   b. Major skeletal injuries. When a history of significant trauma is elicited, radiologic studies are needed to rule out the possibility that a patient has a spinal fracture, or a ligamentous injury severe enough to yield instability. X-rays that include flexion and extension views are usually sufficient.
   c. Widespread "nonanatomic" pain. Physicians who practice musculoskeletal medicine try to explain symptoms following an injury in terms of some structural lesion in joints, periarticular tissues, muscles, and nerves in the body region where the patient is symptomatic.[10] Although this approach often uncovers a potential cause, the symptoms of some patients with chronic pain do not fit a pattern that suggests some discrete injury to a musculoskeletal structure. For example, Figure 23.2 is a pain drawing provided by a chronic pain patient reporting initially lower back pain sustained when lifting a heavy box on her job. Although the patient reported that the only injuries she sustained were localized, the figure indicates that she was now experiencing widespread pain. In interpreting such figures, it is important to note that research has demonstrated that irritation of intervertebral discs and facet joints produce characteristic patterns of referred pain.[11,12] Thus, it is sometimes possible to explain widespread symptoms as indications of referred pain. However, the drawing shown in Figure 23.2 does not lend itself to such an interpretation, since it does not conform to any known pattern of referred pain from a spinal structure. The most plausible interpretation of such widespread pain is that it is a manifestation of altered perception based on central nervous system sensitization (CNSS, described later) or psychological factors.
   d. Musculoskeletal pain apparently emanating from joints of the spine. Patients who present with localized axial cervical spine pain or pain in a pattern suggesting referral from a joint in the cervical spine[11,12] are often very difficult to evaluate medically. In principle, such pain could be the product of irritation of several different structures in the cervical spine, including intervertebral discs, facet joints, and various ligaments. Since a physical examination typically does not identify the structural basis of axial cervical spinal pain, the examining physician is faced with the challenge of deciding whether to refer such a patient for advanced evaluation procedures as discussed later.

Are There Risk Factors for Delayed Recovery?

It is important to evaluate such risk factors in a patient with chronic neck pain. Unfortunately, research on the validity of

Chronic Pain Clinic Evaluation

Use the pictures below to show the origin of your pain (mark with a solid dot)

Does the pain travel or radiate anywhere? (mark with a broken line) no

Is the pain external (outside)? (Mark with an "E") or
Is the pain internal (inside)? (mark with an "I") or both

How much pain do you feel? (mark the area(s) with appropriate number below) el can't answer this since the severity of the pain changes constantly. At it's worst it's 5 or 5+ but at it's least it's 1.

1= Mild 2= Uncomfortable 3= Distressing (fairly severe) 4= Very Severe/horrible 5= unbearable

*Please Note: Since el have Fibromyalgia - Chronic Fatigue Syndrome, the pain el experience waxes & wanes both in terms of body/brain location and in terms of severity.

in the back of my mouth at the beginning of my throat

sometimes sharp pain in eyes due to light

almost never goes away

nausea

no pain in my hands but they are weak & coordination is poor

*Please note; the marks el have made above show locations of pain that el have experienced throughout my body over my entire lifetime (or ever since el can remember). The above indicated pain tends to appear or disappear, strengthen or weaken at any given moment in any given location.

FIGURE 23.2 Patient indication of pain location.

many potential indicators is lacking. Thus, the following list of indicators should be viewed as *plausible* candidates for consideration during the medical evaluation of a chronic pain patient, rather than as proven predictors.

- Presence of a systemic disorder of the musculoskeletal system, such as rheumatoid arthritis or one of the muscular dystrophies.
- History of prior spinal injuries, or of significant prior symptoms in the absence of injury
- Evidence of severe spondylosis
- High pain intensity
- Severe functional limitations on examination
- Evidence of severe emotional distress

Are There Other Issues That Bear on the Patient's Prognosis Or Have Implications for Treatment Planning?

An enormous number of issues have the potential to influence treatment planning for a chronic pain patient. Some of the most commonly encountered ones are:

- Various general medical conditions. For example, if a patient has severe cardiovascular disease, this may have implications for his or her ability to function in a physical therapy program.
- Chemical dependency. The patient's history in this domain is important because it may bear on the appropriateness of prescribing opioids or sedatives.
- Sleep disturbance. Disturbed sleep is a common symptom reported by chronic pain patients, and most clinicians who treat these patients accept the premise that disordered sleep plays a role in perpetuating symptoms and disability. Thus, if a patient reports significantly disturbed sleep, a treatment plan for him or her should include interventions to promote normalization of sleep.
- Disability and litigation issues (discussed later).

Specific Evaluation Procedures

The physician should gather information on most or all of the questions outlined. Broadly speaking, this information will come from three sources: the patient's history, the physical examination, and ancillary studies.

History

It is beyond the scope of this chapter to discuss the elements of a thorough history. It is worth noting, though, that in evaluating a chronic pain patient, the physician should pay careful attention to certain historical items that are considered only cursorily in other clinical settings. In particular, the physician should be careful to assess the patient's history with respect to chemical dependency, his or her reported level of incapacitation, and his or her status with respect to litigation and compensation.

Physical Examination

A neurological and musculoskeletal examination should be performed on all patients with chronic cervical spine pain. In a patient with a normal neurological examination, a musculoskeletal evaluation of the neck (including assessment of soft tissue hypersensitivity and range of motion) is often not especially revealing.[13] In particular, it is virtually impossible to identify a distinct pain generator on the basis of a physical examination of such patients. But some useful information can be gleaned from a musculoskeletal examination. First, the physician can determined the severity of the patient's functional limitations, especially restricted motion of the spine and pain-inhibited weakness of neck and extremity muscles. Second, the physician can check for hyperalgesia over muscles of the neck and shoulder girdle, as well as more widespread hyperalgesia involving remote sites. Third, the physician can determine whether the patient demonstrates significant apprehension and "nonorganic signs."[14,15] Research indicates that patients with nonorganic signs usually have significant somatic anxiety. This emotional distress may impair their recoveries, and may be a focus of treatment.

One caution about physical examination concerns the reliability of the assessment of factors such as range of motion. Evidence suggests that the inter-rater reliability of commonly performed physical examination tests is limited[16,17] and thus it is important to determine whether findings on a single examination are consistent with a patient's history, previous examination findings, and diagnostic tests.

Ancillary Studies

Although laboratory studies and electrodiagnostic evaluations are occasionally helpful in the assessment of chronic pain patients, imaging modalities are the procedures that are done the most frequently. There is significant controversy about how and when imaging should be done on chronic pain patients. When judged against guidelines, one-third to two-thirds of spinal CT and MRI imaging may be inappropriate,[18–20] High imaging rates can be problematic because irrelevant but alarming findings, including herniated discs, are common in asymptomatic people.[2,3,21] Without attempting to resolve these controversies in any systematic way, we suggest the following: (1) for chronic pain involving a trauma, it is reasonable to check for the possibility of a fracture or significant spinal instability using plain x-rays of the spine; (2) additional imaging is generally not needed for such a patient, however, if there is some clinical evidence of a neurologic injury, an MRI scan is generally indicated; and (3) CT scans and bone scans usually have a limited role—they can be obtained to identify an occult fracture or an inflamed facet joint.

Many controversies regarding ancillary studies arise in relation to patients with localized axial cervical spinal pain and no evidence of major skeletal trauma. The basis for the controversies is that some physicians believe that such pain can be ascribed to well-defined injuries to structures in the cervical spine, whereas other physicians are much more skeptical. The following discussion addresses issues related to three types of structural lesions that have been proposed to explain persistent axial pain.

Ligamentous Injuries. Some investigators have reported that ligamentous injuries play a significant role in whiplash injuries[22,23] and that the severity of self-reported disability among people with these injuries correlates with the severity of ligamentous injuries found on MRI scans. However, research on asymptomatic people[24,25] and ones with neck pain secondary to cervical spondylosis rather than injury[26] suggest that the MRI signals which some investigators have interpreted as indicators of ligamentous injuries should actually be considered normal variants or indicators of cervical degenerative disc disease.

Disc Pathology. Some investigators have advocated the use of cervical discography to identify painful intervertebral discs in the cervical spine.[27–29] The presence of an abnormal discogram, defined on the basis of some combination of the morphology of discs and the pain responses of a patient during the procedure, is viewed as an indication for a cervical spinal fusion.[30] However, the validity of using discography to determine that a disc is the pain generator for a patient with spinal pain has been questioned,[31] as have the results of spinal surgery based on abnormal discography.[32] See Chapter 100 for a detailed discussion of the utility of diagnostic discography.

Facet Joint Injury. Bogduk and colleagues[33–35] have asserted that facet joint injuries often underlie persistent cervical pain, and have pioneered techniques for identifying the structural basis of patients' reports of symptoms by careful application of injection procedures designed to provoke or palliate pain. Using these techniques, they have reported that approximately 70% of individuals with persistent neck pain following motor vehicle collisions have pain mediated by one or more of the cervical facet joints. Equally importantly, they have demonstrated that when patients diagnosed with facet-joint-mediated receive facet neurotomies designed to denervate the affected facet joint, approximately 70% experience prolonged symptom relief.[36,37] Although attempts to replicate these provocative results have met with only partial success,[38] the research by Bogduk and others strongly supports the conclusion that at least some individuals with persistent neck pain do have facet arthropathies.

It is beyond the scope of this chapter to review the controversies surrounding the value of discography, medial branch blocks, and ligament injuries diagnosed by MRI (see Chapter 97 for a detailed discussion). Instead, we will offer a few opinions that are consistent with those of leaders in the area of spine care. First, chronic pain patients with obvious concomitant psychological dysfunction or obvious markers of CNSS should not be referred for diagnostic procedures that rely on pain provocation and palliation.[32] Second, the interpretation of discography is so uncertain that we would not recommend it in any circumstance; however, leading experts continue to debate the utility of diagnostic discography. Third, there is research support for the use of medial branch blocks to detect facet arthropathies, combined with treatment of facet joint mediated pain by means of radiofrequency ablations of the appropriate medial branches.[36,37] We believe referral for medial branch blocks is appropriate for patients with chronic whiplash pain who continue to report symptoms despite conservative treatment and who have no evidence of either CNSS or significant psychological dysfunction. Finally, we do not recommend attempting to diagnose ligament injuries by means of MRI scans, in part because of questions about the validity of such diagnoses and in part because there is currently no widely accepted treatment for subtle ligament injuries diagnosed by MRI (as opposed to gross ligament injuries that cause instability).

Conclusion

The previous discussion addresses the medical evaluation of chronic pain within the context of patients with cervical spinal pain. Some of the examination steps and clinical decisions are broadly relevant to almost any patient with chronic pain. Others,

however, are specific to patients with this kind of condition. We have gone into some detail in order to make the point that medical decision-making in relation to cervical spine pain is far from simple. It is our opinion that in order for pain patients to participate fully in evaluations of nonmedical factors contributing to their pain, they need to be confident that their problem has been evaluated thoroughly from a medical perspective. Thus, it is important for physicians participating in a multidisciplinary team either to have a lot of expertise in medical aspects of the problems that afflict their patients, or to consult with colleagues who have this expertise.

ASSESSMENT OF CENTRAL NERVOUS SYSTEM SENSITIZATION

During the past 20 years, CNSS has emerged as an important phenomenon in chronic pain.[39,40] Early research on nonhumans demonstrated that CNSS was associated with characteristic changes in the behavior of dorsal horn neurons in the spinal cord, including a lowered response threshold and an expansion of receptive fields.[41] Expansion of receptive fields was postulated to correlate with referral of pain, and lowered response threshold with hyperalgesia.[42,43] It is beyond the scope of this chapter to discuss the vast literature on central and peripheral nervous system sensitization.

Research indicates that people with chronic pain demonstrate reduced thresholds to multiple modalities of sensory stimulation, including pressure, thermal, and electrical stimuli.[44,45] These abnormalities occur when stimuli are applied to the specific location of the reported pain and even to body regions where patients do not experience clinical pain. Other research has shown that withdrawal reflexes can be elicited among chronic pain patients at lower stimulus intensities than the ones required to elicit the reflexes in healthy people. These findings have been interpreted by several researchers as evidence of CNSS among people with persistent pain[42] and as a central feature in the development of neuropathic pain.[40]

Although these proposals have not been conclusively proven, the widespread belief among many neuroscientists and pain specialists that CNSS is a major factor in chronic pain has implications for the evaluation and treatment of the condition. Practitioners who treat chronic pain patients need to be aware that CNSS may be playing a role in the reports of their patients. Also, they should be aware that many of the inferential rules followed by physicians when they interpret reports of pain are based on a simple model of an isomorphic correspondence between symptoms and dysfunction of tissues (nerves, joints, periarticular tissues, muscles) in the region where the patient indicates pain. The inferential rules are simply not valid when CNSS has occurred. For example, stocking glove numbness has long been considered a nonphysiologic complaint, but it can logically be interpreted as a result of CNSS.[46] Finally, to the extent that persistent chronic pain is mediated by altered nervous system responsivity rather than by ongoing nociceptive input from specific body locations, there is no reason to expect a one-to-one relation between symptoms and a definable structural lesion.

Given the potential importance of CNSS in the symptoms and functional limitations of pain patients, it would be highly desirable to have sensitive and specific tests to determine whether it is occurring in individual patients. Unfortunately, no such definitive assessment tools exist. In this regard, it is important to note that the original research demonstrating CNSS was performed on animals, and that the determination of whether CNSS had developed was made via microelectrode recordings from the dorsal horn of the spinal cord or other CNS structures. For obvious ethical reasons, these invasive procedures are not performed on humans. In the absence of data from direct monitoring of the CNS, investigators of pain in humans have, as noted previously, relied on analogies between clinical phenomena in patients and phenomena demonstrated in animal research. In particular, widespread soft tissue hyperalgesia is considered an indicator of CNSS.[47,48]

The existence of CNSS complicates our understanding of chronic pain, and the process of assessing individuals who report persistent symptoms. At a conceptual level, CNSS challenges the simple dichotomy between organic pain and psychogenic pain that held sway in the orthopedic literature of a generation ago.[10] At the level of clinical evaluation of an individual patient, the absence of definitive tests to determine the presence of CNSS makes it difficult for a clinician to rule in or out the hypothesis that it is affecting symptoms. The ambiguity introduced by CNSS is increased by the fact that although it is usually identified in the context of an examination by a physician, it is not a medical diagnosis in the usual sense. For example, the *International Classification of Disease*, 10th edition, does not include any codes that can be used to designate that a patient's pain is a reflection of CNSS. Also, no clear delineation has been drawn between CNSS versus psychological factors as a cause of persistent symptoms. The evaluation of CNSS is given a separate section in this chapter because of its ambiguous middle ground status between traditional medical processes and psychological processes.

ASSESSMENT OF PSYCHOLOGICAL FACTORS

A comprehensive psychological evaluation of a pain patient is a fundamental component of a multidisciplinary evaluation. It addresses the specific psychosocial, behavioral, and cognitive factors such as current mood (anxiety, depression, anger), interpretation of the symptoms, expectations about the meaning of symptoms, and the responses to the patient's symptoms by significant others (e.g., family members, coworkers), each of which contributes to the subjective experience of pain. This type of information should be included in the development of a comprehensive treatment plan.

Psychological Factors as Causes versus Consequences of Chronic Pain

Psychological Factors as Causal Agents in Development of Chronic Pain

Patients often resist psychological evaluations, because they intuitively sense that the outcome of such evaluations might be the conclusion that their pain is a result of psychological dysfunction rather than the injury to which they attribute their symptoms. Indeed, early reports suggested that pre-existing psychopathology or neurotic traits might be the underlying mechanisms for unremitting chronic pain.[49,50] As early as 1953, Gay and Abbot[49] mentioned "neurotic reactions" noting that particular psychological factors predisposed an individual to chronic problems after an injury. In 1982, Blumer and Heilbronn[51] postulated that patients with chronic symptoms had a distinct personality type that predisposed them to developing chronic pain—"pain-prone personality." They specifically suggested that persistent symptoms offered a solution for their pre-existing neurosis. There has been little empirical support indicating that the majority of chronic pain patients manifest character traits comprising a common and unique disposition.[52] However, some studies have noted the high lifetime prevalence of psychiatric diagnoses observed in chronic pain patients[53] and prospective studies that followed healthy individuals who subsequently develop back pain[21] and from acute injuries to the presence of disabling pain[54] have observed that premorbid psychological factors were the best predictor of persistent pain chronicity.

Psychological Consequences of Chronic Pain

Psychological symptoms following the onset of pain have also been thoroughly documented. Acute and long-lasting psychological symptoms following symptom onset are prevalent.[55,56] Disabling emotional symptoms have been observed in as many as 59% of people following initial pain onset.[53]

A number of studies have implicated the role of the patient's idiosyncratic appraisals of his or her symptoms, expectations regarding the cause of the symptoms, and the meaning of the symptoms, in addition to organic factors, as essential in understanding the individual's report of pain and subsequent disability.[21,57–59] Moreover, the patient's current mood, ways of coping with symptoms, and responses by significant others including physicians may modulate the experience of pain, particularly chronic or recurrent pain.[60,61] Failure to address these factors can result in poor response to treatments that focus exclusively on somatic causes.

The results of many studies implicate psychological symptoms as *concomitants* rather than *precursors* to chronic symptoms after chronic pain.[62] Initial reaction to an injury, rather than the pre-existing psychological status, has been shown to predict chronicity.[63,64] It seems reasonable that pre-existing psychological status may predispose *some* individuals to chronic emotional disturbances following an injury. For example, acute emotional distress has been shown to be related to pain severity one month following a motor vehicle collision.[65] The correct answer is probably somewhere in the middle where pre-existing psychological disturbances, immediate emotional reaction, coupled with medical complications contribute to chronicity of pain, at least for some people. In either case, these studies underscore the importance of evaluating psychological factors for all chronic pain patients.

Elements of the Psychological Evaluation

Table 23.1 contains a brief set of salient issues with the acronym ACT-UP (Activity, Coping, Think, Upset, People's responses) that can be used as a guide for interviewing patients who report persistent or recurring symptoms. Generally, a referral for evaluation may be indicated where disability greatly exceeds what would be expected based on physical findings alone, when patients make excessive demands on the health care system, when the patient persists in seeking medical tests and treatments when these are not indicated, when patients display significant emotional distress (e.g., depression or anxiety), or when the patient displays evidence of addictive behaviors or continual nonadherence to the prescribed regimen. Table 23.2 contains a detailed outline of the areas that should be addressed in a more extensive psychological interview for pain patients.

TABLE 23.1

BRIEF PSYCHOSOCIAL SCREENING: ACT-UP

Activities: How is your pain affecting your life (i.e., sleep, appetite, physical activities, relationships)?

Coping: How do you deal/cope with your pain (what makes it better/worse)?

Think: Do you think your pain will ever get better?

Upset: Have you been feeling worried (anxious)/depressed (down, blue)?

People: How do people respond when you have pain?

Interviews

A psychological interview with chronic pain patients is typically semi-structured. A structured format of psychiatric interview[66] can be incorporated as a tool to examine psychopathology. However, a psychological interview with pain patients needs to go beyond an assessment of psychopathology, since its main purpose is to assess a wide range of psychosocial factors (not just psychopathology) related to a patient's symptoms and disability.

When conducting an interview with chronic pain patients the health care professional should focus not only on gathering information provided by the patient, but also on observing patients' pain behaviors and the manner in which they convey information. We discuss some specific measures that have been proposed to systematically assess pain behaviors later.

Chronic pain patients' beliefs about the cause of symptoms, their trajectory, and beneficial treatments will have important influences on emotional adjustment and adherence to therapeutic interventions. A habitual pattern of maladaptive thoughts may contribute to a sense of hopelessness, dysphoria, and unwillingness to engage in activity. These reactions, in turn, deactivate the patient and severely limit his or her physical and emotional adaptation. The interviewer should also determine both the patient's and the significant others' expectancies and goals for treatment. An expectation that pain will be eliminated completely may be unrealistic and will have to be addressed to prevent discouragement when this outcome does not occur. Setting appropriate and realistic goals is an important process in pain rehabilitation as it requires the patient to attain better understanding of chronic pain and goes beyond the dualistic, traditional medical model.

In order to help chronic pain patients understand the psychosocial aspects of pain, attention should focus on the patients' reports of specific thoughts, behaviors, emotions, and physiological responses that precede, accompany, and follow pain episodes or exacerbation, as well as the environmental conditions and consequences associated with cognitive, emotional, and behavioral responses in these situations. During the interview, the clinician should attend to the temporal association of these cognitive, affective, and behavioral events; their specificity versus generality across situations; and the frequency of their occurrence, to establish salient features of the target situations, including the controlling variables. The interviewer seeks information that will assist in the development of potential alternate responses, appropriate goals for the patient, and possible reinforcers for these alternatives.

Patients with chronic pain problems often consume a variety of medications. It is important to discuss a patient's medications during the interview, as many pain medications (particularly opioids) are associated with side effects that may mimic emotional distress. A clinician, for example, should be familiar with side effects that result in fatigue, sleep difficulties, and mood changes to avoid misdiagnosis of depression. A general understanding of commonly used medications for chronic pain is important, as some patients also may use opioid analgesics to manage mood. During the interview potential psychological dependence and aberrant drug seeking behaviors on pain-relieving medications should be evaluated. In some states, a physician is able to obtain a record of prescriptions of controlled substances. When in doubt, a psychologist may recommend that such a record be obtained and request urine toxicology screening to rule out substance abuse problems (including diversion) and aberrant opioid taking behaviors.[67]

Self-Report Inventories

In addition to interviews, a number of assessment instruments designed to evaluate patients' attitudes, beliefs, and expectancies about themselves, their symptoms, and the health care system

TABLE 23.2

AREAS ADDRESSED IN PSYCHOLOGICAL INTERVIEWS

Experience of pain and related symptoms
- Location and description of pain (e.g., "sharp," "burning")
- Onset and progression
- Perception of cause (e.g., trauma, virus, stress)
- What has the patient been told about the symptoms and condition? Does the patient believe that this information is accurate?
- Exacerbating and relieving factors (e.g., exercise, relaxation, stress, massage)
- Pattern of symptoms (e.g., worse certain times of day or following activity or stress)
- Sleep habits (e.g., difficulty falling to sleep or maintaining sleep, sleep hygiene)
- Thoughts, feelings, and behaviors that precede, accompany, and follow fluctuations in symptoms

Treatments received and currently receiving
- Medication (prescribed and over-the-counter). How helpful have these been?
- Pattern of medication use (*prn*, time-contingent), changes in quantity or schedule
- Physical modalities (e.g., physical therapy). How helpful have these been?
- Exercise (e.g., Do they participate in a regular exercise routine? Is there evidence of deactivation and avoidance of activity due to fear of pain or exacerbation of injury?). Has the pattern changed (increased, decreased)?
- Complementary and alternative (e.g., chiropractic manipulation, relaxation training). How helpful have these been?
- Which treatments have they found the most helpful?
- Compliance (adherence) with recommendations of health care providers.
- Attitudes toward previous health care providers

Compensation and litigation
- Current disability status (e.g., receiving or seeking disability, amount, percent of former job income, expected duration of support)
- Current or planned litigation

Responses by patient and significant others
- Typical daily routine
- Changes in activities and responsibilities (both voluntary and obligatory) due to symptoms
- Changes in significant other's activities and responsibilities due to patient's symptoms
- Patient's behavior when pain increases or flares up
- Significant others' responses to behavioral expressions of pain
- What does the patient do when pain is not bothering him or her (uptime activities)?
- Significant other's response when patient is active
- Impact of symptoms on interpersonal, family, marital, and sexual relations (e.g., changes in desire, frequency, or enjoyment)
- Activities that patient avoids because of symptoms
- Activities continued despite symptoms
- Pattern of activity and pacing of activity (can use activity diaries that ask patients to record their pattern of daily activities [e.g., sitting, standing, walking] for several days or weeks)

Coping
- How does the patient try to cope with his or her symptoms? Does patient view himself or herself as having any role in symptom management? If so, what role?
- Current life stresses
- Pleasant activities

Educational and vocational history
- Level of education completed, including any special training
- Work history
- How long at most recent job?
- How satisfied with most recent job and supervisor?
- What like least about most recent job?
- Would the patient like to return to most recent job? If not what type of work would the patient like?
- Current work status, including homemaking activities
- Vocational and avocational plans

(*continued*)

TABLE 23.2

CONTINUED

Social history
- Relationships with family or origin
- History of pain or disability in family members
- History of substance abuse in family members
- History of or current, physical, emotional, and sexual abuse. Was the patient a witness to abuse of someone else?
- Marital history and current status
- Quality of current marital and family relations

Alcohol and substance use
- Current and history of alcohol use (quantity, frequency)
- History and current use of illicit psychoactive drugs
- History and current use of prescribed psychoactive medications
- Consider the CAGE questions as a quick screen for alcohol dependence (Mayfield, McLeod, & Hall, 1974). Depending on response consider other instruments for alcohol and substance abuse (Allen & Litten, 1998).

Psychological dysfunction
- Current psychological symptoms/diagnosis (depression including suicidal ideation, anxiety disorders, somatization, posttraumatic stress disorder). Depending on responses, consider conducting structured interview such as the Structured Clinical Interview for DSM-IV-TR (SCID) (American Psychiatric Association, 1997).
- Is the patient currently receiving treatment for psychological symptoms? If yes, what treatments (e.g., psychotherapy or psychiatric medications). How helpful are the treatments?
- History of psychiatric disorders and treatment including family counseling
- Family history of psychiatric disorders

Concerns and expectations
- Patient concerns/fears
- Explanatory models of pain held by the patient
- Expectations regarding the future and treatment (will get better, worse, never change)
- Attitude toward rehabilitation versus "cure"

Treatment goals

Adapted from Mayfield, McLeod, & Hall, 1974; Allen & Litten, 1998; and American Psychiatric Association, 1997.

have been developed and published. One survey[68] of clinicians who treated pain indicated that the five most frequently used instruments in the assessment of pain, in order of frequency, were: the McGill Pain Questionnaire,[69,69a] Beck Depression Inventory (BDI),[70,71] Multidimensional Pain Inventory,[72] Coping Strategies Questionnaire,[73] and the Oswestry Low Back Pain Questionnaire.[74]

Standardized instruments have advantages over semi-structured and unstructured interviews. They are easy to administer, require less time, assess a wide range of behaviors, obtain information about behaviors that may be private (sexual relations) or unobservable (thoughts, emotional arousal), and, most importantly, they can be submitted to analyses that permit determination of their reliability and validity. These instruments should not be viewed as alternatives to interviews; rather, they may suggest issues to be addressed in more depth during an interview or investigated with other measures.

There is an important caveat when interpreting the results of self-report inventories. Studies of the psychometric properties of self-report inventories typically involve data collection from a large number of patients. As reliability estimates are influenced by sample size, it follows that the measurement error of questionnaire data from one person should be expected to be much greater than that found in reports based on group data. One way to address concerns about reliability with some measures is to collect data at multiple points over time rather than simply comparing pretreatment and posttreatment data.

Problem Areas to Assess

Assessment of Emotional Distress

The results of numerous studies suggest that chronic pain is often associated with emotional distress, particularly depression, anxiety, anger, and irritability. The presence of emotional distress in people with chronic pain presents a challenge when assessing symptoms such as fatigue, reduced activity level, decreased libido, appetite change, sleep disturbance, weight gain or loss, and memory and concentration deficits. These symptoms are often associated with pain and have also been considered "vegetative" symptoms of depressive disorders. Improvements or deterioration in such symptoms, therefore, can be a result of changes in either pain or emotional distress.

Both the BDI and BDI-2[70,71] and the Profile of Mood States[75] have well-established reliability and validity in the assessment of symptoms of depression and emotional distress, and they have been used in numerous clinical trials in psychiatry and an increasing number of studies of patients with chronic pain.[76] In research in psychiatry and chronic pain, the BDI provides a well-accepted

criterion of the level of psychological distress in a sample and its response to treatment. The Profile of Mood States (POMS)[75] assesses six mood states—tension-anxiety, depression-dejection, anger-hostility, vigor-activity, fatigue-inertia, and confusion-bewilderment—and also provides a summary measure of total mood disturbance. Although the discriminant validity of the POMS scales in patients with chronic pain has not been adequately documented, it has scales for the three most important dimensions of emotional functioning in chronic pain patients (depression, anxiety, and anger) and also assesses three other dimensions that are very relevant to chronic pain and its treatment, including a positive mood scale of vigor-activity. Moreover, the POMS has demonstrated beneficial effects of treatment in some (but not all) recent chronic pain trials.[77,78] For these reasons, administration of the BDI and the POMS are reasonable choices as brief measures of emotional distress.

As noted previously, various symptoms of depression—such as decreased libido, appetite or weight changes, fatigue, and memory and concentration deficits—are also commonly believed to be consequences of chronic pain and the medications used for its treatment.[79] It is unclear whether the presence of such symptoms in patients with chronic pain (and other medical disorders) should nevertheless be considered evidence of depressed mood, or whether the assessment of mood in these patients should emphasize symptoms that are less likely to be secondary to physical disorders.[80]

Assessment of Fear. Many patients with chronic pain, especially those who attribute their symptoms to trauma, are fearful of engaging in activities that they believe may either contribute to further injury or exacerbate their symptoms. Avoidance of activities may, in the short term, lead to symptom reduction. But over time restriction of activities is likely to lead to decreased functional capacities as a result of deconditioning. Also, avoidance of activity has the unfortunate consequence of preventing corrective feedback. Health care providers may inadvertently contribute to avoidance of activity by providing patients with cervical collars that restrict neck movements and advising them to avoid activities that hurt (i.e., hurt = harm). They may contribute to the patient's anxiety that something is seriously wrong with their bodies by continuing to order sophisticated diagnostic tests in search of occult physical pathology.

Assessment of Coping and Psychosocial Adaptation to Pain. Historically, psychological measures designed to evaluate psychopathology have been used to identify specific individual differences associated with reports of pain, even though these measures were usually not developed for or standardized on samples of medical patients. However, it is possible that responses by medical patients may be distorted as a function of the disease or the medications that they take. For example, common measures of depression ask patients about their appetites, sleep patterns, and fatigue. Because disease status and medication can affect responses to such items, patients' scores may be elevated, thereby distorting the meaning of their responses. As a result, a number of measures have been developed for use specifically with pain patients. Instruments have been developed to assess psychological distress, the impact of pain on patients' lives, feeling of control, coping behaviors, and attitudes about disease, pain, and health care providers and the patient's plight.[81]

Assessment of Pain

Although all members of a multidisciplinary assessment team ask questions about pain when they evaluate a patient, the psychologist typically delves into this area in more depth than physicians or other members of a multidisciplinary evaluation team. Psychologists typically rely on a variety of tools to assess the pain experiences of patients, and consider several dimensions of these experiences.

Pain Intensity. Self-report measures of pain often ask patients to quantify their pain by providing a single, general rating of pain: "Is your usual level of pain 'mild,' 'moderate,' or 'severe'?" or "Rate your typical pain on a scale from 0 to 10 where 0 equals no pain and 10 is the worst pain you can imagine." There are a number of simple methods that can be used to evaluate current pain intensity—numerical scale (NRS), verbal ratings scales (VRS), and visual analog scales (VAS).

Each of the commonly used methods of rating pain intensity, NRS, VRS, and VAS, appear sufficiently reliable and valid and no one method consistently demonstrates greater responsiveness in detecting improvements associated with pain treatment.[82] However, there are important differences among NRS, VRS, and VAS measures of pain intensity with respect to missing data stemming from failure to complete the measure, patient preference, ease of data recording, and ability to administer the measure by telephone or with electronic diaries. NRS and VRS measures tend to be preferred over VAS measures by patients, and VAS measures usually demonstrate more missing data than do NRS measures. Greater difficulty completing VAS measures is associated with increased age and greater opioid intake, and cognitive impairment has been shown to be associated with inability to complete NRS ratings of pain intensity.[82] Patients who are unable to complete NRS ratings may be able to complete VRS pain ratings (e.g., none, mild, moderate, severe). Other measures are available to assess pain in children and those who are unable to verbally communicate (e.g., stroke patients, mentally-impaired).[83]

There has been some concern expressed that retrospective reports may not be valid, as they may reflect current pain severity that serves as an anchor for recall of pain severity over some interval.[84,85] More valid information may be obtained by asking about current level of pain, pain over the past week, worst pain of the last week, and lowest level of severity over the last week. This has also led to the use of daily diaries that are believed to be more accurate as they are based on real-time rather than recall. For example, patients are asked to maintain regular diaries of pain intensity with ratings recorded several times each day (e.g., at meals and bedtime) for several days or weeks. One problem noted with the use of paper-and-pencil diaries is that patients may not follow the instruction to provide ratings at specified intervals. Rather, patients may complete diaries in advance ("fill forward") or shortly before seeing a clinician ("fill backward").[86] These two reporting approaches undermine the putative validity of diaries. As an alternative to the paper-and-pencil diaries, a number of commentators have advocated for the use of electronic devices that can prompt patients for ratings and "time stamp" the actual ratings, thus facilitating real-time data capture. Although there are numerous advantages to the use of advanced technology to improve the validity of patient ratings, they are not without potential problems, including hardware problems, software problems, and user problems.[87] These methods are also costly and, although they may be appropriate for research studies, their usefulness in clinical settings may be limited.

Pain Quality. Pain is known to have different sensory and affective qualities in addition to its intensity, and measures of these components of pain may be used to more fully describe an individual's pain experience.[88] It is possible that the efficacy of pain treatments varies for different pain qualities, and measures of pain quality may therefore identify treatments that are efficacious for certain types of pain but not for overall pain intensity. Assessment of specific pain qualities at baseline also makes it possible to determine whether certain patterns of pain quality moderate the effects of treatment. The Short-Form McGill Pain Questionnaire[69a] assesses 15 sensory and affective pain descriptors and its sensory and affective subscales have demonstrated responsivity to treatment in a number of clinical trials.[77,78]

Pain Modifiers. For the majority of people with chronic pain, pain severity varies. Thus, it is useful to inquire as to what the patient believes makes his or her pain worse. For example, are their specific activities that result in increase in symptoms? Are their certain circumstances that contribute to exacerbation of pain such as stress including interpersonal conflicts? Does pain vary with time of day? For example, does the patient notice that his or her pain is worse in the morning or later in the day? In the same way it is important to identify factors that magnify or initiate pain episodes, it is important to ask about what factors result in reductions of pain. For example, do medication, rest, heat or cold, distraction, or exercise result in reductions of pain severity or even elimination of symptoms for some period.

Assessment of Overt Expressions of Pain

As noted previously, patients display a broad range of responses that communicate to others that they are experiencing pain, distress, and suffering. Some of these pain behaviors may be controllable by the person, whereas others are not. Informally, a health care provider can observe patients' behaviors during their interviews and examinations. It is useful to observe patients in multiple contexts when possible. When patients know they are being observed and are presenting information to a healthcare provider they may use behavior to convey information in ways most likely to support the impact of their symptoms. They may feel a need to convince the health care provider of the severity of their symptoms, functional limitations, and distress. Thus, observation of the patient in the waiting room, when ambulating to the examination room, and when departing may allow the clinician to establish the stability and consistency of pain behaviors. We have also found it useful to observe patients in the presence of a significant other to note differences in behaviors when the significant other is present and absent and also how the significant other responds to the patient's pain behaviors.

A number of different observational procedures have been developed to identify and quantify pain behaviors. Structured methods that require patients to engage in a set of behaviors during which their behavior is observed and rated have been proposed by Keefe and colleagues.[89,90] Such structured approaches may be useful in research studies but can be cumbersome in clinical settings. Several investigators have developed observational Pain Behavior Checklists[91,92] that can be used in any setting. Although they have the advantage of efficiency, these methods may be less appropriate to compare among patients who are viewed in different contexts (e.g., during a physical examination or interview). The context may influence the behaviors observed. For example, the nature of pain behaviors observed might be quite different during a stressful physical examination compared to an interview. The number and nature of pain behaviors might be influenced by the presence of significant others during the observation period. At a minimum it is important to note the context in which the behaviors were observed. Studies using pain behavior checklists have found a significant association between these self-reports and behavioral observations. A variant of this observational procedure was developed by Kerns et al.[92a] who developed a self-report version in which patients endorsed specific behaviors that they engaged in when they were experiencing pain.

Uses of the health care system and analgesic medication are other ways to assess pain behaviors. Patients can record the times when they take medication over a specified interval such as a week. Diaries not only provide information about the frequency and quantity of medication but may also permit identification of the antecedent and consequent events of medication use. Antecedent events might include stress, boredom, or activity. Examination of antecedents is useful in identifying patterns of medication use that may be associated with factors other than pain per se. Similarly, patterns of response to the use of analgesic, may be identified. Does the patient receive attention and sympathy whenever he or she is observed by significant others taking medication? That is, do significant others provide positive reinforcement for the taking of analgesic medication and thereby unwittingly increase medication use?

ASSESSMENT OF SOCIAL FACTORS

Social factors are construed as factors in the social environment that influence people independent of their individual psychological characteristics. A good example is the receipt of workers' compensation benefits. There is good evidence that injured workers respond less well to a variety of treatments than individuals with similar medical conditions who do not have workers' compensation claims.[93,94] Although participation in the workers' compensation system exerts its negative influence through effects on the perceptions, goals, and attitudes of injured workers, the influence appears to be robust and not dependent on any particular psychological characteristics of the affected individuals.

Social factors include demographic variables that influence the presentation and clinical course of people with painful conditions. In particular, research indicates that an individual's clinical presentation is associated with his or her age, gender, ethnicity,[95,96] and education level.[97,98]

The social factors that have attracted the most research attention in relation to chronic pain are participation in litigation and participation in a workers' compensation system.[94,99] A significant proportion of individuals involved in injuries file personal injury claims. Research on the relation between litigation and clinical course, however, has been contradictory. For example, whereas several recent studies have reported a negative effect of attorney involvement and litigation on recovery from whiplash disorders,[100,101] Scholten-Peeters et al.[102] concluded in a comprehensive review that "often mentioned factors like age, gender, and compensation do not seem to be of prognostic value" in relation to the clinical course. It is beyond the scope of this chapter to review the often contentious literature on the effect of litigation/attorney involvement on outcomes of chronic pain.[103–107] Our interpretation of this literature is that it does, on balance, support the hypothesis that attorney involvement and participation in litigation is a negative prognostic factor for individuals with pain associated with physical injury. There is also evidence that injured workers with workers' compensation claims respond poorly to a variety of treatments compared to individuals with the same medical conditions, but without workers' compensation claims.[94]

Important social factors also include influences from an individual's immediate social environment. For example, there is good evidence that pain patients generally demonstrate more dramatic pain behaviors when they are in the presence of solicitous spouses.[108]

In multidisciplinary evaluations, social factors are usually evaluated by a psychologist. The evaluation of some social factors is straightforward. These include demographic variables, compensation status, and litigation status. The assessment of influences in a patient's immediate social environment is more difficult, but psychologists typically attempt to determine how a patient communicates his or her pain to significant others, and how the significant others respond to these cues.

ASSESSING FUNCTIONAL IMPACT

A major focus of the discussion above has been on the identification of factors underlying the symptoms of a chronic pain patient. It is important to note, though, that the identification of factors that qualitatively play a role in a patient's symptoms is not the same as an explanation of the severity of these symptoms, or

the extent to which the patient is disabled by them. Thus, we recommend that an evaluation of any chronic pain patient should include an assessment of the extent to which the patient is affected by his or her symptoms. When a multidisciplinary evaluation is done, physical therapists, vocational rehabilitation counselors, physicians, and psychologists may participate in the evaluation of function among pain patients.

Conceptually, the impact of chronic pain on function can be subdivided into: (1) the ability of patients to function in the sense of performing activities of daily living; (2) their physical capacities as demonstrated in a structured setting; and (3) their ability to function in adult roles such as work.

Self-Report Measures of Function

Self-report measures have been developed to assess people's reports of their abilities to engage in a range of functional activities such as the ability to walk up stairs, to sit for specific periods of time, the ability to lift specific weights, perform activities of daily living, as well as the severity of the pain experienced upon the performance of these activities.[109] There are a number of well-established, psychometrically supported generic (e.g., Short-Form 36[110]), pain-specific (e.g., Brief Pain Questionnaire Interference Scale[111]; Pain Disability Index[112]; MPI Interference Scale[72]), and back-pain specific (Oswestry Low Back Pain Disability Questionnaire[74]) measures of functional status.

The Oswestry Disability Index is a 10-item scale that asks patients about disability associated with back pain.[74] It has the advantage of being a disease-specific instrument. In general, disease-specific measures are designed to evaluate the specific effects of a disorder that may not be assessed by a generic measure.[113] In addition, responses on disease-specific measures will generally reflect the effects of comorbid conditions on physical functioning, which may confound the interpretation of change occurring over the course of a trial when generic measures are used. Disease-specific measures may be more sensitive to the effects of treatment on function, but generic measures provide information about physical functioning and treatment benefits that can be compared across different conditions and studies.[113,114] Each of these approaches has strengths. Decisions regarding whether to use a disease-specific or a generic measure, or some combination, will depend on the purpose of the assessment. For individual patients in clinical practice it would be most appropriate to use measures developed on samples with comparable characteristics. If the clinician wishes to compare across a group of patients, then one of the broader-based pain-specific measures should be considered. If the assessment is being performed as part of a research study, some combination might be appropriate to compare chronic pain samples with a larger population of people with diverse medical diseases (e.g., SF-36).

The physical capacities of pain patients are typically assessed by physical and occupational therapists. In some clinical settings, evaluation protocols are developed informally by individual therapists, sometimes in conjunction with a physician. In other settings, formal assessment protocols are used. Although the validity of such protocols has been questioned,[115,116] they are frequently used—particularly when injured workers are being evaluated. The purpose of such evaluations is to obtain objective information about the capabilities of patients. In clinical settings, this information is used in the planning of rehabilitative treatment. In more adversarial settings (e.g., workers' compensation), physical capacities data are used when adjudicative decisions about claims are made.

Ideally, a multidisciplinary evaluation would include having a vocational rehabilitation counselor perform a comprehensive evaluation of the work status of pain patients, and their potential for vocational rehabilitation. In many situations, though, the job of assessing vocational disability falls on the physician or psychologist on the multidisciplinary team. We are not aware of standardized instruments to assess the vocational status of pain patients. In the absence of a standard instrument, we recommend that clinicians assessing these patients address the following issues: (1) Is the patient currently working? (2) If the patient is not working, is this related to his or her health? (3) How long has the patient been out of the workforce? (4) Is he or she receiving any kind of work disability benefits? Which ones?

ORGANIZATION OF MULTIDISCIPLINARY EVALUATIONS

As discussed previously, the professionals who might participate in multidisciplinary evaluations include physicians, psychologists, vocational rehabilitation counselors, physical and occupations therapists, and perhaps other professionals. An obvious question is: How do these professionals orchestrate their evaluations and communicate with each other?

The model that has received the most attention in research literature has been multidisciplinary intensive pain rehabilitation.[117] In the United States, the multidisciplinary pain centers and functional restoration programs that provided intensive pain rehabilitation began in the late 1960s, flourished during the 1980s and early 1990s, and more recently have been in decline.[118]

Given the decline in intensive pain rehabilitation programs, it will probably be necessary in the future for professionals involved in the evaluation of patients with chronic pain to develop a number of informal strategies for working together. There are almost certainly a variety of models that can succeed. The key issue is for professionals to work together in acquiring data on the multiple dimensions that affect chronic pain patients, and to communicate with each other so that the patients benefit from the data that are gathered.

CONCLUSION

Pain and associated symptoms are the results of a complex interplay of factors. Assessment and treatment of chronic pain can be complicated by the web of influential factors that modulate the overall pain experience and associated disability. Furthermore, traditional biomedical approaches with diagnostic tests are often not helpful because structural damage and persistent pain complaints do not necessarily coincide. Pain research in the last three decades has repeatedly shown that pain is not just a physiological phenomenon, and that a range of "person variables," such as psychosocial, environmental, and behavioral factors, play a significant role in determining the occurrence, severity, and quality of pain. Given the multifactorial nature of chronic pain, adequate assessment requires an interdisciplinary team approach. In this chapter, we discussed the assessment of medical factors, altered CNS processing, psychological factors, and social factors in patients with chronic pain. We introduced a number of self-report inventories that can be used in conjunction with interviews and medical examinations. As we have repeatedly stressed, an adequate assessment of patients with chronic pain means the evaluation of the person with the symptoms. We must not just focus on the pathology or symptom report, but must reach out to understand the person and his or her well-being. Although there is no shortcut in this, the delineation of relevant medical, psychosocial, and behavioral factors contributing to pain in a patient are critical in planning and executing a successful treatment plan.

ACKNOWLEDGMENT

Preparation of this chapter was supported by a grant from the National Institutes of Health/ National Institute of Arthritis and Musculoskeletal and Skin Disorders (R01AR044724).

CHAPTER 24 ■ PAINFUL NEUROPATHIES

DAVID WALK AND MISHA-MIROSLAV BACKONJA

PAIN AS A SYMPTOM OF NEUROPATHY

Neuropathy is a common clinical problem. Pain merits attention in any discussion of neuropathy for several reasons. First, insofar as pain varies among neuropathy etiologies, the presence, absence, and type of pain when present can contribute to the diagnostic process. Second, for many people with neuropathy, pain is the chief complaint and the only cause of disability. The traditional neurological focus on deficits rather than positive sensory phenomena does not serve these patients well. Finally, and perhaps most importantly, pain is a neurological symptom. The study of pain due to nerve dysfunction is providing important insights into the function of the nervous system, as has the study of other neurologic symptoms in the past.

THE EVALUATION AND DIAGNOSIS OF NEUROPATHY

Neuropathy Classification

The approach to the diagnosis of neuropathy is fully covered in textbooks devoted to this topic.[1,2] The present section is a conceptual overview to allow readers unfamiliar with neuromuscular practice to better understand the balance of this chapter. Throughout this section, specific neuropathies will be named for the purpose of illustration only. More comprehensive and detailed information about specific types of neuropathy can be can be found later in this chapter under "Painful Neuropathies."

The four principal questions to address in the etiologic classification of neuropathy are the *time course* of symptoms, the *distribution* of neuropathy symptoms and signs, the *modalities* affected (motor, small fiber sensory, large fiber sensory, and autonomic), and the primary *locus of pathology* (axon or myelin). Answers to these four questions will narrow the differential diagnosis substantially.

Time course is self-explanatory. Many common neuropathies, particularly those due to metabolic or genetic conditions, progress insidiously and at a regular pace over years. Some, such as chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), can progress over a period of weeks to months, and often with unpredictable relapses or remissions. Relatively few neuropathies present with florid findings over a matter of days to weeks; among these are Guillain-Barre syndrome (which progresses rapidly in a predictable fashion to a nadir within 2 to 4 weeks), toxic neuropathies (which can present rapidly upon neurotoxin exposure and commonly progress in a predictable fashion until days, weeks, or even months after removal of the cause), and necrotizing peripheral nerve vasculitis (which usually progresses in a stepwise fashion over days to weeks until effective therapy is instituted).

The *distribution of neuropathy symptoms and signs* can be identified by the history and confirmed by the examination and electrophysiological studies. Most neuropathies conform to one of three patterns: symmetric, length dependent; asymmetric, nonlength dependent; and multifocal. The symmetric, length dependent pattern begins with symptoms in both feet and progresses rostrally in a symmetric fashion. The pattern and rate of change are uniform. Symptoms usually do not appear in the hands until lower limb symptoms have progressed to the proximal calves or thighs. Symptoms appear last in the trunk and face. The term *length dependent* refers to the fact that nerve dysfunction in these patients begins in the longest axons and progresses rostrally. The implication vis-à-vis pathophysiology is that all nerves are exposed in equal measure to a systemic stressor, and that the effect of this stressor on nerve function is closely correlated to the distance of the nerve terminal from the cell body. Many metabolic, toxic, and genetic disorders of nerve present in a symmetric, length-dependent pattern. Asymmetric, nonlength-dependent neuropathies are widespread but can affect proximal and distal nerve segments concomitantly and do not present in a symmetric fashion. CIDP typically demonstrates this distribution. Multifocal neuropathies affect individual named nerves or nerve trunks, often with a stepwise progression. Necrotizing vasculitis, granulomatous disorders, hereditary neuropathy with liability to pressure palsies (HNPP), and lymphomatous infiltration are examples of conditions that can present in this fashion. When a sufficient number of nerves are affected, multifocal neuropathies become confluent and are thereby transformed into the asymmetric, nonlength dependent pattern.

The *modalities affected* refers to motor axons, large fiber (Aβ myelinated) sensory axons, small fiber (A∂ and C) sensory axons, and autonomic (cardiorespiratory, vasomotor, and visceromotor) axons. As with *distribution*, the involvement of these fiber classes can be identified by the history and confirmed by the neurological examination and electrophysiological studies; in addition, numerous clinical tools have been developed in recent decades to assist in the confirmation of small fiber sensory and autonomic involvement. Virtually all neuropathies demonstrate prominent involvement of sensory axons, and most symmetric, length-dependent neuropathies with metabolic or toxic etiologies are clinically sensory-predominant or pure sensory neuropathies until they are relatively advanced. The relative involvement of large and small sensory axons varies among, and in some cases within, etiologies. Patients with clinical findings isolated to small-fiber modalities are often referred to as having small-fiber neuropathy (SFN), although there is evidence that this progresses over time to involve both small- and large-fiber types. SFN can be seen in diabetes or HIV infection but is also often idiopathic. Not surprisingly, large-fiber sensory symptoms predominate in those neuropathies in which the primary pathology is a disorder of

myelin, such as Charcot-Marie-Tooth (CMT) type I or CIDP. Necrotizing vasculitis, CMT, and CIDP are among the relatively common neuropathies that usually demonstrate prominent motor and sensory involvement. Motor neuropathies without discernible sensory or autonomic involvement are so uncommon in general clinical practice that patients presenting with isolated weakness in a pattern suggesting neuromuscular disease should be considered to have a disorder of motor neurons, neuromuscular transmission, or muscle until proven otherwise. The few neuropathies that can present as pure motor disorders include multifocal motor neuropathy (MMN) and the neuropathy of acute lead intoxication, and both are rare conditions. Few neuropathies, including those associated with amyloidosis and type I diabetes mellitus, have clinically significant autonomic involvement.

The *primary locus of pathology (axon or myelin)* is most reliably determined by nerve conduction studies and by nerve biopsy, although the neurological examination can be used to draw inferences about this. For example, muscle stretch reflexes are lost early in CIDP, and sometimes in the absence of substantial weakness of the muscle in question. By contrast, because demyelination alone does not result in denervation, denervation atrophy does not develop unless or until there is secondary axonal injury from longstanding demyelination. Thus, CIDP is often associated with early loss of reflexes and relative preservation of muscle bulk in the face of significant weakness. By contrast, axonal neuropathies result in relative preservation of reflexes and early atrophy of clinically affected muscles. Nonetheless, these clinical clues require confirmation by nerve conduction studies which, if interpreted correctly, provide reliable information about the primary pathologic substrate. For this reason, nerve biopsy is rarely needed to determine whether the primary pathology is of the axon or myelin, though it is occasionally useful in demonstrating the nature of the pathologic process. The only common disorders of peripheral myelin are Guillain-Barré syndrome, CIDP, and CMT type I.

Pain is common in some neuropathies and uncommon in others. There are pain descriptors that are common in painful neuropathies and less common in other painful conditions. This clinical observation has led to the development of several neuropathic pain questionnaires.[3–6] The process of validating such questionnaires has resulted in the identification of several symptoms that correlate well with the presence of neurologic dysfunction. These include paresthesias, spontaneous burning, numbness, shooting pains, and tactile allodynia.[7]

The presence, absence, and character of neuropathic pain can help the clinician identify the most likely type and etiology of a patient's neuropathy. For example, neuropathic pain is one of the defining characteristics of small fiber neuropathy. Allodynia is almost universally present in postherpetic neuralgia and is common in other sensory neuronopathy syndromes. Severe, aching, boring pain is an essential feature of neuralgic amyotrophy and a common complaint in necrotizing vasculitis. By contrast, CMT may be associated with musculoskeletal pain but the presence of prominent neuropathic pain would put this diagnosis in doubt. A neuropathic pain symptom questionnaire should be included in every diagnostic evaluation for neuropathy.

History, Examination, and Diagnostic Studies

The medical history of a patient with neuropathy should include a systematic assessment of positive and negative sensory symptoms, motor symptoms, and autonomic symptoms. The neuropathy symptom profile instrument includes all of these.[8] As noted previously, neuropathic pain questionnaires allow systematic and comprehensive assessment of spontaneous and stimulus-evoked positive sensory symptoms, as well as pain descriptors, in patients with neuropathic pain.

The examination of the patient with neuropathy must include bedside assessments of both large and small fiber sensory modalities.

In addition to the standard neurological examination, several laboratory investigations have proven valuable in the assessment of neuropathy in general and painful neuropathy in particular. These include psychophysical, neurophysiological, and anatomic investigations.

Psychophysical tests investigate the relationship between physical stimulus properties and corresponding perceptions of the stimulus.[9] The sensory component of the standard neurological examination is a series of psychophysical tests. The term "quantitative sensory testing" (QST) is often used to describe one of several psychophysical testing paradigms for quantitative determination of thermal or mechanical perception thresholds. In addition to threshold testing, QST can be used to obtain a subjective intensity rating in response to a fixed stimulus. For example, QST can be used to establish either a thermal pain threshold or the perceived intensity of pain evoked by a thermal stimulus of fixed intensity. Like the neurologic examination, QST can be used to determine whether a subject's sensory perception is normal and as a monitoring tool.[10,11]

There is growing interest in developing a standardized assessment protocol for neuropathic pain to include tests of thermal, mechanical, and even chemical allodynia and hyperalgesia. It is hoped that comprehensive assessments of neuropathic pain features such as these will allow clinicians to identify patterns of pain phenotypes that reveal clues to the unique causes and treatments of neuropathic pain in individual patient groups, much as the development of the now-standard neurologic examination has proved useful in lesion localization and disease pattern recognition. Thermal allodynia and hyperalgesia can be tested along with thermal sensory threshold testing, using commercially available devices. A comprehensive test of sensory thresholds, allodynia, and hyperalgesia has been designed and implemented by the German Neuropathic Pain study group.[12] A simpler test which combines mapping of areas of allodynia or hyperalgesia with fixed stimulus intensity rating and multimodality neuropathic pain assessment has been proposed by the Neuropathic Pain Research Consortium (NPRC) in the United States.[13] These efforts are still in their infancy and await further validation and large-scale implementation.

Neurophysiologic studies investigate the activity of electrically excitable tissues (nerve or muscle cells) either at rest, during normal activity, or in response to externally applied stimuli. In the context of peripheral nerve disease, the most commonly used neurophysiologic studies are nerve conduction studies and electromyography (NCS/EMG). As noted in the previous section, NCS/EMG can provide objective evidence of dysfunction of large myelinated (Aβ) nerves, valuable evidence of whether the primary pathology is in the myelin or axon, and information about the distribution of disease.

One of the major limitations of NCS/EMG is that it provides no information about the function of small myelinated (Aδ) or unmyelinated (C) fibers. Because NCS/EMG has been the principal confirmatory and investigational tool in the neuromuscular field since its inception, there has therefore been little or no recognition of the existence of neuropathy preferentially affecting small axons until very recently. The advent of immunohistochemical staining of skin biopsy tissue for evaluation of epidermal nerve fibers (ENFs) has allowed the identification of patients with normal nerve conduction studies but loss of cutaneous nerves.[14,15] In most cases there are corresponding signs of abnormal nociception, consisting of both sensory loss and spontaneous or stimulus-evoked neuropathic pain,[16,17] although such patients likely lose large (Aβ) fibers over time as well.[18] The syndrome of neuropathic pain with impaired thermal and nociceptive sensation, loss of ENFs, and relatively normal nerve conduction studies is often referred to as "small fiber neuropathy" in recognition of the fact that the clinical and laboratory features of this condition are

largely referable to loss or dysfunction of the small caliber Aδ and C fibers. The ability to diagnose small fiber neuropathy with ENF density evaluation has spurred tremendous interest in this syndrome.

Pathologic examination of peripheral nerve trunks also plays an important role in neuropathy diagnosis in selected cases. While NCS/EMG are usually adequate to confirm a diagnosis of neuropathy, define the geographic distribution, and identify whether the primary pathology is demyelination or axon loss, nerve biopsy is occasionally needed to identify those etiologies, such as vasculitis or amyloidosis, that are primarily pathologic diagnoses. Nerve biopsy can also be used to support a diagnosis of CIDP or other chronic demyelinating neuropathies.[19]

PAINFUL NEUROPATHIES

There is a higher incidence of pain among some etiologic categories of neuropathy than others. In this section we describe those common neuropathies that are often painful.

Distal Symmetric Polyneuropathies

Metabolic Causes

Diabetic Neuropathy. The most common cause of distal symmetric polyneuropathy in the developed world is diabetes. Diabetic neuropathy is often but not always painful. The prevalence of painful neuropathy symptoms in one community study of diabetics was 16%.[20] All features of neuropathic pain, including mechanical or thermal allodynia, hyperalgesia, spontaneous shooting pains, and spontaneous burning, may occur. Like the sensory deficits of diabetic neuropathy, diabetic neuropathy pain presents in a length-dependent, symmetric pattern. Therefore, focal neuropathic pain in a diabetic should prompt consideration of an alternative etiology for the pain. Mononeuropathies in diabetes are discussed later under the heading "painful mononeuropathy multiplex and focal neuropathic syndromes."

There is no established metabolic or genetic distinction between diabetics whose neuropathy is or is not associated with neuropathic pain, although it has been suggested that neuropathic pain often develops early in the course of nerve injury and recedes when neuropathy becomes more severe. There is no firm evidence that any one of the several proposed mechanisms of diabetic neuropathy is responsible for diabetic polyneuropathy pain.

Experimental models of diabetic neuropathy have provided evidence that pain in diabetic neuropathy may be due to pathology at multiple sites in the nervous system. Work in the streptozotocin model has demonstrated altered expression of sodium channels in primary afferent neurons,[21] COX-2 release from oligodendrocytes and dysregulation of inhibitory interneurons in the spinal cord,[22,23] and altered descending inhibition of pain.[24] It remains to be determined whether these mechanisms apply in people with diabetic neuropathy.

Investigation of the syndrome of small fiber neuropathy has revealed a disproportionate number of patients with impaired glucose tolerance (IGT), suggesting that the etiology of neuropathy in such cases is incipient diabetes and the mechanism is the same as that of diabetic neuropathy. Although appealing, this remains a hypothesis only. Many such patients also have the metabolic syndrome, presently defined as at least three of the following: central obesity, elevated serum triglycerides, reduced serum HDL, elevated blood pressure, and elevated fasting plasma glucose.[25] Among disorders of lipids, hypertriglyceridemia in particular has been found to be prevalent in this syndrome.[26,27] Conversely, there is some evidence that, among diabetics, the prevalence or severity of neuropathy is greater if other components of the metabolic syndrome are present.[28,29] These observations suggest that microvascular disease exacerbates the nerve injury associated with hyperglycemia.

Infectious Causes

Both HIV infection and several of the commonly used highly active antiretroviral therapies (HAART) for HIV infection are associated with distal symmetric polyneuropathy.[30–32] The two etiologies may coexist and the neuropathies associated with them are clinically indistinguishable; therefore, initial management for DSP in a patient on HAART usually consists of a therapeutic trial of medication change or discontinuation. DSP is most closely associated with the use of dideoxynucleoside analogues stavudine (D4T), zalcitabine (ddC), and didanosine (ddI). The mechanism of this effect is believed to be the inhibition of mitochondrial DNA polymerization, leading to mitochondrial dysfunction and, in turn, reduced energy availability. DSP in HIV infection commonly presents with symptoms of small-fiber involvement, with prominent pain and paresthesias. The mechanism of HIV neuropathy is unknown, although there is some experimental evidence implicating inflammatory mechanisms triggered by infection of periaxonal Schwann cells.[30]

Chronic hepatitis C virus (HCV) infection is a well-recognized cause of polyneuropathy. Distal symmetric polyneuropathy, mononeuropathy multiplex, and cranial neuropathy can all be seen in this context. Polyneuropathy due to HCV infection is usually, but not always, associated with secondary cryoglobulinemia, and nerve biopsy often demonstrates features suggestive or diagnostic of vasculitis.[33] Depending on the severity and time course of the condition, as well as the pathologic findings, treatment can be supportive or may include antiviral therapy, immunomodulating therapy, or both.[33,34]

Lyme disease is a well-recognized cause of cranial neuropathy and polyradiculopathy. Less commonly, polyneuropathy and mononeuropathy multiplex have been described in the context of Lyme disease. While direct infection is difficult to demonstrate, a diagnosis of peripheral nervous system Lyme disease can be inferred in the context of a subacute progressive neuropathy with clinical and serologic evidence of Lyme and clinical improvement with antibiotic therapy. Lyme radiculopathy, polyneuropathy, and mononeuropathy multiplex can all be associated with pain.[35,36]

Toxic Neuropathies

Neurotoxic substances impair a number of neural processes such as protein synthesis, axonal transport, and myelin maintenance. Exposure to several industrial toxins is well known to lead to polyneuropathy. These usually cause motor symptoms and signs, although painful and dysesthetic symptoms may ensue in a minority of patients. Very few pathological studies have been conducted in humans. N-hexane, a common ingredient in household glue, and methyl-n-butyl ketone, an industrial solvent, are known to cause focal swelling of axons to two to three times their normal diameter and can result in painful neuropathy.[37,38]

Several pharmaceutical agents may cause painful polyneuropathy. Vincristine, taxol, paclitaxel, and docetaxel all cause polyneuropathy with pain and dysesthesias. Recent evidence implicates mitochondrial dysfunction and changes in calcium-channel expression in chemotherapy-induced neuropathy, which will probably dictate treatment strategies for this type of painful polyneuropathy.[39,40]

Many other drugs are known to cause polyneuropathies which are not always painful. Among these are isoniazid, gold, disulfiram, nitrofurantoin, amiodarone, and benzafibrate.

Nutritional Neuropathies

Pyridoxine Deficiency From Isoniazid Use. Isoniazid is an effective and inexpensive antituberculosis drug but it is associated

with distal neuropathy when administered in high doses. Patients with a genetic predisposition for slow metabolism of isoniazid are more susceptible to this adverse effect. Isoniazid interferes with essential metabolic functions of pyridoxine, leading to axonal damage. This axonopathy affects small and large fibers, causing motor deficits, sensory deficits, and pain. Pain is described as deep aching pain in calf muscles and burning paresthesiae in upper and lower extremities. Oral pyridoxine in doses of 30–100 mg per day can prevent or reverse isoniazid neuropathy. Excessive doses should be avoided since pyridoxine itself can cause neuropathy if given in excess.

Beriberi. Beriberi is the most widely recognized nutritional neuropathy and is a disease of the peripheral nerves and heart[41] caused by thiamine deficiency. If the heart is affected it presents with heart failure (wet beriberi) but the majority of patients present with neuropathy alone (dry beriberi). Presenting symptoms are slowly progressive distal weakness, paresthesiae, and pain. Rarely beriberi develops acutely. There are multiple presentations of pain symptoms, including dull, constant ache, lancinating brief pain similar to tabes dorsalis, tightness, and burning. Unlike idiopathic distal symmetric small fiber neuropathy, in beriberi burning usually involves the hands as well as the feet shortly after onset. Physical examination reveals symmetric sensory loss across all modalities as well as positive phenomena such as allodynia, hyperalgesia, and hyperpathia, as well as distal weakness and areflexia. Large-fiber involvement is demonstrated by nerve conduction studies.[42] Nutritional supplementation with thiamine is essential. With treatment, beriberi neuropathy improves slowly.

Pellagra Neuropathy. Pellagra is a nutritional disorder which when fully developed affects the skin, gastrointestinal, hematopoietic, and nervous systems. Nervous system manifestations include encephalopathy, myelopathy, and neuropathy. Neuropathy is infrequent but can be quite disabling.

Alcohol Neuropathy. It is well established that excessive and prolonged intake of alcohol is associated with a distal symmetric polyneuropathy which is often characterized by distal paresthesias, burning, and other features of neuropathic pain. The precise cause of alcohol polyneuropathy is unknown. For decades, the principal question has been whether alcohol polyneuropathy is due solely to deficiency of thiamine and, perhaps, other B vitamins, or is due to a direct toxic effect of alcohol, its metabolites, or even other neurotoxins in alcoholic beverages. Support for a neurotoxic role of alcohol comes from an animal model of alcoholic neuropathy in which rats that are provided adequate nutritional supplementation along with alcohol develop polyneuropathy.[43] Some interesting clinical observations support this as well. For example, alcohol polyneuropathy is prevalent among Danish alcoholics despite the fact that beer, which is the alcoholic beverage of choice in that country, is supplemented with B vitamins.[44] In addition, an elegant series of studies of Japanese alcoholics has demonstrated that neuropathy is prevalent among alcoholics with normal serum thiamine levels, and that sural nerve pathology differs between alcoholics with and without thiamine deficiency.[45]

Neuromuscular Manifestations of Intestinal Malabsorption After Bariatric Surgery and Other Gastrointestinal Surgical Procedures. The growing use of bariatric surgery has led to resurgence in awareness of neurological disorders associated with malabsorption, some of which can be associated with neuropathic pain. Wernicke's encephalopathy, beriberi, and subacute combined degeneration due to vitamin B12 or copper deficiency are among the neurologic disorders attributable to known deficiency states that have been described after bariatric surgery. In some cases a presumed nutritional myeloneuropathy has been ascribed to multiple nutritional deficiencies or deficiency of an unknown nutrient in such patients. Neuropathic pain can occur in beriberi and in subacute combined degeneration, the latter most likely as a result of an associated sensory neuropathy.

Hereditary Neuropathies

Charcot-Marie-Tooth (CMT) is the most common hereditary neuropathy, with an estimated prevalence of 40 per 100,000.[46] The clinical syndrome is a progressive symmetric length-dependent motor and sensory neuropathy. CMT differs from the length-dependent polyneuropathy seen in diabetes and most other metabolic, nutritional, and toxic disorders because, in CMT, weakness and atrophy are prominent early signs and both upper and lower extremities are typically affected. Most forms of CMT are inherited in an autosomal-dominant fashion, the exception being the X-linked form (CMTX). Neuropathic pain is uncommon in CMT, and when it occurs it is usually not the most prominent symptom. Fatigue, neuromuscular discomfort, and aching pain from foot deformities and overuse syndromes do occur. Acute intermittent porphyria is an autosomal dominant disorder with neuropathy which may have pain as one of the presenting symptoms, but pain is always overshadowed by weakness.

Fabry's Disease. Fabry's disease is perhaps the sole hereditary neuropathy in which neuropathic pain is the cardinal symptom. Fabry's disease is a multisystem disorder affecting peripheral nerves, kidneys, heart, and skin. It is inherited in X-linked recessive fashion and its symptoms start in childhood or adolescence. The biochemical abnormality is a deficiency of alpha-galactosidase, a lysosomal enzyme. The estimated prevalence is about 2 per 100,000 males.[47]

The clinical features include red punctate skin lesions in the lower body and thighs, corneal opacifications, cardiac and renal failure, and polyneuropathy. Cardiac and renal failure are terminal events for these patients. The neuropathy of Fabry's disease is characterized by continuous burning pain in the hands and feet, with spontaneous paroxysms of more severe pain. On examination there are surprisingly modest sensory deficits, and muscle stretch reflexes are preserved. Nerve conduction studies are usually normal. In addition to pain, patients with Fabry's disease have marked autonomic dysfunction manifesting with episodic diarrhea, vomiting, urinary retention, and diminished sweating. Gastrointestinal symptoms can be relieved with metoclopramide.[48,49]

While idiopathic SFN preferentially affects small fibers, Fabry's disease may be unique in that it appears to exclusively affect small myelinated and unmyelinated axons, at least until such time as renal insufficiency occurs and causes a superimposed mixed polyneuropathy. This has been demonstrated pathologically by comparison of epidermal nerve fiber density with sural nerve morphometry in the same patients. Interestingly, the same study demonstrated a loss of epidermal nerve fibers immediately after an episode of pain in two subjects, suggesting that painful episodes in Fabry's disease reflect acute nerve injury. Enzyme replacement therapy has been shown to have multiple benefits, including an improvement in the Brief Pain Inventory, but not in ENF density or thermal thresholds. Clearly, more needs to be learned about the effect of enzyme replacement therapy on the neuropathy of Fabry's disease.[48,49]

Amyloid Neuropathy. Neuropathy is a common, early, and often prominent manifestation of amyloidosis.[50] Neuropathy can occur in both familial and acquired amyloidosis. There are several distinct clinical groups of familial (transthyretin) amyloidosis but all of them have an autosomal dominant inheritance pattern. The prevalence varies greatly among ethnic groups. The initial symptoms are numbness, paresthesiae, and pain in the feet and lower legs. Autonomic involvement is also common, manifesting with abnormal pupillary reflexes, miosis, anhidrosis, orthostatic hypo-

tension, diarrhea alternating with constipation, and impotence. Cranial nerve involvement manifests late in the disease. About half of the patients have neuropathic symptoms at onset, while half present with cardiac, hematologic, or renal dysfunction. Patients with familial amyloid polyneuropathy can benefit from liver transplantation.[51] The prognosis of primary (nonfamilial) amyloidosis is very poor.[52]

Other Widespread but Nonlength-Dependent Neuropathies

Neuropathy with Paraproteinemia

Monoclonal gammopathy, defined as the presence of a single clone of immunoglobulin identified via serum protein electrophoresis or immunofixation, is common in the elderly. While sometimes due to myeloma or lymphoma, monoclonal gammopathy can present in the absence of a malignant lymphoproliferative disorder and, in such cases, is referred to as monoclonal gammopathy of undetermined significance (MGUS). There is an increased prevalence of neuropathy among individuals with MGUS, and an increased prevalence of MGUS among individuals with otherwise unexplained neuropathy.[52] Despite this, with the exception of a few well-characterized specific antibody-mediated syndromes, such as the syndromes associated with IgM antibodies to the sulfated glucuronyl paragloboside epitope of myelin-associated glycoprotein (MAG-SGPG)[53] and disialosyl antibodies, there is no compelling evidence of a causal relationship between MGUS and neuropathy. Nonetheless, the association is sufficiently common that it is prudent to obtain a serum protein immunofixation as part of the evaluation of idiopathic neuropathy, particularly in patients over the age of 60, and to consider that MGUS in a patient with neuropathy may represent more than a chance association.

Several clinical phenotypes, both axonal and demyelinative, have been described in neuropathy with MGUS. CIDP, a chronic acquired demyelinating neuropathy that usually responds to immune manipulation, is occasionally associated with MGUS. Distal acquired demyelinating syndrome (DADS) is an indolent syndrome of sensory ataxia, often with distal weakness, with electrophysiologic evidence of distal-predominant demyelination. DADS is usually associated with an IgM monoclonal gammopathy which, in about two-thirds of cases, is directed against MAG-SGPG.[54]

Axonal pathology is also common in MGUS-neuropathy, particularly among patients with IgG and IgA monoclonal proteins. Axonal MGUS-neuropathy is usually an indolent condition with prominent negative and positive sensory symptoms.

Neuropathy can be associated with lymphoproliferative malignancies as well. Perhaps most notably, polyneuropathy is part of the POEMS syndrome, an acronym which refers to polyneuropathy, organomegaly, endocrinopathy, M-spike, and skin changes. POEMS syndrome most often occurs in the setting of osteosclerotic myeloma, multiple myeloma, or angiofollicular lymph node hyperplasia (Castleman's syndrome). The polyneuropathy in POEMS syndrome, unlike most polyneuropathies associated with MGUS, is usually progressive and disabling but does often respond to appropriate treatment of the associated lymphoproliferative syndrome. Electrophysiologic studies usually reveal a primary demyelinative pattern.[55]

Neuropathic pain can occur with all paraproteinemic polyneuropathies. While negative sensory symptoms usually predominate in acquired demyelinating neuropathies, pain and paresthesias can occur and are occasionally severe. While speculative, it is possible that this reflects dysfunction or ectopic discharge of small myelinated nociceptors, loss of collateral inhibition of afferent input from small myelinated and unmyelinated axons, or sensitization due to the expression of inflammatory cytokines in nerve.

Autoimmune Demyelinating Neuropathies

Guillain-Barré Syndrome. Guillain-Barré syndrome (GBS) is an inflammatory polyneuropathy with an estimated annual incidence rate of 1.2–1.9 per 100,000.[56] The syndrome is characterized by rapidly progressive, widespread, and often severe weakness of the limbs and cranial musculature with areflexia. Approximately 10% of patients require ventilatory support. Weakness reaches a nadir within 4 weeks, with substantial spontaneous recovery in the majority of patients. Nonetheless, despite a generally good prognosis for recovery of strength, many patients are left with considerable fatigue, and some with distal weakness and paresthesias.

Electrophysiologic investigations demonstrate features of demyelination, including focal motor conduction block, in most patients with GBS. This is concordant with pathologic investigations which demonstrate lymphocytic infiltration and macrophage-mediated demyelination of nerve roots and peripheral nerves.[57] Thus, until recently the descriptive term acute inflammatory demyelinating polyradiculoneuropathy (AIDP) was considered synonymous with GBS. Occasional patients with evidence of axon loss were felt to have suffered secondary axonal injury in a fulminant demyelinating disease. In 1995, a seminal description of Chinese patients with a epidemic form of GBS without electrophysiologic or pathologic features of demyelination led to the elucidation of GBS subtypes, now referred to as acute motor axonal neuropathy (AMAN) and acute motor axonal sensorymotor neuropathy (AMSAN),[58] which appear to reflect immunologically mediated disruption of paranodal sodium channels, leading to reversible conduction failure without myelin disruption.[59] Whether they are AIDP, AMAN, or AMSAN, all forms of GBS often develop several weeks following a systemic infection, suggesting molecular mimicry as a triggering event, but AMAN in particular is strongly associated with preceding gastrointestinal infection with *Campylobacter jejuni* and the subsequent development of serum IgG antibodies directed against ganglioside GM1, which are probably pathogenic.[59] Pain has been reported to be one of the presenting symptoms in more than three quarters of patients with GBS, and in many it precedes weakness. Pain is present throughout the course of GBS and in half of those patients it is rated as severe. Pain intensity upon admission does not correlate with neurological disability.[60] The major pain syndromes observed in GBS are back and leg pain, dysesthetic extremity pain, and myalgic extremity pain.[61]

About two-thirds of patients experience back and leg pain at some time during the course of GBS. This pain is usually described as a deep, aching, or throbbing pain in the low back frequently radiating to the buttocks, thighs, and occasionally to the calves. This pain may reflect root inflammation or endoneurial edema. Dysesthetic extremity pain, described as burning, tingling, or shock-like, involves the legs more frequently than the arms, and is also common in GBS. This type of pain is present in a minority of patients upon admission, although about half experience dysesthetic pain sometime during the course of the illness. It may persist indefinitely in 5% to 10%.[60] It is postulated that neuropathic pain of this type is due to ectopic impulse formation at sites of demyelination and axonal degeneration or regeneration.[62] Myalgic extremity pain, described as aching or cramping pain, often with joint stiffness, is less frequent than radicular low back pain. This pain is most notable during the passive and active assisted exercises associated with physical therapy.[61]

A recent review of pain symptoms in GBS demonstrated that backache, interscapular pain, and myalgias are most common early in the course of the disease and generally resolve during the recovery phase, while dysesthesias and paresthesias are more

likely to persist, sometimes for months or longer.[61] This is compatible with the theorized etiologies noted previously.

Pain Management in Guilllain-Barre Syndrome. In a prospective study, 75% of patients required oral or parenteral opioids to provide adequate pain relief.[60] Epidural morphine has been used as an alternative to systemic opioids in ventilated patients with primarily low back and leg pain.[63] In nonventilated patients in the acute stage of illness, opioid analgesics must be titrated carefully because of increased risk of respiratory depression. During the recovery phase, when muscle and joint pain is routinely precipitated by passive and active exercises, immediate-release codeine or morphine can be given an hour or two prior to treatment to facilitate compliance with physical therapy. Most patients do not require opioid analgesics beyond the first 8 weeks of illness.

A wide variety of medications used to manage neuropathic pain in other settings can be used in GBS, although caution should be taken with medications that can exacerbate hypotension or precipitate cardiac arrhythmias because of the autonomic instability which is common in GBS.

There are no controlled studies on the efficacy of any treatment of pain associated with GBS.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy. Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is a chronic peripheral nervous system disorder which can have progressive, relapsing-remitting, and monophasic courses. The prevalence of CIDP has been estimated at 0.8 to 1.9 per 100,000. In contrast to GBS, association with preceding viral illnesses is uncommon. Some autoimmune and infectious disorders, such as MGUS, lupus, and HIV infection, have been associated with CIDP, but most cases are unrelated to systemic illness. The presenting symptoms are numbness and/or weakness with hyporeflexia progressing over at least 8 weeks' time. Pain may or may not occur but, when it does, it can have any of the features of neuropathic pain. Therapy is aimed at treating the underlying disease process with immunotherapy, usually steroids or IVIg.[64,65] Pain management should follow the basic principles of neuropathic pain pharmacological therapy.

Painful Mononeuropathy Multiplex and Focal Neuropathic Syndromes

The conditions discussed next are commonly associated with substantial pain. About 50% of vasculitic neuropathies are painful and, when present, the pain is usually severe, requiring treatment with multiple medications including narcotic analgesics. In addition to characteristic features of neuropathic pain, a deep, aching, boring pain is often present in peripheral nerve vasculitis. This has been attributed to infarction of vasa nervorum. Immunohistological studies have demonstrated a correlation between neuropathic pain and the presence of cytokines in nerve biopsy specimens, and it is a common observation that the pain of vasculitic neuropathy is alleviated promptly by steroid therapy.

Like vasculitic neuropathy, the pain of neuralgic amyotrophy and diabetic amyotrophy also often has a deep, aching quality and, if treated promptly, often improves with immunomodulating therapy.

Vasculitic Neuropathy

Vasculitis is an autoimmune disorder characterized by inflammation and necrosis of blood vessel walls. The principal primary systemic vasculitides affecting peripheral nerve include polyarteritis nodosa, Churg-Strauss syndrome, and Wegener's granulomatosis. Peripheral nerve vasculitis also occurs as a complication of systemic inflammatory and infectious disorders, including lupus, rheumatoid arthritis, Sjogren's syndrome, progressive systemic sclerosis, chronic hepatitis C infection, and HIV infection. Peripheral nerve vasculitis can also occur in isolation. While immunomodulation is almost always indicated, important differences exist in therapy and prognosis between the types of vasculitis, making classification important.[66] Thus, a comprehensive general medical evaluation and serologic studies relevant to the aforementioned disorders are indicated if vasculitis is suspected. The diagnosis can only be confirmed by tissue biopsy; in cases of peripheral nerve involvement, the sural, superficial peroneal, and superficial radial nerves are most commonly studied. Ideally a biopsy should be taken from a nerve that is affected, based upon clinical and electrophysiologic criteria, but not one that has undergone severe and longstanding injury. The diagnostic histological finding is transmural lymphocytic infiltration and fibrinoid degeneration of the medium size arteries in the epineurium and axonal degeneration that is nonuniform both within and between nerve fascicles.[19]

Most patients with neuropathy due to vasculitis experience sensory loss and weakness in a multifocal pattern, although in longstanding vasculitis the deficits can become confluent and mimic a symmetric process. In about 20% of cases of peripheral nerve vasculitis, the presentation is of a distal symmetric polyneuropathy at onset. When present, as it is in about 50% of cases, pain has characteristics of acute neuropathic pain as well as a continuous deep, aching pain.

The primary treatment goal in vasculitic neuropathy is control of the underlying disease process. This usually requires prompt and aggressive immunotherapy with corticosteroids and, in some circumstances, other immonomodulatory agents such as cyclophosphamide. The pain associated with necrotizing vasculitis is different in character and pathogenesis than the neuropathic pain associated with nonvasculitic neuropathy. A combination of opioids and other medications indicated specifically for neuropathic pain is usually required in this setting.

