE IN TO CLINICAL PRACTICE

1. Study the new technique, the published literature and gain a detailed knowledge of all aspects of the technique
2. Attend a workshop, preferably a hands-on cadaver-based workshop that allows introduction to the technique in as realistic a setting that can be assembled
3. Plan adequate time for your initial procedures
4. Get help at the bedside during initial conduct of new procedures—perhaps another experienced practitioner at your institution, an invited expert to assist, or team up with a colleague in a related discipline
5. Inform your patients that you are introducing a new technique and include this discussion as part of the informed consent process
6. Examine your outcomes carefully in the initial stages of using any new technique and compare them with those of your colleagues and the published literature.

ducing a new technique and include this discussion as part of the informed consent process; (6) *examine your outcomes* carefully in the initial stages of using any new technique and compare them with those of your colleagues and the published literature.

CONCLUSION

The field of evidence-based medicine has emerged as a new paradigm to guide practicing physicians. This field endeavors to educate practitioners about how to frame specific questions based on the clinical problems they are faced with every day. They then venture to the published scientific literature with focused questions about prevention, treatment, and diagnosis of a specific clinical condition. Many evidence-based medicine centers offer concise and periodically updated summaries about specific clinical conditions. The idea is to get the best information available to the practicing clinician. It describes the best available evidence, and if there is no good evidence, it says so. In pain medicine, we are faced with an expanding array of treatment options that strike us as logical developments that s*hould* provide pain relief for our patients. However, there is a dearth of clinical evidence to guide rational choice and application of the majority of these emerging treatments. So how are we to decide when to apply them?

Merrill[32] recently presented a detailed analysis of the current state of evidence guiding the use of interventional treatments in the field of pain medicine. He points out the frequent flaws in existing studies (largely the lack of valid comparators, such as no treatment) and concludes that, "the practice of invasive pain medicine teeters at a particularly critical juncture . . . crippled by a lack of vigorous self-evaluation of its role in the treatment of chronic pain." Merrill[32] goes on to detail the means by which we, as scientists and clinicians, can proceed to build a better body of evidence for the treatments we are using. But the field of pain medicine is young and early in development, and it is perhaps unreasonable to expect an accumulation of randomized clinical trials just yet.

New treatments evolve slowly in clinical medicine. Applying the scientific method in clinical medicine begins with an observation. Perhaps a chance observation that a certain drug typically used for another purpose provides analgesia to a given patient. If the drug is readily available, a clinician may choose to try treatment on other patients with similar presentations. If an academic sort, the clinician may choose to report the limited success in a case series. Case series are a valuable beginning: the very beginning of emerging new ideas. If the problem is uniform and prevalent enough, the new treatment may gain the attention of investigators willing to assemble a randomized clinical trial. All too often, sound treatments are never tested for lack of interest or funding. Those that are tested tend to be those under patent where a manufacturer proceeds with these large endeavors understandably in hope of financial return in the event the treatment proves useful. Patients who are suffering from severe and intractable pain are desperate, and they can easily be convinced that desperate measures, however new or unproven, are warranted.

How, then, are we to proceed? Our patients are begging for us to try anything that offers a glimmer of hope in reducing their pain, and we as scientists embrace the rigor of the scientific method and want desperately to do what is best for our patients. We have treatment after treatment that makes logical sense and shows early promise in case series and observational studies, but little data that support an evidence-based approach to practice. Let us take acute low back pain with sciatica as an example. A number of evidence-based reports have emerged to guide clinicians.[33] The only modalities that are rated as "beneficial" or "likely to be beneficial" are advice to stay active, nonsteroidal anti-inflammatory drugs, behavioral therapy, and multidisciplinary treatment programs. Use of opioid analgesics, acupuncture, back schools, epidural steroid injections, and spinal manipulation were all judged to be of "unknown effectiveness." Yet, in actual clinical practice in the United States, a short course of opioid analgesic and early intervention with epidural steroid injections are common. To complicate matters, the use of fluoroscopic guidance and directing injections to the effected level using an interlaminar of transforaminal approach is gaining widespread acceptance, with only uncontrolled case series to guide us as clinicians. To complicate treatment options, those with persistent pain and contained disc herniations now have a dizzying array of treatment options including laser discectomy, thermal disc decompression, and vacuum disc extraction, all using FDA-approved devices with only uncontrolled observational studies that suggest effectiveness.[34] The new devices are as intellectually appealing as they are minimally invasive, yet only open surgical discectomy has proven superior to conservative management in patients with persistent sciatica due to intervertebral disc prolapse.[35]

The evidence-based medicine movement gives little guidance to practitioners whose tools are still under development. They simply remind us that no evidence regarding many of our techniques exists. Without declaring a moratorium on all of interventional pain, Merrill[8] offers the individual practitioner advice: monitor your own outcomes using valid measures, be more reflective and systematic in studying your own outcomes and patterns of care, and provide this information to your patients as part of the decision-making process. As pain practitioners, we have an expanding range of treatment options available to us, few with convincing evidence of efficacy superior to alternate treatments. We must evaluate each patient and use the limited evidence available to us today to guide compassionate and rational, if not evidence-based, use of therapy for our desperate patients.

The urgent need for expanded clinical research in pain medicine, coupled with the recent efforts to improve multidisciplinary training, are straining the ability of training programs to adequately provide the needed education and research experiences for pain medicine fellows in the course of a 1-year fellowship. The ACGME and ABA are currently working toward expanding the pain medicine fellowship to 2 years in order to accomplish these goals. The idea is to provide more comprehensive and multidisciplinary training and to require meaningful research experience during fellowship training. With this approach, we will create a more homogeneous group of pain medicine specialists, who emerge with similar knowledge and skills, regardless of the parent discipline in which they trained. In this way, we can move toward improving the consistency and quality of care for patients with

acute, chronic, and cancer-related pain. Will the current approach be enough to train the best pain medicine specialists or will the need to move further toward a primary medical specialty continue? The authors of this chapter have been among those who have worked to craft the changes in education that have emerged from the ACGME (James P. Rathmell and David L. Brown), the ABPM (Rollin M. Gallagher), and the European Union (Michael Zenz). It is our hope in preparing this chapter and other publications of its kind that the major groups working toward improving the education of pain medicine specialists can continue to work together to create the best possible training programs that will ultimately advance the science and practice of pain medicine to the benefit of our patients.

CHAPTER 110 ■ EMERGENCIES IN THE PAIN CLINIC

CHRISTOPHER GILLIGAN, MILAN STOJANOVIC, AND JAMES P. RATHMELL

This chapter will seek to provide the pain management specialist with an overview of emergencies and complications that may occur in the course of caring for patients with acute and chronic pain. Throughout this review we will also emphasize strategies for decreasing risk; specifically, strategies for identifying specific risks and considering alternatives, understanding rare event analysis, and maintaining a comprehensive view of the patient when prescribing specialty specific interventions. A prudent first step for practitioners who will be managing emergencies related to pain therapies is to understand the incidence of each of these emergencies. However, because complication rates are quite low for serious complications, and because minor complications frequently go unreported, measuring the true incidence of most complications is not generally feasible.

In the United States, the American Society of Anesthesiologists Closed Claims Project offers a relatively comprehensive database of adverse events secondary to pain management interventions, but no incidence can be calculated due to the lack of any knowl-

edge regarding the overall frequency with which the interventions are conducted. A review of the 5475 claims in the American Society Anesthesiologists Closed Claims Project database between 1970 and 1999 showed that claims related to chronic pain management accounted for 10% of all claims in the 1990s. Of the 276 closed claims in the database, epidural steroid injections accounted for 138 (49%) and other peripheral nerve blocks accounted for 78 (27%) of all chronic pain management claims, reflecting the most frequent invasive procedures conducted by anesthesiologists during that time period (Table 110.1). Nerve damage and pneumothorax were the most common adverse events leading to claims in invasive pain management claims (Fig. 110.1). Surprisingly, serious adverse events leading to brain damage or death did occur in association with chronic pain treatment, but at a far lower rate than that seen in surgical and obstetric anesthesia claims. A closer analysis of the subset of claims associated with epidural steroid injections, revealed that death and brain damage occurred only when local anesthetic or opioid (or both) were administered in conjunction with the steroid (Fig. 110.2). This likely reflects unintended delivery of local anesthetic or opioid to the subarachnoid space, or simply the predictable effects of neuraxial opioids; resultant high spinal anesthesia or neuraxial effects of opioid could both have led to respiratory compromise and underscores the need for close observation following neuraxial administration of local anesthetic or opioid. Not infrequently, claims resulted from the maintenance of spinal drug delivery systems (20/276 claims or 7%); these claims often stemmed from refilling of implanted drug reservoirs with potent opioid by nonphysician personnel in the outpatient or home care settings.

BLEEDING COMPLICATIONS

Within one decade of August Bier's discovery of spinal anesthesia, the first known epidural hematoma as a complication of spinal anesthesia occurred in a 36-year-old male following unsuccessful neuraxial blockade for excision of a pilonidal cyst.[1] In that case, repeated lumbar puncture revealed blood tinged cerebrospinal fluid (CSF) and the patient subsequently developed paresthesias and weakness in both lower extremities. The introduction of heparin in 1937 and warfarin in 1941 introduced the possibility of anticoagulation contributing to epidural hematoma formation. Epidural hematoma is a rare but potentially catastrophic complication of spinal or epidural anesthesia or injections. Because the spinal column is an enclosed space, hematoma formation can cause compression and ischemia of neural structures. Bleeding

may result from injury to the abundant epidural veins or may be arterial. A retrospective study of central neuraxial blocks in Sweden from 1990 to 1999 identified 33 spinal hematomas, during a period when approximately 1,260,000 spinal blocks and 450,000 epidural blocks were administered. In that study, the incidence of spinal hematoma was one in 200,000 after obstetric epidural blockade and one in 3600 among female patients undergoing knee arthroplasty.[2] At a single teaching hospital in Australia, data were collected prospectively over a 16-year period for all epidural catheters placed for postoperative analgesia. During that period, 8210 epidural catheters were inserted and 2 spinal hematomas (1:4105) and 6 epidural abscesses (1:1368) were diagnosed.[3] In rare instances, spinal epidural hematoma has developed following chiropractic manipulation and acupuncture therapy.[4,5] Factors that determine whether epidural hematoma results in injury to neural structures include the location in the spinal column (the level of the cauda equina is relatively resistant to injury, whereas the cervical spinal cord is not), and the rate at which the blood accumulates. Tarlov and colleagues demonstrated in dogs that spinal cord injury due to spinal epidural hematoma depends on both the amount of pressure exerted on the spinal cord and the duration of that pressure elevation.[6] Interestingly, some epidural hematomas cause significant injury despite the fact that their volume is significantly less than that typically used during epidural blood patch placement. Vertebral column neoplasms and vascular malformations are also risk factors. Patients who have an underlying coagulopathy or are being anticoagulated with warfarin, intravenous heparin, subcutaneous low molecular weight heparin, platelet inhibiting medications such as clopidogrel or ticlopidine, platelet glycoprotein IIb/IIIa receptor inhibitors, or fibrinolytic agents are at elevated risk of spinal hematoma formation. In addition, garlic has been shown to inhibit platelet aggregation and has been linked in one case to the development of a spontaneous epidural hematoma. Ginkgo inhibits platelet activating factor and has been linked to several cases of spontaneous intracranial bleeding, and ginseng inhibits platelet aggregation and prolongs both thrombin time and activated partial thromboplastin time, although the clinical significance of these findings remain unclear.[7–9]

Timely diagnosis of spinal epidural hematoma is critical, but in many cases will be challenging. Many patients have few complaints initially, commonly developing progressively worsening back pain as the hematoma expands with or without the immediate or delayed appearance of focal neurologic deficits. A progressive neurologic deficit may develop over a variable interval and with variable severity. Typically, neurologic deficits evolve over the course of several hours but, in some instances, they may develop over several days. In some instances, neurologic deficit rather than pain may be the presenting sign. Physical findings of myelopathy, or the development of the Brown-Sequard syndrome, should be recognized as indicative of spinal cord compression and should prompt emergent diagnostic evaluation and treatment.[10] Intractable leg pain and cauda equina syndrome may develop as well. Urinary retention may precede urinary incontinence. When a spinal epidural hematoma is suspected, a thorough neurologic examination is mandatory. This examination should include evaluation of anal sphincter tone and direct examination in efforts to detect loss of perineal sensation. Furthermore, serial examinations should be performed at short intervals. Findings on physical examination will be variable depending on the level of the lesion. Unilateral or bilateral weakness and/or paresthesias may be present. Hyper- or hyporeflexia may also be present. Depending on the clinical context, the differential diagnosis may include spinal epidural abscess. Urgent laboratory studies should include a complete blood count with platelets as well as a prothrombin time and activated partial thromboplastin time. In addition, a blood bank sample should be sent for type and cross match in preparation for surgery as well as in cases where fresh frozen plasma may be needed to reverse coagulopathies.

Magnetic resonance imaging (MRI) is the preferred radiologic study for diagnosis of spinal epidural hematoma. On sagittal reconstructed computed tomography (CT) or MR images, a spinal epidural hematoma typically appears as a biconvex mass dorsal to the thecal sac, with tapering cephalad and caudad margins (Fig. 110.3). Associated spinal cord edema may also be seen. Acute hemorrhage is characterized by a marked decrease in signal intensity on T2-weighted images. Subacute hematoma is characterized by increased signal intensity on both T1- and T2-weighted images.[11] The dura matter appears as a low signal curvilinear structure separating the hematoma from the spinal cord on T2-weighted gradient echo sequences. In one retrospective study of 17 patients with acute spinal epidural hematoma, 10 patients' T1 weighted images showed isointensity to the spinal cord and, in 7 patients, the hematomas were slightly hyperintense. T2-weighted images showed hyperintensity with areas of hypointensity. Other MRI findings included hematomas showing direct contiguity with the adjacent osseous spine in 13 patients. Posterolateral location of the hematomas was noted in 13 patients. Additional findings were capping of the epidural fat, compression of the epidural fat and ligamentum flavum, and compression of the thecal sac and/or cord.[12] MRI will also help to identify associated spinal cord tumors or arteriovenous malformations. For patients who cannot undergo MRI scanning or in cases where MRI scanning is not immediately available, CT, with or without myelography, is the study of choice. A spinal epidural hematoma appears as a bi-concave dorsal mass typically extending over at least two vertebral levels (Fig. 110.3).[13] Lumbar puncture does not add to

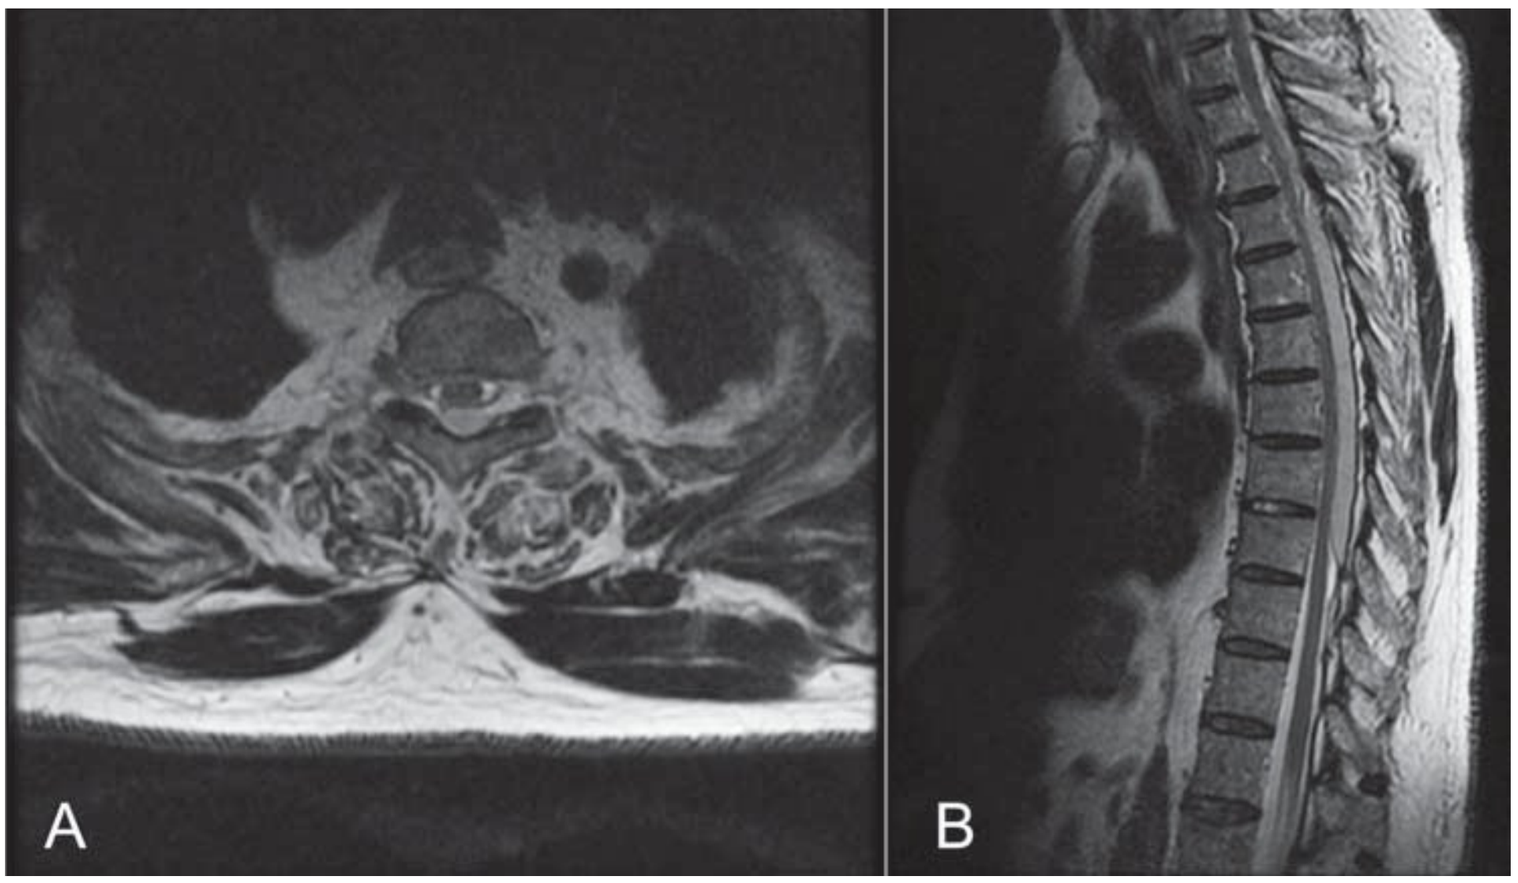

FIGURE 110.3 MRI of the lumbosacral spine demonstrating a lumbar epidural hematoma. **(A)** Axial and **(B)** sagittal reconstructed T2-weighted MRIs demonstrating a biconvex mass dorsal to the thecal sac extending from the cervicothoracic junction to the low thoracic area, with tapering cephalad and caudad margins, the typical appearance of an epidural hematoma.

the diagnosis and may worsen the patient's condition in some instances.

When spinal epidural hematoma is entertained as a diagnosis, urgent neurosurgical consultation should be obtained. In a retrospective study of 30 patients who were treated for spinal epidural hematoma between 1979 and 1993, rapidity of surgical decompression of the spinal cord correlated with neurologic outcome.[12] Patients who were taken to surgery within 12 hours of symptom onset fared significantly better than those whose surgery was delayed beyond 12 hours. In this series, the patients' preoperative neurologic status was also predictive of outcome. Of note, in a series of 30 patients, of 8 patients who had complete loss of neurological function (Frankel grade A), 6 improved with surgical decompression and 2 of these regained normal function.[11] Emergent surgical evacuation remains the standard of care and treatment of choice for spinal epidural hematoma. In some instances, spinal epidural hematomas have been successfully conservatively managed, typically in patients whose neurologic examination was spontaneously, steadily improving.[14]

INFECTIOUS COMPLICATIONS

Infectious complications may ensue following either peripheral or central neuraxial blockade, although the latter is more likely to lead to catastrophic sequelae such as meningitis or compression of neural structures. Both superficial and deep infections have been reported following epidural injections, facet joint injections, and trigger point injections. In the case of indwelling catheters, the risk of infection increases with increased duration of catheter therapy. When epidural catheters are left in place for 70 days, the risk of infection reaches 15% with a 1% risk of epidural infection.[15–17] In the case of implanted spinal cord stimulators and intrathecal drug pumps, a review of four prospective trials found 36 infections in 35 patients out of a total of 700 patients who underwent implantation. The overall infection rate was 5% with 57% to 80% of the infections in the trials involving the pump pocket, 13% to 33% involving the lumbar site, and zero to 14% leading to meningitis.[18] All patients undergoing interventional therapies for pain treatment should be given explicit written postprocedural guidelines that include a clear description of the signs and symptoms that may herald an infection and a clear process for contacting pain clinic personnel on an urgent basis if such signs and symptoms develop.

The source of the pathogen may be either external, as in the case of contaminated equipment or breaches in sterile technique, or internal in the case of patients with local or systemic infections such as skin and soft tissue infections or bacteremia. Risk factors for infection include diabetes, alcoholism, smoking, and immunosuppression. Similarly, infections in the epidural space may spread to other areas via hematogenous spread or local extension. Pathogens include skin flora such as *Staphylococcus aureus* and *Staphylococcus epidermis*. In patients with implanted spinal catheters or devices, the incidence of methicillin-resistant *Staphylococcus aureus* epidural infection is particularly high. Injury to the neural structures may occur due to direct compression by an abscess or due to ischemia caused by septic thrombophlebitis.

Initially, patients with epidural abscess present typically with back pain at the affected level of the spine. Subsequently, they may develop radicular pain corresponding to the involved level. They may then progress to development of motor and sensory deficits accompanied by bowel and bladder dysfunction and finally to frank paralysis. Back pain will be present in roughly three quarters of patients, fever in almost half, and neurologic deficits in about one third. Thus, the classic triad of back pain, fever, and neurologic deficit is seen in only a minority of patients.[19] Both the duration of symptoms prior to presentation and the rate of progression of symptoms can be highly variable. Spinal epidural abscesses typically extend over three to four vertebral levels; however, in rare instances they may involve the whole spine. Laboratory studies should include a complete blood count with differential as about two thirds of patients will have leukocytosis. Erythrocyte sedimentation rate and C reactive protein are almost always elevated, although neither of these tests is specific. Blood cultures should be sent prior to the administration of antibiotics and approximately 60% of patients will be bacteremic. When lumbar puncture is performed, CSF analysis shows elevated protein and pleocytosis in three quarters of patients. Gram staining and culture of CSF are negative in the majority of patients. Lumbar puncture adds little to the diagnosis and entails risk of causing meningitis if the needle traverses the epidural abscess en route to the thecal space; CSF should be analyzed if myelography is undertaken.

MRI with intravenous gadolinium is the study of choice to evaluate possible epidural abscess (Fig. 110.4). MRI is highly sensitive for diagnosing epidural abscess and allows evaluation of the dimensions of the abscess which facilitates surgical planning. If MRI is contraindicated or is not readily available, CT myelography is also quite sensitive, but is more invasive. Plain x-rays or CT scan of the spine without myelography may demon-