Neuralgic Amyotrophy

Neuralgic amyotrophy (NA) usually manifests as sudden, severe, deep aching pain in the shoulder girdle and proximal upper limb, followed within days to weeks by marked atrophy and weakness and relatively modest sensory loss. Weakness can be isolated to the distribution of one or two nerve trunks only, and can include nerves, such as the phrenic nerve, which involve the upper body but not the upper limb per se. Commonly affected nerves include the long thoracic, suprascapular, phrenic, musculocutanoues, and anterior interosseous. NA occurs primarily in patients between 20 and 40 years of age and is more common in men than women. It is also known as idiopathic brachial neuritis and as Parsonage-Turner syndrome. The etiology of this syndrome is not established, although the following clinical observations suggest that it may be dysimmune. First, NA often follows a viral infection, as is the case in GBS. Second, NA often begins with severe focal pain followed by atrophy and weakness, as is often the case in vasculitic neuropathy. Third, NA is a mononeuropathy multiplex, which is the most common pattern seen in peripheral nerve vasculitis. Careful clinical and electrodiagnostic examination often reveals differential fascicular involvement within a nerve trunk. The natural history of neuralgic amyotrophy is of very gradual improvement over the course of 1 to 2 years, as axonal regeneration occurs. Empiric immunotherapy is occasionally used. It is our impression that steroid therapy accelerates recovery and pain relief, but this has not been evaluated systematically.[67,68]

Pain in NA is usually described as deep, aching, and severe. It is made worse with movements of the affected limb and, as a result, patients often avoid movement at the shoulder joint, resulting at times in a secondary adhesive capsulitis (frozen shoulder). Deep aching pain generally improves over a matter of weeks, but can persist and can be followed by painful paresthesias and

dysesthesias. Residual weakness and pain can occur. A hereditary form, known as hereditary neuralgic amyotrophy (HNA), has been identified and may represent a substantial proportion of cases.[69] HNA is inherited in an autosomal dominant fashion and has been linked to a mutation in the SEPT9 gene, which is responsible for the formation of a possible cytoskeletal protein.[70]

Diabetic Amyotrophy

Like neuralgic amyotrophy, diabetic amyotrophy is a well-recognized syndrome characterized by sudden, severe pain, usually in the proximal segment of the limb, followed shortly thereafter by striking atrophy and weakness. Unlike neuralgic amyotrophy, diabetic amyotrophy usually affects the lower limb, although similar presentations involving the upper limb have been described. Also unlike neuralgic amyotrophy, and as indicated by the name, diabetic amyotrophy occurs almost exclusively in diabetics, although an identical syndrome has been described in patients with impaired glucose tolerance. This syndrome is also known as the Bruns-Garland syndrome and as diabetic lumbosacral radiculoplexus neuropathy, which describes the postulated localization of the pathology. Biopsy of proximal cutaneous nerves has demonstrated features of microvasculitis.[71] In keeping with this, there is extensive anecdotal evidence of prompt resolution of pain, and possible acceleration of recovery, after immune manipulation with steroids or intravenous immunoglobulin.

Other Diabetic Mononeuropathies

All healthcare providers should also be familiar with diabetic mononeuropathies, because of their clinical management implications as well as the striking pain associated with these conditions. In addition to inducing a predisposition to entrapment neuropathies, diabetes is associated with several acute, painful mononeuropathies or focal neuropathic syndromes affecting cranial nerves (third, fourth, sixth, seventh), roots (thoracic radiculopathy), and root/plexus (diabetic amyotrophy). In addition, a multifocal polyneuropathy (‘‘diabetic mononeuropathy multiplex’’) can occur in the setting of diabetes. There is published evidence, supported by biopsy material, that several of these diabetic mononeuropathy syndromes are vasculitic.[72]

Recognizing clear risks associated with both treatments in this population, there is also anecdotal evidence that immunotherapy with steroids or immunoglobulin infusions may accelerate pain relief and possibly recovery of function in diabetic focal neuropathies.[73] A sudden, focal, painful neuropathy in diabetes is not due to ‘‘diabetic neuropathy’’ as the term is usually meant, and should be investigated promptly to determine whether it represents another condition or a recognized diabetic mononeuropathy.

Sensory Neuronopathies

The following conditions are believed to reflect pathology in the cell bodies of sensory neurons. Postherpetic neuralgia follows reactivation of a viral infection, while the others are believed to represent primary dysimmune processes. In all cases, neuropathic pain is often the principal symptom. The high prevalence of neuropathic pain in sensory neuronopathies may be attributable to the presence of an inflammatory process in relative proximity to the dorsal horn of the spinal cord.

Postherpetic Neuralgia

Postherpetic neuralgia (PHN) is one of the most common and disabling neuropathic pain states. A recent epidemiologic survey estimated the incidence of herpes zoster at 4.1 per 1,000 person-years, with PHN developing in 18% of cases.[74] Herpes zoster is due to a reactivation of varicella-zoster virus (VZV), which remains sequestered and clinically dormant in cells of sensory ganglia after an initial infection but becomes reactivated in the context of age-related or disease-related reduction in cell-mediated immunity to the virus. There is some evidence of persistent active infection in patients with PHN. PHN is presumed to be due to sensitization of nociceptors and central sensitization after herpes zoster. PHN is more likely to occur in patients with pain associated with acute zoster and patients with zoster affecting multiple dermatomes. There is a positive correlation between age at the time of developing herpes zoster and the likelihood of developing PHN.[75,76] Several studies have demonstrated that antiviral treatment of herpes zoster substantially reduces the risk of developing PHN and the duration of PHN if it develops.[77–79] PHN is described in greater detail in Chapter 27.

Sjogren’s Syndrome

Sjogren’s syndrome (SS) is a systemic autoimmune disorder. The cardinal features are sicca syndrome, supported by objective evidence of diminished tear production, salivary gland inflammation, and serologic evidence of antibodies highly correlated with this disorder.[80] SS is commonly associated with disease of both the peripheral and central nervous systems. The range of neurologic disorders that have been associated with SS is remarkably broad, including multiple sclerosis-like cerebral disorders, myelopathy, polyradiculoneuropathy, sensory neuronopathy, vasculitic mononeuropathy multiplex, and myositis.[81] The peripheral nervous system disorders for which the association with SS is clearest are sensory neuronopathy and vasculitic neuropathy. In patients with SS, sensory neuronopathy can present with sensory ataxia, neuropathic pain, or both, presumably reflecting the relative involvement of large and small sensory neurons. Sensory neuronopathy from SS is usually an indolent, progressive condition.[81–83] Evidence of response to immunotherapy is anecdotal. Dysimmune sensory neuronopathy can occur as an idiopathic phenomenon as well.

As with other systemic autoimmune conditions, necrotizing peripheral nerve vasculitis from SS is a rapidly progressive, disabling, and commonly painful condition which nonetheless does respond to immunotherapy.

Paraneoplastic Sensory Neuronopathy

Paraneoplastic sensory neuronopathy is one of several paraneoplastic syndromes associated with the presence of anti-Hu antibodies which is encompassed under the rubric of paraneoplastic encephalomyelitis. The predominant clinical syndrome is a sensory ataxia rather than neuropathic pain. Paraneoplastic sensory neuronopathy may respond to treatment of the tumor and, occasionally, immunomodulating therapy, but the prognosis is nonetheless poor.[84]

Toxic Neuronopathy

Cisplatin is an antineoplastic agent known to cause sensory loss and neuropathic pain. The pathophysiology is felt to be disruption of mitochondrial DNA synthesis resulting in a sensory neuronopathy.[85–87]

TREATMENT OF PAINFUL NEUROPATHIES

General Principles of Therapy

Treatment of neuropathy and neuropathic pain are complementary. Treatment of neuropathy is targeted at the underlying dis-

ease process. Such therapy should be administered as soon as possible to control or even reverse the process responsible for neuropathy and neuropathic pain. Nevertheless in the authors' experience patients commonly report persistent neuropathic pain even after stabilization or reversal of neuropathy. This is particularly true in vasculitic neuropathy, where progressive weakness and sensory loss can be aborted with steroid therapy but pain often persists even years after resolution of necrotizing vasculitis. Assuming that inflammation and injury in peripheral nerve terminals has stabilized or receded in these cases, this observation might be attributable to central sensitization.

Analgesia Therapy: Guidelines for Pharmacotherapy

Treatment of neuropathic pain should begin as soon as possible and in tandem with treatment of neuropathy. Postulated mechanisms of neuropathic pain and neuropathic pain pharmacotherapy are addressed in other chapters. Here we will address treatment of painful neuropathy in particular.

Diabetic neuropathy is the most prevalent painful neuropathy in developed countries and has therefore been most widely studied as a target for treatment of neuropathic pain from neuropathy. It follows, therefore, that most clinical trial data regarding efficacy of analgesic treatments in painful neuropathy were obtained in patients with diabetic neuropathy pain and that there is little formal evidence that these data apply to other etiologies.

Primary outcome measures of most large clinical trials are overall change in pain severity and improvement in quality of life indicators. There is a growing recognition that clinical trial design in neuropathic pain should also include systematic evaluation of individual neuropathic pain symptoms and signs.[88] Thus, there is potential utility in the systematic evaluation of the effect of treatments on specific neuropathic pain symptoms, such as paresthesias, dysesthesias, and burning; neuropathic pain descriptors, such as sharp, dull, stabbing, or exhausting; and neuropathic pain signs, such as dynamic mechanical allodynia, punctate hyeralgesia, thermal allodynia, and thermal hyperalgesia. It is not clear at present whether it is better to ask the question "which treatment is best for neuropathic pain from this disease?" or, rather, "which treatment is best for this neuropathic pain symptom/sign complex?" Implied in the latter is the hypothesis that pain symptoms and signs inform us about the principal mechanisms of pain in a given individual, which in turn may match the mechanism of action of a particular treatment.

For now, however, evidence-based treatment of neuropathic pain from neuropathy is based largely on evidence of reduction in overall pain severity in diabetic neuropathy and few other conditions, and practitioners are obliged to extrapolate from these data. Most large clinical trials in this arena are industry-supported pivotal trials of the agent in question against placebo. There is very little evidence comparing treatments against each other. One way to try to make such a comparison is by comparing the number needed to treat (NNT), defined as the average number of individuals that must be treated with a medication to obtain a defined degree of pain relief in one subject.[89] NNT takes into consideration treatment failures for any reason, both lack of efficacy and lack of tolerability. While NNT is usually based upon 50% improvement, it has been shown that 30% improvement in pain severity or a reduction in pain severity by at least 2 points on a 0 to 10 Likert scale is clinically meaningful.[90,91]

The medication classes with the best evidence for efficacy in the management of neuropathic pain are tricyclic antidepressants (TCAs), $\alpha_2\delta$ ligands, serotonin and norepinephrine reuptake inhibitors (SNRIs), and opioids.[92] Tramadol, which is believed to both inhibit serotonin and norepinephrine reuptake and act as a mu-opioid agonist, has demonstrated efficacy as well.

Tricyclic Antidepressants

Tricyclic antidepressants are believed to derive their analgesic effect from serotonin and norepinephrine reuptake inhibition as well as sodium channel blockade. The benefit is independent of an antidepressant effect. Most undesirable effects from this class derive from its anticholinergic properties. TCAs have been demonstrated to be beneficial in relieving neuropathic pain from diabetic neuropathy in several small series. A recent Cochrane review found an overall class NNT of 3.6 for moderate pain relief among 17 studies of TCAs for neuropathic pain.[93] TCAs should be used with caution in patients at risk for cardiac arrhythmias because they can prolong the QT_c interval. The most common side effects of the tricyclics are due to their anticholinergic activity and include constipation, dry mouth, blurred vision, cognitive changes, tachycardia, and urinary hesitancy. Sedation and weight gain may occur from antihistaminergic activity. Alpha-adrenergic receptor blockade may result in orthostatic hypotension. All of these potential side effects can be minimized by slow titration. Nortriptyline and desipramine are better tolerated than their parent drugs, amitriptyline and imipramine. Contraindications to the tricyclics include closed-angle glaucoma, benign prostatic hypertrophy, and acute myocardial infarction.

Treatment with a tricyclic should be initiated with a dose of 10 mg or 25 mg a few hours before bedtime to minimize daytime sedation. The lower 10 mg dose should be prescribed for the elderly, frail, or side effect-prone patient. The dose is titrated by one tablet, 10 or 25 mg, every 7 days if the patient has poor pain relief and does not complain of intolerable side-effects. The majority of patients will report significant pain relief or intolerable side effects within the dose range of 30 to 150 mg. The mean dose of amitriptyline that often results in pain reduction is 75 to 150 mg/day. Onset of the analgesic effect occurs within 1 to 2 weeks and peaks around 4 to 6 weeks.[94,95] Improvement in sleep, mood, and anxiety can augment the benefit of pain control.

$\alpha_2\delta$ Ligands

Mechanical allodynia in neuropathic pain is believed to be mediated in part by increased expression of N-type calcium channels in the central terminals of primary afferent neurons, resulting in pathologically enhanced neurotransmission in the dorsal horn. Gabapentin and pregabalin are chemically related compounds that have been shown to have a modulatory effect via binding to the $\alpha_2\delta$ subunit of the calcium channel. Several studies have demonstrated that gabapentin alleviates diabetic neuropathy pain at doses ranging from 900 to 3600 mg per day, with a combined NNT for 50% pain relief of 2.9. Two small series comparing gabapentin with amitriptyline demonstrated improvement in pain ratings with both drugs and no statistically significant difference in benefit between them.[96,97] It should be noted, however, that serious adverse events can occur with amitriptyline and are virtually unknown with gabapentin. Gabapentin can cause weight gain, reversible cognitive symptoms, and peripheral edema.

Gabapentin bioavailability is limited because absorption from the gastrointestinal tract is dependent on a single saturable active transport mechanism. Pregabalin shares gabapentin's presumed mechanism of action but demonstrates more linear kinetics than gabapentin. Presumably for this reason pregabalin is absorbed more quickly and demonstrates more linear kinetics than gabapentin. Pregabalin has been shown to be effective in relieving the pain of diabetic neuropathy, with NNTs for 50% pain relief of 3.4 and 3.3 for the 300 mg/day and 600 mg/day doses, respectively.[98,99] Like gabapentin, pregabalin can cause cognitive side effects which are usually mild to moderate in severity, as well as weight gain and peripheral edema.

Serotonin and Norepinephrine Reuptake Inhibitors

Serotonin and norepinephrine reuptake inhibition is believed to alleviate neuropathic pain by facilitating descending inhibition

of afferent pain signaling. This descending inhibition is mediated by neurons of the rostroventral medulla. It is believed that both neurotransmitters are important in this pathway, which may explain the observation that selective serotonin reuptake inhibitors (SSRIs) alone are of little benefit in alleviating pain from neuropathy.[93] Duloxetine, an SNRI with relative balance between serotonergic and noradrenergic effects, has demonstrated efficacy in relieving pain from diabetic neuropathy, with an NNT for 50% pain relief of 4.3 at a dose of 60 mg/day and 3.8 at a dose of 120 mg/day.[100] Venlafaxine, an SNRI with balanced pharmacology at high doses, has also been shown to be beneficial, with an NNT of 4.5 for 50% pain relief in the 150 to 225 mg dose range.[101] SNRIs can cause nausea, hyperhidrosis, and sexual side effects in some patients. While they do not have substantial anticholinergic properties, they can cause some symptoms of dry mouth and dizziness, possibly on a noradrenergic basis; however, these effects are probably less frequent or severe than with tricyclic medications. Combining SNRIs with other serotonergic agents, including other antidepressants, triptans, and tramadol, should be done with caution because of the risk of serotonin syndrome. SNRIs are also known to inhibit the metabolism of other antidepressants, thus substantially increasing blood levels of such drugs when they are used in combination. For these reasons, it is usually best to avoid the use of SNRIs with other antidepressants, and to consider using one SNRI or tricyclic agent alone to treat both pain and depression if treatment of both conditions is indicated.

Opioids

Opioids strongly inhibit central nociceptive neurons mainly through interaction with μ-opioid receptors, producing neuronal membrane hyperpolarization. Controlled-release oxycodone has been shown to reduce pain from diabetic neuropathy in two small randomized controlled trials, with an NNT for moderate pain relief of 2.6 in one.[102,103] Administration of opioids requires specific treatment programs for patients with a history of chemical dependence and caution in patients with pulmonary disease. Opioid-induced dependence, tolerance, and hyperalgesia are risks of opioid use, although these may be less common in patients with chronic, stable neuropathy than some other chronic pain states. Prophylactic treatment of common side-effects such as nausea or constipation can improve patient compliance.

Tramadol

Tramadol is both an inhibitor of serotonin and norepinephrine reuptake and a μ-opioid agonist. Tramadol has been shown to effectively alleviate pain in diabetic neuropathy as well as a mixed group of neuropathy patients among whom many had diabetic neuropathy.[104,105] Tramadol has a short duration of action and therefore is given every four to six hours or is used on an as-needed basis as an adjuvant medication. It is now also available in an extended release formulation.

Other Pharmacological Agents

Several other agents approved for the treatment of epilepsy have demonstrated limited evidence of efficacy in the management of pain from neuropathy. These include oxcarbazepine, which has demonstrated benefit in one randomized controlled study in diabetic neuropathy pain, lamotrigine, and topiramate, both agents which have demonstrated conflicting results in randomized controlled trials for pain from diabetic neuropathy.[106–110] Despite limited evidence of efficacy, these have all been used on occasion as second- or third-line agents for patients who have not responded to or tolerated other treatments. Carbamazepine, which is approved for pain from trigeminal neuralgia, has been found to be effective in two double-blind placebo-controlled studies for control of pain in diabetic neuropathy.[111,112] Prior to the availability of many of the aforementioned agents for neuropathic pain management, phenytoin was shown to be effective in controlled trials of pain from diabetic polyneuropathy[113] and pain in Fabry's disease.[114] Phenytoin is no longer commonly used to treat pain due to neuropathy.

Bupropion, a unique agent which inhibits norepinephrine and dopamine uptake, has shown benefit in one study involving pain from a variety of neuropathy etiologies.[115]

Acetyl-L-carnitine (ACL) is believed to have several potentially neuroprotective properties that have led to extensive study of this agent as a treatment for diabetic, HIV, and chemotherapy-induced neuropathy.[116–118] It also has analgesic properties. ACL has been administered at doses between 1 and 3 g per day. Alpha-lipoic acid, a potent antioxidant, has also been studied as a potential treatment of both diabetic neuropathy and diabetic neuropathy pain. The recently-completed SYDNEY 2 trial showed that daily oral therapy at a dose of 600 mg/day, the lowest dose yet studied, reduced the neuropathy total symptom score by 50% or greater with an NNT of 2.8.[119,120]

Topical Agents

Capsaicin stimulates the release of substance P from small caliber primary afferent neurons and is believed to alleviate neuropathic pain with regular use by exhausting stores of substance P. Capsaicin also causes prompt epidermal denervation so reliably that capsaicin denervation has become an important human model of neuropathy. While capsaicin can alleviate neuropathic pain with sustained use, it also causes considerable burning discomfort which limits its use. A high-potency capsaicin patch is presently undergoing clinical trials.

Topical lidocaine, a local anesthetic which acts via sodium channel blockade, has been approved for the treatment of postherpetic neuralgia. It is used on occasion to treat cutaneous pain from other neuropathic conditions as well. Systemically administered lidocaine, mexiletine, and tocainide have also been demonstrated to have analgesic effects for control of diabetic neuropathic pain and in postherpetic neuralgia.[121–123] Systemically administered local anesthetics block ectopic discharges due to experimental peripheral nerve injury and in axotomized dorsal root ganglion cells of the peripheral nerves,[124] probably by blocking sodium channels.[125] In addition, there is evidence that lidocaine and similar local anesthetics have actions on G protein-coupled receptors that can result in long-lasting modulation of pain via effects both on sensitization and on the immune response to nerve injury.[126]

Principles of Pharmacotherapy for Pain from Neuropathy

Polypharmacy is common in the treatment of pain from neuropathy for several reasons. First, neuropathy pain can be treated with several classes of agents, with different postulated mechanisms of action. Second, on a more practical level, there is (fortuitously) relative compatibility among these medication classes. And, finally, despite evidence that these treatments are generally efficacious, it is uncommon to achieve complete or even adequate pain relief with a single agent, while it is common to encounter significant adverse effects. Therefore, one usually begins with slow upward titration of one of the first-line drugs (SNRIs, $\alpha_2\delta$ ligands, or tricyclics), followed by the addition of another first-line agent (but generally *not* an SNRI *with* a tricyclic) if pain relief is inadequate at the highest tolerated dose of the first drug. Because these are generally chronic conditions, there is no need to titrate faster than tolerability will permit. Opioids or tramadol are often used as second-line agents or as rescue drugs and are particularly helpful for patients who can predict an increase in pain after a physically active day. Topical and nonpharmacological treatments are particularly valuable as add-on therapy for patients who do not tolerate medication well. Cognitive-behavioral therapy, discussed in Chapter 82, can be very helpful because it is often the distress associated with pain, perhaps more than the pain itself, that causes pain-related disability.

UNRESOLVED QUESTIONS

There have been no attempts to evaluate whether successful treatment with an analgesic medication alters the natural history of pain. There is also insufficient evidence to guide duration of therapy. For example, do patients who report significant pain relief with a certain medication need to be treated with that particular medication at that dose indefinitely? Most pivotal clinical trials in this field run for about 12 weeks' duration, which is woefully inadequate in the context of conditions that usually persist for years.

The mechanisms of neuropathic pain in people with neuropathy also require considerably more study. Much of our understanding of mechanisms, such as ectopic and ephaptic transmission, neurogenic inflammation, descending modulation, and peripheral and central sensitization, comes from animal models that do not mimic human neuropathies. A better understanding of mechanism will likely require better investigation of people with neuropathy. Just as the diagnosis and management of conditions causing neurologic deficit rely upon an ever-more sophisticated clinical/laboratory/radiographic correlation, so too the management of pain from neuropathy must advance with the help of evidence gleaned in a systematic fashion from neuropathic pain questionnaires, neuropathic pain examinations, and relevant imaging, pathologic, and laboratory tools.

CHAPTER 25 ■ COMPLEX REGIONAL PAIN SYNDROME

R. NORMAN HARDEN AND STEPHEN P. BRUEHL

INTRODUCTION

Complex regional pain syndrome (CRPS) is the current diagnostic label for the syndrome previously known by various names, including reflex sympathetic dystrophy (RSD), causalgia, Sudeck's atrophy, shoulder–hand syndrome, neuroalgodystrophy, and reflex neurovascular dystrophy. It was originally recognized as a distinct pain syndrome seen among Union veterans of the Civil War following traumatic nerve injury (causalgia).[1] It is an inflammatory and neuropathic pain disorder principally characterized by involvement of the autonomic nervous system. It is often a chronic disease that involves a full measure of biopsychosocial features, and it can become significantly disabling in some cases.

EPIDEMIOLOGY

Epidemiological data regarding CRPS in the general population are limited, although two large-scale studies are available. Sandroni reported an incidence of 5.46 new cases of CRPS-I per 100,000 annually[2] (Table 25-1 gives the distinction between types I and II). A larger more recent study using current International Association for the Study of Pain (IASP) diagnostic criteria reported an incidence as high as 25.2 new cases per 100,000 annually.[3] Based on this reported incidence, over 50,000 new cases of CRPS-I could be anticipated annually in the United States alone.[4] For physicians making pain diagnoses, the incidence of CRPS in relevant at-risk populations (e.g., postfracture) may be more clinically relevant. Large scale well-designed studies studying this issue are lacking. Several smaller prospective studies suggest that acute CRPS-I may develop in up to 11% to 18% of patients following fracture or total knee arthroplasty, although in some cases the condition may resolve relatively quickly with conservative care.[5–7]

TABLE 25.1

IASP DIAGNOSTIC CRITERIA FOR COMPLEX REGIONAL PAIN SYNDROME*

1) The presence of an initiating noxious event or a cause of immobilization.
2) Continuing pain, allodynia, or hyperalgesia with which the pain is disproportionate to any inciting event.
3) Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of pain.
4) This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction.

Type I: Without obvious nerve damage (aka RSD)
Type II: With obvious nerve damage (aka Causalgia)

*Modified from Mersky and Bogduk[107]

Based on available epidemiological data, fractures and sprains appear to be the most common events triggering CRPS. CRPS appears to be more common in the upper extremities, is more common in females, and is most likely to occur in the 50–70 year age range.[2,3]

PATHOPHYSIOLOGY

CRPS remains one of the most enigmatic and difficult to treat of all pain conditions. Although excellent clinical characterizations started to appear in the literature in the late 1800s,[1] a definitive pathophysiology remains to be determined. This fact, to a great extent, explains the relative lack of clinical progress to date. In the following section, animal and human models that have relevance to understanding CRPS will be described, and then several pathophysiological mechanisms that may contribute will be reviewed. There is increasing consensus that CRPS is unlikely to be caused by a single pathophysiological mechanism.[8] Rather, it is likely to be the result of multiple interacting mechanisms, with varying relative contributions of these mechanisms across different patients.

Animal Models

There are several animal models that may shed light on the mechanisms of CRPS, albeit indirectly. However, as always, one must be cautious in extrapolating from animal models to human syndromes. The most useful animal model, best paralleling CRPS-II (causalgia) in which major nerve injury is a key feature, is the chronic constriction injury model in rat that was first described by Bennett and colleagues.[9] This model produces some behavioral features (e.g., guarding, disuse) that mimic some of the features of human CRPS (e.g., allodynia, hyperpathia, spontaneous pain) as well as some of the sympathetic abnormalities.[9] This model has been utilized in the preclinical screening of pharmacological interventions for CRPS. Another model that may be useful is the spinal nerve injury model,[10] although there is some controversy as to whether this model produces sympathetically maintained pain (SMP) and how similar the resulting pain syndrome is to human CRPS.[8,11] A third model, involving partial ligation of the sciatic nerve, may also have some relevance to human CRPS-II.[12] All three models likely generate ectopic activity at the site of injury and/or the dorsal root ganglion which may (or may not) be responsive to sympathetic outflow and which may cause/maintain central sensitization.[13] These models also result in various other phenomena putatively related to CRPS, such as sprouting of fibers in lamina II of the dorsal horn.[14,15] All of the models above appear most relevant to understanding CRPS-II, although two less widely-used models may be relevant to understanding CRPS-I (no major nerve injury evident). Models using tetanic electrical stimulation[16] and an ischemic reperfusion injury[17] appear to produce a syndrome that mimics some of the features of CRPS-I in the absence of signs of nerve injury.[16] These animal

models may help somewhat in understanding mechanisms of CRPS, but their ultimate value may be in screening pharmaceutical interventions.

Human Models

Intracutaneous injection of capsaicin in humans induces burning pain and cutaneous mechanical hypersensitivity (allodynia) and as such may represent a useful model to study certain features of CRPS. The capsaicin model demonstrates the impact of intense nociceptive stimulation of normal skin with the rapid development of areas of primary and secondary hyperalgesia, allodynia, wheal, and flare.[18–20] This model results in hyperalgesia to suprathreshold heat within the capsaicin-induced secondary hyperalgesic skin, despite the absence of changes in heat pain threshold.[21] Another interesting human model of CRPS-like pain is the controlled heat injury model, which also leads to a zone of secondary hyperalgesia to suprathreshold heat.[22] These models and other lines of evidence suggest a primary role of central sensitization in CRPS[23–25]; however, overlapping regions of flare/vasodilatation and hyperalgesia may also suggest peripheral sensitization.[26] Polymodal C receptors likely mediate the temperature allodynia,[21,27] polymodal A receptors the pinprick hyperalgesia,[28] and A-beta receptors the mechanical allodynia[20] in these models. Whole-body cooling (to induce sympathetic activation) and sympathetic block have shown no effects on features of either the capsaicin or heat injury models,[22,29] although phentolamine (an adrenergic antagonist) reduces the area of allodynia in the capsaicin model.[30] Given these mixed findings, the value of these models in understanding interactions between sympathetic nervous system activity and pain in CRPS remains uncertain. While some features of these models are concordant with signs and symptoms of CRPS, the usefulness of these normal nociception models in unraveling disease specific mechanisms in CRPS is limited to date. As with animal models, a primary use of these human models may be in the testing of interventions for CRPS.[21,31]

Inflammation

Clinical evidence indicates that some features of acute/early CRPS often attributed exclusively to sympathetic hypofunction (i.e., vasodilatation, swelling, and edema) could perhaps be better explained by an exaggerated localized inflammatory process.[32] Sudeck was the first to propose this, along with a "patchy inflammatory osteoporosis,"[33] and Goris revitalized this idea more recently.[34] Consistent with inflammatory mechanisms, one experimental study demonstrated that 82% of acute CRPS patients exhibited a progressive accumulation of immunoglobulin in the affected extremity relative to the unaffected extremity, compared to only 17% of chronic CRPS patients[35] (In this study Oyen et al.[35] arbitrarily defined chronic as 5 months or more since onset. It is more common to label the syndrome chronic after 6 months.) Analyses of joint fluid and synovial biopsies in CRPS patients have shown an increase in protein concentration, synovial hypervascularity, and neutrophil infiltration.[36–38] Free radicals, suspected to play a prominent role in inflammation and ischemic damage, recreate acute CRPS symptomatology in a rat model (vasomotor abnormalities, edema, and pain behavior), and this is the partial rationale for some investigators recommending free radical scavengers in acute CRPS patients.[39] From these lines of evidence, it is logical to conclude that an inflammatory component is likely in CRPS-I, particularly in the early phase.[39,40]

A shift toward a proinflammatory cytokine profile in patients with CRPS suggests a potential pathogenic role for these compounds in the generation of pain.[41] In plasma, no alterations in inflammatory mediators were observed in CRPS patients. However, in blister fluid obtained in the region of CRPS pain, significantly higher levels of interleukin 6 (IL-6) and tumor necrosis factor (TNF)-α were observed in the involved extremity relative to the uninvolved extremity.[42] In addition, significantly elevated cerebrospinal fluid levels of proinflammatory cytokines (interleukin 1b [IL-1b], IL-6) have been shown in CRPS patients compared to healthy controls and those with other types of pain.[41] Results to date do not support genetic factors as determinants of the cytokine profile that may contribute to CRPS.[43] Mast cells also appear to be involved in inflammatory reactions observed in CRPS-I and probably play a role in the production of proinflammatory cytokines such as TNF-α.[42]

Animal studies demonstrate that the sympathetic nervous system can influence the intensity of an inflammatory process.[44–47] In human pain models, sympatholytic procedures can reduce pain, inflammation, and edema.[48,49] A possible autoimmune etiology of CRPS in some cases has also been proposed, and autoantibodies against nervous system structures have been described in some patients.[50] Some evidence suggests that "neurogenic inflammation" is facilitated in CRPS patients. Transcutaneous electrical stimulation caused increased axon reflex vasodilatation and provoked protein extravasation only in CRPS patients, whereas it resulted in decreased axon reflex vasodilatation in healthy controls.[51]

Afferent Dysfunction

CRPS is characterized by "disproportionate" spontaneous and evoked pain (e.g., hyperalgesia, thermal, and mechanical allodynia). Whether these sensory symptoms are due to peripheral and/or central sensitization is the subject of considerable debate and investigation. Sensory impairment occurs in more than 70% of CRPS patients.[52,53] Although traditionally these sensory changes were thought to occur in a distal, regional distribution along with characteristic autonomic disturbances, some early data suggest that the afferent disturbances may be hemilateral or quadrantic.[54] Recent observations corroborate that CRPS may be associated with more generalized sensory impairments.[55,56] The types of remote sensory abnormalities described include the allodynia and hyperalgesia typical of CRPS, but also hypoesthesia and other dysesthesias. Psychophysical technologies, such as temperature quantitative sensory testing, reveal that ipsilateral hypoalgesia is common and contralateral hypoesthesia may occur in some cases.[56] Patients found to have generalized sensory impairment were also found to have ipsilateral weakness.[55] Another study showed that patients with generalized sensory impairment had ipsilateral hemibody increases in thresholds for touch, thermal sensation, and heat pain, whereas those with sensory deficits limited to the distal affected limb showed touch threshold elevations only in the affected limb.[56] In this trial, 46% of patients showed abnormalities in nerve conduction testing and 24% abnormalities in somatosensory evoked potentials, although these abnormalities did not correspond to the extent of sensory impairments observed on quantitative sensory testing.[56] These studies and others suggest that the sensory impairments in CRPS often extend beyond the area affected by pain, and up to 50% of subjects show hypoesthesia and hypoalgesia in a quadrantic or hemibody distribution ipsilateral to the pain. These effects are more likely to occur with greater CRPS chronicity, suggesting centralization of the pathology over time.

Skin biopsies have revealed decreased C-fiber and A-delta fiber axonal densities in the affected limb of CRPS-I patients compared to the unaffected side.[57] It is not known whether such changes are primary to the disease or a consequence of nutritional changes and ischemia caused by chronic vasoconstriction and inflammation.[33] These changes could help account for some of the sensory alterations described above that may occur in CRPS-I (as well as CRPS-II).[58,59]

Central Dysfunction

There is considerable evidence supporting centralization of the pathology in chronic CRPS.[54,60–62] Further support comes from evidence suggesting presence of sympathetic and motor dysfunction in the region of pain (see discussion below). An acute nociceptive barrage from an inciting trauma or due to peripheral sensitization and/or neurogenic inflammation can cause rapid changes in the central nervous system (brain and spinal cord), a process commonly referred to as central sensitization.[63] As a corollary, it has been hypothesized that normalization of afferent activity will reset and/or dampen this sensitization (e.g., increased functional input on large fiber tracts may modulate or normalize activity of small fiber tracts or "shut the pain gate").[64]

Evidence for supraspinal central mechanisms in CRPS also derives from studies using neuroimaging techniques that permit exploration of changes in information processing in the brains of CRPS patients. Studies using magnetoencephalography (MEG), quantitative electroencephalogram, functional MRI (fMRI), and positron emission tomography (PET) techniques all indicate that alterations of afferent input lead to cortical and thalamic plasticity and reorganization of sensory representations in patients with CRPS-I.[65–69] Increased brain responsiveness among CRPS patients in some imaging studies also supports the presence of central sensitization.[68] Some studies suggest a reduced size of the motor cortex devoted to the affected limb in unilateral CRPS-I patients compared to the unaffected side,[68] and the relevance of such brain changes to clinical symptoms is supported by the fact that degree of this shrinkage correlates with the degree of hyperalgesia to pinprick.[70] Functional MRI studies indicate different patterns of cortical activation to pinprick in the CRPS affected side (S1, S2, insula, frontal, anterior cingulate cortex) compared to the unaffected side (S1, S2, insula only).[71] Moreover, prospective research using MEG indicates that stimulation of early, unilateral CRPS-I subjects leads initially only to contralateral activation, whereas after 3 years of CRPS, the same stimulation leads to bilateral activation.[68] Such results suggest one possible brain mechanism by which reported contralateral spreading of CRPS symptoms may occur. Imaging studies suggest that CRPS-related brain changes like those described above may reverse after successful treatment; thus, a reduction or resolution of CRPS pain may correlate with resetting of the cortical reorganization associated with the disorder.[70,72]

Sympathetic Dysfunction

Although autonomic dysfunction has long been implicated as a key mechanism involved with CRPS pathology, the actual role of the sympathetic nervous system (SNS) is incompletely characterized.[73] A seminal role of the SNS in CRPS is pivotal in most diagnostic criteria, emphasizing signs and symptoms of autonomic disturbance (e.g., vasomotor, sudomotor, and fluid regulation changes).[52,74,75] The crucial role of the SNS in at least some cases of CRPS is also suggested by the fact that sympatholytic blocks cause substantial pain relief in a subset of patients (those with sympathetically-maintained pain; e.g., Wasner et al.[76] and see below). Because of the frequent beneficial response empirically seen to sympathetic blocks in chronic, cold, blue, sweaty CRPS, logically, sympathetic hyperactivity was originally thought to be a primary pathophysiological mechanism.[77] However, an analysis of the current available data provides evidence that sympathetic vasoconstrictor activity is inhibited rather than enhanced, at least in early CRPS.[78,79] The clinical presentation of CRPS appears to take two distinct forms, which may be sequential. Acutely, vasodilatation and sudomotor dysfunction (hot, red, occasionally dry) is characteristically observed; in contrast, patients with chronic CRPS often exhibit signs of vasoconstriction and hyperhydrosis (cold, blue, sweaty).[80] This apparent temporal progression of vasomotor dysfunction from hypoactive to hyperactive is in accord with the sequential changes in rat paw temperature observed in the chronic constriction injury animal model of CRPS.[81] In a series of human studies examining thermoregulation and sympathetic reflexes in response to whole-body warming or cooling using a thermal suit, Wasner and colleagues[76,78] have corroborated the temporal progression from acute, relative sympathetic hypofunction, through an intermediate stage, to a chronic state of relative hyperfunction. Whole-body cooling, a very effective stimulus to tonically activate cutaneous vasoconstrictor pathways, induced a much lower level of vasoconstriction in the affected side as compared with the healthy side in acute CRPS patients.[76] Wasner[78] also reported a significant negative correlation ($p < 0.001$) between the duration of the disease and the maximal temperature difference between the affected and unaffected sides achieved during this thermoregulatory testing. The cold symptom pattern often seen in chronic CRPS is most likely related to adrenergic receptor supersensitivity, perhaps resulting from early sympathetic hypofunction due to local sympathetic nerve damage,[82] decreased central drive, or both. This hypothesis is supported by studies examining plasma catecholamines in CRPS and studies using PET scanning techniques.[83–85] These mechanisms do not exclude processes at the capillary and venular site of the vascular bed that may involve the sympathetic and unmyelinated afferent neurons[86] that could contribute to neurogenic inflammation and edema.[49]

Results of thermoregulatory sweat tests and quantitative sudomotor axon tests often reveal increased sudomotor activity in acute CRPS; however, only results of the former are increased in chronic CRPS.[76,87] While these sudomotor changes are not entirely in line with the pattern of reported vasomotor changes in CRPS, they do support a central sympathetic dysregulation in this acute period that is in accord with known thermoregulatory mechanisms.[76,87] The dysfunctional effectors of the SNS that are most prominent in CRPS (vasomotor and sudomotor) are thermoregulatory and are thought to be primarily under hypothalamic control.[73,88] It is important to note that these sympathetic signs and symptoms are highly variable between patients and even within patients over time.[89,90]

During the 1980s and early 1990s, many clinicians and researchers considered the presence of SMP to be a central feature of CRPS. SMP was corroborated by reports of significant analgesia when the efferent sympathetic nerve supply to the affected area was blocked.[91–93] The concept of SMP remains potentially useful clinically, as it suggests an intervention that may provide a relatively pain-free window of opportunity so that responsive patients might begin a functional restoration course. Physiologically, it is well established that nociceptive afferents are not influenced by sympathetic fibers under normal conditions,[94,95] and the specific role of the SNS in perpetuating pain in pathological states such as CRPS is not clear.[96] However, evidence from several studies suggests potential direct interactions between SNS activity and CRPS pain. Drummond[97] introduced a small dose of norepinephrine into capsaicin-treated skin by iontophoresis and showed markedly increased thermal hyperalgesia. Moreover, injection of adrenergic agonists into the symptomatic limb of CRPS patients often provokes or enhances pain, even if the limb has been sympathectomized.[92,98,99] These findings are consistent with the clinical observation that CRPS pain often increases in cold weather or in response to psychological stress, when catecholamine secretion would be expected to increase.[76] Experimentally evoking the startle response also causes increased pain intensity in CRPS-I patients, presumably via sympathetic activation, and these pain changes are paralleled by significantly greater vasoconstriction on the affected side versus the unaffected side.[100] Many of the motor abnormalities of CRPS have also been reported to improve with sympatholytic blocks, implying that some of these motor symptoms may also be sympathetically main-

tained.[101] Despite the hyperalgesic impact of increased SNS activity on CRPS pain in experimental studies and the common clinical assumption that SNS hyperactivity contributes directly to CRPS pain, unilateral fracture patients who later developed CRPS showed impaired SNS shortly after injury (recorded with laser Doppler fluxmetry).[102] In addition, presence of impaired SNS function shortly after facture prospectively predicted who later developed acute CRPS-I.[102]

A theoretical synthesis of this SNS data: there is acute damage to small efferent sympathetic fibers with the original trauma (such as a fracture or crush injury) resulting in relative sympathetic hypofunction (hot, red, dry). Soon thereafter, cholinergic receptor upregulation occurs in the target tissues (vessels, sweat glands) and importantly, adrenergic receptors may become activated/sensitized on afferent pain fibers as well. Ultimately, there may be regeneration of sympathetic fibers into this pathologically altered region (or restitution/upregulation of central sympathetic drive), giving the clinical appearance of sympathetic hyperfunction (cold, blue, sweaty), and providing direct stimulation of noradrenergically sensitized nociceptors.[78,80,82,83]

Trophic, Dystrophic, and Nutritional Abnormalities

Tropic/dystrophic changes to skin (thin and glossy or thickened), nails (thickened, striated), and hair growth (increased or decreased) are ubiquitous in reports of chronic CRPS symptomatology, but are of unknown etiology. These changes may simply be due to relative hypoxia with chronic vasoconstriction,[58,103,104] and a similar process could also lead to the observed nerve drop out[57] and osteopenia[33] reported in CRPS. There is evidence of cellular hypoxia or impaired oxygen utilization in the CRPS affected side compared to the unaffected side based on magnetic resonance spectroscopy.[105] Skin capillary hemoglobin oxygenation has also been shown to be decreased on the affected side in CRPS patients as determined by microlight guide spectrophotometry.[104] Skin, but not venous lactate, was also reported to be increased on the affected side as measured by dermal microdialysis, suggesting decreased oxygenation.[103] The decreased range of motion often seen in CRPS could be due in part to trophic changes of joints, tendons, or ligaments. It is also possible that many of these changes could be caused by inflammation as originally suggested by Sudeck[33] or by hormonal changes.[106]

Motor and Movement Disorders

Although older diagnostic criteria do not mention motor or movement disorders,[107] newer empirically derived criteria and clinical experience feature motor system abnormalities prominiently.[75,108] Most CRPS patients show weakness, spasm, tremor, bradykinesia, and range of motion abnormalities,[109] while a minority (~10%) may show more dramatic aberrations such as dystonia.[110] Weakness of skeletal muscles of the affected distal extremity is common.[110] Tremor may occur in as many as 70% of patients with upper extremity CRPS, with most represented by an apparent increase in physiologic tremor.[108,109] This tremor may decrease with sympathetic block or sympathectomy, suggesting that some motor features of CRPS may be sympathetically maintained.[109] Muscle spindles have extensive adrenergic innervation[111] and may become sensitized as the vasomotor system does. Inflammatory mediators, especially cytokines, may also sensitize muscle spindles.[112] Bradykinesia is a common abnormality in CRPS and is likely a central abnormality at a spinal and/or cortical level.[108,109] Cerebral motor processing abnormalities have been shown in CRPS with kinematic and grip force analysis.[113] Increased reactivity of the motor cortex has been shown by MEG[68] and transcranial magnetic stimulation studies.[114] In sum, numerous findings suggest clinically-important motor abnormalities in CRPS that may be of central origin. There is some evidence that there may be an incongruity between sensory input and motor output, and this hypothesis has been used as the rationale for a treatment that involves ''normalizing'' the sensory input with mirror therapy.[115] An apparent motor neglect syndrome could also contribute to significant motor dysfunction in some patients, further suggesting a central etiology of the motor dysfunction of CRPS.[116] CRPS-related motor dysfunction may worsen problems with disuse (see below). An area of interest in motor dysfunction is the basal ganglia, as this is an area of somatosensory and motor processing ideally positioned to explain motor aberrations in CRPS.[117] Chronic nociceptive input to the basal ganglia may lead to abnormal programming of motor tasks in CRPS patients.

Immobilization and Disuse

Patients with prolonged casting/immobilization of a limb present with many signs and symptoms considered characteristic of CRPS (e.g., sensory disturbances, vasomotor and sudomotor asymmetry, atrophic and dystrophic changes including osteopenia[118]). In rats, casting of hind paw for 4 weeks led to warmer limbs, edema, enhanced cellular extravasation, allodynia, and periarticular osteopenia that reversed after removing the casts, and rats casted after tibial fracture showed vasomotor and nociceptive abnormalities that persisted for several months longer than casting alone.[119] The potential contribution of disuse to CRPS symptomatology provides a primary rationale for functional restoration as treatment.[120,121]

Genetics

One of the unsolved questions in human pain is why only a minority of patients develop chronic pain after identical inciting events (e.g., nerve lesions).[122,123] In contrast, in animal models of nerve lesion, almost all animals develop neuropathic pain behavior.[9,10,12,124,125] In CRPS specifically, it is interesting to consider why some individuals who have frequent, sometimes severe injuries never develop CRPS (e.g., soccer players, American football players); yet in others, trivial injuries may lead to full blown CRPS (e.g., intravenous starts, minor sprains).[122] As always, there may be environmental considerations that predispose, but genetic factors will ultimately prove to be important. The human leucocyte antigen (HLA) molecules encoded by genes of the major histocompatibility complex (MHC) may contribute to several neurologic disorders including CRPS.[126] An early report described three families with two or more members in each affected by CRPS, suggesting the possibility that CRPS risk was heritable.[127] In small studies, the HLA loci A3, B7, DQ1(06), DR2(15) and DR13 are specifically implicated.[128–130] One Japanese study suggests an association between CRPS and the angiotensin-converting enzyme gene (non-MHC axis) and notes elevated angiotensin II in CRPS patients.[131] At present, data regarding possible genetic contributions to CRPS are rather limited, but are sufficient to justify further exploration of this very plausible contribution to pathophysiology.

A Convergent Pathophysiologic Theory

These seemingly divergent factors that are proven, theorized, or hypothesized to be involved in the pathophysiology of CRPS can be synthesized.[8] The peripheral factors such as nerve and tissue damage and inflammation (regional and neurogenic) cause an afferent barrage that begins the process of peripheral and central sensitization. Central effects such as changes in the dorsal horn, brainstem, limbic areas, and cortex acutely and chronically occur. An efferent response evolves as feedback from all these areas

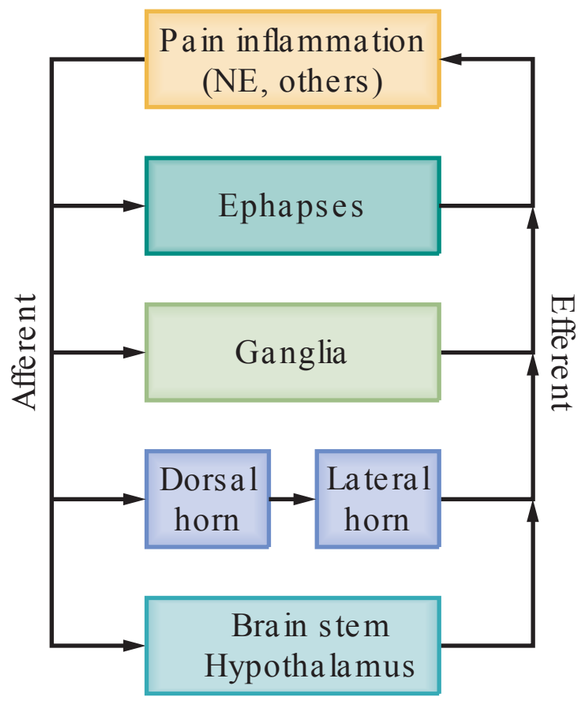

FIGURE 25.1 CRPS maintained and reinforced by nested, reverberating, feed forward (afferent) and feedback (efferent) loops. Overlaying this are the vectors of genetics (endogenous) and sociologic operant paradigms (exogenous).

along the motor (cortico-spinal) and sympathetic (limbic-hypothalamic-brainstem) systems. This efferent outflow may then substantially impact the peripheral dynamic by affecting the nutritional and inflammatory stasis in the damaged region. All of these sites interconnect, for instance by ephapses and short loops in the CNS (e.g., the sensory to sympathetic ganglion, dorsal to lateral horn, brainstem, etc.). Overlying all of this is variance in response on the basis of genetics (nature) and psychosocial factors (nurture). Thus, nested feedback and feed forward loops and cascades within the neuroaxis develop. Importantly, these feedback and feed forward loops can be self maintaining and can spread (come to involve more and more elements of the central nervous) (Fig. 25.1).

DIAGNOSIS

In the past, CRPS was diagnosed using a variety of nonstandardized and idiosyncratic diagnostic systems,[74,132–134] each of which was derived from the authors' clinical experiences and none of which achieved wide acceptance. This lack of a common diagnostic criteria hindered clinical progress for decades.

The International Association for the Study of Pain Criteria

After much debate, the name for the syndrome was ultimately changed to CRPS at a consensus workshop in Orlando, Florida, in 1994,[45,135] with the new name and diagnostic criteria codified by the IASP taskforce on taxonomy (see Table 25-1).[107] This new diagnostic entity was meant to be descriptive, general, and not to imply any pathophysiology (including any direct role for the sympathetic nervous system). According to these criteria, CRPS can be diagnosed regardless of whether the pain is sympathetically-maintained (SNS block responsive) or sympathetically-independent. These IASP-endorsed criteria had the potential to lead to improved clinical communication and greater generalizability across research samples.[45] However, realization of this potential has been somewhat limited by the fact that these criteria were derived solely by consensus. Also, since publication in 1994, utilization of the criteria has been sporadic (although increasing) in the literature,[136] and certain groups have resisted the change (especially certain advocacy groups and payors). As a consequence, the full benefits of common, clearly-defined criteria have not been completely realized.

Experience gained in developing diagnostic criteria in headache and psychiatric disorders indicates that consensus-based criteria can be significantly improved by systematic empirical validation[137] and consensus-derived criteria that are not subsequently validated may lead to over- or underdiagnosis, thus reducing the ability to provide timely, optimal treatment. Results of validation studies to date suggest that the IASP criteria are adequately sensitive (i.e., rarely miss a case of actual CRPS); however, both internal and external validation research suggest potential problems with specificity (overdiagnosis).[75,138,139] The current IASP criteria implicitly assume that signs and symptoms of vasomotor, sudomotor, and edema-related changes provide redundant diagnostic information; that is, presence of any one of these is sufficient to meet criterion 3 (see Table 25-1). This combination of multiple distinct elements of the syndrome into the same diagnostic criterion and allowing patient-reported symptoms are likely elements contributing to overdiagnosis in the IASP scheme.[75,140] An additional weakness of these criteria is the failure to include motor/trophic signs and symptoms, which could lead to important information being ignored that may help discriminate CRPS from other syndromes.

These conclusions are supported by the results of factor analysis (a statistical pattern recognition technique) that was conducted in a series of 123 CRPS patients. These results indicated that signs and symptoms of CRPS clustered into four statistically-distinct subgroups.[75] The first of these subgroups was a set of signs and symptoms indicating abnormalities in pain processing (e.g., allodynia, hyperalgesia). Skin color and temperature changes characterized the second subgroup, indicative of vasomotor dysfunction. Edema and sudomotor dysfunction (e.g., sweating changes) combined to form a third unique subgroup. The finding that vasomotor signs and symptoms were statistically-distinct from those reflecting sudomotor changes/edema is in contrast to the IASP criteria, which treats all three of these as diagnostically equivalent. A fourth and final subgroup was identified that included motor and trophic signs and symptoms. Numerous studies have described various signs of motor dysfunction (e.g., dystonia, tremor) as important characteristics of this disorder,[116,134,141] and trophic changes have frequently been mentioned in historical clinical descriptions. The absence of both of these features from current IASP criteria is therefore notable, especially given factor analytic findings that this subgroup of signs and symptoms does not overlap significantly with other characteristics of CRPS currently used in diagnosis.

External validity, which addresses the ability of the diagnostic criteria to distinguish CRPS patients from those with other types of pain conditions, is also an important issue. In the absence of a definitive pathophysiology of CRPS and thus the absence of a definitive objective test to serve as a criterion standard, providing evidence for the external validity of diagnostic criteria is challenging.[142] However, the upper limit of external validity can be evaluated by using the original criteria themselves as a reference point.[75,138,142] In this methodology, a CRPS patient group is identified using a strict application of the IASP/CRPS criteria with a comparison group of non-CRPS neuropathic pain patients defined by independent diagnostic information (e.g., diabetic neuropathy diagnosed by presence of chronic diabetes with ascending symmetrical pain and corroborated by electrodiagnostic studies). Existing criteria and modifications to these criteria can then be evaluated with regard to their ability to distinguish between these two groups based on patterns of signs and symptoms. This model was used to test the utility of the IASP/CRPS criteria for discriminating between 117 patients meeting IASP criteria and 43 neuropathic pain patients with established non-CRPS etiology. The IASP/CRPS criteria and decision rules (e.g., "evidence at some time" of edema *or* color changes *or* sweating changes satisfy criterion 3) did discriminate significantly between the CRPS and non-

CRPS groups. However, closer examination of the results indicated that while diagnostic sensitivity (i.e., being able to detect the disorder when it is present) was quite high (0.98), specificity (i.e., minimizing false positive diagnoses) was poor (0.36), and a positive diagnosis of CRPS was likely to be correct in as few as 40% of cases.[75,139]

For clinical purposes, sensitivity is extremely important. On the other hand, the issue of specificity is quite important for selection of research samples, as well as for minimizing unnecessary, potentially invasive treatments. The clinical implication of high sensitivity at the expense of specificity is that CRPS may be overdiagnosed and, ultimately, overtreated. It also has the very significant downside of identifying pathophysiologically heterogeneous groups for research, contributing potentially to negative results in clinical trials.[75]

The "Budapest" Criteria

A meeting of international researchers and clinicians with expertise in CRPS (the "Budapest Group") was held in Budapest, Hungary, in 2003 to make consensus recommendations on proposed revisions to the current IASP diagnostic criteria. The criteria ultimately proposed by the Budapest Group were consensus-based modifications of the criteria that were statistically derived from the validation studies, as above.[75,139] These modified criteria assessed CRPS characteristics within each of the four statistically-derived factors described above. Given evidence that objective signs on examination and patient-reported symptoms both provide useful, but nonidentical information, the modified criteria required the presence of signs and symptoms of CRPS for diagnosis.[75,138,143] A test of these modified criteria regarding their ability to discriminate between the CRPS and non-CRPS neuropathic pain groups indicated that they could increase diagnostic accuracy.[75,142] Results indicated that a decision rule requiring that two of four sign categories and three of four symptom categories be positive for a diagnosis to be made resulted in a sensitivity of 0.85 and a specificity of 0.69. This decision rule represented a good compromise between identifying as many patients as possible in the clinical context while substantially reducing the high level of false positive diagnoses associated with current IASP criteria. This decision rule was therefore adopted in a set of proposed clinical diagnostic criteria endorsed by the Budapest Group (summarized in Table 25-2).[75,143]

The proposed clinical diagnostic criteria described reflected an improvement over current IASP criteria for clinical purposes, but still suffered from less than optimal specificity for use in the research context.[143] Tests of the modified CRPS criteria above indicated that modifying the decision rules to require that two of four sign categories and four of four symptom categories be positive for diagnosis to be made resulted in a sensitivity of 0.70 and a specificity of 0.94. Of all the permutations tested, this decision rule resulted in the greatest probability of accurate diagnosis for both CRPS and non-CRPS patients (approximately 80% and 90% accuracy, respectively).[75,139,140,143] This high level of specificity was considered desirable in the research context by the Budapest Group, and therefore was adopted as part of a set of proposed research diagnostic criteria.[140,143] Current distinctions between CRPS-I and CRPS-II subtypes, reflecting respectively the absence and presence of evidence of peripheral nerve injury, were ultimately retained despite ongoing questions by the consensus group as to whether such distinctions have clinical utility.[143]

Thus, CRPS is a clinical diagnosis, made with simple bedside testing techniques known by all physicians. Technical testing procedures are sometimes used to corroborate or objectively document clinical impressions (e.g., thermography, bone scans).[40] To date none of these have been formally validated.

TABLE 25.2

"BUDAPEST" DIAGNOSTIC CRITERIA FOR CRPS

General Definition of the Syndrome
CRPS describes an array of painful conditions that are characterized by a continuing (spontaneous and/or evoked) regional pain that is seemingly disproportionate in time or degree to the usual course of any known trauma or other lesion. The pain is regional (not in a specific nerve territory or dermatome), but may spread, and usually has a distal predominance of abnormal sensory, motor, sudomotor, vasomotor, and/or trophic findings. The syndrome shows variable progression over time.
To make a clinical* diagnosis, the following criteria must be met: 1) Continuing pain, which is disproportionate to any inciting event. 2) Must report at least one symptom in **three of the four** following categories: —**Sensory**: Reports of hyperesthesia and/or allodynia. —**Vasomotor**: Reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry. —**Sudomotor/Edema**: Reports of edema and/or sweating changes and/or sweating asymmetry. —**Motor/Trophic**: Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin). 3) Must display at least one sign **at time of evaluation** in **two or more** of the following categories: —**Sensory**: Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement). —**Vasomotor**: Evidence of temperature asymmetry and/or skin color changes and/or asymmetry. —**Sudomotor/Edema**: Evidence of edema and/or sweating changes and/or sweating asymmetry —**Motor/Trophic**: Evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin). 4) There is no other diagnosis that better explains the signs and symptoms.

*For research purposes, diagnostic decision rule should be at least one symptom **in all four** symptom categories and at least one sign observed at evaluation in two or more sign categories (modified from Harden[143]).

Sequential Stages of Complex Regional Pain Syndrome?

Although not part of clinical diagnosis per se, it is lore among clinicians that CRPS entails three sequential stages that differ in patterns of signs and symptoms. This traditional staging model is summarized by Bonica.[132] The early, acute stage of CRPS (Stage I) was characterized by pain/sensory abnormalities (e.g., hyperalgesia, allodynia), vasomotor and sudomotor dysfunction, and prominent edema. Stage II (Dystrophic Stage) was proposed to occur 3–6 months after onset, and to be characterized by more marked pain/sensory dysfunction, with continued evidence of vasomotor dysfunction and development of significant motor/trophic changes. Stage III (Atrophic Stage) was characterized by decreased pain/sensory disturbance, continued vasomotor disturbance, and markedly increased motor/trophic changes. Although until recently, there had been only limited empirical tests of this hypothesized staging of CRPS, the concept has frequently been accepted as fact in the CRPS literature.[132,144,145]

The limited available prospective research that followed patients who develop CRPS-like symptoms after surgery, fracture, or severe hand injury suggests that in many cases the condition does not progress through increasingly problematic stages like those described above.[6,52,146,147] Retrospective surveys completed by CRPS patients with an average pain duration of over 3 years similarly indicate that CRPS symptoms often tend to remain stable or improve, rather than progressively deteriorate.[138] More recently, the statistical technique of cluster analysis was used to test for evidence of sequential stages.[148] Specifically, three unique subgroups were identified, with patients in each subgroup displaying statistically similar patterns of symptoms but that there were no significant pain duration differences between the three subgroups; in contrast to the traditional staging model, the group with the most motor/trophic signs and symptoms had a slightly shorter mean pain duration.[148] Findings such as these suggest the possibility that the presumed sequential stages often reported by clinicians may reflect CRPS subtypes, rather than an actual staging that follows a progressive, deteriorating course. There is some evidence that "temperature staging" may occur; early CRPS may tend to present with increased temperature ("hot CRPS") and longer duration CRPS to present with decreased temperature ("cold CRPS").[79,149] Data are not yet sufficient to conclude whether such temperature staging occurs in all patients.

Psychological Factors in Complex Regional Pain Syndrome

It is critical to properly deem CRPS (as all chronic pain conditions) as a biopsychosocial disease; as such, it is crucial to clinical success that psychologic and sociologic diagnoses be identified and targeted for intervention. Psychologic factors could theoretically influence onset or maintenance of CRPS via adrenergic mechanisms believed to contribute to CRPS pathophysiology as described above.[82,83,86,93,149,150] The impact of catecholamine release in the pathophysiologic mechanisms described above may be important to recognize given that psychologic factors such as life stress and dysphoric emotional states (e.g., anxiety, anger, depression) can be associated with increased catecholaminergic activity.[151,152] For example, levels of plasma epinephrine were found to correlate significantly with depressive symptoms in a sample of 16 CRPS patients.[153] Similarly, plasma norepinephrine levels were significantly higher in a sample of 15 CRPS patients than in age- and gender-matched healthy controls, and these elevations were associated significantly with higher scores on a measure of posttraumatic stress symptoms.[154] It is plausible that stress and emotional distress could, through their impact on catecholamine release, interact with adrenergically-mediated pathophysiologic mechanisms to contribute to onset or maintenance of CRPS. Interestingly, recent evidence suggests that elevated stress levels in CRPS patients may also be associated with altered immune response, which could potentially impact CRPS as well.[154]

Examination of the historical CRPS literature frequently reveals the implicit assumption that psychologic dysfunction (usually emotional disorders) contributes to CRPS in at least some patients. This assumption probably colored physicians' conceptualization of CRPS patients, despite the absence until 10 years ago of a significant body of controlled studies examining this issue. In the existing research literature, most studies assessing the role of psychologic factors in CRPS have been limited to case series descriptions or cross-sectional psychologic comparisons between CRPS patients and non-CRPS chronic pain patients.[155]

The ability to make conclusions about psychologic factors contributing to onset of CRPS depends on prospective research designs, which are rare in the CRPS literature. One prospective study indicated that higher levels of anxiety symptoms prior to total knee arthroplasty were associated with greater likelihood of displaying CRPS-like symptoms at 1 month post surgery.[6] These latter findings would be consistent with the psychophysiologic model proposed above. However, it is notable that neither anxiety nor depression predicted occurrence of CRPS-like symptoms at 6 months, so the long-term impact of psychologic factors on development of chronic CRPS remains unclear. Even if the psychophysiologic model is accurate, this should not be taken to imply that the presence of psychological risk factors alone would be either necessary or sufficient to cause CRPS. For example, one prospective study indicated that among 88 consecutive patients assessed shortly after acute distal radius fracture, 14 had significantly elevated life stress but did not develop CRPS, and the one patient who did develop CRPS had no apparent psychologic risk factors (i.e., no major life stressors, average emotional distress levels).[156]

In the absence of other prospective studies, the question of whether psychologic factors affect the development and maintenance of CRPS must be addressed solely on the basis of case reports and retrospective or cross-sectional research designs which do not allow causation to be inferred. Two uncontrolled retrospective case series reported a relationship between onset of CRPS and contemporaneous emotional loss or major life stressors,[157,158] although these can at best be considered anecdotal. The only controlled study regarding the role of life stress in CRPS onset found that 80% of patients in a CRPS sample recalled a stressful life event temporally concurrent with the initiating physical trauma, in contrast to only 20% of non-CRPS controls.[159] Although this suggests that stressful life events occurring concurrently with a physical trauma may contribute to development of CRPS, this study's findings still must be viewed with caution due to its retrospective design.

If psychologic dysfunction is somehow uniquely involved in onset or maintenance of CRPS, one might expect an increased prevalence of psychiatric disorders or elevated levels of emotional distress in this population. Based on structured interviews, estimates for prevalence of Axis I psychiatric disorders (e.g., anxiety and depressive disorders) in CRPS patients indicate a prevalence ranging from 24% to as high as 65%.[56,160,161] It should be noted that only Monti et al.[160] included a non-CRPS chronic pain control group, and these authors reported that prevalence of Axis I disorders was not significantly higher in CRPS compared to non-CRPS pain patients. None of the studies above documented psychiatric status prior to CRPS onset and therefore cannot address the issue of causality. At present, there is no evidence that CRPS patients suffer from diagnosable psychiatric disorders at a higher rate than do other chronic pain patients.

Controlled studies have also addressed the issue of whether CRPS patients are more emotionally distressed than other types of chronic pain patients. Several cross-sectional studies have found that CRPS patients report being more emotionally distressed than non-CRPS pain patients, in terms of greater depression and/or anxiety levels.[159,162–165] These findings for depressed mood may be relevant when one considers that in a study using time series diary methodology, depression levels on a given day were a significant predictor of CRPS pain intensity on the following day.[166]

More recently, results of a prospective study indicated that patients displaying signs and symptoms of CRPS 6 months following total knee replacement reported significantly higher levels of anxiety than did patients not displaying CRPS, despite the fact that both groups were continuing to experience at least some degree of pain.[6] However, baseline anxiety and depression did not predict CRPS status at 6 months, suggesting that the observed elevations in psychologic distress were a result of CRPS pain rather than a cause. In light of these findings, one possible explanation for elevated distress often reported in CRPS patients relative to non-CRPS chronic pain patients might be that the unusual and sometimes dramatic symptomatology of CRPS (e.g., allodynia, hyperalgesia, vasomotor changes, significant edema, motor changes) is more distressing than experiencing more common forms of chronic pain. Moreover, the validity of these symp-

toms are often questioned by health care providers, potentially adding to patient distress.

Some studies suggest CRPS patients are more distressed than comparable non-CRPS chronic pain patients, yet other studies have reported no such differences. For example, work by Ciccone and colleagues[165] provided only partial support for this hypothesis, finding that CRPS patients reported more somatic symptoms of depression than non-CRPS patients with local neuropathy, yet displayed no emotional differences relative to low back pain patients. Other studies have found no evidence of elevated distress among CRPS patients compared to low back pain patients[167,168] or headache patients.[167] In the absence of additional well-controlled studies, it remains unclear whether the findings suggesting uniquely elevated distress in CRPS patients are an artifact of sample selection.

Two studies report that emotional distress, when present, may have a greater impact on pain intensity in CRPS than in other types of chronic pain.[164,169] For example, correlations between pain intensity and both anxiety and anger expressiveness are significantly stronger in CRPS patients than in non-CRPS chronic pain patients.[164,169] These results suggest that even if CRPS patients are not uniquely distressed, the impact of that distress may be unique, possibly due to the hypothesized adrenergic interactions described above. These findings could have significant treatment implications, as psychologic interventions that reduce distress may directly contribute to reductions in CRPS symptoms (e.g., pain, vasomotor changes).

Another important operant mechanism that may contribute to CRPS is the sometimes dramatic disuse that patients develop in an effort to avoid stimuli that may trigger. Even in healthy individuals, prolonged disuse leads to temperature/color changes and hyperalgesia similar to those observed in CRPS.[118] Significant inverse correlations between CRPS pain intensity and ability to carry out activities of daily living suggest that pain avoidance is likely one of the common reasons for CRPS-related activity impairments.[159] Learned disuse, reinforced by either avoidance of actual pain or reduced anxiety subsequent to avoiding anticipated pain exacerbations (kinesophobia), may prevent desensitization and eliminate the normal tactile and proprioceptive input from the extremity that may be necessary to restore normal central signal processing.[170,171] Learned disuse may also inhibit the natural movement-related pumping action that helps prevent accumulation of catecholamines, tachykinins, and other nociceptive and inflammatory mediators in the affected extremity, which may impact negatively on CRPS signs and symptoms.[51] Pain-related learned disuse might therefore interact with other pathophysiological mechanisms to help maintain and exacerbate both the pain-related and autonomic features of CRPS (see below).[155]

In summary, while the contribution of psychologic factors to the development and maintenance of CRPS is largely speculative, it is theoretically consistent and highlights the importance of addressing psychologic factors in the clinical management of CRPS.

TREATMENT

The Rationale for Functional Restoration

CRPS can be a very challenging condition to successfully manage. It is biomedically multifaceted and should be treated as such.[172] The patient presentation often changes over time, and the natural history is variable and poorly understood. Evidence for efficacy of various treatment modalities is scarce and has developed slowly,[120] due in large part to the vagaries of diagnosis. The only treatment methodology that can have a reasonable chance of successfully bridging the varied presentation and mechanisms of disease and the profound gaps in treatment evidence is a systematic and orderly interdisciplinary approach.[173] Interdisciplinary treatment is defined as a dedicated, coherent, coordinated, specially trained group of relevant professionals that meet regularly to plan, coordinate care, and adapt to treatment eventualities.[143] It is critical to identify and aggressively treat all spheres of the pain experience in CRPS; obsessing with the biomedical alone dooms the clinician and patient to failure, especially in CRPS in which pathophysiology is incompletely characterized. Psychosocial targets that may impact pain and dysfunction are often readily and effectively treatable, and should be embraced as important avenues of help.

Pain is a central component of CRPS diagnosis and must figure prominently in any treatment regimen. However, its subjective nature makes this symptom a moving target that can only be effectively addressed by addressing not only subjective pain but also learned pain behavior and dysfunction. Thus, it is critical to target both subjective and objective clinical benchmarks and outcomes. Ideally, the treatment of CRPS should rely upon an intuitive, measurable, and stepwise functional restoration algorithm as the pivotal feature of treatment.[148,171,174] This line of reasoning has been codified by two large international consensus-building conferences.[171,175] The Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials has concluded that physical functioning is a "core domain" in the assessment of pain treatment efficacy, second only to pain assessment.[176,177] Functional restoration emphasizes physical activity ("reanimation"), desensitization and normalization of sympathetic tone in the affected limb, and involves a steady progression from the most gentle, least invasive interventions to the ideal of complete rehabilitation in all aspects of the patient's life (Fig. 25.2). [143,171,175] Although the benefits of functional restoration are intuitive (and are becoming dogma), the evidence as to which modalities are optimal, when to use what and for how long, is currently unavailable.[143,175,178] In a early pivotal paper, Davidoff et al.[174] conducted a prospective uncontrolled study in RSD that supported the functional restoration approach with three key findings: (1) that objective functional components and biometric data could be quantified longitudinally; (2) that these components were reactive enough to display change over time (e.g., in response to a functional restoration-based interdisciplinary program); and (3) that they were associated with improvements in subjective outcomes (e.g., decreased pain). This study supplied a primary rationale for a reliance on functional measures as the basis for assessing success in the treatment of CRPS. Various uncontrolled studies suggest that CRPS patients benefited from certain physiotherapeutic modalities, including stress loading and isometric techniques.[170] Oerlemans et al.[178,179] conducted a prospective controlled study of 135 CRPS patients with pain located in an upper extremity and reported that both physical therapy (PT) and occupational therapy (OT) proved valuable in managing pain, restoring mobility, and reducing impairment. Birklein et al.[87] similarly found that pain reports were notably lower for patients undergoing PT.

Immobilization is recognized as a possible cause and/or perpetuating factor in the syndrome.[107] Patients (and animals) with prolonged casting of a limb often have many signs and symptoms considered part of the CRPS syndrome: vasomotor and sudomotor asymmetry, trophic/dystrophic changes including osteopenia, and occasionally sensory disturbances.[180] Diminished active range of motion is common in early CRPS,[181] and CRPS is associated with significantly reduced mobility and impaired ability to use the affected area normally.[182] Thus, normalized movement is a key objective in treating central changes linked with the syndrome, loosely categorized under the rubric of "altered central processing" and salient to this argument, "neglect."[183] "Pain-related fear is more disabling than pain itself," and this fear appears to be a dynamic clinical factor in CRPS.[184,185] The ability to impact this kinesophobia seen in most CRPS patients clinically provides a persuasive argument for functional restoration as fundamental. Meta-analyses have shown that an interdisciplinary

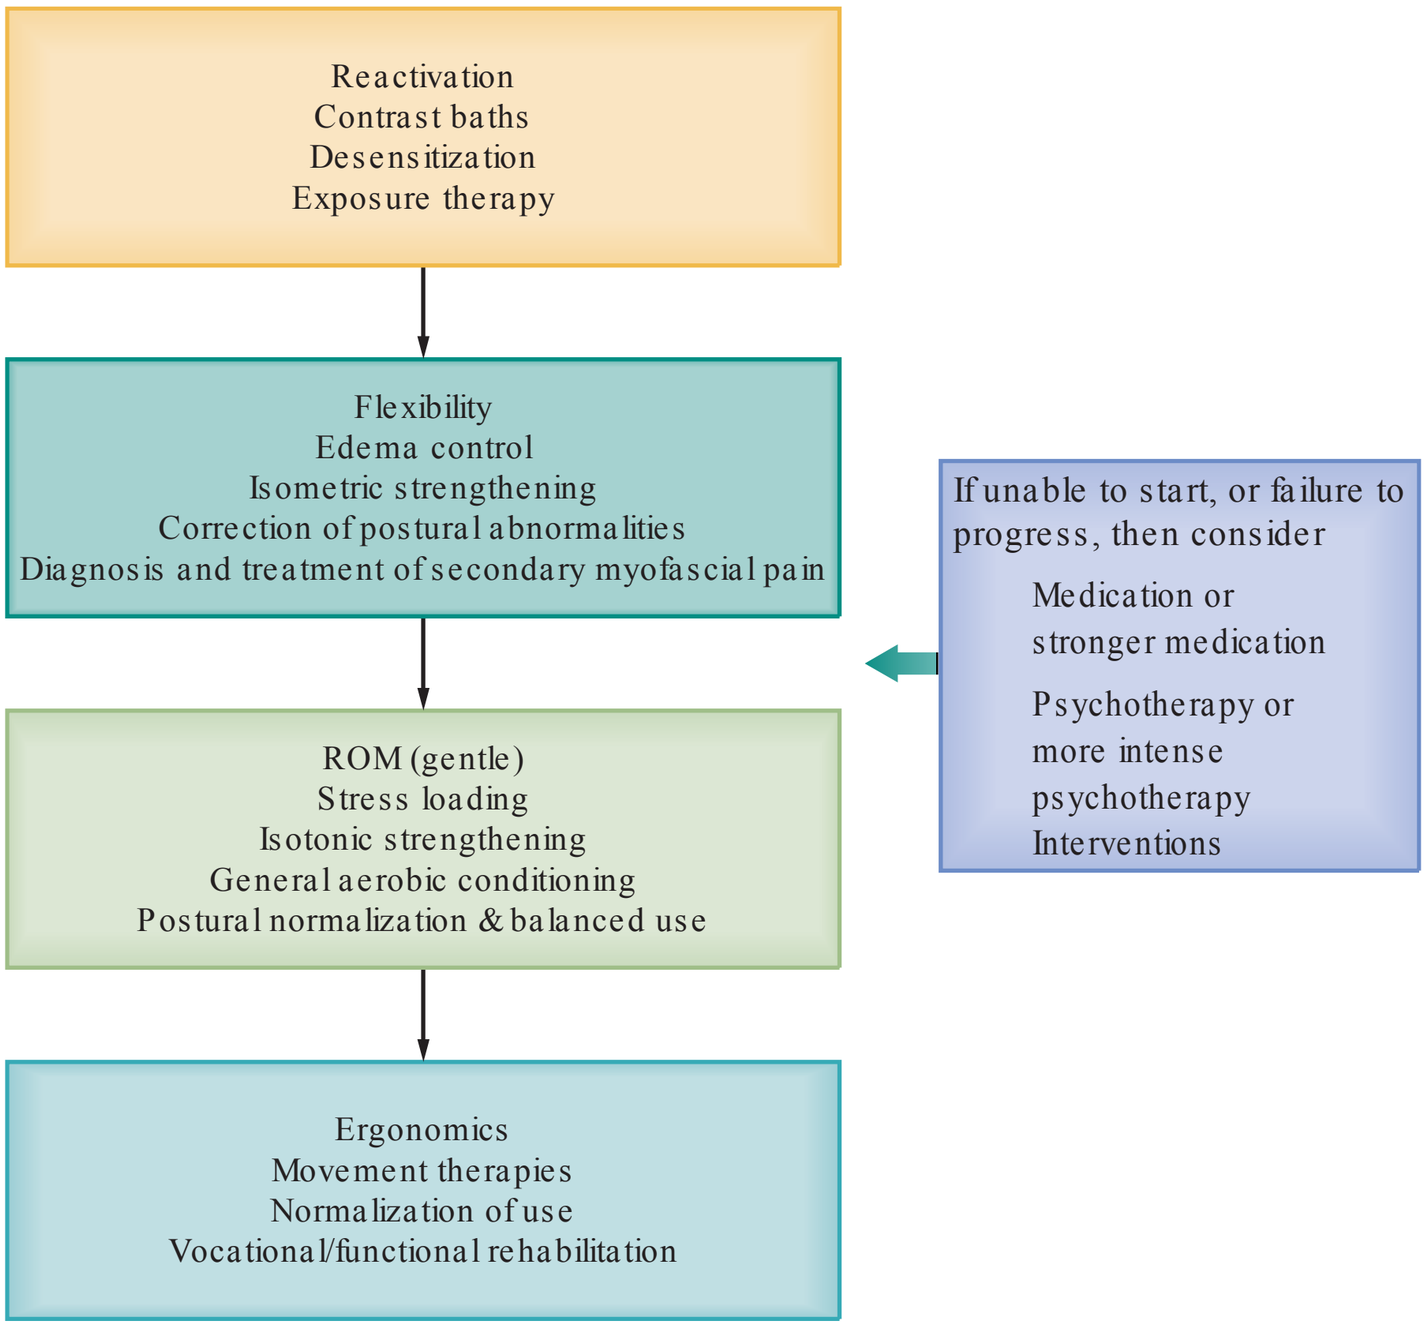

FIGURE 25.2 Functional restoration algorithm. From the outset, in appropriate cases, the patient should have access to medications and/or psychotherapy and/or injections. If the patient cannot begin, or fails to progress, at any step or in any regard, the clinical team should consider starting (or adding) more or stronger medications and/or more intensive psychotherapies and/or interventions (modified with permission from Harden[172]).

approach like that used in comprehensive functional restoration programs for CRPS improves symptoms in patients with chronic pain.[186,187]

Rehabilitation-Based Treatment Modalities

Occupational therapists are the ideal therapeutic leaders in the functional restoration process, as they are trained in the biopsychosocial principles of disease and are primary in functional assessment and treatment.[188] OT begins with an assessment of the patient's status and current function (e.g., range of motion, activities of daily living, edema). OT treatment should aim to normalize sensation and posture, decrease muscle guarding, minimize edema, and increase normal use.[189,190] Specialized garments, bandaging, and manual edema mobilization techniques can help manage edema.[191] Regular use of the affected limb during everyday tasks is promoted and strongly reinforced throughout the rehabilitation process. A stress loading ("scrubbing" and carrying) program should be implemented as soon as possible.[170,192] Later, treatments emphasizing active range of motion, coordination/dexterity, strengthening, and proprioceptive neuromuscular facilitation can be applied (see Fig. 25.2).[193] In extreme CRPS cases, functional splinting may be required to encourage improved circulation/nutrition to the affected area as well as to promote more normal tissue length/positioning during rehabilitation.

PT plays an equally critical role in functional restoration.[194,195] PT emphasizes range of motion, flexibility, posture, and later, weight-bearing and strength through the use of gentle progressive exercise. PT must be executed within the bounds of the patient's tolerance,[196] and never when the affected limb is insensate (such as immediately after a block).[197] Inappropriately aggressive PT can trigger extreme pain, edema, distress, and fatigue, and may in turn exacerbate the inflammation and sympathetic symptoms of CRPS. Oerleman's group has shown that PT (and to a lesser extent OT) improves pain scores and "active mobility" versus controls.[178,179,198] In children with CRPS, a single-blind, randomized trial of PT combined with cognitive–behavioral therapy demonstrated significant improvement on five measures of pain and function[199] and in a prospective review of 103 children with CRPS, intensive PT (aerobic, hydrotherapy, and desensitization) supplemented by psychologic counseling was effective.[190] The therapy program should be primarily based on functional goals and achieved through active or active-assisted means or the use of low-tech devices (e.g., swiss balls, foam rolls, etc.). PT should encourage pacing and include rest breaks and relaxation techniques as well. Mat exercises provide strengthening of both the extremity and the postural muscles in a non–weight-bearing approach and may include movement therapies such as Feldenkrais or Pilates. Virtually all patients with advanced CRPS will present with myofascial pain syndrome of the supporting joint, and effective treatment of this is critical to optimize outcomes. Aquatic therapy can be quite valuable to CRPS patients because of its hydrostatic/compressive principles and its buoyancy effect.[190] Massage, electrostimulation, ultrasound, and contrast baths are empirical modalities administered by PT (see Fig. 25.2).[195]

The recreational therapist is often the first clinician to succeed in getting the CRPS patient to initiate increased movement. The incentive of returning to a favorite pastime is often the appropriate reinforcer to modify kinesophobia and bracing.[200] Through the use of modifications, adaptive equipment, and creative problem solving (e.g., large handled gardening equipment, bowling with the nondominant hand, etc.), a patient can enhance self efficacy and develop confidence through previously lost recreational activities (see Fig. 25.2).[195]

The vocational rehabilitation (VR) counselor helps prepare the appropriate CRPS patient for the ultimate functional restora-

tion: return to work. Consultation with employer, supervisor, employee health nurse and work site visits are potential interactions initiated by VR. The VR counselor uses information from medical, occupational, educational, financial, and labor markets interfaced with the client's job description/analysis to attempt to reset negative operant paradigms and operationalize the benefits of work.[195] The VR counselor should participate in the work capacity evaluation, transferable skills analysis, job-specific reconditioning, work hardening, and functional capacities evaluation, and be central in the development and documentation of modifications, restrictions, return-to-work assessments, and work release documents.[195,201,202] VR counselor, occupational therapist, and responsible physician work closely together in these tasks, with an ideal goal of return to the original job with the original employer (see Fig. 25.2). The sociologic issues surrounding CRPS are pervasive, but very poorly characterized. The best approach to managing these is to compassionately and firmly pursue the goals of optimal functional restoration while proactively providing tools for closure in the forensic and compensation arenas.

Because the symptoms of CRPS patients encompass all the biopsychosocial complexities of chronic pain, the best hope of helping patients is the adoption of a systematic, stable, empathetic, and, above all, interdisciplinary approach that addresses those symptoms.[195] Pharmacotherapy, psychotherapy, and interventional techniques should be efficiently deployed for patients who either cannot begin or fail to progress using the interdisciplinary functional restoration approach outlined above. Many patients will require medication and psychotherapy from the beginning to be successful in the pivotal functional restoration algorithm (see Fig. 25-2).[195,203] That functional restoration can and should be the central intervention and outcome standard in CRPS is a theory that must be tested. Until then, the interdisciplinary approach for treating patients with CRPS clearly remains the most pragmatic, helpful, and cost-effective therapeutic approach available today.

Pharmacotherapy

In the 130 years since Weir-Mitchell recommended laudanum (tincture of opium) and the use of a new invention, the hypodermic syringe, to perform cocaine nerve blocks,[1] multiple pharmacotherapeutic interventions for CRPS have been described.[57,121,203] Unfortunately, there are very few randomized controlled trials (RCTs) in CRPS.[120] The best empirical approach must therefore employ the limited data available, extrapolate from better evidence that is available in related conditions (e.g., neuropathic pain),[204] and pragmatically utilize sequential drug trials in each unique case based on putative mechanisms, driven by close monitoring of outcome and risk (Table 25-3). Pharmacotherapy in CRPS, as with most chronic pain syndromes, achieves the greatest benefit when used in conjunction with an interdisciplinary approach to treatment. In CRPS patients, the initial pain intensity is often sufficient that pharmacotherapy may be necessary to begin available nonpharmacologic treatments, and rational polypharmacy is usually required to optimize analgesia.[121,203] In treating CRPS, the clinician must construct a drug regimen that draws from two basic classes of medications: prophylactic drugs (for maintenance, drugs used on a scheduled basis) to obtain base line analgesia and abortive drugs (rescue agents, pro re nata) for breakthrough pain or symptom flares. Although analgesia for its own sake has obvious value, a unifocal palliative strategy without concurrent functional restoration is useless in CRPS.[143,171,203]

Nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, Cox-2 inhibitors, and free-radical scavengers are generally used to treat CRPS pain in the context of discernible inflammation. As described previously, there is evidence that inflammatory components are critical to the development or perpetuation of CRPS, especially early in the course.[42,205] Anti-inflammatory medications can be used for both rescue and prophylaxis. NSAIDs have shown mixed results in several clinical trials of neuropathic pain, including one trial that showed that NSAIDs had no value in treating CRPS-I.[206] Even though Cox-2 selective inhibitors have not been properly assessed in CRPS, they have been used anecdotally.[207]

Oral corticosteroids are the only anti-inflammatory drugs with strong evidence in CRPS,[120,208] and there are two RCTs supporting their efficacy, at least in acute CRPS.[209,210] Given the data, a short course of steroids in acute CRPS with inflammatory features is indicated, but longer courses have a questionable risk benefit ratio[120] as there are numerous obvious contraindications to chronic steroid use. Free radical oxygen species are known to have a role in inflammatory processes and may be involved in CRPS; thus specific antioxidants in theory might have a role in CRPS treatment.[34] One RCT of the antioxidant vitamin C was found to reduce the incidence of RSD in patients with wrist fractures.[211] Neuroimmune modulators affecting inflammation, such as thalidomide,[212,213] lenalidomide,[214] etanercept, and infliximab,[215] all have some open label support in CRPS, and RCTs of some of these are ongoing.

There is anecdotal support for anticonvulsant drugs in CRPS, but no RCTs. There are meta-analytic and systematic reviews compiling evidence for the efficacy of certain anticonvulsant compounds as prophylactic agents in other forms of neuropathic pain,[216–219] and the diverse mechanisms of action of some anticonvulsants theoretically should be useful in addressing some of the putative pathophysiologic mechanisms underlying CRPS.[121,221] Gabapentin, Pregabalin, and Carbamezepine have strong evidence supporting their use in neuropathic pain conditions and anecdotal support in CRPS.[221–227]

There are also several meta-analyses of the analgesic efficacy of antidepressant/anxiolytics (ADs) in neuropathic conditions,[216,217,228,229] with some low-quality evidence supporting

TABLE 25.3

PHARMACOTHERAPY CONSIDERATIONS

Condition/Presentation	Suggested Response
Mild to moderate pain	Simple analgesics and/or blocks
Excruciating, intractable pain	Opioids and/or blocks or later, more experimental interventions
Inflammation/swelling and edema	Steroids, systemic or targeted (acutely) or NSAIDs (chronically); immunemodulators
Depression, anxiety, insomnia	Sedative, analgesic antidepressant/anxiolytics (and/or psychotherapy)
Significant allodynia/ hyperalgesia	Anticonvulsants and/or other sodium channel blockers and/or *N*-methyl-D-aspartate-receptor antagonists
Significant osteopenia, immobility, and trophic changes	Calcitonin or bisphosphonates
Profound vasomotor disturbance	Calcium channel blockers, sympatholytics and/or blocks

These very general guidelines are overruled by individual patient presentation. It is also important to note that certain drugs, such as bisphosphonates, may be associated with analgesia as well as the more primary action (modified with permission from Harden[172]).

the use of ADs in CRPS.[120,230] These drugs have obvious use in managing some of the comorbidities in CRPS, such as major depression and anxiety.[121,229] Second generation ADs have not been studied in CRPS, but the so-called serotonin/norepinephrine reuptake blockers show some promise.

The use of opioids for general chronic pain management is still the subject of some controversy,[120,231] but this class has anecdotal support for both abortive and prophylactic treatment in CRPS.[232] Only one RCT has been conducted specifically in CRPS, with negative results.[227] In general, neuropathic pain does not respond to opioids as well as nociceptive pain[233–236]; consequently, neuropathic pain may require higher doses (with an increase in the risk of side effects). Moreover, some animal data suggest that long-term opioid use may actually evoke symptoms characteristic of CRPS, such as allodynia and hyperpathia.[237] *N*-methyl-D-aspartate receptor antagonists (e.g., MK-801, ketamine, amantadine, and dextromethorphan), which theoretically should reduce central sensitization, have been considered for the treatment of neuropathic pain, but some of these have proven too toxic for regular clinical use in oral formulations.[238–242] Ketamine has shown favorable results in case reports of patients with CRPS.[243–245] There is some ongoing interest in high dose anesthetic ketamine protocols,[246] although there are no well-controlled studies supporting this approach. Amantadine has shown some benefit in neuropathic pain.[247,248] Dextromethorphan may augment the effect of other medications, especially opioids.[249]

Clonidine has been considered for the treatment of CRPS,[250] but most often by the epidural route.[251] A case series showed that transdermal clonidine could reduce local CRPS-induced hyperalgesia and allodynia,[252] but results of a systematic review failed to support the efficacy of this treatment approach.[120] Nifedipine has demonstrated some benefit in uncontrolled trials, particularly for the management of vasoconstriction.[253,254] Phenoxybenzamine and phentolamine have some low-quality evidence supporting their use in CRPS.[91,253–256] Calcitonin is one of the best-studied drugs in the treatment of CRPS.[257–260] A meta-analysis of a limited number of controlled calcitonin studies supported the therapeutic value of intranasal doses of 100–300 U per day for the management of CRPS.[259,261] However, one study reported no improvement after administration of 200 IU twice daily for 4 weeks.[257]

There are two positive randomized studies of bisphosphonates for the treatment of CRPS.[262,263] Two smaller RCTs and one case series of oral pamidronate have also suggested some benefit.[264,265] The impact of these drugs on the osteopenia (Sudeck's atrophy) that is often prominent in chronic CRPS is unknown.

Topical medications may also be of some use in management of CRPS. There is limited research endorsing the use of local anesthetic creams in neuropathic pain,[266] but RCTs have not been performed. A patch containing 5% lidocaine is FDA-approved for the management of postherpetic neuralgia, and is used anecdotally for CRPS.[267,268] A study of high-dose topical capsaicin with pretreatment with regional anesthesia demonstrated partial efficacy.[269] In one high-quality study, the topical free radical scavenger dimethyl sulfoxide (50% cream for 2 months) showed significant pain reduction when compared with placebo.[270] Topical clonidine has been mentioned, as above.[252]

In most cases, no single drug will provide sufficient analgesia long-term, nor will it completely prevent the need for abortive/rescue agents. This clinical reality usually requires multiple medications to adequately manage the pain (see Table 25-3). There are numerous other medications that have been anecdotally mentioned as treatments for CRPS (e.g., case reports), but there is insufficient evidence to justify their inclusion in this chapter.

Psychologic Interventions

As psychologic and sociologic factors often contribute to CRPS pain and dysfunction and given the relative effectiveness of psychotherapeutic interventions, it is clear psychologic and behavioral treatments must play an important role in CRPS management.[172,173,272] Such interventions are likely to be maximally effective if provided in the context of multidisciplinary care. Psychologic interventions for CRPS, typically based on cognitive–behavioral therapy principles, should target learned disuse, fear of pain, cognitive responses to CRPS (e.g., catastrophizing), life stress, and emotional distress that may contribute to maintenance or exacerbation of the disorder.[172,173] Training in relaxation techniques (progressive muscle relaxation, breathing relaxation, autogenics, imagery) is of anecdotal use in giving patients some degree of control over their symptoms, particularly if complemented with biofeedback (especially thermal and myogenic). Moreover, as in all types of chronic pain, better pain coping skills may lead to improved functioning and quality of life and increased ability to self-manage pain.[172] At minimum, such treatments are likely to enhance patients' sense of control over the condition, and thereby reduce fears that may be a barrier to achieving success in functional therapies. Interventions that target a family's reinforcing responses to the patient's pain may also be helpful in addressing problems with learned disuse and dysfunction. It should be noted that the psychologic interventions above will only be successful to the extent that patients are willing to accept some responsibility for managing their condition, as opposed to an exclusive focus on achieving a medical "cure." Facilitating this cognitive shift to a self-management approach is often the first step necessary to achieve successful outcomes in both functional and psychologic therapies.[172]

A number of studies have addressed efficacy of psychologic interventions for CRPS, although nearly all of these reflect uncontrolled designs that permit only limited conclusions to be drawn. An additional caveat regarding these studies is that the criteria used to diagnose CRPS were often not adequately described and in all likelihood varied substantially across studies. This lack of consistent or specified diagnostic criteria limits the ability to generalize these results to patients diagnosed according to current IASP criteria.

Only one randomized trial specifically testing psychologic interventions in CRPS patients has been published to date. In this pilot study, Fialka et al.[272] randomized treatment for 18 CRPS patients to receive either home PT or home PT plus once-weekly autogenic relaxation training for 10 weeks. In this small trial, both groups showed similar improvements in pain, range of motion, and edema, although patients in the PT + Autogenics group could demonstrate significantly greater improvements in limb temperature.[272] The impact of this learned control over vasomotor tone and the probable improvement is self efficacy are unknown.

Results of several published case studies and small case series in adult CRPS patients further support the potential utility of a variety of psychologic techniques, including relaxation training, imagery, and thermal and muscular biofeedback. In all of these studies, 75% to 100% pain relief was reported, despite the fact that these patients had chronic CRPS that had failed to improve with previous medical treatments.[271,273–276] It should be noted that the complete resolution of symptoms described in some of these cases using only psychologic interventions may be atypical. While the uncontrolled designs used in these studies prevent definitive conclusions from being drawn regarding the efficacy of psychologic techniques for CRPS, they clearly support the recommendation that such techniques should play an important role in effective interdisciplinary treatment. Key to this analysis is the very favorable risk-benefit ratio.[172]

Other research has addressed psychotherapy in the context of multidisciplinary treatment, suggesting that integration of psychologic methods with medical and PT may be helpful in managing CRPS.[179,190,199,277] Two RCTs examining efficacy of physical therapy for CRPS have included components of psychologic treatment in the therapy package. Oerlemans et al.[179,277] tested a PT

protocol that included relaxation exercises and cognitive interventions (designed to increase perceived control over pain). This combined intervention was found to produce significantly greater improvements in pain, active range of motion, and impairment levels than were observed in the social work control group.[179,277] In another RCT of physical therapy, Lee et al.[199] examined two different frequencies of PT treatment (once per week versus three times per week) for child and adolescent CRPS patients, with both groups additionally receiving six sessions of cognitive–behavioral treatment. Although no attentional control group was available for comparison, both groups were found to improve significantly in terms of pain and function when compared to their pretreatment baselines.[199] While the multicomponent interventions in both of these studies do not indicate the unique efficacy of psychologic interventions, they do suggest that psychologic treatment in combination with PT may prove effective in a rehabilitation-focused approach to management of CRPS.[172] The efficacy of psychologic interventions for CRPS would not be surprising, given the strong evidence of their utility in other types of chronic pain.[278–285]

Interventional Therapies

Multiple interventional therapies, including a variety of nerve blocks, infusions, stimulators, and implants have been used over the years for management of CRPS.[175,286] Because the sympathetic nervous system is traditionally implicated in the symptomatology and perhaps the pathogenesis of the syndrome, it is logical (but unfortunately not evidence-based) that sympathetic nerve blocks (SNBs) and surgical sympathectomies have played a prominent role in the treatment (and diagnosis) of CRPS.[132,287] In fact, CRPS diagnosis at one time was determined primarily based on a positive response to a sympathetic block.[74] However, at present, analgesia to SNBs merely indicates the presence of SMP. SMP is a subset of CRPS, whereas some CRPS patients display sympathetically-independent pain.[288] The presence of SMP provides a rationale for using SNBs to relive pain and to provide a therapeutic window to allow initiation of, or continued participation in, functional restoration.

Ideally, the pain relief following SNB should outlast the somatic effect of the local anesthetic and may be very long-lasting in some cases.[289,290] A systematic review of local anesthetic blocks included 19 retrospective reports, 5 prospective case series, 2 nonrandomized controlled studies, and 3 RCTS; unfortunately, due to the wide range of methodology in the studies, the results were inconclusive.[291] In the absence of better evidence, if a SNB provides good analgesia in a specific patient, then a short series of empiric blocks in conjunction with active reactivation-focused therapy is advocated based on consensus recommendations.[175,286]

The brachial plexus is anatomically well suited for continuous regional anesthesia in upper extremity CRPS because of its well-defined perivascular compartment and the close proximity to nerves supplying the upper extremity.[286,292,293] Axillary blocks and catheters have their advocates.[294] Epidural infusions of local anesthetics and sympatholytics (single or continuous infusions) are used empirically and have some research support.[251,295,296] Intrathecal analgesia has less support[297] with the exception of research using baclofen.[297,298] The complications of these interventions must be weighed versus the putative benefits and include bleeding, infection, intravascular injection, intrathecal injection, epidural abscess, pneumothorax, and others.[251,286,299]

Use of systemic infusions, especially of sympatholytics such as phentolamine, has been proposed for both treatment and diagnosis of CRPS. One early study showed positive results with guanethidine regional infusion.[302] A later study suggested that neither placebo, phentolamine, nor phenylephrine infusions conferred any benefit.[301] Phentolamine infusion is now seldom used therapeutically and principally used as a putative diagnostic tool to differentiate sympathetically independent pain from SMP.

Intravenous regional anesthesia (IVRA) is a procedure that allows infusion of medications directly into the affected region, usually using a variety of sympatholytic agents.[302] IVRA with guanethidine, lidocaine, bretylium, clonidine, droperidol, ketanserin, or reserpine have been described.[120,207,261] Although three IVRA studies with active controls have shown positive results,[303–305] the majority of studies and results of meta-analysis suggest no significant benefits.[120,207,261,306,307] Some authors advocate combination drug IVRA therapy,[308,309] and the use of new agents with this technology may eventually establish the worth of this technique (e.g., anticytokine agents).

As surgery is often mentioned as a cause of CRPS, it is somewhat illogical to consider surgery as an effective treatment. Nonetheless, surgical sympathectomy has a long anecdotal history in the treatment of RSD,[287,310] and more recently, endoscopic and radiofrequency sympathectomy have been tried.[311,312] There are no RCTs available and the risks are significant.[310,313] There is also no strong evidence and specifically no RCTs, supporting the efficacy of neurolytic procedures, either chemical or radiofrequency.[286]

There is one prospective RCT comparing spinal cord stimulation versus conservative therapy for upper extremity CRPS.[314] This trial showed a significant reduction in pain and a positive global perceived effect at 6 months, without functional improvement. Marginal improvement in these features, as well as in health-related quality of life, were maintained at 2 years.[315] A definitive trial has never been performed. There are several case reports predictably supportive of the procedure.[316,317] There are a variety of other interventions that have been mentioned, such as peripheral nerve stimulation or cortical stimulation, but there is no compelling evidence supporting such interventions to date.[318,319]

In the face of this lack of evidence for most interventions in CRPS, it is incumbent on the clinician to carefully consider and fully educate patients as to the risks and cost of any intervention entertained, and not overplay anecdotal benefits. One recommended strategy is to use interventional treatments for CRPS only in patients who are having difficulty either starting or progressing in a functional restoration/interdisciplinary program, starting with less invasive blocks, then infusions, and finally, if necessary, progressing to the more experimental neurostimulation techniques.[286]

Other Therapeutic Modalities

Hyperbaric oxygen therapy has been assessed in one RCT and produced a significant decrease in pain and edema versus "normal air."[320] These results need replication, but cost–benefit considerations will also be important. Although acupuncture is mentioned in many treatment reviews, there is only one small RCT in CRPS, and this trial failed to show significance. The authors noted that a definitive trial was planned, but this has been pending since 1999.[321] There is no evidence supporting the use of chiropractic manipulation in CRPS.[322] There are many, many other interventions that have been mentioned in the literature, but without experimental support. Discussion of the myriad anecdotes extant is far beyond the scope of this effort. Obviously, there is a critical need for well-designed, well-executed, randomized, and if possible placebo-controlled trials in CRPS.

In summary, because the symptoms of CRPS patients encompass all the biopsychosocial complexities of chronic pain, the best hope of helping our patients is the adoption of a systematic, stable, empathetic, and, above all, interdisciplinary approach that addresses those symptoms. Drugs, psychotherapy, and interventions should be efficiently deployed for patients who either cannot begin or fail to progress using the interdisciplinary approach out-

lined here. Many patients will require medication and psychotherapy from the beginning to be successful in the pivotal functional restoration algorithm. Treatment guidelines that center on progressive functional restoration delivered by an interdisciplinary team are traditional, have substantial empiric and anecdotal support, and have been assessed and ultimately codified by three large, expert, consensus-building conferences. Although high-level evidence supporting the rationale for interdisciplinary treatment of CRPS is fairly sparse (as it is for any treatment of CRPS), much stronger evidence exists for the efficacy of the interdisciplinary approach in other pain conditions, such as chronic low back pain. That functional restoration can and should be the central intervention and outcome standard in CRPS is a theory that must be tested (see Fig. 25.2). Until then, the interdisciplinary approach for treating patients with CRPS remains the most pragmatic, helpful and cost-effective therapeutic approach available today.[172]

CHAPTER 26 ■ PHANTOM PAIN

HOWARD S. SMITH, IRFAN LALANI, AND CHARLES E. ARGOFF

INTRODUCTION

In 1871, Civil War surgeon Silas Weir Mitchell[1] popularized the concept of phantom limb pain (PLP) and coined the term *phantom limb* with publication of a long-term study on the fate of Civil War amputees. Phantom limb sensations may occur in roughly 85% of amputees and tend to be seen in the first 3 weeks after amputation,[2] although less commonly may develop 1 to 12 months following amputation.[3] Most phantom sensations generally resolve without treatment after 2 to 3 years.

Phantom pain refers to pain perceived in a missing body part and may occur in about 50% to 80% of all amputees.[4] Pain may be related to certain positions or movements of the phantom and may be elicited or exacerbated by a range of physical factors (e.g., changes in weather or pressure on the residual limb) and psychological factors (e.g., emotional stress). It seems to be more intense in the distal portions of the phantom and can have several different qualities, such as stabbing, throbbing, burning, or cramping.[5]

Residual limb pain—previously referred to in the literature as stump pain—refers to a regional pain restricted to the distal residual part. Unlike phantom pain, it occurs in the area of the body that actually exists. Patients may also experience feelings of tingling, itching, cramping, or involuntary movements in the residuum.

Commonly, the phantom is exactly the same size and shape as the missing limb immediately after the amputation.[6] Over time, the phantom may gradually reduce in size and shorten into the residual limb (telescope) so that eventually only the foot, hand, or digits are left on the stump.[7–10] Hill proposed that telescoping occurred in one-third of amputees.[11]

The exteroceptive component describes the feelings within the phantom. Examples are "pins and needles," "tingling," "tickling," "itching," "numbness," and "like it is asleep."[7,11–16] Super-added sensations are the sensation of an object such as a ring, wristwatch, or shoe still being present on the phantom[17,18] or the return of a painful condition such as an ingrown toenail that existed some time before the amputation.[9,19] Super-added sensations were identified by 5 of 68 amputees (7%) in one study.[10,20] Exteroceptive sensations included pins and needles (50%) and itching (42.9%).[10] The high report of itching is interesting in terms of the mechanism of both PLP and itch. It has been found that similar areas of the brain, including the premotor areas, are involved in both sensations.[21,22]

EPIDEMIOLOGY

In 1983 Sherman et al. published a survey of 590 war veteran amputees in which 85% reported phantom pain.[23] A study with 2,694 amputees showed that 51% experienced PLP severe enough to hinder lifestyle on more than 6 days per month, 21% reported daily pain over a 10- to 14-hour period and 27% for more than 15 hours per day.[24] The incidence of PLP increases with more proximal amputation. Residual limb pain is reported in up to 50% of amputees.[25–31]

PLP has been reported to occur as early as 1 week after amputation and as late as 40 years after amputation.[32,33] Phantom pain may diminish with time and eventually fade away. However, some prospective studies indicate that even 2 years after amputation, the incidence is not greatly diminished from that at onset.[31,34]

MODULATION OF PHANTOM PAIN

The development of PLP can best be described as multifactorial. It is becoming appreciated that preamputation pain is a risk factor for the development of significant PLP.[14,35–37] Phantom pain may mimic preamputation pain.[17,38]

Phantom pain may be modulated by multiple factors, both internal as well as external. Exacerbations of pain may be produced by trivial, physical, or emotion stimuli. Anxiety, depres-

sion, urination, cough, defecation, sexual activity, cold environment, or changes in the weather may worsen PLP.[23,34,39–44] It also has been reported that general, spinal, or regional anesthesia in amputees may cause appearance of phantom pain in otherwise pain free subjects.[45–50]

PATHOPHYSIOLOGY OF PHANTOM PAIN

The mechanisms underlying phantom pain are complex and incompletely understood. It is highly likely that phantom pain is mediated by a complex interaction between the brain, spinal cord, and periphery.

Postamputation, damaged C-fiber and A-fiber axons generally undergo ineffective regeneration to form neuromas (e.g., enlarged and disorganized endings of C fibers and demyelinated A fibers that show an increased rate of spontaneous activity[5]) in the residual limb. About 30% of the time these neuromas may act as "pain generators" of PAP.[5] Mechanical (e.g., pressure [Tinel's sign]) and chemical (e.g., norepinephrine) stimulation may further increase the rate of discharge, which seems to be mainly related to spontaneous ectopia (neuronal discharge that is generated along the axon or in the soma), as a consequence of nerve injury and seems to be a result of the upregulation or novel expression of sodium channels.[51,52] These neuromas have aberrant sodium channel expression resulting in increased spontaneous and evoked discharges. These discharges can be provoked by innocuous stimuli such as pressure, light touch, and change in temperature and may be perceived as painful. Clinically, this mechanism appears to be corroborated by the observation that stump and phantom pain can be temporarily reduced in some (but not all) patients by injection of local anesthetics into stump neuromas. Ectopic discharges can also occur at the level of the dorsal root ganglion (DRG), independently of stump neuromas. This can result in amplification of peripheral signals and recruitment of neighboring neurons.

The sympathetic nervous system may play a role in potentiating phantom pain. Sympathetic nerve blocks can temporarily relieve phantom pain in some patients whereas injection of norepinephrine can exacerbate pain. Catecholamines can promote firing of peripheral mechanoreceptors, which in turn may activate sensitized dorsal horn neurons. Increased sympathetic tone can also promote ephaptic neuronal transmission in the periphery. Sympathetic tone is inversely related to skin temperature at the amputated stump.[5] Investigators have also shown an inverse relationship between phantom pain and skin temperature, suggesting that sympathetic tone promotes pain sensation.[5]

Peripheral nerve injury is also accompanied by reorganization of signal processing at the spinal cord level. Selective degeneration of unmyelinated C fibers results in functional denervation of lamina II neurons in the dorsal horn. A compensatory arborization of Aδ and Aβ fibers "sprouting" into lamina II can occur.[53,54] This change in innervation is accompanied by phenotypic switching, whereby Aβ fiber terminals release substance P, a nociceptive peptide. These changes may form the anatomic and neurochemical substrate for the clinical phenomenon of allodynia, where a non-noxious mechanical stimulus is perceived as painful.

Increased excitatory input at the dorsal horn following nerve injury can cause apoptosis of inhibitory interneurons expressing GABA and glycine. Activation of migroglia after neural injury can result in release of BDNF (brain derived neurotrophic factor), which promotes phenotypic switching of inhibitory interneurons, may lead to release excitatory neurotransmitters (e.g., glutamate). Opioid receptors are also downregulated along with upregulation of cholecystokinin, which is an endogenous opioid receptor antagonist.

Nikolajsen and Jensen[55] explained that the pharmacology of spinal sensitization involves increased activity in N-methyl-D-aspartate (NMDA) receptor-complex,[56] and many aspects of the central sensitization can be reduced by NMDA receptor antagonists. This was supported in human amputees where the evoked stump or phantom pain produced by repetitive stimulation of the stump by non-noxious pinprick was reduced by the NMDA receptor antagonist ketamine.[55]

Waxman and Hains proposed that abnormal expression of Nav 1.3 sodium channels in the 2nd and 3rd order neurons along nociceptive pathways after spinal cord injury may make these neurons hyperexcitable.[52] These neurons may then function as pain amplifiers/generators and conceivably contribute to phantom phenomena.

Peripheral injury after amputation is also accompanied by remapping of supraspinal synaptic networks, including those in the primary somatosensory cortex. Some patients with PLP exhibit "topographical remapping," where stimulation of an unaffected site (e.g., face) will result in a sensation perceived in the phantom limb. Functional imaging studies have shown activation of areas in the primary somatosensory cortex and are both adjacent and distant from the area normally subserving the affected limb. Topographical remapping appears to correlate with persistence of phantom pain, with data showing that upper extremity amputees with phantom pain have expansion of the mouth area into the hand area in the sensory homunculus (primary somatosensory cortex). These findings have also been described in the primary motor cortex of amputees, with good correlation between reorganization and presence of phantom pain symptoms.

Melzack observed that a substantial number of children who are born without a limb feel a phantom of the missing part and suggested the existence of a neural network, or *neuromatrix*, that subserves body sensation and has a genetically determined substrate that is modified by sensory experience.[59] Lotze et al. revealed that functional magnetic resonance imaging (MRI) data from amputees with pain and healthy volunteers during a lip pursing task were similar. In amputees with PLP, however, the cortical representation of the mouth extends into the region of the hand and arm. Giummarra et al. proposed that phantom pain may reflect a maladaptive failure of the neuromatrix to maintain global bodily constructs.[60] Cortical map reorganization may be facilitated via selective loss of C fibers, which occurs after amputations. C fibers appear to have an important role in the maintenance of cortical maps.

Psychological factors can also play a role in the pathogenesis of phantom pain. Though these factors may not play a causative role, they may certainly modulate the pain experience.

Longitudinal diary studies showed that there is a significant relation between stress and the onset and exacerbation of episodes of phantom-limb pain, probably mediated by activity in the sympathetic nervous system and increases in muscle tension.[61] Patients who received less support before the amputation tend to report more phantom-limb pain.[62]

Animal work on stimulation-induced plasticity suggests that extensive behaviorally relevant (but not passive) stimulation of a body part leads to an expansion of its representation zone.[63] Intensive use of a myoelectric prosthesis is positively correlated with reduced cortical reorganization and analgesic effects.[64] These effects could not be achieved with standard medical treatment and general psychological counseling because it is felt that in order to achieve analgesia, input into the amputation zone of the cortex is needed in order to "undo" the reorganizational changes induced by amputation. Similar beneficial effects on phantom pain and cortical activation were reported for imagined movement of the phantom, and may also occur to some degree with mirror treatment (where a mirror is used to trick the brain into perceiving movement of the phantom when the intact limb is moved).[65]

PREVENTION OF PHANTOM PAIN

PLP cannot currently be completely prevented; however, perioperative epidural techniques, peripheral nerve catheter techniques, or other analgesic strategies utilized preoperatively, intraoperatively, and postoperatively may at least address postoperative pain control better than not employing any specific perioperative analgesic techniques.[66–72]

Madabhushi and colleagues reported on a patient with a history of PLP from a below-knee amputation who then came for an above-knee amputation in the same extremity.[71] Before transection, the sciatic nerve was infiltrated with 0.25% bupivacaine 5 mL and clonidine 50 mcg. After the nerve was severed, a 20-gauge epidural catheter was inserted into the nerve sheath and externalized laterally through a separate skin incision. Before closure, 0.25% bupivacaine 10 ml and clonidine 50 mcg was injected, and then 0.1% bupivacaine and clonidine 2 mcg/mL was infused perineurally for the first 96 hours postoperatively. The mean postoperative pain score (from 0 to 10) for 96 hours was 1.2 ± 0.7.[71] The patient required a total of 10 mg of oxycodone postoperatively. Over a 1-year follow-up period the patient never reported stump or phantom pain.[71]

TREATMENT OF PHANTOM PAIN

Phantom pain often requires a multimodal approach to treatment. Treatment options include behavioral techniques, antidepressants, anticonvulsants, opioid and nonopioid analgesics, transcutaneous electrical nerve stimulators (TENS), neural blockade, spinal cord stimulation, and motor cortex stimulation. There remains a paucity of data from large randomized controlled trials to guide treatment options. As a general rule, initial treatments should be low risk, low cost, and noninvasive, with more expensive and invasive treatments reserved for patients who fail conservative care.

PHARMACOLOGIC INTERVENTIONS

Antidepressants

Antidepressants are commonly used for many painful conditions but especially for neuropathic pain. Although, antidepressants are utilized for the treatment of PAP conditions, they have not been well studied for PAP. Wilder-Smith et al. studied 94 treatment-naïve posttraumatic limb amputees with phantom pain (intensity: mean visual analog scale score [0–100, 40 [95% confidence interval, 38–41]) who were randomly assigned to receive individually titrated doses of tramadol, placebo (double-blind comparison), or amitriptyline (open comparison) for 1 month. Wilder-Smith and colleagues concluded that in treatment-naïve patients, both amitriptyline and tramadol provided excellent and stable phantom limb and stump pain control with no major adverse events.[73] Alternatively, Robinson et al. studied 39 persons with amputation-related pain lasting more than 6 months in a 6-week randomized controlled trial of amitriptyline (titrated up to 125 mg/day) or an active placebo (benztropine mesylate).[74] No significant differences were found between the treatment groups in outcome variables when controlled for initial pain scores, thus not supporting the use of amitriptyline in the treatment of postamputation pain.[74]

Kuiken et al. studied four individuals with PLP for at least 3 months after amputation.[75] All subjects received oral mirtazapine between 7.5 and 30 mg/day.[75] An 11-point numeric rating scale (0 to 10) measured pain intensity and relief during monitored outpatient follow-up visits. Mirtazapine use improved the PLP experienced by these subjects by at least 50%, measured by a numerical rating scale-11 (NRS-11).[75] Subjects with PLP-related sleeping difficulties reported the greatest pain relief concomitant with improved sleep quality.[75]

Antiepileptic Drugs

Carbamazepine, an anticonvulsant (and heterocyclic), has also been well documented for use in neuropathic pain syndromes and serves as a potent sodium channel blocker. Historically, it has also been the most commonly prescribed anticonvulsant for pain. Despite this, the results of its efficacy on PLP have been mixed. Patterson reported cases of phantom pain that were alleviated with the use of oral carbamazepine.[76,77] However, only brief, shock-like pain was assessed.[76] There are no studies that have shown its effectiveness in treating any of the other qualities of pain.

The effectiveness of gabapentin in postamputation PLP was studied in a randomized, double-blind, placebo-controlled, crossover study by Bone et al.[78] They evaluated analgesic efficacy of gabapentin in PLP in patients attending a multidisciplinary pain clinic. The daily dose of gabapentin was titrated in increments of 300–2400 mg or the maximum tolerated dose. Nineteen eligible patients were randomized, of whom 14 completed both arms of the study. Both placebo and gabapentin treatments resulted in reduced VAS scores compared with baseline. However, the pain intensity difference was significantly greater than placebo for gabapentin therapy at the end of the treatment. They concluded that after 6 weeks, gabapentin monotherapy was better than placebo in relieving postamputation PLP.

Nikolajsen et al. examined whether postoperative treatment with gabapentin could reduce postamputation residual limb and phantom pain and concluded that gabapentin administered in the first 30 postoperative days after amputation does not reduce the incidence or intensity of postamputation pain.[79] Pregabalin may exhibit analgesic effects on postamputation pain states but has not yet been evaluated.

Four PLP subjects[80] were treated during a larger prospective, double-blind, randomized, placebo-controlled pilot study conducted to test the efficacy of topiramate in managing various neuropathic pain conditions associated with rehabilitation.[80]

Three of the four subjects who had experienced over 2 years of refractory PLP experienced significantly reduced pain after treatment with topiramate.[80]

Opioids

Mishra et al. reported a case of intractable PLP whose pain did not respond to usual treatment and only a high dose of morphine made the patient totally pain free.[81]

Wilder-Smith et al. evaluated a recent study, 94 treatment-naive posttraumatic limb amputees with phantom pain who were randomly assigned to receive individually titrated doses of tramadol (mean dose 448mg) or placebo (double-blind comparison) for 1 month. It was found that tramadol provided excellent and stable phantom limb and residual limb pain control with no major adverse events.[73] A review found a 50% to 90% reduction in pain at 12 to 26 months with methadone 10–20 mg per day.[82]

Huse and colleagues studied the efficacy of oral long-acting morphine sulfate (MS) against placebo in a double-blind crossover design in 12 patients with PLP after unilateral leg or arm amputation.[83] The dose of MS was titrated to at least 70 mg/day and at highest 300 mg/day.[83] Pain, reorganization of somatosensory cortex, and pain thresholds were assessed pre- and posttreatment.[83] A significant pain reduction was found during MS therapy but not during placebo. A clinically relevant response to MS (pain reduction of more than 50%) was evident in 42%, with a

partial response (pain reduction of 25% to 50%) in 8% of the patients.[83] Neuromagnetic imaging utilizing magnetoencephalographic recordings of three patients showed initial evidence for reduced cortical reorganization with MS treatment concurrent with the reduction in pain intensity.[83] Huse et al. concluded that opioids show efficacy in the treatment of PLP and may also potentially influence cortical reorganization.[83]

Intravenous lidocaine and morphine have also been evaluated for their therapeutic use in postamputation pain. Wu et al. conducted a randomized double-blind trial to compare the analgesic effects of intravenous morphine and lidocaine on postamputation stump and phantom pains.[84] A bolus of morphine, lidocaine, and an active placebo (diphenhydramine) were used over a span of 3 consecutive days. The results showed that 31 of 32 subjects enrolled completed the study. Eleven subjects had both stump and phantom pains, 11 and 9 subjects had stump and phantom pain alone, respectively. Compared with placebo, morphine reduced both residual limb and phantom pains significantly. In contrast, lidocaine decreased residual limb pain but not phantom pain. The authors concluded that the mechanisms of residual limb pain and phantom pain are different.[84]

NMDA Receptor Antagonists

Stannard and Porter described three cases in which PLP was successfully treated with ketamine hydrochloride.[85] Nikolajsen et al. administered ketamine intravenously to a patient with established stump pain in a double-blind saline-controlled fashion.[86] Following infusion, stump pain was alleviated for 31 hours.[86] Ketamine reduced the allodynic area and wind-up like pain and increased pressure-pain thresholds.[86] Treatment was started with ketamine 50 mg × 4 per day dissolved in juice.[104] No side effects or development of tolerance were observed during a 3-month treatment period.[86]

Nikolajsen et al. administered ketamine (bolus at 0.1 mg/kg/5 min followed by an infusion of 7 micrograms/kg/min) intravenously to 11 patients with established stump and PLP in a double-blind saline-controlled study.[57] All 11 patients responded with a decrease in the rating of stump and PLP assessed by visual analogue scale (VAS) and McGill Pain Questionnaire (MPQ).[57] Ketamine increased pressure-pain thresholds significantly. Wind-up like pain (pain evoked by repeatedly tapping the dysaethetic skin area) was reduced significantly by ketamine.[57] In contrast, no effect was seen on pain evoked by repeated thermal stimuli. Side effects were observed in nine patients.[57]

Although calcitonin may have analgesic effects for PAP postoperatively,[87] it does not appear to be effective for chronic PAP conditions.[88] Eichenberger et al. conducted a randomized, double-blind, crossover study in which 20 patients received four IV infusions of 200 IE calcitonin; ketamine 0.4 mg/kg (only 10 patients); 200 IE of calcitonin combined with ketamine 0.4 mg/kg; placebo; and 0.9% saline. Intensity of phantom pain (visual analog scale) was recorded before, during, at the end, and the 48 hours after each infusion.[88] Ketamine, but not calcitonin, reduced PLP.[88] The combination was not superior to ketamine alone.[88]

TRPV1 Modulators

Topical capsaicin was also utilized for the treatment of PLP. In a study performed in a double-blind fashion with 24 patients, the authors concluded that capsaicin may be used as an alternative treatment for PLP.[89] Future developments may produce higher strength capsaicin products, more potent capsaicin analogues, TRPV1 antagonoists, and intravenous capsaicin formulations.

Interventional Therapy

A wide variety of types of neural blockade have been utilized in the treatment of PLP, including trigger point injections, sympathetic blocks, stump injections, peripheral nerve blocks, epidural, and subarachnoid blocks.[23] Despite this, studies have shown that only 14% of patients report a significant temporary change and 5% report a prolonged change with these blocks.[23]

The use of neural blockade in the treatment of PLP is largely based on anecdotal reports in the literature.[90–92] Blankenbaker[90] reported that sympathetic blocks are successful if amputees are treated soon after the onset of PLP. However, Halbert et al.,[93] in a systematic review to evaluate evidence for the optimal management of acute and chronic phantom pain, were unable to find any trials that met criteria for inclusion.

The use of botulinum-toxin A injections in PLP patients has also been utilized for residual limb pain control. It is conceivable that muscle tension, perhaps resulting from cortical reorganization, may contribute to phantom pain as a trigger of spinal reflexes and botulinum toxin by muscle relaxation in the stump or via inhibition of the release of various neurotransmitters may lead to analgesia. In a small pilot trial, researchers injected 100 IU botulinum-toxin A in four muscle-trigger points of an amputation stump. It was found that the use of botulinum toxin A reduced phantom pain about 60% to 80%.[94]

Kern et al. administered a total dose of 2500 IU of botulinum toxin type B (Neurobloc, Elan Pharma, Munich, Germany) to the arm amputation stumps, 5000 IU for one amputation of the lower leg, and 2500 IU to the other lower leg amputation of a patient with a very low baseline body weight.[95] Two patients reported that the injection was very painful. All patients experienced a reduction in stump pain, which lasted for many weeks.[95] Other reports included a reduction in the frequency of pain attacks, cessation of "balloon feelings," improvement in stump allodynia, and decreased occurrence of involuntary stump movements. In addition, quality of sleep at night significantly improved in one patient.[95]

Multiple other cases have been reported of botulinum toxin injections into the stump for PLP.[95,96]

Furthermore, Kern and colleagues suggested that by diminishing muscle tone, pain, and hyperhidroses, botulinum toxin may facilitate prosthesis use.[96] Four postamputation patients (one with phantom pain, three with stump pain) were each treated with 100 IU botulinum toxin A, divided between several trigger points in the distal stump musculature. In one female patient (along with a pronounced reduction in phantom pain) hyperhidrosis of the stump ceased completely, probably after diffusion of the drug into the dermal sweat glands, leading to longer and safer use of the prosthesis. Intentional intradermal injection for this purpose therefore could be potentially valuable. Another patient was able to use her prosthesis for the whole day again after botulinum toxin A treatment for substantial stump pain, compared with only 4 hours a day before treatment. In two male patients, residual limb pain while wearing the prosthesis subsided to a considerable extent, and one of the two reported an improvement in steadiness of gait. They suggested that stump treatment with botulinum toxin in rehabilitative medicine should be investigated in more detail.[96]

Dahl and Cohen treated six soldiers with residual limb and phantom pain with a series of perineural etanercept injections.[97] Five of the six patients reported significant improvements in residual limb pain at rest and with activity, PLP, functional capacity, and psychologic well-being 3 months after injections.[97] The one soldier who failed therapy was the only patient who presented with pain greater than 1 year in duration. At the reduced doses administered, no adverse effects were observed. These results seem to warrant further large well-designed studies.[97]

Neuromodulation

Transcutaneous electrical nerve stimulation has been used with some success in the treatment of phantom pain. Katz and Melzack reported that 10 minutes after receiving low frequency (4 Hz)

high intensity (10–30 V) auricular TENS, phantom pain patients demonstrated a modest, yet statistically significant decrease in pain as measured by the McGill Pain Questionnaire.[98] Investigators have reported good to excellent results in roughly 25% of patients treated with TENS.[98,99]

Spinal cord stimulation (SCS) has also been used for PLP. Seigfried et al. reported that 51% of patients with SCS had a 50% or more decrease in pain, but without long term follow-up.[100]

Bittar and colleagues concluded that deep brain stimulation (DBS) has been utilized successfully for the treatment of phantom limp pain with a resultant decreased pain, decreased opiate intake, and improved quality of life.[101] Bittar et al. published a meta-analysis supporting this pain improvement as well, especially in the burning component—perhaps via a reorganization in the central nervous system.[102]

Sol et al. used chronic motor cortex stimulation (CMCS) in 3 patients with intractable PLP after upper limb amputation.[103] Functional magnetic resonance imaging (fMRI) correlated to anatomical MRI permitted frameless image guidance for electrode placement. Pain control was obtained for all the patients initially and the relief was stable in 2 of the 3 patients at 2 year follow-up. FMRI data may be useful in assisting the neurosurgeon in electrode placement for this indication.[103]

Surgical Interventions

PLP has generally been difficult to treat with surgical interventions. Part of the difficulty in addressing PLP/stump surgically lies in the postsurgical restriction or growth retardation of stump neuromas. Residual limb neuromas develop at the site of the severed end of peripheral nerves. Surgical management may involve implanting the end of severed nerves into a nearby/adjacent large muscle belly, which may alleviate stump pain somewhat, although it does not permanently cure patients.[104]

Sakai et al. theorized that preventing neuroma formation might also significantly decrease the incidence of postamputation stump pain. Techniques to prevent neuroma formation include nerve transposition of ligation, embedding the nerve end in bone or muscle, and capping the nerve stump with a nerve graft, epineurium, or atelocollagen.[105,106]

Sehirlioglu et al. retrospectively studied 75 patients who were treated for painful neuroma after lower limb amputation following landmine explosions between the years 2000 and 2006.[107] The average time period from use of prosthesis to start of symptoms suggesting neuroma was 9.6 months. The average time period from start of pain symptoms to neuroma surgery was 7.8 months. All clinically proven neuromas were surgically resected.[107] In the mean follow-up of 2.8 years, all patients were satisfied with the end results and all were free of any pain symptoms.[107] In a painful residual with clinical diagnostic findings of neuroma if conservative measures fail, surgery may be considered as a therapeutic option.[107]

Aggressive surgical techniques, such as anterolateral cordotomy and dorsal root entry zone (DREZ) lesions, have been attempted in PLP but do not have large multicenter studies supporting their use at all and have significant morbidity and some mortality.

Behavioral Medicine Interventions

Many psychological modalities have been attempted to manage those with PLP, including cognitive behavioral therapy, biofeedback, and muscular training.[108]

Biofeedback treatments resulting in vasodilatation or decreased muscle tension in the residual limb may help to reduce PLP and seem promising in patients in whom peripheral factors contribute to the pain.[109] Harden et al. conducted a pilot study that examined the effectiveness of biofeedback in the treatment of nine individuals with PLP who received up to seven thermal/autogenic biofeedback sessions over the course of 4–6 weeks.[110] Pain was assessed daily using the visual analog scale (VAS), the sum of the sensory descriptors, and the sum of the affective descriptors of the McGill short form. Interrupted time-series analytical models were created for each of the participants, allowing biofeedback sessions to be modeled as discrete interventions.[110] Analyses of the VAS revealed that a 20% pain reduction was seen in five of the nine patients in the weeks after session four, and that at least a 30% pain reduction (range: 25% to 66%) was seen in six of the seven patients in the weeks following session six.[110]

Relaxation training has also been shown to provide significant benefit in many patients. One report noted that 12 of 14 patients with chronic PLP improved with muscular relaxation training.[108] Hypnotic imagery has been used alone and with relaxation training; however, further studies need to be done before any conclusions regarding this therapy can be made.[111]

Ramachandran and Rogers-Ramachandran[112] described another behaviorally oriented approach: a mirror was placed in a box, and the patient inserted his or her intact arm and the residual limb. He or she was then asked to look at the mirror image of the intact arm, which is perceived as an intact hand where the phantom used to be, and to make symmetrical movements with both hands, thus suggesting real movement from the lost arm to the brain. This procedure may re-establish control over the phantom limb and alleviate pain in some patients, although controlled data are lacking.

Graded motor imagery is a promising, nonpharmacological means of treating PLP. A randomized controlled trial using graded motor imagery to treat CRPS I and PLP showed NNT of 3 at 6 months for a composite end point of 50% pain reduction and improvement in function.[113] Patients in the placebo arm of this study received standard physical therapy and usual medical care. Graded motor imagery involves training patients to improve right/left discrimination and imagine pain free movements of affected and normal limbs followed by practicing pain free movements with the aid of a mirror box.[113]

Murray et al. reported three participants who experienced PLP (two with an upper-limb amputation, and one with a lower-limb amputation) that took part in between two and five immersive virtual reality (IVR) sessions over a 3-week period.[114] The movements of participants' anatomical limbs were transposed into the movements of a virtual limb.[114] All participants reported the transferal of sensations into the muscles and joints of the phantom limb, and all participants reported a decrease in phantom pain during at least one of the sessions.[114] The authors suggested the need for further research studying IVR for PLP using controlled trials.

Schneider et al. evaluated eye movement desensitization and reprocessing (EMDR) treatment with extensive follow-up.[115] Five patients with PLP ranging from 1 to 16 years who were on extensive medication regimens underwent 3 to 15 sessions of EMDR, which was used to treat the pain and the psychological ramifications.[115] EMDR resulted in a significant decrease or elimination of phantom pain, reduction in depression and posttraumatic stress disorder (PTSD) symptoms to subclinical levels, and significant reduction or elimination of medications related to the phantom pain and nociceptive pain at long-term follow-up.[115] Further research is needed to explore the theoretical and treatment implications of this information-processing approach.[115]

Miscellaneous Treatments for Residual Limb Pain

Chronic residual limb pain may occur as a result of skin pathology, vascular insufficiency, infection, bone spurs, or neuromas.[11,106,34,39]

Fitting of a prosthetic socket is a critical stage in the process of rehabilitation of a trans-tibial amputation (TTA) patient, because a misfit may cause pressure ulcers or a deep tissue injury (DTI; necrosis of the muscle flap under intact skin) in the residual limb.[116] To date, prosthetic fitting topically depends on the subjective skills of the prosthetist, and is not supported by biomedical instrumentation that allows evaluation of the quality of fitting.[116] Portnoy et al. concluded that real-time patient-specific finite element (FE) analysis of internal stresses in deep soft tissues of the residual limb in TTA patients is feasible.[116] This method may be improving the fitting of prostheses in the clinical setting and protecting the residual limb from pressure ulcers and DTI.[116]

The use of a myoelectric prosthesis might be one way to influence phantom-limb pain. Intensive use of a myoelectric prosthesis was positively associated with both less phantom-limb pain and less cortical reorganization.[117]

Topical clonidine patches (and other topical therapies) have been utilized on the residuum, but have not been studied. For relatively superficial neuromas, lidocaine via iontophoresis (e.g., LidoSite® patch [developed and manufactured by Vyteris, Inc. of Fair Lawn, NJ]), theoretically may be useful.

Gruber et al. prospectively evaluated "neurosclerosis" of residual limb neuromars, present after amputation,[118] on 82 patients by means of high-resolution sonographically guided injection with up to 0.8 mL of 80% phenol solution. During treatment, all patients had marked improvement in terms of reduction of pain measured with a visual analog scale.[118] Twelve (15%) of the subjects were pain free after one to three treatments, with 9 of the 12 achieving relief with the initial instillation.[118] After 6 months, patients had an overall decrease in median VAS score from 10.0 ± 1.5 (SD) (range, 2–10) to 3.0 ± 2.6 (range, 1–10) after one (25 patients), two (12 patients), and three treatment sessions (15 patients). At the 6-month follow-up evaluation, 20 (38%) of the 52 patients reported almost unnoticeable pain, and 33 (64%) reported pain equal to the minimum pain they had reached during phenol injection therapy. In 18 (35%) of the 52 patients, the incidence of painful periods had markedly decreased.[118] The "neurosclerosis" procedure had a low complication rate (5% rate of minor complications, 1.3% rate of major complications).[118]

Pulsed radiofrequency (PRF) treatment of the dorsal root ganglion (DRG) at the L4 and L5 nerve root level was utilized as a therapeutic option for two patients with peripherally mediated intractable stump pain. A decrease in pain intensity and improved toleration of the limb prosthesis was appreciated in both patients.[106]

Anecdotes of other analgesic strategies such as acupuncture[119] and electroconvulsive therapy (ECT)[120] for PAP conditions exist.

SUMMARY

Phantom pain remains an incompletely understood, difficult to treat pain condition. It is present in a majority of postamputation patients. It is one of the painful conditions in which an obvious loss of sensory information coupled with a disruption of the nervous system leads to pain. Phantom pain also appears to be a painful condition in which the involvement of supraspinal mechanisms may be more intuitive than other painful conditions. Optimal treatment approaches involve the coordination of an interdisciplinary pain medicine team familiar with the therapy of postamputation pain syndromes. Pharmacologic treatment approaches, physical medicine and rehabilitation treatment approaches, behavioral medicine treatment approaches, neuromodulation treatment approaches, and interventional treatment approaches may all be needed in combinations to achieve optimal outcomes. Much basic and clinical research is still required to get a better handle of pathophysiologic mechanisms, prevention strategies, and optimal treatment approaches/situations for a variety of patient and phantom pains.

CHAPTER 27 ■ HERPES ZOSTER AND POSTHERPETIC NEURALGIA

RAJBALA THAKUR, JOEL L. KENT, AND ROBERT H. DWORKIN

INTRODUCTION

The objective of this chapter is to provide an overview of the clinical presentation and management of herpes zoster and its most common complication, postherpetic neuralgia (PHN). Herpes zoster is a viral infection caused by the reactivation of the varicella-zoster virus (VZV). The primary varicella infection occurs when the patient contracts chicken pox. Following the resolution of chicken pox, the virus then remains dormant in dorsal sensory ganglia and cranial nerve ganglia for years to decades. Individuals are asymptomatic while the virus is dormant, and reactivation of VZV results in a characteristic vesicular dermatomal rash. Some patients with herpes zoster develop PHN, and this persisting neuropathic pain can last for years.

Herpes zoster afflicts millions of older adults worldwide each year and causes significant suffering and disability because of both the acute pain that occurs in association with the rash and the chronic pain that is present in those patients who develop PHN. VZV-induced neuronal destruction and inflammation causes pain that interferes with activities of daily living and reduces quality of life. Recent advances have improved our ability to both diminish the incidence of these conditions as well as manage the remaining cases more effectively. These advances include the development of a herpes zoster vaccine, consensus that antiviral therapy and aggressive pain management can reduce the burden of this disease, the identification of efficacious treatments for PHN, and the recognition of PHN as a study model for neuropathic pain research.

CLINICAL PICTURE AND NATURAL HISTORY OF HERPES ZOSTER

Herpes zoster is a neurodermatomal illness that does not cross the midline. Typically, a single dermatome is affected in immunocompetent patients, although in some cases, involvement of adjacent dermatomes can be seen due to normal variation of cutaneous innervation. In immunocompromised patients there can be cutaneous dissemination and, rarely, visceral dissemination. The sequence of events described in the following sections is typically observed.

Prodrome

Herpes zoster may begin with fatigue, headache, or flulike symptoms, including fever, neck stiffness, malaise, and nausea. This may be accompanied by unilateral dermatomal pain and abnormal sensations, including pruritis. The prodromal symptoms usually precede the appearance of a rash by 3 to 7 days, although longer periods have been reported. The prodrome probably occurs in association with the initiation of viral replication and the accompanying inflammatory response. This process results in ganglionitis, as well as the destruction of neurons and supporting cells in the dorsal root ganglion and accompanying dermatome.[1,2] In cases where patients experience a prolonged course of prodromal symptoms, diagnostic investigations are frequently undertaken to identify other medical conditions that may cause pain in the affected anatomical distribution. Common examples

of this include pursuing the diagnosis of glaucoma in cases of herpes zoster ophthalmicus, sciatica in cases of sacral dermatomal involvement, and angina, renal colic, or cholecystitis in cases of truncal involvement. Diffuse or regional adenopathy is seen in a minority of cases and has not been correlated with any residual or long-term complications.

Rash

The reactivated virus replicates in the sensory ganglion and travels antidromically via the cutaneous nerves to the nerve endings at the dermoepidermal junction. Further replication in the skin results in tissue inflammation and necrosis which ultimately leads to the appearance of a rash in the same distribution as the prodrome. The rash is initially maculopapular and evolves into the classic appearance of grouped vesicle formations on an erythematous base. Regional lymphadenopathy may appear at this stage. Over the next 7 to 10 days the lesions progress to a pustular rash. Open lesions will develop superficial crusting. Scabs are cleared within 2 to 3 weeks. Skin in the affected region may be left completely normal or may develop a patchwork of either hypo- or hyperpigmented scarring (Fig. 27.1).

Pain

Pain often precedes or accompanies the herpes zoster rash.[3–5] Pain may be accompanied by other sensations such as itching, paraesthesias, and dysaethesias. The timing of the pain may be constant or intermittent, and the quality of the pain is variously described as burning, throbbing, stabbing, electric shock-like, or various combinations of these. It is frequently associated with increased tactile sensitivity and allodynia (i.e., pain in response to a normally nonpainful stimulus). The pain may interfere with the patient's sleep and other aspects of physical and emotional functioning. The acute pain associated with herpes zoster gradually resolves in most patients around the time that the rash resolves. Pain that persists beyond the acute phase of the rash is considered subacute herpetic neuralgia or PHN, depending on its duration. A distinction between these three phases of pain associated with herpes zoster has been identified and is useful in both clinical and research settings. Acute herpetic neuralgia has been defined as pain that occurs within 30 days of rash onset, subacute herpetic neuralgia as pain that persists beyond 30 days from rash onset but that resolves before the diagnosis of PHN can be made, and PHN as pain that persists for 120 days or more after rash onset (Fig. 27.2).

Distribution of Herpes Zoster

Thoracic dermatomes are the most commonly affected sites. These are followed, in order of incidence, by the ophthalmic division of the trigeminal nerve, other cranial nerves, and cervical, lumbar, and sacral dermatomes (Table 27.1). The reason for this pattern is not understood, but it has been speculated that this may reflect the characteristic distribution of the chicken pox rash. The pattern of rash seen in herpes zoster follows the same centripetal distribution observed with the primary varicella infection. Patients can develop lesions in the adjoining dermatomes, and much less commonly, a diffuse cutaneous or even visceral dissemination can occur, most often in immunocompromised individuals.

Clinical Variants

Herpes Zoster Ophthalmicus (HZO)

HZO occurs in approximately 10% to 20% of herpes zoster cases. For unknown reasons, involvement of the ophthalmic branch of the fifth cranial nerve is five times as common compared with cases involving the maxillary or mandibular branches.

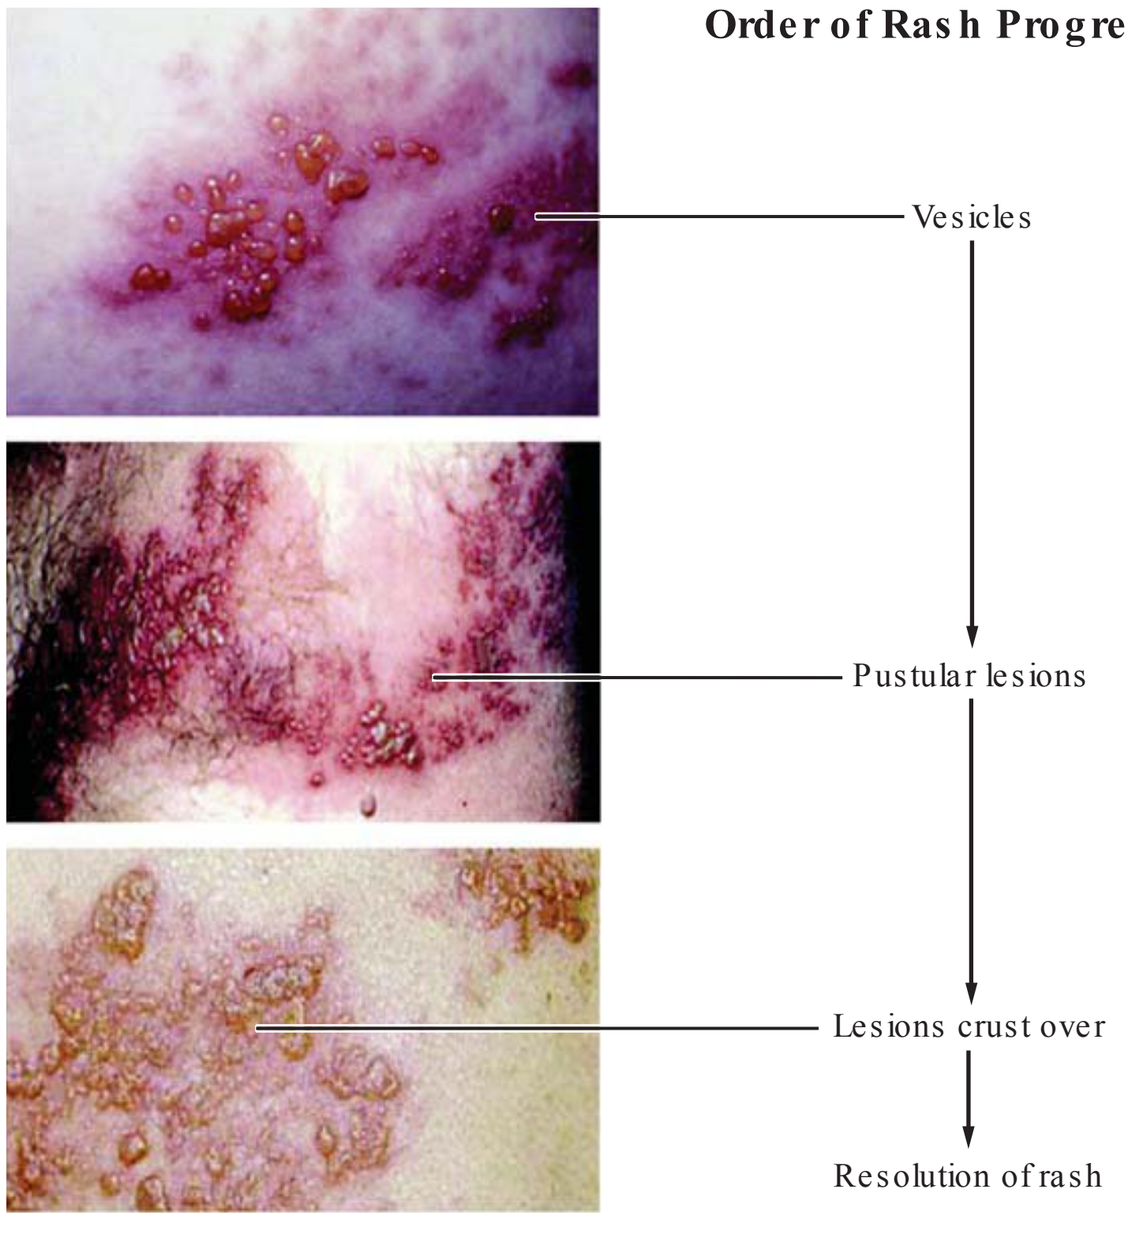

FIGURE 27.1 Herpes zoster rash progression. (From Weinberg M. Herpes zoster: epidemiology, natural history, and common complications. *JAM Acad Dermatol* 2007;57:S130–S135, with permission.)

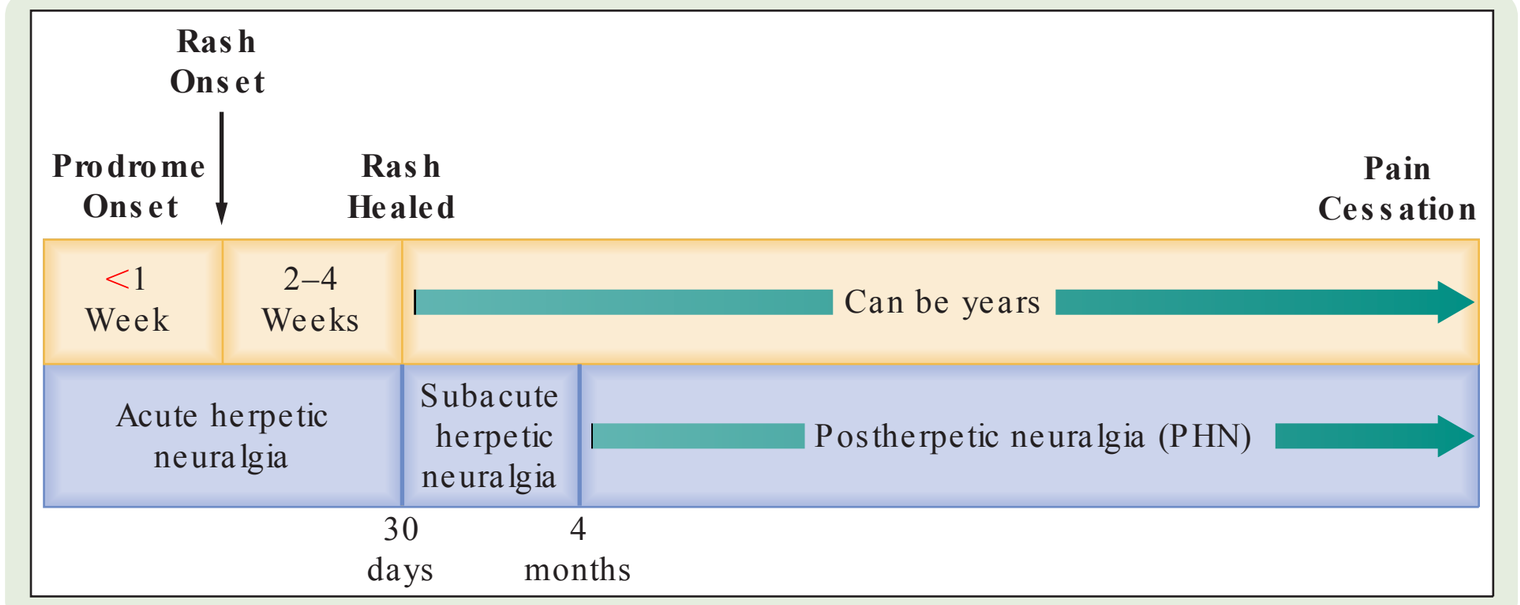

FIGURE 27.2 Natural history of herpes zoster and postherpetic neuralgia.

It is easily recognized by the presence of vesicles and erythema of the ipsilateral forehead and upper eyelid. HZO requires particularly prompt treatment and careful follow-up monitoring because of the possibility of ocular involvement, which occurs in approximately one-half of patients with HZO (Fig. 27.3).

Herpes Zoster Oticus (Ramsay-Hunt Syndrome)

This presentation of herpes zoster is relatively rare but this may reflect, at least in part, a failure to properly recognize and diagnose cases. Classically, herpes zoster oticus begins with otalgia and the formation of herpetiform vesicles within the external ear canal. Associated findings that may be present include facial paralysis resulting from facial nerve (cranial nerve VII) involvement, auditory symptoms including unilateral deafness, and/or vestibular symptoms. This condition may also result from zoster of the ninth or tenth cranial nerves because the external ear has complex innervation by branches of several cranial nerves (V, VII, IX, and X), as well as vertebral nerves C2 and possibly C3.

Zoster Sine Herpete

Herpes zoster infections presenting with only dermatomal pain in the absence of rash have been described in the literature for many years.[6,7] The actual prevalence of this condition is unknown. Positive serology in the acute or convalescent phase is the only definitive way to establish the diagnosis in such patients. Given that it would be rare to perform the required serological studies early in the disease course in most clinical settings, this diagnosis is rarely established in a definitive manner.

DIAGNOSIS OF HERPES ZOSTER

The diagnosis of herpes zoster is usually established based upon the clinical findings of a characteristic dermatomal rash (Fig. 27.4) and the presence of associated pain. The differential diagnosis frequently includes contact dermatitis. Herpes simplex virus (HSV) infection must also be considered, particularly if sacral dermatomes are involved. The main differentiating features of an HSV infection are that it tends to occur predominantly around the mouth or genitalia, there is a higher prevalence in younger patients verses the predilection for herpes zoster to afflict more elderly patients, and HSV has a propensity for recurrent outbreaks which are rare in herpes zoster. In cases of atypical presentations or when there is confusion as to whether VZV or HSV is the pathogen, diagnosis can be confirmed by laboratory testing.

TABLE 27.1

DERMATOMAL DISTRIBUTION OF HERPES ZOSTER IN IMMUNOCOMPETENT PATIENTS

Thoracic: up to 50% of all cases
Cranial: 10% to 20%
Cervical: 10% to 20%
Lumbar: 10% to 20%
Sacral: 2% to 8%
Generalized: <1%

Laboratory Testing

Viral Culture

Isolation of the virus in cell cultures can be done but takes 1 to 2 weeks to complete. The virus is also quite labile and may be difficult to recover from lesion swabs. This test has low sensitivity but high specificity. Treatment of presumed cases should not be delayed to await culture results given the prolonged turnaround time and low sensitivity (and thus high false negative rate) of the test.

FIGURE 27.3 Ophthalmic zoster. (Reproduced from Dworkin RH, Johnson RW, Breuer J, et al. Recommendations for the management of herpes zoster. *Clin Infect Dis* 2007;44(1):S1–S26, with permission.)

FIGURE 27.4 Herpes zoster rash in the T2 dermatomal distribution. (Reproduced from Dworkin RH, Johnson RW, Breuer J, et al. Recommendations for the management of herpes zoster. *Clin Infect Dis* 2007; 44(1):S1–26, with permission.)

Direct Immunofluorescence Assay

Direct immunofluorescence assay is often preferable to viral culture due to its low cost and rapid turnaround time, which can be within 3 hours. Sensitivity is approximately 90% but decreases if the lesions are beyond the vesicular stage.

Viral DNA Testing

Viral DNA can be detected in the vesicle fluid and cutaneous tissue by polymerase chain reaction (PCR) technology. It has the advantage that it can be effective even on old and crusted lesions. It has a turnaround time of 1 day but is generally more expensive than other approaches. This test has exceptional sensitivity and specificity of almost 100%.

Biopsy

A biopsy is not typically needed in clinical practice and should be reserved for difficult to diagnose cases. Histological findings of ballooning degeneration and acantholysis of keratinocytes resulting in intraepidermal vesicles are common to all herpes infections. Multinucleated giant cells with accentuation of nuclear material at the periphery of the nuclei are present. Underlying leukocytoclastic vasculitis is often a prominent finding and helps differentiate zoster from other herpesvirus infections.

Testing for Underlying Disorders

If clinically indicated, testing for HIV or occult malignancy may be advisable, but this is typically not necessary and is not recommended on a routine basis.

EPIDEMIOLOGY OF HERPES ZOSTER

The epidemiology of herpes zoster is primarily affected by a combination of the incidence of primary varicella infections in the population as well as age and level of immunosuppression in the population. At the present time, the lifetime incidence of herpes zoster is 20% to 30%. This incidence is likely to change in the future as a result of implementation of childhood varicella vaccination. At the present time herpes zoster is among the most common of neurological illnesses, affecting about 1 million people in the United States,[8] 1.7 million in the European Union, 100,000 in Canada, and 80,000 in New Zealand and Australia annually. Primary varicella infection typically affects children in temperate climates and adolescents and young adults in tropical climates.[9] The incidence of herpes zoster in Asia and South America is not well studied, but is thought to follow the same pattern as in the U.S. and Europe despite regional differences in patient demographics for primary varicella infection.[10]

Increasing age is the most potent risk factor for herpes zoster in both immunocompetent and immunocompromised individuals (Table 27.2). The incidence of herpes zoster in all age groups is 1.2 to 4.8 cases per 1000 persons per year and increases to 7.2 to 11.8 cases per 1000 persons per year in persons older than 60.[11] The prevalence reaches approximately 50% in individuals living to be 85 years of age.[12,13]

Immunocompromised individuals have a relatively high risk for developing herpes zoster.[14] Patients with a history of HIV infection, solid organ and bone marrow transplantation, immunosuppressive chemotherapy, or systemic lupus erythematosus are 20 to 100 times more likely to develop herpes zoster compared to immunocompetent individuals. Immunocompromised individuals also experience higher recurrence rates of zoster compared to those who are immunocompetent.

Other factors that appear to increase the risk for herpes zoster that are less well replicated include Caucasian versus African-American racial group, presence of elevated psychological stress and/or physical trauma,[15,16] and being female.[17] Exposure to varicella antigen, either through contact with chicken pox or by vaccination, has a protective effect and reduces the incidence of herpes zoster.[8,18]

The epidemiology of varicella and herpes zoster is likely to change as childhood vaccination against the primary infection alters the long established relationships between humans and this viral infection. The incidence of primary varicella infections has declined dramatically in the United States since the implementation of routine childhood vaccination.[19] It has been hypothesized that there will be an initial increased incidence of herpes zoster in the coming decades as the opportunities for subclinical immune boosting in aging adults, which result from exposure to VZV, will decline due to the decreased incidence of chicken pox.[20–22] Adults living in regions where there is widespread varicella vaccination may therefore experience a higher incidence of herpes zoster compared with past generations unless herpes zoster immunization becomes widespread. Such vaccination would confer the immunological boost that past generations obtained through episodic exposure to children with chicken pox. In a similar manner, a single episode of herpes zoster boosts immunity to VZV and thereby appears to prevent recurrent bouts of zoster. This likely

TABLE 27.2

FACTORS ASSOCIATED WITH AN INCREASED INCIDENCE OF HERPES ZOSTER

explains why recurrent zoster is rare,[8,12,23,24] with an incidence generally estimated as less than 5%.[12,25–28] Eventually, as children immunized against VZV grow into adulthood, the number of adults infected with latent wild-type virus will decrease and the incidence of herpes zoster is expected to decline because the live attenuated virus used in the varicella vaccine appears to be less likely to reactivate and cause herpes zoster.

PATHOPHYSIOLOGY OF HERPES ZOSTER AND MECHANISMS OF ACUTE PAIN

As noted above, herpes zoster most commonly manifests in the distribution of a single dorsal sensory or cranial nerve ganglion. Why the reactivation occurs in one ganglion when latent virus is present throughout the patient's sensory ganglia is not clear. Declining cellular immunity is a major risk factor for reactivation of the virus, which is thought to occur when cell-mediated immunity falls below a critical level.[12] This impression is supported by evidence that even individuals with adequate levels of serum antibodies to VZV antigen can, over time, exhibit T cells with reduced ability to proliferate and defend against VZV infections.[23] Hence, cell-mediated immunity appears to play a crucial role in preventing reactivation of latent VZV (Fig. 27.5). Common causes of decreased cellular immunity include increasing age, various diseases, and immune-suppressing medical interventions, all of which are risk factors for herpes zoster.

During reactivation of the virus, newly synthesized viral particles are transported in a retrograde and anterograde fashion to the central and distal axons of the involved spinal or cranial sensory ganglion. Viral replication causes inflammatory and neural tissue injury in the affected dermatome,[1] which can ultimately result in infectious hemorrhagic necrosis and subsequent neuronal loss and scarring centered in the sensory ganglion of affected cranial and peripheral nerves.[1,29] Microscopic examination of the zoster affected ganglion shows significant hypocellularity and collagen scarring. The corresponding peripheral nerves may exhibit a long-lasting reduction in myelinated axons and increased numbers of small unmyelinated axons. These structural changes contribute to the pain and other characteristic sensory findings along the corresponding sensory dermatomes of the involved ganglion. Excessive electrical activity in the damaged peripheral nociceptors is the major cause of pain in the acute herpes zoster infection. Although VZV is a sensory-specific virus, involvement of anterior horn cells, autonomic neurons, and leptomeninges can be observed as a result of a bystander effect,[30] with consequent muscle weakness, palsy, and/or pleocytosis of spinal fluid.

COMPLICATIONS ASSOCIATED WITH HERPES ZOSTER

In general, the frequency and severity of complications are greater in older and immunocompromised individuals. The most common morbidity of herpes zoster in immunocompetent individuals is the development of PHN; this often severe pain can persist well beyond the resolution of herpes zoster. This complication will be discussed in detail in the second half of this chapter.

Ophthalmic Complications

The incidence of complications associated with HZO has been reported to be 2% to 6% of cases. A variety of complications have been described,[31] including retinitis, keratitis, iritis, scleritis, secondary glaucoma, and ptosis. These are obviously serious problems that can result in temporary or permanent deterioration in visual acuity or complete blindness. For these reasons, patients with ophthalmic zoster should be evaluated by an ophthalmologist as promptly as possible following diagnosis.

Motor Neuropathy

Motor nerve involvement is present in 5% to 15% of patients presenting with herpes zoster. Paresis in extraocular nerves, facial nerves, and a variety of other motor nerves has been described. Diaphragmatic paresis is not an uncommon occurrence with the involvement of the phrenic nerve, and intercostal nerve involvement may lead to paresis of intercostal muscles (Fig. 27.6). Involvement of cervical motor nerve roots may present as shoulder and arm weakness, and lower extremity weakness can occur when lumbosacral nerve roots are affected. In some cases, significant motor weakness may be the presenting symptom, and this can delay accurate diagnosis. In general, paresis improves with time and physical rehabilitation; however, the likelihood and completeness of muscle function recovery appears to decrease with older age and greater initial severity of the paralysis.

Rare Neurological Complications

VZV is a common cause of aseptic meningitis. Most patients with VZV meningitis experience a complete resolution of the symptoms in 1–2 weeks,[32] although meningeal involvement can result in long-term sequelae from subsequent scarring of the involved neural structures. Myelitis and encephalitis are other rare central manifestations of reactivated VZV. VZV encephalitis can present as an acute delirium accompanied by few focal neurologi-

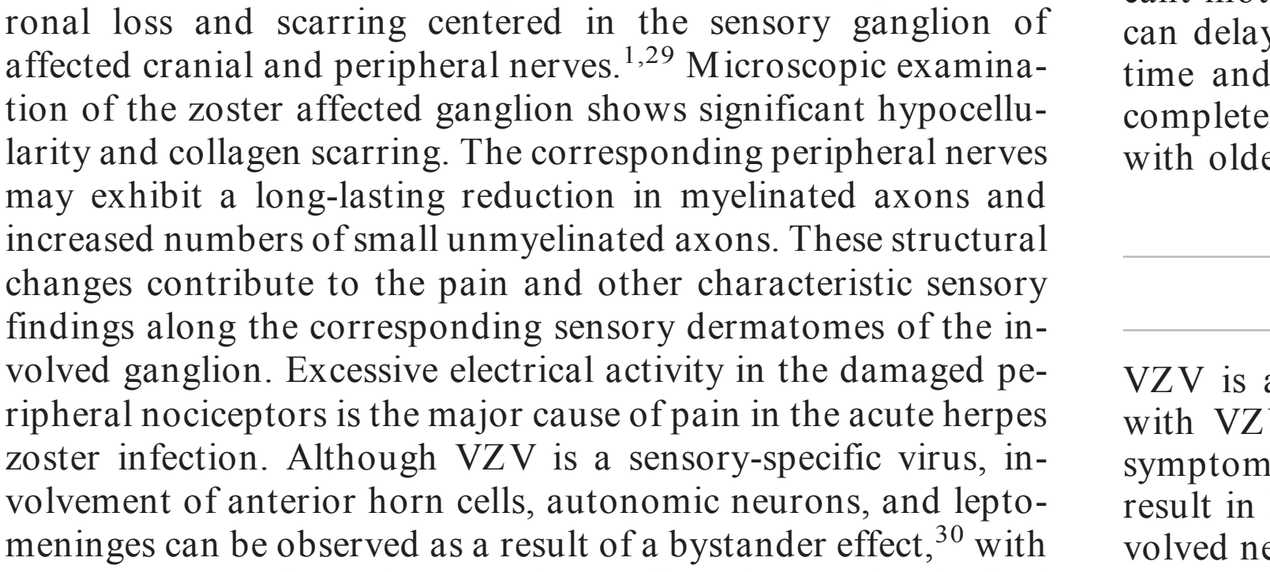

FIGURE 27.5 Host factors in VZV latency and reactivation. Varicella is the primary infection caused by VZV, and its resolution is associated with the induction of VZV-specific memory T cells (blue line). Memory immunity to VZV may be boosted periodically by exposure to varicella or silent reactivation from latency (red peaks). VZV-specific memory T cells decline with age. The decline below a threshold (black line below zoster threshold) correlates with an increased risk of zoster. The occurrence of zoster, in turn, is associated with an increase in VZV-specific T cells. The administration of zoster vaccine to older persons may prevent VZV-specific T cells from dropping below the threshold for zoster occurrence (dashed blue line). (Redrawn after Arvin A. Aging, immunity, and the varicella-zoster virus. *N Engl J Med* 2005;352:2266–2267, with permission.)

FIGURE 27.6 T8 motor neuropathy in an otherwise healthy 59-year-old man who presented with vesicles in the T8 distribution 4 weeks before this photo was taken. The patient was treated with an antiviral agent for 7 days and with analgesics as needed. As the rash resolved, this bulge became apparent; it is consistent with motor damage by varicella zoster virus to the muscles of the abdomen. (Reproduced from Dworkin RH, Johnson RW, Breuer J, et al. Recommendations for the management of herpes zoster. *Clin Infect Dis* 2007;44(1):S1–26, with permission.)

cal signs.[33] Factors that elevate the risk of central nervous system (CNS) involvement include the presence of altered immune function, cranial nerve or ophthalmic involvement, and evidence of cutaneous dissemination. Although more common in immunocompromised patients, CNS involvement has been reported in both immunocompetent and immunocompromised individuals[34] and in both children and adults.[35]

Visceral Complications

Visceral involvement in herpes zoster is rare but may result in organ dysfunction as a consequence of scar formation around the involved structures. In such cases, the associated signs and symptoms would be related to the specific structures mechanically affected by scarring.

Decreased Quality of Life

The acute pain associated with herpes zoster can cause significant suffering and is often accompanied by interference in the patient's ability to carry out normal activities of daily living. In addition, acute pain is associated with the greater use of analgesic medications and their attendant side effects, most notably sedation and constipation.[36–40] The resultant impact of herpes zoster on health-related quality of life is at least as great as what has been found with other chronic diseases such as diabetes or congestive heart failure.[39]

TREATMENT OF HERPES ZOSTER

All patients should have a thorough medical evaluation with added attention to factors related to the individual's immunocompetence. Patient education, reassurance, and supportive therapy are essential to allay fears and promote compliance with pharmacological therapy. The primary goals of pharmacological therapy are to reduce pain and prevent ongoing viral replication. Limiting viral replication has been shown to reduce the incidence and severity of acute pain associated with herpes zoster. The primary pharmacological approaches include the use of antiviral therapy in conjunction with analgesic agents. Steroids have also been used, but their role is more controversial. The potential roles of neural blockade and neuroaugmentation strategies are also controversial.

Patient Education

It is important to educate patients and their family members about their disease. Patients and caretakers can be reassured that herpes zoster does not cause any illness in seropositive individuals who have contact with the patient. Herpes zoster does, however, pose a risk of viral transmission to individuals who do not have preexisting immunity to VZV. Given this, it is important for patients with herpes zoster to avoid contact with individuals who are known to be seronegative for VZV or have known or suspected immune system impairment, especially if it is unclear whether they have a history of chicken pox. Patients should be counseled regarding maintaining appropriate nutrition and optimal levels of social and physical activities. In addition, patients should be told to keep the rash area clean and to avoid application of ointments or adhesive dressings because these can cause skin irritation and secondary infections. Patients should inform their physician if fever, confusion, or other significant constitutional symptoms develop, and should return for further evaluation if rash healing appears delayed.

Antiviral Therapy

Antiviral therapy has been shown to be efficacious in suppressing viral replication and also has beneficial effects on both acute and chronic pain (Table 27.3).[41–43] Antiviral medication is recommended for all herpes zoster patients who are older, have a moderate to severe rash, have ophthalmic involvement, or are immunocompromised.[44] In current clinical practice, most physicians prescribe antiviral therapy to all patients with herpes zoster because of the very favorable risk benefit ratio of these medications. Antiviral treatment should be started as soon as possible; this should ideally be within 72 hours of the onset of rash, the inclusion criterion for initiating treatment in the clinical trials of antiviral agents in herpes zoster patients. The early initiation of antiviral therapy is intuitively logical and an important treatment objective. However, viral replication may continue beyond the third day after rash onset, suggesting that even delayed antiviral therapy may provide some benefit. Unfortunately, there are no well-designed clinical trials examining the efficacy of initiating antiviral therapy beyond 72 hours of rash onset. Two uncontrolled trials examined the effectiveness of antiviral treatment initiated at a later time and the results suggested that such treatment may have beneficial effects.[45,46] In clinical practice, the diagnosis of herpes zoster is often not made within 72 hours of the onset of symptoms; nevertheless, it is important to identify pa-

TABLE 27.3

BENEFITS OF ANTIVIRAL THERAPY[41,42,46,48,49,51,52,53]

- Inhibition of viral replication
- Reduces duration of viral shedding
- Hastens rash healing
- Decrease in degree of neural damage
- Decreases severity and duration of acute pain
- Decreases duration of postherpetic neuralgia
- Decreases incidence of postherpetic neuralgia

tients who could still benefit from antiviral medication even when it is initiated relatively late in the disease course. One example of patients who warrant such later initiation of treatment is those with ophthalmic zoster. The duration of viral shedding from the ocular surface is highly variable[47] and may continue for a longer period of time. Immunocompromised patients, those with disseminated zoster, and patients with neurological complications should also be started on antiviral medication irrespective of whether they are beyond 72 hours of rash onset.