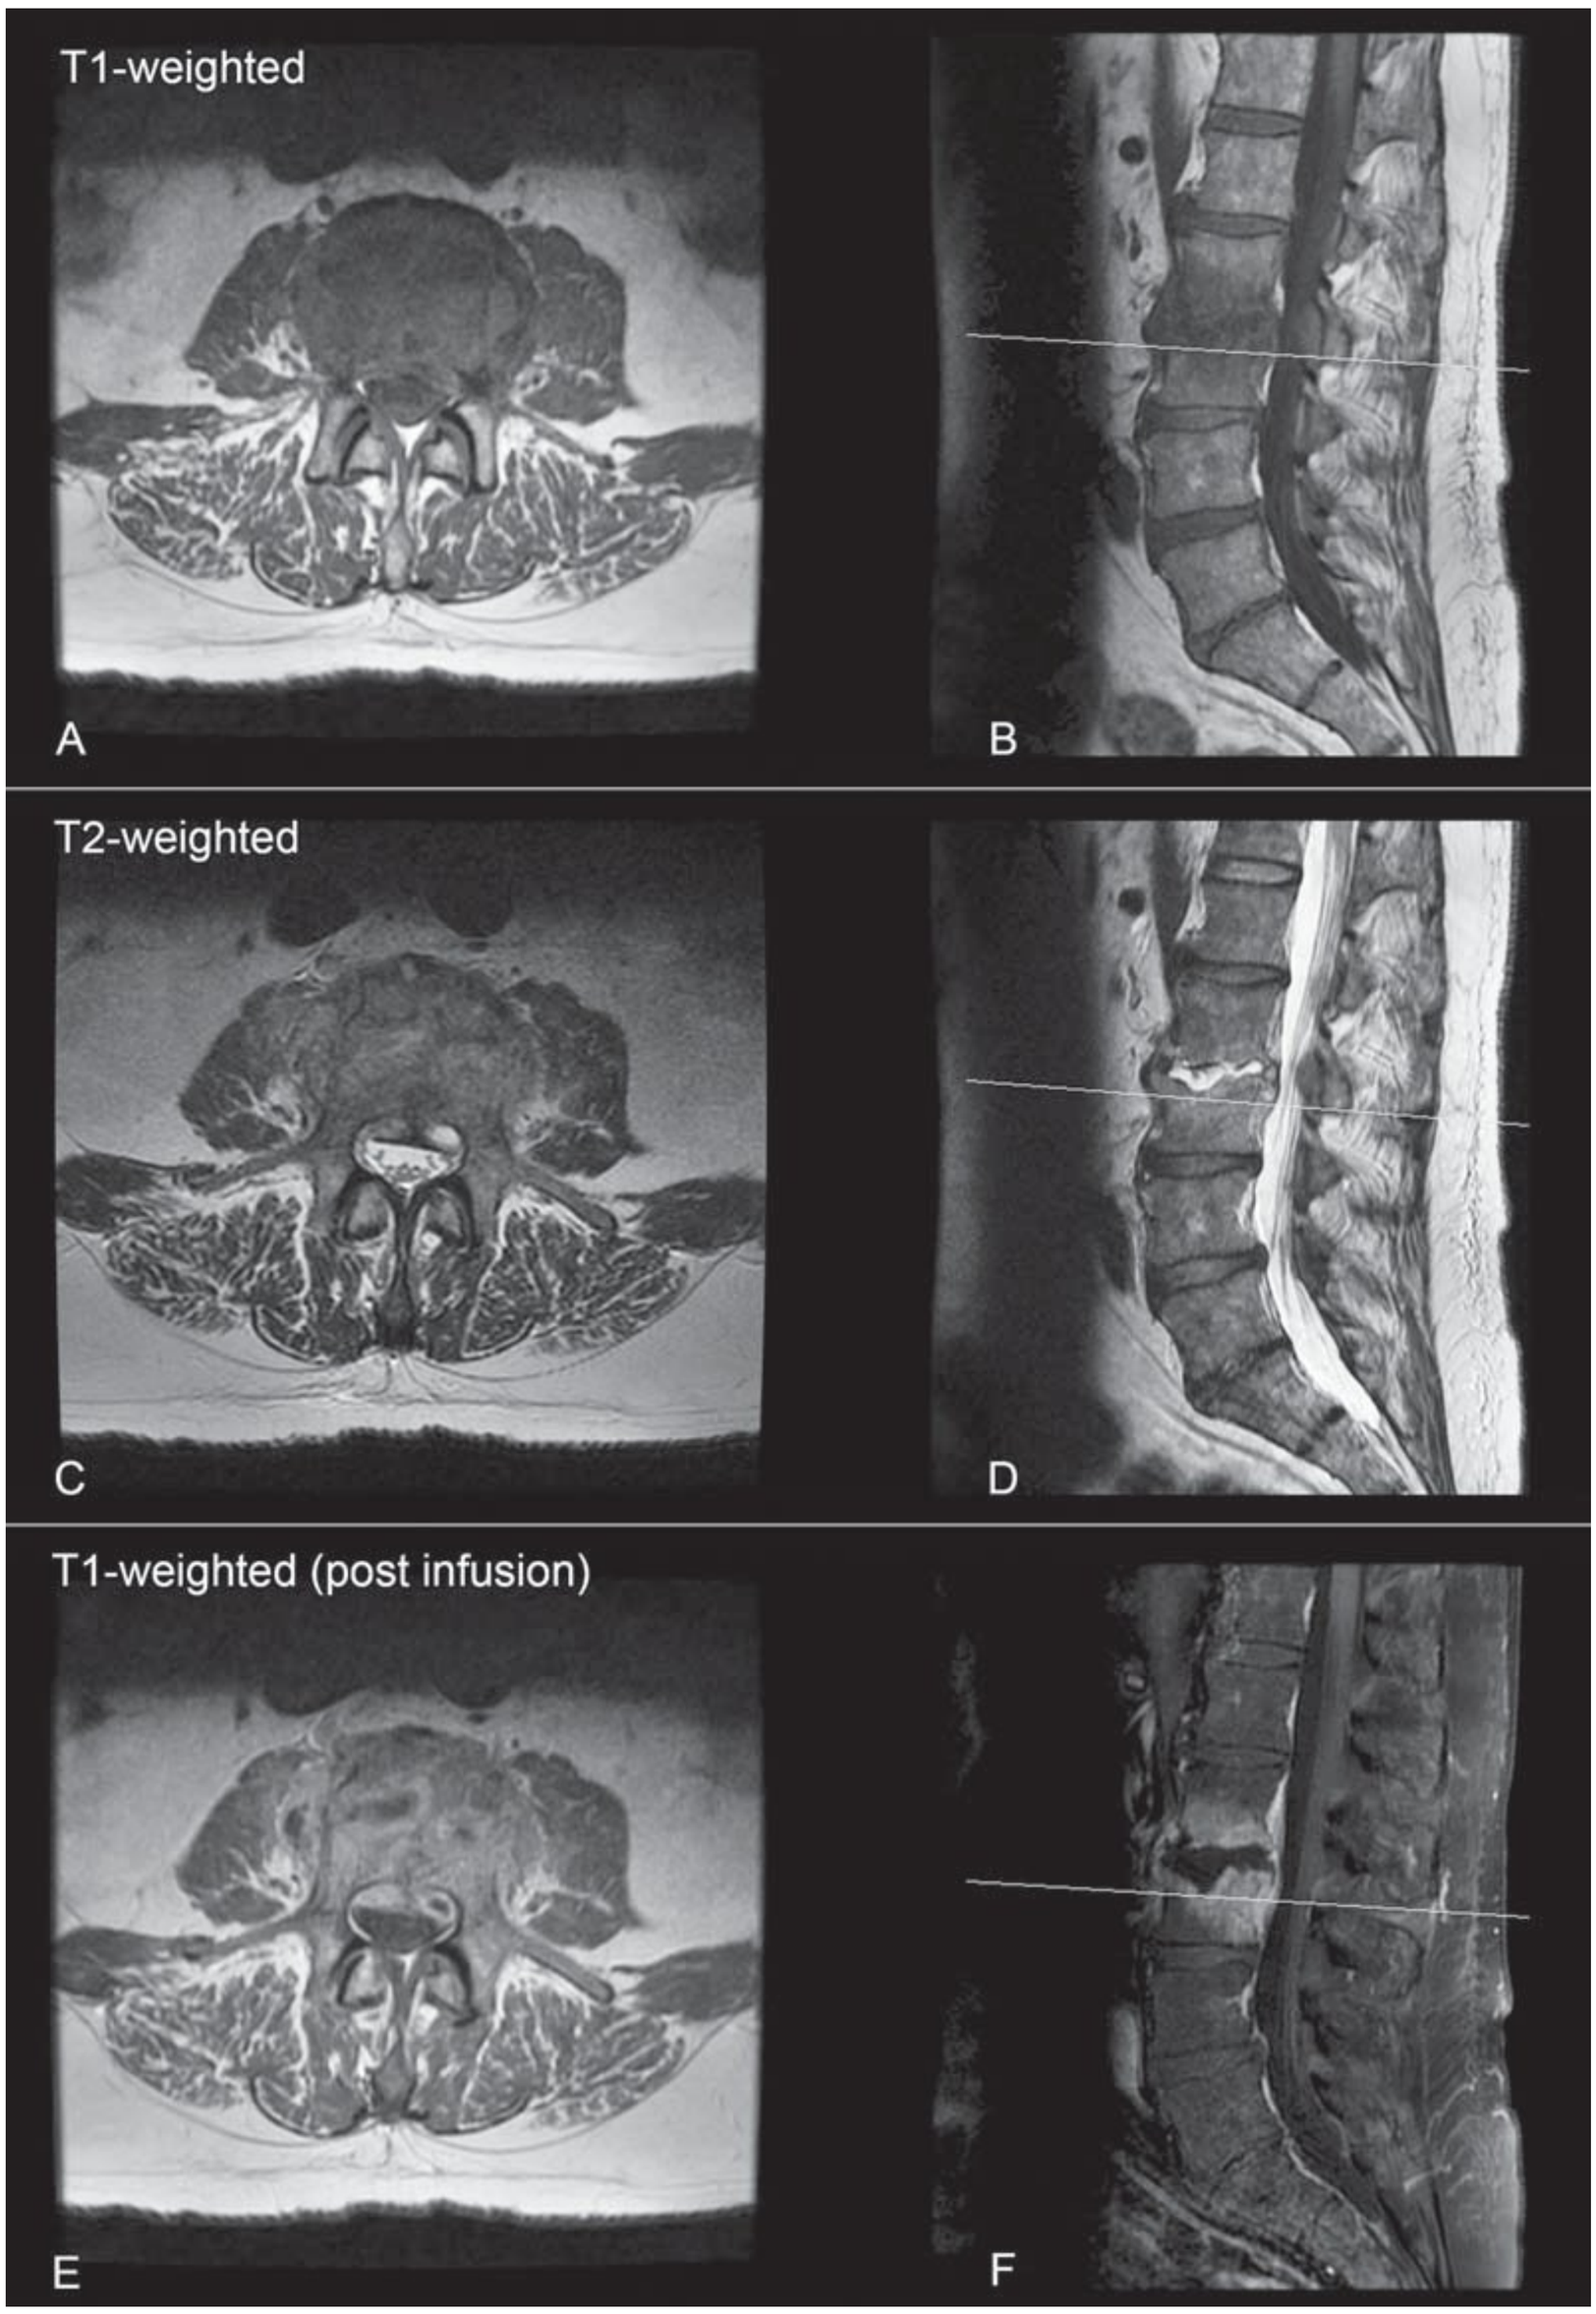

FIGURE 110.4 MRI of the lumbosacral spine demonstrating epidural abscess. This is a 64-year-old who presented with worsening axial low back pain 2 weeks following lumbar epidural injection of steroid for treatment of acute radicular pain. **(A)** Axial and **(B)** sagittal T1-weighted images. **(C)** Axial and **(D)** sagittal T2-weighted images. **(E)** Axial and **(F)** sagittal T1-weighted images following intravenous administration of gadolinium. These findings are compatible with diskitis/osteomyelitis at L2-3, with enhancement of the anterior epidural space and a focus of high T2 and low T1 signal in the left anterior epidural space consistent with epidural abscess.

strate diminished discs space and/or bony destruction suggestive of discitis and osteomyelitis. These conditions coexist with epidural abscess in up to 80% of cases. Urgent surgical drainage accompanied by administration of systemic antibiotics is the standard of care for epidural abscesses.[20] In rare cases, percutaneous drainage with systemic antibiotics or antibiotic treatment in the absence of surgery may be undertaken.[19]

Superficial infections typically present with local erythema, pain, swelling, and, in some cases, purulent discharge. In some instances, superficial infections associated with catheters can be managed with local drainage and antibiotics without removing the catheter.[15] Some cases of superficial infections and pocket site infections following implantations of spinal cord stimulators and intrathecal drug pumps have been successfully managed using oral and parenteral antibiotics that correspond to antimicrobial sensitivities on the basis of wound cultures, while the implanted device has been left in place.[21,22] However, as other authors have noted, device-related infections are rarely completely eradicated without removal of the device in question.[18] This observation mirrors the extensive experience with infected cardiac pacemakers.[23] In all cases, a high degree of vigilance must be maintained in regard to the possibility that a device-related superficial or pocket infection may spread to the neuraxis with catastrophic results. In the event that signs of infection such as erythema, swelling, fluctuance, or tenderness progress along the course of an implanted lead or catheter, the device with all associated hardware should be surgically removed on an urgent basis. Similarly, urgent device removal should be undertaken if the patient displays signs of systemic infection such as fever or chills, or signs of possible meningitis such as fever, neck pain and stiffness, severe headache, or altered mental status. At the time of surgery, separately labeled wound cultures should be sent from all surgical sites and all surgical sites should be extensively irrigated. As with spinal epidural hematoma, the patient's preoperative neurologic function is the best predictor of final neurologic outcome.[24] For any patient where there is a significant concern for systemic infection or meningitis, antibiotics should be administered immediately and should not be delayed until cultures can be obtained. Empiric antibiotic coverage should provide coverage of *Staphylococcus* species, preferably with vancomycin to ensure coverage of methicillin-resistant *Staphylococcus aureus*, and should provide coverage of gram-negative microbes with a third or fourth generation cephalosporin or equivalent.

LOCAL ANESTHETIC SYSTEMIC TOXICITY

Lidocaine and bupivacaine are amide local anesthetics which are widely used in interventional pain management procedures due to their relative safety. Lidocaine is of relatively lower potency and has a rapid onset of action and an intermediate duration of action. Nonetheless, the potential for lidocaine associated systemic toxicity due to excessive dose, inadvertent intravascular administration, or unanticipated rapid absorption is well recognized. Bupivacaine is of higher potency, but has a slower onset and prolonged duration of action. Local anesthetics, including lidocaine and bupivacaine, bind sodium channels and inhibit the sodium permeability that underlies action potentials in both neurons and cardiac myocytes. Local anesthetic inhibition of sodium permeability increases with repeated depolarization. In addition to binding sodium channels, local anesthetics will bind potassium and calcium channels, as well as N-methyl-D-aspartate receptors, beta-adrenergic receptors, and nicotinic acetylcholine receptors. Indeed, local anesthetic toxicity may be mediated in part through binding to these channels and receptors.[25–27] In general, the anesthetic potency of a local anesthetic correlates with its central nervous system (CNS) toxicity. Local anesthetics appear to cause cardiac toxicity through several different mechanisms including inhibition of calcium and potassium channels and inhibition of beta-adrenergic receptors and epinephrine stimulated cAMP formation. Local anesthetics prolong cardiac conduction in a dose dependent fashion. With increasing serum concentration, bupivacaine provokes QT prolongation, ventricular tachycardia, and ventricular fibrillation. Risk factors for the development of local anesthetic toxicity include the extremes of age, reduced hepatic and cardiac function, and pregnancy. The threshold dose of local anesthetic required to provoke seizures is affected by the route and rate of injection, the rate of increase of serum drug concentration, the presence of acidosis, and whether the patient is awake or anesthetized. Local anesthetic toxicity may result from systemic absorption of excessive doses following local infiltration; however, toxicity more commonly occurs due to inadvertent intravascular injection. Intraarterial injection poses a greater risk of CNS and cardiovascular toxicity than intravenous injection because, in the latter case, passage through the lung allows for some clearance of the drug. In the case of intraarterial injection, doses as small as 2.5 mg of bupivacaine or 15 mg of lidocaine have resulted in seizures when injected into the carotid or vertebral arteries, and this is felt to result from direct delivery of the local anesthetic to the brain.[28,29]

In the event of lidocaine toxicity, CNS symptoms typically precede cardiovascular symptoms.[30] CNS symptoms are initially characterized by inhibitory neuronal blockade leading to excitatory manifestations such as perioral numbness, a metallic taste, tinnitus, restlessness, confusion, a sense of impending doom, visual disturbances that are most commonly described as oscillations of objects in the visual fields, shivers, tremors, and tonic-clonic seizures (Fig. 110.5). Sympathetic stimulation is also observed during this phase, with resultant tachycardia and hypertension.[31]

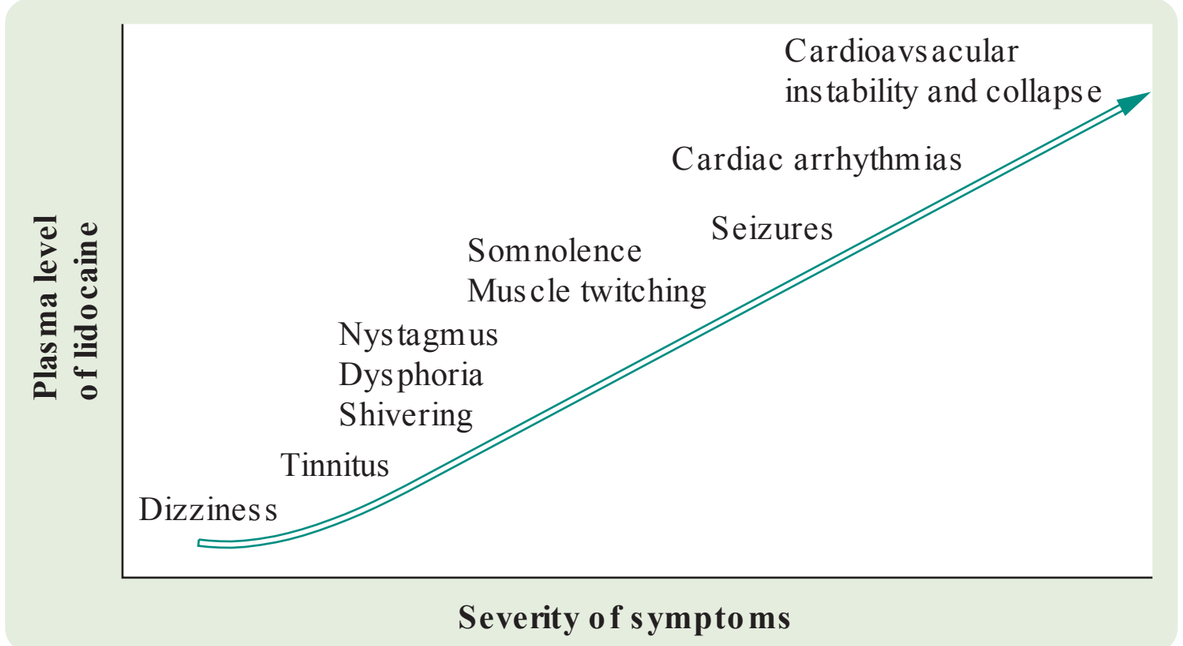

FIGURE 110.5 Relationship between plasma concentration of lidocaine and the development of signs and symptoms of local anesthetic toxicity.

In patients who are receiving procedural sedation with benzodiazepines or other sedatives, the excitatory phase of local anesthetic toxicity may not be apparent. The excitatory phase is followed in episodes of severe toxicity by a depressed phase characterized by coma and respiratory arrest. Cardiovascular toxicity develops at higher serum levels and may include profound bradycardia, arrhythmias, contractile dysfunction, and asystole.[25] In the case of bupivacaine, doses that are insufficient to provoke seizures will provoke cardiac arrhythmias.[32]

Treatment of local anesthetic induced seizures focuses on maintaining the airway and oxygenation. The injection or infusion of local anesthetic must be stopped immediately. Lorazepam, midazolam, thiopental, or propofol may be used to terminate the seizure. Cardiovascular depression with resultant hypotension due to local anesthetic toxicity should be treated with intravenous crystalloids and vasopressors such as norepinephrine, or phenylephrine. In the event of severe contractile dysfunction, epinephrine should be administered. If cardiac arrest occurs, advanced cardiac life support (ACLS) protocol should be pursued, although some authors propose substituting vasopressin for epinephrine. Cardiac arrest due to bupivacaine toxicity has been successfully treated in several cases with intravenous lipid emulsion.[33,34] A 20% lipid emulsion may be administered as a 1.5 mL per kilogram bolus followed by a 0.25 mL per kilogram per minute infusion for 30 to 60 minutes. The mechanism by which lipid infusion is believed to reverse bupivacaine toxicity is by ''scavenging'' the lipophilic bupivacaine. In the presence of persistent cardiovascular collapse associated with local anesthetic administration, urgent institution of cardiopulmonary bypass can be lifesaving.

Unintended Destinations Following Local Anesthetic Administration

The direct effects of local anesthetics are critically dependent on where they are applied. Inadvertent intrathecal injection of local anesthetic can result in a high thoracic or cervical level of sensory and motor block or total spinal anesthesia, with transient loss of consciousness and respiratory arrest. This is most likely to occur during cervical injections or when a large volume of local anesthetic is used during lumbar injections. Signs and symptoms of a high spinal progress rapidly and most typically include flaccid paralysis, apnea, hypotension, bradycardia, and dilated pupils. They initially include lightheadedness, dizziness, nausea, and vomiting.[29] In addition, the patient may develop air hunger due to loss of intercostal muscle activity, followed by phrenic nerve paralysis and eventually apnea due to blockade of the respiratory center in the brain stem. Blockade of the cardio accelerator fibers at T1 through T4 or of the medulla may produce bradycardia, hypotension, or arrhythmias.[35] Blockade of the Edinger-Westphal nucleus with subsequent loss of efferent parasympathetic activity produces dilated, nonreactive pupils.[36] In the case of subdural injection, symptoms develop more slowly, typically 15 to 30 minutes after injection, and are commonly asymmetric. When symptoms do occur, they may progress to respiratory and cardiovascular collapse as with intrathecal injection. When a high spinal occurs, ventilation with 100% oxygen with a bag valve mask or with endotracheal intubation must be initiated if phrenic nerve blockade or apnea is present. Bradycardia and hypotension should be treated with crystalloids, and atropine, ephedrine, phenylephrine, or epinephrine.[35] The patient may remain awake, but paralyzed during a high spinal, so reassurance that the condition is temporary is warranted, as is consideration of administration of an anxiolytic agent.

Vasovagal Reactions

Vasovagal reactions, which may include frank syncope, are one of the most common emergencies encountered in a pain center. Fortunately, these episodes typically have a benign natural history. Sir William Gowers first used the term vasovagal in 1907, and vasovagal syncope is now accepted as the most common form of syncope, accounting for two thirds of syncopal episodes presenting to the emergency department.[37] The pathogenesis of vasovagal syncope remains uncertain, but the current understanding is that it results from venous pooling and reduced venous return, and that vigorous contraction of the heart's chambers when they are inadequately filled provokes the Bezold-Jarisch reflex, resulting in paradoxical hypotension and bradycardia. At the onset of a vasovagal reaction patients typically appear pale and diaphoretic and complain of lightheadedness, sweatiness, nausea, and tunnel vision. Myoclonic jerks may accompany vasovagal syncope and may be clinically indistinguishable from seizure activity. If a patient exhibits signs of a vasovagal reaction during an interventional pain treatment procedure, the procedure should be halted, and the patient should be placed supine if not already in that position. Care should be taken to ensure that the patient will not fall and sustain a secondary injury. Randomized trials have demonstrated that leg crossing, and isometric arm exercises can help prevent progression to vasovagal syncope.[38] Most cases of vasovagal syncope will resolve spontaneously and will require only conservative measures. In the event that blood pressure and heart rate continue to decline, an intravenous line should be placed, crystalloids and oxygen administered, the patient should be placed on a cardiac monitor and a vasopressor, such as ephedrine (in 5–10 mg increments) or a chronotrope such as atropine (0.4–1 mg) should be administered.[29]

COMPLICATIONS ASSOCIATED WITH INTRATHECAL DRUG DELIVERY

When drugs are delivered via the intrathecal route, complications may arise either due to withdrawal or due to administration of an excessive dose. In the case of intrathecal baclofen administration, withdrawal may be particularly severe and can even be fatal. Baclofen is an analogue of the inhibitory neurotransmitter gamma-aminobutyric acid. It acts as an agonist of the GABA-b receptors in the brain stem, dorsal horn of the spinal cord, and other CNS regions. Although the mechanism of intrathecal baclofen withdrawal is not established, it may be due to diffuse disinhibition of GABA-b modulated pathways.[39] Although the most common manifestation of under dosage of baclofen is pruritus and return of the patient's spasticity, abrupt baclofen withdrawal may result in a life-threatening syndrome characterized by fever, tachycardia, labile blood pressure or hypotension, malaise, dysphoria, and hallucinations followed by coma, rebound spasticity more severe than the patient's baseline, hyperreflexia or rigidity, paresthesias, priapism in males, and seizures. If not treated adequately and promptly, the patient may develop rhabdomyolysis, brain injury, kidney and liver failure, and disseminated intravascular coagulation.[39,40] In some cases, death ensues.[41] The differential diagnosis of intrathecal baclofen withdrawal includes infection, neuroleptic malignant syndrome, serotonin syndrome, malignant hyperthermia, and autonomic dysreflexia. Paradoxically, the diagnosis may be more difficult to make in more severe cases of withdrawal. Symptoms of intrathecal baclofen withdrawal typically present 1 to 3 days after interruption of baclofen delivery. Interruption of baclofen delivery may be due to an exhausted drug reservoir after missing a scheduled refill, mechanical pump malfunction, catheter kinking or disruption, or mistakes in drug formulation or pump programming. Restoration of adequate intrathecal baclofen delivery by addressing pump problems or by lumbar puncture or drain represents the most definitive therapy.[42] If the pump catheter remains intact, intrathecal baclofen may be administered via the side port. Evaluation of the pump

should be performed with the manufacturer's interrogation device. If interrogation of the pump does not reveal the underlying problem, a catheter dye study should be undertaken and the pump should be refilled with medication at the correct concentration. To conduct a catheter dye study, radiographic contrast is administered through the side port of the infusion device to assess the integrity and position of the intrathecal catheter. Oral and enteral baclofen administration (up to 120 mg per day of baclofen in six to eight divided doses in adults), accompanied by intravenous benzodiazepine administration should be undertaken until intrathecal baclofen delivery is restored or if this cannot be accomplished. Oral and enteral baclofen alone are often insufficient to treat withdrawal from intrathecal baclofen. Continuous or intermittent infusions of diazepam or midazolam may be rapidly titrated upward until muscle relaxation, cessation of seizure activity, and normal blood pressure and temperature are restored. Propofol infusion and chemical paralytic agents may also be used in the intubated patient.[43] The patient should be treated in a setting where critical care monitoring and ventilator and cardiovascular support is available. In some cases, patients with hyperthermia have been treated with dantrolene. In case reports, cyproheptadine has proven helpful.[39,44]

In contrast, baclofen overdose typically presents with somnolence, comas, seizures, respiratory depression, hypotonia, and arrhythmias. Treatment consists of intubation and artificial ventilation as indicated, and immediately turning off the pump with the manufacturer's programmer or, if this is not available, emptying the pump reservoir. In cases where the overdose is detected within the first few hours, withdrawal of 30 to 40 cc of CSF via the catheter access port of the pump may reverse the overdose.[45] Physostigmine may reverse drowsiness and respiratory depression (adult dose one to 2 mg IV over 5 to 10 minutes, may repeat every 10 to 30 minutes as required; pediatric dose 0.02 mg per kilogram IV, less than 0.5 mg per minute, may repeat every 5 to 10 minutes as required up to 2 mg maximum).

Opioid Withdrawal

Opioid withdrawal can also occur in patients receiving intrathecal drug delivery or systemic opioids, and typically manifests with anxiety, insomnia, yawning, diaphoresis, lacrimation, rhinorrhea, mydriasis, myalgias, piloerection, nausea, vomiting, diarrhea, and abdominal cramping.[46,47] In patients for whom ongoing opioid therapy is indicated, treatment consists of resuming opioid therapy. In some cases an alternate route of administration may be necessary, such as intravenous and/or transdermal delivery for a patient who is no longer able to take oral medications. In cases where opioid therapy is not indicated, symptoms of opioid withdrawal may be mitigated with alpha-2 adrenergic agonists such as clonidine (0.1 to 0.2 mg per dose increasing to a maximum of 1 mg per day) or lofexidine (0.4 to 0.6 mg per dose increasing to a maximum of 2 mg per day). Alpha-2 adrenergic agonists may cause hypotension, fatigue, lethargy, and dry mouth. Nausea and vomiting may be treated with intravenous fluids and antiemetics such as metoclopramide or prochlorperazine. Diarrhea and colicky abdominal pain may be treated with loperamide or hyoscine butylbromide.[47] Agitation may be treated with benzodiazepines.

ANAPHYLAXIS

At the turn of the 19th century, Charles Richet and Paul Portier coined the term anaphylaxis when they observed that several dogs died following repeat challenges with Physalia extracts during experiments that they reported while guests on Prince Albert of Monaco's yacht in the Mediterranean Sea.[48] In an anaphylactic reaction, the inciting allergen binds to previously formed immunoglobulin E (IgE) on the surface of previously sensitized mast cells and basophils. These cells release mediators such as histamine, leukotrienes, prostaglandins, bradykinins, and thromboxanes that cause markedly reduced vascular tone, increased mucous membrane secretions, and increased capillary permeability.[49] Generalized hypersensitivity reactions may be divided into grade 1 or mild reactions, grade 2 or moderate reactions, and grade 3 or severe reactions.[50] Grades two and three correspond with anaphylaxis. Grade one reactions are defined by generalized erythema, urticaria, periorbital edema, or angioedema. Grade two reactions are characterized by dyspnea, stridor, wheezing, nausea and vomiting, dizziness or presyncope, chest or throat tightness, or abdominal pain. Grade 3 reactions are defined by cyanosis or an oxygen saturation less than or equal to 92%, hypotension, confusion, collapse, loss of consciousness, or incontinence. Cutaneous manifestations such as erythema, itch, and urticaria are present in almost all cases, although they may be quite subtle. Therefore, when the diagnosis is unclear, it is crucial to fully undress the patient and carefully examine the skin. In one retrospective study of 1149 cases of generalized hypersensitivity treated in the emergency department, 250 cases were assessed as being due to medications; 145 cases were believed to be due to antibiotics, with the majority being beta-lactam antibiotics. Nonsteroidal antiinflammatory drugs were implicated in 32 cases, narcotics in 11 cases, radiologic contrast in 7 cases, ace inhibitors in 4 cases, vaccines in 4 cases, and other or unclear medications in 47 cases.[50] The median interval between drug administration and fatal collapse is 5 minutes.[51] The differential diagnosis of anaphylactic reaction includes asthma attack, Scombroid poisoning, angioedema either secondary to angiotensin-converting enzyme inhibitors or hereditary, panic attack, and vasovagal syncope (these last two conditions do not cause urticaria, angioedema, or bronchospasm).

There are no randomized trials of therapies for anaphylaxis, so most treatment recommendations are on the basis of consensus. The patient undergoing an anaphylactic reaction should be administered high flow oxygen. Intramuscular epinephrine should be given early to all patients with signs of a systemic reaction such as hypotension, airway edema, or dyspnea (0.3 to 0.5 mg, 1:1000, IM repeated every 15 to 20 minutes if there is no clinical improvement). If anaphylaxis appears to be severe and or imminently life threatening, intravenous epinephrine should be given (0.1 mg, 1:10,000, IV over 5 minutes, followed by an IV infusion of 1 to 4 mcg per minute as needed). Patients receiving epinephrine for anaphylaxis should be monitored in an emergency department or intensive care unit. Aggressive fluid resuscitation with isotonic crystalloids such as normal saline should be undertaken.[52] One to two liters should be rapidly infused. Antihistamines such as diphenhydramine should be given (25–50 mg slowly IV or IM) as well as H2 blockers (e.g., cimetidine 300 mg IM or IV). Bronchospasm should be treated with inhaled beta-adrenergic agents such as albuterol. High-dose intravenous corticosteroids should be administered early, although their therapeutic effects are seen 4 to 6 hours after administration. Other therapies which may be considered in anaphylaxis include vasopressin, which has been beneficial in case reports for severely hypotensive patients, atropine in the setting of severe bradycardia, and glucagon for patients who are unresponsive epinephrine, particularly if they are taking beta-blockers.[49] Pumphrey, who attempted to identify and analyze every fatal anaphylactic reaction in the United Kingdom since 1992, stresses the importance of keeping patients supine with their legs elevated.[51]

Catastrophic Neural Injuries and the Administration of Particulate Steroids

In the cervical spine, the carotid and vertebral arteries lie in close proximity to the stellate ganglion, the cervical facet joints, and

the cervical intervertebral foramina. The anterior spinal artery provides the principal vascular supply to the spinal cord. The anterior spinal artery arises rostrally from the vertebral arteries and receives input from 6 to 9 radicular arteries. It is located at the anterior central sulcus and supplies the anterior two thirds of the spinal cord. The posterior spinal arteries supply the posterior one third of the spinal cord. They are paired and run just medial to the dorsal roots. The arteria radicularis magna (the artery of Adamkiewicz) is the largest of the radicular arteries. It is most commonly located at T10 on the left side, but may occur anywhere from T8 to L2 and occurs on the right in 17% of subjects.[53] In addition, the ascending cervical artery and the deep cervical artery each furnish spinal branches that enter the intervertebral foramina. These spinal branches supply the vertebral column but also give rise to radicular arteries that accompany the dorsal and ventral roots of the spinal nerves (Fig. 110.6). In some individuals, the radicular arteries are substantial in size and reinforce the anterior spinal artery. Such reinforcing arteries can occur at any cervical level and those radicular arteries that supply the spinal cord are termed spinal medullary arteries. If reinforcing radicular arteries are compromised by a transforaminal injection, infarction of the cervical spinal cord could ensue. If the vertebral or carotid arteries are entered, infarction of the brain stem and portions of the brain supplied by the posterior circulation may ensue, causing stroke, often massive stroke resulting in death.

The first report of a complication attributed to cervical transforaminal injection of steroids described a patient who died from a spinal cord infarction.[10] The location of the infarction implied that a radicular artery that reinforced the anterior spinal artery had been compromised, but no evidence was offered about the mechanism by which the artery had been compromised. Images of the placement of the needle were not published.

Reports of spinal cord infarction following cervical[54,55] or lumbar[56,57] transforaminal injection of steroid have appeared, and this topic has been reviewed in detail.[58] Vertebral artery injection with subsequent stroke involving the posterior circulation has also been reported.[59] A similar case of massive infarction involving the posterior cerebral circulation following injection of particulate steroid during attempted intraarticular atlantoaxial joint injection is shown in Figure 110.7.