There are two main classes of antiviral medication and these are differentiated by their reliance on viral phosphorylation to be activated. The first class of drugs requires phosphorylation by viral thymidine kinase and includes acyclovir, brivudin, famciclovir, and valacyclovir (Table 27.4). These drugs are phosphorylated to a triphosphate form that impairs viral replication by inhibiting viral DNA polymerase. Acyclovir, famciclovir, and valacyclovir are all available in the United States and are approved by the FDA for the treatment of herpes zoster. These medications are excreted renally, and dosages should therefore be adjusted in patients with renal insufficiency. Special dosing regimens are also needed in patients on dialysis. Acyclovir must be taken five times daily for 7 days, whereas famciclovir and valacyclovir are taken three times daily. Thus, patient compliance with famciclovir and valacyclovir is likely to be considerably greater than with acyclovir, and this may translate to somewhat greater efficacy. Famciclovir and valacyclovir may also be somewhat better than acyclovir in reducing the incidence of prolonged pain.[48–50] Although brivudin is currently not available in the United States, it has been approved for the treatment of herpes zoster in several other countries; it is dosed once daily for 7 days.

The second class of antiviral medications is not dependent on viral phosphorylation. These agents noncompetitively inhibit viral DNA polymerase, and include vidarabine, foscarnet, and cidofovir. Foscarnet is useful in patients with known resistance to acyclovir due to lack of viral thymidine kinase, which can be seen in patients with AIDS or prolonged exposure to acyclovir (as in transplant patients). Hence, this agent plays an important role in treating infections in individuals with known resistance to acyclovir.

Analgesic Treatment

Antiviral therapy does not completely abolish the acute pain associated with herpes zoster (nor does it completely prevent PHN), and supplemental analgesic medications are required in most pa-

TABLE 27.4

ANTIVIRAL MEDICATIONS FOR HERPES ZOSTER

All antivirals are renally excreted, hence dosage needs to be adjusted in patients with renal insufficiency, including patients on dialysis. Nausea and headache are common side effects.

Medication	Oral bioavailability	Dosage	Duration of treatment (Days)	Uncommon side effects	Special considerations
Acyclovir	15% to 30%	800 mg 5 times daily (every 4–5 h)	7–10	Neurotoxicity and nephrotoxicity	Additive nephrotoxic effects with cyclosporine
Famciclovir	77%	500 mg 3 times daily (approved dosage in United States; in some other countries, 250 mg 3 times daily is approved	7		Probenecid, theophylline increase levels of famciclovir. Digoxin levels increased
Valacyclovir	55%	1000 mg 3 times daily	7		Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome reported at dosages of 8000 mg daily in immunocompromised patients
Foscarnet	NA	40–90 mg/kg I/V for induction and 120 mg/kg/day for maintenance therapy	10–14 days for induction and variable duration for maintenance	Nephrotoxicity, neurotoxicity, neutropenia, anemia	Increased risk of nephrotoxicity with cyclosporine. Increased risk of seizures with ciprofloxacin
*Brivudin		125 mg once daily	7		Contraindicated for patients treated with 5-fluorouracil or other 5-fluoropyrimidines because of drug interaction associated with severe and potentially fatal bone marrow suppression

*Not available in the United States

tients. Effective analgesia improves patient comfort and may also reduce the risk of PHN beyond what is achieved by antiviral therapy alone.[54,55] These considerations argue for aggressive management of the acute pain associated with herpes zoster. A multimodal analgesic strategy should be used to balance efficacy, safety, and tolerability of the medication regimen. Unfortunately, well-designed studies to delineate which combinations of therapies are optimal have not been conducted. In lieu of focused studies, clinicians must use the available data, extrapolate available information, and individualize therapy based on patient-specific factors. The World Health Organization analgesic ladder can be applied as one useful analgesic strategy with well-proven efficacy and ease of application. Patients with mild pain can be started on acetaminophen alone or in combination with a mild opioid analgesic such as tramadol. Nonsteroidal anti-inflammatory drugs (NSAID)s can also be used provided there are no contraindications to their use. Patients with moderate pain can be started on short-acting opioid medications and, if tolerated, can be converted to a timed-release preparation if clinically warranted. Opioids have not been well-studied in patients with herpes zoster, but one recent clinical trial did show that controlled-release oxycodone was superior to placebo in relieving acute pain within the first 2–3 weeks of rash onset, although the small sample size precluded an evaluation of the effect of this treatment on the development of PHN.[56]

If acute pain in herpes zoster patients is not adequately controlled with the analgesics mentioned above, other medications that have demonstrated efficacy in the treatment of chronic neuropathic pain can also be used in combination with antiviral therapy.[44] Gabapentin, pregabalin, and tricyclic antidepressants such as nortriptyline and desipramine can be considered in patients when conventional analgesic medications are not adequate in managing acute pain. Studies are limited, but a single-dose trial of 900 mg of gabapentin vs. placebo did demonstrate a reduction in acute pain over 6 hours in patients with herpes zoster.[57] Both gabapentin and pregabalin would seem like reasonable alternatives because they not only have efficacy in the treatment of PHN but have also demonstrated efficacy in reducing pain and analgesic requirements in some acute pain conditions.[58,59]

Although tricyclic antidepressants have not been well-studied in patients with herpes zoster, they have proven efficacy in chronic neuropathic pain and are additional rational choices for treating acute pain associated with herpes zoster. Dual reuptake inhibitors (selective serotonin and norepinephrine reuptake inhibitors) can be considered in lieu of tricyclic antidepressants given their more favorable side effect profiles. Both duloxetine and venlafaxine have demonstrated efficacy in painful diabetic peripheral neuropathy[60,61] and could thus be considered a potential therapy for the treatment of acute pain in patients with herpes zoster.

A pragmatic approach is to start with a short-acting opioid in combination with acetaminophen or an NSAID. Gabapentin or pregabalin can then be added if conventional analgesics are not entirely effective. Many clinicians would use one of these medications rather than a tricyclic antidepressant because of their generally safer side effect profile. The analgesic regimen should be tailored based on the individual patient's needs and tolerances (Table 27.5). Frequent follow up and reassessment are vital to assess efficacy and tolerability while titrating analgesic therapy.

Corticosteroids

The use of corticosteroids in the treatment of herpes zoster has been controversial.[62,63] One placebo-controlled trial demonstrated a benefit in terms of significantly accelerated return of uninterrupted sleep, cessation of analgesic therapy, and return to normal activity in patients treated with the combination of a corticosteroid and acyclovir as compared to those treated with acyclovir alone.[63] The patients in this trial were 60 years of age on average and possessed no contraindications to corticosteroid treatment. Based on these results, the addition of oral corticosteroids can be considered in healthy older adults with moderate-to-severe pain unrelieved by antiviral therapy and analgesics, provided there are no contraindications to steroid use. Oral steroids are empirically used in VZV-induced facial nerve palsy or other cases of cranial neuritis, although there is limited evidence supporting the effectiveness of such treatment. It must be emphasized that corticosteroids should not be used alone in herpes zoster and must be initiated in combination with antiviral therapy.

Neural Blockade

If pain is not controlled with medical management, referral to a pain specialist should be considered for possible invasive interventions. Sympathetic blockade or neuraxial local anesthetic infusion can be considered. Additionally, perilesional infiltration of local anesthetics and steroids is advocated by some clinicians. All these interventions have been used for years in clinical practice but few controlled studies have been conducted to systematically examine their effects on herpes zoster acute pain or the development of PHN.[64,65] A recent randomized trial demonstrated significant reduction in acute pain following a single epidural injection of steroid and local anesthetic within the first month after rash onset as compared to standard therapy alone. The incidence of developing PHN, however, was not altered in this study.[66] In another study, continuous epidural infusion of local anesthetic with intermittent boluses was found to be superior to continuous infusion of saline and intermittent boluses of local anesthetic in reducing the time to complete resolution of pain in herpes zoster patients who were concomitantly treated with oral acyclovir.[67] This type of treatment requires home nursing care and careful coordination of care under the supervision of a pain physician and should only be considered in the small subset of patients who have relatively severe pain that is not adequately controlled by simpler measures.

There are also some data supporting the use of sympathetic blockade in the treatment of pain associated with herpes zoster.[64] These nerve blocks are used by some clinicians in cases where acute pain has been refractory to more conventional therapy. However, it is also hypothesized that sympathetic blockade may favorably affect the progression of herpes zoster acute pain to PHN because the effective treatment of acute pain may prevent the development of PHN, or at least decrease the severity of subsequent PHN. Unfortunately, randomized clinical trials evaluating this hypothesis are lacking.

Spinal Cord Stimulation

Spinal cord stimulation has been tried in a case series of four patients with herpes zoster and reported to be effective.[68] It is difficult to extrapolate these results to routine clinical practice as the majority of patients with herpes zoster have resolution of their symptoms as part of the natural history of the disease.

PREVENTION OF HERPES ZOSTER

Childhood Vaccination

The propensity to develop herpes zoster and PHN can ultimately be traced back to an individual's primary varicella infection. Thus, one obvious prevention strategy would include the prevention of the primary VZV infection through the use of varicella vaccination in childhood. Two types of vaccines are approved by

TABLE 27.5

PHARMACOLOGICAL OPTIONS THAT CAN BE CONSIDERED FOR TREATMENT OF ACUTE PAIN IN HERPES ZOSTER

Medication	Initial dose	Titration	Maximum daily dose	Side effects
Acetaminophen	500–1000 mg every 6 hrs as needed	Not needed	2.6 g in elderly; 4 g in younger patients	Liver toxicity with prolonged use; avoid alcohol use
NSAIDs (dosages given are for ibuprofen)	400 mg every 6 hrs as needed	Not needed	2400 mg	Gastrointestinal side effects, CV and renal toxicity and increased bleeding tendency
With				
Opioid analgesics (dosages given are for oxycodone)	5 mg every 4 h as needed	Increase by 5 mg 4 times daily every 2 days as tolerated; dosage can be converted to extended release opioid analgesic combined with short-acting medication as needed	No maximum dosage with careful titration	Nausea/vomiting, constipation, sedation, dizziness
Or				
Tramadol	50 mg once or twice daily	Increase by 50–100 mg daily in divided doses every 2 days as tolerated; dosage can be converted to extended release preparation combined with immediate release one as needed	400 mg daily (100 mg 4 times daily); for patients >75 years of age, 300 mg daily in divided doses	Nausea/vomiting, constipation, sedation, dizziness, seizures, postural hypotension
Gabapentin	300 mg at bedtime or 100–300 mg 3 times daily	Increase by 100–300 mg 3 times daily every 2 days as tolerated	3600 mg daily (1200 mg 3 times daily; reduce if renal function is impaired)	Sedation, dizziness, peripheral edema
Or				
Pregabalin	75 mg at bedtime or 75 mg twice daily	Increase by 75 twice daily every 3 days as tolerated	600 mg daily (300 mg twice daily; reduce if renal function is impaired)	Sedation, dizziness, peripheral edema
Tricyclic antidepressants, especially nortriptyline	25 mg at bedtime	Increase by 25 mg daily every 2–3 days as tolerated	150 mg daily	Sedation, dry mouth, blurred vision, weight gain, urinary retention
Oral corticosteroid (dosages given for prednisone)	60 mg daily for 7 days	After 60 mg daily for 7 days, decrease to 30 mg daily for 7 days, then decrease to 15 mg daily for 7 days, and then discontinue	60 mg daily	Gastrointestinal distress, nausea, changes in mood, edema

Note: Dose of opioids, pregabalin, and TCAs can be reduced in frail elderly individuals. Consider a screening electrocardiogram for patients with preexisting cardiac disease.
CV, Cardiovascular; NSAID, Non-steroidal anti-inflammatory drugs.

the FDA for vaccination in children from 12 months to 12 years of age; both are based on the Oka virus. The first agent is a single antigen vaccine, and the more recent vaccine is a combination product and protects against multiple childhood infections (i.e., measles, mumps, rubella, and varicella). The live attenuated Oka vaccine virus establishes latency in sensory ganglia, like wild-type VZV, but it appears to cause herpes zoster much less frequently. Hence, childhood varicella vaccination should eventually result in an overall decrease in the incidence of herpes zoster and PHN.

Varicella-Zoster Immunoglobulin

Temporary passive immunization may be required in specific circumstances. The United States Centers for Disease Control and Prevention currently recommends administration of varicella-zoster immune globulin (VZIG) to prevent or modify clinical illness in immunocompromised seronegative persons with recent exposure to patients with chicken pox or zoster. VZIG provides maximum benefit when administered as soon as possible after the presumed exposure, but VZIG may be effective if administered as late as 96 hours after exposure. Protection after VZIG administration lasts for an average of approximately 3 weeks. Treatment with VZIG should be followed by vaccination if possible.

Herpes Zoster Vaccination for Adults

Herpes zoster is caused by reactivation of VZV from a single sensory ganglion. It appears likely that seropositive adults derive a degree of protection from this viral reactivation by episodic exposure to children with chicken pox and a resulting boost in VZV-specific cellular immunity. With implementation of childhood vaccination programs and the decreased incidence of primary varicella infection in the general population, the majority of adults will not have such exposure and thus could have less protection against reactivation of VZV. Adult vaccination can confer the immunological boost to our current adult population that past generations had obtained through episodic exposure to children with chicken pox infections.

The Shingles Prevention Study—a large, multicenter, randomized, placebo-controlled trial—was conducted to evaluate the efficacy and safety of herpes zoster vaccination.[8] The results of the trial indicated that the herpes zoster vaccine reduces the likelihood of developing herpes zoster in immunocompetent individuals 60 years of age or older. Important results of this study included a decrease in the incidence of herpes zoster by 51.3%, a reduction in the overall burden of illness (BOI) by 61.1%, and a decrease in the incidence of PHN by 66.5%.[69] The effect on decreasing the incidence of herpes zoster was less in older subjects but the effect on reducing the severity of illness was greater in older subjects. Hence the overall reduction in BOI, the primary endpoint of the study, was maintained across all age groups. Based on these data, the FDA approved the use of the herpes zoster vaccine in individuals 60 years and older. This live, attenuated vaccine is contraindicated in children, pregnant women, and immunocompromised individuals. The vaccine has minor side effects, including local skin irritation. No clinically meaningful systemic side effects were observed. This vaccine is not interchangeable with the varicella vaccines used for the primary prevention of chicken pox; although all these vaccines contain the same attenuated strain of VZV, they vary in concentration of plaque forming units.

CLINICAL PICTURE OF PHN

PHN is the most common complication of herpes zoster in the immunocompetent patient. This condition results in significant patient suffering and causes a large economic burden to society. Our ability to diagnose and treat PHN has benefited from recent consensus among researchers as to its definitions and guidelines for treatment of chronic neuropathic pain conditions. Currently, the term PHN is used to describe dermatomal pain that persists for more than 120 days after the onset of the herpes zoster rash.[70] Pain persisting for more than 180 days after the rash onset is less likely to resolve and hence can be considered "well established PHN" to reflect its recalcitrant nature.[71]

A variety of signs and symptoms are characteristic of patients with PHN, although none are pathognomonic. These include various types of stimulus-independent pain, for example, intermittent sharp, shooting, or electric shock-like pain and continuous burning or throbbing pain. Stimulus-evoked pain is also very common in patients with PHN and includes tactile allodynia, one of the most debilitating symptoms associated with this condition. Tactile allodynia can be so severe that patients with truncal PHN may not be able to tolerate the sensation of clothing against their skin and those with craniofacial PHN may not be able to wear hats, glasses, or tolerate even breezes or air conditioning on the affected site. Hyperalgesia, which is an abnormally increased perception of pain in response to a painful stimulus, can occur with application of painful thermal or mechanical stimuli. These types of stimulus-independent and stimulus-evoked pain are caused by nerve damage (i.e., neuropathic pain), but musculoskeletal pain can also occur in patients with PHN as a result of excessive guarding of the affected area. Myofascial trigger points, atrophy, and reduced joint range of motion may be seen in severe cases where pain has resulted in excessive guarding.

Additional sensory abnormalities are also common in PHN. Involved areas may be hypoesthetic, which can occur even in regions that exhibit tactile allodynia. The areas of altered tactile sensitivity may become larger than the sites originally affected by the zoster rash. Alterations in temperature sensation have also been demonstrated. Various paresthesias and dysesthesias (abnormal or unpleasant but not painful sensations) can also occur. Chronic pruritis can persist or develop following herpes zoster and is particularly problematic for some individuals; it may be present with or without comorbid pain.

Areas of hyperpigmentation, hypopigmentation, or scarring may be present in the affected dermatomes following rash healing, and affected areas may also exhibit a persistent reddish or brownish hue. These cosmetic changes do not occur in all patients and the skin in the affected dermatome is normal in appearance in many patients with PHN.

Although less well-studied and generally less disabling than pain, altered motor function occurs in herpes zoster and can persist after rash healing. Facial paralysis may be evident in the form of ptosis or loss of the nasolabial fold in cases of facial nerve involvement. In cases of thoracic involvement, a truncal bulge resulting from intercostal muscle weakness may be present (Fig. 27.6).

Diagnosis and Assessment of PHN

PHN is diagnosed primarily based upon clinical findings. A history of herpes zoster rash, followed by persistent pain in the same distribution, usually establishes the diagnosis. Occasionally, patients report having a quiescent period between the resolution of the initial herpes zoster-associated pain and the onset of the pain associated with PHN. In a study of 156 patients with PHN, Watson et al.[76] noted that 25% of patients with a poor outcome said that they could recall a time after the rash when they had little or no pain. This pain free hiatus has been observed to last for a period of weeks to as much as 12 months. The recurrence of dermatomal pain is not associated with a recurrent episode of herpes zoster but may coincide with changes in the patient's emotional or physical status. As mentioned above, a clear history of rash may not be present in all patients. In these cases, a definitive

diagnosis of VZV-related pain would require serial serologic assessments that are unlikely to be obtained in most clinical settings.

In addition to assessing the location, intensity, and characteristics of the pain, it is important to evaluate the overall impact that the pain has had on the patient. PHN can cause significant deleterious impacts on physical, emotional, and social functioning and therefore can have a widespread adverse effect on health-related quality of life.[72,74,77,78] PHN can result in fatigue, insomnia, anxiety, depression, and suicidal ideation, and careful screening for the presence of any psychiatric comorbidities or any escalation of pre-existing psychiatric symptoms should be performed.

Laboratory Diagnosis

Diagnostic tests have limited application in the clinical management of PHN patients. A variety of studies may be used but are predominately limited to clinical research settings. These include quantitative sensory testing (QST), skin biopsy, and nerve conduction studies. QST has been used to identify different phenotypic subtypes of PHN patients with distinct constellations of signs and symptoms, which are thought to reflect different pathophysiologic mechanisms. This is an especially interesting area of future research, and the hope is that such phenotypic subtypes will ultimately be used to guide mechanism-based treatment.

EPIDEMIOLOGY AND NATURAL HISTORY OF PHN

Systematic studies of the epidemiology of specific chronic pain conditions are very rare, and limited information is available regarding the incidence and prevalence of PHN. The lack of consistency in defining PHN hampers efforts to study its epidemiology, and estimates of the incidence and prevalence of PHN will vary depending on which definition is used. Estimates of the prevalence of PHN have ranged from 500,000 to 1 million in the United States,[79,80] but could decrease if herpes zoster vaccination becomes widespread. If PHN is defined as pain persisting beyond 120 days from rash onset,[70,81–83] available data indicate that 10% to 25% of herpes zoster patients will develop PHN[12,76,84–86]; however, the precise figures differ greatly depending on whether patients in the community or in clinical trials are studied.

PHN is a chronic pain syndrome that can last for years. There is a relative paucity of data on its natural history due to the lack of population-based studies of zoster-related pain. Multiple studies consistently indicate that the majority of patients experience resolution of pain over weeks to months following rash onset.[41,72,76,87] The presence of persistent pain 1 year after the initial diagnosis of PHN has been described to be present in 20% of patients over the age of 60.[25,88,51] There are few prospective studies that have followed patients for more than 6 months following the diagnosis of PHN. Hence, the exact number of patients who enjoy a complete resolution of PHN is unknown.

Risk Factors for PHN

The most well-established risk factors for PHN in patients with herpes zoster include older age, presence of a painful prodrome, greater severity of acute pain, and greater rash severity.[72,73] Increasing age is a particularly potent risk factor for the development of PHN. Approximately 20% of patients older than 50 years of age continue to have pain at 6 months after the onset of rash despite starting antiviral agents in a timely fashion.[41,49,73,74] Using a shorter duration of pain, patients 50 years of age or older were shown to have a 14.7-fold higher prevalence (95% CI, 6.8–32.0) of pain 30 days after rash onset compared with patients younger than 50 years.[75] Elderly patients also seem to be predisposed to developing particularly refractory cases of PHN that do not respond to currently available treatments.[76] Other risk factors for PHN are listed in Table 27.6.

TABLE 27.6

RISK FACTORS FOR PHN[17,25,83,88,89,90,91]

Well replicated
- Older age
- Severity of rash
- Severity of acute pain
- Prodromal pain

Less well replicated
- Female gender
- Greater sensory abnormalities in the affected dermatomes
- Polyneuropathy
- Psychosocial variables
- Ophthalmic distribution

PATHOPHYSIOLOGY OF PHN

Viral replication is thought to result in a combination of neural and inflammatory damage, leading to sensitization of the peripheral and central sensory neural elements. There is evidence that various risk factors identified for the development of PHN make independent contributions to the likelihood of developing this chronic pain condition,[72,83] and these risk factors may reflect distinct underlying pathophysiological mechanisms. For instance, elderly patients who are at high risk for PHN are more likely to have a subclinical polyneuropathy, which may reduce the amount of viral damage needed to cause PHN.[92,93] Other examples of the possible relationships between risk factors for PHN and underlying mechanisms include the presence of a prodrome, reflecting earlier and more extensive viral damage in the affected sensory ganglion;[94] greater rash severity, reflecting greater damage to and loss of epidermal nerve fibers;[95–97] and severe acute pain, reflecting the initiation of processes that ultimately result in central and peripheral sensitization.[98,99] These relatively independent processes may combine to cause more severe cases of PHN.

More severe zoster infections are accompanied by greater neural damage, and it has been proposed that this neural damage contributes prominently to the development of PHN.[98] However, knowledge of the pathophysiological mechanisms of PHN is quite limited. It is mainly derived from autopsy and skin biopsy neuroanatomical studies and research on patterns of sensory dysfunction and pharmacologic response. A variety of pathophysiological mechanisms have been described and are hypothesized to be causally related to the qualitatively different types of pain associated with PHN. Different mechanisms may coexist in an individual patient, and there may be pathophysiologically distinct subgroups of patients.[100,101]

Modern anatomical understanding is based on data limited by the small number of patients studied to date. Watson[94] and colleagues compared autopsy tissue from patients with and without PHN following herpes zoster. They found that patients with PHN showed marked atrophy of the spinal cord dorsal horn on the ipsilateral versus contralateral side, a difference that was not present in the patients with a history of zoster but not PHN. Punch skin biopsy permits quantitative measurement of epidermal sensory nerve endings. Such studies have shown that PHN patients have reduced innervation density in the affected dermatome compared

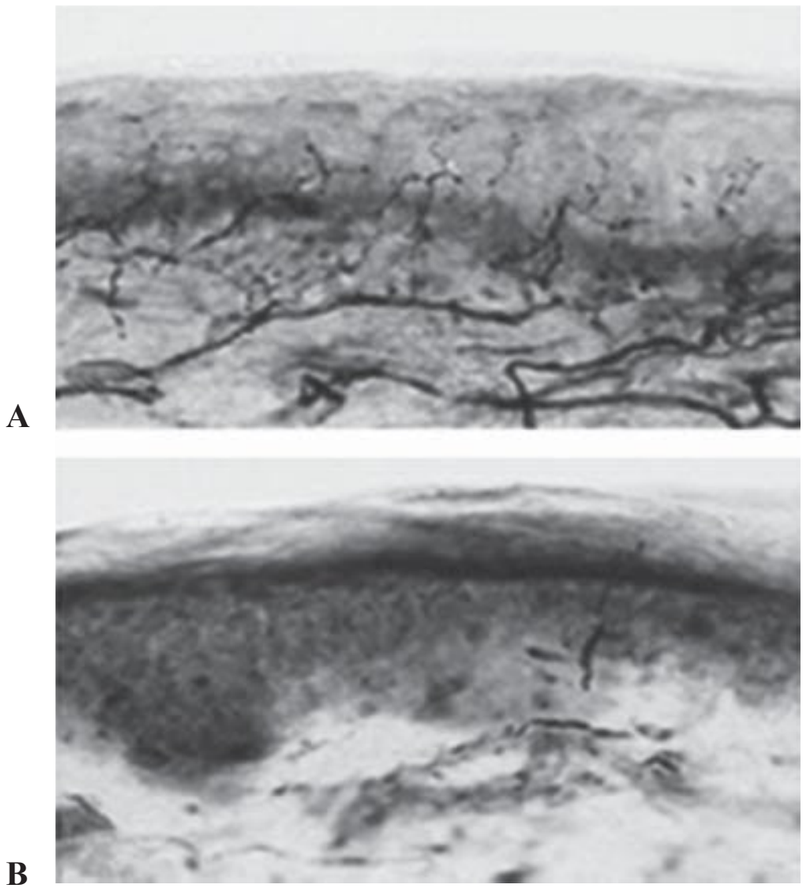

FIGURE 27.7 Representative, immunolabeled, dermal sensory nerve endings from skin biopsies of previously shingles-affected skin, with and without postherpetic neuralgia (PHN). **(A)** Biopsy from the previously affected shingles site on the back of a 75-year-old woman without PHN (1672 epidermal neuritis/mm^2). **(B)** Biopsy from the previous affected shingles site of a 72-year-old woman with PHN (145 neurites/mm^2). The epidermis is at the top of the image and the dermis is at the bottom. Individual neurites and neurite bundles are visible in the superficial dermis. (Reproduced from Oaklander AL. The density of remaining nerve endings in human skin with and without postherpetic neuralgia after shingles. *Pain* 2001;92:139–145, with permission.)

to the contralateral side (Fig. 27.7). Notably, in both the postmortem and skin biopsy studies, pathological features were only identified in PHN patients and were not found in patients with a history of zoster who did not go on to develop PHN.

Sensory testing can be used to investigate the function of small afferent fibers including nociceptors. This type of testing helps create a detailed sensory profile of the affected area. Rowbotham and Fields[100,101] have conducted an important series of studies of sensory dysfunction and pharmacologic response in an attempt to address the pathophysiology of PHN. The results of this research, along with that of others, have emphasized the role of central processes in interpreting sensory dysfunction and its relationship to pain in patients with PHN,[102–104] and have suggested that two different pathophysiological mechanisms contribute to the development of PHN—sensitization and deafferentation.

Both peripheral and central sensitization appear to contribute to PHN. Peripheral sensitization occurs predominately in small unmyelinated C fiber nociceptors. Clinically, there can be minimal sensory loss in areas of marked allodynia.[97,100,103] However, thermal sensory thresholds can be decreased (heat hyperalgesia) by up to 2° to 4° C[95,105] in allodynic regions. Heat hyperalgesia is a well-known consequence of peripheral nociceptor sensitization.[95] These observations all suggest that sensitization of C nociceptors can be responsible for the spontaneous burning pain and heat hyperalgesia seen in some patients. In many PHN patients, the area of mechanical or tactile allodynia is much larger than the area originally affected during herpes zoster and the painful area may continue to change with time. Allodynia in a subset of PHN patients may be caused by ectopic discharges from damaged C nociceptors maintaining a state of central sensitization.[100,106] The major excitatory neurotransmitter involved in spinal cord pain processing is glutamate, and binding at the NMDA receptor has been thought to play a key role in central sensitization.

Dynamic and tactile allodynia may also result from sprouting of A beta fibers into the superficial layers of the dorsal horn in response to partial loss of C fiber input. This sprouting may lead to connections between these fibers, which normally do not transmit pain, and the ascending pain pathways that were formerly responsive to C fiber input. This process would explain why nonpainful stimuli such as light touch or pressure can become painful in patient with PHN.

Deafferentation may also be playing a significant role in the maintenance of PHN. In a subset of patients, there is a loss of both large and small diameter sensory afferent fibers. This loss of peripheral input can result in the development of spontaneous discharge in deafferented central neurons. This may produce constant pain in the area of sensory loss.[100] Interestingly, these patients may still suffer from severe mechanical allodynia.[107] Assuming that the dorsal root ganglion and central connections are lost in such patients, the pain may be due to intrinsic CNS changes.

The data above suggest that there may be subsets of patients within the PHN population who have different underlying mechanisms responsible for the generation and maintenance of their chronic pain. These different mechanisms may account for the varied presentations of pain in patients with PHN. Unfortunately, these observations have not yet been able to provide the foundation for a mechanism-based approach for selecting specific pharmacological treatment options in clinical practice. This, of course, would be an extremely desirable goal to improve the therapeutic effects of existing treatments.

TREATMENT OF PHN

Tricyclic antidepressants, various anticonvulsants, opioid analgesics, and topical lidocaine are efficacious in the management of PHN (Table 27.7). There is a limited role of invasive interventions and alternative modalities, but these are utilized for patients who are refractory to conservative modalities. The choice of which therapy is used is often individualized based upon the patient's comorbidities, concomitant medication use, and associated symptoms. Recent studies have evaluated the relative efficacy of these treatments.[108,109] Additionally, consensus recommendation and guidelines for the pharmacotherapeutic treatment of neuropathic pain, including PHN, have been published and serve as useful guides in selecting between the growing list of treatment options.[110–112] In clinical practice, certain anticonvulsants, topical lidocaine, and tramadol are often used as first-line medications, followed by tricyclic antidepressants and opioids. This is largely because the former agents are better tolerated in elderly patients. Needless to say, all patients should have a thorough assessment and treatment should be tailored to address their individual needs.

Anticonvulsants: Gabapentin and Pregabalin

Although a number of anticonvulsants have been used for many years for the treatment of PHN and other neuropathic pain conditions, the greatest evidence of efficacy exists for gabapentin and pregabalin. Both are well-tolerated and much less toxic than the first-generation anticonvulsants previously used to treat neuropathic pain. There is good evidence to support the use of gabapentin in PHN. Its use was associated with a statistically significant reduction in daily pain ratings as well as improvements in sleep, mood, and quality of life at daily dosages of 1800–3600 mg in two large clinical trials.[113,114] A meta-analysis of these trials indicated that the pooled NNT for gabapentin in the treatment of PHN is approximately 4.4 (95% CI, 3.3–6.1).[58] The precise mechanism of its analgesic action is not known, but evidence derived from rodent models suggests that gabapentin acts at the alpha-2 delta subunit of voltage dependent calcium channels to decrease calcium influx. This effect inhibits the release of the

TABLE 27.7

PHARMACOLOGICAL OPTIONS FOR THE TREATMENT OF PHN

Medication	Starting Dose	Dose-Escalation Scheme	Common Side Effects	Contraindications/Caution	Comments
Gabapentin	100–300 mg	Start qhs and increase to tid dosing; increase by 100–300 mg every 3 days to total dose of 1800–3600 mg	Somnolence, dizziness, fatigue, ataxia, peripheral edema, and weight gain	Decrease dose in patients with renal impairment. QOD dosing in dialysis patients	No clinically significant drug interactions, improved sleep Avoid sudden discontinuation
Pregabalin	50 mg tid or 75 mg bid	300–600 mg/day in 1 wk	Somnolence, fatigue, dizziness, peripheral edema and weight gain, blurred vision, and euphoria	Decrease dose in patients with renal impairment by 50% or more based on CL creatinine	Caution with concomitant use of ACE inhibitors-angioedema; Increased risk for weight gain and peripheral edema in patients on thiazolidinedione antidiabetic agents
Topical Lidocaine	5%, 1–2 patches	Can use up to 3 patches 12 h/d	Local erythema, rash, blisters	Known hypersensitivity to amide local anesthetics Caution in patients receiving class 1 antiarrhythmic drugs (e.g., tocainide and mexiletine)	No significant systemic side effects
Tramadol	50 mg every 6 hours prn	Can titrate up to 100mg q 6 hrs.; max daily dose: 400 mg Extended-release dosing once a day	Nausea/vomiting, constipation, drowsiness, and dizziness	Seizure disorder, concomitant use of SSRI, SSNRI, TCA medications. Decrease dose in patients with hepatic or renal disease	Available as combination products with ibuprofen/acetaminophen Extended release dose max is 300 mg/day
TCAs Nortriptyline Desipramine Amitryptiline	10–25 mg qhs	Increase by 10–25 mg weekly with a target dose of 75–150 mg	Sedation, dry mouth, blurred vision, weight gain, urinary retention, constipation, sexual dysfunction	Cardiac arrhythmic disease, glaucoma, suicide risk, seizure disorder. Concomitant use of tramadol, SSRI, or SSNRIs	The lower starting dose may be more appropriate in the elderly Amitriptyline has the most anticholinergic effects and hence less well tolerated by the elderly Obtain baseline ECG in patients with hx of cardiac disease
Opioids Morphine Oxycodone Methadone *Fentanyl patch	15 mg q 6 hrs prn 5 mg q 6 hrs prn 2.5 mg tid 12 mcg/hr	Titrate at weekly intervals balancing analgesia and side effects. If patient tolerating the medications can titrate faster	Nausea/vomiting, constipation, drowsiness and itching	Driving impairment and cognitive dysfunction during treatment initiation. Be careful in patients with sleep apnea. Additive effects of sedation with neuromodulators	Gradual titration monitoring GI and CNS side effects

ACE, Angiotensin-Converting Enzyme; CL, Clearance; CNS, Central Nervous System; GI, Gastro-intestinal; qhs, Every Night or At Every Bedtime; QOD, Every Other Day; SSNRI, Selective Serotonin-Norepinephrine Reuptake Inhibitor; SSRI, Selective Serotonin Reuptake Inhibitor; TCA, Tricyclic Antidepressant.
*May need to start a patient on short-acting opioid medications before changing over to a fentanyl patch.
Differences in recommended dosages of medications between tables 27.5 and 27.7 are in part because of the acuity of pain in herpetic neuralgia versus PHN.
Adapted with permission from Wu C and Raja S. An update on the treatment of postherpetic neuralgia. J Pain *2008;9:S19–S30*

excitatory neurotransmitters, including glutamate.[115,116] As noted above, glutamate, via its effect at the NMDA receptor, is the primary neurotransmitter responsible for maintaining central sensitization.

Gabapentin is rapidly absorbed after oral administration. However, its absorption is mediated, at least in part, by a transport mechanism that becomes saturated at higher doses. This phenomenon reduces the bioavailability of gabapentin as the dose is increased. For example, the bioavailability of gabapentin at a dose of 300 mg is about 60%, but the bioavailability falls to 40% with a 600 mg dose. Peak serum concentrations are achieved approximately 3 hours after oral administration. Gabapentin does not exhibit significant protein binding, is eliminated unchanged via the kidneys, and is not metabolized by the liver.

The optimal dosing schedule for gabapentin has not been well characterized. A recent review suggested that dosing should be initiated at 300 mg on the first day, followed by 300 mg twice daily on the second day, and then increased to 300 mg three times daily on the third day.[117] At that point, the titration should be slowed down with a goal of reaching 600 mg three times daily over the ensuing 2 weeks. Daily dosages up to 3600 mg have been studied and shown efficacious.[113] The daily dosage should be divided into 3 or 4 doses per day as this drug has a relatively short half life. In elderly patients, dosages should be reduced and titration should be executed more slowly. In frail patients, it is typical to start with 100 mg/day, increasing by 100 mg every 3 to 4 days. Once patients are tolerating a daily dose of 600 mg, the titration rate may be increased by 300 mg/day every 3–4 days to a target of 1800–2400 mg/day. The titration schedule may need to be modified if efficacy is achieved at lower dosages or unmanageable side effects are encountered. Because gabapentin is excreted renally, dosages need to be adjusted in patients with renal insufficiency. Patients on dialysis should be started on a single dose of 100 mg given 1 hour after dialysis treatment on alternate days. This dose then can be titrated slowly and cautiously.

Side effects associated with gabapentin include somnolence, dizziness, peripheral edema, and gait or balance problems. In general these side effects are short lived, but they can require monitoring and, occasionally, dosage adjustment.

Pregabalin appears to have the same mechanism of action as gabapentin, and several large randomized clinical trials have demonstrated its efficacy in the treatment of PHN and other neuropathic pain conditions. Three double-blind trials comprising a total of 776 patients with PHN showed that pregabalin resulted in superior pain relief and improved pain-related sleep interference compared to placebo. Dosages in these studies ranged between 150–600 mg/day,[118] and both fixed as well as flexible dosing schedules have been efficacious in clinical trials.[119,120] Pregabalin can be given in two divided doses each day. Frequently reported side effects are the same as with gabapentin: somnolence, dizziness, peripheral edema, and balance problems.

Pregabalin has also been demonstrated to possess an anxiolytic effect[121,122] in patients with generalized anxiety disorder. Because patients with chronic pain often have comorbid anxiety disorders, it is possible that this anxiolytic effect may provide additional benefit in PHN patients. The analgesic efficacy and side effect profiles of gabapentin and pregabalin appear to be comparable. Pregabalin has greater convenience than gabapentin because of its twice daily dosing and simpler titration, however, and an effective analgesic dosage can be reached more rapidly with pregabalin.

Antidepressant Medications

Tricyclic Antidepressants

Tricyclic antidepressant medications have a number of proposed mechanisms that might explain their efficacy in the treatment of PHN. These include inhibition of the reuptake of norepinephrine and serotonin and sodium channel blockade.[123,124,125] There have been several clinical trials and meta-analyses of these agents demonstrating efficacy in the treatment of pain associated with PHN, with pooled data showing NNTs of 2.1–2.6.[58,126,127]

Amitriptyline has been the most widely studied antidepressant for PHN. Available evidence and clinical experience suggest that nortriptyline and desipramine[128] are equally effective[58,129] but are better tolerated than relatively more side effect prone amitriptyline. Thus, these secondary amine tricyclics are generally preferred, especially in elderly and frail patients. Both amitriptyline and nortriptyline are often helpful in patients with insomnia because of their sedating properties. Desipramine has significantly less sedation than these two medications and is thus preferred in patients who may be intolerant to the sedative effects of this class of medication.

Both significant side effects and toxicities must be considered when using tricyclic antidepressants. Major side effects include tachyarrhythmias, prolongation of QT intervals with the potential for the precipitation of life threatening arrhythmias, and the worsening of acute angle glaucoma. It would be prudent to review a baseline EKG before starting these medications in elderly patients or those who possess other risk factors for increased cardiac toxicity.[130,131] Minor side effects include dryness of mouth, dizziness, weight gain, sedation, constipation, urinary retention, and orthostatic hypotension. These medications should be started at a low dose, typically 25 mg at night, and titrated slowly to a target dose of 75–100 mg/day in a single evening dose. In elderly or frail individuals, these agents can be started using a 10 mg evening dose. Concomitant use with selective serotonin reuptake inhibitor antidepressants should be monitored carefully as there is a risk of developing toxic tricyclic serum levels and serotonin syndrome with such combinations.

Selective Serotonin and Norepinephrine Reuptake Inhibitors (Dual Reuptake Inhibitors)

Two antidepressant medications that are selective serotonin and norepinephrine reuptake inhibitors have shown efficacy in patients with painful diabetic and other peripheral neuropathies but have not been studied in PNH. Duloxetine is approved by the FDA for the treatment of painful diabetic peripheral neuropathy. Clinically, this medication seems to be better tolerated compared with tricyclic antidepressants and hence is being used in clinical practice for PHN. Two randomized clinical trials have shown that venlafaxine at higher dosages is also efficacious in painful diabetic and other peripheral neuropathies, but it has also not been studied in PHN.[111]

Opioid Analgesics

Historically, the role of opioid analgesics in the treatment of chronic nonmalignant pain, and particularly neuropathic pain, has been controversial. Recent evidence, however, has shown that this class of drugs is efficacious in neuropathic pain conditions, including PHN. They are now recommended as second or third line analgesics by several respected sources.[110,111,112] These sources reserve them as second and third line agents based upon concerns regarding their side effects, the potential for the development of tolerance, and concerns regarding misuse and abuse. The efficacy of these agents appears to be comparable to that of antidepressant and anticonvulsant medications.[132] The analgesic efficacy of oral oxycodone was evaluated in a double-blind, crossover trial in which treatment resulted in significant reductions in allodynia, steady pain, and spontaneous paroxysmal pain.[133] Oxycodone treatment also resulted in superior scores for global effectiveness, disability reduction, and patient preference compared to placebo. In another randomized crossover study, treat-

ment with morphine (mean dose 91 mg/day) or methadone (mean dose 15 mg/day) was compared with placebo, and the opioids were associated with superior pain relief.[132] This study also made a direct comparison between opioids and tricyclic antidepressants. The NNT for opioids was 2.79 (2.01–4.6) compared to 3.73 (2.43–7.99) for the antidepressants.[132]

A quantitative review of pooled results for opioid therapy yielded an NNT of 2.67 (2.07–3.77).[58] It is noteworthy, however, that more frequent side effects were associated with the opioid therapy as compared to both tricyclics[132,134] and gabapentin[135] in head-to-head comparisons. If opioids are prescribed, the patients should be carefully counseled regarding common side effects such as nausea, sedation, urinary retention, pruritis, and constipation. Monitoring for immune suppression and hypogonadism is needed if opioid use is required chronically. Other adverse effects associated with chronic opioid use include tolerance, physical dependence, and opioid-induced hyperalgesia, which also require appropriate patient counseling and monitoring. Lastly, opioids cannot be prescribed without some risk of developing misuse, abuse, or addiction, but this appears to be relatively rare in elderly patients with no prior history of addictive disorders.

Clinical recommendations for the use of opioid analgesics in the treatment of PHN include the following: (1) use the lowest effective dose; (2) treatment can be initiated with short-acting opioids, for example, 5–10 mg oxycodone or 10–15 mg morphine every 4 hours as needed; (3) once a patient demonstrates tolerability to the initial opioid therapy, conversion can be made to a long-acting opioid preparation (controlled-release oxycodone or morphine, transdermal fentanyl patch, methadone, oxymorphone, or levorphanol), which can be further titrated up to an effective and well tolerated dose; (4) proactive effort should be made to anticipate and manage common side effects of nausea and constipation (with antiemetics and laxatives); and (5) regular assessment for efficacy and tolerability should be made. If the treatment is not effective, these medications should be tapered gradually to prevent the development of withdrawal symptoms.

Tramadol

Tramadol is an analgesic medication with a unique mechanism of action. It has a mu-agonist effect like opioids, but in addition it inhibits the reuptake of serotonin and norepinephrine like the antidepressants that are efficacious in neuropathic pain. It has been shown to possess efficacy in the treatment of PHN in a randomized, controlled trial in which a sustained release preparation was compared to placebo. Superior pain relief and improved quality of life was seen with tramadol,[136] and the NNT was 4.8 (CI 95%, 3.5–6.0). Tramadol can be dosed 50–100 mg every 4 hours on an as-needed basis. The daily dose should not exceed 400 mg. Lower doses should be used in the elderly and in patients with impaired renal function.

Adverse effects include nausea, vomiting, dizziness, constipation, urinary retention, somnolence, and headache. Concomitant use with medications that are inhibitors of CYP2D6, such as antidepressant medications, can lead to serotonin syndrome. Abuse of tramadol is thought to be rare but has been observed. Tramadol is associated with an increased risk of precipitating seizures in patients who have a history of seizures or who are also receiving drugs that can reduce the seizure threshold. These considerations usually result in clinicians avoiding tramadol in patients receiving CYP2D6 inhibitors or those patients at increased risk for seizures.

Topical Therapies

An inherent advantage of topical therapies is that they are associated with few systemic effects due to minimal systemic absorption of the medication. 5% lidocaine patches are the most commonly used topical modality for PHN in clinical practice and is the only one approved by FDA for this indication. Capsaicin cream and other compounded mixtures are used less commonly.

Topical Lidocaine

Five percent lidocaine patches result in a local analgesic effect. Clinical trials have shown greater efficacy with the use of lidocaine patches as compared to vehicle-controlled patches in PHN patients presenting with allodynia.[137,138] There was no significant difference in the side effects between patients receiving lidocaine versus the control patches. The suggested NNT is 4.4.[139] It is interesting to note that patients may respond well to topical lidocaine even if the skin at the targeted site appears to be completely devoid of nociceptors.[140] Lidocaine patches possess both excellent safety and tolerability profiles. Efficacy can be ascertained within 2 to 3 weeks of initiation of treatment, hence there is no need for a prolonged trial period. The side effects are minimal because of the minimal systemic absorption of the lidocaine. Lidocaine patches are not approved for use in herpes zoster and should not be used in patients with active zoster lesions.

Clinical recommendations for use of lidocaine patches in the treatment of PHN include the following: (1) the patches can be cut to fit the affected area (unlike fentanyl patches); (2) three patches can be applied with no additional risk of systemic side effects; (3) the recommendations are to keep the patches on for 12 hours and off for 12 hours but the patches can be left on for 18 hours at a time to improve effectiveness; (4) patches should be applied only on intact skin and directly over the area of maximum pain; (5) lidocaine gel has also been shown to be efficacious in patients with PHN and allodynia,[141] and its use can therefore be considered if lidocaine patches are not available, affordable, or their application is problematic.

Topical Capsaicin

Capsaicin is an extract of hot chili peppers and an agonist for the vanilloid receptor (TRPV1), which is present on afferent nociceptor terminals. There are no systemic effects with a local application. It is commercially available in two concentrations, 0.025% and 0.075%. Pooled data from two placebo-controlled studies demonstrated superior pain relief following 3–4 times/day application of 0.075% capsaicin to the painful areas compared to an inert topical agent. The NNT was 3.3.[142,143] Blinding in these studies was problematic given that capsaicin produces a distinct burning sensation on initial application. In clinical practice, it is difficult to use, especially in patients who are experiencing significant allodynia. Ironically, these are the very patients who would be expected to be most likely to benefit from this therapy. Recent large clinical trials have evaluated a single application of high concentration (8%) capsaicin following a local anesthetic application. The results of these studies indicate that this approach can produce prolonged relief of pain in some PHN patients.[144]

Low concentration capsaicin is rarely used as a first-line agent in patients with PHN. Patients should be warned about the unpleasant burning sensation it causes with initial application and to avoid contact with their eyes.

Other Topical Treatments

Topical anti-inflammatory preparations have been studied in a few randomized, placebo-controlled trials.[145] There was significant heterogeneity in these studies and definitive recommendations cannot be drawn from this literature. There have also been a few reports of other topical agents including tricyclic antidepressants and vincristine, as well as descriptions of novel delivery mechanisms, such as iontophoresis. The evidence for all these therapies is weak and they are generally not used in clinical practice.

Combination Therapy

Although the use of combination therapy is common in clinical practice, few clinical trials have provided an evidence base for this approach. One recent study has demonstrated that the combination of gabapentin and morphine was superior to either of these medications used alone in relieving pain in patients with either painful diabetic neuropathy or PHN.[135] The goal of combination therapy is to arrive at a balanced, multimodal approach that improves the efficacy and tolerability of treatment while minimizing side effects of the individual medications. Disadvantages of combination therapy include an increased risk of side effects as the number of medications is increased. It may also be difficult to determine which medication is responsible for side effects. Ideally, medications that can cause similar side effects (e.g., sedation) should not be started simultaneously. There should be a judicious interval of time (e.g., at least a week or more) before a new medication is introduced to the regimen.

Other Pharmacologic Therapies

A variety of other agents have been evaluated in the treatment of PHN and other neuropathic pain conditions. Several anticonvulsant and antidepressant medications besides those discussed above have shown evidence of efficacy in other neuropathic pain conditions in single clinical trials but lack convincing evidence of efficacy.[111] NMDA antagonists, including ketamine, dextromethorphan, and memantine, have been studied but no evidence is available for their efficacy in PHN. Similarly, the sodium channel blocker mexiletine has not demonstrated benefit in PHN, although there is some evidence of efficacy in painful diabetic peripheral neuropathy. However, this agent is usually avoided given its high toxicity profile. The use of all these medications can be considered in select circumstances, such as in cases where more conventional treatments have failed.

Invasive Treatments for PHN

A considerable percentage of PHN patients will not respond to currently available pharmacologic treatments. In these cases, a referral to a pain management center should be considered sooner rather than later. Invasive treatments may be considered for patients with refractory pain. A variety of interventional strategies have been described and examined as treatment options for PHN. Unfortunately, the studies conducted to date have either been relatively poorly controlled or have not been replicated by independent investigators (e.g., use of intrathecal methyl prednisone). Given the lack of objective evidence available to compare the efficacy of the various interventions available, the choice of specific therapy has been dependent on the treating physician's clinical experience. The lack of evidence demonstrating the efficacy of interventional treatments points more toward the lack of adequate research as opposed to the conclusion that these interventions are inherently ineffective.

Sympathetic Nerve Blocks

The sympathetic nervous system is considered to be important in mediating pain in some neuropathic pain conditions. It has been hypothesized that in the acute phase of herpes zoster, inflammation induces intense stimulation of the sympathetic nervous system leading to reduced intraneural blood flow with resultant neuronal hypoxia and endoneural edema. Other putative mechanisms of sympathetic nervous system involvement include the formation of ephaptic connections between the sensory system and the sympathetic system as well as the upregulation of adrenoreceptors. These phenomena could result in inappropriate activation of primary nociceptive fibers in response to sympathetic nervous system activation. Blockade of sympathetic nerves with local anesthetics may reverse these effects. Sympathetic nerve blocks have been used for the treatment of both the acute pain of herpes zoster and the chronic pain associated with PHN. Unfortunately, there is little high-quality evidence supporting the use of this treatment in patients with PHN. Retrospective data indicate that these blocks may provide temporary pain relief. These studies reported that 41% to 50% of patients with PHN noted short-term relief following the injection, but the effectiveness waned over time based on long-term follow up.[65] In clinical practice, sympathetic blocks are usually reserved as a second- or third-line treatment option in cases where more conservative treatments have been exhausted.

Neuraxial Blocks

Similar to the literature regarding sympathetic blockade, there is inadequate data to convincingly demonstrate that neuraxial therapy is both safe and effective for the routine treatment of PHN. One study has yielded encouraging results with the use of subarachnoid methylprednisolone,[146] but concerns regarding the association between this therapy and the development of adhesive arachnoiditis have precluded its routine use.

In clinical practice, epidural injections of both local anesthetic and steroids are used in patients with pain that has been refractory to conservative treatment. The authors will occasionally use continuous thoracic epidural analgesia with a home infusion pump for a period of 1–2 weeks in patients with intractable PHN pain for symptom palliation. We have observed this approach to be helpful for severe cases, but objective evidence for this therapy is lacking. It does require home nursing care and significant coordination of care by the treating physician. In general, it is reserved for the most severe cases.

Peripheral Nerve Blocks

Intercostal nerve blocks have been reported to provide long lasting relief in PHN patients.[147] The quality of the evidence is limited, much as it is for the other neural blockade techniques described above. Another intervention that is infrequently used is the injection of steroid into the involved dorsal root ganglion. This approach is performed in a nearly identical manner as that used for performing a transforaminal epidural steroid injection. If an inflammatory process at the level of the dorsal root ganglion is considered to play a role in the pathophysiology of PHN, then this treatment would seem rational. There is, however, no convincing evidence to support the routine use of this treatment.

Spinal Cord Stimulation

There has been an increasing role for neuromodulatory strategies in the management of chronic neuropathic pain conditions. Some encouraging data have been reported regarding the effects of spinal cord stimulation in patients suffering from PHN. In a case series of 28 patients (4 patients had herpes zoster and 24 patients had PHN), the effect of spinal cord stimulation was studied prospectively. Long-term relief was obtained in 82% of the patients with PHN.[68] Patients served as their own controls by intermittently switching their spinal cord stimulator off and then monitoring themselves for the reappearance of pain. This is an interesting case series, but confirmation of the benefit of spinal cord stimulation in PHN patients will require further studies with the inclusion of a formal control group.

Psychological Interventions

PHN has been demonstrated to adversely affect overall quality of life by impairing physical and emotional functioning. Studies

have shown that the degree of catastrophizing predicts the level of pain in elderly patients with PHN,[148] and this has been shown to be independent of depressive symptoms. Although the effects of cognitive-behavioral therapy and other psychosocial treatments have not been specifically studied in patients with PHN, it would seem logical and prudent to utilize these treatments on an individualized patient basis. There is ample data to support the use of these therapies in other chronic pain conditions and it is reasonable to extrapolate this evidence of efficacy to the treatment of patients with PHN.

Transcutaneous Electrical Nerve Stimulation (TENS)

There have been conflicting responses reported to TENS therapy in patients with PHN. There are a few small case series[149,150] that showed beneficial effects with use of this treatment, but other similar reports failed to demonstrate any benefit. TENS is still clinically offered to many patients on a trial basis given its safety profile. Those patients who have a favorable response to the trial therapy can procure a TENS device for more long-term use.

SURGICAL APPROACHES

Multiple surgical approaches are described in the literature for the treatment of PHN. In general these are quite drastic procedures with no proven long-term benefit. Surgical treatments are largely avoided given the limited literature to support their use, their potential for serious sequelae, and the expanding list of safer and more efficacious options.

PREVENTION OF PHN

The prevention of PHN is obviously closely tied to the prevention of herpes zoster. Thus, the salutary effects of vaccines in preventing herpes zoster described earlier in this chapter, apply to the prevention of PHN as well. The beneficial effects of antiviral medication in decreasing the incidence and severity of PHN have also been reviewed above. These approaches are the mainstays in our arsenal to prevent PHN. There are only scant data to suggest any other therapies are genuinely helpful in preventing PHN.

A small, placebo-controlled, randomized trial evaluated the effect of 25 mg daily of amitriptyline initiated within 48 hours of rash onset in herpes zoster patients over 60 years of age.[151] Treatment with amitriptyline was associated with a 50% decrease in pain prevalence 6 months after rash onset. These results should be confirmed in a trial that controls for the presence of antiviral therapy. Although treatment with amitriptyline may have a beneficial effect in reducing the incidence of PHN, its use should be weighed carefully against potential side effects in elderly or otherwise frail patients.

Use of other medications that are efficacious in PHN, such as gabapentin and pregabalin, may decrease the severity of acute pain in herpes zoster and possibly reduce the incidence of PHN beyond what can be achieved by antiviral therapy alone. There are promising data in animal experiments to support this hypothesis, and results of a single-dose trial of gabapentin vs. placebo demonstrated a reduction in acute pain in patients with herpes zoster.[57]

Two double-blind, randomized, controlled trials of corticosteroids given for a 21-day duration in herpes zoster did not show any effect on the incidence or duration of PHN.[62,63] The data currently available do not support the routine use of corticosteroids as a strategy to prevent PHN.

The use of sympathetic blocks has been used for acute pain in herpes zoster and uncontrolled studies have claimed a reduction in the development of PHN.[152,153] Other studies, however, failed to replicate this effect.[154] Since the pain of herpes zoster and PHN improve over time as part of their natural history, a control group is critically important in any study of the effects of these and other treatments intended to reduce the incidence and duration of pain. Thus, currently available uncontrolled studies are inadequate to definitively support the routine use of sympathetic blocks as a strategy for preventing PHN. In clinical practice, injections are still used for pain management in patients who are refractory to conservative therapy. This is empirically recommended by some authors with the rationale that better pain control in the acute phase of herpes zoster is an important clinical objective in its own right and may also favorably affect the likelihood of developing PHN.

CONCLUSIONS

Herpes zoster and its most common complication, PHN, affect millions of people annually. Their epidemiology is expected to change in complex and potentially unpredictable ways as a result of the implementation of varicella and zoster vaccination programs. Nevertheless, it is difficult to imagine a complete disappearance of these challenging conditions in the near future. Hence, there is a need to develop improved strategies for the treatment of both herpes zoster and PHN. Ongoing research into the underlying mechanisms of these conditions will shape the direction of future treatments. For instance, a better understanding of the biological factors that contribute to the transition from acute to chronic pain may guide us toward therapies that will facilitate a more rapid and complete recovery of infected neurons. Genomic research also has the potential to guide us to new therapies.[155]

For now, clinicians should treat herpes zoster with antiviral therapy and analgesic medications. Corticosteroids should not be routinely prescribed, but can be considered in special circumstances, such as patients with ophthalmic involvement, associated motor deficits, or severe acute pain. Supplemental therapy with tricyclic antidepressants, gabapentin or pregabalin, and neural blockade can be considered in refractory cases where more conservatory therapy has failed, although the evidence base for these treatments is weak.[44] The treatment of PHN is likely to be an ongoing challenge, at least into the near future. At the present time, there is good evidence to support the use of some pharmacologic therapies, including tricyclic antidepressants, gabapentin and pregabalin, and topical lidocaine patches as well as opioid analgesics. The potential merits of each of these agents needs to be carefully balanced against each patient's ability to tolerate their side effects. This is a particularly salient consideration given that many patients with PHN are older or otherwise frail. Invasive modalities such as spinal cord stimulation may play an important role in the future, especially in patients with intractable pain. Further controlled clinical trials will be needed before this treatment approach can be recommended for widespread use. Finally, the role of patient and family education and psychological support cannot be overemphasized, given that the currently available treatments will not be effective for all patients.

Our major treatment recommendations may be summarized as follows:

1. Primary varicella vaccine in children is recommended to prevent chicken pox, and this is also expected to ultimately decrease the incidence of herpes zoster and PHN as vaccinated children become adults and replace those with wild-type virus in the population.
2. Herpes zoster vaccination is recommended for older immunocompetent adults to decrease the incidence of herpes zoster and PHN and to reduce the overall burden of illness.
3. Patients with herpes zoster should be treated with antiviral therapy as rapidly as possible to hasten the rate of healing,

minimize neural damage, decrease the pain caused by the acute infection, and decrease the incidence and duration of PHN.
4. Opioid analgesics, tricyclic antidepressants, gabapentin, and pregabalin can be used in patients with herpes zoster to treat acute pain, although it is important to recognize that few studies have investigated the efficacy of such treatments.
5. Tricyclic antidepressants, gabapentin, pregabalin, topical lidocaine patches, opioid analgesics, and tramadol should be used for the treatment of PHN given their well-established efficacy in this and other chronic neuropathic pain conditions.
6. Referral to a pain specialist should be made if pain control is inadequate despite the above measures

CHAPTER 28 ■ CENTRAL PAIN STATES

JOEL D. GREENSPAN, ROLF-DETLEF TREEDE, RONALD R. TASKER, AND FREDERICK A. LENZ

Central pain is defined[1] as "pain associated with lesions of the central nervous system (CNS)" and is among the most intriguing, distressing, and intractable of chronic pain syndromes. For example, transection of the spinal cord can result in chronic pain below the level of the transection (spinal cord injury/SCI central pain), or a stroke can result in central pain on the opposite side of the body (central poststroke pain, CPSP). In both cases, the diagnosis of central pain is based on clear evidence of a CNS injury, evidence of pain and temperature sensory alterations, and the exclusion of other mechanisms of pain. The evidence of CNS injury rests on neurologic signs, radiologic, and electrical studies (see Chapters 18 and 19). Central pain belongs to the group of neuropathic pain syndromes and shares many features with these pain syndromes.[1–3] This chapter is divided into two sections, the first deals with SCI central pain and the second with CPSP. Each section deals both with basic and clinical considerations. A more general discussion of the different types of pain seen after injury to the spine and spinal cord may be found in Chapter 40.

SPINAL CORD INJURY CENTRAL PAIN

Incidence and Etiology

The diagnosis of SCI central pain may be obvious but is conservatively considered to be a diagnosis of exclusion. The patient presents for treatment of pain after therapy after completion of the causative event, such as trauma or transverse myelitis in multiple sclerosis (MS). In the case of trauma there may be pain from direct injury to the spine or the limbs which may confuse the issue. A recent study demonstrated that patients with SCI central pain ($n = 20$) could be identified by clinical criteria among a group of patients with SCI ($n = 40$).[4] These criteria included the presence of pain at least two spinal dermatomal levels below the level of SCI after exclusion of pain secondary to nociceptive, peripheral neuropathic, and psychogenic mechanisms. Only pa-

TABLE 28.1

ETIOLOGY OF 127 CASES OF SCI CENTRAL PAIN

Diagnosis	% of Patients
Trauma	65
Iatrogenic	12

Neoplasm	6
Skeletal pathology	2
Vascular pathology	2
Congenital lesions	4

(Data from Tasker RR, DeCarvalho GT, Dolan EJ. Intractable pain of spinal cord origin: clinical features and implications for surgery. *Neurosurgery* 1992;77(3):373–378.)

tients with an injury above the conus medullaris were included because of the presence of combined injury to the central and peripheral nervous systems for lesions of the conus, that is, skeletal level above T10.

Trauma is the most common cause of spinal cord central pain, as shown in Table 28.1, which lists the etiology of pain in a series of 127 patients with SCI central pain.[5] In this series, 76.4% were men, and 57.4% were younger than 40 years at the time of the injury. Forty-two percent of the patients had lesions in the cervical area, 21% in the T1-9, and 37% in the T-10–L-2 areas; 32% of lesions were clinically complete, 64% incomplete, and 4% of patients had no clinically detectable sensory loss. There appeared to be no correlation between patterns of pain and etiology, level of injury, and completeness of spinal cord transaction. A retrospective study of 380 patients (questionnaire response rate 38%) who suffered from SCI revealed that 65.5% experienced pain, of which the steady, burning, dysesthetic component was the most common.[6]

Patients with traumatic SCI and central pain (n = 20) were compared with those with SCI but without central pain (n = 20) in a Danish prospective series.[4] There were no significant differences between these two groups by demographics, interval since injury, level of injury, posttraumatic interval, degree of disability, degree of spasticity, or sensory diminution.

The time of onset of SCI central pain after the causative event could be correlated with the mechanism of pain.[6] When onset was delayed beyond 1 year, 56% of these patients were found to suffer from a syrinx; 37% of those with onset before 1 year did so too. Although the pain rarely, if ever, subsides on its own, it may change slowly but significantly over time. The presence of facial pain or late onset of pain should alert the physician to the possibility of posttraumatic syringomyelia.[7]

A large series of patients with syringomyelia correlated MRI findings with clinical features.[8] This study identified segmental burning pain, hypersensitivity, and dysesthesias and trophic phenomena in patients with syringomyelia (51/137, 37%) at the time of presentation. Forty-three of these 51 (84%) had extension of the syrinx into the dorsolateral quadrant of the cord ipsilateral to the pain at the appropriate level.

Clinical Features

The clinical features and types of pain have been reported in 127 patients with SCI central pain.[7] The temporal course of the pain was characterized as: steady in 95% of cases, intermittent (usually shooting) in 31%, and evoked (allodynia, hyperpathia, or hyperesthesia) in 45%. Steady pain was usually causalgic (75%) or dysesthetic (28%). The dysesthetic element was variably described as tingling in 20%, numb in 6%, crawling in 2%, and pricking in 1%. The quality of pain sometimes included a mechanical component described as aching in 13%, had a sense of compression or distraction in 18% (crush, 3%; tight, 2%; squeeze, 2%; pull, 2%; pinch, 2%), whereas it was rhythmic in 9% (throb, 5%; cramp, 3%; pound, 1%; pump, 1%), cold in 4%, and had the feeling of a cut in 2%. These results are generally consistent with a smaller detailed study of 19 patients in which the following sensations commonly occurred: (30% to 70%): cutting, burning, piercing, radiating, and tight.[9] A steady, burning, dysesthetic component was the most common in a study of 102 SCI central pain patients.[7] The only obvious clinical correlation with pain type was the association of intermittent pain with lesions at the T10–L2 vertebral level.[7]

Patients with traumatic SCI and central pain are similar to those without central pain in terms of sensory alteration as measured by mechanical, thermal, and pain thresholds.[4] However, the populations of SCI with central pain were distinguished from those without by increased sensitivity to painful or nonpainful mechanical or temperature stimuli. This is consistent with another report of 16 patients with SCI and dysesthetic pain, comparing the somatosensory function in normal, painful, and nonpainful denervated skin.[10] No difference existed between the degree of deficit in dorsal column and spinothalamic tract function, but allodynia and wind-up were more common in painful than nonpainful denervated cutaneous areas in both studies.

The prevalence of a band of steady pain at the upper margin of sensory loss and diffuse pain below the level of injury is more characteristic of an incomplete lesion.[5] Visceral, perineal, and anal pain were more common in complete lesions. Pain may resemble that of musculoskeletal disease or muscle tension (see previous discussion, quality of pain). When this type of pain occurs in an innervated area above the level of injury, it may be associated with mechanical problems in traumatic SCI patients. However, such pain may occur below the level of a complete injury, and so may be neuropathic in origin. Alternately, there may be a painful or nonpainful phantom below the level of a complete lesion. In this series, facial pain was pathognomonic of a syrinx in the cervical area interfering with the descending tract of the trigeminal nerve.

Forty-seven percent of patients experienced allodynia or hyperalgesia or both, but only in areas of preserved sensation.[5,7] This was usually associated with spontaneous pain, although in 4% of patients, evoked pain occurred in isolation. It affected 39% of patients with complete lesions where it usually occurred as a band at the upper level of the sensory loss, and 51% of patients with incomplete lesions. In these latter it was found diffusely in 67%, and as a band at the upper level of the sensory deficit in 18%. Taking complete and incomplete lesions together, in 21% it occurred in a band at the upper level of the sensory loss, in 29% diffusely, and in 50% patchily below the patient's level. This was similar to the findings of a more recent Danish study in which 40% (8/20) of patients had allodynia to touch and one patient also had cold allodynia.[4] Seven of the eight had allodynia in the border of anesthetic area. One patient had pain below the lesion level and one had widespread allodynia, including face, when the spontaneous pain was severe. It could also occur in radicular distribution from damage to a root near the level of spine injury.

Patients with lesions of the cauda equina and conus pain often had a neuralgic intermittent component shooting down the legs.[5,7] This type of pain may well be the result of injury to both central and peripheral nervous systems, and affected 31% of patients. It was present in 82% of patients with complete T10–L2 lesions, and 64% of incomplete lesions at this level. Pain resembling abdominal or pelvic disease usually occurred below a level of complete sensory loss and often led to extensive investigation of the viscera, and even to abdominal surgery. These types of pain were not apparently observed in the more recent study which

excluded patients with lesions of the conus.[4] These results suggest that injury to the central and peripheral nervous systems are responsible for these pain types.

These findings demonstrate that patients with SCI central pain, have diminution of STT mediated thermal sensation or pain sensation or both on quantitative sensory testing.[4,10,11] However, this characteristic does not identify the subset of patients with SCI central pain among those patients with SCI.[4] Therefore diminution of STT-mediated sensations is a necessary but not sufficient condition for the development of SCI central pain. All patients with SCI central pain have diminished thermal or pain sensation or both on quantitative sensory testing.[4,10,11] However, the presence of SCI central pain is correlated with the presence of hypersensitivity to cold or tactile stimuli. When compared to SCI patients without central pain, those with central pain more frequently had hypersensitivity to mechanical and cold stimulation at dermatomes corresponding to the lesion level. The intensity of brush-evoked pain at the lesion level is correlated with spontaneous pain below the level of the injury.[4] These results point to the role of brainstem, thalamic, and cortical neurons in somatic sensory pathways in the mechanism of central pain (see later discussion).

Animal Models

The best model of SCI lesions leading to central pain is the hypersensitivity of nonhuman primates with lesions of the anterolateral quadrant of the spinal cord.[12,13] The response of these monkeys with these lesions could be divided into those which recovered their prelesion purposive escape response and those which did not. The animals which did recover were those which had lesions extending medially into the grey matter of the spinal cord. The reflexive response to electrocutaneous stimuli was initially reduced contralaterally, but to some extent ipsilaterally. The recovery tended to be bilateral, leading to a greater reflexive response ipsilaterally. This pattern distinguished itself from the purposive/escape behavior, in which the changes tended to be contralateral.[13,14]

Anatomic studies of the thalamus have been carried out in monkeys with thoracic spinal cord lesions both of the ipsilateral anterolateral quadrant of the spinal cord and of the contralateral dorsal quadrant. Compared with controls these lesioned animals show decreased GABA immunoreactive elements in the thalamic ventrobasal nucleus.[15] Electron microscopic analysis demonstrates the presence of two types of GABAergic elements, including F elements which are mostly axonal terminals of the neurons in the thalamic reticular nucleus. The second type of terminal is a presynaptic dendrite of local interneurons (PSD). Results in three monkeys demonstrated significant decreases in both types of GABA immunoreactive elements in the ventral basal complex.

Detection of electrocutaneous stimuli was not impaired in these animals, suggesting that other spinal pathways, perhaps the ipsilateral STT, can transmit activity evoked by this electrocutaneous stimulus. Thalamic recordings in the hind limb representation of the ventral basal complex were carried out in these animals and demonstrated absent responses to thermal and mechanical somatic sensory stimuli, graded into the painful range. In the forelimb representation evoked responses were increased for thalamic multi-receptive cells (MR) which responded to both cutaneous brushing and compressive stimuli with activity that was not graded into the noxious range. In the forelimb representation low threshold spike (LTS) bursts were increased during spontaneous activity. In the hind limb representation there were no responses to somatic stimulation. Burst rates were increased, and firing rates between bursts were decreased, consistent with studies in humans.[16]

Thalamic recordings were also carried out in monkeys with thoracic anterolateral cordotomies.[17] Some of these animals showed increased responsiveness to electrocutaneous stimuli and thus may represent a model of central pain.[18] In comparisons with normal controls, MR cells in the monkeys with anterolateral cordotomies showed significant increases in the number of low threshold bursts occurring spontaneously or in response to brushing or compressive stimuli. Thalamic low threshold bursts were those associated with a low threshold calcium spike deinactivated by a prolonged hyperpolarization of the neuron membrane (approximately 100 ms). The changes in bursting behavior were widespread, occurring in the thalamic representation of upper and lower extremities, both ipsilateral and contralateral to the cordotomy.

The location of this bursting activity in the forelimb representation ipsilateral to the spinal injury suggests that bursting is not sufficient for pain which is contralateral in this syndrome.[19] However, such bursting could cause pain if activation of the bursting cell produced the sensation of pain consistent with the increased frequency of pain evoked by thalamic stimulation with a grouped/bursting pattern of pulses in patients with central pain.[20–22]

Some monkey species with anterolateral cordotomy display autotomy behavior (self-inflicted destruction of denervated parts of the body).[23] This behavior is often interpreted to indicate the presence of dysesthesias, and perhaps central pain.[24,25] The presence of autotomy in patients with congenital analgesia, and without the sensation of pain, has been taken to indicate that autotomy is not necessarily an indicator of chronic pain.[26]

Autotomy reactions have been studied following lesions of rodent spinal cord pathways.[27–29] Autotomy was not present after posterior quadrant sections, simultaneous section of ipsilateral, lateral, or anterolateral quadrants in addition to anterolateral quadrant section or hemisection on the other side of the spinal cord. The conclusion of these studies is that autotomy occurs only in cases where section of the anterolateral quadrant or one half of the spinal cord allows for sensory transmission through ipsilateral nociceptive pathways.

A number of studies of spinal cord injury in rats have led to models of the mechanism of spinal cord injury. Behavioral evidence of hyperalgesia and abnormal hypersensitivity of dorsal horn neurons has also been reported in rats after cavitary lesions of the spinal cord central gray. These cavitary lesions were created by injection of quisqualic acid, an excitotoxin acting at non-NMDA glutamate receptors.[30,31] This excitatotoxic SCI injury leads to a cascade of chemical and inflammatory events resulting in increased extracellular excitatory amino acid (EAA) concentrations, which may be important mediators of the delayed injury which occurs in this model. Studies by Hulsebosch have highlighted the role of the metabotropic EAA receptor (mGluR) class in the release of EAA.[32] Some receptors of this class (mGLuR) group I (mGluR1 and mGluR5), seem to activate several intracellular pathways that lead to increased extracellular EAA concentrations. The results demonstrate that this pathway can initiate a number of intracellular cascades which lead to increased extracellular EAA concentrations, possible mediators of the delayed injury and central neuropathic pain behaviors observed in this model.

A role for sodium channels in SCI central pain is suggested by studies carried out in rats with a spinal cord contusion injury.[33,34] In these animals the expression of non-tetrodotoxin (TTX) dependent sodium channels in dorsal horn and thalamic neurons may correlate with the presence of thalamic bursting behavior similar to that found in humans with SCI central pain. These animals also displayed spontaneous behaviors and responses to sensory stimulation consistent with those observed in central pain. Administration of anti-sense in these animals reversed thalamic bursting and the behaviors which are related to pain.[33] These studies suggest that the presence of non-TTX dependent sodium channels of this type may be the factor which leads to central pain, in response to or in addition to STT-

mediated sensory attenuation, or both. It is unclear how these studies in rodents relate to the clinical features and treatment of human SCI central pain after complete or partial SCI.

Treatment of Spinal Cord Injury Central Pain: Medical Treatment

SCI central pain is a particularly refractory chronic pain syndrome. One-third to one-half of patients who experience SCI central pain have severe pain.[7] Chronic pain syndromes can almost never be eradicated and, even after successful treatment, the chronic pain of SCI tends to recur with time, regardless of the treatment modality. Therefore, initial treatment should be conservative and carry low risk. First, musculoskeletal and visceral causes of pain from spinal cord injury should be assessed and if identified, treatments directed at these causes can effectively relieve the pain. It is also important to evaluate and treat motor spasticity as treatment of spasticity may result in a significant reduction in pain. Treatments discussed in this chapter will focus on neuropathic pain since treatment of neuropathic pain is usually more difficult. Pharmacological treatment of SCI pain is the standard for most patients although there are a limited number of trials that can guide drug selection. A summary of controlled trials on the pharmacological treatment of SCI pain is presented in a paper by Basastrup and Finnerup.[35]

The anticonvulsant drugs have been studied the most of all antineuropathic agents and currently gabapentin and pregabalin are considered first-line drugs even though there are both positive and negative studies. The most comprehensive study was by Siddall et al. who used a flexible dosing schedule of pregabalin and found doses ranging from 150–600 mg (mean dose of 460 mg) were better than placebo.[36] Another recent trial supported these findings with pregabalin doses of up to 600 mg day being better than placebo.[37] Two trials with gabapentin using doses up to 3600 mg/day showed mixed results with one showing gabapentin better than placebo[38] and a second trial showing no difference from placebo.[39] A third study showed gabapentin no more effective than placebo; however, this study used doses up to only 1800 mg/day and only included seven subjects.[40] Trials with other anticonvulsant drugs lamotrigine and valproic acid have not been effective in the treatment of SCI pain.[41,42]

There is an extensive literature supporting the use of antidepressants for the treatment of neuropathic pain and therefore it is reasonable to believe that they have a place in the treatment of SCI pain. Only amitriptyline and trazodone have been subjected to randomized, placebo-controlled trials and the results have been mixed. One study at doses up to 150 mg/day of amitriptyline resulted in better pain relief than plabebo[39] whereas a second study using doses ranging from 10–125 mg/day showed no effect over placebo.[43] A study of trazodone at doses ranging from 50–150 mg/day showed no effect.[44] The selective serotonin reuptake inhibitors (SSRIs) and the selective norepinephrine reuptake inhibitors (SNRIs) have not been studied for SCI pain. These agents have a better side effect profile than the tricyclic antidepressants; however, the SSRI have demonstrated inconsistent effects in the treatment of neuropathic pain. Clinical trials with the SNRIs have consistently demonstrated efficacy and therefore are reasonable alternatives for SCI pain.

Sodium channel antagonists may have a role in the treatment of SCI pain. Galer and colleagues found intravenous (IV) lidocaine infusion was useful in patients with central pain in a population of mixed SCI and post-stroke central pain, although the effect in central pain was less than that in peripheral neuropathic pain.[45] A randomized control trial by Finnerup also showed a positive effect of IV lidocaine on SCI pain.[46] Mexiletine, an oral analogue of lidocaine, did not have any significant effect on SCI pain at a dose of 450 mg three times per day. There were severe side effects at this dose which is a limitation of mexiletine.[47]

The systemic opioids have been shown to be effective in the treatment of a variety of neuropathic pain syndromes; however, there are few studies in SCI pain. Only one study has looked at the effects of a systemic opioid on SCI pain. Attal et al. showed studied the effects of IV morphine on spontaneous and evoked pain of CPSP and SCI pain and found no difference from placebo.[48] A randomized double-blind crossover study compared the putative *N*-methyl-d-aspartate receptor antagonist ketamine and the opioid receptor agonist alfentanil.[49] Both agents reduced both spontaneous and evoked pain. Ketamine did not affect wind-up pain and was associated with significant side effects, although it did diminish allodynia. The recently published neuropathic treatment guidelines recommend the opioids as second-line therapy which is a reasonable approach for SCI pain.[50]

GABA receptors are widely distributed throughout the CNS and thought to control pain transmission.[229] A controlled trial of propofol (Diprivan 1% in an oil and water emulsion containing 10% soy bean oil, AstraZeneca) a putative $GABA_A$ agonist has found that propofol decreased spontaneous and evoked pain in a population of patients with SCI central pain and CPSP (see later discussion, Treatment of CPSP: Medical). Balofen, a $GABA_B$ agonist, is widely used to treat spasticity in SCI patients. There have been reports emerging in the literature on the effects of intrathecal baclofen on neuropathic pain. A small study in seven patients showed that a single dose of baclofen (50 mcg) decreased dysesthetic pain and spasm related pain in SCI patients.[52]

Studies have shown that intrathecal lidocaine reduces the pain of SCI suggesting that pain generators exist in the spinal cord of such patients.[53] A number of intrathecally delivered agents have been shown be effective in the treatment of SCI including the opioids, clonidine, baclofen, and the calcium channel antagonist ziconotide. In SCI central pain syndromes intraspinal delivery of opioids (alfentanil) was found to be effective for the treatment of spontaneous and evoked pain[49] while morphine was reported to be ineffective except in combination with clonidine.[54] Both epidural and intrathecal clonidine has been reported to relieve SCI pain.[55] Although the role of $GABA_B$ agonists on the treatment of SCI related spasticity is clear, the effects of these agents on SCI pain is less clear. A study by Herman et al. found that intrathecal baclofen reduced pain in a SCI central pain syndrome patients.[56] A study by Loubser and Akman showed no effect of intrathecal baclofen on SCI neuropathic pain.[57] There is one case report of two patients with SCI pain and spasticity that responded to the calcium channel blocker ziconotide.[58]

Treatment of Spinal Cord Injury Central Pain: Surgical Procedures

As discussed previously, there are a number of conservative options available for the treatment of SCI pain. Given the risks associated with surgical procedures, conservative therapies should be exhausted before using the more invasive therapies. If the patient fails systemic therapies, they should be first evaluated for spinal drug delivery since this therapy is reversible. The discussion of surgical procedures for SCI central pain must balance the limited success and incidence of complications, against the severity and impact of pain. Nondestructive procedures should be considered first. If destructive procedures are to be used, spinal procedures should be considered first. Aggressive medical therapy, psychological evaluation, and assessment of narcotic intake must be considered before commencing surgical treatment.[7]

Imaging studies help in the planning of operations which address the pain directly such as the dorsal root entry zone (DREZ) procedure and spinal cord stimulation (SCS). Imaging will also identify structural abnormalities such as a syrinx that, if progressive, must be dealt with first. If the preliminary investigation discloses the presence of a syrinx, it should first be treated by a

procedure to shunt cyst fluid to the subarachnoid space or the pleural space.[8] Syringomyelia should be suspected in long-delayed onset of SCI central pain and in patients who show delayed changes in their neurologic status or who have facial pain.[7] Drainage of a syrinx relieved pain in the majority of patients (22/37, 59%), partially in 40%, and completely in 19% at 6 weeks after surgery. Any improvement was maintained for a year in only 24% of patients, all of whom retained unpleasant symptoms. In summary, the syrinx must be treated to prevent additional neurologic deficits; pain, when present, is not usually alleviated by treatment of the syrinx. Success after pain surgery is measured by the patient's pain ratings, quality of life scales, the patient's overall satisfaction with the procedure, and subsequent treatment, particularly consumption of analgesics.

One of the first procedures to be considered is spinal cord stimulation (SCS), because of its simplicity and low risk (see Chapter 95). It is indicated in SCI central pain patients in whom sufficient dorsal columns survive above the lesion so that stimulation produces paresthesiae in the patient's area of pain, although some consider that the success rate is too low to justify a trial.[5,60] The inability to produce adequate paresthesiae with SCS is the probable cause of the low success rate in treating SCI central pain.[7] Another problem is that spinal cord injury itself or the primary surgical treatment of the pain-causing lesion may have so disturbed the local anatomy that SCS carries a significant surgical risk.

Deep brain stimulation (DBS) of the thalamus, periventricular grey, or medial lemniscus bilaterally is sometimes considered for treatment of the steady component of SCI central pain when SCS fails.[7] Large retrospective series of DBS have reported mixed results in SCI central pain. An early report found that success (50% pain relief) occurred in the short term in 3/8 patients and 2/8 long term.[61] Another study found pain relief of 0% to 25% in 2/12 patients, and 25% to 50% in 1/12.[62,63] If SCS produces adequate paresthesiae and fails to relieve the pain, paresthesia-producing DBS also fails. Paresthesiae-producing DBS is preferable to periventricular DBS for the steady neuropathic pain, the latter being preferable for nociceptive pain.[61–64]

Local anesthetic diagnostic blocks performed proximal or distal to the causative lesion, are used to determine if pain relief is obtained after blocking a specific nerve or nerve group. If so, an ablative procedure of the same nerve or nerve group might be helpful.[65,66] Permanent section of the same neural structure affected by the block does not lead to long-term pain relief.[3] Nerve blocks may be useful in monoradicular syndromes by allowing confirmation of the fact that division of a particular root can stop the allodynia or hyperpathia. They also allow an assessment of the degree of sensory attenuation, particularly position sense, to be expected should that root be divided in an attempt to relieve the pain. Sympathectomy may be useful for complex regional pain syndrome type I that is superimposed on spinal cord injury (see Chapter 102).

The differential response of SCI central pain to stimulation or augmentative versus destructive procedures is a basic organizing principle of the surgical approaches to this type pain. Chronic stimulation that produces paresthesiae in the area of pain has limited efficacy for the relief of spontaneous, steady pain while destructive procedures such as cordotomy, cordectomy, and the DREZ operation are useful treatment for intermittent spontaneous pain or allodynia/hyperalgesia.[7]

Hypersensitivity following peripheral lesions may result from altered processing of peripheral stimuli in the dorsal horn, which is transmitted to the brain through the STT, resulting in pain.[59,67] It seems likely that hyperalgesia secondary to peripheral lesions would be relieved by medical or surgical strategies that block transmission in the STT either by destructive or augmentative procedures. The mechanism of hyperalgesia caused by spinal cord lesions is more difficult to understand because the causative lesion in these cases is proximal to the dorsal horn. Nevertheless, SCI central pain can be relieved by transection of the STT, the DREZ procedure, and cordectomy (see Chapter 104).

There is a selective differential benefit of cordotomy on the neuralgic compared with the steady element of the patient's pain.[7,24,60] In a recent series (n = 39) undergoing cordotomy, mostly by the percutaneous technique, 54% enjoyed good relief and 32% fair relief of the neuralgic pain, 50% good relief and 25% fair relief of the evoked pain, and 6% good relief and 21% fair relief of the steady elements of SCI central pain.[5] However, percutaneous cordotomy carries a small risk of producing ipsilateral limb paresis, or impaired automatic respiration, and of aggravated bladder dysfunction, crucial matters for the spinal cord–injured patient with an incomplete lesion. Furthermore, the pain of many etiologies, perhaps including SCI central pain, tends to recur after cordotomy.[68,69] Long-term follow-up of Rosomoff series revealed that cordotomy initially relieved pain in 90% of patients, but that after 3 months relief had fallen to 84%, after 1 year to 61%, after 1 to 5 years to 43%, and after 5 to 10 years to 37%.

The DREZ operation has proved as successful as cordectomy and cordotomy in the relief of the neuralgic and evoked elements of spinal cord central pain. Like cordectomy, it results in an elevation of the patient's sensory level and requires a laminectomy. Conus DREZ may interfere with surviving bladder function. The DREZ procedure has been found to be most useful for the relief of end-zone pain (i.e., pain starting at the level of injury and extending distally), and not so effective for the diffuse, often sacrally distributed pain.[70] This procedure is most effective for pain in the dermatomes immediately caudal to the level of injury. Pain extending into areas remote from the injury site described as phantom, body, or diffuse burning pain is not very responsive.[71]

Destructive stereotactic procedures such as medial thalamotomy or mesencephalic pain tract section yield such poor relief of SCI central pain that they are contraindicated.[60,72,73]

The spontaneous, intermittent neuralgic component of SCI central pain has been recognized by many authors to be associated with conus and cauda lesions.[74] Such pain may be the result of root damage. Like hyperalgesia, it is relieved by interrupting the STT or inputs to the STT, by the DREZ operation, or by transection of the spinal cord.[7,75] In the literature concerning DREZ operation,[76,77] it is recognized that this procedure, like cordectomy,[7] is ineffective for the relief of the spontaneous, steady pain. However, it can relieve pain starting at the level of the lesion and extending caudally for a variable number of dermatomes as well as radicular pain.

The most common aspect of SCI central pain, the spontaneous, steady, causalgic, or dysesthetic element, is similar to that seen in all types of neuropathic pain. In spinal cord central pain, this is more characteristic of lesions above the level of the conus and can also occur in radicular distribution. This is the type of pain that is most difficult to relieve. It is not stopped by spinal cord transection above the level of the injury,[7] but responds best to chronic stimulation that produces paresthesiae in the area of the patient's pain.[78]

The relative merit of these destructive and augmentative procedures was assessed in a series of 127 patients with SCI central pain refractory to medical treatment.[7] The surgical procedures consisted of percutaneous cordotomy in 39 cases, cordectomy in 12, dorsal root entry zone (DREZ) surgery in 4, dorsal cord stimulation in 35, and brain stimulation in 13. Destructive surgery (cordotomy, DREZ surgery, or cordectomy) affected the three chief types of pain differently from treatment with SCS or brain stimulation. Destructive surgery resulted in reduction of steady pain in 26% of affected cases, of intermittent pain in 89%, and of evoked pain in 84%. Stimulation resulted in pain reductions in 36%, 0%, and 16% of cases, respectively. The differential effect of destructive surgery on steady and intermittent pain is consistent with published experience. These observations suggest differing mechanisms for the three types of pain.

In the patient with a conus/cauda lesion with significant neuralgic pain shooting up or down the legs below this level, relief is unlikely with SCS, although a trial may be attempted.[7] The next simplest step is a destructive procedure to interrupt the pain pathways such as cordotomy, cordectomy, or DREZ lesion. Transection of the spinal cord just above the level of the patient's injury is referred to as cordectomy. It is carried out at the expense of elevating the sensory level one or a few segments and of denervating the lower abdominal muscles.[7] However, the promise of therapies which may allow the spinal cord to heal makes this last approach unacceptable at present.

BRAIN CENTRAL PAIN

Central pain caused by lesions of the brain is as intractable as that arising from lesions of the spinal cord. It can arise from lesions of any etiology above of the spinal-medullary junction. Most cases of brain central pain are caused by strokes as shown in Table 28.2, which lists the etiology in 73 cases reported in Tasker's series.[5] This included hematomas which occurred in 17% of patients in the series. These lesions can be minimal or massive or associated with minor or major neurologic deficit. Like other types of neuropathic pain, it is idiosyncratic, often has a delayed onset, may occur in the absence of clinically detectable sensory loss, and commonly has three features: spontaneous steady pain, neuralgic pain, and evoked pain (allodynia and hyperpathia).[5] Papers by Head and Holmes and by Dejerine and Roussy[79] are pioneering studies of the clinical description of CPSP.[80,81]

TABLE 28.2

ETIOLOGY IN 73 CASES OF BRAIN CENTRAL PAIN (EXPRESSED AS PERCENTAGES)

Vascular	90.6%
Supratentorial	78.1
Thrombotic stroke	67.1
Spontaneous	57.5
Subarachnoid hemorrhage	2.7
Iatrogenic	
Artery ligation	2.7
Angiography	1.4
Postoperative	1.4
Trauma	1.4
Hematoma	11.0
Spontaneous	9.6
Thalamotomy lesion	1.4
Infratentorial	
Thrombotic stroke	6.9
Lateral medullary syndrome	5.5
Other	1.4
Hematoma	4.2
Hematobilia	1.4
Infection: Abscess	2.7
Vaccinia encephalitis	1.4
Other: Trigeminal tractotomy	1.4
Syringobulbia	1.4
Thalamic astrocytoma	1.4
Degenerative, not yet diagnosed	1.4

Clinical Features

Most cases of CPSP are caused by strokes. Brain central pain has been reported to be uncommon, occurring in only 1% to 2% of all strokes.[1,82] A more accurate estimate of the incidence may be that of Andersen and colleagues who studied 267 consecutive stroke patients at one institution over a 1-year post-stroke interval.[83] Two hundred seven survived more than 6 months, and were cognitively intact so that they could participate in sensory testing. Among this group, 47% had sensory abnormalities, while central pain developed in 8%, and a central nonpainful dysesthesia syndrome developed in 1 patient. All but one patient with CPSP also developed allodynia to heat or cold (9 patients each) or both. Central pain began by 1 month in 10 patients and after greater than 6 months in 3. Pain was mild in 6 (3%), and moderate to severe in 10 patients (5%).[83] Therefore, CPSP is not uncommon among patients with stroke and, when present, spontaneous and evoked pain are frequently severe.

Dejerine and Roussy have stated that stroke-induced pain depended on thalamic lesions. They coined the term "thalamic pain syndrome."[80] This statement and term was disputed by Biemond.[84] Modern imaging has confirmed that pain can arise from lesions in brainstem, thalamus, subcortical white matter, and cerebral cortex.[85–88] The location of nuclear thalamic lesions in these studies is unclear since they employed routine interpretation of CT and MRI scans.

There are three series of CPSP in which quantitative sensory testing was carried out along with descriptions of central pain qualities (Table 28.3). In one recent series, the patients' ongoing pain was characterized by temperature descriptors in eight (62%) cases, while mechanical descriptors were endorsed by nine (69%) patients.[89] These results are similar to those reported in the two comparable studies of CPSP.[86,90] Patients in the more recent study had higher pain ratings than did patients in the other two series, suggesting that there may be differences in the populations included in these studies.

The recent results are compared with previous studies of quantitative sensory testing reported as individual patients with CPSP.[86,90,91] Tactile hypoesthesia was documented in 50% of the patients tested, similar to the proportion reported in previous studies.[89] These previous studies documented hyperalgesia, by using a rotating von Frey hair[83] or a pin prick.[90] The sensations normally evoked by the rotating von Frey were not described; thus, it may not be appropriate to compare their results with the recent study.

All studies reported a large proportion of patients with cool hypoesthesia, while no more than 23% showed cold allodynia (Table 28.3). All studies described a small number of patients with bilateral cool hypoesthesia. All studies reported a large proportion of patients with warm hypoesthesia, but very few cases of heat allodynia. Thus, these studies demonstrated no clear relationship between compromise of painful sensation and allodynia within any particular submodality.

The most consistent characteristic of patients with CPSP is abnormal sensibility to some aspect of the STT-mediated sensations, particularly the innocuous thermal sensations of warmth (85%, 11/13), and cool (85%, 11/13) in patients with either CPSP[86,90] or SCI.[11] The patients show less consistent abnormalities of painful than nonpainful sensibility. Abnormal cold pain thresholds were observed in 9/13 patients, abnormal heat pain thresholds in only 1/13, and brush allodynia in 7/13. The other two series of patients with CPSP had higher proportions of abnormalities in cold, heat, and tactile pain sensibility than did the present series.[86,91]

A descriptive report of 73 patients with CPSP found that the onset of pain was often delayed, consistent with previous studies.[5,90] Pain in CPSP pain was commonly characterized by steady (usually burning 64.4%), dysesthetic (31.6%), intermittent pain

TABLE 28.3

COMPARISON OF SERIES OF PATIENTS WITH CPSP WHO WERE STUDIED CLINICALLY AND BY QUANTITATIVE SENSORY TESTING

Reference	89	85, 90	Descriptors, 86; sensory testing, 83
Burning cold/cold pain	53% overall; 38%, burning and cold; 15%, hot and cold	59%, 16/27	38%, 6/16 (freezing 3/16)
Mechanical pain	77% overall; 33%, sharp/stab; 23%, pressure heavy; tight/squeezing, 7% each	Aching 30%, pricking 30%, lacerating 26%	86%, 23/27
Pain rating	7.1 mean, 2.0 SD	2.5–7.9 mean by stroke location	3.3 median (0–7)
Touch—method	**Von Frey for threshold; brushes for allodynia**	**V Frey for threshold, Pin prick for hyperalgesia**	**V Frey hair, V Frey rotating for hyperalgesia**
Normal threshold	50%, 5/10	48%, 13/27	54%, 6/11
Hypoesthesia	50%, 5/10	52%, 14/27	27%, 3/11
Allodynia/Hyperalgesia	54% 7/13	16/27, 59% hyperalgesia	1/11 hyperalgesia
Cool—method	**Peltier Medoc**	**Peltier Somedic, warm minus cool threshold**	**Peltier Somedic**
Normal threshold	15%, 2/13	0/27	9%, 1/11
Hypoesthesia	85%, 11/13, 3 with equal bilateral hypoesthesia	Diff in cool-warm thresholds 17/27; larger change in cool 2/27	91%, 10/11
Cold pain—method	**As above**	**As above**	**As above**
Normal threshold	31%, 4/13	7% normal difference between cold & heat pain threshold	18%, 2/11-unaffected side lower
Hypoalgesia	46%, 6/13 (2 indeterminate)	93% abnormal difference between cold and heat pain threshold	45%, 5/11 (4/11-bilateral hypoalgesia)
Allodynia	23%, 3/13	No abnormally sensitive thresholds, but 5/22 (23%) reported discomfort to metal at room temperature	0/11
Warm—method	**As above**	**As above**	**As above**
Normal threshold	15%, 2/13	–	–
Hypoesthesia	85%, 11/13	Diff in cool-warm thresholds, 17/27; larger change in warm threshold, 8/27	11/11
Heat pain – method	**As above**	**As above**	**As above**
Normal	93%, 12/13	7% normal difference between cold and heat pain threshold	9%, 1/11
Hypoalgesia	7%, 1/13 (2 indeterminate)	93% abnormal difference between cold and heat pain threshold	91%, 10/11
Allodynia	0/13 (2 borderline)	No abnormally sensitive thresholds	0/11

The fourth column includes both clinical findings (n = 16)[86] and quantitative sensory testing (n = 11).[83] Similarly, the third column includes both clinical[85] and sensory testing results (both n = 27).[90] Another very large series could not be included because of quantitative sensory testing population statistics.[91] (From Greenspan JD, Ohara S, Sarlani E, Lenz FA. Allodynia in patients with post-stroke central pain (CPSP) studied by statistical quantitative sensory testing within individuals. *Pain* 2004;109:359–366, with permission.)

(16.4%), and allodynia or hyperalgesia (64.9%).[5] Distribution of intermittent pain was similar to that of spontaneous pain overall and to that of sensory diminution. Onset is often delayed between 1 and 4 weeks in 47% to 63% and greater than 4 weeks in approximately 20%.[5,83,92] Distribution of pain varied and bore no relation to any clinical features. Size, side, or location of the lesion; degree of sensory diminution; age; and sex all had no apparent relationship to the quality or severity of the pain.

The original description of the Dejerine-Roussy syndrome included abnormal movements and dystonia on the same side of the body as the pain.[80] Dystonia affected 8.2% of Tasker's series, all in patients with thalamic lesions,[5] although stroke-induced

dystonia occurs regularly in the absence of central pain.[93] In the same series of patients with CPSP, 6.8% had tremor in addition to central pain, especially in the case of brainstem lesions, and so could be classified as midbrain or Holmes tremor.[94]

Lesions Resulting in Central Poststroke Pain

The recent version of the disinhibition hypothesis proposes that central pain results from a lesion involving a lateral, cold-signaling, STT pathway which projects to the insula through nucleus ventral medial posterior (VMpo; see later discussion).[95] According to this hypothesis, lesions of VMpo or posterior insula lead to cold hypoesthesia, which results in the burning pain of CPSP. Therefore, the location of thalamic and cortical strokes in CPSP provides a critical test of this hypothesis.

Lateral (Vc, Vcpc) and posterior thalamus (Vcpor, Vmpo, Po) and perisylvian or primary sensory cortex are most clearly linked to the sensory-discriminative aspect of pain. Injections of lidocaine into monkey VP, corresponding to human Vc, are associated with a decreased ability to detect small changes in temperature in both the innocuous and noxious range.[96] A study in patients with pure somatic sensory stroke (n = 21) identified 11 thalamic strokes, 9 lacunes, and 2 hemorrhagic strokes. The lacunes were confined to "posterior lateral thalamus probably involving the Vc." Five involved both tactile and thermal/pain sensations, six were lacunes which involved either tactile or thermal/pain sensations, and nine were located in the ventral posterior lateral thalamus of corresponding to Vc.[88,97,98] Six of these were small lacunes which were associated with diminution of some and sparing of other somatic sensory modalities. Although central pain was not explicitly assessed, most patients reported unpleasant sensations in areas of sensory deficits.

Four patients with CPSP secondary to small thalamic lesions were studied with quantitative sensory testing.[99] All had alterations of cold pain sensation (either allodynia or hypoalgesia), while three patients had cool hypoesthesia. The patient with the least involvement of Vc had normal cool detection thresholds, suggesting that a lesion involving a critical volume of Vc is required to impair this modality. Perception of warm was impaired only in lesions involving nuclei posterior to Vc, consistent with the effect of injection of local anesthetic into monkey ventral posterior thalamus (corresponding to human Vc).[88,96] Heat pain threshold was not abnormal in any of these cases. Tactile perception was always impaired on the involved side. In a subject with cold allodynia, a single subject protocol positron emission tomography (PET) study measured the responses to immersion of either hand in a 20°C waterbath. The scan during stimulation of the affected hand (evoking allodynic pain) was characterized by intense activation of contralateral sensorimotor cortex. Therefore, there appear to be modality-specific elements in the human posterior thalamus, but lesions of Vc are sufficient to impair cold sensibility and to produce CPSP.

Lesions of the thalamus and cortex have also been studied in imaging studies of patients with CPSP. Previous studies have used computed tomography (CT) to localize lesions in thalamus in patients with central pain (n = 12). In four cases the lesions involved the thalamus, all of which involved other structures in addition to the thalamus.[83] In a similar study of 27 patients with CPSP, 9 out of 27 had thalamic lesions that could not be further specified, of which 2 were limited to the thalamus.[100] In a study of magnetic resonance imaging (MRI) scans in patients with central pain, 49/70 patients had lesions including the "ventral posterior nucleus" (corresponding to Vc).[101] Finally, MRI- and atlas-based methods have been used to demonstrate that thalamic lacunes leading to CPSP were located in Vc and do not involve VMpo,[99,102] contrary to the hypothesis that VMpo involvement is critical for thalamic lesion induced central pain, cool hypoesthesia, and cold allodynia.[95]

Similar techniques have been used in studies of sensory function following cortical lesions. Lesions of cortical elements of the STT-thalamocortical system in patients with central pain involve the somatic sensory structures. Imaging analysis of patients with CPSP have identified lesions in the parietal lobe in 4/5 patients with cortical lesions leading to central pain[86]; precise anatomy of capsular lesions (2 patients) could not be further specified. In another study, patients with central pain had parietal lesions in all extrathalamic cases.[85] A prior study of MRI scans in patients with CPSP had cortical lesions localized to insula or parietal cortex.[101] A patient with compression of the retro-insula and the parietal operculum posterior to the central sulcus had elevated pain thresholds to mechanical, heat, and cold stimuli.[103] Decreased unpleasantness associated with experimental pain was reported in a series of insular strokes identified by CT scan.[104] A study employing comprehensive quantitative somatic sensory testing revealed that lesions of the parietal operculum decreased the discrimination of pain while lesions of the insula increased the tolerance for pain.[105] Lesions of SI reduce the ability to discriminate painful stimuli[106,107]and reduce chronic pain.[108] A case study of an isolated stroke in the arm area of S1 decreased pain discrimination but did not decrease the unpleasantness of pain.[79] Therefore, the precise insular and parietal lesions associated with CPSP are unclear.

Mechanisms of Central Pain: Imaging Studies of Spontaneous Pain

Functional imaging studies have reported both hypo- and hyperactivity of the thalamus in central pain patients. Multiple PET studies reported decreased cerebral blood flow (CBF) in the ipsilesional thalamus in central pain patients during rest.[109–112] Due to poor spatial resolution of these PET studies, the exact thalamic nuclei could not be specified. This relative thalamic hypoactivity could be reversed by motor cortex stimulation[113] or by repeated cycles of daily IV lidocaine infusion.[110] At the same time, motor cortex stimulation and lidocaine treatment reduced pain compared to the resting state. Similar decreases in thalamic perfusion have been found in chronic peripheral neuropathic pain, such that the thalamus contralateral to the affected body region exhibited substantially lower CBF than the ipsilateral thalamus.[114–116]

Hyperactivity of the thalamus has also been described, typically under conditions of increased pain. A single photon emission computed tomography (SPECT) study reported bilateral regional metabolic increases in the thalamus in a case of SCI central pain during the experience of spontaneous high intensity paroxysmal central pain. However, reduced thalamic blood flow was observed when the spontaneous pain was at a low intensity compared to resting values of healthy subjects.[117] However, these data are descriptive in nature; no statistical analyses were done. Other SPECT and PET studies of CPSP patients demonstrated hyperactivity in the thalamic area after stimulating the allodynic side compared to stimulating the nonallodynic side and/or to patients without allodynia.[109,118–120]

An interesting SPECT study in patients with CRPS demonstrated hyperperfusion of the thalamus contralateral to the painful limb compared to the ipsilateral thalamus in patients with symptoms for only 3–7 months, but hypoperfusion of the contralateral compared to the ipsilateral thalamic in patients with long-term symptoms (24–36 months).[121] In contrast, symmetric perfusion of bilateral thalami was found in controls. No differences between controls and patients were seen with symptoms of the disease for 10–13 months. It remains to be determined if the same holds for central pain. Therefore, thalamic spontaneous blood flow may be increased or decreased in central pain syndromes, perhaps related the duration of the syndrome. Blood flow activations evoked by allodynic stimuli in central pain are considered in later discussions.

Neurochemical Studies

The most basic study of neurochemistry in central pain reported changes in magnetic resonance spectroscopic (MRS) signals consistent with different classes of thalamic cells. An MRS study found that thalamic concentrations of the neuronal marker *N*-acetyl-aspartate (NA) and the glial cell marker *myo*-inositol (Ins) differed between patients with or without central pain after SCI.[122] Mean NA concentrations and the NA/Ins ratio were significantly lower for pain patients compared to pain-free patients. Mean Ins concentrations were higher for pain patients versus pain-free patients, and the difference approached significance. Further, NA concentrations were negatively correlated with pain intensity and Ins were positively correlated with pain intensity in the pain group. No significant differences were found between the right and left thalamus, but it is unclear if pain was localized unilaterally. These results reflect dysfunction or loss of neurons in the thalamus in patients with central pain secondary to spinal cord injury.

It has been suggested that up or down regulation of receptors may be involved in the development of central pain, which could also explain the delayed time course of the development of central pain.[101] Recent PET studies of opioid receptor binding in both healthy subjects and central pain patients can be interpreted in the light of a recent study of healthy volunteers.[123] This study demonstrated that many areas traditionally thought to be involved in pain processing have a high binding potential for opioids. Highest binding potentials were found in the thalamus (nuclei not identified), basal ganglia (putamen and caudate), amygdala, anterior cingulate cortex (ACC), midsagittal corpus callosum (MCC), and operculo-insular region. SI and MI have significantly less binding potential. No hemispheric differences were found.

Recent PET receptor binding studies demonstrate reduced nonspecific opioid-receptor binding in many of these areas in CPSP patients versus healthy controls.[124–126] Significant reduced regional binding was found independent of lesion site, mainly involving the thalamus, SII, insula, prefrontal cortex, ACC, and inferior parietal cortex (BA 40). Reduced radio-labeled opioid binding may reflect decreased binding of the exogenous ligand resulting from increased receptor occupancy by endogenous opioid peptides. However, the observation that two patients who received naloxone infusions did not develop increased pain contradicts this explanation.[126] Other explanations are loss of receptors due to the lesion, transneuronal degeneration, or receptor mechanisms such as receptor internalization or down-regulation.[125] Reduced opioid receptor binding in central pain patients may explain the poor response of these patients to opioid treatment.[127,128]

Up-regulation of receptors is also possible following lesion-induced denervation. SCI can also dysregulate sodium channel expression, specifically in neurons of the dorsal horn of the spinal cord and thalamus.[34] An imbalance of central excitatory and inhibitory mechanisms has been proposed to contribute to central pain. Pharmacological studies support the importance of neuronal hyperexcitability as a mechanism of central pain. Agents that inhibit hyperexcitability such as lidocaine (by blocking voltage-sensitive sodium channels), ketamine (by blocking NMDA receptors and thereby glutamatergic excitation), and lamotrigine (blocking both sodium channels and glutamate receptors) have been shown to be effective in relieving central pain.[129,130] Also increasing GABAergic inhibition with either baclofen or propofol has been shown to be effective.[129,130] However, it is not possible to identify the site of action of the agents in these clinical studies.

Motor Cortex and Central Pain

Motor cortex stimulation has been used for the treatment of central pain with success rates reported between 50% and 75%,[131,132] perhaps by modulation of activity in the spinal dorsal horn. Electrical stimulation of the motor cortex inhibited spinal neuronal responses to noxious pressure and pinch stimuli in a graded fashion, so that higher voltage of electrical stimulation reduced neuronal activity.[133] Motor cortex stimulation had no effect on the response to innocuous brush as recorded from wide dynamic neurons in lumbar spinal dorsal horn in rats. However, mixed results from motor cortex stimulation have been reported in monkeys so that motor cortex stimulation resulted in excitation or excitation followed by inhibition of STT cells.[133]

A recent imaging study shed new light on the possible underlying mechanism of motor cortex stimulation in relieving central pain. This recent PET blood flow study demonstrated that motor cortex stimulation in chronic neuropathic pain patients induced activation, partly during the stimulation period but mainly in the post-stimulation period, in the posterior mid-cingulate cortex (MCC), pregenual ACC, orbitofrontal cortex, putamen, thalamus, and brainstem (PAG and pons).[134] Regional CBF changes during this post-stimulation period correlated with pain relief. A functional connectivity analysis showed that these areas are all connected and provide a network that is influenced by motor cortex activation. Lack of efficacy of motor cortex stimulation in a subset of patients may be due to damaged corticospinal tracts or intracortical connections.

A recent study examined the effect of repeated sessions of repetitive transcranial magnetic stimulation (rTMS) at 20 Hz for 10 minutes each day on 5 successive days over the motor cortex. This pattern of stimulation reduced pain by about 40% compared to baseline and sham rTMS in patients with CPSP for at least 2 weeks after the end of the treatment.[135] Therefore, epidural or transcranial magnetic stimulation of motor cortex can have a substantial analgesic effect upon CPSP.

Involvement of the Spinothalamic Tract in the Mechanism of Central Pain

Many studies suggest that impairment of temperature and pain sensation are associated with the development of central pain.[136] A broad range of evidence links pain and temperature sensibility to the human STT, the principle somatic sensory nucleus (ventral caudal, Vc), and the nuclei below and behind. This thalamic area is involved in pain mechanisms based on the presence of a dense termination of the STT.[137,138] Stimulation of the STT produces thermal and pain sensations[139] and lesioning of the STT by cordotomy causes thermal and pain sensory loss.[140] In Vc or posterior/inferior to Vc, neurons respond to cold or painful stimulation[141–143] and stimulation may evoke painful or nonpainful heat and cold sensations.[142–144]

Temperature and pain sensation are signaled by the STT and surgical lesions leading to central pain often involve STT.[2] Therefore, it is reasonable to suppose that lesions of pain- and temperature-signaling pathways are common to all central pain syndromes. In fact, imaging studies (see previous discussion) outline anatomic evidence that lesions of STT-thalamocortical pathways are associated with CPSP.

These lesions also lead to sensitization of the STT-thalamocortical pathway in patients with CPSP. In such patients, electrical stimulation at micro-ampere current levels (microstimulation) in Vc and in the region inferior and posterior to Vc evokes pain sensations more commonly and nonpainful cold less commonly than in patients without central pain.[145,146] Stimulation of this region evoked pain more commonly in patients with hyperalgesia in the setting of central pain than in those without hyperalgesia.[21,137,142,144] Therefore, sensitization of this pathway may lead to the ongoing pain and hyperalgesia of central pain syndromes.

A broad range of evidence suggests that the cortical targets of these thalamic nuclei are involved in cold allodynia. The largest PET study of cold allodynia involved patients with a lateral medullary stroke (Wallenberg syndrome).[119] The allodynic test stimu-

lus was a cold/mechanical stimulus described as "a cold non-noxious stimulus (ice in a flat plastic container) moved slowly" over the skin. When this stimulus was used on the affected side it produced activation of structures very similar to those activated in response to 20°C waterbath stimulation of the affected hand in a patient with CPSP secondary to a small stroke of the thalamic nucleus Vc.[99] These studies showed absence of ACC activation and the presence of sensorimotor activation. The sensorimotor responses were similar to those in another study in which healthy controls were stimulated with a 20°C waterbath, although ACC was activated in this study.[148]

This increased blood flow activation of sensorimotor cortex is consistent with hypersensitivity to electrical stimulation of Vc and primary somatic sensory cortex. Such stimulation produces pain more commonly in patients with central pain than those without.[20,21,142–144] Lesions of the sensorimotor cortex can dramatically relieve pain in patients with thalamic central pain.[151–153] Therefore, the evidence of blood flow, stimulation, and lesion studies forcefully makes the case that Vc and sensorimotor cortex are involved in the development of CPSP.

There is also evidence of sensitization of medial and intralaminar nuclei which receive nociceptive input, including medial dorsal nucleus. Electrical stimulation of the medial and intralaminar thalamus has evoked a range of effects and sensations which are usually unpleasant.[154] These sensations include dyspnea and dizziness,[154,155] pain and heat,[156] pupillary dilation and contraversive eye movements,[157] and nonspecific painful sensations.[158–160]

In Tasker's series of operative cases, burning and pain were evoked much more commonly by stimulation in medial and intralaminar thalamus than at other thalamic sites. Macrostimulation-induced burning was nearly always on the contralateral side of the body.[139] Forty-three percent of the sites where burning was evoked occurred in the 89% of patients with movement disorders, usually sporadically, in isolation from other pain sites, and 57% occurred in the 13% of patients operated on for chronic pain.[139] In the latter group, the pain sites were usually clustered. Burning was induced contralaterally without somatotopographic organization. Eighty percent of the sites at which stimulation induced burning occurred in the 41% of pain patients who experienced neuropathic pain; but only 20% occurred in the 59% with cancer pain. Similar results were obtained for the 67 points at which painful, nonburning responses were recorded.

The most detailed description of the pain evoked by stimulating these nuclei reported two types of sensation.[158,161] The first type was a diffuse, burning pain referred to the contralateral half of the body, or occasionally to the whole body. The sites at which these sensations were produced were usually concentrated near the posterior half of the internal medullary lamina, corresponding to the parvocellular regions of central medial, plus parafascicularis and limitans. The first response to stimulation was exacerbation of the patient's spontaneous pain. The other type of sensation was a generalized "unpleasant" sensation, not localized to a particular body part. The sites at which these sensations were produced were concentrated in the very medial and anterior regions, possibly the medial dorsal and periventricular nuclei. Rinaldi and coworkers have also produced sensations by microstimulation in the medial thalamus, but these were not considered painful.[162] Instead a sensation of "pulling" was produced by stimulation in parafascicularis, while throbbing was produced by stimulation in the central medial nucleus.[139,163,164]

The Disinhibition Hypothesis of Central Pain

The sensory abnormalities in patients with central pain speak to the hypothesis that central pain/dysesthesia syndromes are associated with lesions of a cool-signaling STT pathway which disinhibits a nociceptive STT pathway.[95] This hypothesis proposes that a cool-signaling STT pathway passing from spinal lamina 1 through a lateral thalamic nucleus VMpo to the insula normally inhibits a heat-pinch-cold (HPC) nociceptive STT pathway passing from spinal lamina 1 through a medial thalamic nucleus (medial, dorsal, ventral caudal part to the ACC).[95] In patients with central pain, it is proposed that a lesion of the lateral cool pathway disinhibits the medial pain pathway, so that cold allodynia and the burning, cold, ongoing pain of CPSP occur in the absence of cold sensibility.[95]

Several lines of evidence help to evaluate this hypothesis. A study of small thalamic lesions leading to central pain uniformly involved the human principal sensory nucleus (Vc) but did not involve the VMpo (see previous discussion).[99] Approximately 50% of patients with central pain described their pain with temperature descriptors, while only about 25% demonstrated cold allodynia.[89] In the same study, strong cold allodynia was associated with normal cool detection thresholds in one case. Cool hypoesthesia, while frequently present, was not significantly associated with cold allodynia, however, it may be related to burning and/or cold ongoing pain.[89] These studies do not support the disinhibition theory of central pain.

There is contrary evidence that CPSP is mediated through sensory pathways including the dorsal columns. Patients with SCI central pain uniformly have diminution or loss of pain and/or temperature sensation.[4,10,11] However, the degree of sensory diminution for thermal or pain sensations is not a predictor of central pain in the population of patients with SCI.[4,10] Therefore, compromise of STT function is a necessary but not sufficient condition for the development of central pain in patients with SCI. Abnormal sensitivity to tactile and thermal stimuli is more common in SCI patients with central pain than in those without. The intensity of tactile allodynia at the border of sensory loss is a significant predictor of the intensity of spontaneous pain in the levels below the lesion.[4] These results suggest that SCI central pain is associated with hyperactivity in neurons higher along the somatic sensory pathways including structures receiving input from the dorsal columns.[22] This is consistent with a range of anatomic and physiologic studies of CPSP as reviewed next.

Involvement of the Dorsal Column Pathway in the Mechanism of Central Pain

A study of quantitative sensory testing in CPSP described previously has also demonstrated that tactile allodynia is more often associated with normal tactile sensibility than tactile hypoesthesia.[89] Tactile sensibility measured by von Frey hairs and a moving brush are mediated through the dorsal column pathway,[165–167] more than the STT pathway.[167–170] Sensory testing in patients with lesions of the dorsal columns revealed mild deficits in tactile sensation, while lesions of the STT (sparing the dorsal columns) were associated with no deficit in tactile sensation.[171] Therefore, the reduced tactile thresholds in the recent study are likely due to decreased transmission of stimuli through the dorsal column-thalamic-cortical pathway.[89] In those patients with CPSP, brush allodynia occurred in the presence of normal tactile thresholds, implying no lesion of the dorsal column-thalamic-cortical pathway in those patients.[171]

These results support a model in which brush-evoked allodynia involves input to the forebrain through an intact pathway dorsal column–thalamic Vc–post central gyrus and parietal operculum.[166,172,173] Activation of afferents known to project through the dorsal columns was associated with unpleasant dysesthesias only in stroke patients with post-stroke dysesthesias, a variant of CPSP.[174] This suggests that post-stroke dysesthesias result from transmission of activity through the dorsal columns.

The involvement of the dorsal column pathway in central pain is supported by electrophysiologic studies of the forebrain. Microstimulation in Vc evokes painful sensations more commonly in patients with CPSP than in controls operated for treatment of

either movement disorders or non-CPSP pain syndromes.[20,21] In patients with CPSP and hyperalgesia, microstimulation in Vc evoked pain more frequently than in patients without hyperalgesia.[21] Stimulation in Vc evoked pain more frequently in the representation of the part of the body where the patient experienced hyperalgesia than did stimulation in the representation of other parts of the body.[21] The pain-related function of Vc is demonstrated by the presence of STT terminals,[138] sites where stimulation evokes pain,[143] and recording studies which demonstrate that some cells in Vc respond differentially or selectively to painful stimuli.[167] In combination with the present results, these studies are strong evidence of a role for the dorsal column–thalamic Vc-somatic sensory cortical pathway (SI) in tactile allodynia.

A few imaging studies examined cortical activation after tactile-evoked allodynia. A PET study using the capsaicin experimental pain model reported similar activation patterns during nonpainful light brush stimulation and capsaicin induced experimental tactile allodynia mainly in SI, bilateral parietal lobule/SII, ACC, ipsilateral insula, and ipsilateral putamen.[175] Activation specific to allodynia was mainly observed in bilateral superior frontal gyrus, ipsilateral posterior insula, and ipsilateral inferior parietal lobule/SII. In a functional MRI (fMRI) study using this same capsaicin model,[176] SI and SII activation were only found during nonpainful mechanical stimulation using von Frey filaments. When stimulating the area that provoked secondary mechanical hyperalgesia, significant activation was found in the prefrontal cortex, and middle and inferior frontal gyrus. No activation in the ACC was found.

The only imaging study of clinical tactile allodynia was carried out in SCI central pain patients with STT injuries. Tactile allodynia in these patients produced a pattern of brain activation distinct from that of cold allodynia in patients with CI.[120] Tactile stimuli consisted of repetitive stroking with a soft brush applied in the allodynic area of patients with and without central pain and normal controls. The pattern of activation for tactile allodynia was very similar to nonpainful brushing in normal volunteers and patients without pain. In all groups, activation was observed in the contralateral SI, contralateral SII, inferior, and superior parietal areas. Activation specific to allodynia was elicited in the contralateral thalamus, bilateral middle frontal gyrus, caudate nucleus, and supplementary motor areas. Tactile allodynia was not associated with activation in the insula or anterior cingulate. The most striking activation shared by tactile and cold allodynia was activation of S1 cortex, although prefrontal cortex was activated most reliably.

Thalamic Low-Threshold Spike Bursting Activity in Central Pain

Thalamic low-threshold spike (LTS) bursting occurs at rates above those found in patients with movement disorders.[16] In patients with spinal transection, the highest rate of bursting occurs in cells that do not have peripheral receptive fields and that are located in the representation of the anesthetic part of the body. These cells also have the lowest firing rates in the interval between bursts (principal event rate).[16] The low firing rates suggest that these cells have decreased tonic excitatory drive and are hyperpolarized, perhaps due to loss of excitatory input from the STT.[177–180] Therefore the available evidence suggests that affected thalamic cells in patients with spinal transection were dominated by spike-bursting consistent with membrane hyperpolarization.[21,181–184]

Spike-bursting activity is maximal in the region posterior and inferior to the core nucleus of Vc.[16] Stimulation in this area evokes the sensation of pain more frequently than does stimulation in the core of Vc.[145,185–187] Thus, increased spike-bursting activity may be correlated with some aspects of the abnormal sensation (e.g. dysesthesia or pain) that these patients experience. However, in patients with spinal transaction, the painful area and the area of sensory loss overlap.[16] Thus, the bursting activity might be related to sensory loss, rather than to pain.

These findings about spike-bursting activity in spinal patients have been called into question by a recent study in patients with chronic pain.[146] It has been reported that the number of bursting cells per trajectory in patients with movement disorders (controls) is not different from that in patients with chronic pain. However, there are significant differences between the two studies[16,146] in terms of patient population (spinal cord injury vs. mixed chronic pain), location of cells studied (Vc vs. anterior and posterior to Vc), and analysis methods (incidence of bursting cells vs. bursting parameters). The increase in bursting activity demonstrated in the earlier study is more applicable to SCI central pain.[16]

Further support for increased spike-bursts occurring in spinal cord transected patients is found in thalamic recordings from monkeys with unilateral thoracic anterolateral cordotomies.[17] Some of these animals showed increased responsiveness to electrocutaneous stimuli and thus may represent a model of central pain[18] (see previous discussion). The most pronounced changes in firing pattern were found in thalamic MR cells. In comparison with normal controls, MR cells in the monkeys with cordotomies showed significant increases in the number of bursts occurring spontaneously or when evoked by brushing or compressive stimuli. The changes in bursting behavior occurred in the thalamic representation bilaterally in upper and lower extremities.

The relationship between spike-burst firing and pain does not appear to be direct. Increased bursting is found in the thalamic representation of the monkey upper extremity and of the representation of the arm and leg ipsilateral to the cordotomy. Pain is not typically experienced in these parts of the body in patients with thoracic spinal cord transection or cordotomy.[11] Spike-bursts are increased in frequency during slow wave sleep in all mammals studied[181] including man.[188] However, such bursting could cause pain if grouped, or bursting stimulation pulses, which activate bursting cells can produce the sensation of pain, as previously reported.[20–22]

Evidence for Ipsilateral Mechanisms of Stroke Pain

Projected fields (PF) refer to the perceived location of sensations evoked by stimulation of the nervous system. We compared PFs with receptive fields (RFs) which refers to the part of the body where stimulation evokes a response in the nervous system. In patients with spinal transaction thalamic stimulation produced pain referred to the part of the body which was anesthetic, although no RFs were found in thalamic neurons by stimulation of that part of the body. Therefore, the anesthetic part of the body retained intact PFs, demonstrating the following, that thalamic neurons and thalamocortical connections can be left intact and apparently isolated after a stroke, yet still capable of generating conscious effects, and presumably capable of activation by alternate somatosensory input, possibly to generate pain.

A CPSP patient had a massive right-sided thrombotic stroke causing left homonymous hemianopsia, spastic hemiplegia, and multimodality hemisensory hypoesthesia with allodynia and hyperpathia. Stereotactic exploration with microelectrode presence before DBS was carried out.[5] An extensive exploration of the region of Vc thalamus revealed no neuronal activity.

A hemispherectomized patient has been reported who complained of touch-evoked pricking and burning pain in her paretic hand, especially when the hand was cold.[189] QST demonstrated confused cool and warm temperatures on the paretic side, and confirmed that she had a robust allodynia to brush stroking that was enhanced at a cold ambient temperature. fMRI showed that during brush-evoked allodynia, brain structures implicated in normal pain processing, such as the posterior part of the anterior

cingulate cortex, secondary somatosensory cortex, and prefrontal cortices, were activated. The fMRI findings thus indicate that the central pain in this patient was served by brain structures implicated in normal pain processing.

QST studies in patients undergoing cingulotomy for psychiatric disease suggest that hyperalgesia for thermal sensations is found postoperatively.[190,191] Single subject PET studies in one patient demonstrated preoperative contact heat pain-evoked activation of the bilateral MCC/SMA (supplementary motor area) and the left (contralateral) frontoparietal operculum.[191] Postoperative pain-evoked activation was demonstrated in the right (ipsilateral) perisylvian cortex but not of the MCC/SMA. This pattern would be unusual in a population study protocol of healthy controls,[192] although the ipsilateral activations occur commonly in an fMRI study of healthy single subjects.[193] Ipsilateral perisylvian activation has also been observed during the increased (allodynic) responses to thermal stimuli in patients with central pain related to lesions of the brain or spinal cord.[109,120,194]

A similar pattern has been found in neurogenic allodynia secondary to injection of capsaicin.[175] Experimental tactile allodynia following cutaneous injection of capsaicin led to activation of superior frontal gyrus (BA 10) bilaterally, insula bilaterally, portions of the inferior frontal gyrus (BA 47 contralaterally), putamen/globus pallidus ipsilaterally, SII/inferior, parietal lobule (BA 40) bilaterally, middle frontal gyrus (BA 6, 8, and 10), and cingulate gyrus (BA 24, midline/ipsilateral), and contralateral SI. These and the previously reviewed results suggest that ipsilateral activations are a common factor in increased ratings of pain following brain lesions, whether clinically significant or not.

The mechanism of the increased activation of ipsilateral perisylvian structures postoperatively may be disinhibition of pain-related inputs to these structures by the cingulotomy.[191,195–197] This disinhibition could lead to pain-related increased synaptic activity and blood flow. In addition, postoperative pain-related activation of the right (ipsilateral) parietal and insular cortex after cingulotomy might be consistent with reports of activation of right inferior parietal cortex following stimulation of either side.[198] In that study, pain intensity–dependent activation was not entirely lateralized, but was localized to contralateral regions of the primary somatosensory cortex, secondary somatosensory cortex, insular cortex, and bilateral regions of the cerebellum, putamen, thalamus, anterior cingulate cortex, and frontal operculum. In contrast, right sided activation was found in thalamus, inferior parietal cortex (BA 40), dorsolateral prefrontal cortex (BA 9/46), and dorsal frontal cortex (BA 6) in response to painful (and nonpainful) stimulation, regardless of the side of stimulation.

These observations implicate ipsilateral pathways in the generation of the steady pain and allodynia and hyperpathia that plague such patients. Whatever the ipsilateral paths responsible for the pain, they must be somatotopically organized to preserve the somatotopic features of the pain and capable of inducing steady pain and allodynia, incriminating the ipsilateral STT.

Treatment of Central Poststroke Pain: Medical Treatment

As with SCI pain, the number of studies on the treatment of CPSP is remarkably small. It is reasonable to postulate that therapies that work for SCI pain should also be effective for CPSP. Frese et al. provide a good summary of the pharmacologic treatments for CPSP.[199] There are several studies in the literature that specifically look at drug therapy for CPSP. The first randomized, placebo-controlled, crossover trial of chronic oral medication compared amitriptyline versus carbamazepine versus control and the results demonstrated statistically significant pain relief from the second week of the trial onward for amitriptyline but no pain relief from carbamazepine at any time point.[85] Two thirds of patients were responders and there was a positive correlation between pain relief and plasma amitriptyline levels >300 ngmol/L. The majority of responders stayed on amitriptyline following the trial suggesting that this agent provided durable analgesia.

There are several studies evaluating the efficacy of the anticonvulsants in CPSP. A randomized, placebo-controlled crossover trial of the anti-epileptic agent lamotrigine showed a significant decrease in pain ratings for the last week of the trial (30%), at doses of 200 mg/day. No significant effect was found at lower doses (25 or 50mg/day); 44% of patients were identified as responders.[200] The hypothesis that amitriptyline is effective for the prevention of CPSP was examined in a randomized, double-blind, placebo-controlled trial of amitriptyline with 1-year follow-up.[201] At the termination of the trial (1 year follow-up), no statistically significant benefit was found.[201] Other open label studies on the efficacy of the anticonvulsants phenytoin, gabapentin, and zonisamide for CPSP are too small to draw conclusions.[202–204]

There have also been a number of trials of local anesthetic agents for the treatment of CPSP. In a double-blind, placebo-controlled study in 6 patients with CPSP and 10 with SCI pain, IV lidocaine resulted in a significant short term relief of spontaneous pain, mechanical allodynia, and mechanical hyperalgesia.[205] After completing this study, 12 subjects were started on oral mexiletine (400–800 mg/day) with no effect on pain.[206] Edmondson and colleagues also found an analgesic effect in response to IV lidocaine infusion analgesic in 4/4 CPSP patients. Mexiletine, an oral congener of lidocaine, produced durable analgesia (1 year) in two of these four patients, while intolerable side effects developed in the other two patients.[207] IV lidocaine led to significant decreases in ongoing pain, allodynia to static and dynamic (brush) stimuli in a study of three patients.[208] Lidocaine-induced spinal block successfully relieved CPSP with allodynia in two of three patients; one of the successes and the failure had thalamic lesions.[209]

Studies on systemic opioids have shown no effect or limited effects in CPSP. A double-blind, randomized trial of levorphanol on neuropathic pain showed almost no effect in a subset of five patients with CPSP.[127] A randomized, double-blind placebo-controlled proof of principle trial of methadone showed no change in the pain rating in one patient, and a 50% reduction in the other.[210] In a randomized, double-blind study of opioids for treatment of all categories of neuropathic pain most of the patients with CPSP did not complete the study.[127] Those who did complete the study had approximately a 25% decrease in pain. IV morphine and IV fentanyl had no effect on CPSP[211–216] and on the pain of MS[217]; however, IV alfentanil led to a significant decrease in spontaneous and evoked pain.[49] In another study, intrathecal morphine with clonazepam led to significant pain relief, although neither agent was effective alone.[218] A double-blind, placebo-controlled trial of IV naloxone did not produce analgesia in patients with CPSP.[219] However, an open label trial of intravenous naloxone reported that "pain and hyperpathia were completely obtunded" in 7 out of 13 CPSP patients studied, and "partially obtunded" in one patient.[220]

In a mixed population of patients with SCI central pain and CPSP, the injection of putative GABA agonist propofol produced significant relief of both spontaneous and evoked pain.[221] This double-blind, placebo crossover trial employed a subhypnotic bolus dose of propofol. Decreases in spontaneous pain and allodynia (both cold and tactile) were significantly greater following injections of propofol than placebo. Differences between SCI central pain and CPSP were not significant. Four patients, with pain secondary to SCI or thalamic hemorrhage, had worse pain after propofol but not after placebo.[222] Overall, the injections were well tolerated without hemodynamic side effects. Burning at the site of injection was observed for a few patients, and a few patients complained of short-lasting lightheadedness in both the

propofol and placebo groups. In an uncontrolled study, IV thiopental, a GABA-a agonist, resulted in pain relief in 22 of 39 patients with CPSP. However, oral amobarbital did not result in any pain relief even at plasma levels equivalent to the thiopental infusions.[223] An early study reported intravenous infusions of 50 to 225 mg of sodium pentothal reduced CPSP in 73% of CPSP patients.[215] One study reported positive effects of intrathecal baclofen, a GABA-b agonist, in 6 of 8 patients with CPSP.[56]

Other trials examined the role of a noncompetitive NMDA blockers, dextromethorphan and ketamine, on CPSP. The first of these was also a randomized, double-blind, placebo-controlled, crossover trial which found that dextromethorphan was ineffective for the treatment of CPSP.[224] A similar trial of dextromethorphan in a group of patients with neuropathic pain of mixed etiology also found no benefit.[225] Studies of ketamine given intravenously in patients with CPSP led to transient analgesia which lasted for less than 3 hours in two out of three patients.[218]

There are few studies on cannabinoid receptor agonists in the treatment of neuropathic pain. One randomized controlled trial of cannabinoids in multiple sclerosis patients produced significant decreases in pain.[226] A similar study did not find an analgesic effect but found significant improvements in symptom control, particularly in the case of insomnia.[227]

On the basis of the effectiveness of amitriptyline and the proof of principle trial of mexiletine,[201] Bowsher suggested that CPSP should be treated first with a trial of adrenergic antidepressants, then mexilitine.[87] In the German literature, opioids have been proposed to have had a major role in the long-term treatment of central pain.[228] Two recent consensus conferences evaluating database searches regarding pharmacologic approaches to the treatment of neuropathic pain of all types recommended tricyclics and calcium channel ligands (gabapentin) as the first line of treatment and antiepileptic drugs plus opioids as the second line.[50,229] The data reviewed here are consistent with these recommendations and it is reasonable to apply these recommendations to the treatment of CPSP.

Treatment of Central Poststroke Pain: Surgical Procedures

As with SCI pain, all conservative therapies should be exhausted before resorting to surgical interventions. Reversible treatments such as stimulation should be considered before resorting to neuroablative procedures. Of the stimulation procedures, motor cortex stimulation has been the most studied.

Tsubokawa and colleagues described motor cortex stimulation for the treatment of CPSP, placing paddle-type electrodes designed for SCS extradurally parallel to the central sulcus 3 to 4 cm from the midline for upper limb, and 1 cm from midline for lower limb pain.[230] These authors applied stimulation below the threshold for motor events, at which level it usually caused tingling or mild vibration in the area of pain. Pain typically diminished after 5 to 10 minutes of stimulation, and pain relief outlasted a 10-minute period of stimulation by 2 to 6 hours. Thus, patients would typically use five to seven bouts of stimulation daily. They believed that to relieve neural injury pain, it was necessary to stimulate rostral to the *causative* lesion, hypothetically activating the fourth-order sensory neurons whose nonnociceptive impulses induced by cortex stimulation inhibited nociceptive neurons.

Yamamoto and colleagues[224] tried to correlate certain pharmacologic tests with the success of motor cortex stimulation. They concluded in 25 cases of CPSP with thalamic lesions and 14 with suprathalamic lesions that those patients whose pain was diminished by thiamylal and ketamine administration but not by morphine responded best to motor cortex stimulation. Ninety percent of 10 cases of CPSP so treated did well after 1 year of follow-up.[230] Eleven patients were described with CPSP, 73% of whom enjoyed initial pain relief, with 45% long-term pain relief at 2 years' follow-up.[231] A small series reported that 50% of six patients were effectively controlled by motor cortex stimulation.[232] More recent studies suggest that motor cortex stimulation provides moderate success rates varying approximately between 50% and 75% of patients with CPSP.[131,132]

The overall level of evidence supporting the use of motor cortical stimulation for the treatment of pain has been assessed in detail. A database study of the European Association of Neurology Panel on Neurostimulation for the Treatment of Pain concluded that the use of motor cortical stimulation was supported by multiple retrospective studies without validated measures of outcome in the case of upper extremity, amputation pain, (phantom and stump), CPSP, facial pain, and headache.[233,234] They concluded that there is convincing evidence that motor cortex stimulation (MCS) is useful in 50% to 60% of patients with CPSP and trigeminal neuropathic pain.

A number of different stimulation approaches have been adopted for treatment of CPSP. Seven patients treated with trigeminal stimulation for the relief of chronic neuropathic facial pain suffered from CPSP, three with lateral medullary syndrome, one with a middle cerebral artery area infarct, one with a massive thalamic and suprathalamic infarct, one with an infarct after internal carotid artery ligation, and one with neuropathic pain after a medullary trigeminal tractotomy.[215] Five of these seven patients reported relief during trial stimulation and went on to enjoy more than 50% ongoing pain relief after implantation of a permanent device, a good result. The chief complication of this procedure was superficial infection at hardware sites.

SCS was of no benefit in CPSP among twelve cases in Tasker's series.[7] In this series, six reported pain relief during trial stimulation and received a permanent stimulator, but only 17% of the original group experienced ongoing relief. In four patients, all with allodynia, hyperpathia, or both, SCS was unsuccessful because stimulation was perceived as painful. This observation recalls the experience described previously in which microstimulation of the tactile relay of thalamus is often painful in patients experiencing stroke-induced pain with allodynia, hyperpathia, or both.[20,21]

The dichotomy between paresthesia-producing thalamic stimulation versus PVG/periaqueductal grey DBS in nociceptive versus neuropathic pain is a basic principle which may be used in planning DBS.[8,62] Thus, paresthesia-producing DBS may be more appropriate for CPSP than PVG/periaqueductal grey DBS. Anecdotal evidence suggests that stimulating in the internal capsule is preferable to other sites,[235] but until larger numbers of patients have been reported it is difficult to draw conclusions (see Chapter 96).

Two large retrospective series of DBS have reported mixed results in CPSP. An early report found success (50% pain relief) occurred in the short term in 8/13 patients and 6/13 long-term (2–14 years).[61] In another retrospective series including 12 patients with CPSP, pain relief was rated at 0% to 25% (2/12), 25% to 50% in 1/12, and 50% to 75% in 1/12.[62] In Tasker's series, six patients, all of whom suffered from allodynia, hyperpathia, or both, found stimulating in the Vc painful, preventing use of that treatment modality. On the other hand, patients with neuropathic pain not caused by cerebral lesions who had allodynia or hyperpathia seldom found such stimulation painful.[237] In three patients with stroke-induced allodynia, hyperpathia, or both, PVG stimulation relieved the allodynia and hyperpathia. Microelectrode recordings and stimulation in patients with central pain demonstrated that stimulation in the region of nucleus Vc was painful more frequently in this group than in controls, and in patients with allodynia or hyperalgesia than in those without.[20,21]

A database search identified three recent studies using current standards of MRI target localization in thalamus or PAG/PVG.[233] The first described results in 15 patients with CPSP who identified

success (pain relief >30%) in 67% of patients at long-term follow-up. The other reported on 21 patients with mixed neuropathic pain syndromes, and concluded that only 24% of patients had durable pain relief as defined by use of DBS for over 5 years. Another study compared the benefit of SCS, thalamic DBS, and MCS in 45 patients with CPSP, reported success with DBS in only 25% of patients. Overall, they considered that there was weak positive evidence for use of DBS peripheral neuropathic pain.[233] In CPSP, further trials were suggested because DBS results were equivocal and required further comparative trials.

Trigeminal subnucleus caudalis DREZ lesions have been reported to relieve facial pain of CPSP in one patient with CPSP caused by a pontine infarct and another with an arteriovenous malformation of the tectum of the mesencephalon.[237] Both patients suffered from facial pain that was relieved by a DREZ procedure on the trigeminal nucleus caudalis. The first patient had allodynia and some steady pain; the second had steady pain. In both cases, the DREZ procedure induced mild ipsilateral upper limb dysmetria.

Retrospective studies point to the effectiveness of lesions of the mesencephalic reticular formation and mesencephalic STT in the treatment of central pain.[238,239] There are also a number of anecdotal case reports of different procedures for the treatment of CPSP. Relief of evoked pain has been reported following lesions of the STT by cordotomy[2] and mesencephalic tractotomy.[240]

Medial thalamotomy has been reported to be effective in 25% to 89% of patients[161,162,241] although the durability of this effect is limited.[242] Success of this procedure was also reported as percent pain relief in a population of patients with mixed etiology, either central (33% pain relief, n = 20 patients), peripheral (55%, n = 53), or mixed central and peripheral pain (33%, n = 23).[242] In this, the largest study (n = 96 patients including central or peripheral neuropathic pain or both), significant complications were reported including three bleeds (two thalamic, one intraventricular) and two cases of thalamic vascular compromise or edema.

CONCLUSION

This review demonstrates that there are substantial clinical similarities between SCI central pain and CPSP. There is evidence that sensory compromise in modalities mediated through the STT is a necessary but not sufficient condition for the development of these syndromes. Other factors which may lead to the development of central pain may include the presence of blood products at the site of spinal cord injury, the expression of particular non-TTX dependent sodium channels, or the balance of neuromodulator inputs to the spinal cord, thalamusm or cortex. Agents that are proven effective in the clinic are noradrenergic antidepressants, and with the antiepileptic drug lamotrigine at relatively high doses. Destructive procedures targeting the spinal cord, thalamus, and midbrain may be effective for the intermittent, shooting pains or the evoked pain of these syndromes, at some risk. Motor cortex or thalamic stimulation may be effective for the treatment of the spontaneous pain of CPSP. Therefore, central pain remains a mysterious syndrome which has yielded grudgingly to medical and surgical treatment.[242]

CHAPTER 29 ■ THE PSYCHOPHYSIOLOGY OF PAIN

C. RICHARD CHAPMAN

INTRODUCTION

Psychophysiology is a field of study that seeks to relate subjective awareness and behavior to physiological events.[1–3] As a field of scientific inquiry, it concerns itself with central mechanisms of perception, cognition, and behavior, including learning, the emotions, and the relationship of brain activity to consciousness. As a clinical area, psychophysiology has classically addressed somatoform disorders, stress (most recently posttraumatic stress disorders), and affective disorders in general. As a field, psychophysiology is an important resource for the pain field for two primary reasons. On one hand, it offers a framework for understanding how stress contributes to pain, including the persistence of chronic pain. On the other hand, it uncovers links between cognitive processes (attention, expectancy, meaning, belief) and pain, as well as pain relief through psychological intervention.

Most physicians think of pain as an unpleasant sensation that originates in traumatized or inflamed tissues; however, pain is more than sensory information about the condition of the body. Strong emotion is an intrinsic part of pain. Any reasonable and unbiased observer studying mammals, particularly humans, would have to conclude that pain's affective features rather than its sensory properties govern behavioral responses to injury. People who experience pain do not quietly report the fact; they express negative emotions.

Is the affective dimension of pain as important as its sensory aspect? A lay writer described pain's qualities as comprising extreme aversiveness, an ability to annihilate complex thoughts and other feelings, an ability to destroy language, and a strong resistance to objectification.[4] Her perspective resonates with the lessons of everyday life: While pain has sensory features and lends itself to sensory description, it is above all else a powerful negative feeling state. One cannot evaluate and address the suffering of a person in pain without an appreciation of its emotional nature.

The International Association for the Study of Pain (IASP) acknowledged the central role of emotion in its keystone definition: ''Pain [is] an unpleasant sensory and *emotional* experience associated with actual or potential tissue damage, or described in terms of such damage"[5] (emphasis added). This definition clearly emphasizes the role of affect as an intrinsic component of pain. Emotion is not a consequence of pain sensation that occurs after a noxious sensory message arrives at somatosensory cortex. Rather, it is a fundamental part of the pain experience.

Psychophysiology has revealed that emotion and cognition are interdependent. Strong emotions can alter thought processes, perceptions, beliefs, attitudes, and expectancies. Conversely, thoughts can generate negative or positive emotional states, and the physiological changes associated with such states can interact with tissue injury or inflammation and alter both the sensory and affective aspects of pain.

Because pain states never exist in isolation, it is important to consider the psychophysiological context of a pain problem. The cognitive, emotional, and physiological state of the patient presenting with pain is potentially very important for both assessment and intervention. I propose here that the best framework for characterizing this state is stress theory. Stress involves physiological arousal related to defense, derives in part from cognition, and generates physiological processes that feed emotions and feelings.

The purposes of this chapter are to describe the psychophysiology of pain and to explore the importance of psychophysiological mechanisms for the assessment and care of patients with pain. The psychophysiology of pain requires an incursion into mind–body issues, consideration of the nature of emotion and its interdependence with cognition, and the overarching influence of stress. In this chapter I show that:

Pain (awareness of tissue trauma) has intrinsic emotional properties, including negative emotional arousal.

The brain creates bodily states of arousal (negative emotions) in response to threat to biological and psychological integrity.

The affective dimension of pain is intrinsically linked to the related processes of defense and stress, and the physiological mechanisms of these processes shapes the affective dimension of pain.

HISTORICAL PERSPECTIVE: MIND–BODY ISSUES

Through most of the 20th century, our understanding of the relationship between mental processes and the body stemmed directly from Cartesian notions of mind–body dualism. For Descartes, a 17th century philosopher and mathematician, human beings are dualistic: the mind and body are separate entities. Descartes described the life processes of the body as though they were clockwork mechanisms. The actions of the mind were, in his thinking, the workings of the soul.

Descartes believed that the awareness of pain, like awareness of other bodily sensations, must take place in a specific location where the mind observes the body. Dennett[6] termed this hypothetical seat of the mind the *Cartesian theater*. In this theater, the mind observes and interprets the array of multimodality signals that the body produces. The body is a passive environment; the mind is the nonphysical activity of the soul.

Today, most people will agree that such a theater of the mind cannot exist. Scientifically, the activity of the brain and the mind are inseparable; yet, Cartesian dualism is endemic in Western thought and culture. Classical approaches to psychophysiology stemmed from Cartesian thinking, as did psychophysics. Early work on psychosomatic disorders focused on mind–body relationships. Today, much of the popular movement favoring alternative medicine emphasizes the ''mind–body connection,'' keeping one's self healthy through right thinking, and the power of the mind to control the immune system. It is hard to avoid Cartesian thinking when the very fabric of our language carries it along as we reason and speak.

Cartesian assumptions are a subtle but powerful barrier for someone seeking to understand the affective dimension of pain. Relegating emotions to the realm of the mind and their physiological consequences for the body is classical Descartes. It prevents us from appreciating the intricate interdependence of subjective feelings and physiology, and it detracts from our ability to comprehend how the efferent properties of autonomic nervous func-

tion can contribute causally to the realization of an emotional state. This chapter emphasizes the interdependence of mental processes and physiology. What we call the mind is consciousness, and consciousness is an emergent property of the activity of the brain. In a feedback-dependent manner, the brain regulates the physiological arousal of the body, and emotion is a part of this process.

EMOTIONS: DEFINITION AND MECHANISMS

What Are Emotions?

The first step in understanding pain as an emotion is appreciating the origins and purposes of emotion. Many physicians regard emotions as epiphenomenal feeling states associated with mental activity, subjective in character, and largely irrelevant to the state of a patient's physical health. In fact, emotions are primarily physiological and only secondarily subjective. Because they can strongly affect cardiovascular function, visceral motility, genitourinary function, and immune competence, patient emotions can have an important role in health overall and especially in pain management. Simple negative emotional arousal can exacerbate certain pain states such as sympathetically maintained pain, angina, headache, and fibromyalgia. It contributes significantly to musculoskeletal pain, pelvic pain, and other pain problems in some patients.

Emotions are complex states of physiological arousal and awareness that impute positive or negative hedonic qualities to a stimulus (event) in the internal or external environment. The objective aspect of emotion is autonomically and hormonally mediated physiological arousal. The subjective aspects of emotion, *feelings*, are phenomena of consciousness. Emotion represents in consciousness the biological importance or meaning of an event to the perceiver.

Emotion as a whole has two defining features: valence and arousal. Valence refers to the hedonic quality associated with an emotion—the positive or negative feeling attached to perception. Arousal refers to the degree of heightened activity in the central nervous system and autonomic nervous system associated with perception.

Although emotions as a whole can be either positive or negative in valence, pain research addresses only negative emotion. Viewed as an emotion, pain represents a threat to the biological, psychological, or social integrity of the person. In this respect, the emotional aspect of pain is a protective response that normally contributes to adaptation and survival. If uncontrolled or poorly managed in patients with severe or prolonged pain, it produces suffering.

Emotion in a Sociobiological Perspective

Psychologists have many frameworks for studying the psychology of emotion. I favor a sociobiological (evolutionary) framework because this way of thinking construes feeling states, related physiology, and behavior as mechanisms of adaptation and survival. Nature has equipped us with the capability of negative emotion for a purpose; bad feelings are not simply accidents of human consciousness. They are protective mechanisms that normally serve us well but, like uncontrolled pain, sustained and uncontrolled negative emotions can become pathological states that can produce both maladaptive behavior and physiological pathology.

By exploring the emotional dimension of pain from the sociobiological perspective, the reader may gain some insight about how to prevent or control the negative affective aspect of pain, which fosters suffering. Unfortunately, implementing this perspective requires that we change conventional language habits that involve describing pain as a transient sensory event. *Pain is a compelling and emotionally negative state of the individual that has as its primary defining feature awareness of, and adaptive adjustment to, tissue trauma.*

Adaptive Functions of Emotion

Emotions, including the emotional dimension of pain, characterize mammals exclusively, and they foster mammalian adaptation by making possible complex behaviors and adaptations. Importantly, they play a strong role in consciousness, producing and summarizing information that is important for selection among alternative behaviors. According to MacLean, emotions "impart subjective information that is instrumental in guiding behavior required for self-preservation and preservation of the species. The subjective awareness that is an affect consists of a sense of bodily pervasiveness or by *feelings localized to certain parts of the body*"[7] (emphasis added). Because negative emotions, such as fear, evolved to facilitate adaptation and survival, emotion plays an important defensive role. The ability to experience threat when encountering injurious events protects against life-threatening injury.

The strength of emotional arousal associated with an injury indicates and expresses the magnitude of perceived threat to the biological integrity of the person. Within the contents of consciousness, threat is a strong negative feeling state and not a pure informational appraisal. In humans, threatening events, such as injury, that are not immediately present can exist as emotionally-colored somatosensory images.

Phenomenal awareness consists largely of the production of images. Visual images are familiar to everyone: we can readily imagine seeing things. We can also produce auditory images by imaging a familiar tune, a bird song, or the sound of a friend's voice. Similarly, we can generate somatosensory images. We can, for example, imagine the feeling of a full bladder, the sensation of a particular shoe on a foot, or a familiar muscle tension or ache. Cognition operates largely on images and plays a strong role in the experience of symptoms.

Patients can react emotionally to the mental image of a painful event before it happens (e.g., venipuncture), or for that matter they can respond emotionally to the sight of another person's injury. The emotional intensity of such a feeling marks the adaptive significance of the event that produced the experience for the perceiver. In general, the threat of a minor injury normally provokes less feeling than one that incurs a risk of death. *The emotional magnitude of a pain is the internal representation of the threat associated with the event that produced the pain.*

Emotions and Behavior

Negative emotions compel action, such as fight or flight, along with expression through vocalization, posture, variations in facial musculature patterns, and alterations of activity. This represents communication and often elicits social support, thus contributing to survival. Darwin,[8] observing animals, noted that emotions enable communication through vocalization, startle, posture, facial expression, and specific behaviors. He held that emotions must be inborn rather than learned tendencies. Darwin pursued this issue by comparing the facial and other emotional expressions of children born blind with those of other children, reasoning that blind children would express emotion differently if emotion is primarily a learned behavior. As others have since confirmed,[9] Darwin learned that the basic blueprints for human emotional expression are innate.

Contemporary investigators who study emotions and human or animal social behavior emphasize that communication is a fundamental adaptive function of emotional expression.[10,11] So-

cial mammals, including humans, depend upon one another or their social group as resources for adaptation and survival. The emotional expression of pain in the presence of supportive persons is socially powerful; it draws upon a fundamental sociobiological imperative: communicating threat and summoning assistance.

The Central Neuroanatomy of Emotion: Limbic Structures

The limbic brain represents an anatomical common denominator across mammalian species,[7] and emotion is a common feature of mammals. Consequently, investigators can learn much about human emotion by studying mammalian laboratory animals. Humans and animals differ in that the limbic brain is more developed in humans, the frontal lobes are unique to our species, and the interdependence of cognition and emotion is greatest in humans.

Early investigators focused on the role of olfaction in limbic function and this led them to link the limbic brain to emotion. Emotion may have evolutionary roots in olfactory perception. MacLean introduced the somewhat controversial term "limbic system" and characterized its functions.[12] He identified three main subdivisions of the limbic brain: amygdala, septum, and thalamocingulate[7] that represent sources of afferents to parts of the limbic cortex. He also postulated that the limbic brain responds to two basic types of input: interoceptive and exteroceptive. These refer to sensory information from internal and external environments, respectively. Figure 29.1 summarizes and extends this concept. Noxious signaling can arise from an injurious event in the external environment or from a pathological condition in the internal environment.

Over the last decade, numerous studies have employed functional brain imaging to investigate how the human brain responds to painful laboratory stimulation as well as how it behaves in chronic pain conditions. These studies reveal unequivocally that limbic structures involved in emotion and cognition are active during pain. In addition, related studies show that cognitive processes such as threat appraisal and perceived control are related to pain modulation. Apkarian et al.[13] performed a meta-analysis of the literature and extracted consensus that the following brain structures are consistently active during states of pain: thalamus, primary, and secondary somatosensory cortices, insular cortex, anterior cingulate, and the prefrontal cortices. Thalamus and the somatosensory cortices played a prominent role in early neurophysiological models of pain. Insular cortex may play a role in the somatosensory representation of the body, and it appears to integrate multimodal sensory information.[14] Craig[15] holds that anterior insula integrates emotional and motivational processes while anterior cingulate cortex activates in numerous pain-related and other studies involving emotion and cognition. Prefrontal cortices control the executive functions of the brain and the sense of self. They are involved in threat appraisal, meaning, and the integration of information from the internal and external environment.

Peripheral Neuroanatomy of Emotion: The Autonomic Nervous System

The autonomic nervous system (ANS) plays an major role in regulating the constancy of the internal environment, and it does so in a feedback regulated fashion under the direction of the hypothalamus, the solitary nucleus (nucleus tractus solitarius) and ventral lateral medulla, the amygdala, and other brain structures.[16,17] In general, it regulates activities that are not normally under voluntary control. The hypothalamus is the principal integrator of autonomic activity. Stimulation of the hypothalamus elicits highly integrated patterns of response that involve the limbic system and other structures.[18]

Many researchers hold that the ANS has three divisions: the sympathetic, the parasympathetic, and the enteric.[19,20] Others subsume the enteric under the other two divisions. Broadly, the sympathetic nervous system makes possible the arousal needed for fight and flight reactions, while the parasympathetic system governs basal heart rate, metabolism, and respiration. The enteric nervous system innervates the viscera via a complex network of interconnected plexuses.

The sympathetic and parasympathetic systems are largely mutual physiological antagonists—if one system inhibits a function, the other typically augments it. There are, however, important exceptions to this rule that demonstrate complementary or integratory relationships. The mechanism most heavily involved in the affective response to tissue trauma is the sympathetic nervous system.

During emergency or injury to the body, the hypothalamus uses the sympathetic nervous system to increase cardiac output, respiration rate, and blood glucose. It also regulates body temperature, causes piloerection, alters muscle tone, provides compensatory responses to hemorrhage, and dilates pupils. These responses are part of a coordinated, well-orchestrated response pattern called the defense response.[21–23] It resembles the better known orienting response in some respects, but it can only occur following a strong stimulus that is noxious or frankly painful. It sets the stage for escape or confrontation, thus serving to protect the organism from danger. In an awake cat both electrical stimulation of the hypothalamus and infusion of norepinephrine into the hypothalamus elicit a rage reaction with hissing, snarling, attack posture with claw exposure, and a pattern of sympathetic nervous system arousal accompanies this.[24–26] Circulating epinephrine and norepinephrine produced by the adrenal medulla during activation of the sympa-

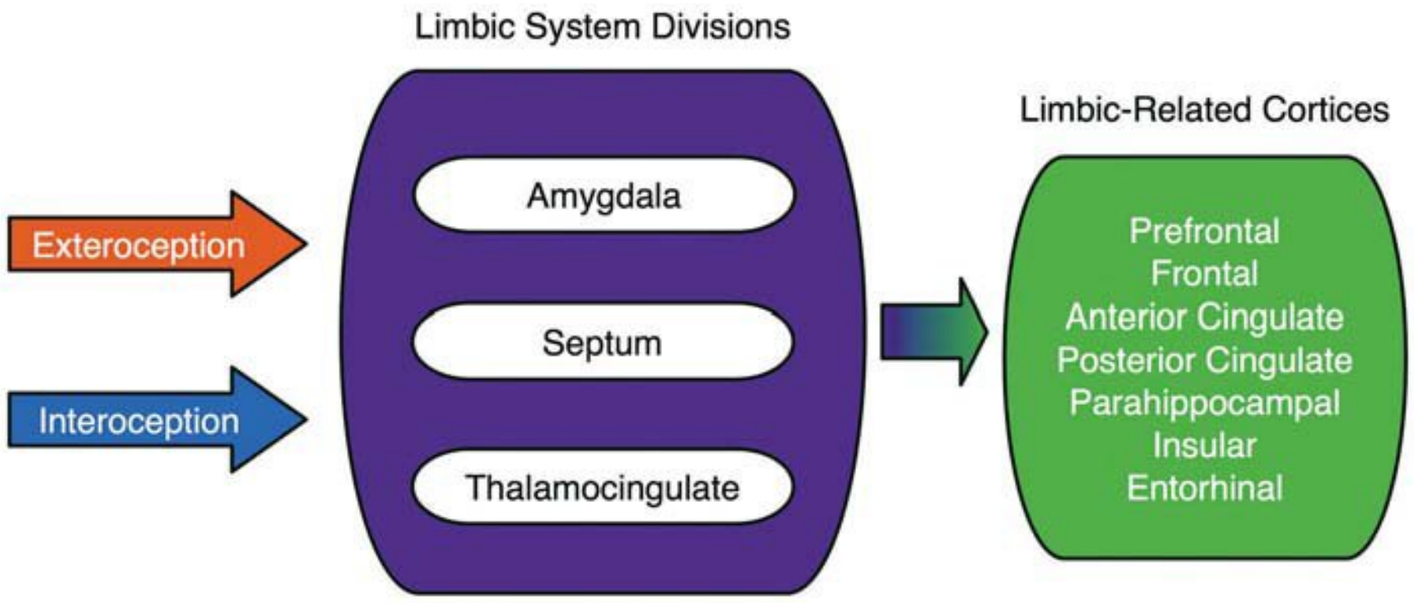

FIGURE 29.1 Three subdivisions of the limbic brain and their relationship to limbic cortices. MacLean[7] proposed a three-part grouping of limbic structures and functions: amygdalar, septal, and thalamocingulate subdivisions. These divisions receive information, including noxious signaling, from the external environment (exteroceptors) and the internal environment (interoceptors). Cortical areas related to limbic function include the prefrontal and frontal cortices (related to executive function and sense of self), the cingulate cortices (the anterior cingulate cortex is related to attentional states), the parahippocampal and entorhinal cortices, which are important in memory, and the insular cortex (emotional–motivational integration).

thoadrenomedullary axis accentuate the defense response, fear responses, and aversive emotional arousal in general.

Autonomic Arousal and Subjective Experience

Because the defense response and related changes are involuntary in nature, we generally perceive them as something that the environment does to us. We typically describe such physiological changes, not as the bodily responses that they are, but rather as feelings. We might describe a threatening and physiologically arousing event by saying that "It scared me" or that "It made me really mad."

Phenomenologically, feelings seem to happen to us; we do not "do" them in the sense that we think thoughts or choose actions. Emotions are who we are in a given circumstance rather than choices we make, and we commonly interpret events and circumstances in terms of the emotions that they elicit. ANS arousal, therefore, plays a major role in the complex psychological experience of injury and is a part of that experience.

Early views of the ANS followed the lead of Cannon[21] and held that emergency responses and all forms of intense aversive arousal are undifferentiated, diffuse patterns of sympathetic activation. While this is broadly true, research has shown that definable patterns characterize emotional arousal, and that these are related to the emotion involved, the motor activity required, and perhaps the context.[16,17] An investigator attempting to understand how humans experience emotions must remember that the brain not only recognizes patterns of arousal; it also creates them.

The Role of Feedback

One of the primary mechanisms in the creation and management of emotion is feedback. Feedback means that information about the output of a system passes back to the input and thereby dynamically controls the level of the output. System self-regulation and self-organization depend upon feedback, as does self-direction. Feedback loops can be negative or positive. Negative feedback permits stability while positive feedback allows the organism to mount emergency responses. The regulatory processes of homeostasis and allostasis are negative feedback dependent. Negative feedback ensures system stability and maintains homeostasis. Feedback is positive when a variable changes and the system responds by changing that variable even more in the same direction, generating escalation and rapid acceleration.[27] This process abandons stability for instability. From an adaptation point of view, positive feedback loop capability is essential for meeting acute threat with defensive arousal. Each mode of operation has adaptive value as a short-range response in certain types of injurious events.

In general, defensive reactions involve a pattern of rapid arousal created through positive feedback that prepares the body and brain for emergency response, followed by a negative feedback-controlled transition to recovery and return to normalcy. Because smaller physiological systems are nested within larger physiological systems, higher order systems typically limit positive feedback processes in smaller systems. In some cases, top down regulation of positive feedback fails; for example, in a panic attack. In other cases, the event that triggered the emotion terminates and the positive feedback process then stops. Sustained periods of positive feedback have the potential for destructive consequences.

Feedback is the basis of neuroendocrine regulation, as I describe it below. Neuroendocrine feedback depends on blood-borne messengers that are typically hormones or peptides. The ANS uses feedback for afferent and efferent functions. The afferent mechanisms signal changes in the viscera and other organs while efferent activity conveys commands to those organs. Consequently, the ANS can maintain feedback loops related to viscera, muscle, blood flow, and other responses. The visceral feedback system exemplifies this process.

The feedback concept is central to the field of psychophysiology: Awareness of physiological changes elicited by a stimulus is a primary mechanism of emotion. The psychiatric patient presenting with panic attack, phobia, or anxiety is reporting a subjective state based on patterns of physiological signals and not an existential crisis that exists somewhere in the domain of the mind, somehow apart from the body. Similarly, the medical patient expressing emotional distress during a painful procedure, or during uncontrolled postoperative pain, is experiencing the sensory features of that pain against the background of a cacophony of sympathetic arousal and neuroendocrine stress response.

Relationship of Central and Peripheral Mechanisms

Figure 29.2 illustrates that noxious signaling undergoes parallel processing at the cognitive, affective, and sensory levels. An event representing a threat to biological integrity elicits strong patterns of sympathetic and neuroendocrine response. These, in turn, contribute to the awareness of the perceiver. Sensory processing provides information about the environment, but this information exists in awareness against a background of emotional arousal, either positive or negative, and that arousal may vary from mild to extreme.