The exact mechanism of spinal cord injury following transforaminal injections has not been determined. As analyzed using MRI, the pattern of injury strongly implicates a reinforcing radicular artery. Spasm of the artery would seem to be an unlikely mechanism since it is inconsistent with the vasodilatory effect of local anesthetic agents when applied to arterial walls. Embolism

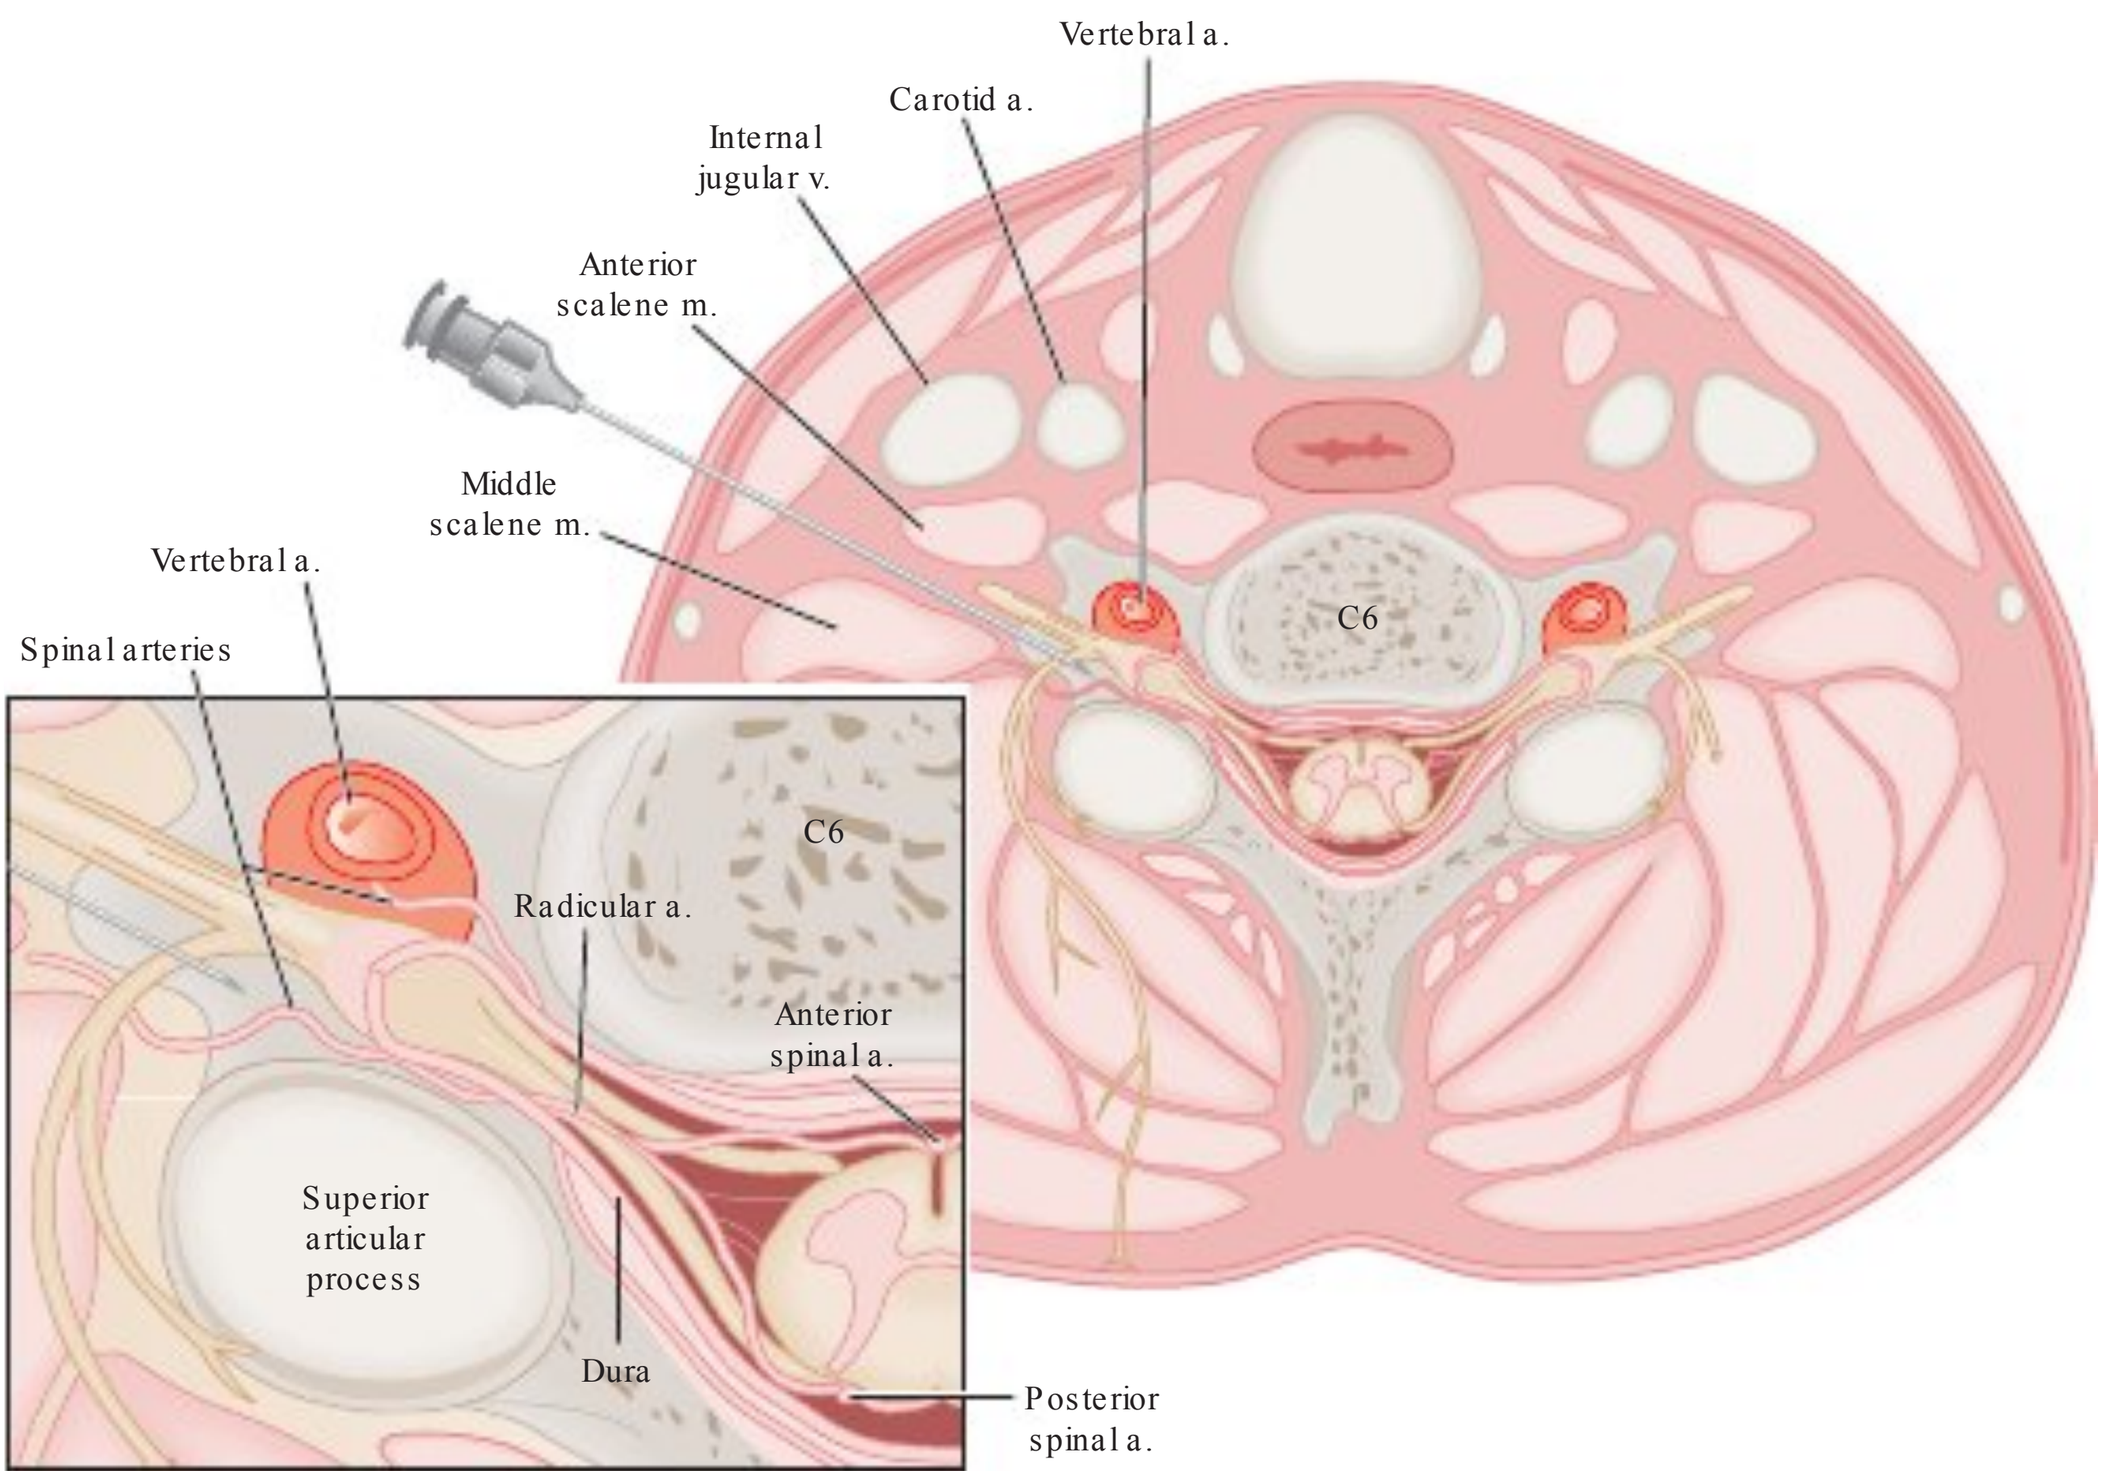

FIGURE 110.6 Axial view of cervical transforaminal injection at the level of C6. The needle has been inserted along the axis of the foramen, and is in final position against the posterior aspect of the intervertebral foramen. Insertion along this axis places the needle behind the spinal nerve, and behind the vertebral artery, which lies anterior to the foramen. *Inset*: A spinal artery arises from the vertebral artery. It supplies the vertebral column. Another spinal artery enters the intervertebral foramen from the ascending cervical artery or deep cervical artery. It furnishes radicular branches that accompany the nerve roots and ultimately reach the anterior and posterior spinal arteries of the spinal cord. (Redrawn after Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. Philadelphia: Lippincott Williams & Wilkins, 2005.)

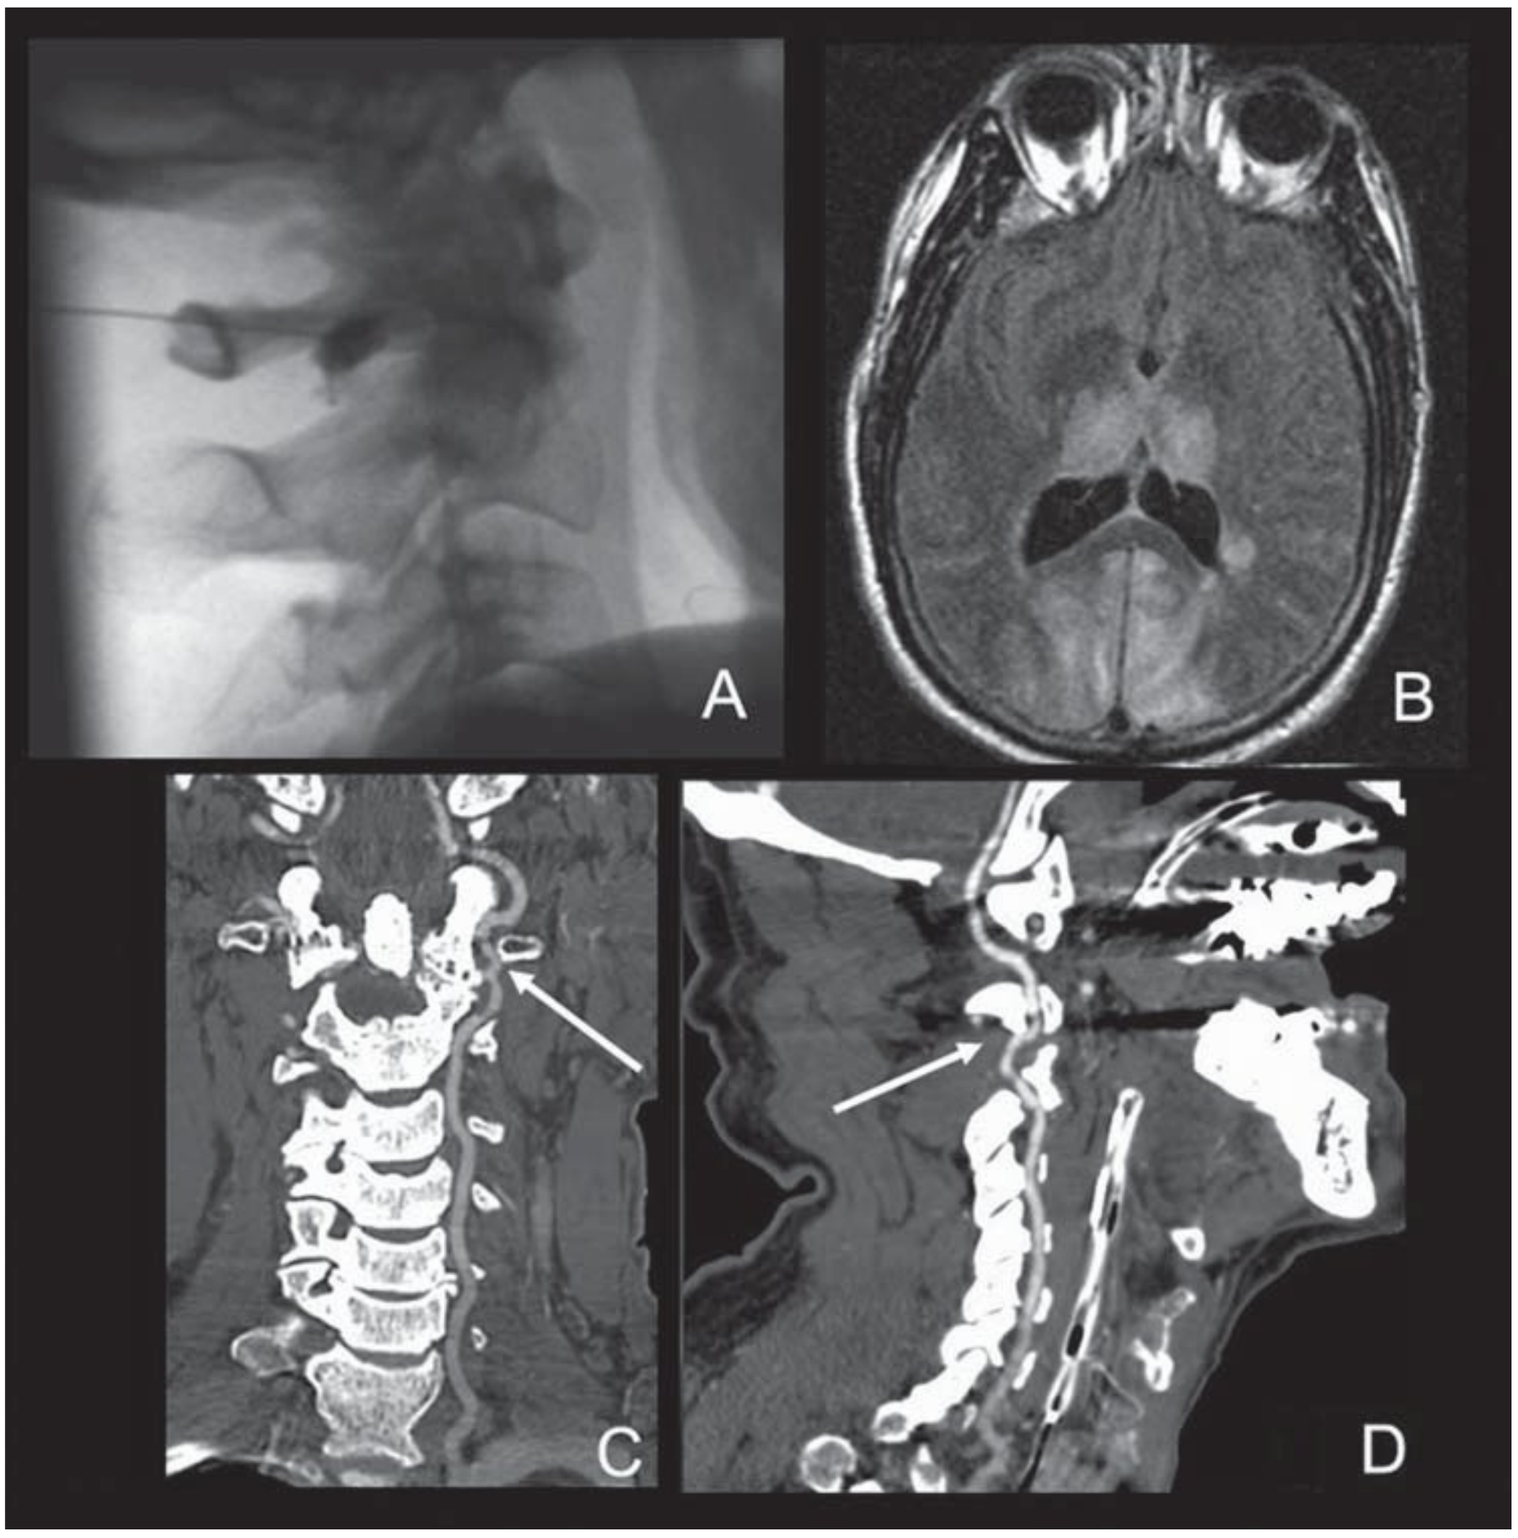

FIGURE 110.7 Cerebrovascular accident following intraarterial injection of particulate steroid during attempted intraarticular atlantoaxial (C1/2) joint injection. **(A)** Lateral fluoroscopy imaging demonstrating needle position adjacent to the C1/2 facet joint. **(B)** Axial MRI (T1 FLAIR sequence) of the brain. **(C)** Frontal and **(D)** axial CT angiography of the vertebral arteries; *arrows* point to a small filling defect within the left vertebral artery adjacent to the left C1/2 facet joint, suggesting the point of needle entry in to the vertebral artery. The proximity of the vertebral artery to the C1/2 facet joint is immediately apparent from the images.

of particulate steroids ranks as the leading hypothesis, but direct evidence is still lacking. In cases involving the vertebral artery, a similar uncertainty remains. The injection of contrast medium cannot be an explanation; in the past, direct puncture of the vertebral artery has been used for angiography. Steroid embolism remains the most likely explanation.

The guidelines for the conduct of cervical transforaminal injections[58] are designed to guard against these complications. These guidelines stipulate that the needle must be accurately and correctly placed. Once the needle has been placed, a test dose of contrast medium should be injected and its flow carefully monitored during injection. That injection tests two things. First, under normal circumstances, it should show that the injectate is correctly flowing around the target nerve and into the lateral epidural space. Simultaneously, but more critically, it shows if intravascular injection occurs.

Neurologic complications of transforaminal injections are typically catastrophic. They are clinically obvious upon the onset of spinal weakness and numbness. Spinal cord infarction due to embolization of a radicular artery is clinically indistinguishable from the anterior spinal artery syndrome, also known as Beck's syndrome. Patients develop abrupt onset of weakness below the level of the infarction, flaccid paralysis, areflexia, loss of pain and temperature perception, and atonic urinary bladder. Position and vibratory sensation will typically be relatively intact. Preserved proprioception at symptom onset has been associated with better outcomes.[60] In contrast to cerebrovascular infarction, spinal cord infarction is frequently painful. Patients may experience a radicular or back pain and, in some cases, spinal cord infarction will mimic angina pectoris.[61] Later in the clinical course, the patient may develop spasticity, hyperreflexia, Babinski responses, and clonus.[53] In the setting of possible acute spinal cord infarction, the differential diagnosis may include spinal cord compression by a mass lesion such as a spinal epidural or subdural hematoma or abscess, or a herniated nucleus pulposus. When spinal cord infarction is suspected, emergent MRI of the spinal cord should be undertaken to rule out the presence of any space occupying lesion that may be amenable to surgical decompression. When spinal cord infarction is present, sagittal T2-weighted MRI scanning performed at least 4 hours after symptom onset commonly reveals "pencil-like" hyper intensities and cord enlargement. Diffusion weighted imaging is particularly sensitive for detecting ischemic changes in the spinal cord.[62] Common diagnostic pitfalls include failure to image higher levels of the spinal cord when the patient develops a sensory level that is caudad to the infarction.

There is no emergency management known to reverse spinal cord infarction. Many of the principles guiding treatment of acute spinal cord infarction are derived from experience treating ischemic cerebrovascular accidents. Initially, emphasis should be placed on reducing the likelihood of secondary injury to the spinal cord by preventing hypotension and/or hypoxia. In addition, rapid triage and transport to a definitive care facility with appropriate imaging, critical care, and surgical capabilities should be undertaken. In the case of ischemic cerebrovascular accidents, induced hypertension to achieve a mean arterial pressure of 20% to 30% above baseline or to achieve a predefined target mean arterial pressure has been advocated although this therapy remains controversial.[63] Although aspirin has been advocated for the treatment of spinal cord infarction related to atherosclerotic

disease or dissection, principally on the basis of its use in the treatment of ischemic stroke, there does not appear to be a role for antiplatelet or anticoagulant therapy in the treatment of spinal cord infarction presumed secondary to embolization of particulate steroids. In a prospective study of 77 patients with acute neurologic deficits secondary to spinal cord injuries, patients treated with 7 days of volume resuscitation with crystalloids, transfusion of blood products to maintain a hematocrit greater than 32, as well as dopamine and Levophed as needed to maintain a mean arterial blood pressure greater than 85 mm Hg had better neurologic outcomes than historical controls.[64] This therapy has not been studied in prospective randomized controlled trials. Treatment of nonpenetrating acute spinal cord injury with methyl prednisolone remains controversial despite evaluation in three large, prospective randomized double blind controlled trials.[65–67] At the current time, there is insufficient evidence to advocate routine administration of methylprednisolone to patients with acute spinal cord infarction. Standard measures to prevent complications of acute paraplegia should be implemented, including measures directed at prevention of deep venous thrombosis and pulmonary embolus, as well as bladder catheterization if indicated. Early consultation with physiatrists should be undertaken in order to optimize functional recovery and prevent development of spasticity and decubiti.

CONCLUSION

Although emergencies in the pain clinic are quite rare, when they do occur they can be catastrophic and even deadly. The pain specialist should be familiar with the most common complications and their mechanisms, as well as techniques that can be used to reduce the risk of said complications. Familiarity with common complications, including their clinical presentations and natural histories, will facilitate prompt recognition and treatment, thereby improving the chances of good outcomes. Pain specialists should educate patients about specific signs and symptoms of complications that may ensue from their treatment and provide them with clear instructions for reaching members of the pain clinic staff in a timely manner, both during clinic hours and on evenings and weekends, in order to achieve prompt identification and treatment of complications when they arise.

CHAPTER 111 ■ PAIN MANAGEMENT IN THE EMERGENCY DEPARTMENT

KNOX H. TODD AND JAMES R. MINER

INTRODUCTION

The specialties of both emergency medicine and pain medicine are relatively new members of the modern house of medicine. The first academic department of emergency medicine was established in 1971 and the American Board of Medical Specialties recognized emergency medicine as a distinct specialty by conferring primary board status only 20 years ago. The numbers of visits to U.S. emergency departments (EDs) have increased markedly over the past decade. From 1995 to 2005, annual ED visit volumes increased from 96.5 million to 115.3 million, a 20% increase. During this time, the total number of EDs actually decreased from 4176 to 3795, thus the annual volume for an average-sized ED increased by more than 30%.[1] More than 25,000 emergency physicians are represented by the American College of Emergency Physicians, our specialty's largest physician support organization.

EDs provide care for patients with an extraordinarily broad range of illnesses and injuries associated with both acute and chronic pain. It is commonly believed that injury and trauma are responsible for the majority of ED visits associated with pain; however, this impression is misleading. In a recent multicenter study of adults presenting to EDs in the United States and Canada with moderate to severe pain, two-thirds of presentations resulted from medical, rather than traumatic, conditions.[2] Major categories of discharge diagnoses reported in this study appear in Figure 111.1.

In the United States, the ED serves as a safety net for our fragmented health care system. Pain is but one of many conditions for which emergency physicians treat not only acute clinical presentations, but also care for those with chronic or recurrent painful conditions who are unable to access other parts of the health care system. Emergency physicians also frequently cause pain in the course of performing emergent diagnostic and therapeutic procedures.

This chapter discusses the prevalence of acute and chronic pain in the ED, its assessment, barriers to adequate pain treatment, the influence of substance abuse disorders and aberrant drug-related behaviors on ED pain practices, as well as a variety of commonly employed pain treatment and procedural sedation modalities. Space limits prohibit a discussion of the wide variety of specific painful conditions that present to the ED.

THE PREVALENCE OF PAIN IN THE EMERGENCY DEPARTMENT

Pain is the most frequent reason for seeking ED treatment, and as a presenting complaint, pain accounts for over 70% of visits to U.S. EDs.[3–5] Several single-site ED studies have attempted to define the prevalence of pain more precisely. Over a single week, Johnston et al.[3] conducted a prospective study to determine the incidence and severity of pain among patients presenting to non-

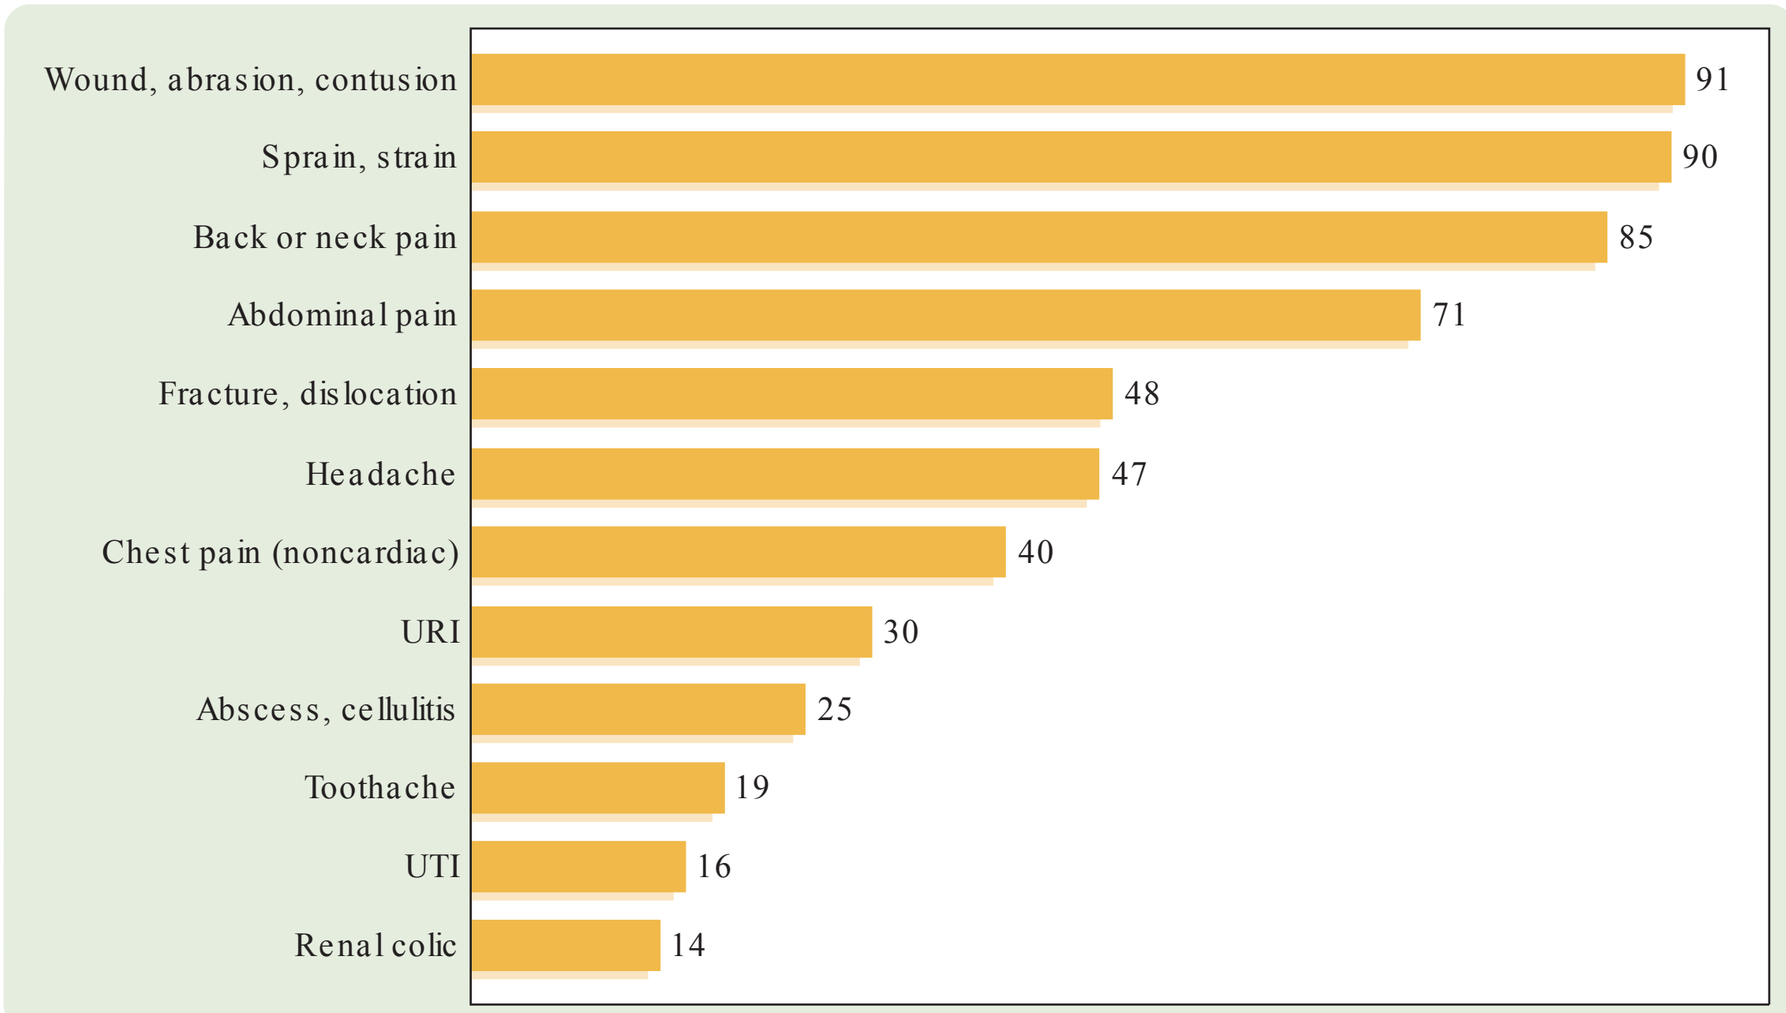

FIGURE 111.1 Major categories of discharge diagnoses among patients presenting to the ED with moderate to severe pain. Note: Other diagnoses present for 243 patients. (Redrawn after Todd KH, Ducharme J, Choiniere M, et al. Pain in the emergency department: results of the Pain and Emergency Medicine Initiative [PEMI] Multicenter Study. *J Pain* 2007;8[6]:460–466.)

critical treatment areas within the EDs of two urban hospitals in Canada. Fifty-eight percent of adults and forty-seven percent of children reported pain on ED arrival. For approximately one-half of both groups reporting pain, the intensity of this pain was considered moderate to severe. At the time of discharge, one-third of both groups continued to experience pain of moderate to severe intensity. In fact, 11% of children and adults in this study actually reported clinically important increases in pain intensity during the ED stay.

A second prospective study, conducted by Tanabe and Buschmann,[4] found that among adults treated at one Chicago ED, 78% presented with a chief complaint related to pain. Of these patients, only 47% received analgesics. For patients receiving analgesics, an average of 74 minutes elapsed from the time of arrival to the time of treatment. Only 15% of patients were treated with opioids, despite high levels of pain intensity. Interestingly, 16% of patients with pain in this study indicated that they would have refused analgesics had they been offered. The principal reported reason for their refusal was the fear of addiction resulting from opioid exposure, even when opioids were indicated for the treatment of pain.

In 2002, Cordell et al.[5] reported an analysis of secondary data from an urban, tertiary-care ED using explicit data abstraction rules to determine the prevalence of pain and to assign painful conditions into standard categories. With inclusion of all age groups, they found evidence of pain in 61% of patients. Pain was the chief complaint for 52% of patient visits. After excluding patients less than 5 years of age for whom chart reviews are obviously less reliable, almost 70% of patient encounters involved pain complaints.

While the high prevalence of pain among ED patients is well-documented, the underlying conditions responsible for pain in this population are less well characterized. In Cordell's[5] retrospective study, 11% of patients presenting to the ED were judged to be suffering from pain that was chronic in nature. In a recent prospective multicenter study conducted in the United States and Canada, 44% of ultimately discharged patients presenting to the ED with pain reported underlying chronic pain syndromes.[2] In one-half of these cases, the ED visit was prompted by an exacerbation of this chronic pain condition. Importantly, patients with chronic pain reported three to four times the number of annual physician visits when compared to those without chronic pain. Median and mean durations of symptoms for those reporting chronic pain syndromes were 24 and 52 months, respectively. For physicians who view themselves as experts in the management of acute medical and surgical emergencies, chronic pain may represent a less familiar condition with which to contend.

EDs frequently treat patients with chronic or recurrent pain who are often frustrated by a lack of information about ongoing pain management and poor access to specialty-level care. In 2007, we used random digit dial survey methods to interview 500 U.S. adults with chronic or recurrent pain and an ED visit within the past 2 years.[6] Sixty percent were female, their median age was 54, two-thirds were under the care of a physician, and only 14% were uninsured. They reported an average of 4.2 ED visits within the past 2 years. Relatively large proportions reported pain relief during the ED visit and 57% endorsed that "the ED staff understood how to treat my pain" as "definitely true." Although over three-fourths of patients felt receiving that additional information on pain management (82%) or referrals to specialists (74%) was "extremely" or "very" important, only one-half reported receiving such referrals (46%) or information (55%). A significant minority (11%) reported that the "ED staff made me feel like I was just seeking drugs." The majority (55%) were "very" or "completely" satisfied with their medical treatment, while 24% were "neutral" to "completely" dissatisfied. In multivariate models, greater age, male gender, higher level of education, shorter waiting time, use of imaging, and pain relief contributed to patient satisfaction with ED care.

Findings from this survey provide a more precise estimate of the prevalence of ED use associated with chronic and recurrent pain in the United States. The final survey incidence rate of adults reporting a recent ED visit for chronic or recurrent pain was 15% of all those reached by phone. Given the U.S. adult population of approximately 225 million, this survey incidence rate suggests

that 34 million adults meet our criteria of an ED visit within the past 2 years for chronic or recurrent pain. Within this population, approximately 43%, or 15 million people, experience recurrent pain, while 57%, or 19 million people, have underlying chronic pain syndromes.[6]

THE ASSESSMENT OF PAIN IN THE EMERGENCY DEPARTMENT

Pain is inherently subjective and inevitably complex. Patients experience pain and suffering as individuals; clinicians assess it only indirectly. The emergency provider's task is to use a commonly understood vocabulary and classification system in assessing pain so that our findings can be communicated consistently. Only by quantifying the pain experience in meaningful ways can we move beyond practices that are influenced by myth and opinion toward a scientific approach to our many questions regarding the pain experience. This challenge is at the root of our difficulties in treating pain and not only in the ED setting, thus issues surrounding pain assessment should have primacy in our attempts to understand our patients' pain experiences.

EDs employ a number of practical unidimensional pain assessment tools. Viewing pain as the "fifth vital sign," as encouraged by The Joint Commission on Accreditation of Health Care Organizations, has fostered the widespread use of such tools. For those without cognitive impairment, pain intensity is routinely assessed with either an 11-point numerical rating scale (NRS) or a graphical rating scale (GRS). The NRS is sensitive to the short-term changes in pain intensity associated with emergency care and is the most commonly employed pain assessment instrument.[7,8] GRS or picture scales are particularly useful for populations with limited literacy, including children.[9,10] The visual analog scale (VAS) is used by some EDs; however, this instrument is more commonly employed in research settings. There is no demonstrated advantage in using a VAS over a NRS in the ED setting; both are reliable and valid measures of pain intensity.[11] In fact, certain patient populations find the NRS easier to complete; therefore, it is preferred over the VAS for routine use.[7,12]

Among nonverbal patients, including infants or those with cognitive impairment and dementia, a number of observational pain scales are available for use. Both the Face, Legs, Activity, Cry, and Consolability observational scale for use in very young children, and the Pain Assessment in Advanced Dementia scale for use in the setting of advanced dementia are used with some frequency in the ED; however, adequate observational pain assessments are less the exception than the rule.[13,14]

No matter the specific pain scale used, assessments should be repeated after therapeutic interventions and at the time of ED discharge. One multicenter study found that relatively few ED patients are reassessed after an initial pain score, reporting that fewer than one-third of ED patients presenting with moderate to severe pain had repeat pain assessments while in the ED.[2] Despite efforts to promote pain intensity as an outcome measure with which to judge the quality of ED pain practice, the finding that pain intensity is measured only once in most EDs may mirrors medicine's traditional view of pain as a diagnostic indicator rather than an outcome deserving of attention in its own right.

OLIGOANALGESIA IN THE EMERGENCY DEPARTMENT

Notwithstanding the clinician's duty to provide compassionate care, pain that is not acknowledged and managed appropriately causes anxiety, depression, sleep disturbances, increased oxygen demands with the potential for end-organ ischemia, and decreased movement with an increased risk of venous thrombosis.[15,16] Failure to recognize and treat pain may also result in dissatisfaction with medical care, hostility toward the physician, unscheduled returns to the ED, delayed complete return to full function, and, potentially, an increased risk of litigation.[17] Although adequate analgesia in the ED would appear to be an important goal of treatment, the underuse of analgesics, termed "oligoanalgesia" by Wilson and Pendleton[18] in 1989, occurs in a large proportion of ED patients.[18–23] A variety of factors are felt to give rise to pain undertreatment and these are listed in Table 111.1.

TABLE 111.1

FACTORS CONTRIBUTING TO EMERGENCY DEPARTMENT OLIGOANALGESIA

1. Lack of educational emphasis on pain management
2. Inadequate ED quality improvement systems
3. Lack of ED pain research, particularly among geriatric and pediatric populations
4. Emergency providers' concerns regarding opioid addiction and abuse
5. Fear of opioid adverse effects
6. Racial and ethnic bias

Emergency medicine investigators have identified a number of risk factors for oligoanalgesia in this setting. As in other settings, the very young or old tend to receive less intensive treatment for pain in ED.[24–26] Studies have documented oligoanalgesia and delays to analgesic administration among those of minority ethnicity for a variety of painful conditions, even when objective evidence for the presence of pain is obvious (e.g., long-bone fractures).[27–30] Although patients' expectations for pain treatment and perceptions of pain intensity do not differ by ethnic groups, when patients are matched for socioeconomic factors, differences have been noted in the manner in which patients of different cultural backgrounds express their pain.[31–33] Differences in the interactions of physicians and patients of different ethnic groups have been described, and subtle differences within these interactions may affect the physician's pain assessment.[34,35] When affect, actual patient-physician interaction, and cultural expressions of ethnicity are removed from a case presentation, such as through written clinical vignettes, patients with similar pain tend to be similarly treated by physicians.[36] Cultural discordance between the patient and the physician may hinder the ability of patients to confer an understanding of their pain to the physician.

Of course, any treatment of pain is dependent on the physician's accurate assessment of the patient's pain. In fact, the only predictor of treatment that Bartfield and colleagues[37] found for ED patients with back pain was the physician's assessment, regardless of the patients' ethnicity, age, or insurance status. Disparities in the treatment of pain are more likely to result from variations in physicians' assessment of pain intensity than variations in treatment among patients judged to have similar degrees of pain.

Although emergency physicians may be reluctant to accept patient report as the most reliable indicator of pain, and disparities between patient's and physician's pain intensity ratings may lead to inadequately treated pain, even patients themselves may be reluctant to report the presence of pain and its intensity. This may be due to low expectations of obtaining pain relief, fear of analgesic side effects, and perhaps the notion that pain is to be expected as part of an underlying disease or from medical treatments. Some patients exhibit an inappropriate fear of addiction when prescribed opioids or fear the stigma associated with opioid use, even in the short term.

PAIN AND OPIOID ABUSE IN THE EMERGENCY DEPARTMENT

ED personnel commonly identify patients who they feel are attempting to obtain opioids for illegitimate purposes. Although drug addiction occurs in all patient populations, it is likely that the ED sees a higher proportion of such patients than a typical office-based practice. Unfortunately, the true prevalence of addiction and aberrant drug seeking behaviors in the ED is unknown and difficult to measure. When the prevalence of such problems is overestimated, oligoanalgesia is the predictable result.

DEFINITIONS

In discussing issues of chemical dependency and aberrant behaviors related to opioid use, a valid system of nomenclature is necessary for clear communication and measurement. Historically, the meaning of different terms has changed, particularly in light of the increased use of chronic opioid therapy for malignant and nonmalignant chronic pain conditions. In treating pain in this population of patients with chronic opioids, confusion over the concepts of physical dependence, tolerance, addiction, and pseudoaddiction may constitute a barrier to understanding and to appropriate treatment. These phenomena are discrete, and standard definitions may be helpful in caring for such patients. Currently accepted definitions of these terms are as follows[38]: *Addiction* is a primary, chronic, neurobiologic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving. *Physical dependence* is a state of adaptation that often includes tolerance and is manifested by a drug class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist. *Tolerance* is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time. *Pseudoaddiction* is a term which has been used to describe patient behaviors that may occur when pain is undertreated. Patients with unrelieved pain may become focused on obtaining medications, may "clock watch," and may otherwise seem inappropriately "drug seeking." Even such behaviors as illicit drug use and deception can occur in the patient's efforts to obtain relief. Pseudoaddiction can be distinguished from true addiction in that the behaviors resolve when pain is effectively treated.

The term, "substance abuse" is particularly problematic and resistant to precise definition. The American Psychiatric Association has defined substance abuse as a maladaptive pattern of drug use associated with some manifest harm to the user or others.[39] Other groups using consensus methodology have defined abuse as any use considered to be outside of socially accepted norms.[40] Determining the bounds of "socially accepted norms" within the broad range of social strata treated within any ED is a difficult task. Physicians may believe that they "know abuse when they see it," and its identification may be influenced by subjective judgments that may or may not correspond to socially accepted norms for the index patient's particular social group. Often the term, "substance misuse" is applied to behaviors that are not perceived as particularly extreme (e.g., taking opioid analgesics to relieve symptoms other than pain such as anxiety or boredom).

The difficulty in determining whether a given set of behaviors fall within accepted definitions of substance use, misuse, or abuse has important implications outside the clinical realm. Physicians may prescribe controlled substances for the treatment of pain while patients may use these drugs to treat a broad range of symptoms with varying degrees of relatedness to underlying pain syndromes and may, in fact, use drugs in a manner totally unrelated to the physicians' intent (i.e., to obtain euphoric, rather than analgesic, effects). Given the unclear distinctions between use, misuse, and abuse, and a regulatory climate in which practitioners prescribing patterns are increasingly scrutinized, emergency physicians are understandably reluctant to prescribe controlled substances to patients with whom they expect to have only a transitory relationship.

Using any definition, substance abuse is a highly prevalent problem. The National Survey on Drug Use and Health (formerly the National Household Survey on Drug Abuse) reports that in 2003, an estimated 19.5 million Americans, or 8.2%, of the population aged 12 or older, used an illicit drug during the month prior to the survey interview. Illicit drugs included marijuana, cocaine, heroin, hallucinogens, inhalants, and nonmedical use of prescription-type pain relievers, tranquilizers, stimulants, and sedatives.[41] Importantly, the survey documents an increase in the lifetime reported nonmedical use of pain relievers between 2002 and 2003, from 29.6 million to 31.2 million persons. To be considered nonmedical use, the respondent had to take drugs not prescribed for them or take them only for the "experience or feeling" they caused. Specific analgesics showing statistically significant increases in lifetime use were (in order by magnitude): Vicodin, Lortab, or Lorcet (combination analgesics containing hydrocodone); Percocet, Percodan, or Tylox (combination analgesics containing oxycodone); hydrocodone; OxyContin (extended-release oxycodone); methadone; and tramadol.

In contrast to the prominence of ED-based data collection systems in efforts to monitor deleterious outcomes associated with substance abuse, relatively few studies have systematically assessed substance abuse prevalence and treatment needs in the ED population. As an example, the Drug Abuse Warning Network is a federally financed, public health surveillance system that monitors drug-related ED visits and drug-related deaths investigated by medical examiners and coroners. This reporting system involves hundreds of hospital EDs throughout the United States and provides valuable data with which to monitor drug abuse trends. In contrast to this large monitoring research enterprise, relatively little focus has been given to use of the ED as a setting in which to intervene in substance abuse problems.

In 1997, Soderstrom et al.[42] assessed the prevalence of psychoactive substance use disorders in a large, unselected group of seriously injured patients treated in one Baltimore ED, using standardized diagnostic interviews and explicit criteria. Psychoactive substance use disorders were diagnosed using the Structured Clinical Interview, an instrument based on the Diagnostic and Statistical Manual of Mental Disorders.[43] Of 1118 patients consenting to the study, more than half had one or more lifetime abuse or dependence psychoactive substance use disorders, and 18% were currently considered dependent on drugs other than alcohol.

In 1996, Rockett et al.[44] used direct interviews to ascertain unmet substance abuse treatment needs in a statewide probability sample survey of adults presenting to seven Tennessee EDs. While only 1% of ED medical records indicated a diagnosis of alcohol or drug-related problems, as many as 27% of patients were determined by the researchers to need substance abuse treatment on the basis of explicitly defined case definitions. Less than 10% of patients that were ultimately determined to need substance abuse treatment in this study were actually receiving such care. Thirty-two percent of all patients in this study had a positive saliva or urine assay for psychoactive drugs and 9% screened positive for opioid use. Unmet substance abuse treatment needs varied directly with the frequency of ED visits and inversely with patient age.

A subsequent study by Rockett et al.[45] examined the association between unmet substance abuse treatment needs in the ED and excess utilization of health services in order to estimate the health care costs savings that might result from effective ED-based substance abuse treatment interventions. The researchers estimated that pa-

tients with unmet substance abuse treatment needs accounted for an estimated 777 million dollars in extra hospital charges for Tennessee, or 1568 dollars per ED patient when compared to those without substance abuse treatment needs. They suggested that the costs of ED-based screening and intervention efforts targeted to substance abuse disorders would be more than offset by savings from decreased health care utilization and that these programs were likely to be highly cost-effective if implemented.

PAIN AND "DRUG-SEEKING BEHAVIOR" IN THE EMERGENCY DEPARTMENT

The preceding discussion makes clear the high prevalence of both pain and substance abuse disorders in the ED. Although acute and chronic pain is far more common than substance abuse disorders, it is inevitable that emergency physicians will frequently encounter patients presenting with both pain and substance abuse disorders. Professional discussions of pain treatment in the ED frequently center on concerns of being duped by such patients who fabricate painful symptoms in order to obtain opioids, so-called "drug-seeking behavior."[46] Drug-seeking behaviors may represent an entirely appropriate response by those with chronic pains who are routinely undertreated by the medical profession and for who comprehensive pain treatment centers are in short supply. Although the term drug seeking behavior is poorly defined, it is used in the emergency medicine literature and will be used with acknowledgement of its imprecision.

Only a limited amount of emergency medicine research has addressed this problematic issue. In 1990, Zechnich and Hedges[47] attempted to measure community-wide use of ED services by patients at high risk for drug seeking behavior. In this retrospective, observational study, patients were categorized as exhibiting drug seeking behavior if they sought care at a university hospital in Portland, Oregon, for a specific pain-related diagnosis (i.e., ureteral colic, toothache, back pain, abdominal pain, or headache) and were either independently identified on at least one other local hospital's "patient alert" list or suffered a drug-related death during the year in question. After identifying 33 such patients, they determined the frequency of their ED visits at each of seven local hospitals and conducted detailed chart reviews of their visits at three of these hospitals. The patients identified as drug seeking were generally young and one-half of drug seekers were female. The latter is a surprising finding given that substance abuse disorders are more than twice as common among males.[41] This suggests that drug seeking behaviors are exhibited (or identified) more commonly among female ED patients with substance abuse problems than among males. The 33 patients visited EDs, urgent care clinics, or were hospitalized a total of 379 times over the study period, for an average of 12.6 visits per person annually. Interestingly, although chart reviews identified 17 patients who were told that he or she "would receive no further narcotics" at a given facility, these patients subsequently received controlled substances from another hospital in 93% of cases and from even the same facility in 71%. The authors suggested that information sharing between hospitals could help to identify drug seeking patients and promote more consistent community-wide care and appropriate substance abuse interventions.

The maintenance of lists that include the names and medical information for patients frequently seen in the ED is thought to be a common practice. In a mail survey conducted in 1995, Graber et al.[48] described the use of what were referred to as "problem patient files" in the state of Iowa. Fifty-eight percent of ED medical directors acknowledged the use of such files and responded that the files were consulted an average of 2.6 times per week. Calls between EDs either seeking or responding to requests for information about patients listed in these files were estimated to occur 23 and 20 times per year respectively. Rarely were explicit policies established for limiting access to these files and information was added to the records in an informal fashion.[48]

In 2000, Pope et al.[49] from Vancouver described a case management program for frequent visitors to their inner-city tertiary care ED serving a large number of patients with multiple psychosocial problems, including substance abuse. Of 24 patients described in this study, 5 were said to exhibit drug seeking behavior, and 8 patients suffered from alcohol and drug abuse, personality disorders, and chronic pain. These 24 patients accounted for a staggering 616 visits annually (median 26.5 visits per year). After the implementation of individualized chronic care plans that included social work interventions at the time of the visits, ED use by this group of super-utilizers dropped to a median of 6.5 visits per person per year. In 2003, a publication by Geiderman discussed ethical, legal, and regulatory considerations surrounding the use of what were termed "habitual patient files."[50] The article acknowledged the common and informal use of such files, and set forth standards intended to promote the development of formal policies and procedures to govern their use. The author noted that such files have never been demonstrated to be effective in either reducing ED use by drug seeking patients or in altering care patterns and suggested the need for a research program to explore the impact of their use. Finally, the author called for a coordinated and comprehensive program of physician education to promote the identification and treatment of ED patients with substance abuse disorders.

PAIN AND SUBSTANCE ABUSE IN THE EMERGENCY DEPARTMENT: A BALANCED PERSPECTIVE

In managing pain, emergency physicians are responsible for beneficence as well as nonmaleficence. We must treat pain and ameliorate suffering while minimizing the extent to which our treatment strategies enable substance abuse by our patients. For the vast majority of patients presenting with a first episode of acute pain, whether from trauma, acute medical illness, or procedures performed in the ED, there is little danger of enabling substance abuse and a great deal of room for improvement in the quality of analgesic practices. For a small subset of ED patients, particularly for those presenting with chronic or recurrent pain syndromes, the physician may have legitimate concerns regarding an underlying substance abuse or related disorder. Our task is to balance the often unclear risk of fostering substance abuse, and even diversion, in this subset of patients with the well-known and well-documented risk of under treating painful conditions.

Certainly, the presence of an obvious painful condition (e.g., appendicitis, fracture) should preempt concerns about illegitimate drug-seeking behaviors. Given the high prevalence of chronic pain and the widespread unavailability of chronic pain management resources, particularly for populations served by the ED, pseudoaddiction is the most likely cause for a large proportion of drug-related behaviors deemed aberrant. In particular, patient reports of distress associated with unrelieved symptoms, aggressive complaining about the need for higher doses of analgesics, and unilateral dose escalation by the patient are suggestive of pseudoaddiction. Establishing the diagnosis of pseudoaddiction is particularly difficult if the patient has both pain and a comorbid substance use disorder; however, the two can coexist. The signature of pseudoaddiction is that aberrant behaviors disappear when adequate analgesics are given to control pain.

In dealing with complex chronic pain patients, the emergency physician practicing in isolation may exhibit symptoms of despair and direct his or her anger toward the patient with pain, resulting in more alienation of patients who may have already been abandoned by other sectors of the health care system. This is particularly likely to happen in communities without multidisciplinary

treatment centers for either substance abuse disorders or chronic pain and for those with inadequate health care insurance. Thus the patient with chronic pain joins the larger group of those with unmet health care needs that currently crowd our EDs. The hectic nature of emergency medicine practice often does not allow sufficient time for precisely characterizing patients with complex pain complaints and clinicians may lump legitimate pain behaviors with the ploys of those seeking opioids inappropriately. Both groups of patients may be ultimately mistrusted and treated with disdain.

Aside from considerations of pseudoaddiction, chronic pain is often accompanied by mood disorders and psychiatric comorbidities that complicate the management of these challenging patients.[15] The presence of aberrant drug-related behaviors in patients with borderline personality disorders may represent an expression of fear and anger or an attempt to cope with chronic boredom. Patients may use opioids and alcohol in attempts to lessen symptoms of anxiety, panic disorder, depression, or insomnia. Emergency physicians often receive limited training in dealing with such disorders and the specialty's deficiencies in dealing with such problems have been documented.[51] Psychiatric consultation, if available, may be useful in both suggesting alternative causes for aberrant behaviors and tailoring the physician's therapeutic approach to deal with these complicating factors.

For some patients, aberrant drug-related behaviors represent criminal intent to divert or sell controlled substances. The prevalence of behaviors occasioned by such intent is unknown and it is likely that in many cases, multiple etiologies of aberrant behaviors coexist. Certainly, patients with active or past substance use disorders are at increased risk for injuries and illnesses that can lead to chronic pain (e.g., motor vehicle injury).

Finally, although federal regulators and state medical boards do not perceive emergency medicine as a specialty prone to inappropriate prescribing, and investigations of emergency physicians are rare, if not unheard of, many emergency physicians express fears of such scrutiny or sanctions related to prescribing or administering opioids. While this concern is often voiced, it seems likely that this fear represents concern about other, less obvious physician uncertainties related to pain management and substance abuse disorders. Emergency physicians may be concerned about being overburdened by the inherent difficulties of managing patients with complicated pain syndromes and the potential of coexisting substance abuse disorders.

THE EXAMPLE OF SICKLE CELL DISEASE

The condition that best exemplifies the problem of ED-based pseudoaddiction is sickle cell disease. Vaso-occlusive pain crises are the most common reason for ED visits by patients with sickle cell disease and the genetics, molecular biology, and pathophysiology of this disease are relatively well understood. Although the management of sickle cell vaso-occlusive pain crises is viewed as challenging by emergency physicians, it has been a relatively neglected area of research investigation by the specialty.[52] Despite the fact that almost all of the 75,000 annual hospitalizations for pain crises occur after ED treatment, the *Annals of Emergency Medicine*, emergency medicine's premier research journal, has published no clinical research on sickle cell pain management within the past 10 years.

Despite our understanding of the sickle cell disease process, many health professionals are reluctant to prescribe adequate doses of opioids for these patients experiencing pain largely due to addiction concerns.[53] In one survey study, 53% of emergency physicians were of the belief that more than 20% of patients with sickle cell disease were addicted to opioids, while only 23% of hematologists shared this belief.[54] Also, in this survey, 35% of hematologists reported that they followed pain management protocols when treating painful crises as compared to only 17% of emergency physicians.

Nurses' attitudes regarding the prevalence of addiction among this patient population are even more extreme, with 63 respondents reporting that addiction was prevalent.[55] Thirty percent of nurses in this survey reported that they were hesitant to administer high-dose opioids for painful vaso-occlusive crises. A hesitant approach to ED opioid administration in the setting of vaso-occlusive pain crises will predictably lead to continued pain, increased anticipation of pain, and increased patient anxiety. This experience may generate pain-avoidance manifestations by patients that are interpreted by physicians as aberrant drug-related behaviors. Eventually, larger doses of opioids may be administered to control pain that is spiraling out of control with resultant excessive sedation. This apparent sedation in the setting of a painful condition may reinforce the physician's disbelief in the reality of his or her patient's initial pain reports.

It has been demonstrated that this cycle of inadequate care can be broken by the institution of pain management protocols that emphasize continuous opioid infusions and sustained courses of orally administered controlled-release opioids. In 1992, Brookoff and Polomano[56] reported the institution of such a structured analgesic regimen on hospital use by patients with sickle cell disease presenting to the ED of an inner-city university hospital in Philadelphia with remarkable results. After institution of the pain management protocol, the number of hospital admissions for sickle cell pain decreased by 44%, the number of total inpatient days by 57%, the hospital length of stay by 23%, and the number of ED visits by 67%. The authors asserted that these positive results were seen without a subset of patients being "chased away" from the hospital. Others have reported marked decreases in aberrant drug-related behaviors and the number of ED visits by patients with sickle cell disease after instituting long-term management of pain with chronic opioid therapies typically used to treat malignant pain.[57]

PAIN TREATMENT AND PROCEDURAL SEDATION IN THE EMERGENCY DEPARTMENT

Effective pain management involves both pharmacologic and nonpharmacologic modalities. Simply asking about pain and validating the pain reports impacts patients' satisfaction with ED pain management. In one study, patient satisfaction with pain management was predicted more strongly by the perception that ED staff asked about pain than by the actual administration of an analgesic.[58] Other nonpharmacologic modalities, such as reassuring the patient that pain will be addressed, immobilizing and elevating injured extremities, and providing quiet, darkened rooms for patients with migraine headaches are important aspects of quality pain management. Pharmacologic therapies should begin as soon as is practical after presentation to the ED. Analgesic protocols allowing early pain treatment can decrease the time to effective treatment and improve patient outcomes.[59–61]

Analgesics may be administered by a variety of routes; however, the vast majority of medications are administered by the oral or parenteral routes. Oral therapies are most commonly employed as they are convenient and inexpensive for patients who can tolerate oral intake. When pain is severe, analgesics must be given immediately and titrated to effect, generally by parenteral routes. The intravenous, rather than intramuscular, route is indicated in this context. Intramuscular injections are painful, do not allow for rapid titration, exhibit unpredictable absorption, and result in a slower onset of drug action. Unless intravenous access is elusive, there is little to recommend the intramuscular route. In general, it is inappropriate to delay analgesic use until a diagnosis has been made. In the case of acute abdominal pain, for which surgical dogma historically discouraged adequate analgesia, a large series of studies report no deleterious effect of intravenous opioid therapy on our ability to make appropriate diagnoses.[62–68]

SPECIFIC TREATMENT MODALITIES

Analgesics are the most commonly administered class of drug in the ED. The National Center for Health Statistics reports that analgesics account for the top three therapeutic classes of drugs used in the ED (Fig. 111.2).[1] In a recent 20 site survey of ED analgesic practice, a total of 735 doses of 24 different analgesics were administered to 506 patients receiving analgesics while in the ED. Analgesics administered to this cohort of ED patients are listed by prevalence in Table 111.2.[2] The majority of analgesics administered were opioids (59%); morphine being the most commonly used analgesic (20%), followed by ibuprofen (17%).

Nonopioids

Commonly used ED analgesics include opioids, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs). When opioids are required for pain treatment, nonopioids should be included in order to potentiate the opioid analgesic effect and decrease the severity of side effects. Unfortunately, nonopioid agents exhibit an analgesic ceiling effect and cannot be titrated to effect. This limits their usefulness in the setting of severe or fluctuating pain; however, they should be used as an adjunct to opioid therapies unless otherwise contraindicated.