The transition from acute to chronic pain may involve complex changes in these pathways. The HPA and SAM axes are vulnerable to dysregulation with prolonged exposure to a stressor or series of stressors. This can include prolonged noxious signal-

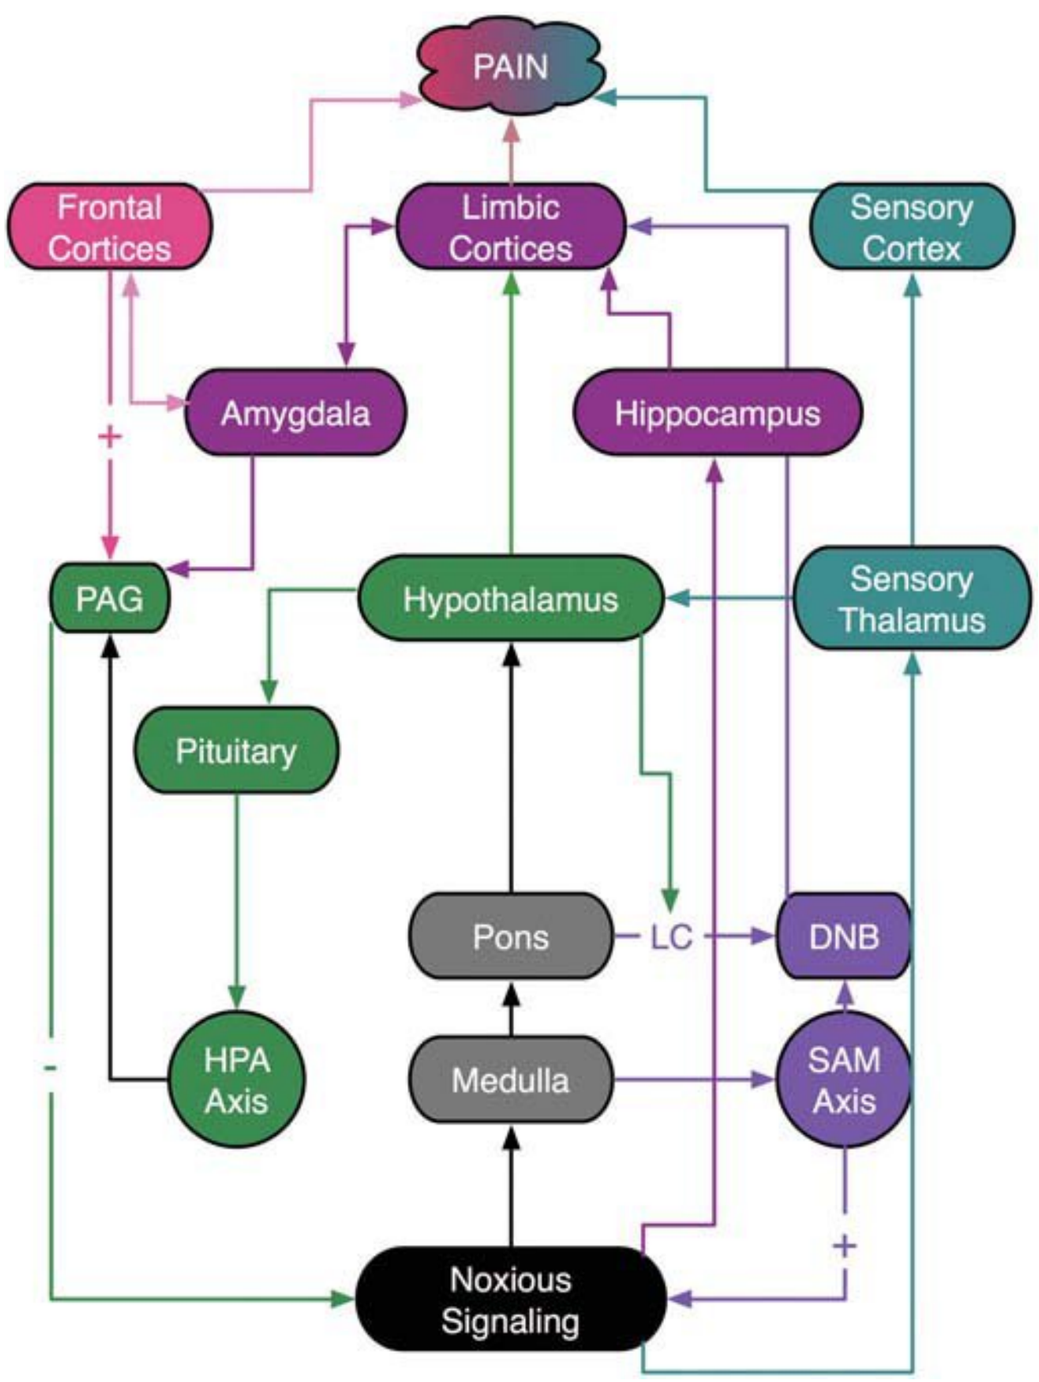

FIGURE 29.2 Parallel sensory, affective, and cognitive processing of noxious signaling arising from nociceptive or neuropathic sources. Parallel activation of sensory transmission and noradrenergic/limbic pathways leads to processing in somatosensory, limbic, and prefrontal/frontal cortical areas. In addition, noxious signaling triggers activity in the sympathoadrenomedullary (SAM) and the hypothalamo–pituitary–adrenocortical (HPA) axes. LC = locus coeruleus.

ing, as might occur with degenerative disease, or unrelenting noxious neuropathic signaling. Dysregulation in these systems may cause sensitization or impair normal inhibitory modulation. Moreover, neural networks associated with threat, dysphoria, or other negative emotions such as the frontal-amygdalar system may strengthen and become self-sustaining so that they can persist even in the absence of noxious signaling. Duric and McCarson[28] demonstrated that prolonged noxious signaling can produce stress-like damaging effects on the hippocampus, which is involved in the pathogenesis of depressive symptoms.

Noxious Signaling and Central Limbic Processing

Central sensory and affective pain processes share common sensory mechanisms in the periphery. As other chapters in this book describe, A-delta and C fibers serve as tissue trauma transducers (nociceptors) for both, the chemical products of inflammation sensitize these nociceptors, and peripheral neuropathic mechanisms such as ectopic firing excite both processes. In some cases neuropathic mechanisms may substitute for transduction as we classically define it, producing afferent signal volleys that appear, to the central nervous system, like signals originating in nociceptors. Differentiation of sensory and affective processing begins at the dorsal horn of the spinal cord. Sensory transmission follows spinothalamic pathways and transmission destined for affective processing takes place in spinoreticular pathways.

Noxious centripetal transmission engages multiple pathways: spinoreticular, spinomesencephalic, spinolimbic, spinocervical, and spinothalamic tracts,[29,30] as Figure 29.3 indicates. The spinoreticular tract contains somatosensory and viscerosensory afferent pathways that arrive at different levels of the brain stem. Spinoreticular axons possess receptive fields that resemble those of spinothalamic tract neurons projecting to medial thalamus, and, like their spinothalamic counterparts, they transmit tissue injury information.[31,32] Most spinoreticular neurons carry noxious signals and many of them respond preferentially to noxious activity.[33,34] The spinomesencephalic tract comprises several projections that terminate in multiple midbrain nuclei, including the periaqueductal gray, the red nucleus, nucleus cuniformis, and the Edinger-Westphal nucleus.[30] Spinolimbic tracts include the spinohypothalamic tract, which reaches both lateral and medial hypothalamus[35,36] and the spinoamygdalar tract that extends to the central nucleus of the amygdala.[37] The spinocervical tract, like the spinothalamic tract, conveys signals to the thalamus. All of these tracts transmit tissue trauma signals rostrally.

Central Neurotransmitter Systems

Central processing of noxious signals to produce affect undoubtedly involves multiple neurotransmitter systems. Four extrathalamic afferent pathways project to neocortex: the dorsal noradrenergic bundle (DNB) originating in the locus coeruleus (LC); the serotonergic fibers that arise in the dorsal and median raphe nuclei; the dopaminergic pathways of the ventral tegmental tract that arise from substantia nigra; and the acetylcholinergic neurons that arise principally from the nucleus basalis of the substantia innominata.[38] Of these, the noradrenergic and serotonergic pathways link most closely to negative emotional states.[39–41] The set of structures receiving projections from this complex and extensive network corresponds to classic definition of the limbic brain.[7,41–43]

Although other processes governed predominantly by other neurotransmitters almost certainly play important roles in the complex experience of emotion during pain, I emphasize the role of central noradrenergic processing here. This limited perspective offers the advantage of simplicity, and the literature on the role of central noradrenergic pathways in anxiety, panic, stress, and posttraumatic stress disorder provides a strong basis.[39,44] This processing involves two central noradrenergic pathways: the dorsal and ventral noradrenergic bundles (see Fig. 29.4).

Locus Coeruleus and the Dorsal Noradrenergic Bundle

Substantial evidence supports the hypothesis that noradrenergic brain pathways are major mechanisms of anxiety and stress.[39] The majority of noradrenergic neurons originate in the locus coeruleus (LC). This pontine nucleus resides bilaterally near the wall of the fourth ventricle. The locus has three major projections: ascending, descending and cerebellar. The ascending projection, the dorsal noradrenergic bundle (DNB), is the most extensive and important pathway for our purposes.[45] Projecting from the LC throughout limbic brain and to all of neocortex, the DNB accounts for about 70% of all brain norepinephrine.[46] The LC gives rise to most central noradrenergic fibers in spinal cord, hypothalamus, thalamus, hippocampus,[47] and, in addition, it projects to limbic cortex and neocortex. Consequently the LC exerts a powerful influence on higher-level brain activity.

The *noradrenergic stress response hypothesis* holds that any stimulus that threatens the biological, psychological or psychosocial integrity of the individual increases the firing rate of the LC, and this in turn results in increased release and turnover of norepinephrine in the brain areas involved in noradrenergic innervation. Studies show that the LC reacts to signaling from sensory stimuli that potentially threaten the biological integrity of the individual or signal damage to that integrity.[46] Spinal cord lamina one cells terminate in the LC.[31] The major sources of LC afferent input are the paragigantocellularis and prepositus hypoglossi nuclei in the medulla, but destruction of these nuclei does not block LC response to somatosensory stimuli.[48,49] Other sources of afferent input to the locus include the lateral hypothalamus, the amygdala and the solitary nucleus. Whether noxious signaling stimulates the LC directly or indirectly is still uncertain.

It is quite clear that noxious signaling inevitably and reliably increases activity in neurons of the LC, and LC excitation appears to be a consistent response to noxious signaling.[46,50–52] Notably,

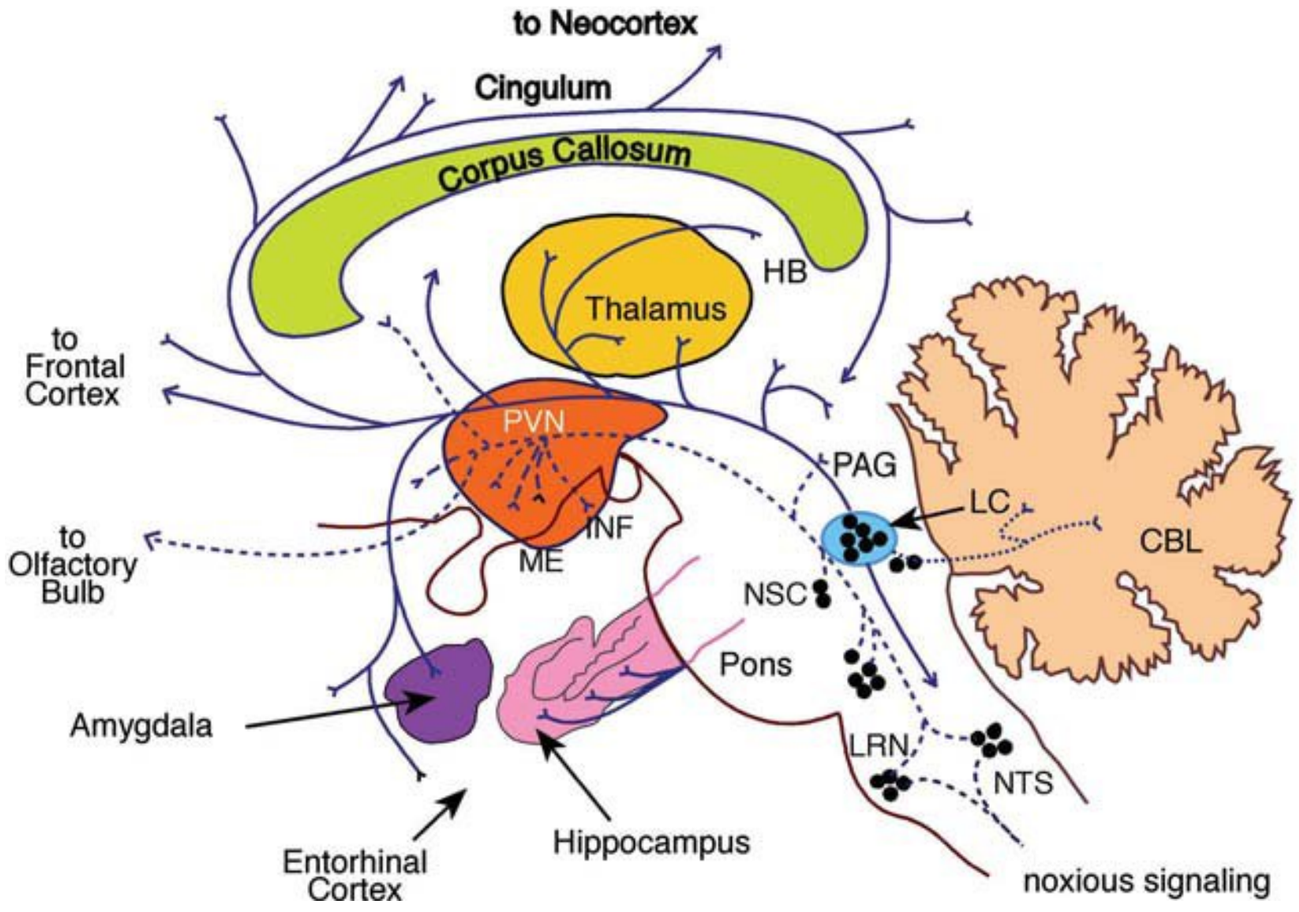

FIGURE 29.4 Central noradrenergic transmission. This parasagittal view identifies cell bodies of neurons that produce norepinephrine as black circles. The major projections of these cell bodies are the dorsal noradrenergic bundle (DNB) and the ventral noradrenergic bundle (VNB). The solid blue lines are DNB projections while the broken blue lines are VNB. The projection from the locus coeruleus (LC) to the cerebellum appears as a dotted line. Hypothalamus is orange. Noxious signaling from spinoreticular pathways excites the primarily noradrenergic LC, activating the DNB, which extends throughout the limbic brain and to neocortex. ME, median eminence; PAG, periaqueductal gray; HB, habenula; NSC, nucleus subcoeruleus; LRN, lateral reticular nucleus; NTS, nucleus tractus solitarius; INF, infundibulum; PVN, paraventricular nucleus of the hypothalamus; CBL, cerebellum.

this does not require cognitively-mediated attentional control since it occurs in anesthetized animals. Foote, Bloom, and Aston-Jones[53] reported that slow, tonic spontaneous activity at the locus in rats changed under anesthesia in response to noxious stimulation. Experimentally induced phasic LC activation produces alarm and apparent fear in primates,[54,55] and lesions of the LC eliminate normal heart rate increases to threatening stimuli.[56] In a resting animal, LC neurons discharge in a slow, phasic manner.[57]

The LC reacts consistently, but not exclusively, to noxious signaling. LC firing rates increase following non-noxious but threatening events, such as strong cardiovascular stimulation,[51,58] and certain visceral events, such as distention of the bladder, stomach, colon, or rectum.[46,59] Highly novel and sudden stimuli that could represent potential threat, such as loud clicks or light flashes, can also excite the LC in experimental animals.[57] Thus, the LC responds to biologically threatening or potentially threatening events, of which tissue injury is a significant subset. Amaral and Sinnamon[60] described the LC as a central analog of the sympathetic ganglia. Viewed in this way, it is an extension of the autonomic protective mechanism described above.

Invasive studies confirm the linkage between LC activity and threat. Direct activation of the DNB and associated limbic structures in laboratory animals produces sympathetic nervous system response and elicits emotional behaviors such as defensive threat, fright, enhanced startle, freezing and vocalization.[61] This indicates that enhanced activity in these pathways corresponds to negative emotional arousal and behaviors appropriate to perceived threat. LC firing rates increase two to threefold during the defense response elicited in a cat that has perceived a dog.[24] Moreover, infusion of norepinephrine into the hypothalamus of an awake cat elicits a defensive rage reaction that includes activation of the LC noradrenergic system. In general, the mammalian defense response involves increased regional turnover and release of norepinephrine in the brain regions that the LC innervates. The LC response to threat, therefore, may be a component of the partly "prewired" patterns associated with the defense response.

Increased alertness is a key element in early stages of the defense response. Normally, activity in the LC increases alertness. Tonically enhanced LC and DNB discharge corresponds to hypervigilance and emotionality.[39,53,62] The DNB is the mechanism for vigilance and defensive orientation to affectively relevant and novel stimuli. It also regulates attentional processes and facilitates motor responses.[38,41,46,63] In this sense, the LC influences the stream of consciousness on an ongoing basis and readies the individual to respond quickly and effectively to threat when it occurs.

LC and DNB support biological survival by making possible global vigilance for threatening and harmful stimuli. Siegel and Rogawski[64] hypothesized a link between the LC noradrenergic system and vigilance, focusing on rapid eye movement (REM) sleep. They noted that LC noradrenergic neurons maintain continuous activity in both normal waking state and non-REM sleep, but during REM sleep these neurons virtually cease discharge activity. Moreover, an increase in REM sleep ensues after either lesion of the DNB or following administration of clonidine, an alpha-2 adrenoceptor agonist. Because LC inactivation during REM sleep permits rebuilding of noradrenergic stores, REM sleep may be necessary preparation for sustained periods of high alertness during subsequent waking. Siegel and Rogawski contended that "a principal function of NE in the CNS is to facilitate the excitability of target neurons to specific high priority signals"[64(p226)]. Conversely, reduced LC activity periods (REM sleep) allow time for a suppression of sympathetic tone.

Both adaptation and sensitization can alter the LC response to threat. Abercrombie and Jacobs[65,66] demonstrated a noradrenergically mediated increase in heart rate in cats exposed to white noise. Elevated heart rate decreased with repeated exposure as did LC activation and circulating levels of norepinephrine. Libet and Gleason[67] found that stimulation via permanently implanted LC electrodes did not elicit indefinite anxiety. This indicates that the brain either adapts to locus excitation or engages a compensatory response to excessive LC activation under some circumstances. In addition, central noradrenergic responsiveness changes as a function of learning. In the cat, pairing a stimulus with a noxious air puff results in increased LC firing with subsequent presentations of the stimulus, but previous pairing of that stimulus with a food reward produces no alteration in LC firing rates with repeated presentation.[57] These studies show that, despite its apparently "prewired" behavioral subroutines, the noradrenergic brain shows substantial neuroplasticity. The emotional response of animals and people to a painful stimulus can adapt, and it can change as a function of experience.

From a different perspective, Bremner et al.[39] postulated that chronic stress can affect regional norepinephrine turnover and thus contribute to the *response sensitization* evident in panic disorder and posttraumatic stress disorder. Chronic exposure to a stressor (including perseverating noxious signaling) could create a situation in which noradrenergic synthesis cannot keep up with demand, thus depleting brain norepinephrine levels. Animals exposed to inescapable shock demonstrate greater LC responsiveness to an excitatory stimulus than animals who have experienced

escapable shock.[68] In addition, such animals display "learned helplessness" behaviors—they cease trying to adapt to, or cope with, the source of shock.[69] From an evolutionary perspective, this is a failure of the defense response as adaptation; it represents surrender to suffering. Extrapolating this and related observations to patients, Bremner and colleagues[39] suggested that persons who have once encountered overwhelming stress and suffered exhaustion of central noradrenergic resources may respond excessively to similar stressors that they encounter at a later time.

The Ventral Noradrenergic Bundle and the Hypothalamo-Pituitary-Adrenocortical (HPA) Axis

The ventral noradrenergic bundle (VNB) originates in the LC and enters the medial forebrain bundle. Neurons in the medullary reticular formation project to the hypothalamus via the VNB.[70] Sawchenko and Swanson[71] identified two VNB-linked noradrenergic and adrenergic pathways to paraventricular hypothalamus in the rat: the A1 region of the ventral medulla (lateral reticular nucleus, LRN), and the A2 region of the dorsal vagal complex (the nucleus tractus solitarius, or solitary nucleus) which receives visceral afferents. These medullary neuronal complexes supply 90% of catecholaminergic innervation to the paraventricular hypothalamus via the VNB.[72] Regions A5 and A7 contribute in a comparatively minor way to the VNB.

The noradrenergic axons in the VNB respond to noxious stimulation[46] as does the hypothalamus itself.[73] Moreover, noxious-signaling neurons at all segmental levels of the spinal cord project to medial and lateral hypothalamus and several telencephalic regions.[30,35,36] These projections link tissue injury and the hypothalamic response, as do hormonal messengers in some circumstances.

The hypothalamic paraventricular nucleus (PVN) coordinates the HPA axis. Neurons of the PVN receive afferent information from several reticular areas including ventrolateral medulla, dorsal raphe nucleus, nucleus raphe magnus, LC, dorsomedial nucleus, and the nucleus tractus solitarius.[71,74,75] Still other afferents project to the PVN from the hippocampus, septum amygdala.[76] Nearly all hypothalamic and preoptic nuclei send projections to the PVN. This suggests that limbic connections mediate endocrine responses during stress. Feldman et al. note that limbic stimulation always increases adrenocortical activity in rats.

In responding to potentially or frankly injurious stimuli, the PVN initiates a complex series of events regulated by negative feedback mechanisms, as Figure 29.5 indicates. These processes ready the organism for extraordinary behaviors that will maximize its chances to cope with the threat at hand,[77] but they must limit overshooting and return to recover when the stressor has passed. While laboratory studies often involve highly controlled and specific noxious stimulation, real life tissue trauma usually involves a spectrum of afferent activity, and the pattern of activity may be a greater determinant of the stress response than the specific receptor system involved.[78] Traumatic injury, for example, might involve complex signaling from the site of injury, including inflammatory mediators, baroreceptor signals from blood volume changes, and hypercapnea. Tissue trauma normally initiates much more than noxious signaling.

Diminished noxious signal transmission during stress or injury helps people and animals to cope with threat without the distraction of pain. The medullary mechanisms involved in this are complex and include the response of the solitary nucleus to baroreceptor stimulation.[79] Laboratory studies with rodents indicate that animals placed in restraint or subjected to cold water develop analgesia.[80–82] Lesioning the PVN attenuates such stress induced analgesia.[83]

Some investigators[84,85] emphasize that neuroendocrine arousal mechanisms are not limited to emergency situations, even though most research emphasizes that such situations elicit them. In complex social contexts, submission, dominance, and other transactions can elicit neuroendocrine and autonomic responses, modified perhaps by learning and memory. This suggests that neuroendocrine processes accompany all sorts of emotion-eliciting situations.

The hypothalamic PVN supports stress-related autonomic arousal through neural as well as hormonal pathways. It sends direct projections to the sympathetic intermediolateral cell column in the thoracolumbar spinal cord and the parasympathetic vagal complex, both sources of preganglionic autonomic out-

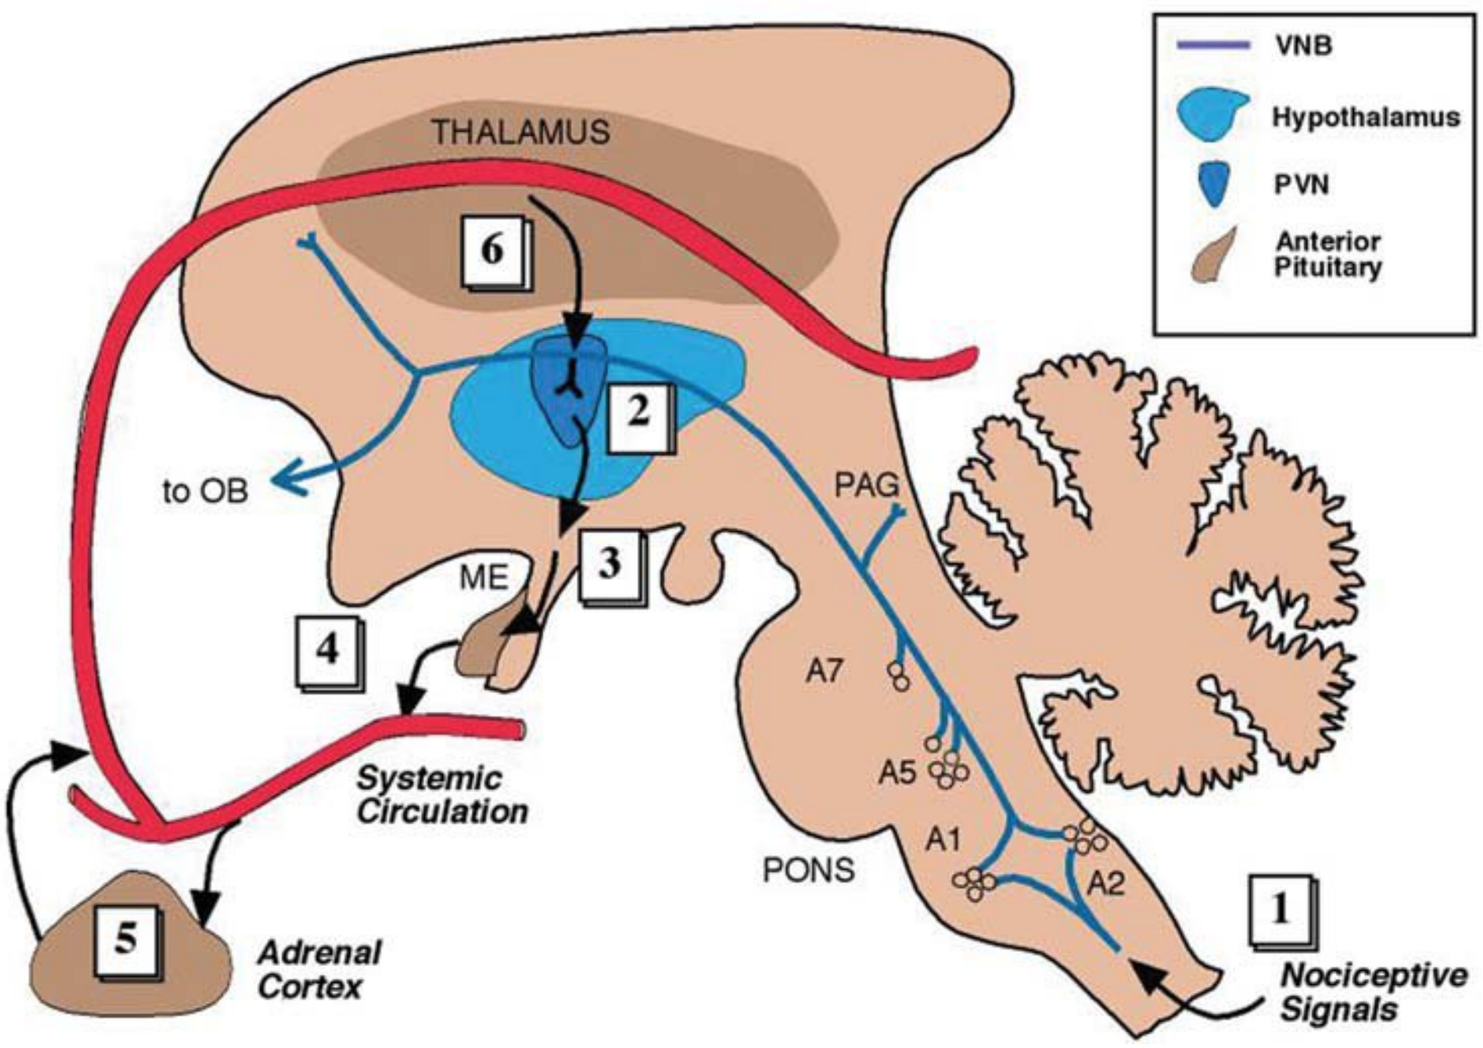

FIGURE 29.5 Response of the hypothalamo–pituitary–adrenocortical axis (HPA) to noxious signaling. The feedback modulated response involves six steps. In the first, noxious signaling excites the ventral noradrenergic bundle (VNB), including several medullary and pontine nuclei (designated A1, A2, A5, and A7). When such signals reach hypothalamus, they stimulate the paraventricular nucleus (PVN); this is Step 2. The PVN produces corticotropin releasing hormone (CRH). CRH-producing neurons extend from the PVN to the median eminence (ME) where they release CRH into the portal circulation, Step 3. At this point the response becomes neurohumoral rather than neuronal. The anterior pituitary responds to CRH by releasing adrenocorticotropin (ACTH) into the systemic circulation (Step 4). ACTH causes the adrenocortex to release corticosteroids into systemic circulation (Step 5). In addition to their extensive metabolic effects, the corticosteroids bind to receptors at the PVN (Step 6), thus closing the negative feedback loop.

flow.[86] In addition, it signals release of epinephrine and norepinephrine from the adrenal medulla. ACTH (adrenocorticotrophic hormone) release, while not instantaneous, is quite rapid: it occurs within about 15 seconds.[87] These considerations implicate the HPA axis in the neuroendocrinologic and autonomic manifestations of emotion associated with tissue trauma.

In addition to controlling neuroendocrine and autonomic nervous system reactivity, the HPA axis coordinates emotional arousal with behavior.[88] As noted above, stimulation of the hypothalamus in animals can elicit well-organized action patterns, including defensive threat behaviors and autonomic arousal.[89] The existence of demonstrable behavioral subroutines in animals suggests that the hypothalamus plays a key role in matching behavioral reactions and bodily adjustments to challenging circumstances or biologically relevant stimuli. Moreover, stress hormones at high levels may affect central emotional arousal, lowering startle thresholds and influencing cognition.[87] Saphier[90] observed that cortisol altered the firing rate of neurons in limbic forebrain. Clearly, stress regulation is a complex, feedback dependent, and coordinated process. The hypothalamus appears to coordinate behavioral readiness with physiological capability, awareness, and cognitive function.

Primary and Secondary Features of the Affective Dimension of Pain

The physiology of emotion suggests that the affective dimension of pain involves a two-stage mechanism. The primary mechanism generates an immediate experience akin to hypervigilance or fear. In nature, this rapid response to injury serves to disrupt ongoing attentional and behavioral patterns. At the same time, efferent messages from the hypothalamus, amygdala, and other limbic structures excite the autonomic nervous system, and this in turn alters bodily states. Cardiac function, muscle tension, altered visceral function, respiration rate, and trembling all occur, and awareness of these reactions creates a strong negative subjective experience. This body state awareness is the second mechanism of the affective dimension of pain.

Damasio[91] contended that visceral and other event-related, autonomically-mediated body state changes constitute ''somatic markers.'' That is, they serve as messengers, delivering affective evaluations of perceptual experiences that either confirm or deny the potential threat inherent in an event. A somatic marker is essentially a somatic image. Perceptually, the brain operates on images that are symbolic representations of external and internal objects or events. Just as it is more efficient for a listener to work with words in language as opposed to phonemes, cognition is more efficient when it uses images rather than simple sensations. The somatic marker images associated with tissue trauma are often complex patterns of physiological arousal. They serve as symbolic representations of threat to the biological (and sometimes the psychological or social) integrity of the person. Like other images, they can enter into complex patterns of association. Because the secondary stage of the affective response involves images and symbols, it represents cognition as well as emotion.

EMOTION AND COGNITION

Negative emotions and somatic markers are much more than reactions to undesirable events; in nature they help an organism determine which things benefit and which things threaten survival, and they compel behavior consistent with such evaluations. Moreover, emotional expression communicates this judgment to others and thus sets up group approach or avoidance behaviors. MacLean[7] described emotion as a process that imparts subjective information. In these respects, our feelings approximate crude intelligence. How we feel about something is often as important, or more important, than what we know about it. If emotion is a proto-intelligence, then evolutionarily newer structures, namely the later stages of cortical development, should have demonstrable links with limbic structures and functions.

Such interconnections exist. Parts of the frontal lobe (the dorsal trend) appear to have developed from rudimentary hippocampal formation while other parts (the paleocortical trend) originated in olfactory cortex. While these two areas interconnect anatomically, the former analyzes sensory information while the latter contributes emotional tone to that sensory information.[92(66–67)] Pribram,[93] noting that limbic function involves frontal and temporal cortex, offered a bottom-up concept for how cognition relates to feelings; that is, emotion determines cognition. However, the multimodal neocortical association areas project corticofugally to limbic structures,[94] which suggests that cognitions may drive emotions.

The debate on whether emotion or cognition is primary may never resolve. For immediate purposes, it seems best to conclude that knowing and feeling are closely interrelated. Still, these processes are not identical. We can know something about our feelings, and we can have emotional responses to what we know. The brain is a complex, dynamic organ, constantly constructing its internal model of reality from sensory input and memory storage. Feeling and thinking are major processes in this construction.

THE SENSE OF SELF

Cognitive Perspective

Pain informs the brain of injury to bodily integrity and its emotional aspect reflects the importance of that injury to the individual. An injury does not just cause objective harm, it harms ''me.'' That is, it harms what I consider myself. Similarly, a social affront harms what I consider myself, and I might metaphorically describe the incident as something that ''hurt'' me. What constitutes the self? What would happen if an injured person had an altered or poorly developed sense of self? Clinical observations of schizophrenic patients and other psychiatric patients indicate that they sometimes mutilate themselves horribly and apparently with little or no pain.[95] This suggests that the sense of self may be an intrinsic part of the complex experience of pain because it is the focal point around which perceptions form and from which cognitions arise.

Multiple Perspectives on the Self

The *self* is a hierarchical construct that has different meanings at different levels of the neuraxis. Multiple levels of the self exist, and each level becomes a precondition for the existence of higher levels. At least two biological definitions merit inclusion in the construct. At the level of the human genome, the self is the unique genetic code that makes each of us an individual. It sets the basic rules of life by defining sex, size and features, and basic abilities.

At a higher biological level, the self is what the immune system recognizes as ''me'' versus ''not me.'' The immunological self is an enigma because ''me'' and my genetic code are not identical. Our bodies host elaborate microbial ecosystems, and disturbing or damaging these systems (e.g., via antibiotic use) compromises health. Various microorganisms in our digestive tracts, oropharyngeal passages, and on our skin qualify as self to our immune systems; we live comfortably with them in a symbiotic relationship. Our microbial floras are clearly us, even though they do not carry our genetic code. For the immune system, there is no single chemical marker that defines individuality, nor is the self limited to certain biological structures. Thus, even at this basic level, the boundaries of the self are fuzzy.

At a neurological level, the self exists as a central representation of the body. Melzack[96–98] termed this the body neuromatrix. The brain maintains a detailed map of the body at several levels of the neuraxis. Study of phantom limb patients and patients born without limbs reveals that the brain has an elaborate internal representation of the body. If a person loses a leg, the brain maintains its representation of the leg and the person experiences a phantom limb. Even patients born without limbs have an internal sense or representation of the absent body parts. Thus, humans and almost certainly higher order animals carry within them a phenomenal representation of a body self.

These biological selves exist below the level of consciousness. They are very much a part of every person, but they normally play little or no part in what we think of as "me." Humans and animals do not differ with regard to self at this level.

Multiple psychological dimensions of the self also exist. At the most fundamental level there is the self-as-agent, which engages in biological adaptation and survival. From an evolutionary perspective, it is the agent that struggles to survive. The self-as-agent sets goals, chooses among alternatives, and engages in behaviors. Animals and humans share self-as-agent, and this self is, in part, social. That is, it exists not alone but in relation to others of its kind. Animals, including humans, engage in social dominance and submission. In this respect each organism defines its relationship to others, often via struggle or conflict. The defined relationship often determines the extent of one's opportunity to reproduce or one's access to the resources necessary for survival. The self-as-agent is primitive and does not require cognition. It is something that the individual does; not something that the individual experiences as a phenomenal reality. In other words, this is a self of behavior. It does not entail subjective awareness.

At a higher, and perhaps uniquely human, level the psychological self is also a point of view (self-as-perspective). It is the center of experiential gravity about which the brain organizes present circumstances, past history, future goals, and expectations. This is an inevitable outcome of the higher order self-organizing processes of the brain. This aspect of the self stems from recognition of one's physical being as an entity in the environment, and it becomes a frame of reference for all that happens to the person.

On still another level, the self represents the individual's complex sense of identity, to which I have referred above as "me," *vide supra*. This self-as-identity resembles the self-as-agent in some respects, but it is an age-dependent, autobiographically based narrative and interpretation, modified by the immediate circumstances and surroundings. Unlike the self-as-agent, the self-as-identity is the product of a developmental process and it changes over time.

Finally, every human has a sociological self. That is, we have an identity defined by our relationships to social groups and to society and culture as a whole. Gender roles, social class, education level, age roles, and our culture constrain who we are. To some degree, we are the roles that we play in our families, vocational settings, recreational pursuits, and elsewhere.

An injury to the body or a painful disease condition often has important social effects. A chronic pain syndrome might serve as a badge of honor for a former police officer wounded in the line of duty, and this would impact the extent to which he suffers. The pain of a patient dying of AIDS, who feels intense guilt toward his nuclear family for his homosexuality or drug abuse habits, takes on the opposite meaning. All pain occurs in the context of, and modifies, the sociological self. Consider the following examples: the fakir piercing himself in the public square of a European town, apparently without pain; the religious martyr dying a horrible death but apparently without pain; and the adolescent piercing her eyebrow and tongue with conspicuous pins for the social status that this brings. These cases all illustrate situations in which the sociological self gains from socially visible tissue trauma. These observations suggest that this aspect of the self can affect pain behavior and possibly the experience of pain itself. The sociological self is uniquely human.

The role of sense of self in pain merits study, but as yet it has gained little or no attention from pain researchers. The constructs of self may prove important in defining the relationship of pain to suffering. The role of the sense of self in the initiation and organization of defense and stress responses merits inquiry.

STRESS, SICKNESS, AND PAIN

Basic Definitions: Stress, Homeostasis, and Allostasis

Human life entails repeated adverse physical and psychosocial events, and these challenges require an adaptive response. The brain mounts a coordinated, adaptive reaction characterized by physiological arousal. This response is often associated psychologically with the experience of threat or other negative affect. The term for this arousal reaction is the *stress response*, and any event that triggers such a response is a *stressor*. Some stressors are singular events, such as traffic accidents or surgery. Other stressors are constellations of vexing problems that never end. Examples include dysfunctional family relationships and vocational disorders. Stress and negative emotion feed one another, and the processes involved affect pain.

I have discussed the defense response above. It resembles the stress response and shares common mechanisms. The defense response and stress have historically different origins in science but seem to be different perspectives on a common adaptive mechanism. In order to integrate relevant information in these two fields, I consider the stress response to be a subset of the more general defense response. This position has the shortcoming of potentially obscuring an important distinction. Classically, the defense response pertained to threats appearing in the external environment and not the internal environment. However, the concept applies equally well to threatening internal events. The pain of a kidney stone, angina, or a migraine headache is threatening and can function as a stressor and elicit the physiological changes common to the defense response and the stress response.

In everyday life, stress is the resource-intensive process of mounting adaptive coping responses to challenges that occur in the external or internal environment. A stressor may be a physical or social event, an invading microorganism, or, in the case of a chronic pain, patient pain itself. Selye[77] first described this response as a syndrome produced by "diverse nocuous agents." He eventually characterized the stress response as having three stages: alarm reaction, resistance, and, if the stressor does not relent, exhaustion. The normal stress responses of daily living consist of the alarm reaction, resistance, and recovery. Stressors have as their primary features intensity, duration, and frequency. The impact of a stressor is the magnitude of the response it elicits. This impact involves cognitive mediation (thought processes) because it is a function of both the predictability and the controllability of the stressor.

A stressor can threaten homeostasis,[99] which strictly means a limited set of systems concerned with maintaining the essentials of the internal milieu. Homeostasis represents the control of internal processes truly necessary for life, such as thermoregulation, blood gases, acid base balance, fluid levels, metabolite levels, and blood pressure. Generic threats to homeostasis include environmental extremes, extreme exercise, depletion of essential resources, abnormal feedback processes, aging, and disease. Of course, various defensive processes must exist to protect homeostasis.

The term for the general adaptive process that protects against threats to homeostasis is *allostasis*. Allostatic processes dynamically adapt multiple internal systems to changes in the environment and coordinate their responses.[99,100] Allostasis exists when

changes in the external or internal environment trigger physiological coping mechanisms such as autonomic arousal. These mechanisms ensure that the processes sustaining homeostasis stay within normal range. Allostasis is the essence of the stress response because it mobilizes internal resources to meet the challenge that a stressor represents. When a stressor, such as neuropathic signaling, persists for a long period of time, or when repeated stressors occur in rapid succession, allostasis may burn resources faster than the body can replenish them. The cost to the body of allostatic adjustment, whether in response to extreme acute challenges or to lesser challenges over an extended period of time, is called *allostatic load*.

Physiological Mechanisms of Stress

The major mechanisms of the stress response are the hypothalamo–pituitary–adrenocortical (HPA) axis based in the hypothalamic periventricular nucleus (PVN),[101] and the sympathoadrenomedullary (SAM) axis,[102] which includes the LC noradrenergic system (see Figure 29.1). The peripheral effectors of these mechanisms are the autonomic nervous system, the SAM circulating hormones, principally the catecholamines epinephrine (E) and norepinephrine (NE) together with the sympathetic cotransmitter neuropeptide Y (NPY),[103] all of which originate in the chromaffin cells of the adrenal medulla. Circulating catecholamines increase blood pressure and heart rate, dilate pupils, and increase skin conductance, thereby initiating arousal for the fight or flight response. The stress response involves hypothalamically-induced release of peptides derived from pro-opiomelanocortin (POMC) at the anterior pituitary. The POMC-related family of anterior pituitary hormones includes ACTH, β-lipotropin, β-melanocyte stimulating hormone, and β-endorphin.

The hypothalamic PVN initiates the HPA stress response and controls it through negative feedback mechanisms. Corticotropin-releasing hormone (CRH) produced at the PVN initiates the stress response. CRH initializes and coordinates the stress response at many levels,[104] including the LC.[105] It is the key excitatory central neurotransmitter and regulator in the endocrine response to injury.

The PVN triggers another aspect of the stress response in the SAM axis by recruiting catecholaminergic cells in the rostral ventrolateral medulla. This structure is a cardiovascular regulatory area involved, along with the solitary nucleus, in the control of blood pressure. The rostral ventrolateral medulla activates the solitary nucleus and, together with it, provides tonic excitatory drive to sympathetic vasoconstrictor nerves that maintain resting blood pressure levels. A normal stress response involves a complex pattern of autonomic arousal that includes increased blood pressure followed by a period of recovery when blood pressure and other aspects of arousal return to normal.

Neural Substrates

Viewing stress as a mechanism of defense brings additional neural substrates into focus. Chief among them are the medial hypothalamus, amygdala, and dorsal periaqueductal gray (PAG). These structures respond reliably but not exclusively to noxious signaling, interact with one another, and actively integrate cognitive, sensory, and emotional processes. Some pain researchers have begun to address the issue of integration. Tracey et al.,[106] for example, employed functional brain imaging to study subjects attending to or distracting themselves from painful stimuli cued with colored lights. Distraction and pain reduction occurred in conjunction with activation of the PAG, linking cortical control and the PAG.

Frontal-amygdalar circuits are a well-studied aspect of the defense response.[107–109] Cognitive variables such as interpretation, attention, and anticipation can influence amygdalar response through the frontal-amygdalar circuit. The amygdala, in turn, can influence the HPA axis.[110–112] Frontal influences also affect patterns of activity at the LC, which is a part of the SAM axis.

An important implication of viewing stress within the defense response framework is that endogenous cognitive activity (thoughts) generated during anticipation or memory reconstruction can activate complex neural circuits that mobilize the stress response in the absence of tissue trauma. In other words, mental activity has direct and deleterious physiological consequences. Chronic pain patients can stress themselves through negative thought processes, termed catastrophizing, and in so doing exacerbate and perpetuate their pain.[113]

The central nucleus of the amygdala projects to the PAG, which coordinates defensive behaviors.[114] In general, the amygdala is proving to be a key mechanism of conditioned fear.[115,116] It communicates with the hypothalamus via neural circuitry,[117,118] as well as the frontal cortices.

A second, and underestimated, aspect of the defense response depends predominantly upon the immune system. The brain controls the immune system via the actions of the sympathetic nervous system and the hypothalamic secretion of releasing factors into the bloodstream. These messenger substances activate the anterior pituitary via the HPA axis.[119] The pituitary body releases peptides related to pro-opiomelanocortin, such as ACTH and beta-endorphin, and these in turn trigger the release of glucocorticoids. Because the cells and organs of the immune system express receptors for these hormones, they can respond to humoral messenger molecules of central origin. In this way, the brain enlists the immune system in the defense response.

Immune Mechanisms

Just as the nervous system is the primary agent for detecting and defending against threat arising in the external environment, the immune system is the primary agent of defense for the internal environment. Kohl[120] described the immune system as "a network of complex danger sensors and transmitters." This interactive network of lymphoid organs, cells, humoral factors, and cytokines works interdependently with the nervous and endocrine systems to protect homeostasis.

Physical trauma produces specific tissue breakdown, triggering release of nitric oxide (NO), bradykinin, histamine, and peptides, some of which are immunostimulatory. The neuropeptides SP and NKA activate T cells and cause them to increase production of the pro-inflammatory cytokine IFN-g.[121] In addition, another pro-inflammatory cytokine, IL1-β, stimulates the release of SP from primary afferent neurons.[122] Thus, the neurogenic inflammatory response contributes to the immune defense response and at the same time is in part a product of that response.[123]

The immune system detects an injury event in at least three ways: (1) through bloodborne immune messengers originating at the site of injury; (2) through nociceptor-induced sympathetic activation and subsequent stimulation of immune tissues, and (3) through SAM endocrine signaling. Immune messaging begins with the acute phase reaction in the injured tissues.[124] Local macrophages, neutrophils, and granulocytes produce and release into intracellular space and circulation the pro-inflammatory cytokines Il-1, Il-6, IL-8, and TNF-α. This alerts and activates other immune tissues and cells that have a complex systemic impact.

The acute phase reaction to tissue trauma is the immune counterpart to noxious signaling in the nervous system in that it encompasses transduction, transmission, and effector responses. This is a feedback-dependent process. Sympathetic outflow following tissue injury can directly modulate many aspects of immune activity and provide feedback. This can occur because all lymphoid organs have sympathetic nervous system inner-

vation[125] and because many immune cells express adrenoceptors.[126–128]

In addition to the familiar acute phase reaction, the immune system manifests several complex response patterns to tissue injury. In a primitive world, microbial invasion normally accompanies any breach of the skin, and when the microorganisms reach the bloodstream, sepsis occurs. Resultant inflammation therefore assists the immune system in defense. Redness, pain, heat, and swelling are its cardinal signs. The inflammatory process creates a barrier against the invading microorganisms and activates a variety of cells, including macrophages and lymphocytes, that find and destroy invaders. It also sensitizes the injured tissue and thereby minimizes the risk of further injury. Inflammation reduces function and increases pain by sensitizing nociceptors. Tracey[129] described the "inflammatory reflex" as an Ach-mediated process by which the nervous system recognizes the presence of, and exerts influence upon, peripheral inflammation. Through vagal and glossopharyngeal bidirectional processes, the nervous system modulates circulating cytokine levels.[130] Put another way, the nervous system can sense the activities of the immune system.

The Sickness Response

The immune system can mount a system-wide defense response characterized by fatigue, fever, and sickness with associated pain.[131–136] This is the "sickness response," and although it is cytokine mediated, it depends on the central nervous system. Macrophages and other cells release pro-inflammatory cytokines including IL1-β, IL-6, IL-8, IL-12, IFN-γ, and TNF-α in response to tissue trauma. These substances act on the vagus nerve, the glossopharyngeal nerve, the hypothalamus, and elsewhere to trigger a cascade of unpleasant, activity-limiting symptoms.[133,137]

Subjectively, the sickness response is a vivid and dysphoric experience characterized by fever, malaise, fatigue, difficulty concentrating, excessive sleep, decreased appetite and libido, stimulation of the HPA axis, and hyperalgesia. The sickness-related hyperalgesia may reflect the contributions of spinal cord microglia and astrocytes.[135] Functionally, this state is adaptive; it minimizes risk by limiting normal behavior and social interactions and forces recuperation. Curiously, this response does not always resolve with physical healing.

The Sickness Response and Depression

Mounting evidence supports the hypothesis that the sickness response and depression are related immune response patterns. This hypothesis derives from evidence that pro-inflammatory cytokines are agents of depression. The specific mechanisms are still at issue,[138] but pro-inflammatory cytokines instigate the behavioral, neuroendocrine, and neurochemical features of depressive disorders.[139–142] The therapeutic use of pro-inflammatory cytokines INF-α and IL-2 for cancer treatment produces depression,[143,144] and their administration generates hyperactivity and dysregulation in the HPA axis. These are common features of severe depression. The sickness response and depression overlap in that many of the behavioral manifestations of sickness are also manifestations of a depressive disorder. Whether sickness and depression constitute separate states of the system is still uncertain. It is becoming clear, however, that the immune defense responses associated with tissue damage contribute to bodily awareness and the complex, multidimensional experience of pain.

Summary

This review of mechanisms reveals that the emotional aspects of pain are the product of the defensive and stress responses that tissue trauma, a related stressor, or a constellation of stressors evokes. These responses comprise two forms of allostasis. At the neuroendocrine level, the defense response is an adaptive reaction characterized by sympathetic arousal, hypervigilance, and a sense of threat. However, a coordinated immune system adaptive defense response also occurs at the immune level. Mediated by pro-inflammatory cytokines, it produces a sense of sickness and curtails normal activity. The sickness response produces fatigue, general malaise, fever, and hyperalgesia typically experienced as musculoskeletal pain. Depression is apparently related to the sickness response in that both are the product of pro-inflammatory cytokines. Thus, the defensive responses generate negative emotions in the general domains of anxiety/threat, depression, and fatigue and sickness.

Stress and Chronic Pain

Stress and related defensive responses can promote chronic pain and related disability in at least three ways. First, noxious somatic or neuropathic signaling or central mechanism generating the perception of pain can function as stressors, thereby triggering a defense response and stress. As the mechanism discussion indicates, this can lead to negative emotional states, depressed mood, general sickness, and fatigue. If this is prolonged, patients typically undergo physical deconditioning that makes the pain worse. Second, psychosocial stressors such as dysfunctional family relationships or poor vocational adjustment can trigger the stress response and lead to all of the consequences noted above. Third, comorbid disorders and associated interventions are stressors and can contribute to pain by producing negative affective states, the sickness response, and, ultimately, physical deconditioning. Immunological diseases, cancer, diabetes, neurological disorders, and other disease states can increase patient vulnerability to chronic pain through these mechanisms.

The three mechanisms are not mutually exclusive: they can exist in any combination. The normal course of a stress response or defense response is immediate arousal with subsequent slow recovery to normalcy. When stressors confront a patient as a chain of events, the recovery process to the first may not finish before the second sets off another arousal pattern. A chain of stressors can dysregulate one or another feedback dependent aspect of the stress response system, such as the HPA axis. Hypercortisolemia, for example, characterizes almost half of severely depressed patients. Stress-induced chronobiological dysregulation is perhaps more common. Patients with chronic pain often complain of disturbed sleep patterns.

FUTURE DIRECTIONS

Psychophysiology is a rapidly expanding domain of inquiry. I have been able to cover only a small fraction of the field in this review. Other relevant areas include sleep and sleep disorders, chronobiology, physiological mechanisms of learning and memory, somatic representation, and psychoneuroimmunology. Painful conditions influence these various domains and in turn change in response to changes within these domains. Furthermore, functional brain imaging has opened new opportunities for pursing the relationship of brain activity to physical and psychological manipulations and also subjective experience. Building an interdisciplinary scientific evidence base in the domain of psychophysiology should be a priority in pain research because this field bridges psychological states and physiological health.

Multisymptom syndromes such as fibromyalgia syndrome, irritable bowel syndrome, and tempormandibular disorder pose major challenges in pain medicine and other medical areas. It is clear that these problems are related to stress, but the causal mechanisms of such disorders and their resistance to treatment remain ill-defined. These disorders are mind–body problems that refuse to yield to either purely physiological or purely psychological intervention. Psychophysiology is the only approach formally

organized to pursue such mechanisms from an integrated body–mind perspective. Future research on the nature of multisymptom disorders and the development of management strategies or curative interventions can benefit from a psychophysiological approach.

Finally, psychophysiology as a field offers unique tools and methods for research that can address the mechanisms and benefits of interdisciplinary pain management. It is no surprise to experienced pain clinicians that psychological interventions and events have physiological consequences and, conversely, physiological events and interventions have psychological consequences. Psychophysiology as a field is well-positioned to characterize such phenomena and also to optimize interdisciplinary intervention through the coordinated examination of subjective and objective outcomes.

CHAPTER 30 ■ PAIN AND LEARNING

ROBERT J. GATCHEL, BRIAN R. THEODORE, NANCY D. KISHINO, AND CARL NOE

INTRODUCTION TO PAIN AND LEARNING

One of the major contributions of the behavioral sciences to the area of medicine has been the application of learning principles to the development of effective illness management techniques. This has been especially true in the area of pain management. Before discussing these learning-based management techniques, an overview of the three major principles of learning will be provided.

OVERVIEW OF THE THREE MAJOR PRINCIPLES OF LEARNING

Classical Conditioning

Classical conditioning is one of the most basic forms of learning in which a learned association or connection develops between two stimuli or objects. As noted by Baum, Gatchel, and Krantz,[1] the eminent Russian physiologist Ivan Pavlov (1849–1936) was the first to describe the process of classical conditioning with his work on the conditioned reflex. Reflexes are specific, automatic, unlearned reactions elicited by a specific stimulus. For example, if you have ever touched a surface that you did not know was hot (such as a hot stove), you showed a reflexive behavior—the immediate withdrawal of your hand from the stove. Similarly, if a piece of dust suddenly enters your eye, your eye will automatically blink and begin to secrete tears. These **unconditioned reflexes** are automatic and have a great deal of survival value for the organism. Pavlov demonstrated that such unconditioned reflexes could be **conditioned**, or learned. While studying dogs in order to understand more fully the digestive process, he began to notice that many of the dogs secreted saliva (an unconditioned reflex to the sight or smell of food) before food was delivered to them. He observed that this phenomenon occurred whenever the dogs either heard the approaching footsteps of the laboratory assistant who fed them or had a preliminary glimpse of the food. In order to investigate this phenomenon more systematically, Pavlov developed a procedure for producing a conditioned reflex. This procedure came to be called **classical conditioning.** It is one of the most basic forms of learning.

Pavlov conducted a series of well-known studies on the process of classical conditioning using dogs as experimental subjects (Fig. 30.1). In these studies, Pavlov studied situations in which a neutral stimulus or event (such as a bell) was presented to a dog just prior to the presentation of food (an unconditioned stimulus that normally elicits an automatic unconditioned reflex of salivation). After a number of such presentations, the bell (now a conditioned stimulus) would elicit a conditioned or learned salivation re-

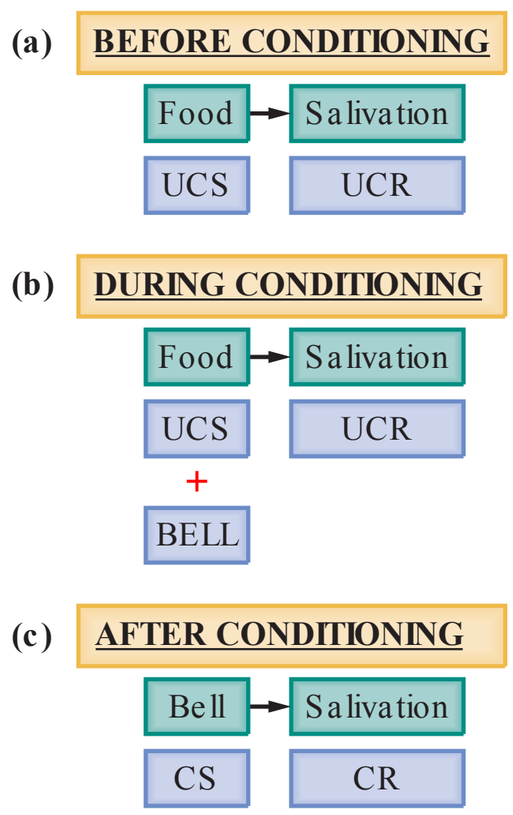

FIGURE 30.1 Pavlov's procedure of classical conditioning.

sponse when presented by itself in the absence of food. The conditioned reflex of salivation occurred to the bell alone. This represents the process of classical conditioning, and it is based on the learned association or connection between two stimuli, such that the bell is associated with food, that have occurred together at approximately the same point in time. An association is learned between a weak stimulus (such as the bell) and a strong stimulus (such as the sight of food) so that the weak stimulus comes to elicit the response originally controlled only by the stronger one (i.e., salivation).

Pavlov also subsequently demonstrated what would happen if the neutral stimulus, such as a bell, was presented just prior to the presentation of an aversive stimulus such as an electric shock or a pin prick. Normally, such aversive stimuli presented alone will produce a variety of negative responses such as whining/whimpering and fear-type reactions such as urination. When the bell preceded such an aversive stimulus, eventually the formerly neutral bell stimulus would automatically produce the negative emotional responses.

In another variety of this design, Pavlov then evaluated what would happen if, instead of preceding food with the sound of the bell, it was preceded by the aversive stimulus such as electric shock. What Pavlov found in this situation was that, after this conditioning, the dogs subsequently failed to demonstrate any negative emotional responses to the aversive stimulus. Instead, these dogs began perceiving these painful stimuli as signals that food was on the way. The electric shock now actually elicited salivation and approach behaviors!

Operant Conditioning

Operant conditioning (also referred to as instrumental conditioning) is a different form of learning that was originally formulated by Edward Thorndike (1874–1949), and then more comprehensively developed by B. F. Skinner (1904–1990). Unlike classical conditioning, operant conditioning develops new behaviors that bring about positive consequences or remove negative events. In classical conditioning, a new stimulus (such as a bell) is conditioned to elicit the same responses that had previously occurred to the unconditioned stimulus, whereas in operant conditioning, a new response is learned. For example, new behaviors that produce food, social approval, or other positive consequences, or that reduce damaging or aversive events, illustrate operant behavior. The behavior ''operates'' on the environment to bring about changes in it. Thus, animal training, such as that involved in the learned performance of circus animals, involves basic principles of operant conditioning. Although operant training has existed for centuries, the behaviorist revolution in psychology provided the first carefully delineated methods and procedures of operant conditioning so that such training could be accomplished most efficiently.[1] The key stimulus is **reinforcement**. Reinforcement refers to any consequence that increases the likelihood that a particular behavior will be repeated or that strengthens that behavior. **Extinction** involves the gradual decrease in the strength or tendency to perform a response due to the elimination of reinforcement. Based upon these principles, what came to be known as the ''Skinner box'' was devised as an enclosed plexiglas box in which there was a light above a lever. The lever could be pressed down by the animal with its paws (rats were used in these early studies). Below the lever was a food tray into which food pellets could be dispensed. The task of the animal was to learn that pressing the lever (a certain number of times or at a certain rate, predetermined by the experimenter) resulted in food pellets being dispensed in the food tray. Thus, the animal learned to operate on the environment (the lever in the box) in order to receive reinforcement (food pellets).

Once the above response was learned, one could then introduce different **reinforcement schedules** in order to produce different patterns of responding. Reinforcement could now require variable numbers of bar presses or could be available every so often. Also, a *discriminative stimulus* could be introduced, so that the rat received reinforcement for pressing the bar only when the light was on in the box. The animal would soon learn not to respond when the light was off. In this manner, the rat's bar-pressing behavior came under **stimulus** (e.g., light) **control**.

This same shaping procedure is used in training circus and other animals to perform complicated acts. Dolphins can be shaped to leap out of the water and lions can be taught to jump through flaming hoops in order to receive some reinforcement. These techniques are used in virtually every zoo and marine animal show.

Observational Learning

Finally, the third major form of learning is called observational learning. There has been a great deal of research indicating that learning can occur through simple observation without the presence of any form of tangible direct reinforcement. Such learning, besides being called *observational learning*, is sometimes called imitation learning, cognitive learning, vicarious learning, or modeling. Observational learning is defined simply as that learning which occurs without any apparent direct reinforcement.[2] Many behaviors can be acquired if an individual sees the particular behavior performed or modeled by another person. In addition, behavior is often strongly guided by social norms, resulting in a given individual being motivated to adopt a set of behaviors that are consistent with these norms.[3,4] Observational learning is one such mechanism that transmits knowledge of these norms to the individual. These norms can be either explicit or implicit, and they can operate at the level of specific groups an individual may identify with, in addition to norms dictated at the larger societal level.

One of the earliest laboratory studies of observational learning[5] involved nursery school children. One group of children observed an adult perform a series of aggressive acts, both verbal and physical, toward a large toy Bobo doll. Another group watched a nonaggressive adult, who simply sat quietly and paid no attention to the doll. A third group of children was not exposed to a model. Later, after being mildly frustrated, all children were placed in a room alone with the Bobo doll and their behavior was observed. It was found that the behavior of the two model groups tended to be similar to that of their adult model. That is, children who had viewed the aggressive adult performed more aggressive acts toward the doll in the free-play situation than the other groups and also made more responses that were exact imitations of the model's aggressive behavior. Those children who had observed a nonaggressive adult model performed significantly fewer aggressive responses than the aggressive model group.

OPERANT CONDITIONING AND PAIN

The Hallmark Work of Wilbert Fordyce

As discussed earlier, and as reviewed by Gatchel,[6] operant conditioning refers to the strengthening of a response and behavior through reward or reinforcement. That is to say, the probability that a behavior will be performed again is increased if it is followed by some form of reinforcement. Behavior is controlled by its consequences. If a behavior is followed by a reward, it has a high probability of recurring; if it is ignored or punished, it has a low probability of recurring. Obviously, a great deal of our everyday behavior is learned and maintained through operant

conditioning. For example, most of us work because of the rewards (both tangible, such as money, and intangible, such as a pleasant work environment) that it produces.

In terms of pain, many times a person in pain will elicit a great deal of sympathy and attention (both of which are rewarding). In addition, suggestions are usually made by others to rest and stay inactive, pain-relieving medications are usually administered, and often financial compensation is provided. The longer these reinforcing consequences continue, the longer the patient is likely to display the maladaptive pain behaviors such as inactivity and avoidance of work. Thus, this type of learning or conditioning can significantly contribute to the maintenance of pain behavior.

As pointed out by Baum, Gatchel, and Krantz,[1] this operant conditioning conceptualization of pain was systematically employed in the operant pain treatment program originally developed at the University of Washington's Department of Rehabilitation Medicine by Fordyce and colleagues.[7] This program involved a 4 to 8 week inpatient period, designed to gradually increase the general activity level of the patient, and to decrease medication usage. The program was based on the assumption that, although pain may initially result from some underlying organic pathologic condition, environmental reinforcement consequences (such as attention of the patient's family and the rehabilitation staff) can modify and further maintain various aspects of "pain behavior," such as complaining, grimacing, slow and cautious body movements, requesting pain medication, and so on. Viewing pain as an operantly conditioned behavior, Fordyce assumed that the potentially reinforcing consequences, such as the concern and attention from others, rest, medication, avoiding unpleasant responsibilities and duties, as well as other events, frequently follow and reinforce the maladaptive pain behavior and, as a consequence, hinder the patient's progress in treatment.

In their treatment program, Fordyce and colleagues[7] systematically controlled environmental events (e.g., attention, rest, medication) and made them occur contingent on adaptive behaviors. A major goal of the program was to increase positive behaviors, such as participation in therapy and activity level, while simultaneously decreasing or eliminating negative pain behaviors. It should also be noted that members of the patient's family were actively involved in the treatment program and worked closely with the rehabilitation staff. They were taught how to react to the patient's behavior in a manner that would reduce pain and to maximize the patient's compliance with, and performance in, the rehabilitation program. Using this operant approach, the patient was basically taught to reinterpret the sensation of pain and tolerate it, while performing more adaptive behaviors that would gain the attention and approval of others. Such a program was initially conducted in the hospital, and would later be continued on an outpatient basis. These programs proved to be very successful at decreasing pain behaviors while increasing the levels of activities of daily living.

Of course, such examples do not imply that all pain is learned. The point being made is that our pain perceptions and responses often have a significant psychologic learning component that directly and significantly contributes to these experiences of pain. Thus, psychologic variables play a direct role in the pain experience. How one reacts to pain sensations is as important an issue as the specific physiologic mechanisms involved in transmitting and generating pain experiences. Pain is a complex behavior and not simply a sensory effect.

With the above view in mind, it is clear that one must conceptualize pain like any other form of complex behavior, consisting of multiple behavioral components. As Fordyce and Steger[8] have indicated, in order to describe pain, "there must be some form of pain behavior by which diagnostic inferences and treatment judgments can be made. A patient will signal the type of pain he or she is experiencing by describing the intensity, frequency, location, and type of pain experienced. In addition to these verbal cues available to the patient's environment as an indication of his or her pain, there is a myriad of nonverbal signs used to communicate pain experiences. These include grimaces, sighs, moans, limps, awkward or strained body positions, the use of a cane or crutch, and many other symbols associated in our society with discomfort or physical problems.

Traditionally, in attempts to describe pain, the focus was only on the physiologic or structural mechanisms underlying the report of pain and not on other components such as behavioral indices and self-report. The reliance on strictly one component, such as structural measures, does not yield a valid or precise measure of an individual's pain. Again, pain is a complex behavior and not purely a sensory event. One needs to consider multiple behavioral components in the assessment and treatment of this behavior.

Operant Conditioning and Chronic Pain: The Basics

Sanders[9] has provided an excellent overview of the key ingredients involved in the use of operant conditioning methods when managing chronic pain. Of course, as he appropriately points out, operant conditioning methods should not be viewed as the only technique to use in managing chronic pain. Rather, it is just one of a number of behavioral science methodologies that can be used in combination/unison with other methodologies. Operant techniques can be used to help significantly decrease many common overt pain behaviors, such as the following:

- Verbal pain behaviors, such as overt expressions of hurting (e.g., moaning, sighing, complaining, etc.)
- Nonverbal pain behaviors, such as limping, grimacing, overreliance on a cane or brace, rubbing the affected area, etc.
- Overly sedentary activities, such as decreased activity level, sitting, and lying down.
- Overconsumption of medications and the sole reliance on other therapeutic devices to control pain.

Rather than engagement in the above maladaptive pain behaviors, the patient is encouraged and reinforced to engage in "well behaviors" that involve more positive activity and alteration away from the overfocusing on pain. Through a comprehensive approach, health care professionals, family members, and others reinforce and encourage these well behaviors while other effective pain management techniques are learned by the patient, such as biofeedback, stress management, coping skills, and appropriate pharmacotherapy, which is closely maintained. The overall goal is to increase function which will then be accompanied by a decrease in pain.[6]

CLASSICAL CONDITIONING AND PAIN

Aversive Classical Conditioning and Pain

As discussed earlier in this chapter, Pavlov conducted studies demonstrating that when an initially neutral stimulus (such as a bell) was presented just prior to the presentation of an aversive, painful stimulus (such as electric shock) which will, in turn, produce negative emotional responses (such as whimpering, fear, avoidance, etc.), then the bell itself will produce the negative emotional response when presented by itself. We then may generalize this to a patient who developed a sudden painful back problem at work, which does not go away after several days, after which just the act of going to work and anticipating lifting a heavy object may produce a negative emotional response such as fear of lifting and possible avoidance of the workplace because of pain.

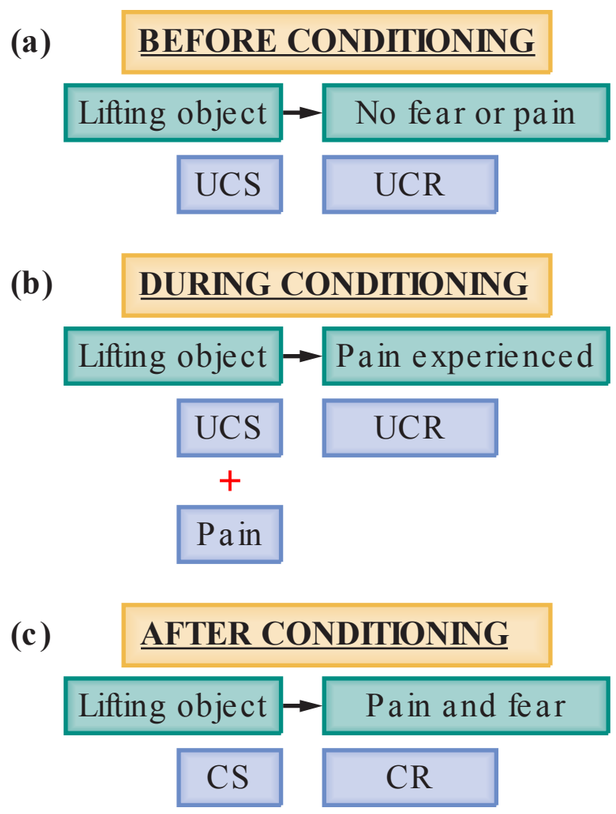

FIGURE 30.2 Classically conditioned fear and pain during a work task (lifting an object).

Classically Conditioned Fear/Avoidance and Pain

Figure 30.2 presents the conditioning sequence that a person may go through in the situation described above. (a) At first, before conditioning, there is no association between lifting an object at work and any avoidance of lifting because of fear of pain. (b) During conditioning, the individual now begins to experience some back pain while lifting objects at work. This pain becomes progressively worse over time, to the point that this person hesitates to lift anything because of fear of exacerbating the back pain he/she is already experiencing. (c) After conditioning, any prompting or requirement to lift an object automatically produces a fear response and active avoidance of any lifting to avoid pain. There is now a classically conditioned negative emotional response of lifting objects at work because of the fear of pain.

How can the above classically conditioned association between lifting and a fear of pain response be broken? As Pavlov's experiments have shown, just as a conditioned association can be learned, it can also be subsequently extinguished or broken under the right situations. One such method would be to initially teach patients how to correctly lift, while keeping their back muscles relaxed. The weight they are then asked to lift is kept relatively light and then progressively made heavier as the individual is able to lift a certain weight while relaxed and not experiencing any pain. The person is also taught appropriate pacing skills so that enough time is given between lifts for his or her back muscles to recuperate before performing the next lift. Thus, fear of lifting becomes "deconditioned" or extinguished in this work situation.

OBSERVATIONAL LEARNING AND PAIN

Observational learning is defined simply as that learning which occurs without any apparent direct reinforcement.[2] Many behaviors can be acquired if an individual merely sees the particular behavior displayed or modeled by another person. Examples of behaviors acquired by observational learning abound. For example, investigations of dental fears in children have revealed that the attitudes and feelings of a child's family toward dental treatment are important in determining that child's own anxiety toward dental treatment. In one such study, it was found that children with anxious mothers showed significantly more emotionally negative behaviors during a tooth extraction than did children of mothers with low anxiety.[10]

In our society, there is a great deal of potential observational learning that can negatively influence comprehensive pain management effects. We are constantly being bombarded by advertisements that certain medications or pills will make us feel better. This, in turn, produces an unfortunate iatrogenic effect on patients who assume that there is some magic "silver bullet" pill or procedure that will automatically make them feel better and take away their pain. Unfortunately, such expectations are often not realized. Thus, patient education is often initially needed to dissuade patients of the notion that there is an immediate magical cure for their pain, especially as it becomes more chronic in nature.

Social norms can also influence an individual's response to pain, often through the mechanisms of observational learning. These normative influences play a role in behaviors associated with the reporting of pain, seeking treatment for pain, and level of pain tolerance. A study by Sternbach and Tursky[11] was among the earliest investigations that illuminated our further understanding of how normative factors influence responses to pain. In this study, the results implied that cultural differences associated with ethnicity played a role in an individual's tolerance of painful electrical stimulation. Parallel results in terms of ethnic differences were also demonstrated when physiological indices (such as heart rate and palmar skin resistance levels) were measured in response to painful electrical stimulation, despite relatively large intraethnic group variation.[12]

Recent studies have also demonstrated the role played by ethnic differences. For example, ethnicity has been reported to account for differences in self-reported levels of pain, as well as for tolerance of induced ischemic pain, during a study on a sample of chronic pain patients.[13,14] Cultural differences are also apparent in treatment preference and levels of health care utilization. A large population-based survey in the United States indicated that Caucasians had greater number of visits on average compared to African-Americans and Hispanics and were more likely to have received complementary or alternative therapies for chronic pain.[15]

Early research on the association between gender and responses to pain also indicated that females had a lower tolerance level for experimentally induced pain,[16] and were also more likely to report pain within clinical settings.[17] However, recent research has indicated that the extent of an individual's identification with their own gender group norms moderate their tolerance of pain. Gender differences in the tolerance of experimentally-induced pain are present only among individuals strongly identifying with social norms that dictate that men should tolerate more pain than women.[18] While it remains to be seen whether social norms also dictate gender differences in the probability of seeking treatment for pain, there is a demonstrable gender difference in health care utilization among chronic pain patients, with females being more likely to seek treatment for pain.[19]

INTEGRATING LEARNING PRINCIPLES IN THE TREATMENT OF PAIN

Cognitive–Behavioral Therapy and Pain

As Turk[20] has highlighted in his discussion of the cognitive–behavioral treatment (CBT) approach to pain, there are important behavioral learning theory principles that are part of this overall therapeutic perspective. Certainly, classical conditioning (a focus on eliminating conditioned fear avoidance), operant conditioning (such as not reinforcing pain behavior), and observa-

tional learning (such as education about the negative iatrogenic expectation of immediate pain relief) are all important components. However, in addition, Turk[20] appropriately points out the fact that cognitive factors, in addition to behavioral factors, need to be considered: ''The critical factor for the C–B model, therefore, is not that events occur together in time or are operantly reinforced but that people learn to predict them based on experiences and information processing. They filter information through their preexisting knowledge and organized representations of knowledge (e.g., cognitive scheme) . . . and react accordingly . . . Because interaction with the environment is not a static process, attention is given to the ongoing reciprocal relationships among physical, cognitive, affective, social, and behavioral factors'' (p. 140). This perspective is in keeping with the biopsychosocial approach to pain,[6] to be discussed later.

With this above perspective in mind, there is no doubt that CBT is an effective treatment modality for the management of pain. Morley, Ecclestan, and Williams,[21] on the basis of their systematic review of the scientific literature and a meta-analysis of randomized controlled trials, found that CBT produced significantly greater changes in self-reported pain and cognitive coping, as well as reduced behavioral expressions of pain, relative to waiting list control patients and alternative treatment control conditions. In a more recent comprehensive review, Gatchel and Okifuji[22] found comparable results. Table 30.1 provides a summary of some of the components of CBT, as delineated by Gatchel.[6]

Cognitive–Behavioral Therapy as an Essential Component of a Comprehensive Interdisciplinary Approach to Pain Management

The biopsychosocial perspective of pain is now accepted as the most heuristic approach to the understanding and treatment of pain disorders.[6,23] It views physical disorders, such as pain, as a result of a complex and dynamic interaction among physiologic, psychologic, and social factors that perpetuate and may worsen the clinical presentation. Moreover, each individual experiences pain uniquely. Therefore, the range of psychologic, social, and economic factors can interact with physical pathology to modulate a patient's report of symptoms and subsequent disability. As a consequence, a comprehensive biopsychosocial approach to assessment and treatment must be employed with each patient because of the unique interactions, as well as to tailor the treatment to the specific needs of the patient. This is why comprehensive interdisciplinary pain management programs have proven to be more therapeutic and cost-effective than traditional unimodal treatment approaches.[22]

Within an interdisciplinary treatment program, there is a comprehensive treatment team that consists of the following: physician/nurse team to deal with medical issues, psychologist or psychiatrist to deal with the psychosocial issues of patients, a physical therapist to address any issues related to physiologic bases of pain, as well as any issues related to physical progression toward recovery, and an occupational therapist who is involved in both physical and vocational aspects of the patient's treatment. For such a program to be effective, constant and efficient communication among all treatment personnel is imperative, during which patient progress can be discussed and evaluated. This is important so that patients hear the same treatment philosophy and message from each of the treatment team members. The overall goal is to produce an increase of functioning and the ability to manage pain and disability.

It is a major goal of the psychologist or psychiatrist to increase the patient's understanding of pain, as well as their coping skills required to manage the pain. This is where CBT plays a major role. Of course, in keeping with the biopsychosocial perspective, it is not a stand alone treatment, but must be integrated with the other components of therapy in order to yield the best long-term outcomes.[6]

TABLE 30.1

SUMMARY OF SOME OF THE MAJOR COMPONENTS OF COGNITIVE–BEHAVORIAL THERAPY

- Education of patients about pain and their particular syndrome.
- Engender in patients a self-management and coping skills perspective to pain.
- Help patients focus on increasing physical functioning and management of their pain, rather than expecting a sudden cure.
- Teaching biofeedback, relaxation, and stress management techniques.
- Providing patients with coping skills in other areas, such as with interpersonal problems, work-related problems, marital problems, etc.
- Emphasize to patients the importance of identifying, and then eliminating, maladaptive thoughts about pain.
- Provide patients with guidance about increasing activities of daily living (in order to distract them from pain), with appropriate pacing activities.
- Provide help to improve sleep.
- Review the appropriate use of potential adjunctive modalities, such as medications, exercise, and physical methods (e.g., cold and heat packs).
- Assist patients with appropriate goal setting for the future (e.g., when to return to work or other activities).
- Provide relapse prevention strategies in order to help cope with potential future relapses.

(Adapted from Gatchel RJ. Clinical Essentials of Pain Management. Washington, DC: American Psychological Association; 2005.)

CONCLUSION

Pain is a complex behavior and is, therefore, subject to the general principles of learning and behavior change. The three major principles of learning include classical conditioning, operant conditioning, and observational learning. These principles play an important role in the development of pain behavior (e.g., social or environmental factors that can reinforce maladaptive pain behavior). However, these learning principles can also be effectively utilized in the treatment and management of pain. The biopsychosocial approach to the treatment and management of pain emphasizes interdisciplinary treatment modalities and eschews a ''one-size-fits-all'' approach in dealing with pain. Learning principles are therefore an important component in this approach due to its flexibility in addressing complex behavioral history at the individual level. CBT incorporates these learning principles and has been documented as an effective component of interdisciplinary pain management.

CHAPTER 31 ■ PSYCHIATRIC ILLNESS, DEPRESSION, ANXIETY, AND SOMATOFORM PAIN DISORDERS

AJAY D. WASAN, MARK D. SULLIVAN, AND MICHAEL R. CLARK

INTRODUCTION

Chronic pain and psychiatric illness are fundamentally linked in prevalence, pathophysiology, and patient outcomes.[1] Yet, the high rates of psychiatric illness in patients with chronic cancer and noncancer pain are still poorly understood. Diagnostic hierarchies taught to physicians in medical school and residency, impairment rating strategies used by compensation systems, and the natural scientific method used by medicine that looks for objective causes for clinical phenomena force us into a mind–body dualism. Engel did much of the early research to codify this Cartesian concept into the notion of psychogenic pain.[2] *Psychogenic pain* is defined as pain due to psychological factors in the absence of an organic basis for pain.[3] Subsequently, Merskey and others extended this concept into our lexicon of pain taxonomy.[4] If we cannot explain pain in terms of objective tissue pathology, Western biomedicine lures us to explain it in terms of patients' psychopathology.[5,6] Although this dichotomy has been popular in clinical settings historically, current scientific evidence for it is lacking.[7]

Evidence indicates that the majority of patients with chronic pain and psychiatric illness have a physical basis for pain in the body, whose perception is made worse by overlying psychiatric illness.[8] Epidemiologic evidence supports the use of inclusive rather than exclusive models of psychiatric diagnoses in medical settings that allows for the presence of both medical disease and mental disorders (i.e., a comorbidity model). Medical illness in no way excludes the possibility of a clinically important psychiatric illness. Medically ill patients are much more likely to have psychiatric illness than patients without medical illness. Psychiatric illness in no way precludes the possibility of a clinically important medical illness. Psychiatric illness is, in fact, associated with health behaviors and psychophysiologic changes known to promote medical illness. Even disorders seeming purely of the mind, such as conversion disorder, have been correlated to alterations in brain structure and function,[9] illustrating the interplay between mind and brain.

The structure of our clinical settings makes the integrated delivery of mental and physical health care difficult. Nowhere is this more important than in the care of the patient with chronic pain. Psychotherapeutic and psychopharmacologic interventions for chronic pain are rarely effective in isolation from somatic treatments, and the success of somatic treatments is diminished by co-occurring mental illness. Distress, disuse, and disability are important facets of a chronic pain problem, and all require clinical attention by the pain practitioner. Neglect of one of these components can result in treatment failure even in the presence of excellent care for the other components. Research has indicated that psychiatric comorbidity has an adverse impact on treatments for chronic pain, such as rehabilitation, spinal cord stimulation, or opioid therapy.[3,10] While the details of these interactions are quite relevant to understand, this chapter concentrates on the recognition and diagnosis of psychiatric illness in patients with chronic pain, a sizable task in itself. Similarly, psychiatric comorbidity has been shown to be particularly prevalent in and salient to the outcomes of a range of noncancer pain disorders (e.g., chronic low back pain,[11] fibromyalgia,[12] temporomandibular joint disorders,[13] chronic daily headache,[14] and chronic pelvic pain[15]). However, the specific role comorbid psychopathology plays in each of these disorders is beyond the scope of this chapter.

This chapter will first outline an approach to psychiatric diagnosis and to categorizing psychiatric symptoms in patients with chronic pain. Because of the breadth of psychiatric symptoms in pain patients, this section is substantial in order to provide a framework for organizing symptoms into diagnostic and treatment categories. Then the chapter will discuss the main illness categories of depression, anxiety, personality, and somatoform disorders. It is beyond this chapter to discuss to what extent a pain practitioner should evaluate and treat psychiatric problems and when to refer to a psychologist or psychiatrist.

PSYCHIATRIC NOSOLOGY AND DIAGNOSTIC AND TREATMENT APPROACHES

As noted, any discussion of psychiatric disorders in patients with chronic pain is haunted by the concept of psychogenic pain. We are drawn to the concept of psychogenic pain because it fills the gaps left when our attempts fail to explain clinical pain exclusively in terms of tissue pathology. Psychogenic pain, however, is an outdated concept that should be vanquished from our vocabulary of pain. Positive criterion for the identification of psychogenic pain, mechanisms for the production of psychogenic pain, and specific therapies for psychogenic pain are lacking. Furthermore, neuroimaging studies indicate that anticipated pain, imagined pain, or empathizing with the pain of another are associated with activations of the same brain areas involved in processing a painful stimulus, such as applied noxious heat (the lateral and medial pain systems).[16,17] Thus, there is a dynamic interaction between our mental states (mind) and brain function. The dichotomy between mind and body (including brain) underlying the concept of psychogenic pain is hollow. As will be discussed later in this chapter, it may be more useful to frame the contributions of the mind to pain perception in terms of a process of somatization.