Acetaminophen is indicated for mild to moderate pain, and is often combined with opioid agents. Acetaminophen, unlike NSAIDs, has no antiplatelet activity or anti-inflammatory effect. Although a great deal of attention has been paid to acetaminophen hepatotoxicity, especially in the setting of chronic malnutrition, alcoholism, or liver disease, such effects are uncommon, particularly when contrasted to the underappreciated high prevalence of NSAID-related adverse effects.

NSAIDs, including salicylates, act to inhibit prostaglandin synthesis by interfering with cyclooxygenase enzymes. They cause platelet dysfunction and can precipitate renal failure in patients with renal insufficiency or volume depletion, a particular concern in the elderly or those presenting to the ED with hemodynamic instability. Ketorolac, the only parenteral available in the United States, is commonly used in the ED and is felt to be particularly useful in the setting of renal colic. One recent study of renal colic in the ED found that a combination or ketorolac and morphine resulted in superior analgesia and reduced adverse effects when compared to the use of either agent alone.[69]

TABLE 111.2

ANALGESICS ADMINISTERED IN THE EMERGENCY DEPARTMENT (735 DOSES GIVEN TO 506 PATIENTS)

Analgesic	N (%)
Morphine	148 (20.1)
Ibuprofen	127 (17.3)
Hydrocodone/acetaminophen	93 (12.7)
Oxycodone/acetaminophen	83 (11.3)
Ketorolac	60 (8.2)
Acetaminophen	53 (7.2)
Hydromorphone	36 (4.9)
Antacid	26 (3.5)
Meperidine	24 (3.3)
Fentanyl	23 (3.1)
Metoclopramide	13 (1.8)
Codeine/acetaminophen	12 (1.6)
Oxycodone	10 (1.4)
Naproxen	9 (1.2)
Other	18 (2.4)
Total	735 (100)

From Todd KH, Ducharme J, Choiniere M, et al. Pain in the emergency department: results of the Pain and Emergency Medicine Initiative (PEMI) Multicenter Study. *J Pain* 2007;8(6):460–466.

Opioids

Opioid combination analgesics are commonly used for moderate to severe pain. Although the opioid component in these agents does not exhibit ceiling analgesic effects, the nonopioid component dose must be limited; thus, one cannot titrate these analgesics. The convenience of combination therapy must be balanced

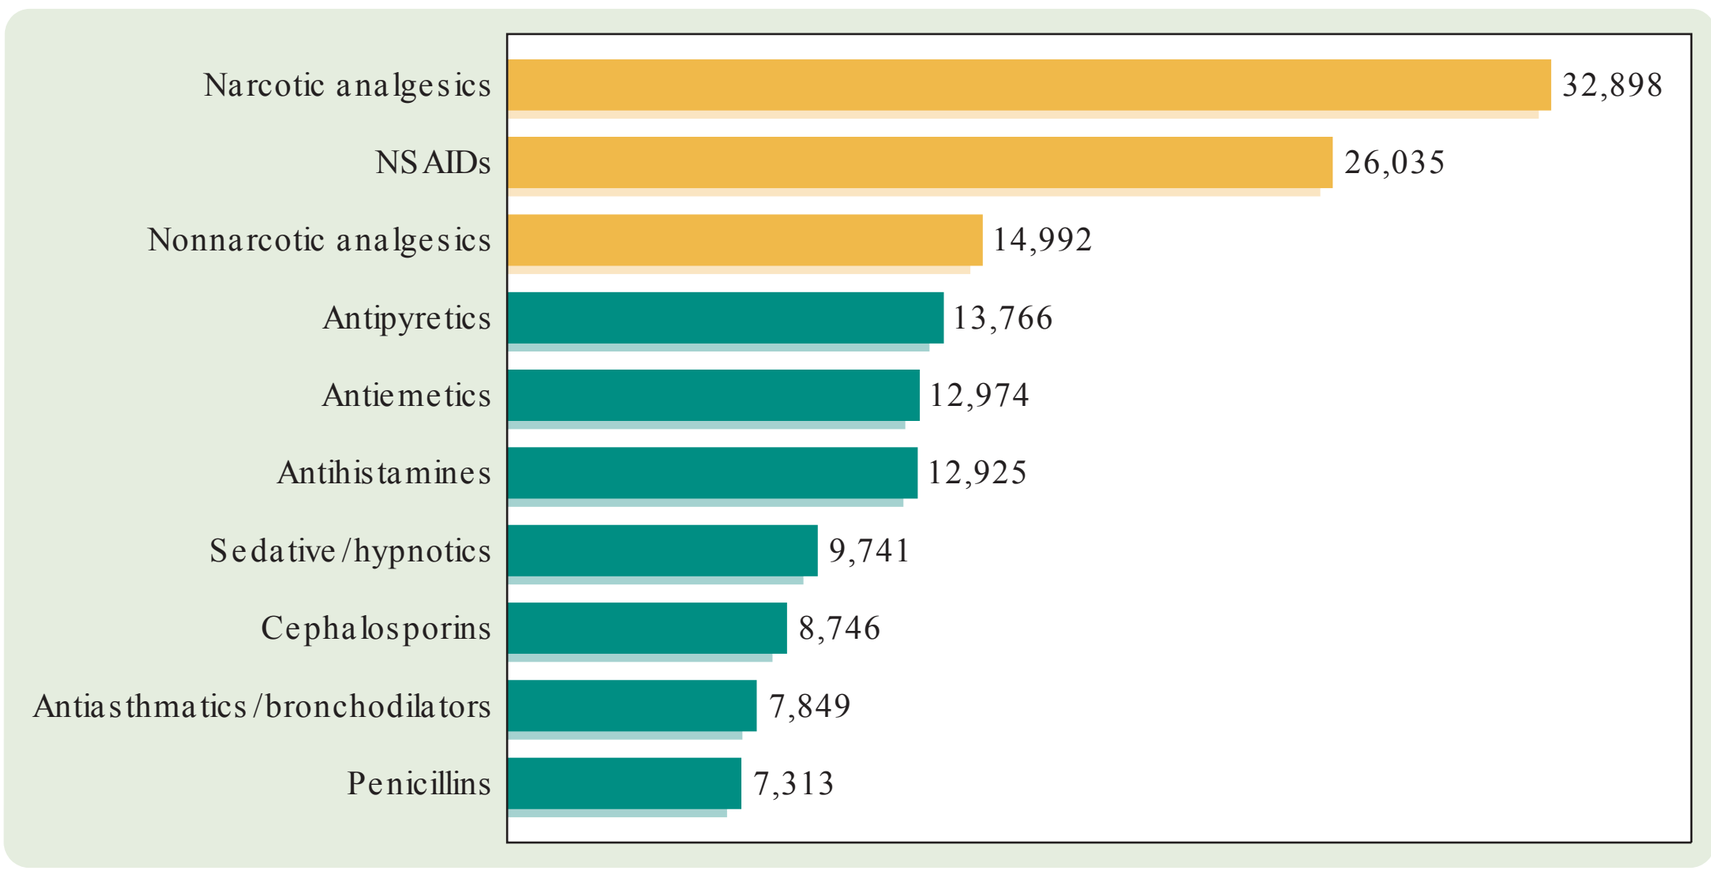

FIGURE 111.2 Top 10 therapeutic drug classes mentioned at emergency department visits. Note: Based on data for 204,851,000 drug mentions in 2005. (Redrawn after Nawar EW, Niska RW, Xu J. National Hospital Ambulatory Medical Care Survey: 2005 Emergency Department Summary. Advance data from vital and health statistics; no. 386. Hyattsville, MD: National Center for Health Statistics; 2007.)

against this limitation. Hydrocodone and oxycodone combination agents are associated with less nausea and vomiting and are preferable to codeine combinations agents. Also, significant proportions of the population are poor metabolizers of codeine, which must be metabolized to morphine in order to manifest analgesic effects, further limiting its effectiveness.

The tramadol/acetaminophen combination agent is indicated for acute pain; however, experience with this agent in the ED setting is limited. In one recent trial of acute ankle sprains presenting to the ED, the tramadol/acetaminophen combination agent had comparable clinical utility to that of hydrocodone with acetaminophen.[70] Tramadol's mechanism of action is unclear: it binds only weakly to opioid receptors and inhibits the reuptake of both norepinephrine and serotonin.

Opioids are the mainstay of ED therapy for moderate to severe pain, and morphine is the standard of comparison for all agents of this class. If contraindicated due to allergy or other sensitivity, hydromorphone or fentanyl may be substituted. These opioids can be rapidly titrated intravenously to control severe pain, allowing early institution of an oral regimen. Fentanyl has the advantage of being relatively short-acting and is preferred in the setting of multiple trauma, head injury, and potential hemodynamic instability. Intravenous morphine is the standard of treatment for severe pain in the ED. Morphine 0.1 mg/kg bolus has been found to be safe but not usually adequate to effect pain relief.[71] Repeat boluses of 0.05 mg/kg every 5 minutes until pain relief represents a safe incremental strategy.

Meperidine is a problematic opioid for a number of reasons. Many EDs have eliminated meperidine completely because of its metabolism to normeperidine, a toxic metabolite causing central excitation and seizures, as well as its contraindication in patients taking monoamine oxidase inhibitors.[72] Historically, subtherapeutic doses of intramuscularly administered meperidine have been used to treat a wide variety of acute pain complaints by generations of physicians. The availability of other opioid agents of equal efficacy with fewer contraindications and less adverse effects argues against its routine use.

Agonist-antagonist opioids, such as nalbuphine and butorphanol, have mixed effects on opioid receptor subtypes, exhibiting ceiling effects on both analgesia and respiratory depression. Because clinically important respiratory depression is distinctly rare in the setting of acute pain treatment, it is difficult to justify their routine use. One possible exception is for patients with advanced pulmonary disease. A particular drawback is that one cannot titrate these drugs to maximal effect because of analgesic ceiling effects. Additionally, these drugs are contraindicated and will induce withdrawal symptoms in patients who are physically dependent on opioids, either because of opioid therapy for chronic pain, methadone maintenance therapy, or active opioid addiction.

Patient-Controlled Analgesia

The use of patient-controlled analgesia (PCA) has been described in emergency medicine for both adults and children.[73,74] While no specific advantage has been found over the titration of opioids, PCA is at least as effective in relieving pain. In the setting of high demands on nursing resources, PCA could serve to ensure that patients' pain treatment needs are addressed in a timely fashion. In addition, patients admitted from the ED to inpatient hospital beds often experience a "pain window" between the last dose of an analgesic in the ED and the first dose administered on the hospital ward. Wider use of ED PCA might obviate this common problem.

Alternative Delivery Routes

Multiple alternative delivery routes for the administration of pain medications have been described. The use of nebulized fentanyl has been described and holds promise as a route of opioid delivery that can be initiated before an intravenous line has been placed.[75–77] Nebulized pain medications, especially for children who have severe pain but have not had an intravenous line placed, could be of use in the ED.

Procedural Sedation and Analgesia

Patients often present to the ED in need of painful or complex procedures that require patient cooperation and must be done emergently. Procedural sedation and analgesia (PSA) practices and policies have evolved rapidly in the ED, and this is a growing area in the practice of emergency medicine. PSA in the ED is complicated by the occurrence of unpredictable concurrent events as well as time and space constraints of the ED. Furthermore, unlike most patients who undergo sedation in other settings, patients in the ED typically have an unpredictable "nothing by mouth" (NPO) status, often have concurrent severe systemic disease, and usually are in severe pain before the procedure begins.

The indications for ED PSA range from pain control for short painful procedures to the need for patient compliance with a complex emergency procedure. The typical target sedation level for ED PSA ranges from minimal through moderate and deep sedation, depending on the demands of specific procedures. Deep sedation can inadvertently result in the patient achieving a level of sedation consistent with general anesthesia, but this is not an intended target level of ED PSA.

Minimal sedation describes a drug-induced state during which patients are sedated but are still able to respond appropriately to verbal commands (according to their developmental age) and whose eyes remain open. Depending on the agent, it is possible to achieve amnesia of the procedure at this level of sedation, but by definition, patients will still respond to their surroundings. It is generally performed for procedures that require patient compliance but are not typically intensely painful when performed with local anesthesia. Minimal sedation is typically used for procedures such as lumbar puncture, evidentiary exams, simple fracture reductions (in combination with local anesthesia), and the incision and drainage of small abscesses.

During minimal sedation, cardiovascular and ventilatory functions are generally maintained, although patients should be monitored for inadvertent over sedation to deeper levels using oxygen saturation monitors and direct observation. Agents typically used for minimal sedation include alfentanil, fentanyl, midazolam, combinations of the two, and low dose ketamine.

Moderate sedation is performed on patients who would benefit from a deeper level of sedation to augment the procedure. Moderate sedation describes patients sedated to the point at which their eyes are closed but they open in response to verbal commands (appropriately to their developmental age) alone or to light tactile stimulation. Patients at this level usually have an intact airway and maintain ventilatory function without support. As with minimal sedation, inadvertent oversedation to deeper levels can occur with moderate sedation. Appropriate monitoring including oxygen saturation, cardiac monitoring, and blood pressure measurements should be done throughout the sedation, and direct observation of the patient's airway should be maintained throughout the procedure. Agents used for moderate sedation in the ED include propofol, etomidate, ketamine, and the combination of fentanyl and midazolam.

Deep sedation is performed on patients who would benefit from a deeper level of sedation, often in order to complete a procedure already begun that requires more patient relaxation than was achieved at a lighter level of sedation. Generally, amnesia of the procedure is similar between moderate and deep sedation, and it is not necessary to sedate patients to a deep level only to obtain amnesia.[78] Deep sedation is achieved in the ED with the same agents as moderate sedation; the difference is in the

intended level of sedation. Monitoring requirements for deep sedation are similar to those for moderate sedation.

End tidal carbon dioxide has also been described in ED PSA, but its utility over the direct observation of a patient's ventilatory efforts and airway protection has not been established.[79] Deeply sedated patients can develop respiratory depression but generally maintain a patent airway and adequate ventilation. Patients sedated to this level can progress to a level of sedation consistent with general anesthesia. This can occur after the procedure for which the patient was sedated has been completed. Pain is a powerful stimulant, and after it is removed due to the completion of a procedure or the application of local anesthesia, patients may progress to a deeper level of sedation.[80–82] There is some evidence that the inadvertent progression to general anesthesia occurs more frequently in patients targeted for deep sedation than in those undergoing moderate sedation.[83] For this reason, it is usually safer to use moderate sedation than deep sedation in the ED unless the procedure requires progressively deeper levels of sedation to complete successfully, such as the reduction of hip dislocations.

Patients who progress to an unintended level of sedation consistent with general anesthesia are not arousable, even to pain. The ability to independently maintain ventilatory function is usually impaired, and patients often require assistance in maintaining a patent airway. Patients can quickly progress to the level of general anesthesia using agents commonly employed for moderate and deep sedation, and physicians performing ED PSA must be prepared to provide ventilatory support until the patient's level of consciousness has improved and they are able to protect their airway and ventilate normally.

In order to decrease the likelihood of aspiration, patients who are undergoing moderate or deep sedation in the ED are often kept NPO. Regardless of the target depth of sedation or the agent administered, there is insufficient evidence to support specific fasting requirements prior to procedural sedation. A recent guideline for emergency physicians has made recommendations for the proper risk stratification of patients based of their last oral intake.[84] In general, the risk of aspiration from recent oral intake increases with the depth of sedation and must be balanced with the urgency of the procedure when deciding whether or not to delay sedation due to recent oral intake.

Patients who have not had oral intake other than clear liquids for 3 hours prior to their procedure have a low risk of aspiration at any level of sedation. In patients with recent oral intake in need of an emergent procedure, the risk of aspiration is unlikely to outweigh the risk of delaying the procedure. Since the risk of aspiration likely increases with the depth of sedation, it is prudent to target the lightest level of sedation feasible for the necessary procedure. For nonurgent procedures where a time delay is unlikely to have a negative effect on the patient, patients who have eaten more than clear liquids in the prior 3 hours should have the procedure delayed until 3 hours after their last intake. For urgent procedures falling in between emergency and nonurgent procedures, lighter levels and shorter durations of PSA should be used as the size of oral intake taken within 3 hours of the procedure increases.

Patients who are intoxicated, especially with alcohol, can be especially difficult to sedate. They often have food in their stomachs and the achieved level of sedation can be difficult to predict. In emergent reductions, this increases their risk but does not change the procedure. In patients who can safely have the procedure delayed, intoxicated patients may benefit from a delay in their sedation until the progression of their mental status (getting worse or getting better) can be ascertained through observation.[84–87]

ED PSA is necessarily used for both patients who are medically healthy or have uncomplicated co-existing medical conditions (American Society of Anesthesiologists Physical Class 1 and 2) and those who have more significant or life-threatening co-existing mecical conditions (Class 3 and 4). PSA for critically ill children has been described using ketamine[88] and in adults using propofol or etomidate.[89] The degree of respiratory depression noted in these patients was similar to patients with physical status scores of 1 or 2, but an increased rate of hypotension was seen in physical status 3 and 4 patients who received propofol. It may be that ketamine and etomidate are better suited for the emergent sedation of critically ill patients, but there is not yet sufficient data to make a definite recommendation.

The ventilatory status of sedated patients must be monitored. This is generally accomplished with pulse oximetry and direct observation of the patient's respiratory effort. Pulse oximetry is a sensitive measure of oxygenation. If a patient receives supplemental oxygen prior to starting PSA and during the procedure, this monitor may not be as sensitive to changes in the patient's ventilatory status.[79,90,91] End tidal carbon dioxide has been recommended as an additional modality for the monitoring ventilatory status.[87,92] It provides a graphic display of ventilatory status that can be used to detect respiratory depression before it becomes clinically apparent.[79] In the event of hypoventilation, the end tidal carbon dioxide value increases as the respiratory rate decreases. In the event of increasing airway obstruction, the baseline end tidal carbon dioxide value decreases along with a blunting of the waveform due to increased mixing of the nasal expiratory sample with ambient air due to the turbulence from the obstruction.

Ketamine use has been described in adults[93] but is more commonly used for children undergoing ED PSA.[94] Ketamine is a dissociative anesthetic that provides 15–20 minutes of sedation when given intramuscularly, with a return to baseline mental status in 30–60 minutes. It can be given in doses of 1 to 4 mg/kg intramuscularly and should be combined with atropine 0.01 mg/kg to prevent hypersalivation. The 1 mg/kg dose achieves minimal sedation sufficient for such procedures as lumbar puncture, dressing changes, and simple laceration repair. Doses from 2 to 4 mg/kg result in increasingly deeper levels of moderate to deep sedation. Patients sedated with ketamine usually maintain a patent airway and ventilate normally. Patients receiving ketamine should be monitored for respiratory depression and rare occurrences of laryngospasm.[94,95] Emergence phenomena, unpleasant perceptual experiences as patients regain consciousness, have been described in both adults and children.[96–98] The addition of 0.1 mg/kg of midazolam to ketamine has been described to prevent emergence phenomena, but no difference in the occurrence of emergency phenomena has been found with its use.[96] Intravenous ketamine is also used for ED PSA at doses of 1 mg/kg with an onset of 1–2 minutes, followed by moderate sedation lasting 8 to 12 minutes. The adverse effects of intravenous ketamine are similar to those of intramuscular use.

The combination of fentanyl and midazolam has been used for minimal, moderate, and deep sedation in the ED.[79,83,97,99,100] This combination results in longer periods of sedation than other agents and carries a higher rate of respiratory depression than other commonly used agents. While adequate for minimal sedation, the high level of respiratory depression and long duration of action makes this combination less useful for moderate or deep sedation. Dosing for minimal sedation has been described as 0.1 mg/kg intravenous midazolam followed by 0.05 mg/kg intravenous fentanyl, with repeated fentanyl boluses every 1–3 minutes until the patient is adequately sedated. The sedation typically lasts 30–60 minutes with a return to baseline mental status by 45 to 120 minutes. This method of PSA requires direct ventilatory monitoring.

Pentobarbital is a sedative agent typically used for minimal to moderate sedation for radiologic procedures.[101,102] This agent has no analgesic properties and patients who appear sedated after its administration can be aroused with less stimuli than is typical for many of the other agents used in ED PSA, which is an excellent characteristic for preventing over sedation for radiologic procedures, but is of limited utility for painful procedures. The medicine is administered at 2.5 mg/kg intravenously, followed by 1.25

mg/kg every 5 minutes until adequate sedation is achieved. Pulse oximetry should be used; however, the rate of respiratory depression is lower than for other agents.[103]

Methohexital has been used for moderate and deep PSA.[104–106] It is a very short-acting agent with excellent amnestic properties. It is administered at 1 mg/kg intravenously with 0.5 mg/kg repeat boluses every 1–2 minutes as needed. It has an onset of 30 seconds, with sedation lasting 2–4 minutes and returning to baseline within 5–10 minutes. It has been associated with respiratory depression and a quick progression to deeper levels of sedation than intended and can cause over sedation even when carefully titrated. It should therefore be used with close ventilatory monitoring. Compared to propofol, methohexital is similarly effective and safe with single bolus use, but is less safe than propofol when multiple doses are required.[104] It should be used principally for very brief procedures expected to last less than 2–4 minutes, such as the reduction of simple fractures and dislocations.

Propofol is well described for ED PSA.[79–83,89,104,107–112] It is administered as a 1 mg/kg bolus with repeat boluses of 0.5 mg/kg every 2–3 minutes until the patient achieves the desired level of sedation. The sedation persists 2–5 minutes after a single bolus, and longer for patients receiving multiple boluses, with a return to baseline within 10–15 minutes. This medication has been associated with rates of clinically apparent respiratory depression from 4.0% to 7.7% in ED PSA. As with similar agents, close ventilatory monitoring is required. Propofol causes hypotension in critically ill patients and should be used with caution in hemodynamically unstable patients.[89]

Etomidate is also frequently used for ED PSA.[89,113–118] It is given as a single bolus of 0.1 to 0.3 mg/kg, with an onset of sedation in 30–60 seconds, and sedation lasting 7–10 minutes. It is not associated with hypotension and is more commonly used when this is an issue; however, its use is associated with myoclonic jerking in up to 25% of patients. This adverse effect can complicate the procedure for which the patient has been sedated, making it inferior to propofol for the sedation of healthy patients.[89] Etomidate, in single boluses of 0.3 mg/kg, has been shown to cause transient adrenal suppression, but no significant changes in cortisol levels occur, and the significance of this finding remains unclear.[119]

EVOLVING EMERGENCY DEPARTMENT PAIN MANAGEMENT PRACTICE

Pain management practices in the ED continue to evolve. The American College of Emergency Physicians, emergency medicine's principal specialty organization, established its first general policy statement regarding analgesic practices in 2004.[120] Prior to this, data from the National Hospital Ambulatory Medical Care Survey showed that, from 1997 through 2001, there was an impressive 18% increase in analgesic use in U.S. EDs (from 47.2 to 56.2 mentions per 100 visits), with marked increases in both NSAID agents and opioid analgesics.[121]

At the local level, adoptions of pain management guidelines and quality improvement processes have demonstrated dramatic improvements in practices. In one three site study, rates of ED analgesic treatment increased from 54% to 84% over 1 year as a result of individual and group feedback.[122] In a recent study from one Swiss ED, educational programs and guideline implementation led to marked increases in pain intensity documentation, analgesic administration, reduction in pain intensity scores, and improved patient satisfaction over a 4-month period.[123]

We do not know the reasons for the rapid evolution of ED pain management practice. Policy and regulatory initiatives, institutional quality improvement programs, pharmaceutical marketing campaigns, educational efforts, and new knowledge from basic and clinical research are all likely to be influential factors. No matter the cause, emergency medicine pain research is increasing at a rapid pace, and ED pain management practices will continue to evolve.

CONCLUSION

Relieving pain and reducing suffering are primary responsibilities of emergency medicine and much can be done to improve the care of ED patients in pain. Emergency physicians and nurses continue to refine their approach to the problem of pain and, in time, the current large amount of variability in ED pain practices will no doubt lessen. Clinicians, researchers, and policy makers continue to define specialty-specific standards for emergency medicine pain practice. Ongoing quality improvement initiatives are essential to achieving these goals.

CHAPTER 112 ■ PAIN MANAGEMENT IN THE INTENSIVE CARE UNIT

RICHARD A. MULARSKI, CURTIS N. SESSLER, AND GREGORY A. SCHMIDT

INTRODUCTION

Pain management in the intensive care unit (ICU) has unique characteristics and challenges. Critically ill patients receive state-of-the-art interventions in an aggressive and fast-paced setting with high morbidity and mortality. Concomitant with the life-saving priority of medical management and curative therapy, caregivers in the ICU have a duty to provide equally aggressive assessment and palliation of pain and other distressful symptoms.[1–3] Pain in ICU care is nearly ubiquitous and the challenges of managing pain in this setting are significant.[4–17] Sources of pain include the therapies and treatments used to preserve and restore life, such as invasive procedures, surgery, and monitoring devices, as well as direct nociceptive stimuli from injury, inflammation, and immobility.[4–11,18]

The motivations to treat pain in the ICU include the humane dictum of medicine to relieve suffering as well as the clinical duty to mitigate systemic and physiologic harm that can result from unabated pain, such as altered glucose control, myocardial ischemia, immune system dysfunction, hypercoagulability, ventilator dyssynchrony, restrictive lung physiology, and disrupted sleep.[1,2,19–27] Clinicians who care for the critically ill are obliged to be proficient in the assessment and management of pain. However, barriers to optimizing management of pain in the ICU include a paucity of a high-level evidence-based risk that treatment principles extrapolated from other settings may not be transferable to the ICU, and a challenge of complexity and overlapping needs where unique considerations and patient variability in response can further convolute care delivery.

The delivery of quality pain management must account for the complex critical care setting and is best accomplished using team-directed approaches. The resulting coordinated efforts and different team members with unique specialized skills helps to

overcome one major barrier to pain management—multiple competing interests of the clinicians who care for the critically ill patient. This chapter will summarize the science of pain management in the ICU, including pain evaluation and monitoring in the ICU, general pharmacologic treatment of pain, specific ICU syndromes, postoperative pain, regional anesthesia, comanagement of sedation and analgesia, daily awakening and ventilator liberation strategies, proactive interdisciplinary and patient-centered care, and approaches to pain management at the end of life.

INTENSIVE CARE UNIT PAIN MANAGEMENT WITHIN AN INTERDISCIPLINARY MODEL OF CARE

A principled approach to pain management facilitates care for critically ill patients, whether they are enjoying restoration of health or are actively dying. The grounding of pain management in the ICU stems from a broad goal of relieving suffering that is approached from a care model inclusive of palliation as an integral part of the overall care of the critically ill patient.[1,2,27–30] While the evidence-based treatment of pain is guided by technical issues of management and pharmacologic titration, the delivery of optimal pain care requires individualized, patient-centered care with the objective of relieving suffering along a continuum of balanced curative and palliative care.[1,2,13,21,31] In the ICU, the paramount focus on support of vital organ function may lead to the aggressive use of interventions that obscures the holistic perspective of patient-centered goal-directed care.[32] A strategy that incorporates the palliative medicine framework and a holistic care paradigm can facilitate better pain management.

The interdisciplinary paradigm fosters the integration of diverse talents and individual skills and is an appropriate model for aiding the direction of complex ICU care, inclusive of pain management.[33–37] Intensive care medicine is directed and delivered by multiple members of an interdisciplinary team, coordinated by a shared and explicit patient-centered goals for care.[31,32,38] Assessment of pain and the initiation of management strategies begin at the time of admission to the ICU and are guided by pre-existing knowledge of patient's pain experiences and daily reassessment.[1,39,40] The care provided has a foundation of open communication with patients and families to understand how therapies may help achieve an individual's care goals within the reality of illness and disability. The continuity and continuance of care relies on reassessing how the clinical condition, therapies, and symptoms change in lieu of fluid goal-oriented perspectives by patients and families. Such an approach to pain management, within the spectrum of therapeutic modalities used in the ICU, may in itself be one of the most important aspects of healing the suffering that accompanies critical illness.

The key principles that guide pain management in the ICU are that (1) clinicians should be biased toward the provision of analgesia operating from a presumption of pain when objective measures are conflicting or limited, and (2) in general, the prevention of prolonged untreated pain through early recognition and control is preferred to undertreatment and pain escalation. The approach to comprehensive and concurrent palliative treatment in the ICU must be tempered by anticipated side effects and complications, including the ability of pharmacotherapy to prolong the duration of cognitive recovery and mechanical ventilation. Analgesics and sedatives should be interrupted daily in almost all patients, unless the goal of care is comfort only.[41] The balance of palliation and curative therapy requires constant titration and evaluation to optimize the use of sedative and analgesic therapy.

PHYSIOLOGY OF PAIN SPECIFIC TO THE INTENSIVE CARE UNIT

Pain has been defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[42] The pathophysiologic mechanism is activation of the nociceptive pathways—neural afferent signals that arise from tissue damage. In the ICU, pain originates from repeated episodes of acute or short-duration stimuli and, frequently, some degree of chronic or sustained pain. Episodic or short duration pain occurs as an immediate experience of localized tissue damage. In critical care settings, acute pain includes both manifestations of underlying illness and iatrogenesis from therapies, such as catheters, surgery, limited procedures, tissue inflammation, and immobility.[4–11,18] Common painful procedures include endotracheal intubation and endotracheal suctioning, phlebotomy, gastric tubes, vascular access devices, and chest tubes. Turning has been shown to be one of the most painful and distressing procedures endured in routine ICU care.[43] Although chronic pain is primarily thought to develop from longstanding processes of tissue injury or sustained pain that include altered tissue responsiveness and subjective sensitivity, chronic pain can be acquired during an ICU stay from prolonged and repeated pain experiences.[4,5,43]

Pain subtypes identified in ICU care include acute postoperative and posttraumatic pain as well as neuropathic pain, and seeking to differentiate types is indicated to guide therapeutic approaches. The major subdivisions include somatic, visceral, neuropathic, and mixed.[19,20] In the ICU, the ability to differentiate the subjective experience of pain is limited by patients' capacity to clearly describe symptoms. For the most part, pain in the ICU is primarily in the somatic domain. Somatic pain is experienced as dull and aching, is often well-localized, and is particularly amenable to opiates and nonsteroidal anti-inflammatory agents that form the mainstay of ICU pain analgesia. Visceral pain that is cramping and colicky can arise from poor bowel care or from underlying gastrointestinal pathology. This type of pain responds well to anticholinergic therapy. Neuropathic pain that manifests with burning and shooting pain along radicular distributions is less well documented in the ICU but deserves consideration along with the potential use of antidepressants and anticonvulsants when appropriate.

Pain produces systemic effects that may add to the critical illness of the ICU patient; these deleterious effects can be lessened by comprehensive pain management.[19,22,23,44–46] Observation and documentation of the physiologic effects of pain both aids its evaluation and titration of pain therapy. Pain affects all systems of the body through neurohormonal mechanisms, catecholamine release, sympathetic outpouring, and the general stress response (Table 112.1).[20,44,47] Pain results in anxiety, tachycardia, diaphoresis, and catabolic metabolism with the resultant effects including increased myocardial oxygen demand, increased bowel motility, tachypnea and altered pulmonary mechanics, water retention as a result of activation of the renin-angiotensin-aldosterone axis, and cytokine production. Untreated pain may result in immune system dysfunction, hypercoagulable states and an increase in thromboembolic disease, altered glucose control, myocardial ischemia, ventilator dyssynchrony, acute restrictive respiratory physiology, and disrupted sleep quality.[19–23] Among the released cytokines are tumor necrosis factor, interleukin-1, and interleukin-6 that may contribute to blood pressure instability in the critically ill.[22,23] Pain also has synergistic effects with anxiety, depression, and sleep disturbances that may compound the detrimental effects on the body and exacerbate the pain experience.[19,21,44,46,48,49] Abatement of pain and treatment effects on the systemic manifestation of pain may be even more important for the tenuous ICU patient. Although a spectrum of excitatory (glutamate, tachykinins, and neurokinins), inhibitory (gamma amino butyric acid), and regulatory (noradrenaline, serotonin,

TABLE 112.1

SYSTEMIC AND PHYSIOLOGIC CONSEQUENCES OF PAIN IN THE INTENSIVE CARE UNIT

Physiologic system and effects	Consequences
Immune: cytokines elaboration and leukocyte dysfunction	Decreased ability to fight infection and hemodynamic instability
Cardiovascular: increased adrenergic tone and increased vascular resistance	Increased myocardial oxygen demand, stress, and ischemia; venous stasis
Renal: activation of renin-angiotensin-aldosterone axis	Water and sodium retention, anasarca
Endocrine: hormonal imbalance, especially cortisol and insulin	Hyperglycemia and hypotension
Respiratory: restrictive physiology, hyperventilation, lowered residual capacity	Ventilator dyssynchrony, atelectasis, hypoxia, increased pneumonia risk, disrupted sleep
Psychological/Neurological: altered sleep stage and serotonergic imbalance	Depression, fatigue, psychosis, sleep deprivation, anxiety
Hematological: hypercoagulability and platelet dysfunction	Gastrointestinal bleeding and thromboembolic disease

opioid) receptors are involved in the complex experience of pain, the mu, kappa, and delta opiate receptors are the prevailing target for pain management in the ICU.[50,51]

EVALUATION AND MONITORING OF PAIN IN THE INTENSIVE CARE UNIT

Pain management in the ICU is based on a universal anticipation for the presence of pain in all patients and the recognition that measurement is requisite for therapeutic guidance.[4,5,52–58] While most patients will require specific therapies to alleviate pain, observational research demonstrates that the minority of patients receive adequate pain assessment and treatment in the ICU.[4,5,16,59–63] Amongst the barriers to measuring pain in the ICU are the paucity of high-level evidence to guide ICU pain management, the lack of valid and reliable instruments for assessing pain when subjective input is not available, the risk that some therapies may potentiate medical problems, and problems with rapid titration and bioavailability. The assessment of pain in the ICU is further complicated by insufficient attention to pain monitoring and lack of subjective patient reports for critically ill patients with altered sensorium.

Despite these limitations, pain management is based on and guided by assessment efforts in the ICU just as in any other practice setting. Professional societies and regulatory bodies have increased efforts to improve the recognition and treatment of pain for hospitalized patients.[25,27,64] The Joint Commission on Accreditation of Health Care Organizations formally requires assessment using standardized techniques, and various groups have proposed quality measures for pain management in the ICU.[65–73] The Veterans Health Administration enacted a directive in 1999 requiring medical providers to assess and record a patient's self-report of pain using a 10-point numerical or visual rating scale.[74] These policy decisions are based on the concept that to appropriately manage pain, providers need to systematically and serially evaluate the presence and characteristics of pain.

Pain Assessment in the Communicative Patient

Pain assessment begins with the recognition that pain is a subjective interpretation of a unique experience—there is no overt measure of its presence or magnitude. As such, pain is best characterized by a coherent, interactive patient. Although the intensity of pain is a subjective experience, quantifying via rating scales aides in management.[19,66,75–79] In optimal circumstances, formal pain evaluation should assess intensity, duration, site, and type of pain. This evaluation should focus on understanding the cause and prior responses to therapy. In general, more thorough pain assessment is linked to improved pain management.[14,21,23,52,56,80–82]

The intent of asking a patient to rate his or her pain on a valid and reliable scale is to aid therapeutic efforts to relieve the pain. A simple approach for awake and aware patients in the ICU is to quantify pain intensity along a numeric rating scale, particularly assisted with a visual aid. For example, the numerical rating scale shown in Figure 112.1 can aid in serial assessments of pain along a continuum, such as from 0 = no pain to 10 = the worst pain they have ever experienced.[75,77] A pictorial scale, like the Wong-Baker FACES scale (see Fig. 112.1), presents a graphical means of ascribing numbers to a patient's perception and can be used with some reliability even in those with mild alterations of sensorium. While some children may be able to confirm the presence or absence of pain, young children may be limited in their ability to provide additional description when asked. Pain assessment for infants and preverbal toddlers is typically limited to indirect measures similar to other cognitively impaired patients.

Pain Assessment in the Cognitively Impaired Patient

The patient-reported determination of pain intensity is problematic in the ICU since many patients have cognitive impairment. Although pain manifests with various physiologic and behavioral markers, these are relatively poor surrogates for the patient who is unable to express the experience of pain.[19,20,79,81,83] Clinicians, however, can be attentive to patient movement, facial expression, and posturing as a supplementary source of data in patients able to respond but not able to quantify pain with a scale. Methods that combine data from multiple sources are needed to guide evaluation in the cognitively impaired ICU patient.

The earliest pain assessment tools for the noncommunicative ICU patient were developed for infants and young children. The COMFORT Scale[84] and the Face, Legs, Activity, Cry, Consolability (FLACC) Observation tool[85] are two instruments that have confirmed validity and interrater reliability and are in common use today. The COMFORT Scale contains eight behavioral and physiologic factors, each scored 1 to 5.[84] The FLACC Tool assesses pain uses behavioral indicators and body movements, verbal responses (cry), and consolability; it has been validated in a variety of pediatric populations.[85,86]

For adult patients who are marginally conscious or uncommunicative, two behavioral assessment scales have been developed and tested in the ICU with improved psychometric properties over physiologic indicators.[63,87–89] The Behavioral Pain Scale (BPS) has three domains and has been demonstrated to discriminate pain experience distinct from levels of sedation (Table 112.2).[87]

The Critical Care Pain Observation Tool (CPOT) has four domains: facial expression, body movements, muscle tension, and compliance with the ventilator for intubated patients or vocalization for nonintubated patients (Table 112.3).[88,89] Each behavior is rated from 0 to 2 and the total summed for a score ranging

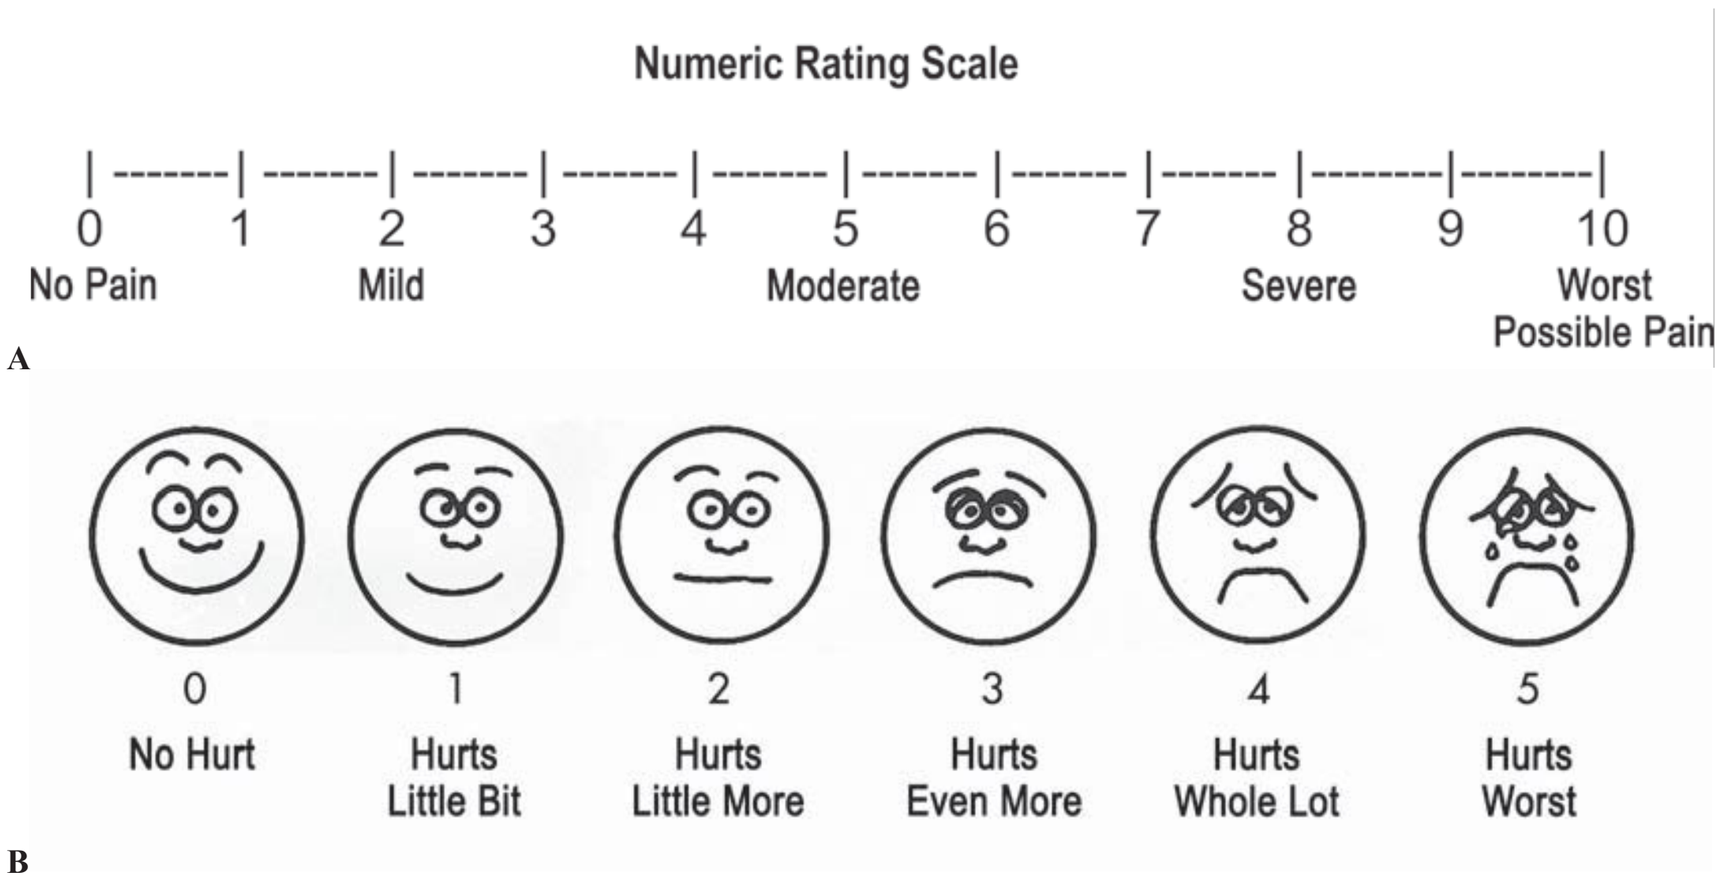

FIGURE 112.1 The numerical rating scale **(A)** and the Wong-Baker FACES scale **(B)** are advocated as interactive ways for patients in the ICU to rate the intensity of pain. (**A** reproduced from Partners against pain. Available at: www.partnersagainstpain.com/html/assess/scales/as_scale3.htm. St. Louis: Mosby; 2005:1259, with permission.)

from 0 to 8. A score greater than 3 yielded sensitivity of 67% and specificity of 83% for self-reported pain in conscious ICU patients.[89] The CPOT has been validated in several ICU settings. Gélinas and colleagues[88] studied 105 cardiac surgery patients during periods of rest and during nociceptive and nonnociceptive nursing interventions. Good associations between CPOT and self-reported pain rating were demonstrated for awake patients. Additionally, scores increased significantly during nociceptive, but not nonnociceptive procedures.[88] Responsiveness of CPOT to noxious stimuli suffers somewhat with deepening levels of unconsciousness,[89] much like observations for the BPS.[87] Excellent interrater reliability has been demonstrated for both BPS and CPOT.[87–89] These scales can be combined with measurement of sedation (see management section) and confusion/delirium, such as with the Confusion Assessment Method for the Intensive Care Unit[90,91] or the Intensive Care Delirium Screening Checklist,[92] to aid in comprehensive care.

Assessment using multiple sources of physiologic markers and creative interrogation, for example educating patients to signal with hand movements or blinking when pain is inadequately controlled, may improve day-to-day treatment. Changes in physiologic indicators, such as increased heart rate, increased blood pressure, increased respiratory rate, diaphoresis, and mydriasis, especially reductions after analgesic therapy, may provide additional evidence to guide the titration of analgesics, although these are less reliable than behavioral indicators. Family input may be solicited and provide an additional source of data to guide pain care; however, evidence suggests that surrogates lack reliability and should not be the sole source for monitoring.[93–98] Effective strategies are those that are tailored to the capability of an individual patients and are employed frequently and regularly by the care team.

Agitation can have multiple sources in the ICU, but for most ICU patients a preliminary search for pain and a therapeutic trial of analgesia is appropriate prior to sedation. Agitation is characterized by excessive, usually nonpurposeful motor activity associated with internal tension.[99,100] Prospective surveillance indicates that most ICU patients experience some evidence of overt agitation during hospitalization.[101] Agitated behavior can have serious consequences such as patient-initiated removal of critical tubes and catheters or even caregiver injury from combativeness.[101–103] The use of a sedation-agitation scale, such as the Richmond Agitation-Sedation Scale (RASS), Sedation Agitation Scale (SAS), or Adaptation to Intensive Care Environment (ATICE) instrument can promote recognition and documentation of agitation.[104–107] Agitation is often a manifestation of delirium[92] that may arise as a result of many forms of medical illness, alcohol or sedative drug withdrawal, and a variety of medications.[99] It is important to consider that agitation may be a manifestation of unrecognized or undertreated pain. Additionally, agitated behavior may herald life-threatening patient distress from unexpected conditions such as a malpositioned or occluded endotracheal tube, tension pneu-

TABLE 112.2

THE BEHAVIORAL PAIN SCALE. THREE DOMAINS ARE USED TO APPROXIMATE PAIN INSTENSITY FOR NONCOMMUNICATIVE ICU PATIENTS.

Item	Description	Score
Facial expression	Relaxed	1
	Partially tightened (e.g., brow lowering)	2
	Fully tightened (e.g., eyelid closing)	3
	Grimacing	4
Upper limbs	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with ventilation	Tolerating movement	1
	Coughing but tolerating ventilation for most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

Reproduced from Payen JF, Bru O, Bosson JL, et al. Assessing pain in critically ill sedated patients by using a behavioral pain scale. *Crit Care Med* 2001;29(12):2258–2263, with permission.

TABLE 112.3

THE CRITICAL-CARE PAIN OBSERVATION TOOL. FOUR DOMAINS ARE USED TO APPROXIMATE PAIN INTENSITY FOR NONCOMMUNICATIVE ICU PATIENTS.

Indicator	Description	Score	
Facial expression	No muscular tension observed	Relaxed, neutral	0
	Presence of frowning, brow lowering, orbit tightening, and levator contraction	Tense	1
	All of the above facial movements plus eyelid tightly closed	Grimacing	2
Body movements	Does not move at all (does not necessarily mean absence of pain)	Absence of movements	0
	Slow, cautious movements, touching or rubbing the pain site, seeking attention through movements	Protection	1
	Pulling tube, attempting to sit up, moving limbs/thrashing, not following commands, striking at staff, trying to climb out of bed	Restlessness	2
Muscle tension Evaluation by passive flexion and extension of upper extremities	No resistance to passive movements	Relaxed	0
	Resistance to passive movements	Tense, rigid	1
	Strong resistance to passive movements, inability to complete them	Very tense or rigid	2
Compliance with the ventilator (intubated patient)	Alarms not activated, easy ventilation	Tolerating ventilator or movement	0
	Alarms stop spontaneously	Coughing but tolerating	1
OR			
Vocalization (extubated patient)	Asynchrony: blocking ventilation, alarms frequently activated	Fighting ventilator	2
	Talking in normal tone or no sound	Talking in normal tone or no sound	0
	Sighing, moaning	Sighing, moaning	1
	Crying out, sobbing	Crying out, sobbing	2
Total, range			0–8

mothorax, or myocardial ischemia that must be rapidly recognized and treated.

A structured management protocol for agitation and pain can be implemented effectively in the ICU setting and can result in substantial benefits (Fig. 112.2). Chanques and coworkers[108] implemented a protocol for detection of agitation using RASS[104] and pain using a numerical pain scale and the BPS,[87] plus structured management of agitation and pain that included detection of underlying conditions, specific medication selection, and medication de-escalation. They demonstrated significant reductions in the frequency of pain and agitation, as well as a 50% reduction in the duration of mechanical ventilation, compared to prior to protocol. Accordingly, pain and agitation should be routinely sought using validated instruments and managed in a structured logical fashion. In addition to searching for underlying causes, the noncommunicative patient with agitation should be considered to possibly have pain as a causative factor and consideration given to a therapeutic trial of analgesic medication.

PHARMACOLOGIC TREATMENT OF PAIN IN THE INTENSIVE CARE UNIT

General Principles for Pain Management

Pain management is a requisite part of critical care for all ICU patients based on the motivation to attempt to relieve human

FIGURE 112.2 ACCM/SCCM/ASHP ICU Algorithm for Sedation and Analgesia. This joint statement provides clinical practice guidelines for the sustained use of sedatives and analgesics in the critically ill adult. (Reproduced from Jacobi J, Fraser GL, Coursin DB, et al. Clinical practice guidelines for the sustained use of sedatives and analgesics in the critically ill adult. *Crit Care Med* 2002;30[1]:119–141, with permission.)

suffering and to mitigate systemic physiologic effects engendered by untreated pain. Opiate therapy remains the dominant treatment in the armamentarium for pain therapy in the ICU. Amongst pharmacologic anesthetics, intravenous opiates have the most appropriate potency, absence of a ceiling effect, and usually desirable mild sedative and anxiolytic effects that lead to their dominance in the ICU. Opiates, however, are not without adverse drug effects, including bowel complications, delirium, respiratory suppression, and others. More comprehensive recommendations exist in other chapters of this text (see Chapter 78) and in the general literature for details on opiate therapy.[19,20,52,56,82,109,110] Nonpharmacologic and adjuvant therapies also have a complementary role and should be considered in ICU care.

Opiate Therapy

The objective of administering opiates in the ICU is to improve patient comfort and outcomes for critically ill patients.[19,46,58,110,111] For those with substantial injury, massive surgeries, or severe illness requiring life-support, scheduled or continuous intravenous infusions are part of usual care. For the patient who is not responding to therapy, consistent analgesia is certainly warranted in those who eventually die of their illness. For many ICU patients, however, opiate therapy may interfere with timely achievement of anticipated outcomes, even when other therapies are resulting in restoration of health. Opiates, like other medications administered for prolonged periods, can manifest protracted durations of effect.[20,41,55,83,109,110,112,113] Analgesia and sedation can persist for days to weeks after sustained infusions are discontinued, and it is common for patients with hepatic or renal disease to experience oversedation. Evidence-based therapeutic recommendations favor bolus dosing and daily interruption of sedative and analgesic medications, except for the dying and those with uncontrolled pain.[1,110,114] For the most part, pain management in the ICU is based on data extrapolated from other settings, and even in existing Society of Critical Care Medicine (SCCM)/American Society of Health-System Pharmacists (ASHP) clinical practice ICU guidelines, no recommendations were based on high level or grade "A" evidence.[25,26,110]

No specific agent has been demonstrated to be preferable in all ICU patients or across all clinical entities. Optimized agent and dosing is a patient-specific quality that is based on the therapeutic balance that pain is relieved without intolerable adverse effects.

Selection of initial analgesic therapy should be based on individual patient characteristics and knowledge of prior opiate exposure, experience, and side effects, when available. Surveys and prospective surveillance studies indicate that morphine and fentanyl are widely used around the world.[63,115–118] For agents like morphine, the intravenous pharmacokinetics include peak effects at 30 minutes and an approximate duration of 2 hours, thus leading to bolus therapy at a frequency of every 30 to 60 minutes. Many critically ill patients' metabolisms are altered, however, which can substantially lengthen the duration of effect.[110]

Morphine and hydromorphone have an active hepatic metabolite in a glucuronide form that accumulates during renal failure.[19,83,119–121] Morphine-6-glucuronide has a half-life greater than 12 hours, has been demonstrated to cross the blood-brain barrier, and has been associated with prolonged sedation after discontinuation of continuous infusions. Caution is warranted in using these drugs in critically ill patients with renal and/or hepatic failure. Vasodilation, cardiovascular instability, and bronchospasm from histamine release are additional side effects that can complicate ICU care. The histaminic response can be differentiated by associated rash or pruritis, response to antihistamines, and short duration (less than a week) if therapy is continued.

Fentanyl has shorter peak and duration of action and can be bolus dosed as often as every 5 minutes, but it has been shown to accumulate when given by continuous infusion based on its lipophilic properties with half-times reported as lasting weeks after steady-state infusion.[19,55,83,109,110,113,122] Fentanyl may produce less hemodynamic instability than other opiates but has a unique side effect of muscle rigidity that appears dose-related.

Remifentanil is a selective mu-opioid receptor agonist approved for use in anesthesia induction and maintenance that may have advantageous properties for ICU care. The novelty in this agent, in contrast to fentanyl, is that remifentanil is metabolized by multiple ubiquitous esterases and its half-life is not known to be protracted by critical illness nor organ dysfunction.[123–127] Due to its pharmacokinetic properties, this agent has a terminal half-life of less than 30 minutes and may reduce the incidence of prolonged sedative complications seen with continuous infusions of other opiates. Preliminary work demonstrates shorter periods of mechanical ventilation when this agent is used over other opiates in short-term studies.[128–130] The agent may adversely produce bradycardia and hypotension, however, which limits it widespread use in the ICU. The agent has been used in traumatic brain injury and neurosurgical settings with favorable effects on neurologic function assessment and a dose-dependent reduction in coughing associated with endotracheal suctioning. Concern remains, however, that the fast offset of this agent may lead to withdrawal and agitated behavior.[131–133]

Other agents may have a role in the ICU, but many possess properties that limit utility in critical care settings. Meperidine is associated with neuroexcitation due to a metabolite, normeperidine. Meperidine has been used in the short term for shivering associated with general anesthesia or to abate drug-induced rigors. It should never be given for more than 1 day or at a cumulative dose over 600 mg in a renal competent patient. Codeine by itself needs conversion to morphine for activity but a proportion of the population lack the enzymatic mechanism. Oxycodone is pharmacologically similar to morphine but only available in oral preparations.

Methadone has many advantages in the non-ICU setting over other agents for the management of chronic pain. However, the oral requirement, slow titration to steady-state, and variable potency limits its utility in the initial unstable period that most ICU patients experience. Methadone is advantageous in those with prior pain syndromes, is inexpensive, and may be preferable for complex pain syndromes due to its *N*-methyl-D-aspartate antagonism. Methadone can increase the QTc and has been associated with dysrhythmias.

Dosing and frequency are based on providing sufficient and frequent opiates to control underlying and breakthrough pain as well as anticipated prevention from interventions. Reassessment and titration are essential skills for pain management. Patients will have individualistic responses to different opiate medications that cannot be predicted based on underlying characteristics and suggest a role for switching between agents to minimize adverse effects. Changing agents requires skills in equianalgesic dose calculations. Equianalgesic dosing (see Chapter 78) may be estimated by the use of tables, but in general should be decreased in the new agent, especially in the critically ill.[20,109,110,119,134,135] When changing agents, the sum of administered opiates for the prior 24-hour period can be converted to 50% to 80% of the new agent's equivalent dose and then dosed as a continuous infusion or at intervals. Rotation of agents during protracted courses of treatment or combination therapy with different opiates may minimize untoward effects and optimize efficacy.[19,83,136]

Many critically ill patients suffer from chronic progressive diseases and thus do not present opiate naïve to the ICU. Particular care must be taken to avoid withdrawal syndromes and the physiologic consequences that can complicate ICU management. Recognition of withdrawal is crucial to avoid overtreatment with sedative or hypnotic agents. Physical and physiologic dependence can be predicted, and ICU practitioners need to anticipate its occurrence with regular use of opiates, either in the pre-ICU care or during prolonged ICU stays. Acute withdrawal has been shown to occur in ICU patients treated with opiates for greater than a week and may present within 6–12 hours after discontinuation of opiates.[137] The opiate withdrawal syndrome can include sweating, discomfort, agitation, lacrimation, diarrhea, tachycardia, and rebound pain. These symptoms, however, may be blunted in the critically ill patient or in those with concomitant use of sedating medication.

In titrating opiates in those with chronic pain, a breakthrough dose should be provided with a sustained or continuous basal administration. In general, the breakthrough dose can be approximated as 10% to 20% of the 24-hour total opiate requirement. For example, an ICU patient requiring 100 mg of sustained-release oral morphine every 12 hours should have 20–40 mg of oral morphine available every 1–2 hours or 7–14 mg of intravenous morphine available every 30–60 minutes. Breakthrough doses may also be titrated every 30 minutes and by as much as 50% to 100% in subsequent doses if the initial dose did not provide sufficient relief. When increasing opiate needs are sustained, the total daily dose should be adjusted by calculating 24-hour needs and administering approximately 80% of the daily dose as a basal rate for those with stable syndromes.

For the less severely ill and especially postoperative patients in the ICU, patient-controlled anesthesia (PCA) is often appropriate. In the immediate postinsult period, PCA typically includes three methods of delivering intravenous opiates: a patient-controlled dose that is given on demand using short lockout periods for breakthrough pain,[1] a basal or continuous infusion for patients with higher initial needs or prior tolerance from pre-existing opiate use for chronic pain,[2] and the potential for professional care givers to administer a provider-controlled bolus as needed.[3] Side effects and total dosage is often reduced with PCA and, as a result, less sedation and respiratory depression is experienced.

Nonintravenous administration of opiates is appropriate for some patients in the ICU. A subcutaneous infusion may be beneficial for rare patients, usually those at the end of life following the withdrawal of invasive measures and is dosed similarly to intravenous opiates. In general, the sublingual, buccal, or rectal routes are less desired as palliation can be inconsistent and side effects are increased. The transdermal route is an option for continuous basal opiate therapy, but is less desirable in the ICU, especially early in illness where decreased or variable perfusion may convolute stable absorption. The oral route is ideal for ongoing pain when critical illness is resolving but is often inconsistent early in the ICU process with enteral absorption often compromised.

Epidural routes are advantageous in the postoperative patient and have advantages in reducing systemic side effects.[138,139] For many ICU patients, however, the safe placement and maintenance of epidural anesthesia is limited. When considering analgesia, as in most therapies administered in the ICU, dosing should be responsive to moment-to-moment experiences of pain and proactive in prevention or preemptive treatment of anticipated pain. For example, dosing an opiate at a time interval just shorter than the peak onset is appropriate before painful dressing changes or other planned procedures. The ICU patient often manifests clinical variability and instability that requires frequent intervention, including responsiveness to pain therapy and dosing adjustments based on hemodynamic and metabolic derangements.

In general, there is no upper limit in opiate dosage, and titration is based on pain levels, the patient's tolerance, and adverse effects. Note that for many nonopiate analgesics, toxic metabolites limit this dosing strategy and thus are not the preferred agent to begin treating pain in the ICU. All patients should be anticipated to have predictable and manageable adverse effects with opiate use.

All opiates stimulate intestinal mu receptors and result in dysmotility and constipation. This activity and resultant constipation do not seem to be lessened over time with continued treatment. Thus, prophylaxis with stimulant medications combined with stool softener is appropriate. In the ICU, where enteral routes are not completely compromised, these agents should be administered with the first dose of opiates and titrated to loose stools. Obstipation is not infrequent and requires a digital rectal exam prior and disimpaction before beginning more aggressive bowel routines.