Psychiatric diagnosis of many disorders, such as depression, can be helpful to the clinician and patient by pointing to specific effective therapies. The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) lists the current diagnoses treated by psychiatrists and the specific symptoms that serve as descriptive criteria for each condition.[18] However, the *DSM* offers only consistency and reliability and does not differentiate the disorders according to the basic natures from which the phenomenology emerges, demonstrate any interrelationships among disorders, or prove that there is a criterion on which the validity of the diagnosis rests.[19] This is particularly true of psychiatric disorders in those with medical illness. Most psychiatrists tend to use the *DSM* as a guide to or an outline of the major diagnoses, not as a definitive diagnostic method. As a descriptive tool, many of the symptom lists for *DSM* diagnoses are quite complete and will be referred to throughout this chapter. However, when patients with chronic pain are in need of psychiatric care, they want to know the generative nature of their conditions and how to differentiate them for the sake of receiving prognoses and treatments.[20] The *DSM* and its descriptive companion, the biopsychosocial approach, offer only the ingredients and end products but not the recipes and processes for validation. Multidisciplinary pain treatment functions with the same limitations.[21,22] Without the method to determine a set of unique causes and direct specific treatments, the patient receives symptomatic treatments with the expected "partial" response. Despite the involvement of more disciplines, the message is clear cures for "organic" problems and management for "functional" problems. Cartesian dualism lives.

Patients with chronic pain come to or are referred to a psychiatrist because they are ill. In some way, they are considered a diagnostic dilemma.[23,24] Despite the utilization of extensive health care resources to perform an exhaustive evaluation, the patients remain ill. A temptation emerges to diagnose them with a psychogenic problem because no "good" cause can be found for their persistent pain and the accompanying disability and suffering.[25] The cause for their illness cannot be found until the investigation expands to include the domain of personal consciousness.[26] This realm contains not only the diseases of the brain (cerebral faculties) but also the disruptions of the motivational rhythms of behavior, the psychological constitution of the individual, and the personal chronicle of desire and encounters. All mental disorders are expressions of life under altered circumstances that affect characteristic mental capacities and generate particular expressions.[27,28] These distinctions allow for independently informed perspectives about the nature of mental disorders and what may have happened to generate the disorder. Four perspectives (diseases, behaviors, dimensions, and life stories) represent classes of disorders that each have a common essence and logical implications for causation and treatment.[29,30] In this approach to patient care, diseases are what people *have*; behaviors are what people *do*; dimensions are what people *are*; and life stories are what people *encounter*. The formulation of a patient with chronic pain should address the contributions from each perspective to the overall presentation and inform the design of a treatment plan that can address each component of the patient's illness. While the basis for a mental illness may be dominated by one perspective (i.e., the disease perspective in schizophrenia), generally each psychiatric diagnosis has contributions from each perspective that are responsible for the onset and maintenance of the disorder.

Diseases of the brain manifest psychologically. The psychological faculties of the brain include but are not limited to consciousness, cognition, memory, language, affect, and executive functions. Abnormalities in the structures or their associated functions of these faculties are expressed in the criteria that describe the common diagnoses such as delirium, dementia, panic disorder, and major depression. However, the patient may describe deficits in these faculties with difficulty and rely on somatic symptoms (e.g., pain) as incomplete proxies for these criteria. The physical symptoms occur because the brain is malfunctioning and suggesting pathology in the body. The unifying feature of diseases is a broken part within the individual that is causing pathology.[30] The pathology causes the characteristic signs and symptoms typically manifested by the affliction.[28] For the patient, there is no meaningful interpretation to be understood, no individual deficiency to be addressed, and no goal that is trying to be achieved. Finding a cure may repair the broken part, prevent the initial damage from progressing, or compensate for the pathology through secondary compensatory measures.

The perspective of *behavior* encompasses a wide range of actions and activities. The complex behaviors of human beings are designed with the purpose of achieving goals. Human consciousness is characterized by the regular, rhythmic alterations of attention and perception produced by internal drives that increase a person's motivation toward a particular activity.[30,31] The drive pushes the individual into action. Then, after the actions, the drive is satisfied and a state of satiety emerges. Over time, drives re-emerge with subsequent effects on the individual's perceptual attitude toward his setting. In addition, personal assumptions or external opportunities increase the likelihood of certain behaviors. These present a choice to the person, who must decide what action to take. After the choice is made and the behavior completed, external consequences emerge from the outcome and influence future actions. The person learns which choices are most effective. When aspects of choice and control over behavior become disrupted, physicians will be asked to address the distorted goals, excessive demands, damaging consequences, and a lack of responsiveness to negative feedback.[32,33] Eating disorders are but one example. Treatment of behavioral disorders begins with regaining temporary control of the situation by stopping the behavior.[34] Restricting the patient's actions and preventing these prob-

lematic behaviors eventually limits the chaos of destructive actions. This stable foundation is required for the patient to gain insight about and motivation toward appropriate choices that will result in less distress and more satisfaction.[35] This basis for the effectiveness of behavioral approaches to chronic pain management is outlined in other chapters.

In contrast, many mental disorders emerge not from a disease of the brain or some form of abnormal illness behavior but a patient's personal affective or cognitive constitution.[30,31] Each individual possesses a set of personal *dimensions*, such as intelligence, extraversion, and neuroticism. These traits describe who a person is, and they are carried into the world as a set of innate capabilities of their psychological makeup. Which traits are relied upon and how much of them a person possesses will determine his potential to cope with different situations. Some circumstances are overwhelming and provoke a person's vulnerability to distress. The patient cannot manage the situation and what is required because of who he is. Borderline personality disorder is an example. It is probably the most severe personality disorder and generally is evident prior to the onset of pain. Assessment of personality traits are discussed at greater length below. Treatment for disorders of the dimensional type focuses on remediation of specific deficiencies and guidance about overcoming potential vulnerabilities through adaptations such as education about, assistance with, or modification of the particular stressors.[22,34]

The *life story* perspective utilizes a narrative composed of a series of events that a person encounters and determines to be personally meaningful.[30,31] These self-reflections are the means by which a person judges the value of his life as a whole. They impart a sense of self as the agent of a life plan unfolding in a social setting as well as the reflective subject experiencing and interpreting the outcome of such plans and commitments. If events occur as planned, then the person feels on track and successful. However, if the sequence of events results in an unexpected or disappointing outcome, the person will feel a sense of distress about this failure. Life story disorders are interpretive responses to life encounters such as grief from loss or anxiety due to expected threats.[32,36,37] In patients with chronic pain, the demoralization resulting from the inability to work or perform normal duties is a good example. Treatment begins with the expectation to forge a narrative of setting and sequence that suggests some role of the patient in his life and that illuminates the troubled state of mind as the outcome of that role and course of events.[22,34] The effective treatment of life story disorders requires reframing and reinterpretation to remoralize the patient by transforming the story into one with the potential for success and fulfillment.

The four perspectives provide a comprehensive yet flexible approach to the evaluation of a patient in distress with chronic pain and other somatic symptoms.[30,38] The treatments prescribed are now designed from the individual formulation and relevant perspectives. If a patient's symptoms and distress continue, the physician must consider other factors that may have been overlooked. Usually these factors are within one of the perspectives initially thought to be less important. A new combination of therapies is then required to treat the patient successfully. In the discussion that follows, categories of psychiatric disorders as defined in the *Diagnostic and Statistical Manual*, fourth edition, of the American Psychiatric Association (*DSM-IV*, 1994) are used as an organizing strategy. Understanding the relevant contributions from each perspective is important to formulating treatment.

FRAMEWORK FOR DESCRIBING PSYCHIATRIC SYMPTOMS

Figure 31.1 illustrates common psychiatric symptoms in patients with chronic pain. However, Figure 31.1 does omit substance use disorders, which are beyond the scope of this chapter. It is important to note that approximately 15% of all patients with chronic pain have a comorbid substance use disorder, whether it is alcoholism or prescription opioid abuse, etc.[39] Psychiatry-based research and health psychology–based research have contributed important insights into characterizing the mental life of patients with chronic pain. The findings from these epistemologies overlap significantly, but, unfortunately, there is no agreed-upon model for integrating these results.[40] Common terms to describe the psychological condition in pain patients are heightened emotional distress, high negative affect, and elevated pain-related psychological symptoms (i.e., those that are a direct result of chronic pain, and when the pain is eliminated, the symptoms disappear). These can all be considered forms of psychopathology and psychiatric comorbidity, since they represent impairments in mental health and involve maladaptive psychological responses to medical illness. This approach melds methods of classification from psychiatry and behavioral medicine to describe the scope of psychiatric disturbances in patients with chronic pain. *Psychiatry* is the field of medicine that is concerned with someone's mental life, such as their emotions, experiences, thoughts, and behav-

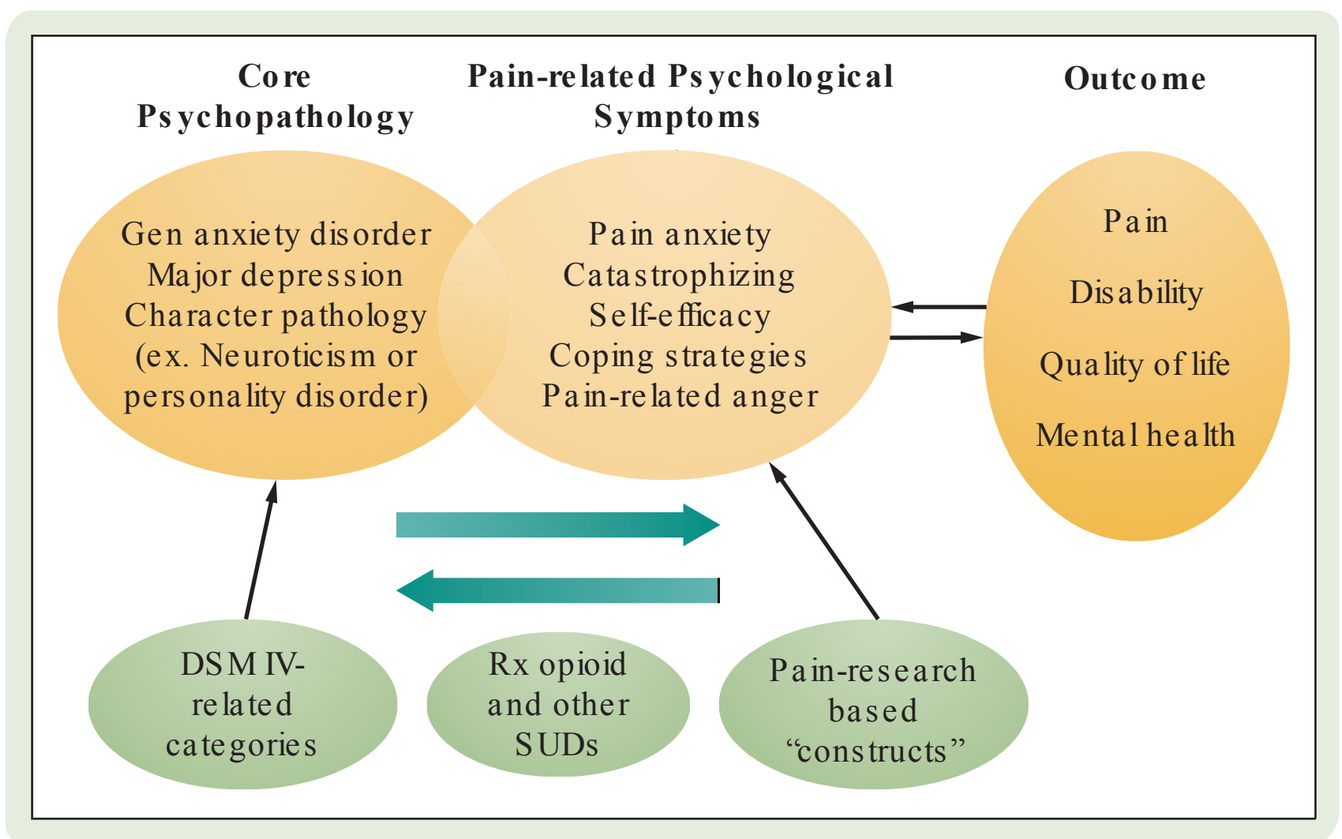

FIGURE 31.1 Common psychiatric symptoms in patients with chronic pain.

iors. It is focused particularly on disruptive, disordered, or pathological psychological states. Thus the constructs from pain-psychology are situated in Figure 31.1 as psychiatric symptoms, which in themselves can be at pathological levels, just as depression symptoms can rise to a level considered abnormal.

In pain patients the most common manifestations of psychiatric comorbidity involve one or more core psychopathologies in combination with pain-related psychological symptoms. For instance, poor pain self-efficacy or high levels of pain catastrophizing are most often found in conjunction with high levels of depression or anxiety symptoms.[41] These categories interact and some component of each are part and parcel of other psychopathologies. In other words, "lumping" (a diagnostic approach) and "splitting" (a construct-based approach) are both valid approaches to psychiatric phenomenology. As described in the previous section, not all patients and their psychiatric symptoms fit neatly into *DSM* categories of illness. This is true not just of those with chronic pain, and hence looking beyond *DSM* to broader and more specific methods of illness description and diagnosis is more prudent.

The pain-related psychological symptoms are described at length in other chapters, but it is important to understand how they interact with other psychiatric diagnoses. For example, pain-related anxiety (which includes state and trait anxiety related to pain) is the form of anxiety most germane to pain.[42] Elevated levels of pain-related anxiety (such as fear of pain) also meet *DSM-IV* criteria for an anxiety disorder due to a general medical condition. Since anxiety straddles both domains of core psychopathology and pain-related psychological symptoms, the assessment of anxiety in a patient with chronic pain (as detailed below) must include a review of manifestations of generalized anxiety as well as pain-specific anxiety symptoms (e.g., physiological changes associated with the anticipation of pain).

As indicated in Figure 31.1, elevated pain-related psychological symptoms have a clear, negative predictive relationship to many outcome areas. Poor coping skills often involve passive responses to chronic pain; for example, remaining bed-bound and mistakenly assuming that chronic pain is indicative of ongoing tissue damage as a reason for inactivity. Poor copers employ few self-management strategies (such as using ice, heat, or relaxation strategies for 10 to 20 minutes before resuming activities). Pain catastrophizing (cognitive distortions that are centered around pain), and low self-efficacy (a low estimate by the patient of what he/she is capable of doing) are linked with higher levels of pain and disability and worse quality of life.[40] A tendency to catastrophize often predicts poor outcome and disability, independent of other psychopathology such as major depression. Duration of chronic pain and psychiatric comorbidity are each independent predictors of pain intensity and disability. High levels of anger (which occur more often in men) can also explain a significant variance in pain severity.[43]

TABLE 31.1

DIAGNOSTIC AND STATISTICAL MANUAL, FOURTH EDITION, CRITERIA FOR MAJOR DEPRESSIVE EPISODE

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
   1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). Note: In children and adolescents, can be irritable mood.
   2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others).
   3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or a decrease or increase in appetite nearly every day. Note: In children, consider failure to make expected weight gains.
   4. Insomnia or hypersomnia nearly every day.
   5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
   6. Fatigue or loss of energy nearly every day.
   7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
   8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
   9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The symptoms are not caused by the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

D. The symptoms are not better accounted for by bereavement (i.e., after the loss of a loved one) or the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:395, with permission.

DEPRESSION

One must begin by distinguishing between depressed mood and the clinical syndrome of major depression. It is important to note, especially when working with chronic pain patients, that depressed mood or dysphoria is not necessary for the diagnosis of major depression. Anhedonia, the inability to enjoy activities or experience pleasure, is an adequate substitute. It is common for patients with chronic pain to deny dysphoria but to acknowledge that enjoyment of all activities has ceased, even those without obvious relation to their pain problem (e.g., watching television for a patient with low back pain).

The *DSM-IV* criteria for major depressive episodes are listed in Table 31.1. These include psychological symptoms, such as worthlessness, and somatic symptoms, such as insomnia. The three core symptoms of major depression in patients with pain (which also holds true in those without pain) are low mood, impaired self-attitude, and neurovegetative signs.[44] It is important to note that somatic symptoms count toward a diagnosis of major depression unless they are caused by "the direct physiologic effects of a general medical condition" or medication. The poor sleep, poor concentration, and lack of enjoyment often experienced by patients with chronic pain are frequently attributed to pain rather than depression. However, they may or may not be a direct physiologic effect of pain. Given the high rates of depression in chronic pain patients, in the context of low mood com-

plaints it is best to attribute these symptoms to a diagnosis of depression. Indeed, studies of depression in medically ill populations have generally found greater sensitivity and reliability with "inclusive models" of depression diagnosis than with models that try to identify the cause of each symptom.[45] Similarly, just as in those without pain, those with depression and pain are very likely to also have high levels of anxiety.[46,47]

Suicidal Ideation and Behavior

Suicide accounts for 1.8% of all deaths in the world.[48] In the United States, 4.6% of the population surveyed had made a suicide attempt and 13.5% reported a history of suicidal ideation.[49] The majority of suicide attempts occur within a year of the onset of suicidal ideation. The risk of suicidality is greatest in patients with affective disorders (e.g., depression and anxiety), personality disorders, substance use disorders, and chronic debilitating physical illnesses.[50,51] Depression is the most consistent and strongest predictor of suicidal ideation.[52] In one study of patients with major depressive disorder, 58% reported suicidal ideation during a current episode of illness.[53] Suicide was attempted by 15% of these patients with 95% preceded by suicidal ideation. Hopelessness, low levels of function, perceptions of poor social support, and disorders of alcohol use predicted suicidal ideation.

Medical illnesses and chronic pain in particular, increase the risk of suicide. In a study of suicide in the elderly, medical conditions such as congestive heart failure, chronic obstructive lung disease, seizure disorder and urinary incontinence were significantly associated with suicide with treatment for multiple illnesses increasing the risk.[54] Yet, except for bipolar disorder, the highest risk of suicide was found in patients with severe pain (OR = 7.52). Pain has been studied as a contributory factor in episodes of deliberate self harm involving patients with medical problems admitted to a general hospital.[55] Multiple studies have shown that patients with chronic pain are at greater risk for suicidal ideation, suicide attempts, and suicide completions.[56]

A recent comprehensive review notes that the likelihood of death by suicide in patients with chronic pain is 2 to 3 times the rate described in the general population.[51] The lifetime prevalence of suicide attempts in patients with chronic pain ranged from 5% to 14% and the rate of suicide attempts is double that found in the general population. The lifetime prevalence of suicidal ideation associated with chronic pain is approximately 20%. The rate of suicidal ideation in patients with chronic pain is estimated to be between 5% and 24%. While a number of methods are used to commit suicide, overdoses with medications are the most common. The relationship between chronic pain and suicidality is complex. While the associations are consistent, the cause and effect pathways of transition from suicidal ideation to suicide attempt to suicide completion are more difficult to describe. At this time, no successful algorithm exists and only an in-depth and longitudinal evaluation of the patient with chronic pain offers the best strategy for detecting who is considering suicide as a personal option. While understandable, it is not the norm to be suicidal even in those with severe pain. Most commonly, suicidality in a patient with chronic pain is indicative of an underlying psychiatric disorder. Thinking one is better off dead (a passive death wish) is not the same as actively trying or wanting to kill oneself (suicidality). It is important to bear this distinction in mind in evaluating any patient with thoughts about death.

Part of the concern regarding the association between chronic pain and suicidality lies in whether chronic pain is an independent risk factor for suicidal behavior or the presence of depression completely explains this association. A thorough review described the evidence for eight pain-specific risk factors of suicidality, which is defined as suicidal ideation, suicide attempt, or suicide completion.[51] The studies available suffer from significant limitations including inadequate assessments, retrospective designs, limited control groups, and the failure to distinguish between the potential risk factors of pain versus pain-related disability. However, the existing pain literature coupled with the general knowledge of suicide supports the following as the strongest predictors of suicidality: family history of suicide, previous suicide attempts, and presence of comorbid depression. Evidence exists for other risk factors including pain characteristics (intensity, location, type, duration), female gender, comorbid insomnia, catastrophizing and avoidance, desire for escape, helplessness and hopelessness, and problem-solving deficits.[57–59] The prevention of suicide should remain a priority for the care of patients with chronic pain.

Which Came First, Depression or Pain?

Patients with chronic pain often dismiss a depression diagnosis, stating that their depression is a direct reaction to their pain problem. Psychiatry has long debated the value of distinguishing a *reactive* form of depression caused by adverse life events from an *endogenous* form of depression caused by biological and genetic factors.[60] Life events are important in many depressive episodes, although they play a less important role in recurrent and severe or melancholic or psychotic depressions.[61] Only bereavement excludes someone from a depression diagnosis who qualifies on the basis of symptoms. Determining whether a depression is a *reasonable response* to life's stress may be important to patients seeking to decrease the stigma of a depression diagnosis and has been of interest to pain investigators (for a review, see Fishbain and colleagues).[8] It is not, however, important in deciding that treatment is necessary and appropriate. Indeed, no clinical benefit is gained from debating whether the depression caused the pain or the pain caused the depression, although such information may be useful in psychotherapy. If patients meet the diagnostic criteria outlined previously, it is likely that they can benefit from appropriate treatment. There is evidence that subsyndromal depression—depression symptoms not quite satisfying the threshold for major depression but debilitating nonetheless—also benefits from treatment, and should be treated.[62–64]

Prospective studies of patients with chronic musculoskeletal pain have suggested that chronic pain can cause depression,[65] that depression can cause chronic pain,[66] and that they exist in a mutually reinforcing relationship.[67] One fact raised to support the idea that pain causes depression is that the current depressive episode often began after the onset of the pain problem. The majority of studies appears to support this contention.[68] However, it has been documented that many patients with chronic pain (especially those disabled patients seen in pain clinics) have often had episodes of depression that predated their pain problem by years.[69] This has led some investigators to propose that there may exist a common trait of susceptibility to dysphoric physical symptoms (including pain) and to negative psychological symptoms (including anxiety and depression).[70,71] They conclude that "pain and psychological illness should be viewed as having reciprocal psychological and behavioral effects involving both processes of illness expression and adaptation."

It may be useful when initiating depression treatment to accept that the pain caused the depression because it builds rapport and is consistent with epidemiologic evidence about the current depressive episode. And most frequently, depression follows the onset of chronic pain and is not preceded by it.[72]

Differential Diagnosis

When considering the diagnosis of depression in the patient with chronic pain, important alternatives include bipolar disorder,

substance-induced mood disorder, and dysthymic disorder (particularly if accompanied by a severe personality disorder, such as borderline personality disorder). Patients with bipolar disorder have extended periods of abnormally elevated as well as abnormally depressed mood. These periods of elevated mood need to last more than 1 continuous day and include features such as inflated self-esteem, decreased need for sleep, and racing thoughts. A history of manic or hypomanic episodes predicts an atypical response to antidepressant medication and increases the risk of antidepressant-induced mania. Substance-induced mood disorders can also occur in those with pain. Patients with chronic pain may be taking medications such as opioids, corticosteroids, dopamine-blocking agents (including antiemetics), or sedatives (including muscle relaxants) that produce a depressive syndrome. Current medication lists should be scrutinized before additional medications are prescribed for any patient.

Biological Tests for Depression

A variety of biological tests for depression have been investigated.[73] These tests have included the dexamethasone-suppression test, thyrotropin-releasing hormone stimulation test, clonidine-induced growth hormone secretion, and rates of imipramine binding to platelet membrane serotonin transporters. Of patients with major depression, 40% to 50% do not show normal suppression of morning plasma cortisol after receiving dexamethasone the night before. However, high false-positive rates for this dexamethasone-suppression test exist in patients who are pregnant; patients with dementia, alcoholism, anorexia nervosa, and other chronic debilitating diseases; and patients who are taking medications that induce microsomal enzymes, including barbiturates and opioids. This has limited the clinical value of this test.[74] The serotonin transport mechanism on platelet membranes is similar to that on serotonergic neurons. ^{3}H-imipramine binding to this platelet receptor is reduced in patients with major depression. It appears to be further reduced in patients who have both pain and depression.[75] Lower level of serotonin in the cerebral spinal fluid have been found in depressed patients and have been linked to suicidal ideation.[76] Although patients show significant differences on these tests, when considered as a group, substantial variation between individual patients limits the usefulness of these tests in the clinical setting. In the future, they may be able to provide a better understanding of the biochemical links between pain and depression.

Dysthymic Disorder

Dysthymic disorder is a chronic form of depression lasting 2 years or longer. The symptoms are generally less severe than those during an episode of major depression. Individuals with dysthymia can develop major depression as well. This combined syndrome has often been called *double depression*.[77] It is important to note dysthymia, because it is frequently invisible in medical settings, often being dismissed as "just the way that patient is." Dysthymia has been shown to respond to many antidepressants, including the selective serotonin reuptake inhibitors (SSRIs).[78] Treatment of double depression can be particularly challenging because of treatment resistance and concurrent personality disorders.[79] Psychiatric consultation should be considered when dysthymia or double depression is suspected.

Epidemiology of Depression

The prevalence of depression is much higher in medical settings and in patients with chronic illnesses than in the general population. It has been shown in studies using structured psychiatric interviews that a linear increase occurs in the prevalence of major depressive disorder when comparing community, primary care, and inpatient medical populations. Although 2% to 4% have major depression in the community, 5% to 9% of ambulatory medical patients and 15% to 20% of medical inpatients meet diagnostic criteria.[80] Primary care patients with major depression have been found to have more severe medical illness than those who are not depressed.[81] Even among community samples, the risk for depression appears to increase with worse perceived health status, number of chronic medical conditions, and number of medications taken.[82]

Prevalence rates of depression among patients in pain clinics have varied widely depending on the method of assessment and the population assessed. Rates as low as 10% and as high as 100% have been reported.[83] The reason for the wide variability may be attributable to a number of factors, including the methods used to diagnose depression (e.g., interview, self-report instruments), the criteria used (e.g., *DSM-IV*, cut-off scores on self-report instruments), the set of disorders included in the diagnosis of depression (e.g., presence of depressive symptoms, major depression), and referral bias (e.g., higher reported prevalence of depression in studies conducted in psychiatry clinics compared with rehabilitation clinics). The majority of studies report depression in more than 50% of chronic pain patients sampled.[84,85] There is a direct relationship between the duration of pain and the incidence of major depression. Certain chronic painful conditions are associated with higher rates of depression than others. For example, fibromyalgia, chronic daily headache, and chronic pelvic pain each are associated with higher rates than arthritis.[46,86]

Studies of primary care populations (in which generalization is less problematic) have revealed a number of other factors that appear to increase the likelihood of depression in patients with chronic pain. Dworkin and colleagues[87] reported that patients with two or more pain complaints were much more likely to be depressed than those with a single pain complaint. Number of pain conditions reported was a better predictor of major depression than pain severity or pain persistence.[87] Von Korff and colleagues developed a four-level scale for grading chronic pain severity based on pain disability and pain intensity: (a) low disability and low intensity; (b) low disability and high intensity; (c) high disability, moderately limiting; and (d) high disability, severely limiting. Depression, use of opioid analgesics, and doctor visits all increased as chronic pain grade increased.[88] Engel and colleagues showed that depression was associated with high total health care costs, but not high back pain costs among health maintenance organization patients with back pain.[89] When dysfunctional primary care back pain patients are studied for a year, those whose back pain improves also show improvement of depressive symptoms to normal levels.[90]

These epidemiologic studies provide solid evidence for a strong association between chronic pain and depression, but do not address whether chronic pain causes depression or depression causes chronic pain. As indicated previously, this question has more importance in medicolegal contexts than clinical contexts. Overall, in most instances depression follows the onset of pain.[72]

Pain and Depression: Mechanisms of Association

Beyond documenting the association of chronic pain and depression lies the question concerning mechanisms by which they may interact. Biological, psychological, and social mechanisms have been proposed to explain the high co-occurrence of chronic pain and depression. There is also substantial evidence (beyond the

scope of this chapter to recount) that the following mechanisms underlie the other psychiatric comorbidities of pain, such as anxiety disorders.

Biological Theories

Pain Sensitivity. It is well documented that patients with major depression, or even depressive symptoms, have more pain complaints that those without depression. Studies have shown that 30% to 60% of depressed patients complain of pain.[91] These findings raise the possibility that depressed patients may have a greater sensitivity to noxious stimuli. In other words, depressed patients may have a reduced pain threshold. This has not been true in depressed patients without pain.[92,93] In patients with depression, anxiety, and pain, they appear more pain sensitive than those with chronic pain alone. Widerstrom-Noga and colleagues have demonstrated that patients with temporomandibular disorder and depression and anxiety symptoms were more sensitive to noxious stimuli and had lower pain thresholds.[94,95]

Biogenic Amines, Cytokines, and Neural Pathways. The highly variable relationship between injury severity and pain severity has been known since Beecher's studies of the soldiers at Anzio beach in World War II. Since the 1970s, great strides have been made in identifying the central nervous system mechanisms of endogenous pain modulation. Opioid and nonopioid branches to this system have been identified. Stimulation of the rostral ventromedial medulla or the dorsolateral pontine tegmentum produces behavioral analgesia in animals and inhibition of spinal pain transmission. The rostral ventromedial medulla is the principal source of serotonergic neurons that project to the spinal dorsal horn. The dorsolateral pontine tegmentum is the major source of noradrenergic neurons that project to the dorsal horn. Both neurotransmitters serotonin and norepinephrine inhibit nociceptive dorsal horn neurons when locally applied.[96] The descending inhibitory system is modulated by serotonin and norepinephrine, which are also thought to modulate mood. This is perhaps best illustrated by the effects of selective serotonin norepinephrine reuptake inhibitors (SNRIs) on depression and pain. The two drugs approved for use in this class are duloxetine and venlafaxine. Both are FDA approved antidepressants that have analgesic properties independent of their effects on mood.[97,98] These medications enhance serotonergic and noradrenergic neurotransmission. Additional studies indicate that opioid analgesia is enhanced in the presence of antidepressant treatment[99] and decreased after serotonin and norepinephrine depletion.[100] Therefore, it appears that biogenic amines play a critical role in endogenous pain modulation. To the extent that depletion or impaired function of amines such as serotonin and norepinephrine occurs in depression, this may contribute to the pain experienced and reported by those with major depression. Family history studies of depressed patients without pain illustrate that there is a heritable susceptibility to developing major depression.[101] It is thought that this genetic predisposition influences the vulnerability of biogenic amine systems.[102] Similarly, it has also been shown that those with major depression (without pain) have a diminished endogenous opioid response than healthy normals.[103]

Just as cytokine responses are important to the initiation and maintenance of chronic pain,[104] they have also been implicated in the pathogenesis of depression.[105] Depressed patients without pain have been found to have higher levels of proinflammatory cytokines and acute phase proteins. Administration of the cytokine interferon-alpha leads to depression in up to 50% of patients. Proinflammatory cytokines affect neurotransmitter metabolism, neuroendocrine function (particularly the hypothalamic-pituitary-adrenal axis), and synaptic plasticity.

Cortical Substrates for Pain and Affect. Advances in neuroimaging have linked the function of multiple areas in the brain which

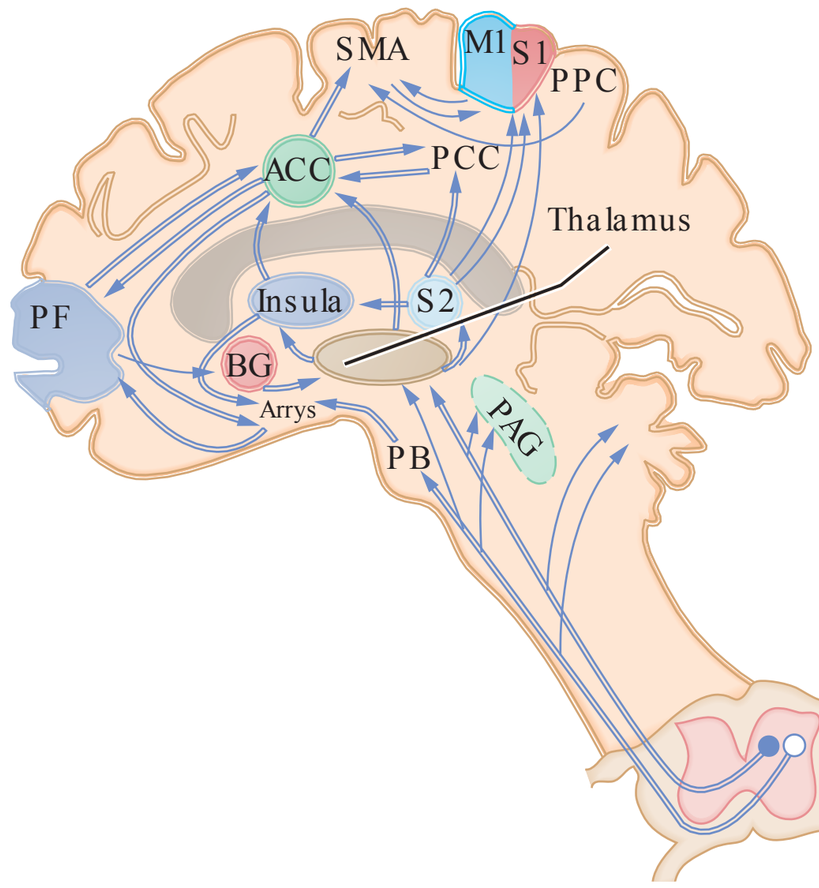

FIGURE 31.2 Supraspinal pathways of pain perception.

process pain and mood simultaneously, described at length in a previous chapter. This system is often termed the medial pain system or spinolimbic pain system.[106] These cortical areas (e.g., the anterior cingulate cortex [ACC], the insula, amygdala, and the dorsolateral prefrontal cortex [DLPFC]) form functional units through which psychiatric comorbidity may amplify pain and disability (Fig. 31.2). They are also laden with opioid receptors.[107] The ACC, insula, and DLPFC are less responsive to endogenous opioids in pain-free subjects with high negative affect (e.g., depression, anxiety, and anger symptoms).[108] Thus, high negative affect may diminish the effectiveness of endogenous and exogenous opioids through direct effects on supraspinal opioid binding. The medial pain system runs parallel to the spinothalamic tract and receives direct input from the dorsal horn of the spinal cord. The interactions among the function of these areas, pain perception, and psychiatric illness are still being investigated. But the spinolimbic pathway is involved in descending pain inhibition, whose function may be negatively affected by the presence of psychopathology. This, in turn, could lead to heightened pain perception. Coghill and colleagues have shown that differences in pain sensitivity between patients can be correlated with differences in activation patterns in the ACC, the insula, and the DLPFC.[109] The anticipation of pain—a form of anxiety for pain—is also modulated by these areas, suggesting a mechanism by which anxiety about pain can amplify pain perception. Ploghaus and colleagues have demonstrated that anticipation for an acute painful stimulus in healthy volunteers is marked by brain activation patterns throughout the medial pain system.[16]

Sleep Disturbance. Depression produces well-documented disturbances to sleep architecture. Polysomnographic recordings have documented reduced slow wave sleep, early onset of the first period of rapid eye movement (REM) sleep, and increased phasic REM sleep in patients with major depression.[110] Sleep continuity disturbances and increased phasic REM sleep tend to normalize with depression remission, even with psychotherapeutic treatment. However, reduction of REM latency and decreased slow wave sleep tend to persist despite clinical recovery. In sum, there appear to be *state* and *trait* elements to the sleep disturbance associated with depression. Studies have also demonstrated that sleep disturbance may be a result of chronic pain, which in turn can make it worse.[111] Fibromyalgia patients who were sleep deprived reported worsening pain and were found to be hyperalgesic (beyond their baseline pain) on pressure sensitivity testing.[112]

Thus, whether depression or pain precipitated or worsened a sleep disturbance, its presence makes pain worse and is an important link between the two conditions.

Psychological Theories

Psychodynamic Theory. In classic psychoanalytic theory,[113] depression is postulated to be derived from anger unconsciously turned inward, excessive dependence on others for self-esteem, and feelings of helplessness in achieving one's goals. Some have suggested that the depression in some chronic pain patients is a manifestation of a personality style that draws from early developmental conflicts of guilt, anger, and masochism.[114,115] From this perspective, chronic pain may be a symptom of depressive disorder.[116]

Psychoanalytic theory stresses the fundamental parallelism between mental and physical pain and the possible displacement from the former to the latter. Intrapsychic links between pain and depression suggest that pain may function as a *hysterical* or conversion symptom that may prevent the breakthrough of more severe depression. These intrapsychic links largely correspond with the dynamics of *pain proneness* that were originally described by Engel[117] and, in a further elaboration, connected with the concept of *masked depression* by Blumer and Heilbronn.

Blumer and Heilbronn[114] proposed a new psychological disorder, the "pain-prone" disorder, building on Engel's[117] notion of the pain-prone patient. In this view, pain should be considered as a variant of depressive disease. The central explanation is unconscious core conflicts. Core issues include "strong needs to be accepted and to depend on others, as well as marked needs to receive affection and to be cared for."

Pain in the absence of organic pathology is considered by Blumer and Heilbronn[114] to be a *depressive spectrum disorder*. According to this model, pain and depression are viewed as manifestations of a single, common disease process. Specifically, the pain-prone disorder is viewed as a masked "depressive equivalent . . . the prime expression of a muted depressive state." No empiric research has supported the psychoanalytic formulation as presented by Blumer and Heilbronn.[118,119]

Behavioral (Operant Conditioning) Theory. The behavioral model of depression concentrates on the most obvious symptom of depression, the motivational deficit characterized by a reduction in active behavior. A central feature of the behavioral model is response-contingent reinforcement (i.e., the responses from significant others to the individual's behavior). From this perspective, depressive behavior and depression are associated with low rates of positive reinforcement from the environment. Lack of positive reinforcement leads to a decrease in the frequency of the individual engaging in these behaviors and ultimately, they may be extinguished completely. These low rates of reinforcement may occur because (a) positive reinforcers in the environment may become less available, or aversive events in the environment may have become more prevalent; (b) the positive effect of previous reinforcers may have declined, or the negative impact of aversive events may have increased; or (c) the individual may lack the skills either to attain the available positive reinforcers or to cope with aversive aspects of the environment. When individuals experience low rates of positive reinforcement, they reduce the performance of those behaviors, unless they are self-reinforcing. The reduction of behavior decreases further opportunities to receive positive reinforcement.

In the case of chronic pain, the individual may reduce his or her behavior because of physical impairments or because of fear of additional pain or further injury. Thus, by the restriction in behavior and social contacts, chronic pain patients may reduce the opportunity to achieve positive reinforcement and to engage in previously rewarding activities and consequently become depressed. The family can also reinforce maladaptive behavior. While many families of patients with chronic pain are supportive with the best of intentions, excessive catering to the patient at the expense of maintaining function can perpetuate illness behavior, leading to depression. In other words, patients can occupy the sick role for reasons other than causal disease.

Cognitive Theory. According to Beck,[120] people may be vulnerable to depression because, from an early age, they have possessed negatively biased conceptualizations (schemas) of themselves and their experiences. When they are challenged by stressful life events, these schema become activated, which in turn elicits negative thoughts about themselves, the world, and the future (the *negative cognitive triad*). These patients view themselves as hopeless, hapless, and helpless (i.e., "my life is not going to get better, no one can help me, and I can't help myself"). The latter can also be termed poor self-efficacy, or the belief that one is incapable of doing things to improve their life. Poor pain self-efficacy is the related belief that a patient cannot do anything to improve their pain or function.

In depressed patients, Beck suggests that the cognitive triad serves as a filter for incoming information. This filter creates a negative bias that serves to put a pessimistic light on information and reinforces the depressed state. It also creates low expectations about their ability and thus may lead to lack of effort. Moreover, these people tend to discount their performance, underestimating their accomplishments.

Beck's[120] cognitive theory of depression emphasizes the importance of peoples' appraisal processes. In particular, it is believed that depressed persons show faulty information processing reflected by errors of logic. Through these cognitive errors (collectively referred to as *cognitive distortions*), depressed persons systematically misinterpret or distort the meaning of events so as to consistently construe themselves, their world, and their experiences in a negative way (the negative cognitive triad). According to this perspective, differences in cognitive errors and cognitive distortions, in general, should differentiate depressed and nondepressed patients. One of the most common cognitive distortions is *catastrophizing,* a tendency to view the most negative possible outcome as the only likely outcome. Pain catastrophizing (discussed at length in previous chapters) is the extension of this concept to patients viewing their pain as unbearable, uncontrollable and leading to tissue damage. It has a significant co-occurrence and conceptual overlap with other depression and anxiety symptoms in pain patients. In other words, when pain patients with depression or anxiety catastrophize, they most often catastrophize over their pain.

Cognitive-Behavioral Perspective. The cognitive-behavioral perspective is based on five central assumptions: (a) People are active processors of information and not passive reactors. They attempt to make sense of information and determine what constitutes positive reinforcers. (b) Thoughts (e.g., appraisals, expectancies, beliefs) can elicit and influence mood, affect physiologic processes, have social consequences, and serve as impetuses for behavior; conversely, mood, physiology, environmental factors, and behavior can influence the nature and content of thought processes. (c) Behavior is reciprocally determined by both the individual and environmental factors. (d) People can learn more adaptive ways of thinking, feeling, and behaving. (e) Individuals should be active collaborative agents in changing their maladaptive thoughts, feelings, and behaviors.[121] From the cognitive-behavioral model, the way in which one thinks about pain and behaves in response to pain affects the extent of depression experienced. Like Beck's cognitive theory, its essential difference from the purely behavioral model is its view of patients as active interpreters of their environment.

Depression in chronic pain patients is postulated to result from patients' interpretations of the meaning and effect of their symptoms and their inability to exert any control over their symptoms.

It is only when patients interpret their pain as interfering with important life activities and believe that they (or anyone) can do little to control the symptoms that they become depressed (i.e., they become depressed when they feel helpless and hopeless to exert any control, overwhelmed by the disruption of their lives, and unable to attain significant positive reinforcement from previous activities).[67] Thus, the cognitive-behavioral approach integrates the principles of operant conditioning and behavioral techniques with the emphasis of cognitive theory on the patients' appraisals, beliefs, and attributions.[122]

Diathesis-Stress Model. This is discussed at length in other chapters, but should be restated here because it is the dominant model for understanding the interactions between pain and comorbid psychopathology, including depression.[3,123] This model frames the biological and psychological mechanisms discussed above as diatheses, or vulnerabilities. Under a condition of mental or physical stress, such as pain, the diatheses interact to produce the conditions of chronic pain and depression.[124,125] One can rephrase this notion such that in any given person genetic susceptibilities to chronic pain and/or mental illness interact with the environment (e.g., physical experience of acute pain, reinforcement from the family, inability to work) leading to changes in the functioning of mental processes (mind, such as negative cognitive schema) and brain (such as neurotransmitter systems and endogenous opioid response), resulting in chronic pain and psychiatric comorbidity.[126]

Anthropological Theories

Traditional and industrial societies appear to hold individuals less responsible for somatic symptoms than psychological symptoms. This difference may be especially prominent in modern Western biomedicine, in which symptom complexes are validated or invalidated through their correspondence with objective disease criteria.[127] A somatic "idiom of distress" may become the favored means for communicating distress of any origin that is overwhelming or disabling.[6,128] In other words, complaints about pain may be indicative of depression rather than a pain syndrome of a somatic origin. In many cultures including Western nations, pain is a more acceptable reason for disability than depression. Therefore, cultural incentives exist for translation of depression into pain. Because depressed patients have many physical symptoms, these can become the focus of clinical communication and concern. Giving patients with chronic pain permission to talk of distress in the clinical setting, using nonsomatic terms, can facilitate treatment as long as they do not feel that the somatic elements of their problem are being neglected or discounted.

This is one of the bedrock principles of narrative medicine,[129,130] which through the patient's description of their illness experience helps them to articulate the inter-relationships between their physical symptoms, psychological states, and their roles amongst family, coworkers, and within society. The physical symptoms of chronic pain and the pathophysiology underlying them can be thought of as the *disease* of chronic pain. The constellation of disease, a patient's psychological state, and their experience of suffering can be termed the *illness* of chronic pain.[129] Questions from the practitioner, such as "what have you lost as a result of your pain," "how do you manage with your pain," and "is it a lot of work to stay well despite having pain?" are important to evoking an illness narrative and describing these inter-relationships.[131]

Depression Treatment

Just as in the treatment of major depression in patients without chronic pain, the best quality treatment of depression in pain patients is to combine psychotherapy with medication management.[132,133] One of the most effective psychotherapy modalities in chronic pain patients is cognitive behavioral therapy (CBT), discussed below and in further detail in other chapters.

Pharmacologic Agents

In choosing an antidepressant agent in a patient with chronic pain, an important principle is that the medication should have independent analgesic properties. This means that the medication can be helpful for pain independent of its effect on mood (i.e., it works as an analgesic in those with and without depression). The two main classes with this property are the tricyclic antidepressants (TCAs) and the selective serotonin norepinephrine reuptake inhibitors (SNRIs). In the United States duloxetine and venlafaxine are the SNRIs currently available. The monoamine oxidase inhibitors (MAOIs, such as selegiline or tranylcypromine) are excellent antidepressants which do also have analgesic properties. But they are rarely used anymore except by psychiatrists (due to their side effect profile and medication interactions), and their use is confined to a third or fourth line agent in treatment resistant depression. Antidepressant medication can effectively treat depression in the presence of chronic pain, but there is some evidence that depression with comorbid pain is more resistant to treatment.[134] When depression accompanies chronic pain, as when it accompanies other chronic medical disorders, there may be some extra hurdles for depression treatment to overcome. These include aversive physical symptoms, severe deactivation, vocational dysfunction, marital conflict, social isolation, and concurrent medications. Comprehensive assessment of these issues and formulation of a treatment plan that takes them into account increase the likelihood of successful depression treatment in the chronic pain patient. If depression can be relieved, many other aspects of rehabilitation, such as physical therapy, are often much more easily accomplished. Pain often subsides with improvement in depressive symptoms.[135] Patients will typically report that they may still have pain but that, "it doesn't bother me anymore." This statement is very telling that the affective component of pain has significantly improved.

All currently marketed antidepressants are equally effective for the initial treatment of depression. However, there is some evidence that medications with effects on dual neurotransmitter systems, such as serotonin and norepinephrine (the SNRIs), are associated with a faster rate of improvement and lower rates of depression relapse.[136] Overall, whatever differences may exist among antidepressants in efficacy for neuropathic pain do not appear to affect their ability to treat depression.

The clinical art of depression treatment for those with chronic pain consists of establishing a solid therapeutic alliance around the problem of depression and finding a medication regimen with independent analgesic properties and a side-effect profile that the patient can tolerate. Because patients with chronic pain can be vigilant and catastrophic in thinking about somatic symptoms, care must be taken to educate them about antidepressant side effects. Sometimes it becomes necessary to initiate an antidepressant regimen at the lower doses used for geriatric patients to ease habituation to side effects. Because of their analgesic properties, the SNRIs and TCAs are the treatments of choice for patients with chronic pain and depression.

While the TCAs are considered first-line, their side effect profiles and the slower rate of titration needed to reach a therapeutic dose limit their usefulness compared to SNRIs. However, since the TCAs are used frequently in the management of neuropathic pain, it is very common to encounter a patient on lower doses of TCAs (10–75 mgs). Typically, these patients have acclimated too many of the side effects and gradual escalation of the dose to antidepressant ranges (approximately 100–300 mgs, depend-

ing on the compound) can easily be performed in the pain management setting. In monitoring their use for depression, it is important to obtain serum blood levels of TCAs to make sure that they are in the therapeutic range. Disadvantages of TCAs include a wide range of adverse effects, including anticholinergic effects, orthostatic hypotension, effects on the cardiac conduction system, weight gain, sedation, sexual dysfunction, restlessness, "jitteriness," heightened anxiety on initial dosing, and cardiotoxicity in overdose. Before starting a TCA, in those over 45 years or in any patient with a history of cardiac disease, the QTc interval on an EKG should be checked to see if it is <450 ms. Using TCAs in patients with QTc intervals >450 ms places them at a greater risk of developing torsades de pointes arrhythmia, even when lower doses of TCAs are used (10–75 mgs), as is common in pain medicine. Of the TCAs, nortriptyline has the lowest incidence of side effects, and thus is the preferred TCA for use in chronic pain patients, either for treatment of pain or depression. While nortriptyline is more sedating than desipramine, it has a lower incidence of orthostatic hypotension and dizziness. Nortriptyline also has a comparable rate of analgesia to amitriptyline, despite the latter perhaps having broader effects on multiple analgesic mechanisms, such as sodium channel blockade.

The selective serotonin reuptake inhibitors (SSRIs, those available in the United States include citalopram, escitalopram, fluoxetine, fluvoxamine, sertraline, and paroxetine) have become the most popular antidepressants because of their favorable side-effect profiles, but are more useful as second line agents in a pain population because they do not have significant independent analgesic properties. Nefazodone is a useful alternative for patients who have problems with agitation or insomnia on the SSRIs, but care must be taken to monitor liver enzymes. Bupropion has effects on dopamine and norepinephrine reuptake systems (DNRIs). Because of its energizing effects it is very useful in those with chronic pain, since many experience fatigue and poor concentration, either due to the pain itself or as side effects from pain medications. One study has shown that bupropion has analgesic properties in neuropathic pain.[137] More detailed information on prescribing antidepressants is available in one of the standard psychopharmacology manuals.[138–140] In situations of treatment resistant depression, studies have indicated that electroconvulsive therapy can be useful for treatment of depression and pain, across a variety of painful disorders.[141,142] However, no carefully controlled studies demonstrate the effectiveness of electroconvulsive therapy for treatment of chronic pain.

Chronic pain is frequently associated with insomnia and anxiety. It is, therefore, common that patients are treated with benzodiazepines or other sedatives (e.g., the muscle relaxers). Some patients begin taking these medications during the acute phase of the pain problem and then continue to take them for many months or years. Assessing chronic pain patients who take benzodiazepines for depression is important. These medications mask some symptoms of depression (e.g., initial insomnia, agitation), but they are not adequate treatments for depression. Indeed, dangerous levels of depression can develop under the cover of benzodiazepines. It has been suggested that benzodiazepines can induce depression with chronic use, but the evidence for this is not strong.[143] More important is the masking of depression by benzodiazepines.

Few conditions exist for which chronic benzodiazepines are the treatment of choice.[144] The treatment of choice for chronic anxiety disorders, which are almost always accompanied by depressive symptoms, is antidepressant medication.[145] Buspirone (a 5-HT_{1a} partial agonist) is marketed as an anxiolytic, but is more similar to the antidepressants in its pharmacology and side-effect profile. It is a reasonable alternative to the benzodiazepines for the treatment of breakthrough anxiety, particularly for those who experience agitation on the antidepressants.

Psychotherapy

Psychodynamic Psychotherapy

In general, psychodynamic theory emphasizes the long-term predisposition to depression, rather than the losses that occur in the short term. Treatment of depression from the classical psychoanalytic perspective tries to help the patient achieve insights into the repressed conflict and often encourages outward release of hostility turned inward. In the most general terms, the goal of therapy is to uncover latent motivations for the patient's depression. The psychodynamic approach to the depressed individual with chronic pain emphasizes the importance of individual differences in patients based on their developmental history, intrapsychic conflicts, interpersonal difficulties, and the subsequent failure to adapt to chronic illness. Patients' premorbid characteristics are hypothesized to color their adaptation to their current situation and affect their vulnerability to depression.

Psychodynamic therapy emphasizes the need for patients to address unconscious conflicts that may contribute to and maintain the depression and makes use of the therapeutic relationship, assuming that the patient will transfer or project his or her feelings onto the therapist.[146] This approach can be contrasted with treatment based on operant conditioning, in which it is assumed that the basic principles of learning apply to all individuals and the environmental contingencies of reinforcement can influence the reports of pain, distress, and suffering . As a treatment for depression, there is no good standardization of psychodynamic therapy and thus it is difficult to evaluate the studies of its effectiveness.

Behavioral Model

As noted, the behavioral model of depression concentrates on the reduction in active behavior that is a central feature of depression. The focus of treatment for depression is on the shaping of behavior through the use of graded task assignments and response-contingent reinforcement. Depressed individuals are encouraged to engage in more activities and to behave in ways that are likely to be regarded more positively by others. In some instances, it is believed that depressed patients are deficient in certain skills necessary to achieve positive reinforcement. Social skills training may also be included when the therapist determines that the patient is deficient in specific skills (e.g., communication skills). Attention may also be given to assisting the patient in planning pleasant events that the patient will find reinforcing.

Cognitive Model

From the cognitive perspective, therapy is based on the rationale that an individual's affect and behavior are largely determined by the ways in which he or she construes the world and the therapeutic techniques were designed to identify, test, and correct distorted conceptualizations and the dysfunctional beliefs (schemas) underlying these cognitions. Beck's[120] therapy for depression is based on the assumption that the affected people engage in faulty information processing and reasoning and subscribe to a schema that is self-defeating. In particular, depressed people are subject to the negative cognitive triad, in which they have feelings of pessimistic helplessness about themselves, the world, and their future. The aim of the cognitive therapist is to identify and then help patients to correct these distorted ideas and also to improve their information processing and reasoning. In contrast to psychodynamic therapy, the focus is on the here and now. Thus, attention to the origin of dysfunctional schemas in the cognitive model is limited.

The therapeutic procedures are highly structured, time limited, and begin with the recognition of the connections between cognitions and affect, careful recording of these connections, collection of evidence for and against the ideas, followed by substitution

of more adaptive and realistic interpretations. The cognitive approach is most frequently combined with behavioral techniques to treat patients with chronic pain, even though some debate exists about the compatibility of these approaches.[120,121]

Cognitive-Behavioral Model

No one cognitive-behavioral model exists, but rather sets of models that share a perspective and incorporate some common features, namely: (a) an interest in the nature and modification of patients' thoughts, feelings, and beliefs, as well as behaviors; and (b) some commitment to behavior therapy procedures in promoting change (e.g., graded practice, use of homework, training in relaxation, coping skills training, problem solving, and relapse prevention).[122]

Depressed people may focus attention selectively on and become preoccupied with somatic symptoms and their potentially ominous significance for their health and future. They may view themselves as helpless and their situation as hopeless and beyond their control. In depressed patients with chronic pain, the cognitive distortions often center around their pain, such as excessive fear of pain or fear of movement. To break this vicious circle, the cognitive-behavioral therapist applies a comprehensive approach to treatment that combines physical, psychological, behavioral, and social interventions. Coping skills training, problem-solving strategies, communications skills training, and directing patients to attend to their appraisals, interpretations, and beliefs surrounding pain are commonly used techniques. One of the most effective CBT methods in pain patients is to combine coping skills training focusing on fear of pain, re-injury, and movement with gradual activity and movement-based physical therapy.[147]

The cognitive-behavioral therapist attempts to assist patients to try new behaviors and to adopt more adaptive modes of thinking. Alterations in behavior become information that the patients are encouraged to use as the basis for changing their views of their situation and themselves from being helpless, hopeless, and out of their control to being resourceful and capable of exerting at least some control over their plights. Changing the cognitive schema by cognitive and behavioral means is designed to result in different interpretations of information about themselves and their futures. Thus, changing behaviors and thoughts may be reciprocally related and mutually reinforcing. Neither attending exclusively to behavior, as in the behavioral model, nor only attending to patients' thinking, as in the cognitive model, is adequate to alleviate depression.[121] The cognitive-behavioral approach has become a central component for treating depression in many multidisciplinary pain rehabilitation and functional restoration programs.

All of the psychological therapies emphasize patients' active role in alleviating depression. In contrast to the psychodynamic model, in which the therapist plays a relatively passive role, in behavioral, cognitive, and cognitive-behavioral therapies, the therapist takes an active, directive role, attempting to guide patients into changing their behavior and reorganizing their thinking and actions. The behavioral, cognitive, and cognitive-behavioral therapies are all centered in the present, compared with psychodynamic therapy, which focuses on the past.

ANXIETY DISORDERS

It is not unusual for patients with symptoms of pain to be anxious and worried. This is especially true when the symptoms are unexplained, as is often the case for chronic pain syndromes. For example, in a large-scale, multicenter study of fibromyalgia patients, between 44% and 51% of patients indicated that they were anxious.[148] In other clinic samples, rates of an anxiety disorder ranged from 16% to 29% among pain patients.[149,150] Most researchers agree that the prevalence of anxiety disorders in patients with chronic pain is underestimated by these data.[1,56]

Anxiety and concern about symptoms are not synonymous with a psychiatric diagnosis of an anxiety disorder, necessarily. When anxiety is debilitating, it may meet criteria for an anxiety disorder. Anxiety disorders are a broad spectrum of disorders which include generalized anxiety disorder, posttraumatic stress disorder, obsessive-compulsive disorder and panic disorder. As noted earlier in this chapter, pain anxiety is the most prevalent and salient form of anxiety in pain patients.[151] Though distinct in some respects, there is significant overlap of pain anxiety symptoms with the constructs of fear of pain, fear of movement, and pain catastrophizing.[152] High levels of pain anxiety (which are impairing, maladaptive, and predictive of higher pain levels[153]) also meet *DSM-IV* criteria for anxiety due to a general medical condition.[154] While this diagnosis was intended originally for anxiety secondary to chronic hypoxemia or steroid use, for example, chronic pain is a medical condition primarily, and falls within the scope of this diagnostic category. Fears, worries, and preoccupations about pain are all secondary to having pain and if the pain resolves, so do these psychological symptoms.

Anxiety disorders frequently accompany other affective disorders, such as major depression, so clinicians should remain alert to the possibility of a mood disorder when patients complain of severe anxiety.[1] In general, the approach is to diagnose and treat initially the most prominent mood disorder in a patient, whether it be depression or anxiety. For instance, in a patient with significant depression and anxiety symptoms, if the depression symptoms seem to be greater or more debilitating than the anxiety symptoms, the diagnosis is major depression with anxious features. In these situations, addressing the depression will also improve the anxiety symptoms. In a major depression with significant overlying anxiety, clinicians will often choose an antidepressant with significant anti-anxiety properties, such as the SNRIs or SSRIs.

Generalized Anxiety Disorder

Table 31.2 outlines the criteria for generalized anxiety disorder (GAD). Generalized anxiety disorder is characterized by excessive nxiety and worry (apprehensive expectation) and difficulty controlling the worry for at least six months, accompanied by at least three of the following symptoms: restlessness or feeling keyed up, being easily fatigued, difficulty concentrating, irritability, muscle tension, or sleep disturbance.[1] There is significant debate whether a six month duration of symptoms is necessary to make the diagnosis, and many psychiatrists contend that this is unnecessarily lengthy.[155] Often there are significant associated depression symptoms, but they do not rise to the level of a major depressive disorder. It is very common for patients with GAD to also have panic attack symptoms or post-traumatic stress symptoms. There are trait and state (situational) components to anxiety disorder presentations in patients with pain. The trait components include excessive worry and concern, often about routine matters. The amount of worry and anxiety is out of proportion to the likelihood of the negative consequences occurring, and the patient has great difficulty controlling worry. In making a diagnosis of GAD, trait anxiety in this context does not imply that the symptoms or the tendency toward these symptoms have been present since the beginning of adulthood.

The situational (state) anxiety is often centered on the pain itself and its negative consequences (pain anxiety). Patients may have conditioned fear, believing that activities will cause uncontrollable pain, causing avoidance of those activities. Pain may also activate thoughts that a person is seriously ill.[42] Questions such as the following can be helpful: "Does the pain make you panic? If you think about your pain, do you feel your heart beat-

TABLE 31.2

DIAGNOSTIC AND STATISTICAL MANUAL, **FOURTH EDITION, CRITERIA FOR GENERALIZED ANXIETY DISORDER**

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).

B. The person finds it difficult to control the worry.

C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 months). Note: Only one item is required in children.
   1. Restlessness or feeling keyed up or on edge
   2. Being easily fatigued
   3. Difficulty concentrating or mind going blank
   4. Irritability
   5. Muscle tension
   6. Sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep)

D. The focus of the anxiety and worry is not confined to features of an Axis I disorder; the anxiety or worry is not about having a panic attack (as in a panic disorder), being embarrassed in public (as in social phobia), being contaminated (as in obsessive-compulsive disorder), being away from home or close relatives (as in separation anxiety disorder), gaining weight (as in anorexia nervosa), having multiple physical complaints (as in somatization disorder), or having a serious illness (as in hypochondriasis), and the anxiety and worry do not occur exclusively during posttraumatic stress disorder.

E. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

F. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism) and does not occur exclusively during a mood disorder, a psychotic disorder, or a pervasive developmental disorder.

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:395, with permission.

ing fast? Do you have an overwhelming feeling of dread or doom? Do you experience a sense of sudden anxiety that overwhelms you when you feel more pain?"

The best quality of treatment for GAD is CBT plus medications. The CBT is pain-based as in major depression treatment. Psychotherapy alone is highly effective for anxiety disorders.[156] Successful CBT in patients with obsessive-compulsive disorder has been shown on neuroimaging studies to correlate to changes in the functioning of frontal lobe limbic areas.[157] As discussed, the most frequently chosen medication classes are the SNRIs or SSRIs. Unlike depression treatment and despite their lack of analgesic properties, in anxiety disorders the SSRIs are considered first line because of their efficacy over most other antidepressant classes. The TCAs can be effective, but higher doses are often needed which are difficult for patients to tolerate. Benzodiazepines should almost always be avoided, as discussed previously. Breakthrough anxiety can be addressed with buspirone, hydroxyzine, or low dose antipsychotics (which is beyond the scope of this discussion).

TABLE 31.3

DIAGNOSTIC AND STATISTICAL MANUAL, **FOURTH EDITION, CRITERIA FOR PANIC ATTACK**

A discrete period of intense fear or discomfort, in which four (or more) of the following symptoms developed abruptly and reached a peak within 10 minutes:

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, lightheaded, or faint
9. Depersonalization (feelings of unreality) or depersonalization (being detached from oneself)
10. Fear of losing control or going crazy
11. Fear of dying
12. Paresthesias (numbness or tingling sensations)
13. Chills or hot flushes
14. Persistent concern about having additional attacks
15. Worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, "going crazy")
16. A significant change in behavior related to attacks

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:395, with permission.

Panic Disorder

Panic disorder is a common, disabling psychiatric illness associated with high medical service use and multiple medically unexplained symptoms. The diagnosis of panic disorder requires recurrent, unexpected panic attacks (Table 31.3) followed by at least 1 month of worry about having another panic attack, the implications or consequences of the panic attacks, or behavioral changes related to the attacks. These attacks should not be the direct physiologic consequence of a substance or other medical condition. The panic attacks should not be better accounted for by another mental disorder, such as posttraumatic stress disorder (PTSD; see following discussion) or obsessive-compulsive disorder. At least two unexpected attacks are required for the diagnosis, although most patients have many more.

One of the most common problems with panic disorder is the fear of an undiagnosed, life-threatening illness. Patients with panic disorder can receive extensive medical testing and treatment for their somatic symptoms before the diagnosis of panic disorder is made and appropriate treatment initiated.

Epidemiology

Lifetime prevalence of panic disorder throughout the world is estimated to be 1.5% to 3.5%. One-year prevalence rates are from 1% to 2%. Panic disorder is two to three times more common in women than in men. Age of onset is variable, but most patients typically start between late adolescence and the mid-30s. Of all common mental disorders in the primary care setting, panic disorder is most likely to produce moderate to severe occupational dysfunction and physical disability.[158] It was also associated with the greatest number of disability days in the past month. In some studies, in pain patients it has a prevalence of 5% to 8%, significantly higher than the general population.[1,159]

The most common complication of panic disorder is agoraphobia, or fear of public places. Patients with panic disorder learn to fear places where escape might be difficult or help not available in case they have an attack. One-half to two-thirds of patients with panic disorder also suffer from major depression. These patients are the most disabled panic disorder patients. The differential diagnosis of patients presenting with panic symptoms in the medical setting includes thyroid, parathyroid, adrenal, and vestibular dysfunction, seizure disorders, cardiac arrhythmias, and drug intoxication or withdrawal. Patients with panic disorder typically present in the medical setting with cardiologic, gastrointestinal, or neurologic complaints. These include chest pain, abdominal pain, and headaches.[160]

Chest pain is one of the most common complaints presented to primary care physicians, but a specific medical etiology is identified in only 10% to 20% of cases. From 43% to 61% of patients who have normal coronary arteries at angiography and 16% to 25% of patients presenting to emergency rooms with chest pain have panic disorder. A number of these patients eventually receive the diagnoses of vasospastic angina, costochondritis, esophageal dysmotility, or mitral valve prolapse. High rates of psychiatric disorders have been found in some of these groups as well.[161] Many of these patients remain symptomatic and disabled 1 year later despite reassurance concerning coronary artery disease.[162]

Patients with documented coronary disease also have elevated rates of panic disorder. A number of studies have found nearly identical rates of panic disorder in chest pain patients with and without coronary disease. Increased mortality has been noted in those with anxiety and coronary disease. These data point to the importance of remaining alert to both medical and psychiatric diagnoses in those presenting with chest pain. Patients with unexplained chest pain who were given low-dose imipramine (50 mg per day) reported significant reductions in pain regardless of whether they had increased anxiety symptoms or another psychiatric disorder. This has been postulated to be caused by a *visceral analgesic effect* of imipramine.[163] It is possible, however, that imipramine was treating subthreshold anxiety and depressive symptoms, because 63% of the sample had a history of these disorders at some point in their lives.

Approximately 11% of primary care patients present the problem of abdominal pain to their physician each year. Less than one-quarter of these complaints are associated with a definite physical diagnosis in the following year. Among the most common reasons for abdominal pain is irritable bowel syndrome. It is estimated that irritable bowel syndrome accounts for 20% to 52% of all referrals to gastroenterologists. Various studies have found that 54% to 74% of these patients with irritable bowel syndrome have associated psychiatric disorders. Walker and colleagues determined that patients with irritable bowel syndrome have much higher current (28% versus 3%) and lifetime (41% versus 25%) rates of panic disorder than a comparison group with inflammatory bowel disease.[164] This suggests that the psychiatric disorder was not simply a reaction to the abdominal distress.

Among 10,000 persons assessed in a community survey who consulted their physicians for headache, 15% of female and 13% of male subjects had a history of panic disorder. Further studies have suggested that migraine headache is most strongly associated with panic attacks.[165] Often, anxiety symptoms precede the onset of the headaches, whereas depressive symptoms often have their onset after the headaches. Some authors have suggested that a common predisposition exists with headaches (especially migraines and chronic daily headache), anxiety disorders, and major depression.

Treatment

Psychopharmacologic and psychotherapeutic treatments for panic disorder have been proven effective. The American Psychiatric Association has released a *Practice Guideline for the Treatment of Patients with Panic Disorder*.[166] Panic-focused cognitive-behavioral therapy and four classes of medications (SSRIs, tricyclic antidepressants, monoamine oxidase inhibitors, and benzodiazepines) have demonstrated effectiveness. These drugs may be used in combination with cognitive-behavioral therapy. Panic-specific cognitive-behavioral therapy includes psychoeducation, continuous panic monitoring, development of anxiety management skills, cognitive restructuring, and *in vivo* exposure. As discussed previously with depression, the SSRIs likely are the easiest antidepressants to use for panic disorder. However, starting doses should be halved to avoid any initial exacerbation of agitation or anxiety. Tricyclic antidepressants and monoamine oxidase inhibitors are now reserved for those patients who do not respond to the SSRIs. Benzodiazepines should only be used for early symptom control in conjunction with one of the other classes of effective medication.

POSTTRAUMATIC STRESS DISORDER

Diagnosis

At the time of initial physical trauma, patients who develop chronic pain may also experience overwhelming psychological trauma. George Crile, a surgeon and experimental physiologist, laid the foundation for our modern concept of psychological trauma. He suggested that fear is the memory of pain. This fear holds an adaptive advantage in directing individuals to anticipate and avoid injury. Freud added anxiety to our modern conceptualization. Anxiety is the capacity to imagine pain and not merely to remember it. In other words, anxiety is memory of pain set loose.[167]

After direct personal exposure to an extreme traumatic event, some individuals develop a syndrome that includes reexperiencing the event, avoidance of stimuli associated with the event, and persistent heightened arousal. PTSD was originally described after exposure to military combat, but is now recognized to occur after sexual or physical assault, natural disasters, accidents, life-threatening illnesses, and other events that induce feelings of intense fear, hopelessness, or horror. Persons may develop the disorder after experiencing or just witnessing these events. *DSM-IV* diagnostic criteria are shown in Table 31.4.

Epidemiology of PTSD in Chronic Pain Patients

Approximately 13% of all veterans returning from service in Iraq and Afghanistan receive diagnoses of PTSD. These constitute about half of all mental health diagnoses received.[168] Up to 80% of Vietnam veterans with PTSD report chronic pain in limbs, back, torso, or head.[169] Increased physical symptoms, including muscle aches and back pain, are also more common in Gulf War veterans with PTSD than in those without PTSD.[170] The prevalence of PTSD in medical populations has been shown to be quite high. For example, a number of patients presenting at medical clinics with myocardial infarctions[171] and cancer[172,173] often meet the criteria for PTSD. Averaging the prevalence rates of PTSD across a number of studies reveals that after motor vehicle accidents sufficient to require medical attention, 29.5% of patients meet the criteria for PTSD.[174] For more than one-half of these patients, the symptoms resolve within 6 months. In one study, 15% of idiopathic facial pain patients seeking treatment were found to have PTSD.[175] In another study, 21% of fibromyalgia patients were found to have PTSD.[176] Case reports have associated reflex sympathetic dystrophy (complex regional pain

TABLE 31.4

DIAGNOSTIC AND STATISTICAL MANUAL**, FOURTH EDITION, DIAGNOSTIC CRITERIA FOR POSTTRAUMATIC STRESS DISORDER**

A. The person has been exposed to a traumatic event in which both of the following were present:
   1. The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others.
   2. The person's response involved intense fear, helplessness, or horror. Note: In children, this may be expressed instead by disorganized or agitated behavior.

B. The traumatic event is persistently reexperienced in one (or more) of the following ways:
   1. Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. Note: In young children, repetitive play may occur in which themes or aspects of the trauma are expressed.
   2. Recurrent distressing dreams of the event. Note: In children, there may be frightening dreams without recognizable content.
   3. Acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on awakening or when intoxicated). Note: In young children, trauma-specific reenactment may occur.
   4. Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.
   5. Physiologic reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.

C. Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by three (or more) of the following:
   1. Efforts to avoid thoughts, feelings, or conversations associated with the trauma.
   2. Efforts to avoid activities, places, or people that arouse recollections of the trauma.
   3. Inability to recall an important aspect of the trauma.
   4. Markedly diminished interest or participation in significant activities.
   5. Feeling of detachment or estrangement from others.
   6. Restricted range of affect (e.g., unable to have loving feelings).
   7. Sense of foreshortened future (e.g., does not expect to have a career, marriage, children, or normal life span).

D. Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:
   1. Difficulty falling or staying asleep.
   2. Irritability or outbursts of anger.
   3. Difficulty concentrating.
   4. Hypervigilance.
   5. Exaggerated startle response.

E. Duration of the disturbance (symptoms in criteria B, C, and D) is more than 1 month.

F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:427–429, with permission.

syndrome) with PTSD. Other studies suggest that 50% to 100% of patients presenting at pain treatment centers meet the diagnostic criteria for PTSD.[176,177] Among adult urban primary care patients, 23% had PTSD, of whom 11% had it noted in the medical record. The prevalence of PTSD, adjusted for demographic factors, was higher in participants with chronic pain, major depression, and anxiety disorders.[178]

Pain patients with PTSD have been shown to have more pain and affective distress than those without PTSD,[179] so it is not surprising that PTSD rates among pain patients increase as treatment settings become more specialized.

PTSD and Associations with Pain

The relationship between pain and PTSD is multifaceted, as suggested by the early thinking by Crile and Freud discussed previously. Pain and PTSD may result from a traumatic event. Sometimes acute pain can constitute the traumatic event, as described in a case of traumatic eye enucleation.[180] In a nationwide survey of patients admitted after trauma, 23% of injury survivors had symptoms consistent with a diagnosis of PTSD 12 months after their hospitalization.[181] Greater levels of early post-injury emotional distress and physical pain were associated with an increased risk of symptoms consistent with a PTSD diagnosis. Pain may also be a consequence of PTSD or a manifestation of it. In a sample of patients admitted to an orthopedic hospital, back pain after major trauma was not associated with measures of injury severity or demographic factors, but was significantly associated with the presence of posttraumatic stress disorder, the use of a lawyer, the presence of chronic illnesses, and lower education levels.[182] Functional brain imaging studies suggest altered processing of noxious signaling in the brain of patients with PTSD. In one study, patients with PTSD revealed increased activation in the left hippocampus and decreased activation in the bilateral ventrolateral prefrontal cortex and the right amygdala.[183] Much research remains to be done on the relative contributions of physical trauma and psychological trauma to chronic pain problems.

Treatment

It is best to institute treatment for PTSD as close in time to the trauma as possible. Acute crisis intervention may reduce the development of chronic PTSD and other complications, including, possibly, chronic pain. This treatment should establish support, promote acceptance of what happened, provide education and information about symptoms, and attend to general health needs. Beyond the acute phase, the cognitive-behavioral therapy treatment described for panic disorder earlier has been shown to be effective with PTSD as well. Stress-inoculation training, implosive therapy, and systematic desensitization have also been reported to have some efficacy.[175,184] Medications are rarely adequate as the sole treatment for PTSD. Controlled trials of tricyclic antidepressants, SSRIs, and monoamine oxidase inhibitors have demonstrated some benefit by 8 weeks at reducing core intrusive features. These benefits appear to be in addition to the antidepressant and antianxiety effects of these medications.[185] Recent PTSD treatment trials have demonstrated effectiveness of venlafaxine ER[186] and prazosin[187] but these trials have not specifically monitored the effects on pain.

PERSONALITY DISORDERS

Epidemiology

Several studies have reviewed the personality characteristics and disorders of patients with chronic pain.[149,150,188–190] The preva-

lence of personality disorders among clinic populations ranges from 31% to 81% and is greater than in the general population or in populations with either medical or psychiatric illnesses. The Minnesota Multiphasic Personality Inventory (MMPI) is the most widely used personality assessment tool of patients with chronic pain but is probably not purely a personality trait measure.[191–193] Previous studies have identified profiles defined by Minnesota Multiphasic Personality Inventory (MMPI) scale elevations that are proposed to be characteristic of chronic somatic symptoms such as pain.[194] The hypochondriacal reaction, conversion 'V' and neurotic triad profiles exhibit different multivariate relationships between other constructs such as somatization, coping strategies, depression, pain severity, and activity level.[195] However, while patients with chronic pain differ from nonchronic pain controls in their scale profiles on the MMPI, there is no single personality trait or disorder associated with medically unexplained chronic pain or chronic pain from ''organic'' diseases.

Overview of Personality Disorders

Personality pathology is best thought of along a continuum of traits present to greater or lesser degrees. Personality disorders described in the *DSM* represent the pathological extreme of personality traits. Patients with personality disorders are one type of ''difficult patient'' characterized by an inflexible, pervasive, and maladaptive inner experience and set of behaviors.[18,131] Traits have been conceptualized as dimensional aspects of individual variation while personality disorders are represented as categorical aberrations within the realm of psychopathology. This section will present an overview of personality pathology and not a discussion of the criteria for each specific personality disorder.

Analytic approaches undertaken to understand the features of temperament have described several core factors. The five-factor model is one of the most popular and characterized by the trait dimensions of neuroticism, extraversion, openness, agreeableness, and conscientiousness as described by the revised NEO Personality Inventory.[196–198] In contrast, the Temperament and Character Inventory (TCI) is comprised of four heritable and stable dimensions of temperament (Harm Avoidance, Novelty Seeking, Reward Dependence, Persistence) that represent individual differences in associative learning and three dimensions of character (Self-Directedness, Cooperativeness, Self-Transcendence) that develop over time as a function of social learning and maturation of interpersonal behavior.[199] This psychobiologic model defines personality as the interaction of temperament and character. Studies have described three dimensions (HA, SD, C) as a core feature of all personality disorders.[200] However, this profile has also been associated with other constructs such as depressive and anxiety disorders.[201,202]

Only a portion of the variance in the factors or dimensions characterizing personality disorders is explained by core personality traits.[203] Personality traits are generally considered to be enduring features of an individual. The stability of personality after age 30 has been consistently documented with long term follow-up studies.[204] Longitudinal studies also demonstrate that dimensional models of personality disorders may represent a manifestation of personality traits interacting with life events or illness consistent with the diathesis-stress model.[205,206] Caution should be exercised in making the diagnosis of a personality disorder in the presence of any illness. Personality traits should be appreciated as sustaining or modifying factors that have the potential to complicate the treatment process rather than as causes of or the sole explanation for illnesses such as chronic pain.[188] Personality vulnerabilities contribute to the degree of potential disability that individuals experience by modifying their response to pain. While these patients are more likely to be ''difficult'' because of their complexity, their prognosis should not be viewed as hopeless or unresponsive to treatment.

The diathesis-stress model may partly explain the high rates of personality pathology but also, the decreases in these rates that have been observed with chronic pain treatment.[189,190] A comprehensive review of the effect of pain on the measurement of personality characteristics found substantial evidence that trait inventories are not pain state independent.[207] Pain treatment resulted in improvement in trait scores across the majority of studies that utilized the MMPI and measures of trait anxiety, coping/self-efficacy, and somatization/illness behavior. In a significant number of the studies reviewed, the trait changes could be attributed to improvements in pain. This state-trait interaction contradicts the notion that personality inventories catalog only enduring aspects of the individual. Instead, there is increasing evidence that a state disorder (psychiatric, medical, stress-related, pain) may distort the measurement of traits and that treatment of that condition will decrease the presumed trait disorder.[208–211] Just as personality pathology may improve with adequate pain treatment, personality disorders may emerge in the context of chronic pain, even if prior to pain there was no evidence of maladaptive personality traits. The explanation for this change may include several mechanisms or confounders including that trait measurements are being contaminated by state-specific questions, pain treatments (medications, cognitive-behavioral therapy) directly alter traits, pain treatments improve state disorders which were previously affecting trait measurement, test-retest related problems, and that standardized tests are actually measuring both states and traits.

Personality and Pain Treatment Outcome

Current research has focused on how personality relates to treatment outcome, the transition from acute to chronic pain, and the persistence of pain-related disability. However, results have been inconsistent and more likely to detect emotional distress and psychopathology. Recently, a Disability Profile based on elevations of 4 or more clinical scales of the MMPI-II has been proposed as more common than those described above.[1] In a prospective investigation of almost 1500 patients with chronic occupational spinal disorders, this Disability Profile was associated with 5 times the likelihood of having a personality disorder and 14 times the likelihood of having an Axis I disorder. While associated with high levels of psychopathology, patients with the Disability Profile compared to those with neurotic triad, conversion V, and normal profiles showed no significant differences in response to treatment with an interdisciplinary rehabilitation program. In a 30-year longitudinal study of healthy college students, elevations on MMPI scales 1 and 3 were associated with increased reports of chronic pain conditions at mid-life.[212] However, the magnitude of this association was small and the clinical significance was unclear.

In a similar study, patients with chronic pain due to nonspecific musculoskeletal disorders exhibited higher levels of harm avoidance (HA) and lower levels of self-directedness (SD) on the TCI.[213] This trait profile would characterize patients as cautious, insecure, pessimistic, lacking self-esteem and long term goals, failing to accept responsibility, and struggling with their identity. Another study of patients with chronic pain of all types identified the same profile plus low levels of cooperativeness (C).[150] Low levels of self-directedness have been associated with learned helplessness, poor self-efficacy, and an external locus of control. High levels of harm avoidance overlap with the construct of fear-avoidance behavior, fearful cluster C personality disorders, and the development of pain-related disability. The fear-avoidance model and expectancy model of fear provide explanations for the initiation and maintenance of chronic pain disability, proposing that anxiety sensitivity amplifies reactions such as avoidance of spe-

cific activities.[214–217] Anxiety sensitivity is a significant predictor of fear of, and anxiety about, pain.[218] Fear of pain, movement, reinjury, and other negative consequences that result in the avoidance of activities promote the transition to and sustaining of chronic pain and its associated disabilities such as muscular reactivity, deconditioning, and guarded movement.[219]

Fear-avoidance beliefs have been found to be one of the most significant predictors of failure to return to work in patients with chronic low back pain.[220] Operant conditioning reinforces disability if the avoidance provides any short-term benefits such as reducing anticipatory anxiety or relieving the patient of unwanted responsibilities. In a study of patients with chronic low back pain, improvements in disability following physical therapy were associated with decreases in pain, psychological distress, and fear-avoidance beliefs but not specific physical deficits.[221,222] Decreasing work-specific fears was a more important outcome than addressing general fears of physical activity in predicting improved physical capability for work among patients participating in an interdisciplinary treatment program.[223] These studies suggest that certain personality traits or profiles should alert the clinician to the presence of psychological problems and psychiatric disorders that would benefit from more specific treatments as opposed to defining a group of patients with chronic pain who should be condemned to no treatment because of an expected poor outcome.

SOMATOFORM DISORDERS, ILLNESS BEHAVIOR, AND SICK ROLE

Definitions

Sickness is a complicated psychological and social state that has been understood from a variety of perspectives over the years. We consider those of sick role, illness behavior, and somatoform disorder.

The concept of the *sick role* was first introduced by Talcott Parsons in 1951[224] and was formulated more concretely 12 years later.[225] The sick role is granted to an individual provided that he or she regards his or her condition as undesirable, and is not held responsible for it (i.e., under his or her control and able to be reversed voluntarily). If granted, the individual is allowed exemption from his or her usual obligations to a greater or lesser extent and is considered to be deserving of care and attention. Associated with the sick role are the obligations of seeking the advice and assistance of a person regarded as competent to diagnose and treat the condition and of cooperating with that person.