Other common adverse effects of opiate administration include sedation, myoclonus, nausea, and physiologic dependence. Additionally, opiates may have immunomodulating properties that could be worrisome in the ICU where infectious complications are common.[140,141] Nausea and emesis are usually due to stimulation at the chemoreceptor trigger zone, vestibular apparatus, or direct gastrointestinal effects. Antiemetics may be indicated, but the magnitude of this effect often diminishes with continued use. Myoclonus is occasionally seen when high doses of opiates are required and may be tempered by benzodiazepines, neuroleptics, or coadministration of multiple lower dosages of single agents.

Various opiates may produce reactions of varying intensity and types. If adverse effects are intractable and limit appropriate pain management, changing agents or using adjuvant therapies may be advantageous. Sedative side effects of opiates may be desirable when caring for mechanically ventilated patients. Sedation can be minimized, however, by aggressive use of nonopiates and nonpharmacologic agents as well as concurrent administration of central stimulants, such as dextroamphetamine and methylphenidate. Care must be taken to avoid withdrawal reactions once physiologic dependence has developed. Naloxone may be required in some situations where respiratory insufficiency in the spontaneously breathing patient is suspected to be caused by opiates. When used, naloxone should be dosed judiciously and slowly to avoid precipitating withdrawal.

Drug therapy in the ICU is subject to alterations in volume status, plasma protein binding, end-organ dysfunction, and resultant disturbances in bioavailability, clearance, volume of distribution, and pharmacokinetics that, especially for opiate medication, can manifest in protracted durations of effect and other adverse effects.[20,41,55,83,109,110,112,113] Pharmacokinetics and pharmacodynamics for analgesic agents are covered in much detail in other sections of this text (see Chapter 76).In the ICU, therapeutic drug monitoring does not generally apply to the predominant agents used for analgesia and, for the most part, dosing should be reduced and closely monitored for desired and adverse effects.[20,109,110,119,134,135] Specific caution should occur with continuous intravenous dosing of morphine and hydromorphone in the presence of renal insufficiency, as active glucuronide metabolites can accumulate and increase the duration of undesired sedative complications.[19,83,119–121] For the most part, altered pharmacokinetics in the ICU for analgesia and sedative medications are dealt with through proactive assessment and monitoring of clinical end-points (see approaches and details in the subsequent section on management of analgesia and sedation).

Nonopiate and Adjuvant Pain Therapies

Nonopiate pain therapies are less desirable as first-line pain management in all but the least injured or ill ICU patient, but these agents do have roles as adjuvant treatments. Ketorolac is an intravenous nonsteroidal anti-inflammatory medication that may be useful for anti-inflammatory effects, but produces gastrointestinal toxicity and increases the risk for gastrointestinal bleeding that limits its use to less than 5 days at a time or not at all in ICU patients already at risk for bleeding. Corticosteroids, ketamine, and adenosine may have opiate sparing effects as adjuvant therapy, but have not been evaluated in the ICU.[142,143] Lidocaine has also been used as an effective adjuvant for complex or neuropathic syndromes but may be limited in the ICU due to its arrhythmogenic properties.[144] Acetaminophen is a weak analgesic that carries the risk of hepatotoxicity with chronic use that similarly restricts its utility in the ICU except as an intermittently administered antipyretic. Clonidine and its related isomer, dexmedetomidine, are alpha agonists that provide mild sedation and mild analgesia. Dexmedetomidine avoids central respiratory suppression and may be a useful sedative in the spontaneously breathing or weaning ICU patient.[145]

Nonpharmacologic modalities are incompletely studied and infrequently used in the ICU, but have the potential to improve pain management.[19,21,83,146–148] Comprehensive palliative care therapies may include distraction therapies, behavioral modification, touch therapy, meditation, music therapy, palliative radiation or chemotherapy, acupuncture or acupressure, and massage. Epidural strategies, nerve blocks, electrophysiologic options, and specific nonpharmacologic options are receiving increased attention and study in the ICU. Consultation or routine involvement of pain or palliative specialists in interdisciplinary ICU care is expanding and includes the opportunity for mainstream ICU providers to broaden their expertise and experience.

Providers should recognize and anticipate analgesic needs in the ICU, particularly before noxious stimuli such as initiating procedures. Preemptive administration of analgesia improves pain control, decreases sedation and overall dose requirements, decreases catecholamine and stress response, and lessens physiologic complications of pain.[19,82,109,149–151]

TREATMENT OF PAIN—SPECIFIC APPROACHES

The analgesic needs of most critically ill patients are best met with systemic opiate infusion. For some patients, however, there are opportunities to improve analgesic management through more targeted techniques. In large part, the potential advantage of specific analgesic methods is attributable to fewer systemic adverse effects compared to an equivalent degree of analgesia provided intravenously. For example, in a mechanically ventilated patient with multiple, unilateral rib fractures, a paravertebral block or continuous thoracic epidural analgesic infusion might produce better control of pain while simultaneously facilitating an awake patient capable of cooperating with physical therapy and tolerating spontaneous breathing. At the same time, critically ill patients present numerous challenges to the pain practitioner by virtue of increased risk and difficulties in neurologic

assessment. The specific techniques for delivering regional anesthesia are delineated more fully in other chapters of this text (see Chapter 51).

Regional Anesthesia

Appropriate use of regional analgesic techniques in the ICU requires four key attributes: (1) an awareness of the range of available methods; (2) technical expertise to deliver a broad array of specialized skills, typically through a ‘‘pain service’’ or an intensivist trained in anesthesiology; (3) high-quality nursing conversant with the unique complications and associated early warning signs[152]; and (4) an organized system for placing catheters aseptically, examining the devices regularly, and recognizing the presence of infections. Because many ICUs do not possess all of these attributes, some specific analgesic techniques are probably underutilized in intensive care. A stronger evidence base, delineating the benefits while determining systematically the magnitude of adverse reactions, could serve to change current practice.

Indications

Regional analgesic approaches should be considered when the nature of the pain is particularly localized anatomically or when systemic administration of narcotics is unduly risky. Surgery and trauma, particularly of the extremities, often cause anatomically localized pain that can be treated regionally. For example, benefits of epidural analgesia have been demonstrated following thoracic surgery, orthopedic procedures of the lower extremities, abdominal operations, cardiac surgery, and multiple rib fractures due to trauma,[153–157] although not all studies have confirmed these findings.[158,159] Epidural analgesia often confers improved pain relief but few studies have been able to demonstrate meaningfully improved outcomes. Nevertheless, in patients with multiple, traumatic rib fractures, a prospective comparison of epidural analgesia (generally bupivacaine, morphine, and fentanyl) and intravenous opioids (morphine, hydromorphone, and fentanyl), showed that the neuraxial approach shortened the duration of mechanical ventilation and reduced the rate of nosocomial pneumonia.[160] Moreover, new evidence emphasizing the importance of vigorously reducing the amount of sedatives and analgesics given to critically ill patients points to an increasing role for regional techniques.[41,161] For brief operative procedures, such as tube thoracostomy, a regional technique provides short-term control of pain with few systemic effects. Localized pain due to severe pancreatitis, malignancy, arterial insufficiency, and cardiac angina may also be amenable to regional techniques. Systemic reasons to avoid or minimize opiates include hemodynamic instability or compromised respirations when intubation is undesirable. One subset of patients in whom regional techniques may be particularly useful is the group with known or suspected sleep-disordered breathing in whom systemic opiates are prone to precipitate respiratory failure from hypoventilation and/or obstructive apnea.

Also, for brief operative procedures, such as tube thoracostomy, a regional technique provides short-term control of pain with few systemic effects. Systemic reasons to avoid or minimize opiates include hemodynamic instability or compromised respirations when intubation is undesirable. One subset of patients in whom regional techniques may be particularly useful is the group with known or suspected sleep-disordered breathing in whom systemic opiates are prone to precipitate respiratory failure from hypoventilation and/or obstructive apnea.

Challenges and Adverse Effects

Critically ill patients, especially outside the postoperative subset, are often poor candidates for regional analgesia. It may be especially difficult to place needles and catheters (difficulties in positioning, tissue edema, anatomic deformity) or to ascertain their position (which is often judged based on the feedback of an alert and cooperative patient). There is great interest in the potential for ultrasound imaging to improve success rates and decrease complications of regional anesthesia, even extending to patients with coagulopathies.[162,163] Even when a catheter is placed properly, it subsequently may be dislodged related to patient agitation, general nursing activities, performance of radiologic imaging, and other common ICU activities. When malposition is suspected, confirmation may be difficult due to a change in the patient’s level of consciousness, coagulation status, or risk of transport. Hazards of placement are higher than in a typical perioperative setting due to coagulopathy, thrombocytopenia, and drugs that impair hemostasis. Attention to measures of clotting function can reduce this risk, but some of these conditions develop during the course of critical illness and after the placement of a potentially risky catheter. Consensus guidelines are available for patients receiving antiplatelet drugs, heparins, oral anticoagulants, thrombolytic drugs, and herbal therapies delineating risk factors, complications, and recommendations for regional anesthesia.[164]

Infection is another consideration when therapy requires catheters. Full barrier precautions during catheter insertion, just as with intravascular catheters, are recommended to lessen the risk of contamination. Sepsis is a daily concern in many critically ill patients. Even when sepsis is absent, systemic inflammation may accompany many illnesses, prompting questions as to the sterility of all invasive devices, including analgesic catheters, possibly necessitating their early withdrawal. Finally, the large number of caregivers of the typically critically ill patients, extending over a number of days, raises the risk of accident related to analgesic catheters. Conspicuous labeling may lower the chances that, for example, an epidural catheter is misidentified as a nephrostomy tube, biliary drain, intravascular device, or pacemaker lead. In addition to hematoma at the site of needle or catheter and infection of the device, regional anesthesia may also be complicated by bradycardia and hypotension (from sympathetic blockade), respiratory depression, itching, nausea, and depressed sensorium. Various factors should be weighed when considering using a regional analgesic technique in the ICU setting (Table 112.4).

TABLE 112.4

CONSIDERATIONS IN THE USE OF REGIONAL ANALGESIC TECHNIQUES

Question	Factors to consider
Can pain be ameliorated simply?	Repositioning or fixation of limb or body
Are there provoking factors?	Fixation, adjustment (e.g., withdrawal of endotracheal tube), or removal of devices
Is pain sufficiently localized to make a regional approach effective?	Postoperative or procedural pain is most amenable
Will it be possible to deliver the analgesia to the proper location and assess its impact?	Patient level of consciousness, limiting anatomic factors
Are there contraindications?	Coagulopathy, sepsis, anatomic concerns
How can risks be minimized?	Tunneled catheters, labeling of catheters, nursing education, repair of coagulopathy

Postoperative Pain

In many regards, postoperative pain presents the ideal conditions for local and regional analgesic techniques. Pain typically arises in a defined anatomic site, catheters can be placed intraoperatively, assuring good placement and reducing complications, surgery is planned, allowing time for full consideration of analgesic options, and most operative patients are not laden initially with systemic inflammation, coagulopathy, and impaired mentation. Further, many studies have compared the addition of local or regional approaches to postoperative analgesia so there is accumulating evidence regarding safety and efficacy.

Pain following median sternotomy is amenable to continuous local anesthetic infusion. In a prospective, randomized, double-blind trial, subjects undergoing open-heart surgery had a pair of infusion catheters inserted at the incision site at the end of the operation.[165] Continuous local infiltration with bupivacaine 0.5% at 4 mL/hour reduced the need for opioids, improved patient satisfaction, facilitated earlier ambulation, and reduced hospital stay. Similar results were reported following coronary artery bypass when ropivacaine was infused locally through a pair of multihole catheters.[166]

Epidural Analgesia and Nerve Blocks

Epidural analgesia has been used extensively for postoperative pain, particularly following thoracic, vascular, and orthopaedic procedures. In one series of patients undergoing thoracoabdominal esophagectomy, thoracic epidural analgesia with bupivacaine plus morphine provided superior analgesia with fewer opioid-related side effects (especially excessive sedation, respiratory depression, hallucinations, and confusion) than intravenous morphine analgesia.[153] There were no differences, however, in length of ICU stay, hospital length of stay, or mortality. Moreover, the catheter was inadvertently displaced in 18% of subjects and, in many patients in the epidural group, analgesia was insufficient or terminated early.

Some data suggest that epidural analgesia can improve relevant postoperative outcomes, especially in high-risk patients. Potential benefits include reduced thromboembolism and myocardial infarction along with improvements in pulmonary and bowel function.[167] A Cochrane review comparing epidural and systemic anesthesia following elective abdominal surgery concluded that the epidural approach reduced time on the ventilator, the risk of prolonged ventilation, cardiovascular and gastrointestinal complications, and the incidence of acute renal failure, even while improving pain control.[154] For nonsurgical patients, intrathecal approaches are used rarely because of the heightened risk of complications.[168] For pain management in the ICU, clinicians should consider the techniques, indications, and special concerns related to such procedures in the critically ill (Table 112.5).

Procedural and Iatrogenic Pain Episodes

Pain regularly accompanies a wide range of common ICU procedures. Drain and intravascular catheter removal, tracheal suctioning, deep breathing exercises, and turning cause pain and produce measurable increases in pain scores.[169,170] The majority of patients are not premedicated for these procedures despite evidence that patients report significant pain,[63,171] perhaps because clinicians systematically underestimate the pain they cause.[172]

MANAGEMENT OF ANALGESIA AND SEDATION IN THE INTENSIVE CARE UNIT

Core principles of ICU care include providing comfort, relief of distress, and improving tolerance of the ICU environment includ-

TABLE 112.5

TECHNIQUES AND INDICATIONS FOR REGIONAL AND EPIDURAL ANALGESIA IN THE INTENSIVE CARE UNIT

Technique	Indication	ICU Considerations
Thoracic epidural	Chest surgery, trauma, refractory angina Abdominal surgery Pancreatitis	Potential for sympathetic blockade with hypotension or bradycardia; epidural hematoma or infection
Lumbar epidural	Lower extremity surgery or trauma	Potential for hypotension
Paravertebral thoracic block	One-sided thoracic surgery, trauma, or chest pain	Potential for pneumothorax
Intercostal nerve block	Chest tube placement, rib pain or fracture	Highly vascular area; potential for pneumothorax
Femoral and sciatic blocks	Thigh and leg pain	Fewer hemodynamic complications than lumbar epidural
Brachial plexus blocks	Arm pain, surgery, trauma	Depending on the particular technique, potential for pneumothorax; epidural, intrathecal, or intra-arterial injection; or phrenic nerve block

ing optimizing acceptance of mechanical ventilation and indwelling tubes and catheters.[99,110] Further, in addition to pain, many patients have anxiety and apprehension related to these experiences. Accordingly, a combination of opioid analgesic and sedative-hypnotic anxiolytic medications are administered to many, if not most, critically ill patients, often by continuous intravenous infusion.[63,172–174]

It is important to employ a structured approach to providing analgesia and sedation in the ICU, with emphasis on interdisciplinary management.[99,110,174] Key concepts include (1) patient assessment and optimizing the ICU environment, (2) evaluation and documentation of pain, agitation, and level of sedation using validated instruments, (3) implementing a patient-focused management strategy that emphasizes matching patient characteristics to appropriate medications, targeting a specific level of sedation, and utilizing algorithms to avoid oversedation, and (4) proper de-escalation of therapy with avoidance of opioid and benzodiazepine withdrawal.[110,175]

Patient assessment should include recognition of underlying medical conditions that might influence analgesic and sedative management, such as chronic pain syndromes, use of analgesic or sedative medications prior to ICU admission, and history of substance abuse. The presence and severity of pain should be sought, preferably by self-reporting and utilizing a numerical pain scale or similar instrument to detect, quantify, and document pain and the patient's response to therapy.[107] Although it is less reliable than self-reporting, the use of a validated tool to infer pain from observed graded patient behaviors may be helpful for the patient who is sedated or otherwise unable to self-report.[173]

The CPOT and the BPS are two of the more thoroughly validated among such tools (see Tables 112.2 and 112.3).[26,87,88] Agitation should be recognized and documented, preferably using a validated tool such as the RASS, the SAS, or the ATICE instruments.[104–106] The level of sedation should be measured and documented regularly (e.g., every 4 hours) using a validated tool that is accurate, simple to use and recall, and has sufficient levels for titration of medications.[173,175] The Ramsay sedation scale (RSS),[176] RASS, and SAS are among the more widely used tools; we favor using RSS, RASS, and the awakeness scale of ATICE since these tools use a logical progression of common actions (eye opening and, in some, following a command) spontaneously, to voice, and if no response to voice, then response to physical stimulation in a stepwise fashion. A sedation level can be targeted and communication is enhanced using a sedation scale.

Selecting the medications best suited to the individual patient is vitally important. Propofol, for example, is preferred when rapid awakening is important.[177] Midazolam and morphine have active metabolites that are subsequently cleared by the kidneys, thus avoidance of these medications in patients who have renal insufficiency is important.[119,174,178] The 2002 *Clinical Practice Guidelines for the Sustained Use of Sedatives and Analgesics in the Critically Ill Adult*, published by SCCM,[110] recommends using fentanyl, hydromorphone, or morphine for intravenous administration (see Fig. 112.2). Prospective surveys from various countries indicate widespread use of fentanyl and morphine, although sufentanil and remifentanil are increasingly used in Europe.[63,115–118] Some clinicians favor emphasizing primary titration of opioids, followed by adjustments in the sedative medication, so-called analgosedation or cosedation.[127,179–180]

Dexmedetomidine is a selective alpha-2-adrenergic receptor agonist with a short half-life of about 2 to 3 hours that has sedative, analgesic, anxiolytic, and sympatholytic effects without depressing respiratory drive. Drug-related adverse effects are primarily cardiovascular, including hypotension and bradycardia, particularly when loading doses are used. In comparative studies, dexmedetomidine is associated with more alert level of consciousness but higher rates of pain and agitation than comparison drugs.[145,181,182] Although dexmedetomidine is considered to have analgesic properties, these appear insufficient in abating pain in the ICU setting. For example, in a head-to-head comparison with lorazepam in mechanically ventilated adults, the median dose of fentanyl was nearly four-fold higher with dexmedetomidine than with lorazepam.[145]

Continuous infusion of analgesic and sedative medications can provide a smooth course of sedation but has been linked to delayed recovery and longer duration of mechanical ventilation and ICU length of stay.[55] Accordingly, a number of strategies have been demonstrated in prospective randomized controlled studies to result in superior sedation, shorter duration of mechanical ventilation, reduced need for tracheostomy, and/or fewer tests for altered mental status. Strategies include a protocol with preference for intermittent over continuous administration of opioid analgesic and sedative medications,[114] daily interruption of opioid and sedation medications until the patient becomes alert or agitated,[41] preference for using shorter-acting opioid or sedative medications, and systematic approaches to managing sedation, pain, and agitation using repeated measurement and titration of medications to eliminate pain and agitation without inducing oversedation.[108,183] Many hospitals have adopted daily interruption of opioid and sedation (DIS), also referred to as "daily awakening" protocols or a "sedation vacation," in part because organizations such as the Surviving Sepsis Campaign[184] and the Institute for Healthcare Improvement Campaign[185] promote DIS as a component of evidence-based bundled ICU strategies. With DIS, opioid and sedative medications are temporarily discontinued until the patient becomes agitated or is able to follow more than three out of four simple commands, at which time the medications are restarted at half the original dosage. DIS has been demonstrated in prospective trials to be associated with short duration of mechanical ventilation, shorter ICU length of stay, fewer tests for unexplained altered mental status, fewer ICU complications, less posttraumatic stress disorder, and to be safe among patients with risk for coronary artery disease.[41,186] The combination of a daily awakening trial plus a spontaneous breathing trial (SBT) to determine ability to breathe independently is superior to a SBT alone.[161] Safety for patients at high risk for alcohol or analgesic or sedative drug withdrawal syndrome or for having adverse consequence of catecholamine surge remains to be proven.

Preferential use of short-acting agents that have a rapid offset of action has been linked to shorter duration of mechanical ventilation. As discussed above, the use of remifentanil, which is metabolized independently from organ function, has shorter duration of mechanical ventilation in comparison to other opioids.[123–127] Infusion of propofol is associated with shorter duration weaning than midazolam in postoperative patients.[177] In a recent randomized controlled trial, continuous infusion propofol with DIS was associated with shorter duration of mechanical ventilation and, despite its higher acquisition price, cost savings when compared to intermittent lorazepam.[187,188] While dexmedetomidine is regarded as a short-acting agent, no difference in the duration of mechanical ventilation has been noted in randomized controlled trials comparing dexmedetomidine to other sedative hypnotic drugs.[145,182]

Finally, de-escalation of analgesic and sedative medications is important to address carefully as the patient improves and the need for ICU care lessens. Patients who have had a prolonged course of treatment, such as those with acute respiratory distress syndrome, have a higher risk of developing opioid or benzodiazepine withdrawal.[137,189] Clinicians must be alert for possible withdrawal with manifestations such as restlessness, insomnia, delirium, nausea, hypertension, tachycardia, diaphoresis, and fever. It may be necessary to add oral or topical agents to provide a more gradual course.[190,191] Such tapering therapy should be complete

prior to discharge unless the use of these medications predated hospitalization.

APPROACHES TO PAIN MANAGEMENT AT THE END OF LIFE

Health care providers play an active role in managing end-of-life care for ICU patients.[192,193] Polling reveals that most people wish to die at home; however, over 50% of deaths continue to occur in the hospital, many with ICU care.[59,194–198] Approximately 15% of patients admitted to the ICU or over 500,000 per year in the United States eventually succumb to advanced illness and die in the ICU setting.[1,71,196,197,199–204] Studies have documented that the majority of dying ICU patients experience moderate to severe pain and distress.[4,5,16,59] Especially at the end of life, pain management should be included within the range of palliative care delivered.[27,29,30] As discussed above, a comprehensive care paradigm that incorporates concurrent palliative management is applicable to all ICU patients. For those dying, an explicit shift in management from curative therapy to comfort-oriented care is indicated.[192,193,205,206]

Although dying in the ICU is frequent, many barriers, including ethical and legal concerns, preclude optimization of pain management at the end of life. Ethical discourse has consistently upheld the appropriateness of withdrawing unwanted or unhelpful therapies to avoid the prolongation of the dying process and the administration of medications with the intent of relieving suffering.[28,207–211] Providers should administer pain medications and other palliative therapies for the dying patient in the ICU, even if the possibility exists that such treatment could possibly hasten death. A doctrine of "double-effect" supports adequate and aggressive palliation of pain to be differentiated from active hastening of death and ethically justifiable, as long as the provider's primary intent is mitigating suffering.[209–211] A clinician should document the reason and titration of agents used for the alleviation of pain well and avoid undertreatment by relying on patient self-report and physiologic responses.

Data suggests that aggressive pain management in the critically ill, contrary to anticipated short-term side effects like transient respiratory depression, may be life-prolonging, as uncontrolled pain can compromise vital organ function (see Table 112.1).[1,212–217] Documentation and physician orders should have specific guidance regarding therapies to avoid ambiguity with medication escalation and delineate the discussions and process that has led to terminal care, such as the observations and reasons for dose escalation of opiates. Dying patients will experience a range of symptoms and other palliative treatments, and a comprehensive care model (Table 112.6) that includes the family and other bereaved acquaintances of the patient are appropriate.[13,19,21,48,83,109]

Guidelines and specialized approaches have been developed for analgesic therapy during the removal of life-sustaining interventions.[12,28,48,52,218] Titration of agents used for the unconscious, dying patient is done by assessing physiologic indicators, such as tachypnea and tachycardia, and observation of behavioral markers, like facial grimacing and restlessness. For some patients at the end of life who are able to have meaningful interactions with loved ones, brief interruption of sedatives and analgesia may be reasonable, maintaining vigilance for the precipitation of withdrawal. An interdisciplinary approach unites the talents of complementary providers to aid in delivering seamless palliative and end-of-life care in the ICU (see Table 112.6). At times, the dying process may be protracted and transition to another setting may be appropriate. As part of the spectrum of good end-of-life care, patients and their families expect pain management to be a central part of quality ICU care.[19,20,28,205,219–222]

TABLE 112.6

END-OF-LIFE CARE AND PAIN MANAGEMENT IN THE DYING INTENSIVE CARE UNIT PATIENT

- Clarify and document the goals of care
- Notify interested parties (surgeon, oncologist, specialty nurse, outpatient physician, or nurse)
- Emphasize to family that care continues, but with new goals (i.e., care is not being "withdrawn," but rather is directed at dignity and comfort)
- Discontinue interventions and treatments that do not contribute to comfort (phlebotomy, imaging, remove inessential [not needed for comfort] devices, silence alarms)
- Provide sufficient analgesia, generally with systemic narcotics (assure reliable intravenous access, take into account recent and or chronic narcotic use, avoid arbitrary "upper limits" on analgesic dosing, begin with a bolus of drug if planning to remove devices, including the endotracheal tube, that raise the possibility of discomfort)
- Educate and reassure family and staff that the purpose of narcotic is to relieve and prevent suffering, not to hasten death
- Consider withdrawing the endotracheal tube since this can generally be done with no discomfort to the dying as long as adequately premedicated
- Reassess regularly whether the goals of care (comfort) are being met and titrate pharmacologic agents and interventions (clinically examine for signs of discomfort), determine whether vital signs respond to interventions, solicit family input: Do you feel he/she is comfortable?
- Invite ministry, palliative care, or pain specialists, where appropriate
- Consider transfer out of the ICU for continued comfort care

CHAPTER 113 ■ THE FUTURE OF PAIN MEDICINE: AN EPILOGUE

SCOTT M. FISHMAN AND JAMES P. RATHMELL

The creation of this 4th edition of *Bonica's Management of Pain* reflects a major collaboration among many of the world's leading authorities in the basic and clinical sciences. As in prior editions, this text serves as a resource for those who seek to increase their understanding of this aspect of the human condition. However, it also provides an important reference point—an elaboration on how far we have come and how far we have to go in order to prevent, markedly reduce, and perhaps even cure the pervasive problem of pain as a cause of unnecessary suffering, debility, and economic hardship. With this compendium behind us, we now briefly look ahead to where this journey may—and should—lead us before the next edition of this textbook is written.

The future is unpredictable; nonetheless, there are many current trends that portend an optimistic course ahead. Foremost is the pivotal recognition that pain is much more than a symptom and that its consequences, in the acute or chronic form, may be devastating at every level of human health. This profound understanding has begun to transform the perspective of modern medicine, offering greater possibilities for dealing with the burden of disease than ever before. It is reported that the number of patients with chronic pain exceeds that of diabetes, heart disease, and cancer combined.[1] Yet, clinicians remain substantially undereducated about pain and ill-prepared to respond. Nonetheless, significant advances herald great things to come. Prior to the first edition of this textbook, there were no pain specialists, pain journals, pain specialty organizations, pain advocacy groups, pain training programs, or laws or regulations specifically addressing the issues involved in delivering pain relief. At the time that the third and most recent edition of this text was written, the number of published reports in the realm of pain within the medical literature was a fraction of those today and there was no pain consortium at the National Institutes of Health (NIH). Clinical training of pain specialists was in its infancy, with minimal guidance from accrediting bodies. Certification of pain specialists through the American Board of Medical Specialties (ABMS) was available only to anesthesiologists and the immense problem of pain management in primary care had barely been raised.

Recent unprecedented events suggest that we are on a trajectory toward improved knowledge about pain and increased commitment to pain relief. These events include increasing demands for standards for pain-related assessment and treatment in all health care facilities, mandates for undergraduate medical and continuing education in pain and its management, and the increasing frequency with which administrative and legal complaints are lodged against practitioners who under-treat pain. There is little doubt that the future for pain management is inextricably linked to both science and education. Today, pain has growing representation in the NIH and professional societies are working diligently to further increase this new commitment. As an example of the growing recognition of the need for pain education for all clinicians, the largest state in the U.S., California, legislated mandatory continuing medical education on pain and end of life care for all licensed physicians. Subspecialty clinical training has become much more integrative and multidisciplinary as a result of ground breaking revisions to requirements set by the Accreditation Council of Graduate Medical Education (ACGME.) Previously, such requirements were predominantly

directed by the discipline of anesthesiology, but have now been revised through an extraordinary collaboration of multiple disciplines. Unavailable even 10 years ago, training for a physician from any primary clinical discipline is now possible in accredited programs that lead to certification as a pain specialist by the ABMS. Similarly, the multidisciplinary field of palliative medicine is designated as a subspecialty that is intertwined within many ABMS primary specialties, a most recent example of medicine's increasing assimilation of symptom management and quality of life interventions. Although pain medicine has also developed as a broad-based, multidisciplinary subspecialty, its place in the overall structure of the field of medicine as a whole is still in evolution. Reform initiatives are well underway to refine the position of this emerging discipline in effort to advance its research, education, and clinical missions. Great debate remains over whether pain medicine should evolve into a more robust subspecialty that integrates parts of many clinical disciplines or whether it should become a primary specialty in its own right. How pain medicine is ultimately positioned will greatly impact the field of medicine's ability to meet its fundamental obligations to mitigate suffering.

We have recently witnessed unprecedented legislative and regulatory attention to pain and its treatment. Much of this activity relates to the overlap of pain management and prescription drug abuse. Recent developments suggest that states and the federal government remain uncertain how to balance the needs of patients in pain to have appropriate access to controlled substances with safety concerns for the general public. Potential solutions have gained intense scrutiny by the pain and law enforcement communities, respectively. Over time, national policies by the U.S. Drug Enforcement Administration (DEA), Food and Drug Administration (FDA), and the overarching Departments of Justice and Health and Human Services will hopefully evolve into rational approaches that balance compassion and safety. Although many feel that regulators and lawmakers have prioritized prescription drug abuse over undertreated pain, evidence suggests that both public health crises are receiving unprecedented attention and action. With no prior track record of pain related legislative success, 2008 saw the US Congress pass a Veterans Affairs (VA) Pain Care Act (S2162, HR 6122) and incorporate a military pain care act into the National Defense Authorization Act (H.R. 5658.) Each of these bills mandate increased attention to pain and development of pain services within the VA health system and the Department of Defense. On the heels of this remarkable legislative success, the National Pain Care Policy Act of 2008 was passed by the U.S. House of Representative but failed to emerge from committee within the U.S. Senate. In 2009, this bill was again passed by the U.S. House of Representative and has been subsequently incorporated into a much larger health care reform act by the U.S. Senate. As would seem appropriate, the future of this important national pain legislation is now linked to the overall future of health care reform.

The clinical practice of pain management, now more commonly termed pain medicine, has changed dramatically since the creation of this textbook in 1953. Under the direction of John Bonica, the establishment of specialized centers that focus on pain management arose from anesthesiology roots. These centers were initially based on an intensive multidisciplinary model of care. Despite several decades of research firmly establishing its effectiveness, such care is expensive and has been largely unsustainable. Centers dedicated to this model have faced drastic reorganization or become extinct.

These same anesthesiology roots of pain medicine also shaped another important aspect of the field. With the influx of anesthesiologists came a rise in the use of specific pain treatments that adopted regional anesthetic or injection based techniques. Although any action taken to manage pain should be considered an "intervention," this new clinical arena based on more invasive procedures, such as analgesic injections in the spine or placement of implantable devices for pain, has been termed "interventional pain medicine." Currently, some experts contend that general pain medicine and interventional pain medicine should be discrete disciplines with practitioners separated based on interventional and noninterventional pain practice. The heightened role of procedural-based pain practices, and some of the drive to isolate this part of care from the rest of pain medicine, has almost certainly been driven by health care reimbursement systems, such as those in the U.S., that reward practitioners with higher payment for procedural care than for almost all other aspects of pain care. Indeed, the reimbursement for pain specialists who perform procedural interventions is often many times that for those who treat the same group of patients and spend the same amount or more time with them, but do not provide such interventions, regardless of the level of evidence of predictive outcomes that might reasonably justify one type of care over another. With lucrative salaries in the private sector, too few of this new breed of interventional pain physician have stayed in the academic realm and fewer still have gone about conducting meaningful clinical trials to examine the efficacy of their interventions.

As major health reform appears imminent in the U.S., pain medicine, and particularly interventional pain medicine, stands at a crossroads as many of the treatments that are part of currently accepted pain practice are expensive but have little or no scientific evidence to support their efficacy. As the forces of health care reform and evidence-based medicine unite to guide clinical practice, many of the treatments that are commonly used today are likely to be used less often. The unbridled growth of interventional pain medicine will incur increasing scrutiny and practice will undoubtedly moderate toward a more balanced form, where practitioners provide a broad range of interventional and noninterventional treatment for common pain conditions. Indeed, for economic, medical, social, and ethical reasons, it seems likely that the field will move toward a more uniform discipline, in which individualized pain care is more similar than dissimilar, based on a relatively broad spectrum of mainstream treatment options, with therapeutic choices based on weighing all available evidence and driven by the best interests of each individual patient.

There is widespread agreement that existing systems are inadequate for training clinicians to treat pain. Despite this, today's clinicians are armed with an unprecedented array of effective tools including pharmacologic, behavioral, and physical therapies; invasive procedures; and cross-cultural complementary and alternative treatments such as acupuncture and meditation. Bringing these and new tools to bear on all cases of pain will be a major challenge, requiring education for nonspecialist clinicians at the professional school and postgraduate levels. Mandating substantive pain education for all clinicians has been a missed opportunity that must be corrected.

If the past predicts the future, pain will continue to be a pervasive problem for mankind, science will continue its exponential growth in knowledge of pain and its treatment, and society will increasingly recognize that pain management is integral to the humane and economically viable practice of medicine. The current economic crisis in health care, if not medicine's covenant to mitigate suffering, demands nothing less than systemic solutions to timely, integrated, and cost-effective pain relief. The current controversies and opportunities in association with better understanding and treatment of pain will likely push us toward a tipping point beyond which the very structure of medicine is likely to have to change.

Currently, medicine possesses greater knowledge and more tools to treat pain than ever before. Despite the undertreatment of pain, undereducation of clinicians, and underfunding of research, medicine is much further along today than it was even a decade ago—a trajectory that bodes well for the future. The optimal organizational structure of science and medicine for advancing understanding and treatment of pain is yet to be defined. But it

will most certainly require transcending current barriers that serve to fragment care, such as the illogical separation of the mind and body within the whole person or the splintering of core elements of pain management due to obsolete lines that separate one discipline from another. Change will likely be proportionate to the value we place on reducing suffering along with curing disease. Moreover, how general clinicians and pain scientists of the future are supported and trained, and how the emerging discipline of pain medicine is positioned for continued development and integration throughout health care will greatly impact medicine's ability to meet its mission to understand and treat pain. Looking to the future, we appear to be headed for sweeping change in health care that may well lead to new heights in medical research, education, and clinical care for pain. This, in the light of the remarkable progress that has already been made, is a signal that medicine is rediscovering its fundamental ethos; most assuredly, to cure when possible, but to relieve suffering and provide comfort always.

  acute, 900, 901*t*–903*t*, 904–905
    aggravating/relieving factors, 900, 904
    associated factors, 905
    chronology for, 900, 904*f*
    drug history, 905
    past medical history, 905
    physical examination, 905
    quality of, 904–905
    site of pain, 900
    treatment of, 915
  in children, 768, 776–777
  chronic, 905–906, 906*f*, 907*t*–912*t*, 913
    aggravating/relieving factors, 906, 913
    associated factors, 913
    chronology, 906
    drug history, 913
    family history, 913
    lifestyle factors, 913
    nongastrointestinal symptoms, 913
    physical examination, 913
    quality of pain, 913
    site of pain, 905–906
    treatment of, 915–916
  diagnosis of, 899–913, 900*t*
  functional abdominal pain syndrome, 922, 922*t*
  functional dyspepsia, 920–922, 920*t*
    epidemiology of, 920–921
    IBS comorbidity with, 921
    psychiatric comorbidity with, 921
  functional gastrointestinal disorders, 913–915
    enhanced perception of visceral pain in, 914
    general considerations of, 913–914
    pathophysiology of, 914
    stress sensitivity in, 914–915, 915*f*
  in HIV infection and AIDS, 830
  irritable bowel syndrome, 916–920, 916*t*
    chronic abdominal pain and, 907*t*–912*t*
    comorbid conditions/extraintestinal manifestations, 917
    epidemiology of, 916
    esophageal sensory testing in, 890
    hypnosis for, 920, 1247
    pathophysiology of, 917–918
    psychiatric comorbidity of, 917
    symptoms of, 916–917
    treatment of, 918–920
  in pancreatic cancer, 564, 639
  in SCD, 815–817, 815*t*, 816*f*
  treatment of, 915–916
Abdominal viscera, sympathetic and nociceptive nerve supply to, 112*t*–113*t*
Abdominal wall pain, in cancer pain, 552–553, 553*f*
Abducens pollicis brevis (APB)
  carpal tunnel syndrome and, 232
  radiculopathies with, 230
Aberrant drug-related behaviors, 419–420, 419*t*–420*t*, 847*t*
  differential diagnosis of, 419–420, 420*t*
  interpretation of, 855
A-beta (Aβ) fibers, 101
Ablation. *See* Image-guided ablation
Ablative neurosurgery, for chronic pain, 1515–1520
  cingulotomy, 1515–1517, 1515*t*, 1516*f*, 1517*f*
  hypothalamotomy and hypophysectomy, 1520
  medullary and pontine spinothalamic tractotomy, 1519
  mesencephalic tractotomy, 1519
  postcentral gyrectomy, 1515
  prefrontal leukotomy, 1517
  radiosurgical thalamotomy, 1518–1519
  thalamotomy, 1517–1518, 1518*f*, 1518*t*
  trigeminal tractotomy, 1519–1520
ABMS. *See* American Board of Medical Specialties
Above-level neuropathic pain, after SCI, 527*t*, 528, 528*f*, 530–531
ABPN. *See* American Board of Psychiatry and Neurology
Absorption, of acetaminophen and NSAIDs, 1160–1161, 1162*t*–1163*t*
Abuse. *See* Sexual abuse; Substance abuse
Acamprosate, for chemical dependency treatment, 1337
ACC. *See* Anterior cingulate cortex
Acceptance and Commitment Therapy (ACT), 1235
Acceptance-based approaches, to persistent pain, 273–274
Accessibility, of opioid analgesics in developing and nonindustrialized countries, 194–207
  availability of controlled medicines, 196–197, 202–205, 202*t*
  disparities in opioid consumption, 197–199, 198*f*, 198*t*
  health professional and government barriers to opioid use, 199–201, 199*t*, 201*f*
  methods and examples of implementing UN recommendations, 202–205, 202*t*
  opioids as controlled drugs, 195–196, 195*f*
  opioids as essential medicines, 195
  for pain relief as part of cancer and AIDS control, 194–195

synopsis of, 1433, 1434*t*
utilization, 1432
fluoroscopically guided, 1424–1425, 1424*f*, 1425*f*, 1426*f*, 1427*f*
efficacy of, 1432
synopsis of, 1433, 1434*f*
historical background of, 1423–1424
indications for, 1426, 1428
for low back pain
chronic, 1115
efficacy of, 1432
lumbar, 1424, 1425*f*, 1426*f*
efficacy of, 1430–1431, 1431*t*, 1432*t*
rationale for, 1425–1426
techniques for, 1424–1425
transforaminal, 1425, 1428*f*, 1429*f*
complications of, 1429–1430
efficacy of, 1432–1433, 1433*f*, 1433*t*
quantity of, 1425
synopsis of, 1433, 1434*f*
Epinephrine
for epidural analgesia, 708
intrathecal drug delivery of, 1445
for obstetric pain, 799*t*, 800
Epistatic genes, in SCD, 810
Equivalence trials, 128
EREM. *See* Extended-release epidural morphine
Ergonovine stimulation test, for noncardiac chest pain, 885
Ericksonian Naturalistic Approaches to pain and symptom management, 1251–1252
Erosion, bullous dermatosis with, 502–503
Erosive reflux esophagitis, chronic abdominal pain and, 907*t*–912*t*
ERPs. *See* Event related potentials
ERT. *See* Enzyme replacement therapy
Erysipelas, 499
Erysipeloid, 500
Erythema nodosum, 500
Erythermalgia, primary, 29
Es, for communicating with patient, 426, 426*t*
ESAS. *See* Edmonton Symptom Assessment Scale
Escitalopram
for depression, 401
for neuropathic pain, 1195*t*
Esophageal candidiasis, chronic abdominal pain and, 907*t*–912*t*
Esophageal dysmotility, noncardiac chest pain and, 878–879, 878*f*, 885
Esophageal manometry, noncardiac chest pain with, 885
Esophageal pain, in HIV infection and AIDS, 829–830
Esophageal pH monitoring
ambulatory 24-hour, for noncardiac chest pain, 883
proton pump inhibitor test v., 884–885
Esophageal-evoked potentials, 889
Esophagitis, chest wall pain and, 1055*t*–1067*t*
Esophagus
physiologic response autonomic stimulation of, 116*t*
sensory testing of, 886–890, 886*f*
sympathetic and nociceptive nerve supply to, 112*t*
Essential medicine, opioids as, 195
Estate of Henry James v. Hillhaven Corporation, 186–187
Estrogen therapy
for cancer pain, 663*t*–664*t*
for cancer-related bone pain, 632
Etanercept
for ankylosing spondylitis, 441
for CRPS, 323
for discogenic pain, 1462–1463
mechanism of, 30
for rheumatoid arthritis, 439, 439*t*
Ethics
of care of dying patients, 153–164
care beyond patient–physician dyad, 164
contributions and limitations of ethical analysis in end-of-life care, 153–154
physician-assisted death, 162–164
quest for moral order amid existential disorder, 153
responding to demands for nonbeneficial treatment, 160–162, 161*f*, 161*t*–162*t*
surrogate decision making, 157–160
transition from curative to palliative and end-of-life care, 154–157
pain experience and, 139–140
of pain management, 145–151
embracing a new ethic of pain relief, 149–151
ethical implications of barriers to pain relief, 149
pain, suffering, and core values of health care, 145–146
undertreated pain, 146–149
Ethnicity
cancer pain and, 538
as part of sociocultural dimension of pain, 135–136
response to pain and, 90–91
response to pain treatment and, 91
Ethnomedicine, 138
Etiology of pain, pain classification based on, 18
Etodolac, 1158*t*–1159*t*, 1164
Etomidate, for PSA in emergency departments, 1585
Eugene Whitney, accusation of, 185–186
Euphoria, opioids and, 1173, 1177*t*
Europe, pain medicine training in, 1561–1563
Evaluation procedures, 209–301
in cancer pain, 539–540
for chronic low back pain, 1108–1109, 1110*t*
for chronic pain in children, 769–772
conundrums in, 288–289
for diagnosis of neuropathies, 303–305
for disability. *See* Disability evaluation
for elderly patient, 784–785
electrodiagnostic. *See* Electrodiagnostic evaluation
in HIV infection and AIDS, 832–834, 833*t*
imaging. *See* Imaging techniques
in infants and children, 681–683, 682*f*–684*f*
medical. *See* Medical evaluation
multidisciplinary assessment. *See* Multidisciplinary assessment
in pediatric cancer pain, 670
for pain due to bone marrow infiltration or bony metastasis, 671–672
for painful invasive procedures, 671
psychological issues. *See* Psychological evaluation
psychosocial issues. *See* Psychosocial issues, evaluation of
for substance abuse in chronic pain patient, 850–851, 850*t*
Event related potentials (ERPs), in FM, 478–479
Evidence-based medicine (EBM)
complementary and alternative medicine and, 1366
pain medicine, 1564
Ewing's sarcoma, pediatric cancer pain associated with, 673
Excitatory amino acids (EAAs)
for acute pain, 704–705
ionotropic receptor/channels of, 42–44
in SCI central pain, 359
Exercise. *See also* Strength training; Stretching exercises
behavioral group treatment v., 1277
for low back pain, 1356–1363, 1357*f*, 1362*t*, 1363*t*
acute, 1358
application of, 1359–1361, 1361*t*
chronic, 1114–1115, 1139
designing individualized programs for, 1358
efficacy of, 1361–1362
musculoskeletal examination, 1357–1358, 1358*t*
persistent, 1359
relapse management, 1359
subacute, 1358–1359
TENS and, 1350
Exertional headache, 869
Existential distress, at end of life, 1553–1554
Experimental pain
ethnic group differences in, 90–91
genetic contributions to, 91–93, 92*t*
sex and gender differences in, 88–89
Expert-based classification of pain, 17–18
Expertise-based trials, 128
Extended-release epidural morphine (EREM), 728
Extinction, in operant conditioning, 389
Extramedullary lesion, chest wall pain and, 1055*t*–1067*t*
Extra-spinal pathology, FBSS and, 1131–1132, 1132*t*
Extremity pain, dorsal rhizotomy and ganglionectomy for, 1499
Eye
physiologic response autonomic stimulation of, 116*t*
sympathetic and nociceptive nerve supply to, 111*t*

Eye disorder pain, 977–982, 979*t*
from intracranial disease, 982
ocular and orbital causes of, 977–978, 980–982, 980*t*
eye and periocular pain, 981–982, 981*t*
red eye, 980–981

Progestins, for cancer pain, 663*t*–664*t*
Prognosis
  of cancer, tumor markers in, 568*t*
  in transition from curative to palliative and end-of-life care, 155
Prognostic blocks, 1404–1409, 1404*t*
  cervical spinal nerve blocks, 1405, 1405*f*
  lumbar spinal nerve blocks, 1405–1406, 1406*f*
  sacral spinal nerve blocks, 1406, 1407*f*
  spinal nerve blocks, 1404–1405
  thoracic spinal nerve blocks, 1407, 1408*f*
  validity of, 1407, 1409
Progression, of cancer pain, 546–547, 547*t*
Progressive muscle relaxation (PMR)
  complications with, 1262, 1263*t*, 1264
  effectiveness of, 1260–1262
  history of, 1255–1256
  techniques for, 1257–1258
Projection. *See also* Axonal projection
  classification of nociceptive neurons according to, 39–40
Proliferation therapy. *See* Prolotherapy
Prolotherapy, 1369
  for chronic low back pain, 1115
Promethazine, in cancer pain, 588*t*
Pronator drift, in physical examination, 215
Pronator syndrome, nerve entrapment release for, 1494
Propacetamol, for acute pain, 703
Propantheline, for oral mucositis, 624–625
Propionic acid derivatives, 1158*t*–1159*t*, 1165
Propofol
  for brain CP, 368–369
  in burn pain, 760
  for pain after SCI, 532
  for palliative sedation, 1554, 1555*t*
  for pediatric cancer pain, 671
  for PSA in emergency departments, 1585
  for SCI central pain, 360
Propoxyphene
  for cancer pain, 597
  characteristics of, 1182
  in elderly patient, 786–787
  for HIV infection and AIDS pain, 834*t*
  metabolites of, 1184*t*–1185*t*
Prosecutions, over pain management, 190–191
  United States of America v. McIver, 191
  United States v. Hurwitz, 190–191
  United States v. Rosen (1978), 190
Prostaglandin (PG)
  inhibitors of, intrathecal drug delivery of, 1449
  in myofascial pain syndrome, 455, 460
  synthesis and pharmacology of, 1157
Prostanoid biosynthesis, ontogeny of, 685
Prostate, sympathetic and nociceptive nerve supply to, 114*t*
Prostate cancer
  chemotherapy for, 657*t*, 658
  pain in, 563, 565–566, 566*t*
  prevalence of, 559
Prostate pain syndrome, 942–944, 944*t*, 949
Proton pump inhibitors (PPI)
  for functional dyspepsia, 922
  test for noncardiac chest pain, 883–885
Provocation disc injections, in FBSS, 1138
Provocative maneuvers, in physical examination in cancer pain, 549–553, 551*t*, 552*f*–553*f*
Pruritus
  with intrathecal opioids, 1454
  from neuraxial blockade, 801–802
  from opioids, 725, 729
PSA. *See* Procedural sedation and analgesia
PSDC neuron. *See* Postsynaptic dorsal column neuron
Pseudoaddiction, 16–17, 150, 419, 842, 847*t*, 1579
Pseudoclaudication, 513
Pseudogout, 443–444
Pseudorheumatoid disease, 444
Pseudotolerance, 847*t*
Psoas, in male pelvic pain, 946
PSOCQ. *See* Pain Stages of Change Questionnaire
Psoriatic arthritis, 442–443, 443*f*
PSWD. *See* Pulsed short wave diathermy
Psychiatric comorbidity
  of chronic abdominal pain, 913
  of functional dyspepsia, 921
  of irritable bowel syndrome, 917
  in multidimensional assessment, 210
Psychiatric illness, 393–413
  anxiety disorders, 403–405, 403*t*–404*t*
  depression, 396–403, 396*t*, 399*f*
  biological tests for, 397–398
  differential diagnosis of, 397
  dysthymic disorder, 398
  epidemiology of, 398
  mechanisms of association between pain and, 398–401, 399*f*
  pain in, 397
  psychotherapy for, 402–403
  suicidal ideation and behavior in, 396–397
  treatment of, 401–402

sick role, 408–410, 409*t*–410*t*
somatoform disorders
  conversion disorder, 411–412, 412*t*
  definitions, 408
  hypochondriasis, 412–413, 413*t*
  pain disorder, 410–411, 411*t*
  somatization disorder, 408–410, 409*t*–410*t*
Psychiatry, pain medicine contribution of, 1560–1561, 1562*t*
Psychodynamic psychotherapy, for depression, 402
Psychodynamic theory, on interaction between pain and depression, 399–400
Psychogenic conceptualization, of chronic pain, 79–80
Psychogenic pain, 17, 393–394, 412
Psychogenic pain disorder, 410
Psychologic interventions
  for chronic pain in children, 774–775
  for CRPS, 324–325
  for male pelvic pain, 950
Psychological adaptation, assessment of, 297
Psychological aspects of pain, 74–85
  behavioral formulations, 80–81
    classical conditioning, 80
    gate control model, 81
    operant conditioning, 80
    social learning, 80–81
biopsychosocial model, 82, 141, 392, 669
in burn pain, 756–757
in cancer pain, 561–562, 562*f*, 562*t*, 575
in chest wall pain, 1053
cognitive factors, 74–76
  appraisal and beliefs, 75
  catastrophizing and fear-avoidance beliefs, 75–76
  perceived control and self-efficacy, 76, 80–81
  predispositions, 74–75
cognitive-behavioral perspective, 81–82
in CRPS, 320–321

emotion, 76–79
anger, 78–79
anxiety, 77–78
depression, 78
family systems perspective, 82–83
in FBSS, 1136–1137
childhood abuse, 1137
coping abilities, 1137
fear-avoidance, 1136–1137
treatment for, 1140
female chronic pelvic pain and, 931
history-taking on, 212–213
multidisciplinary assessment of, 293–298, 294*t*, 295*t*–296*t*
as cause v. consequence, 293–294
evaluation elements, 294–296, 294*f*, 295*f*–296*f*
problem areas, 296–298
with noncardiac chest pain, 882
in pain after SCI, 527–530, 533
with pain rehabilitation, 1323
psychogenic conceptualizations, 79–80
spine clinics and, 1534
stress and autonomic responses: hypothalamic-pituitary-adrenal axis dysregulation, 76
in visceral pain, 636
Psychological constructs, anger and, 1210–1211, 1212*t*
Psychological evaluation, 270–276, 294–296, 294*f*, 295*f*–296*f*
adjustment to chronic pain, 273–274
chemical health, 275–276
for chronic low back pain, 1108–1109, 1110*t*
history-taking in, 212–213
interviews, 294
for intrathecal drug delivery, 1439, 1439*t*
lifestyle habits and motivation, 274–275
psychopathology, 270–273
self-report inventories, 294, 296
on social and personal cost of pain, 212–213
for spine surgery, 1143–1150
personality and emotional factors, 1143–1147, 1144*t*
Psychological intervention
for chronic abdominal pain, 916
for noncardiac chest pain, 893, 894*f*
for PHN, 353–354
Psychological theory, on interaction between pain and depression, 399–400
Psychologist, in interdisciplinary management, 1525
Psychology
of addiction, 417–421
aberrant drug-related behaviors, 419–420, 419*t*–420*t*
barriers to treatment for pain or addiction, 420
definitions, 418–419
development of therapeutic approaches using opioid therapy, 420
four As for ongoing monitoring, 420, 852
guidelines for treatment with opioids, 420–421
prevalence of substance abuse, 417–418
of chronic pain in children, 769
of FM, 480–481, 480*f*
of male pelvic pain, 949
Psychometric properties, in pain classification, 22
Psychoneuroendocrine axis, in irritable bowel syndrome, 919
Psychopathology, 270–273
Psychophysiology of pain, 375–386
emotions in, 376–382, 377*f*–381*f*
adaptive functions of, 376
behavior and, 376–377
central neuroanatomy of: limbic structures, 377, 377*f*
cognition and, 382
HPA axis in, 381–382, 381*f*
LC and DNB in, 379–381, 380*f*
noxious signaling and central limbic processing, 379, 379*f*–380*f*
peripheral neuroanatomy of: ANS, 377–379, 378*f*
primary and secondary features of affective dimension of pain, 382
in a sociobiological perspective, 376
VNB in, 379, 380*f*–381*f*, 381–382
future directions in, 385–386
historical perspective of: mind-body issues, 375–376
sense of self in, 382–383
stress, sickness, and pain in, 383–385
definitions of stress, homeostasis, and allostasis, 383–384
depression and sickness response, 385
physiological mechanisms of stress, 384–385
sickness response to pain, 385
stress and chronic pain, 385
Psychosocial approach, for pain in elderly patient, 787–788
Psychosocial issues
evaluation of, 270–276, 294*t*
adjustment to chronic pain, 273–274
chemical health, 275–276
lifestyle habits and motivation, 274–275
psychopathology, 270–273
of exercise for low back pain, 1360–1361
of facial pain, 997
in multidimensional assessment, 210
in musculoskeletal examination, 1357
peripheral nerve stimulation and, 1376
Psychostimulants, for HIV infection and AIDS pain, 837*t*, 838
Psychotherapeutic management
of anger, 1216–1218
cognitive change in, 1282
homework adherence and skills practice in, 1282
therapist skill in, 1282–1283
Psychotherapy
for depression, 402–403
for irritable bowel syndrome, 919
Psychotropic drugs, for cancer pain, 589–591
PT. *See* Physical therapy
PTSD. *See* Posttraumatic stress disorder
Public health issues, unrelieved pain as, 166
Pudendal block, for obstetric pain, 802
Pudendal nerve
in female pelvic pain, 936, 936*f*
in male pelvic pain, 944–945, 947–948
Pulmonary embolism
in ACS, 814–815, 814*f*
chest wall pain and, 1055*t*–1067*t*
Pulmonary hypertension, chest wall pain and, 1055*t*–1067*t*
Pulse generator, for SCS, 1387, 1387*f*
Pulsed radiofrequency, 1479–1480, 1480*t*
Pulsed short wave diathermy (PSWD), 1349–1350
contraindications for, 1350
Punctate, for physical examination, 216
Pupil constriction, opioids and, 1177, 1177*t*
Putative energy therapy, 1371–1372
acupuncture and oriental medicine, 1371
ayurvedic medicine, 1371–1372
craniosacral therapy, 1371
homeopathy, 1371
Reiki and energy healing therapies, 1372
touch therapies, 1372
PVB. *See* Paravertebral nerve block
PVD. *See* Peripheral vascular disease

Pyelonephritis, acute abdominal pain and, 901*t*–903*t*
Pyridostigmine, nerve conduction studies and, 230
Pyridoxine deficiency, neuropathy associated with, 305–306

QOL. *See* Quality of life
Quackery, 1365
Quality of life (QOL), 17
in cancer pain, 575–577, 577*t*
of children with chronic pain, 769
of elderly patient, 783
of herpes zoster patients, 343
in HIV infection and AIDS, 832
HAART impact on, 828
Quality of pain
acute abdominal pain, 904–905
acute low back pain, 1095, 1097
assessment of, 297
chronic abdominal pain and, 913
as descriptive and outcome measure, 258–259, 260*f*–262*f*, 263
as diagnostic aid, 255, 257–258
in FBSS, 1137
measurement of, 255, 257–259, 260*f*–262*f*, 263
recommendations for assessing, 263
Quantitative sensory testing, for SMP, 1501
Quinine, historical use of, 10

Race
as part of sociocultural dimension of pain, 135–136
response to pain and, 90–91
response to pain treatment and, 91
Radial nerve
entrapments of, 1494–1495
injury of, 244, 246*f*
Radial nerve block, 737
Radial tunnel syndrome, nerve entrapment release for, 1494–1495
Radiation of pain
in chronic low back pain, 1108
medical evaluation of, 211, 211*f*
Radiation therapy
in cancer pain, 644–655
for bony metastasis, 645–648, 647*t*–648*t*
clinical applications of, 645–646
for diffuse bone metastasis, 654–655, 655*t*
for pathological fracture, 649, 650*f*
single fraction radiation, 648–649
for spinal cord compression, 649–654, 651*f*–653*f*
tumor response to, 646–648, 647*t*–648*t*
as cause of pain in HNC, 619
cystitis induced by, 641
enteritis induced by, 639, 641
ITDD during, 610
oral mucositis in, 621–622, 622*t*, 638
for pediatric cancer pain, 672
plexopathy induced by, 571*t*, 572
proctitis induced by, 641
visceral pain after, 641

Radical neck dissection (RND), pain after, 573–574, 619–620
Radicular pain, 512
in cancer, 552, 569, 572
Radiculopathy
in cancer, 569
electrodiagnostic evaluation for, 230–231, 231*f*, 231*t*
Radiofrequency dorsal root ganglion (RF-DRG), for discogenic pain, 1479
Radiofrequency thermocoagulation. *See* Thermal radiofrequency
Radiography
for acute low back pain, 1100
of bone cancer, 630
for chronic low back pain, 1110–1111
of FBSS, 1138
for imaging guided injection, 248
for neck and arm pain, 1029–1030, 1030*f*, 1030*t*
Radiologic studies, electrodiagnostic studies with, 223
Radiological medicine, pain medicine contribution of, 1560–1561, 1562*t*
Radionucleotides
for cancer-related bone pain, 632–633
for diffuse bone metastasis, 654–655, 655*t*
Radiosurgery, for trigeminal neuralgia, 1510–1511
Raeder's paratrigeminal syndrome, 981
Raich, Angel, 192
RAIS. *See* Rostral agranular insular cortex
Raised cerebrospinal fluid pressure headache, 873
Raj approach, for sciatic nerve block, 742, 742*f*
Ramsay sedation scale (RSS), in ICU, 1597
Ramsay-Hunt syndrome, 340
Ramus communicans lesions, for discogenic pain denervation, 1460
Randomization, in clinical trials, 124
Randomized allocation, of treatment and control groups, 123–124, 123*t*
Range of motion, lack of, 1294–1295, 1295*f*
Rash, of herpes zoster, 339, 339*f*
RASS. *See* Richmond Agitation-Sedation Scale
Raynaud phenomenon, 516
Raynaud's disease, 516
cryotherapy and, 1347
spinal cord stimulation for, 1384
Raynaud's syndrome, 516
Reactive arthritis, 442
Readiness to change, for CBT, 1225–1226
Receptor. *See also* Nociceptor
in joints, 432
of neurotransmitters, 42–47, 43*t*–44*t*
from glia or unknown sources, 46–47