The basic concept of *illness behavior* was introduced by Mechanic and Volkart[226] and later fully formulated by Mechanic.[227] Mechanic's concept of illness behavior complements the sick role, because it delineates the contribution of the patient to the role-granting process. Illness behavior was originally defined as the ways in which individuals differentially perceive, evaluate, and respond to their symptoms. This concept proved to be an extremely useful one, because it has facilitated the empiric study of behaviors that are of considerable importance to clinicians and other health care providers, as well as to the individual's family and society.

Although useful as it stands, health care providers find Mechanic's definition restrictive because it refers to *symptoms* as the focus of behavior, and consequently deemphasizes actions directed toward avoidance of the illness. A slightly modified definition describes illness behavior as "the ways in which individuals experience, perceive, evaluate, and respond to their own health status." This definition recognizes the possibility that a person may be concerned about illness in the absence of symptoms.

Illness behavior is a concept more easily applied to individual patients than sick role and has therefore seen more use in clinical settings. However, it is dependent on social definitions of what constitutes legitimate illness. Although medical science determines what qualifies as *disease* based on objective changes in anatomy and physiology, society determines what qualifies as illness. These often follow each other quite closely, but there can be interesting discrepancies. Essential hypertension is a disease usually without symptoms. It has taken a concerted educational effort on the part of the medical profession to convince the public that it is an illness that should be monitored and treated. Chronic fatigue syndrome and fibromyalgia are illnesses increasingly recognized and accepted by the public. Because the medical profession has not been able to identify objective changes in physiology with these illnesses, many physicians question whether they qualify as legitimate diseases. Physicians, insurance companies, and compensation systems can find themselves in disagreement with patients experiencing chronic pain about whether a legitimate disease or illness is causing the pain.

Pilowsky introduced the concept of *abnormal illness behavior* for those situations in which physician and patient disagree about the applicability of the sick role to the patient's condition.[228] He contends that patients with truly abnormal illness behavior have extreme difficulty accepting the advice of any physician if it does not agree with their own appraisal of their health status. He cautions that misdiagnoses of abnormal illness behavior can occur when physician and patient do not share a common culture. We might add that it is also important to keep in mind the limitations of current diagnostic tests and disease criteria when diagnosing the patient's disagreement with his or her physician as pathologic.

Overview of Somatoform Disorders

Current psychiatric thinking frames the diagnoses of abnormal illness behavior or misuse of the sick role as somatoform disorders. The essential feature of the somatoform disorders is the presence of physical symptoms that suggest a general medical condition but are not fully explained by a general medical condition. These symptoms must cause impairment in social and occupational functioning. The somatoform disorders are distinguished from factitious disorders and malingering in that the symptoms are not intentionally or voluntarily produced in the somatoform disorders. Malingering is the deliberate feigning of symptoms for a clear gain, often financial. In factitious disorder, while there is a feigning of symptoms, the patient is only partially aware that they are doing so and their gain or benefit is much less clear. In factitious disorder, the maintenance of symptoms is for the psychological benefits of the sick role, similar to the gain in somatoform disorders.

In the majority of patients with pain and somatoform illness there is a physical basis (including functional or structural pathology, such as neuropathic pain) for at least a portion of the pain complaints, in which symptom-reporting is magnified by somatizing. Somatization is best thought of as a process (versus somatization disorder, discussed below). The spectrum of somatization includes amplification of symptoms, which entails "focusing upon the symptoms, racking with intense alarm and worry, extreme disability, and a reluctance to relinquish them."[229] Pain-related psychological symptoms amplify pain perception and disability. Hence, there is a tremendous overlap between the somatoform component of a chronic pain syndrome and other psychiatric comorbidities. In other words, in a patient with pain and any psychiatric comorbidity, somatization is a ubiquitous, mediating process by which pain and disability are worsened. It has psychological and physiological bases, which are still being elucidated. Similarly, pain complaints may become an "idiom of distress"[128] in which psychological distress or needs are commu-

nicated through the proxy of pain reporting. Four somatoform disorders may involve pain: somatization disorder, conversion disorder, hypochondriasis, and pain disorder (with or without a physical basis for pain). Somatoform disorders without any physical basis for pain are estimated to occur in 5% to 15% of patients with chronic pain who receive pain treatment.[230]

Somatization Disorder

Somatization disorder is a chronic condition characterized by a pattern of multiple and recurrent somatic complaints resulting in medical treatment and impairment in role functioning, but not explained by a general medical condition. For this particular somatoform diagnosis, the somatic symptoms must be persistent and pervasive. These complaints must begin before 30 years of age and last for a period of years. Diagnostic criteria are displayed in Table 31.5.

TABLE 31.5

DIAGNOSTIC AND STATISTICAL MANUAL**, FOURTH EDITION, DIAGNOSTIC CRITERIA FOR SOMATIZATION DISORDER**

A. A history of many physical complaints beginning before age 30 years that occur over a period of several years and result in treatment being sought or significant impairment in social, occupational, or other important areas of functioning.

B. Each of the following criteria must have been met, with individual symptoms occurring at any time during the course of the disturbance:
   1. Four pain symptoms: a history of pain related to at least four different sites or functions (e.g., head, abdomen, back, joints, extremities, chest, rectum, during menstruation, during sexual intercourse, or during urination).
   2. Two gastrointestinal symptoms: a history of at least two gastrointestinal symptoms other than pain (e.g., nausea, bloating, vomiting other than during pregnancy, diarrhea, or intolerance of several different foods).
   3. One sexual symptom: a history of at least one sexual or reproductive symptom other than pain (e.g., sexual indifference, erectile or ejaculatory dysfunction, irregular menses, excessive menstrual bleeding, vomiting throughout pregnancy).
   4. One pseudoneurological symptom: a history of at least one symptom or deficit suggesting a neurologic condition not limited to pain (conversion symptoms such as impaired coordination or balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia, urinary retention, hallucinations, loss of touch or pain sensation, double vision, blindness, deafness, seizures; dissociative symptoms such as amnesia; or loss of consciousness other than fainting).

C. Either 1 or 2:
   1. After appropriate investigation, each of the symptoms in criterion B cannot be fully explained by a known general medical condition or the direct effects of a substance (e.g., a drug of abuse or medication).
   2. When there is a related general medical condition, the physical complaints or resulting social or occupational impairment are in excess of what would be expected from the history, physical examination, or laboratory findings.

D. The symptoms are not intentionally produced or feigned (as in factitious disorder or malingering).

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:449–450, with permission.

Many of the somatoform diagnoses, including somatization disorder, have their historic roots in the diagnosis of hysteria.[231] The Egyptians first ascribed multiple unexplained somatic symptoms to the displacement of other organs by a wandering uterus. In the seventeenth century, Thomas Sydenham dissociated hysteria from the uterus and associated it with psychological disturbances. In 1859, Briquet described the multisymptomatic and protracted course of the illness in 430 Parisian patients. This description was taken up in the 1950s by investigators at Washington University in St. Louis.[231] They described *Briquet's syndrome* as a multisymptomatic form of hysteria with 25 symptoms from 10 different symptom groups. By the publication in 1980 of *DSM-III*, the diagnosis had been streamlined to require 14 of 37 potential symptoms, and the name had been changed to *somatization disorder*. Through these changes, the essential feature of somatization disorder has remained multiple unexplained somatic symptoms producing disability and health care use. Somatization disorder must be distinguished from medical disorders producing multiple and scattered symptoms, such as multiple sclerosis or systemic lupus erythematosus. It must also be distinguished from panic disorder that also produces multiple somatic symptoms but is a more acute and treatable psychiatric disorder.

Epidemiology. The prevalence of somatization disorder in the community has been reported to be between 0.13% and 0.4%, with the vast majority of cases occurring in women.[232] Prevalence estimates in the primary care setting have ranged from 0.2% to 5.0%. Studies of patients referred to pain clinics have produced estimates from 8% to 12%. Although prevalence rates clearly increase when moving from community to primary care to tertiary care settings, somatization disorder patients remain in the clear minority in all settings. Unexplained somatic symptoms are a common problem in medical settings that extend far beyond the bounds of somatization disorder. Various attempts have been made to assess the prevalence of an abridged version of somatization disorder in primary care, requiring four to six unexplained symptoms (4.4% of patients) or three symptoms persistent over a 2-year period (8.2% of patients).[233] Even these abridged forms of somatization disorder are associated with increased rates of disability, health care use, and mood and anxiety disorders. Although the initial emphasis with Briquet's syndrome and somatization disorder was on a discrete, familial, even genetic, disorder, evidence suggests that somatization is a process that exists along a spectrum of severity.[234] A large international study confirms that medically unexplained somatic symptoms are common, whereas full somatization disorder is quite rare.[235] A great deal of confusion exists between somatization as a process and somatization as a disorder. Somatization as a process, meaning the somatic experience of distress, is ubiquitous.[236] It accounts for the majority of symptoms presented to primary care physicians. It is most frequently associated with transient stressors (therefore time limited) or acute psychiatric disorders (which are treatable). Somatization disorder is a rare, chronic, and treatment-resistant condition that characterizes the most severely and chronically distressed individuals. When clinicians use the term *somatizer* to refer to a patient with unexplained symptoms, it is unclear whether they are implying the process or the disorder.

Although somatization disorder frequently occurs within families and has a genetic component, it also appears to have a strong association with childhood physical and sexual abuse.[237] A significant percentage of patients who meet criteria for somatization disorder also meet criteria for borderline personality disorder.[238] This has led some investigators to question the independence of these diagnoses and others to stress their common origin in severe childhood abuse. Borderline personality disorder is a severe, chronic pattern of chaotic and dysfunctional interpersonal relationships. Diagnostic criteria are presented in Table 31.6.

In a study of 200 patients with back pain attending a pain clinic, 51% of patients had some personality disorder and 15%

TABLE 31.6

DIAGNOSTIC AND STATISTICAL MANUAL, **FOURTH EDITION, DIAGNOSTIC CRITERIA FOR BORDERLINE PERSONALITY DISORDER**

A pervasive pattern of instability of interpersonal relationships, self-image, and affects and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment. Note: Do not include suicidal or self-mutilating behavior covered in criterion 5.
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.
3. Identity disturbance: markedly and persistently unstable self-image or sense of self.
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating). Note: Do not include suicidal or self-mutilating behavior covered in criterion 5.
5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior.
6. Affective instability caused by a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days).
7. Chronic feelings of emptiness.
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights).
9. Transient, stress-related paranoid ideation or severe dissociative symptoms.

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:654, with permission.

had borderline personality disorder determined by structured psychiatric interview.[239] This is a strikingly high prevalence of these disorders compared with other clinical populations. As discussed above, some controversy exists about the validity of these diagnoses, especially as to whether they constitute a cause or effect of the chronic pain problem.[240]

Treatment. Recognizing patients with somatization disorder is important, because they are among the most difficult patients to treat in the entire health care system. Above all, it is important to prevent iatrogenic damage to these patients through overly focused and invasive attempts to treat pain complaints. These patients are typically resistant to standard cognitive-behavioral treatment strategies used in chronic pain. They have extreme problems with trust and do not form therapeutic relationships easily. Any attempt to reframe somatic distress in emotional terms is likely to be experienced as an invalidation until a therapeutic alliance is well established. An adaptation of cognitive-behavioral therapy called *dialectical-behavioral therapy* has been shown effective for patients with borderline personality disorder, but has not been tested in patients with somatization disorder.[241]

Psychotropic medications have highly unpredictable effects in this group.[242] Any medications associated with tolerance and dependence, such as opioids and benzodiazepines, should be avoided, because they are often associated with clinical deterioration. Antidepressant medications also have unpredictable effects and should be prescribed only in collaboration with a psychiatrist. For patients with soft psychotic symptoms, such as depersonalization and derealization, low-dose antipsychotic medication may be of some benefit.

PAIN DISORDER

Diagnosis

In many prevalent pain syndromes (e.g., low back pain, headache, fibromyalgia), it is difficult to identify the tissue pathology giving rise to symptoms. When a somatic cause for pain cannot be identified, many clinicians begin to seek psychological causes. The identification of psychogenic pain is a difficult and perhaps impossible task. *Pain disorder* is the current psychiatric diagnosis that most closely corresponds to the diagnosis of psychogenic pain.

Because pain disorder is an important but problematic concept at the interface of pain medicine and psychiatry, it is important to understand some of the history of the concept. In *DSM-II* (published in 1968), no specific diagnoses existed that pertained to pain. Painful conditions caused by emotional factors were considered part of the psychophysiologic disorders. In 1980, *DSM-III* introduced a new diagnostic category for pain problems, *psychogenic pain disorder*.[243] To qualify, a patient needed to have severe and prolonged pain inconsistent with neuroanatomic distribution of nociceptors or without detectable organic etiology or pathophysiologic mechanism. Related organic pathology was allowed, but the pain had to be "grossly in excess" of what was expected on the basis of physical examination. Accepted evidence that psychological factors were involved in the production of the pain were (a) a temporal relationship between pain onset and an environmental event producing psychological conflict, (b) pain appearing to allow avoidance of some noxious event or responsibility, and (c) pain promoting emotional support or attention the individual would not have otherwise received. It is important to note that this kind of evidence never proves that psychological factors have caused a pain complaint.

Difficulties in establishing that pain was psychogenic led to changes in the diagnosis for *DSM-III-R*, which was published in 1987.[244] In *DSM-III-R*, the diagnosis was renamed *somatoform pain disorder*, and three major changes were made in the diagnostic criteria. The requirements for etiologic psychological factors and lack of other contributing mental disorders were eliminated, and a requirement for "preoccupation with pain for at least six months" was added. The diagnostic criteria were thus reduced to the following:

1. Preoccupation with pain for at least 6 months
2. Either a or b:
   a. Appropriate evaluation uncovers no organic pathology or pathophysiologic mechanism to account for the pain.
   b. When there is related organic pathology, the complaint of pain or resulting social or occupational impairment is grossly in excess of what would be expected from the findings.[245]

In *DSM-III-R,* therefore, somatoform pain disorder becomes purely a diagnosis of exclusion. The diagnosis is made when medical disorders are excluded in a patient *preoccupied* with pain.

The *DSM-IV* subcommittee on pain disorders found that, despite these changes, *somatoform pain disorder* was rarely used in research projects or clinical practice. They identified a number of reasons for this: (a) the meaning of "preoccupation with pain" is unclear, (b) whether pain exceeds that expected is difficult to determine, (c) the diagnosis does not apply to many patients disabled by pain in which a medical condition is contributory, (d) the term *somatoform pain disorder* implies that this pain is somehow different from organic pain, and (e) acute pain of less than 6 months' duration was excluded.[246] They therefore proposed the *DSM-IV* category of pain disorder described in Table 31.7.

The *DSM-IV* subcommittee has tried to devise a broader diagnostic grouping encompassing both acute and chronic pain prob-

TABLE 31.7

DIAGNOSTIC AND STATISTICAL MANUAL, **FOURTH EDITION, DIAGNOSTIC CRITERIA FOR PAIN DISORDER**

A. Pain in one or more anatomic sites is the predominant focus of the clinical presentation and is of sufficient severity to warrant clinical attention.

B. The pain causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. Psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of the pain.

D. The symptom of deficit is not intentionally produced or feigned (as in factitious disorder or malingering).

E. The pain is not better accounted for by a mood, anxiety, or psychotic disorder and does not meet criteria for dyspareunia.

Code as follows:

307.80, Pain disorder associated with psychological factors: Psychological factors are judged to have the major role in the onset, severity, exacerbation, or maintenance of the pain. (If a general medical condition is present, it does not have a major role in the onset, severity, exacerbation, or maintenance of the pain.) This type of pain disorder is not diagnosed if criteria are also met for somatization disorder.

Specify if:
Acute: duration of less than 6 months
Chronic: duration of 6 months or longer

307.89, Pain disorder associated with both psychological factors and a general medical condition: Both psychological factors and a medical condition are judged to have important roles in the onset, severity, exacerbation, or maintenance of the pain. The associated general medical condition or anatomic site of the pain (see following) is coded on axis III.

Specify if:
Acute: duration of less than 6 months
Chronic: duration of 6 months or longer

Note: The following is not considered to be a mental disorder and is included here to facilitate differential diagnosis.

Pain disorder associated with a general medical condition: A general medical condition has a major role in the onset, severity, exacerbation, or maintenance of the pain. (If psychological factors are present, they are not judged to have a major role in the onset, severity, exacerbation, or maintenance of the pain.) The diagnostic code for the pain is selected based on the associated general medical condition if one has been established (see Appendix G) or on the anatomic location of the pain if the underlying general medical condition is not yet clearly established—for example, low back (724.2), sciatic (724.3), pelvic (625.9), headache (784.0), facial (784.0), chest (786.50), joint (719.4), bone (733.90), abdominal (789.0), breast (611.71), renal (788.0), ear (388.70), eye (379.91), throat (784.1), tooth (525.9), and urinary (788.0).

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:461–462, with permission.

lems. They wanted to have all the factors relevant to the onset or maintenance of the pain delineated and also to have a diagnostic category that does not require more training than the majority of *DSM-IV* users would be expected to have. These two requirements may not be compatible. Furthermore, no guidance is given in determining when psychological factors have a major role in pain or are considered important enough in the presence of a painful medical disorder to be coded as a separate mental disorder. Given the high rates of mood and anxiety disorders among disabled chronic pain patients, many patients most appropriate for the diagnosis would be excluded. Although depression and anxiety diagnoses point toward specific proven therapies, this is not true for pain disorder. The diagnosis thus continues covertly as a diagnosis of exclusion with neither clear inclusion criteria nor implications for therapy. However, these revised criteria are more useful in thinking about somatization as a psychiatric amplification process applied to pain.

Epidemiology

Because pain disorder has poor interrater reliability[247] and (as suggested previously) poor validity, there have been few epidemiologic studies of the *DSM* pain disorders. There have, however, been good studies of pain complaints and unexplained medical symptoms. In a study of adult health maintenance organization members, Von Korff and colleagues found the prevalence of pain over a 6-month period was 41% for back pain, 26% for headache, 17% for abdominal pain, 12% for chest pain, and 12% for facial pain.[248] These pain complaints were typically long-standing but nondisabling. However, 9% to 40% reported 1 or more days of disability in the past 6 months. Persons with a pain condition had higher levels of anxiety, depression, and nonpain somatic complaints.

Multiple studies have also demonstrated the association between medically unexplained symptoms (pain and nonpain) and psychiatric disorders. A linear relationship has been demonstrated between the lifetime number of medically unexplained physical symptoms and the lifetime number of depressive and anxiety disorders or the degree of neuroticism or harm avoidance the patient demonstrates on psychological testing.[249] Increased psychiatric morbidity has been repeatedly demonstrated for levels of unexplained medical symptoms far below the number required for a *DSM* diagnosis of somatization disorder.[250] This suggests that the somatoform disorders may be less distinct than implied by their separate *DSM* categories and that they have a strong kinship with the depressive and anxiety disorders. It may be more accurate and productive to think of somatization as a process present in varying degrees throughout the population rather than a set of disorders affecting a small subset of the population.[236]

Treatment

Because chronic pain often has multiple causes or contributing factors, it often does not respond to purely somatic or purely psychological modes of treatment. Persistent pain can set a vicious cycle of reinforcing features into motion that then becomes a self-perpetuating problem independent of the initiating illness or injury. Deactivation, depression, disuse, medication misuse, and vocational dysfunction are all common contributing factors to the suffering and disability associated with chronic pain. Although simpler cases of chronic pain may respond to an approach based on the biomedical model, this is not true for the extremely disabled or prolonged cases likely to be referred to psychiatrists or psychologists.

Patients with disabling chronic pain are prone to *doctor shopping*, in which they obtain medications and procedures from a number of physicians unknown to each other. It is not possible to successfully treat a patient with chronic pain who has not formed a solid and honest therapeutic alliance with his or her treating physician. When evidence of doctor shopping becomes apparent, the patient should be confronted immediately and a conversation opened about the doctor–patient relationship. If the patient does not agree to stop unannounced visits to other physicians, he or she should be dismissed from care, as it is impossible to provide appropriate service in this situation.

The needs of patients with disabling chronic pain often outstrip the resources of the most enlightened and eager primary care physician. These patients are most appropriately treated by a multidisciplinary team experienced in the treatment of chronic pain. Members of this team may include a psychiatrist, psychologist, neurologist, neurosurgeon, physical therapist, occupational therapist, nurse, and vocational counselor. Although each case does not require the expertise of each of these disciplines, all of these disciplines have expertise relevant to the management of chronic pain.

The treatment of chronic pain is in many ways counterintuitive to the clinician and the patient. Many medications used for acute pain are contraindicated. Relief from pain must often be secondary to reduction in disability and deactivation. Clinical phenomena that seem clearly caused by the pain (e.g., depression must be addressed before pain relief is possible).

Most important, pain is not itself a psychiatric disorder. Chronic pain is frequently complicated by psychiatric disorders, however. The most common of these is depression. Psychiatric treatment of these disorders has an important role to play in the rehabilitation of the chronic pain patient.

CONVERSION DISORDER

The essential feature of conversion disorder is an alteration in voluntary motor or sensory function that suggests a neurologic or general medical disorder. Classic examples include hysterical paralysis, blindness, or mutism. Psychological factors must be associated with the initiation or exacerbation of this deficit. Diagnostic criteria are displayed in Table 31.8.

TABLE 31.8

DIAGNOSTIC AND STATISTICAL MANUAL, **FOURTH EDITION, DIAGNOSTIC CRITERIA FOR CONVERSION DISORDER**

A. One or more symptoms or deficits affecting voluntary motor or sensory function that suggest a neurologic or other general medical condition.

B. Psychological factors are judged to be associated with the symptom or deficit because the initiation or exacerbation of the symptom or deficit is preceded by conflicts or other stressors.

C. The symptom or deficit is not intentionally produced or feigned (as in factitious disorder or malingering).

D. The symptom or deficit cannot, after appropriate investigation, be fully explained by a general medical condition, or by the direct effects of a substance, or as a culturally sanctioned behavior or experience.

E. The symptom or deficit causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or warrants medical evaluation.

F. The symptom or deficit is not limited to pain or sexual dysfunction, does not occur exclusively during the course of somatization disorder, and is not better accounted for by another mental disorder.

Specify type of symptom or deficit:
- With motor symptom or deficit
- With sensory symptom or deficit
- With seizures or convulsions
- With mixed presentation

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:457, with permission.

Great caution must be exercised in making the diagnosis of conversion disorder, because the presence of relevant psychological factors does not exclude the possibility of a concurrent organically caused condition.

In "Psychogenic Pain and the Pain-Prone Patient," George Engel proposed that psychogenic pain arose from guilt and an intolerance of success.[117] He indicated that it functioned as a substitute for loss or a replacement for aggression. He furthermore stated that ". . . patients with conversion hysteria constitute the largest percentage of the pain-prone population." Others have also contended that pain is probably the most common conversion symptom encountered clinically.[251] However, only case reports exist to support this contention. Pain is not a classic conversion disorder symptom, and it is controversial whether chronic pain can ever qualify as a conversion disorder by itself. Some, for example, have contended that reflex sympathetic dystrophy (complex regional pain syndrome) can be understood as a conversion reaction; however, this is highly controversial.[252] Some elements of conversion disorders appear to be present in reflex sympathetic dystrophy/complex regional pain syndrome patients (e.g., indifference or neglect toward the affected body part), although it is highly unlikely that the condition is entirely psychogenic.

Rather than labeling some chronic pain problems as conversion reactions and others as not, it may be more useful to understand what components of conversion reaction may be present in chronic pain problems. Again, the emphasis should be on thinking about somatoform illnesses as a process. Being ill surely creates problems in living for those affected, but it can also solve problems in living. For example, being ill provides an excuse for not being at school or not meeting a deadline at work. These interpersonal advantages of illness were originally recognized by Freud and termed *secondary gain*.

The term *secondary gain* has been distorted and misunderstood in the care of chronic pain, probably because of medicolegal pressures. A number of corrections are in order. First, all illnesses are characterized by some secondary gain, not just illnesses considered to be psychogenic. Being sick always has advantages as well as disadvantages. Second, secondary gain includes all potential interpersonal benefits of illness, not just monetary advantages. Many of the advantages of illness are quite subtle and individualized. Third, secondary gain must be understood in the context of *primary gain*, the intrapersonal advantages of illness. For example, focusing on pain rather than depression may allow patients to avoid self-blame and thereby achieve primary gain. This is a common phenomenon in chronic pain. Indeed, blame avoidance has been hypothesized by some to be one of the main functions of somatization.[253] Thus, traditional elements of conversion disorder may be present in many chronic pain problems without many pain problems qualifying as conversion disorders *per se*.

Purely psychogenic or conversion models of chronic pain have some questionable implications for diagnosis and therapy of chronic pain disorders. Interview of the patient with a suspected conversion disorder with the aid of a sodium amobarbital (Amytal) infusion has been a standard tool in psychiatric diagnosis.[254] More recently, lorazepam interviews have been substituted. It is more common that motor and sensory deficits than pain resolve under Amytal or benzodiazepine sedation. Furthermore, some patients have had violent or suicidal reactions to abrupt resolution of their somatic symptoms under Amytal, possibly caused by loss of face-saving primary gain aspects of the illness. Psychodynamic theories of the origin of conversion symptoms imply that psychological treatments alone will be effective.

Psychodynamic treatments for chronic pain, however, have little documented success. The most effective psychological treatments, such as cognitive-behavioral therapy, include a reactivation component that addresses the profound disuse and deconditioning found in many patients with chronic pain.

HYPOCHONDRIASIS

Many patients with chronic pain resist their physician's reassurance that "nothing is wrong" or that the "tests reveal nothing." These patients know that they hurt and cannot accept that a bodily cause cannot be identified for their pain. This has been described as *disease conviction* in the chronic pain literature. Disease conviction has been measured with the Illness Behavior Questionnaire, and Hypochondriasis is assessed with the Minnesota Multiphasic Personality Inventory. In *DSM-IV* there also exists a disorder called *hypochondriasis*. Diagnostic criteria are list in Table 31.9.

The prevalence of hypochondriasis in primary care has been reported to be 4% to 9%.[255] The prevalence of hypochondriasis in pain clinic populations is difficult to determine, but is likely to be high if patients are not excluded by qualifying for pain disorder, because of the likelihood of disagreement between patient and physician about the cause of the pain problem.

Treatments of hypochondriasis have attempted to shift patient focus from cure of the disease causing the symptoms to strategies of symptom management.[256] These strategies are common components of multidisciplinary pain treatment programs as well. It is indeed critical to achieve early in treatment some agreement with the patient about the cause of the pain that acknowledges the reality of the pain and yet points away from invasive attempts to cure disease or repair broken parts. The task is not to convince the patient that "nothing serious is wrong," because his or her pain may be severe and persistent. The task is to convince the patient that the appropriate treatment is different than the treatment he or she thought necessary.

TABLE 31.9

DIAGNOSTIC AND STATISTICAL MANUAL**, FOURTH EDITION, DIAGNOSTIC CRITERIA FOR HYPOCHONDRIASIS**

A. Preoccupation with fears of having, or the idea that one has, a serious disease based on the person's misinterpretation of bodily symptoms.

B. The preoccupation persists despite appropriate medical evaluation and reassurance.

C. The belief in criterion A is not of delusional intensity (as in delusional disorder, somatic type) and is not restricted to a circumscribed concern about appearance (as in body dysmorphic disorder).

D. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

E. The duration of the disturbance is at least 6 months.

F. The preoccupation is not better accounted for by generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, a major depressive episode, separation anxiety, or another somatoform disorder.

Specify if:
With poor insight: If, for most of the time during the current episode, the person does not recognize that the concern about having a serious illness is excessive or unreasonable.

From *Diagnostic and Statistical Manual*, 4th ed. Washington, DC: American Psychiatric Association, 1994:465, with permission.

CONCLUSION: PAIN AND SUFFERING AND PSYCHIATRY

Psychiatric diagnosis and treatment can add an essential and often neglected component to the conceptualization and treatment of chronic pain problems. The high rates of psychiatric comorbidity and the negative impact they have on chronic pain necessitate that a psychiatric assessment be part of any comprehensive pain evaluation. The expanse of psychiatric symptoms in patients with pain is broad and deep, and thus a comprehensive framework for describing psychiatric symptoms and the relationships between them is essential to thorough diagnosis and treatment. Advances in neuroimaging have elucidated some of the interrelationships between pain perception and psychological states, underscoring that most painful conditions have an affective component to the pain experience.

It is this disordered affective experience of pain and consequently, suffering, that form a key interaction between pain and overlying psychiatric disorders. It is absolutely critical to avoid a dualistic model that postulates that pain is either physical or mental in origin. This model alienates patients who feel blamed for their pain. It also is inconsistent with modern models of pain causation. Since the gate control theory of pain, multiple lines of evidence suggest that pain is a product of efferent as well as afferent activity in the nervous system. Tissue damage and nociception are neither necessary nor sufficient for pain. Indeed, it is now widely recognized that the relationship between pain and nociception is highly complex and must be understood in terms of the situation of the organism as a whole.

We are only beginning to understand the complexities of the relationship between pain and suffering. Pain usually, but not always, produces suffering. Suffering can, through somatization, produce pain. We have traditionally understood this suffering, as we have understood nociception, as arising from a form of pathology intrinsic to the sufferer. Hence, the traditional view that pain is caused by either tissue pathology (nociception) or psychological states (suffering). Psychiatric comorbidity represents an additional layer of suffering, which also magnifies the perception on pain. Yet this is still somewhat dualistic; an alternative model is to think of pain as a *transdermal process* with causes outside as well as inside the body. For humans, social pathology can be as painful as tissue pathology. We can investigate the physiology and the psychology of this *sociogenic* pain without losing sight of its origins in relations *between* people.

Psychiatric care for patients with chronic pain should occur within the medical treatment setting whenever possible. This is the most effective way to reassure patients that the somatic elements of their problems are not neglected. It also allows integration of somatic and psychological treatments in the most effective manner.[1] The success of multidisciplinary approaches to pain underscores the value of psychiatric assessment and treatment by the pain medicine provider.

CHAPTER 32 ■ THE PSYCHOLOGY OF ADDICTION

LAUREN J. ROGAK, TATIANA D. STARR, KENNETH L. KIRSH, AND STEVEN D. PASSIK

INTRODUCTION

Within the past several decades, the treatment of pain has made remarkable progress.[1,2] Pain assessment and treatment have became priorities of medical care ranks and are focused on attempting to bring relief to the overwhelming population of chronic pain patients.[3,4] Among these many efforts is the use of opioid therapy for the treatment of nonmalignant pain. Even with the potential benefits seen in association with opioid treatment, the pain community's rhetoric tended to trivialize addictions and the intricacy of risk stratification now seen as inherent to the proper delivery of opioid treatment.[5]

The integration of pain management and addiction medicine has been slow in coming. A fundamental inconsistency exists in specialists in addiction, who have a tendency to pinpoint the role of these drugs as a major cause of abuse, and pain specialists, who perceive them as essential medications for pain and suffering. These philosophical differences in these camps emphasizes the historical lack of communication between them.[6]

The gap in communication must be closed, given the significant prevalence and interactions between pain and chemical dependency. A multitude of surveys, both national and international, have shown a prevalence rate for chronic pain as high as 40%.[4] Domestic surveys of substance abuse have reported a prevalence of 6% to 10% of the population who use illicit drugs habitually and one-third have sampled one of these drugs at least once.[7–9] These prevalence rates suggest that clinicians will commonly encounter patients with comorbid pain and drug abuse.[6]

The growth of opioid therapy demands an ongoing evaluation of the associated benefits and risks. The populations are often merged as chronic pain patients are obviously not "immune" to problems of misuse, abuse, addiction, or diversion.[10]

Prevalence of Substance Abuse

It is estimated that 6% to 15% of the United States' population have some type of substance use disorder with approximately one-third having used illicit drugs.[7–9] Additionally, there has been a significant increase in prescription drug abuse over the past decade, with rates rising nearly 94%, from 7.8 million in 1992 to approximately 15.1 million in 2003.[11] The growing rates and high prevalence of prescription drug abuse raises concerns surrounding the use of such medications in the medical setting. When not used properly, opioids and central nervous system stimulants and depressants can be fatal.[12] In 2002, controlled substances were implicated in 30% of drug-related emergency room deaths and 23% of emergency room admissions.[11] According to the National Center on Addiction and Substance Abuse, approximately one-third of prescription drug abusers in 2000 were new users. Between 1992 and 2003, there was a 225% increase in new opioid abusers, 150% increase in new tranquilizer abusers, 127% increase in new sedative abusers, and a 171% increase in new stimulant abusers.[11]

The high prevalence of drug use, generally along with the overwhelming increase in prescription drug abuse, raises concerns regarding the manner in which pain is treated. Chronic pain patients who have current or remote histories of drug abuse face a number of physical and psychosocial concerns that could potentially affect their medical treatment and pain management. Even when patients do not have a history of abuse, questionable, problematic behaviors may manifest during pain treatment. It is evident that the interface between medical usage of potentially abusable prescription medications and the misuse and abuse of these drugs is complex and must be understood in order to provide optimal patient care.[12]

Definitions

Among the most significant challenges associated with management of substance abuse in chronic pain patients is the lack of clear, consistent terminology.[13] Defining abuse and addiction in medically ill populations can be highly problematic due to the current use of definitions that were originally developed to assess addicted populations without medical illness. The utilization of this terminology can create confusion in the clinical setting for a number of reasons. Many pain patients will be prescribed potentially abusable drugs such as opioids for legitimate medical purposes and subsequently experience the pharmacological phenomena of tolerance and physical dependence after long-term use.[13] This is further complicated by the fact that many clinicians do not specialize in treating cooccurring substance abuse, and often confuse behaviors associated with tolerance and dependance with abuse and addiction.[13] Therefore, it is inappropriate to apply this terminology to chronic pain patients as it further hinders the ability to distinguish between aberrant and appropriate drug-taking behaviors. Improper use of these terms also creates confusion and impedes the communication between the patient and clinician, which is a necessary component of adequate pain management.[12,14] Clarification of this terminology is a critical step in improving pain management and overall patient care.

Tolerance

Tolerance is defined as a pharmacological experience in which an increase in dosage is necessary to maintain the effects of the medication.[15,16] This phenomenon is not necessarily an indication of abuse or addiction, and the experience of tolerance is frequently associated with escalating pain or disease progression.[17–25] Tolerance to nonanalgesic effects (i.e., respiratory depression and cognitive impairment) are often seen in the clinical setting.[26] Tolerance to the analgesic effects of opioids has been reliably observed in animal models; however, analgesic tolerance rarely interferes with the clinical efficacy of opioids.[27] The need to increase the dosage is often indicative of progressing pain.[17,20,23,25,28–30] Clinically relevant analgesic tolerance, the need to increase the dosage without disease progression, seems to be a rare occurrence. There is also little evidence supporting the conclusion that tolerance significantly contributes to the development of addiction.[12]

Physical Dependence

There is considerable confusion among the medical community regarding the differences between physical dependence and addic-

tion. Physical dependence is defined exclusively by the occurrence of a withdrawal syndrome after there is a sudden decrease in dosage or following the administration of an antagonist.[15,16,31] This phenomenon is likely to occur as a result of prolonged use of opioids when the prescribed dosage no longer offers sufficient pain relief. Physical dependence, much like tolerance, has also been conceptualized as a component of addiction[32,33] in that avoidance of withdrawal symptoms potentially lead to behavioral contingencies that reinforce drug-seeking behavior.[34] It is important to note, however, that the experience of physical dependence does not inevitably lead to complications during discontinuation of opioids in patients with nonmalignant pain[35] and cessation of opioid therapy frequently occurs without difficulty in cancer patients whose pain is diminished after completion of antineoplastic therapy. Animal models of opioid self-administration have also provided evidence demonstrating a fundamental distinction between physical dependence and addiction; these models have indirectly shown that persistent drug-taking behavior can continue despite the absence of physical dependence.[36]

Addiction

There are a number of issues surrounding the terms "addiction" and "addict." The confusion caused by using these labels to describe all patients who exhibit questionable drug-taking behaviors can be highly problematic. This is due to the lack of a discernible categorization between individuals who are engaging in aberrant drug-taking behaviors and those that are experiencing tolerance and physical dependence, thus needing to increase their dosage in order to achieve sufficient pain relief.[37] Clinicians and other medical professionals must be mindful in their application of these labels in order to avoid additional confusion. The terms "addict" and "addiction" should never be used in reference to a patient only believed to have the capacity for an abstinence syndrome. The term "physically dependent" is more appropriate in describing such patients. Medical staff should also be careful about using the word "dependent" without specifications toward physical or psychological dependence, which are both elements of addiction. With this in mind, use of the word "habituation" is also discouraged.[12]

Definitions of the terms "addict" and "addiction" should be based on the ability to identify questionable drug-related behaviors that fall outside cultural and societal norms. However, in categorizing aberrant drug-taking behaviors (e.g., escalating dosage or using medication for purposes other than prescribed) as unacceptable according to societal norms, it is not without the assumption that there is a universal understanding of the boundaries of normative behavior. If a significant proportion of patients demonstrate a specific type of behavior it could be considered normative and assessments regarding deviation from this norm would be influenced accordingly. However, in the context of prescription drug use, no empirical data exist that define the parameters of normative behavior. This issue was recently addressed in a pilot study performed at Memorial Sloan-Kettering Cancer Center (MSKCC). Findings indicated evidence concerning patients' attitudes supporting the misuse of drugs in response to symptom management issues. Additionally, women with HIV treated at MSKCC for palliative care were found to engage in aberrant drug-taking behaviors more commonly.[38]

Definition of Addiction in Medically Ill Populations

The prevalence of questionable drug-related behaviors among medically ill populations raises the issue of their predictive validity as an indication of any diagnosis related to substance abuse. Empirical data evaluating patients' drug-taking attitudes are needed to shed light on the prevalence of such behaviors across different medically ill populations.[12] Defining addiction is also complicated by changes that occur as a result of disease progression. It becomes increasingly difficult to establish clear distinctions between deterioration in physical and psychosocial functioning caused by the disease and treatments and the morbid effects of drug use.[12] This could potentially complicate efforts to assess the concept of "use despite harm," which is crucial to the diagnosis of addiction. For example, if a patient develops social withdrawal or changes in cognition following brain irradiation for metastases, it may be difficult to identify the nature of questionable drug-related behavior. Even if the cognitive deficits are associated with the medication used to treat the symptoms, this result might only reflect a small therapeutic window rather than the desire for these psychic effects on the patient's part.[12,14]

As previously mentioned, terminology that fails to distinguish the pharmacologic phenomena of tolerance and physical dependence frequently encountered in chronic pain patients creates additional barriers in identifying and treating addiction. A more suitable definition of addiction should focus on the chronicity of the disorder, characterized by "the compulsive use of a substance resulting in physical, psychological, or social harm to the user and continued use despite that harm."[39] Although this definition was taken from evaluation of addicted populations without medical illness, it addresses that addiction is, in essence, a psychological and behavior syndrome which allows it to flexibly apply to medically ill populations.[12] Concepts such as loss of control and compulsive drug use, as well as continued drug use despite harm, are essential components of an appropriate definition of addiction and should be included.[12] However, even with these ideas incorporated, these definitions still fall short in describing the broad scope of aberrant drug-taking behaviors that arise in the clinical setting.[12]

Pseudoaddiction

Assessing and interpreting drug-taking behaviors in the medical setting can be challenging. Even when there is an appropriate medical indication for drug use, the occurrence of questionable drug-related behavior is at the least an important sign that reevaluation of the patient's drug-taking regimen is necessary. When a drug-related behavior is classified as aberrant, it is important to further evaluate the behavior for a "differential diagnosis." Pseudoaddiction refers to the escalation of dosages in response to insufficient analgesia but with the behavior resolving once adequate pain relief is achieved.[40] Pseudoaddiction may be an appropriate consideration when a patient reports discomfort and distress associated with unremitting symptoms. Continuous requests for higher doses of medication, or sporadic unilateral dose escalation, may initially be perceived as addiction; however, it is likely such behaviors are indicative of desperation resulting from unrelieved pain and will cease once the patient experiences relief.

Pain specialists and addiction specialists have recently combined their efforts to develop a definition of a more universal and acceptable definition of addiction.[6] The following definition is currently endorsed by the American Society of Addiction Medicine, the American Pain Society, and the American Academy of Pain Medicine:

> Addiction is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors . . . It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.[41]

Although this definition can be a helpful reference for clinicians and investigators, further research is necessary in order to empirically differentiate each of the criteria and to demonstrate the predictive validity of the numerous behaviors included in each.[6]

Aberrant Drug-Related Behaviors: Assessment and Differential Diagnosis

The concept of aberrant behavior was first put forward by Portenoy and then expanded on by Passik and Portenoy.[12,42,43] This concept suggests that pain clinicians who prescribe opioids are expected to see varieties of noncompliance behaviors, ranging on scales of commonality and aberrancy. A broad scope of aberrant drug-related behaviors is seen in the clinical setting because opioids and other potentially abusable drugs are prescribed for legitimate medical purposes. These behaviors range from those that are considered mild or limited (e.g., use of a prescribed dose to self-medicate a problem not intended by the clinician, such as insomnia) to severe or overwhelming behaviors (e.g., injection of an oral formulation) and have the potential to predict addiction[6] (Table 32.1). Noncompliance must be spoken about clearly and at length between patients and doctors, because typical signs of addictions are not applicable and may be misleading.[12]

Differential Diagnosis

Once the behaviors are detected, within the spectrum of aberrant drug-related behaviors, a differential diagnosis needs to be formulated so that a response can be made to bring the behavior under control.[6] A differential diagnosis should be explored if questionable behaviors occur during pain treatment (Table 32.2). These potential disorders will benefit from continuous and meticulous evaluation. The major goal of these assessments is to establish the nature of the problem for the overall purpose of developing a therapeutic intervention.[44,45]

Incorporated in the differential diagnosis of aberrant drug-related behaviors is the notion of "pseudoaddiction." An added challenge surfaces when patients have both pain and comorbid substance use disorders. An increase in self-reported distress for the lack of pain relief should be considered a marker of pseudoaddiction. An increase in drug-seeking behaviors may occur in those patients with addiction disorders as a result of experiences of uncontrolled pain. This can reflect both addiction and pseudoaddiction. This distinction is one of the most confounding differential diagnoses.[40]

Impulsive drug use may also be unrelated to both addiction and pseudoaddiction. Rather, it may be indicative of the presence of another psychiatric disorder. An example of this is seen in patients with borderline personality disorder who make use of prescription drugs to convey fear, anger, or other expressive emotions and may present with aberrant behaviors. Likewise, patients may self-medicate with opioids to suppress symptoms of anxiety, depression, or insomnia.[6]

In addition to the previously mentioned causes of problematic drug-related behaviors occurring in the clinical setting, there is a litany of more uncommon, yet probable sources seen. One example is that drugs are misused because of a state of confusion. Infrequently, patients will exhibit criminal behavior by selling controlled prescription drugs.[14,44]

TABLE 32.1

ABERRANT DRUG-RELATED BEHAVIORS

Behaviors more suggestive of an addiction disorder
Selling prescription drugs
Prescription forgery
Stealing or "borrowing" drugs from others
Injecting oral formulations
Obtaining prescription drugs from nonmedical sources
Obtaining drugs from multiple medical sources without informing or despite prohibition
Concurrent abuse of alcohol or illicit drugs
Multiple episodes of self-escalation of dose, despite warnings not to do so
Multiple episodes of prescription "loss"
Evidence of functional deterioration unexplained by the pain or other comorbidity
Repeated resistance to changes in therapy despite clear evidence of adverse effects
Behaviors less suggestive of an addiction disorder
Aggressive complaining about the need for more drug
Drug hoarding during periods of reduced symptoms
Requesting specific drugs
Openly acquiring similar drugs from other medical sources
Occasional unsanctioned dose escalation
Unapproved use of the drug to treat another symptom
Reporting psychic effects not intended by the clinician
Resistance to a change in therapy associated with "tolerable" adverse effects
Expression of family concerns

TABLE 32.2

DIFFERENTIAL DIAGNOSIS OF ABERRANT DRUG-RELATED BEHAVIOR

Addiction
Pseudoaddiction
Psychiatric disorders
Axis 1 disorders (e.g., depression, anxiety, somatoform disorder)
Axis 2 disorders (e.g., borderline personality, sociopath personality)
Encephalopathy (confusion in dose and interval of prescription)
Criminal intent

The Four A's for Ongoing Monitoring

Recognizing potentially dangerous drug-taking behaviors is an important step toward providing optimal treatment and ongoing pain management. Extensive clinical experience has led to the development of a useful guideline for monitoring chronic pain patients receiving opioid treatment known as the "4 A's." This guideline incorporates the domains of pain relief, side effects, physical and psychosocial functioning, and the presence of any questionably aberrant or nonadherent drug-taking behaviors.[46] These domains are summarized as: (1) analgesia; (2) activities of daily living; (3) adverse side effects; and (4) aberrant drug-taking behaviors.[47] Ongoing monitoring of these domains throughout pain treatment provide clinicians with a framework that informs decision making and fosters adherence to therapeutic use of these controlled substances.[48]

Developing a Therapeutic Approach

As in any therapeutic approach, a comprehensive assessment and strategy must be based on a solid diagnostic foundation. When a clinician chooses to utilize opioid therapy for pain management, the clinician needs to be able to employ the current tenets for prescribing these medications. Additionally, these clinicians must assess each patient for the risks associated with misuse, abuse, addiction, and diversion, with the added responsibility of manag-

ing these risks over time. Those people within the chronic pain population who have a history of substance abuse require the prescribing clinician to be proficient in these aspects of treatment.[49]

Chronic pain can be described as nothing less than a multifaceted phenomenon that is often correlated with other symptoms and functional disturbances. Chronic pain is true to its name in its unceasing and unremitting nature. Therefore a cure is not a regular treatment result, but management is. As a result, the goals of therapy center about comfort, functional restoration, and improved quality of life.[6]

Assessment

A multidimensional syndrome, like chronic pain, requires a comprehensive assessment including compiling a history that focuses on the pain complaint, its consequences, prior treatments (e.g., prescribed and nonprescribed), relevant comorbidities, and other elements in a routine history. In regard to the pain itself, intensity, temporal features (e.g., onset, course), location, quality, and provoking or relieving factors should all be taken into account. The impact the pain has on a person's quality of life as well as the physical and psychosocial functioning needs to be accounted for.[6]

In addition to the comprehensive pain assessment, a detailed history of any drug abuse, including duration and frequency, is vital. In patients with a known history of substance abuse, the interview must gather detailed information on the specific pattern of addictive behaviors (e.g., drugs, routes, frequency of administration, means of acquisition, and means of financing). The perceived relationship between these behaviors and the pain should be clarified.[6] Adopting a nonjudgmental stance and using empathic and truthful communication is the best strategy to obtain a complete and honest history.[14,37,44] It is important to note that patients may have a history of misrepresenting their drug use for a variety of logical reasons, such as stigmatization, mistrust of the interviewer, or concerns regarding fears of undertreatment. Thus, there is a need to explain to a patient that the necessity of an accurate account of drug use is to concurrently prevent withdrawal states.[21,44,50]

Barriers to Treatment

Patients may become immersed in a routine where pain functions as a barrier to seeking treatment for addiction, with addiction potentially complicating treatment for chronic pain.[51] Also, as pain is undertreated, a patient's risk of escalating use and being perceived as abusing prescription medications and or other substances increases.[52]

The motivation behind substance abuse in the medical setting differs significantly from the seemingly pleasurable experience associated with social alcohol and even illicit drug use. In the clinical setting, patients' behavior is frequently motivated by avoidance of unpleasant physical experiences (i.e., pain) and the associated emotional consequences. Even though clinical observation demonstrates that addiction is a negative and unpleasant experience, clinicians may still perceive the motivation behind patient drug abuse as a desire to feel "high." The central premise of substance abuse and dependence is the out-of-control use despite the fact that there are substantial health, legal, and social consequences. This form of abuse is a struggle, and not motivated by an attempt to experience pleasure but rather an attempt to avoid experiencing discomfort.[53]

Chemically dependent patients spend a minimal amount of their time experiencing a "high." On the contrary, the majority of the time they feel depressed, isolated, and withdrawn and are often preoccupied with thoughts surrounding their drug use. It is important to recognize that substance abuse still persists despite the fact that there seems to be little reward associated with continued drug use. In addition, many addicts do not abuse drugs that produce feelings of euphoria, and these drugs frequently have unpleasant side effects.[53]

Guidelines for Treatment

There are several principles that can aid the clinician in ascertaining structure control and monitoring of addiction-related behaviors, whether the patients' substance abuse is current or historical.[50] An overarching guideline is to utilize outside consultants, such as pain and palliative care experts, social workers, and mental health professionals for an effective collaboration, or rather a multidisciplinary approach.[14,50]

Employing the widely accepted guidelines for cancer pain management will optimize long-term opioid therapy.[54,55] These stress patient self-report as the foundation for dosing, consistent monitoring, and the individualization of therapy in order to identify a complementary balance between efficacy and side effects,[50] and are valid for the concurrent treatment of side effects as the basis for enhancing the balance between both palliative and adverse effects.[21]

In response to unrelieved pain, aberrant drug-related behaviors may develop if the pain is undertreated. Despite understanding these behaviors as pseudoaddiction, their presence should be taken into serious consideration when prescribing medication.[50] Based on clinical experience, pseudoaddiction can lead patients with a history of substance abuse to genuinely becoming out of control.[56]

Maintaining open lines of communication will uphold a therapeutic environment with constant dialogue, which monitors the development of aberrant drug-taking behaviors. Regular evaluations are necessary for patients who are prescribed drugs with the potential for abuse, in addition to monitoring their behaviors regularly.[44] This is particularly true for those patients with a remote or current history of drug abuse, including alcohol abuse.

All patients with a history of abuse and addiction should be monitored especially closely. Patients who are actively abusing substances should be seen on a more regular basis than those patients who are not.[44,50]

Written agreements are helpful tools in structuring outpatient treatment. These agreements should clearly state the roles of each member of the team and the rules and expectations for the patient. Patients' behaviors should be used as the basis for the level of restrictions, and graded agreements that clearly state the consequences of aberrant drug use should be enforced.[44,50,57]

Within the context of outpatient management, a clinician may choose to refer patients to a 12-step program. This referral must stipulate that documented attendance is a condition for ongoing drug prescriptions.[44,50] Twelve-step programs pose a risk, because the liberal use of opioids may not be supported and the side effects misunderstood despite the patient's terminal status.

In order to endorse compliance and reveal any concurrent use of illicit substances or unprescribed licit drugs, patients with a history of aberrant drug use should be asked to submit to periodic urine toxicology screens. This will determine the early recognition of any aberrant drug-related behaviors. Patients should be provided with a detailed explanation that this is a method of monitoring, which can both reassure the clinician and provide a foundation for aggressive symptom-oriented treatment, thereby enhancing the therapeutic alliance.[44,58]

CONCLUSION

The emergent abuse of prescription drugs has mandated the field to take a new look at opioid prescribing and to seek balance in its risks and benefits. Today, all practitioners involved in pain management have the dual mission of relieving suffering while

avoiding contributing to drug abuse and diversion. If all practitioners can become better acquainted with the principles of addiction medicine as they apply to the world of pain management, pain management can be kept safe and available for all who need it. The assessment of aberrant behaviors in patients with chronic pain is one key aspect of mastering these principles.[49]

The problem of prescription drug abuse has been amplified over the past decades. The initial reports that focused on the increasing production and use of opioids was not accompanied by a growth in the abuse and diversion of these drugs had an optimistic tone[59]; however, over time, magnitude of the problem has become more blatant.[49] As a result, it is up to the prescribers to acknowledge that there is a deteriorating environment around opioid use prompted by a significant level of public concern and to therefore follow guidelines meticulously. The problem of prescription drug abuse nationally is only part of the issue however.[49]

It has become well known[60,61] that, at least in the case of cancer patients, those with pain tolerate low levels of pain relief. Understanding the foundation of this level of satisfaction has been qualified by a complex combination of expectations, relationship issues (i.e., not wanting to distract the physician from treating their disease), past experiences with relief of pain, and goals of care.[48] This satisfaction with low levels of pain relief can be traced to the realistic fears of addiction and abuse.[48,49] In general, successful pain management is dependent on a mutual relationship and open communication between doctor and patient. The goal of chronic pain management is to enable people with pain to live a full and rewarding life in the face of chronic illness. As stated previously, however, this is complicated by the problems of drug abuse, addiction, and diversion.

CHAPTER 33 ■ THE DOCTOR–PATIENT RELATIONSHIP IN PAIN MANAGEMENT: DEALING WITH DIFFICULT CLINICIAN–PATIENT INTERACTIONS

ROBERT N. JAMISON

Pain management physicians commonly have to deal with doctor–patient conflicts because of the nature of persons with chronic pain, the personalities of the pain practitioners who treat them, and added pressures stemming from the health care system. Persons with chronic pain frequently present with psychosocial stressors including sleep disturbances, loss of function, disability issues, and depression, which affect their ability to cope.[1] Medical conditions such as diabetes, hypertension, asthma, gastrointestinal distress, and other comorbidities such as substance abuse and psychiatric disorders make these patients challenging to manage. Chronic pain patients can be time-consuming when doctors are under increasing pressure to see more patients in a shorter amount of time. The need to provide detailed documentation and written justification of each treatment decision and to remain current with the latest treatments adds further time pressure for the pain practitioner. All of these conditions can add to difficulties that set up doctor–patient conflicts.[2]

Between 10% and 60% of patients treated in health care settings exhibit "difficult behavior,"[3–6] which can include extreme aggression, threats of homicide and suicide, and behavior related to substance abuse. Pain patients can be especially difficult since they have a tendency to be angry, mistrustful, anxious, and depressed.[7,8] Depression and anxiety disorders are two to three times more prevalent among chronic pain patients than in the general population,[9,10] and pain patients can frequently present with added behavioral symptoms of inflexibility, negativity, or entitled behavior.

The aim of this chapter is to describe difficult doctor–patient relationships in a pain center or primary care setting and focus on communication issues that may be useful in avoiding treatment dissatisfaction and possible legal reprisals. In this chapter I first review the reasons that patients can be difficult and identify those patients who are prone to exhibit problems. Next, I discuss some of the major issues that lead to doctor–patient conflicts and review possible communication strategies to help the pain specialist successfully manage these patients. Finally, I outline common clinical scenarios leading to potential doctor–patient conflicts and give appropriate responses that may be beneficial in dealing with difficult patients. As implied in the title, this chapter focuses on the doctor–patient relationship, although it should be noted that this same information could easily be applied to any clinician and any person receiving treatment.

DIFFICULT PATIENTS AND DIFFICULT DOCTOR–PATIENT RELATIONSHIPS

In a study of over 500 adults presenting to a primary care clinic, Jackson and Kroenke[6] found that treating physicians rated over 15% of their patients to be difficult. These difficult patients tended to have a depression or anxiety disorder, poor functional status, unmet expectations, reduced satisfaction, and a greater use of health care services. The study also showed that physicians who were less empathic were more likely to experience encounters with these patients as difficult. In a subsequent study, Jackson and Kroenke[11] found that patients' unmet expectations were common in those individuals experienced as difficult by the clinicians. These patients were also likely to have a mental disorder, with somatic symptoms, poorer function status, greater expectations for care, less satisfaction, and higher use of health services than patients who were not difficult ($p < .001$). Every clinician will encounter at least one extremely difficult patient who may require behavioral limit-setting and possible hospitalization and/or psychotropic medication.[12]

Vegni and colleagues,[13] after analyzing difficult doctor–patient relationships, concluded that the doctor's personal and professional issues as well as changes in the health care system are the chief contributors to conflicts. Likewise, Haas and others[2] identified the fact that difficult doctor–patient relationships can be based on (1) patient factors—medical, psychiatric, personality, and substance abuse risk, (2) physician factors—workload, communication skills, personality, level of experience, and practice setting, and (3) the health care system—financial and productivity pressures, fragmentation of care, availability of outside resources, and documentation and treatment guidelines. In a survey of 750 patients and 200 physicians performed by Roper Starch Worldwide Inc.,[14] the qualities of physicians that were most frustrating to patients were being too rushed (30%), hard to reach (19%), and not down to earth (11%). The qualities that described the most difficult patients were hostility or anger (49%), noncompliance (19%), and being too demanding or needy (19%).

Hahn and others[4] developed the Difficult Doctor–Patient Relationship Questionnaire (DDPRQ) and established its reliability and validity. The results of the DDPRQ, completed by physicians who had just concluded a patient encounter, showed that 10% to 21% of patient encounters were labeled as difficult. Most of these patients showed signs of psychosomatic symptoms and psychopathology. In subsequent studies by this same group[5,15] conducted in four primary care clinics, physicians rated 96 patients (15%) out of 627 to be difficult. Compared with patients who were described as not difficult, difficult patients had more functional impairment, higher health care utilization, lower satisfaction with care, and more psychiatric disorders of somatization, panic, dysthymia, anxiety, depression, and alcohol abuse or dependence.

Psychiatric and Personality Issues

Difficult pain patients can display destructive psychiatric behaviors such as suicidal ideation, self-mutilation, extreme noncompliance with treatment, or opioid misuse, and most pain specialists have little training in psychiatric assessment and treatment. Many clinicians avoid pain medicine practice altogether because of the emotional challenge of working each day with demanding and draining patients. Patients with pain can be fearful of flare-ups and worry that their clinic will be unresponsive to the urgency of their condition. Their heightened anxiety adds to a need for frequent contact with their doctors, resulting in endless emails and phone messages. Patient–relations departments of hospitals and the state boards of registration and medical examiners are notified most often by patients who complain that their doctor is unresponsive to their care. As a result, physicians should be watchful about the perception of inadequately treating or abandoning their patients.[16]

Epidemiological studies indicate that 35% of chronic back and neck pain sufferers in the United States have a comorbid depression or anxiety disorder[17] and up to half of all patients with chronic pain can have a comorbid psychiatric condition.[18,19] Further studies also report that patients who are most difficult frequently have a personality disorder, which includes psychotic episodes, impulsivity, superficiality, problems with interpersonal relations, and affective disorders.[20,21] Surveys of chronic pain clinic populations as a whole indicate that 50% to 80% of chronic pain patients have some signs of psychopathology, making this the most prevalent comorbidity in these patients.[10,19] Major depression alone is thought to affect 30% to 50% of patients,[7] with anxiety disorders being next most prevalent.[10,22] Outcome studies highlight the poor response of patients with psychiatric comorbidity to many different treatments for chronic pain,[23] especially those patients with chronic low back pain.[24,25] Boersma and Linton have shown that patients with chronic pain with a combination of anxiety and depression have a 62% worse return to work rate at 1 year than those with no psychopathology.[26]

Opioid Therapy

Chronic pain patients with a mood disorder are likely to be prescribed opioids more often than those without a mood disorder, which can lead to doctor–patient conflicts. In a study of 50 Veterans Administration (VA) patients and 50 patients treated in outside primary care practices with opioids for noncancer pain, Carrington-Reid and colleagues found a 50% prevalence of major depression and a 20% prevalence of an anxiety disorder.[27] In a similar study, Breckenridge and Clark determined a high prevalence of mood disorder among pain patients who were prescribed opioids.[28] In a study of 191 patients examining factors that led pain physicians to prescribe opioids for noncancer pain, Turk and Okifuji concluded that neither pain severity nor objective physical pathology influenced the decision to prescribe.[29] Rather, greater affective distress and pain behaviors drove the decisions. Thus, patients with chronic pain and psychopathology are likely to be prescribed opioids, and these patients report greater pain intensity, more pain-related disability, and a larger affective component to their pain than those without psychopathology.[30] Patients with borderline and antisocial personality disorders can be commonly found in a pain management clinic. These patients often trigger the strongest negative reaction among their providers.

In terms of the impact of mood disorders on opioid response, a recent study examined the effects of intravenous (IV) opioid analgesia in chronic pain patients with high and low levels of psychiatric comorbidity.[31] Sixty patients with low back pain stratified into three groups of severity of psychological symptoms (low, moderate, and high) were given intravenous morphine and placebo in random order on separate visits and completed pain ratings over 3 hours at each session. The low-psychopathology group had a 40% greater reduction in pain with IV morphine than the high-psychopathology group ($p < .01$). This study found that patients with chronic pain who had a high degree of negative affect benefited less from opioids in controlling their pain than those with a low degree of negative affect.

Difficult "Normal" Patients

Not all patients with difficult behavior exhibit significant psychopathology, such as major depression or anxiety or a personality disorder. Patients who are otherwise "normal" can be perceived as difficult, for example, when they arrive at a pain center for treatment with unrealistic expectations about what should happen. They may have had problems with previous health care settings in which they were accused of exaggerating their pain. Lack of sleep, extreme fatigue, poor eating habits, and long travel to their appointments can also contribute to volatile and unstable behavior. They may experience their physicians as dismissive or skeptical of their pain, rather than being understanding and sympathetic. Even comparatively well-adjusted patients can sometimes develop the idea that their pain physician should be able to eliminate all of their pain and that failure to do so is tantamount to withholding treatment. This becomes critical when medication regimens involving opioids are concerned. Patients may worry about being prescribed adequate amounts of medication or undergoing withdrawal if they are to be tapered off opioids.

Some pain patients are entitled consumers who are no longer willing to be passive in their treatment but rather prefer to take control of their medical care. Medical information through the

Internet is more accessible than ever, and patients frequently come to their appointments armed with information about a particular therapy. Patients are increasingly opinionated about their care. They look to have a mutually respectful relationship with their health care providers and want to take an active role in the decision-making process. They become dissatisfied with their treatment when their provider is unresponsive to their suggestions and not willing to hear their own ideas. Cultural and ethnic differences can also act as barriers to an effective doctor–patient relationship.[32]

Comorbid Medical Conditions

Most persons with chronic pain also have significant medical conditions that impact treatment decisions. Some are medically challenging as well as being interpersonally difficult. Pain patients may report asthma, COPD, diabetes, coronary artery disease, hypertension, ulcers, kidney, bladder and liver problems, and history of cancer. Persons with chronic pain often smoke cigarettes, have gained weight, and have lost bone density. Multiple providers can prescribe multiple medications including blood thinners, blood pressure and heart disease medications, inhalers, and antidepressants. These patients are also noted for allergies and reactions to certain medications. Occasionally they have implanted medical devices (e.g., pacemakers, rods, stimulators) or wear prostheses. Some of the most challenging patients tend to be older, take many medications, have multiple psychosocial problems, have poor social support, limited education, and come from disadvantaged backgrounds.[33,34]

Kenny[35] points out in a survey study of 20 chronic pain patients and 22 pain specialists that differences in communication interactions—especially when patients embrace a medical model to explain their pain and physicians perceive a psychogenic etiology of pain—can significantly negatively affect the doctor–patient relationship. In a study of how and why physicians dismiss patients from their practice, 25 general practitioners identified two types of patients who tend to be dismissed over others: (1) patients who break the rules of the doctor–patient relationship or clinic practice, and (2) patients whose difficult personality makes it hard to care for them.[36]

Substance Use Disorders

There are notable links between chronic pain and substance abuse.[37,38] Studies show that 10% to 16% of patients treated in a general practice and 25% to 40% of hospitalized patients have problems related to drug or alcohol addiction.[39,40] Other studies indicate that patients with pain and high rates of mood disorders are at high risk for alcohol or opioid abuse.[41]

With the growing support of the use of opioid analgesics in the treatment of chronic pain, the United States Government General Accounting Office (GAO) recently recommended efforts to improve identification of abuse and diversion of controlled substances by health care providers.[42] Physicians are now in the difficult position of providing appropriate pain relief while minimizing the inappropriate use of pain medications by being ever watchful of substance use disorders.[43] Inappropriate use can include the following: selling and diverting prescription drugs; seeking additional prescriptions from multiple providers; concurrently using other illicit drugs; and manipulating the formulation to snort or inject the medications or use them in a manner in which they were not intended. It is important for the successful treatment of chronic noncancer pain to be able to frequently monitor patients on opioid regimens and to identify those patients who exhibit ongoing abuse behaviors, which can be an added burden to providers.[44,45]

Unfortunately, physicians can be deceived,[40] which is all the more reason that steps are needed to perform a thorough evaluation for risk factors and to closely monitor patients on opioid therapy. History of substance abuse further complicates treatment because it increases the potential for inadequate treatment of pain.[46] Thus, encounters with patients can be made difficult by underlying issues of substance abuse and addiction.

PHYSICIAN FACTORS

Difficult doctor–patient relationships are not completely due to the patient. The attitudes and behavior of the physicians play an important role as well. Some doctors take patient behavior personally instead of realizing that this is how the patient responds and behaves in other situations as well. An understanding of the patient's situation helps in depersonalizing any reactions that they may experience. Doctors who show disrespect or have inward anger toward their patients transmit negative emotions that lead to distrust. Some physicians have hidden feelings of inadequacy or poor self-esteem and others have an inability to listen to what the patient is saying.[47] Those personality and behavior qualities of doctors can lead to difficult relationships, including inward anger, impatience, lack of empathy, depression, poor self-esteem, and feelings of vulnerability.[48]

For health care providers, treating chronic pain patients can also lead to reactive feelings of being manipulated, which, in turn, can lead to extreme dislike for certain patients.[49] Because physicians are frequently under pressure to see patients within a short period of time, pain patients who show vague symptoms and who are unresponsive to many different interventions can be particularly frustrating, especially when the burden of providing treatment is shouldered alone instead of being shared by an interdisciplinary team. More problematic patient issues, including verbal abuse or physical threats to the clinician and staff, stalking, criminal behavior, and gross noncompliance, can trigger negative reactive emotions in the provider.

Krebs et al.[50] interviewed 1,391 physicians to assess personal and practice characteristics associated with greater frustration with patients. Physicians who were younger, worked more hours, had symptoms of depression and anxiety, were under higher stress, and had more patients with psychosocial and substance abuse problems reported increased frustration with their jobs. Tam[51] points out that pain clinicians may have extensive training in their area of expertise, but have had little instruction in communication skills.

HEALTH CARE SYSTEM FACTORS

Health care system factors also indirectly contribute to doctor–patient conflicts. Physicians frequently report being overworked and under constant pressure to be productive. The demands of the job include reading reports and meticulously documenting treatments. Many have also witnessed changes in health care financing and fragmentation of care. Commercial insurance carriers and the Joint Commission Centers for Medicare and Medicaid Services frequently revise regulations in medical record documentation. Physicians are more than ever being asked to expand their role in the identification and management of psychiatric conditions and addictive disorders.[52] Keeping abreast of the latest pharmacological therapies and screening devices can also be daunting.[53–56] Advances in information technology can radically transform decision-making and treatment processes, although there is no indication of whether they decrease the physician workload.[57,58] It has been suggested that the use of the Internet can have a negative effect on doctor–patient relationships by discrediting conventional therapies, misleading patients, and adding to consultation times.[57] Thus, productivity pressures from

hospitals and medical centers, changes in health care financing, threats of legal repercussions related to treatment decisions, fragmentation of care, and the rising use of information technology can place burdens on the provider and add to additional external stress.

PATIENT INTERACTION STRATEGIES

It is surprising to some outsiders when patients cherish their pain provider even though their treatment outcomes are not successful. These patients may openly admit that their pain was made worse by a particular surgery or procedure, but still feel that their doctor did all that could have been done without placing fault or blame on him or her. Conversely, other patients may hold their physician directly at fault for a negative outcome in what they perceive was inadequate or faulty treatment, even though the treatment technique was appropriate without evidence of complications. The differences may lie in the interpersonal skills that the physician used to help deal with the poor outcome, diffusing conflicts and building patient rapport. These same skills may have been lacking in another provider who was accused of causing further problems. Thus, the medical expertise and competence of the clinician is not the only quality needed for acceptance and satisfaction of treatment, regardless of the outcome, but rather the nonspecific effects of the doctor–patient relationship play an important role. Here we review the components of positive doctor–patient relations, especially when dealing with challenging, difficult patients.

Much has been written on useful strategies in dealing with difficult patients, and an exhaustive review of the literature is beyond the scope of this chapter; however, a brief review of some studies will be useful. Elder and colleagues[59] interviewed 102 physicians who were identified as having excellent skills in interacting with difficult patients about how they identified, managed, and coped with these patients. The authors concluded that the key ingredients of changing a difficult encounter into a successful one included the use of empathy, appropriate use of power, and an understanding of the need for doctor–patient collaboration. Lown[60] also proposed strategies to deal with anger in the clinician–patient relationship, suggesting that clinicians who cultivate personal awareness, practice self-monitoring, understand the reasons for patient anger, demonstrate specific communication skills, set clear boundaries, and seek personal support are best at managing difficult patient encounters.

Halpern[49] also describes ways for physicians to manage difficult patients: recognize one's own emotions, attend to negative emotions, attune to patients' verbal and nonverbal emotional messages, and become receptive to negative feedback. These steps allow clinicians to reduce anger through increased empathy and ultimately increase therapeutic impact. Finally, Nasselle[61] felt that, by considering the difficulties in the relationship, doctors would be less prone to labeling patients as difficult. Strategies in managing difficult patients included acknowledging the problem, setting boundaries, using communication skills, and including external resources when necessary.

Patient-Focused Care

In a study on physicians' communication style and perceptions of patients, Street et al.[62] audio-taped and coded interactions among 29 physicians and 207 patients. They concluded that more positive communication from one participant led to similar responses from the other and that reciprocity and mutual influence had a strong effect on quality of care. Klitzman[63] interviewed 50 doctors who had experienced a serious illness in which they were required to be hospitalized as patients. Because of their own experiences as a patient, these physicians acknowledged increased sensitivity to patients' experiences and the importance of empathy in the doctor–patient relationship. They included hospital practice recommendations of charting with the patient present, acknowledging whenever they keep a patient waiting, and being sensitive to nonverbal aspects of care. Their conclusions are in keeping with the differences described by Irwin and Richardson[64] between patient-focused care and a disease-centered model of care. They loosely define patient-focused care as care we would like those we care most about to receive. Having a disease-focused management approach does not exclude having a good bedside manner; however, patient-focused care takes in the whole person's experience in a way that suggests understanding and caring. This point is well illustrated in a study of 316 cancer patients among whom satisfaction with pain management was strongly related to the doctor–patient relationship, and not related to the severity of the pain.[65] Likewise, studies of postoperative satisfaction with pain have been found to be more related to perception of care than actual report of pain.[66,67]

It has been suggested that poor communication style is the underlying problem in most medical–legal cases.[68] In a sample of 45 physician-related plaintiff dispositions, relationship issues appeared to be central to 71% of the lawsuits.[69] In fact, it has been suggested that the majority of negligence cases are not related to quality of care, but are brought on by inadequate doctor–patient communication—often occurring before the incident that leads to a claim.[70] By concentrating more on the medical than the human needs of the patient, there is an increased chance of breakdown in communication and a greater perception of inadequate care. Those physicians who are less prone to legal action demonstrate skills in listening, empathy, and expressing understanding.[68] Gafaranga and Britten[71] believe that the opening statement made by the physician during the first patient encounter may have a lasting impression on the relationship. Roy and others[72,73] have also shown that doctors who inform their patients of changes that impact their care in person rather than by mail have greater patient satisfaction. Back et al.[74] identified some common pitfalls of doctor–patient communication that they label as blocking, lecturing, depending on a routine, collusion, and premature reassurance. They encourage instead employing open-ended communication skills they label as "ask-tell-ask" and "tell me more." Caregivers who show good patient communication skills are ones who speak in a caring way with an open body posture and do not transmit the impression of defensiveness or indifference when they engage in conversation with their patients. Thus, as pointed out in some training programs, the secret of caring for patients is really caring for patients.

Pomm, Shahady, and Pomm[47] suggest that clinicians also need to understand the patient's perspective, attempt to actively listen to their patients, recognize what they can or cannot change, and get help from colleagues and friends for support if problems occur. They describe this as the CALMER approach to dealing with difficult patients (Catalyst for change, Alter thoughts to change feelings, Listen and then make a diagnosis, Make an agreement, Education and follow-up, Reach out and discuss feelings).[46] The literature on stages of change[75,76] also indicate that patients go through stages in which they are more prone to make positive behavioral changes than at other times. Physicians who recognize when a patient is not ready to change, despite the patient's giving lip service to what needs to be done, are less inclined to transmit disappointment when no changes are made.

COMMUNICATION FRAMEWORK: WIPS AND E'S

Different models have been promoted to improve doctor–patient communication. Kathleen Gordon (Connecting with Care, un-

TABLE 33.1

FOUR EXPECTATIONS FOR CLINICAL ENCOUNTERS (WIPS)

All patients want to:
1. Feel **W**elcome
2. Feel **I**mportant and informed
3. Believe their **P**erspective was understood
4. Feel **S**ecure that their needs will be met

published manual, 2006) identified what she believes are needs and expectations of all pain patients and used the letters WIPS (welcome, important and informed, perspective, and secure) to help remember what all patients expect during each doctor–patient encounter (Table 33.1. First, patients want to feel welcome. They like to believe that their provider is happy to see them and is concerned about their condition. Second, patients want to feel important and to be informed about what is going on and what will take place. The impression that there is mutual respect and collaboration is key to meeting these needs. Third, patients need to believe that their perspective is understood, which necessitates listening skills and body posture that convey a sense of caring. Fourth, the patient wants to feel secure that his or her doctor is competent and knows what needs to be done. To this end, patients like to have the expectation that their needs will be met as well as possible.

The Bayer Institute for Health Care Communication adopted a consensus model for essential elements of physician–patient communication.[77,78] Even if the encounter is brief, those clinicians who follow particular interaction strategies are able to improve patient rapport. These strategies are remembered as the 4 E's: (1) Engage, (2) Empathize, (3) Educate, and (4) Enlist. A revised version is presented in Table 33.2. First the clinician connects with the patient and builds rapport by greeting the patient warmly, having good eye contact, showing interest, and addressing any physical barriers by using nonverbal posturing that improves options for engagement (Engage). Second, the clinician listens to the patient and shows attentiveness by repeating the information back to the patient. The clinician acknowledges feelings and shows understanding. When appropriate, humor is also used (Empathize). Third, the clinician assesses the patient's understanding and informs the patient and answers any questions that might arise in order to address concerns and to alleviate anxiety (Educate). Fourth, the clinician seeks the patient's input about the treatment plan. Priorities are negotiated and different scenarios are discussed in order to address realistic expectations (Enlist). Finally, the clinician ends the encounter by summarizing the plan and outlining the next steps. Reassuring comments as well as positive concerns are expressed. The effective clinician will also be sure to follow through with what was discussed.

CLINICAL SCENARIOS

The following are some common scenarios encountered in a pain management clinic. How the clinician responds to these situations is important in preventing escalating problems and potential litigation. Although at times patients present with a borderline personality disorder or have an underlying substance use disorder, employment of communication techniques can make clinicians more adept at managing these situations and improving outcomes. The following brief scenarios were chosen to address some of the points raised above. As you read them, try and picture what you might do in these situations.

TABLE 33.2

COMPONENTS OF EVERY PATIENT ENCOUNTER

1. **Engage** (Build rapport)
   a. Build rapport and professional partnership
   b. Greeting that is pleasant, warm, consistent
   c. Eye contact
   d. Consider barriers
   e. Nonverbal show of interest
   f. Be curious of how patient is doing
   g. Get patient's story with expectations and concerns
2. **Empathize** (Patient feels seen, heard, accepted)
   a. Listen and feed back what you hear
   b. Be aware of feelings, values, and thoughts
   c. Note body language and demeanor
   d. Reflect understanding
   e. Acknowledge and legitimize feelings
   f. Employ humor when appropriate
3. **Educate** (Inform and answer questions)
   a. Assess what the patient understands
   b. Address key concerns–let them know you reviewed their medical record
   c. Answer with compassion–what will happen; who will be there; what are the risks; what are some realistic expectations
4. **Enlist** (Invite the patient's involvement)
   a. Seek the patient's input on the treatment plan
   b. Ask for patient's agreement and active participation
   c. Provide options
   d. Negotiate priorities
   e. Explain what will happen if a problem arises
5. **End**
   a. Anticipate and forecast close of visit
   b. Summarize the encounter
   c. Review the plan and next steps
   d. Express personal confidence, caring, and hope
   e. Follow through

(Modified from Bayer Institute of Health Care Communication, 2001.)

Scenario No. 1

You are seeing a patient for the first time. You begin to ask questions about the patient's medical history. The patient becomes very angry.

PATIENT: "*I sent you all of my records and medical notes. Didn't you even bother to read them? I keep having to repeat myself over and over again.*"

CLINICIAN: *"I am sorry that I have to ask you the same questions as everyone else, but I want to make sure that we do not miss anything. It is also important that I get a fresh look at how you are doing and what the main issues are. The goal is to improve your quality of life as best as possible and your patience and cooperation are important."*

Main issues: This interaction might happen with a patient who has had many previous problematic contacts with health care providers. The clinician's appearing impatient and demanding will not help the situation. Rather, maintaining an open empathic stance, acknowledging the patient's frustration that the first session may be repetitive and tedious, and showing caring will encourage the patient to cooperate.

As with any initial interview, listening and understanding are

vital. It is important to summarize the major concerns and to help reconcile the issues. Many physicians choose to ignore anger for fear that addressing it will bring out more anger or for worry that it will lead to greater time involvement. However, addressing the situation early will pay dividends later on. Appearing impatient or demanding cooperation is an invitation for patient dissatisfaction and increased difficulties later on.

Scenario No. 2

It is late afternoon and you have had several patients in the clinic with time-consuming complications. You are running 1 1/2 hours late. You enter the room to see your next patient and you can tell this patient is very upset about having to wait so long.

CLINICIAN: "*Hello Mrs. Black.*"
PATIENT: *(noticeably upset) "I have been waiting a long time and I have to get back home. Can we hurry this up?"*
CLINICIAN: *"I recognize that you have been waiting a long time and I am sorry that you have had to wait so long. I hate it when anyone has to be kept waiting. As with all my patients, I want to spend as much time with you as you need."*

Main points: Apologizing ahead of time for any delay, even if it is for a short period, will acknowledge that you recognize that this person's time is valuable and he or she may be legitimately irritated. Validating the feelings of the patient first helps to defuse the situation. When running late, some clinicians make a point to quickly acknowledge that the patient is there and waiting and to let them know that they will be with them shortly.

Scenario No. 3

A patient is expecting to have a procedure, but the scheduler failed to put it in the schedule. You are running behind, and you can tell that this patient is very upset about the scheduling error.

CLINICIAN: *(Sits down facing the patient with good eye contact and caring body posture). "I need to apologize that there has been a mix-up about the schedule. I am afraid that we will not be able to do your procedure today."*
PATIENT: *"What? I have had this appointment for weeks and I brought a friend with me to drive me home. Why can't you just do it ?"*
CLINICIAN: *"I can appreciate how upsetting this is especially when you have someone along with you. We simply can't do this today. Mistakes like this don't happen very often, and I am sorry that this happened to you. We will try and sort this out as best we can. I will have the scheduler set up another time as soon as possible."*

Main issues: It is important to reflect the patient's perspective. If a mistake was made, it is always best to admit it and apologize without making excuses or directing the blame at others. Coming up with excuses or reasons for the problem right away without listening would not help to defuse the situation. It is important to use active-listening techniques when patients are angry, including repetition, summary, validation, and empathy. Acknowledging that something will be done to help resolve the situation is important.

Scenario No. 4

A patient who calls and pages you often is pleasant when with you but is extremely disruptive while in the clinic. This patient is known to yell at the schedulers and the receptionist. Your receptionist insists that you speak to this patient.

CLINICIAN: *"Mrs. Smith, I need to speak to you about your behavior in the clinic. I am aware that you get angry and raise your voice with staff at the front desk. We need to follow a protocol in our clinic, which means that everyone must respect each other. We cannot permit shouting or swearing in the waiting room."*
PATIENT: *"But your receptionist has been rude to me and has accused me of coming just to get drugs. I don't put up with that from anybody."*
CLINICIAN: *"The staff here have difficult jobs to do, but we try and treat others with respect by not raising our voice or causing a scene. We expect the same from everyone who is being served here, including you. I am afraid that if you persist in this behavior we will not be able to continue to see you."*
PATIENT: *"I don't have a problem with you, doctor. But I can't stand some members of your staff."*
CLINICIAN: *"Whether you like them or not, you cannot be disruptive while you are here."*

Main issues: Some providers have difficulty in setting limits with difficult patients, but this is a case when firm limit-setting is needed. Stating that it is difficult to work with anyone who is disruptive in the clinic and identifying the expected behaviors without showing anger or being demanding or blaming is best. For patients who are very disruptive in the waiting room, inviting them to come to a clinic room and to meet to discuss the issues privately would help to prevent further escalation of behavior.

Scenario No. 5

An elderly patient becomes combative and delusional following a procedure. This patient requires sedation and restraints. Family members see this patient in restraints and are very angry.

FAMILY MEMBER: *"What are you doing to my mother? Is this a hospital or a prison? You should have notified us first. I want to transfer care to another facility."*
CLINICIAN: *"I can see why you would be upset seeing your mother in restraints. I want to reassure you that she is being cared for with her safety in mind."*
FAMILY MEMBER: *"But this can't be the way you are supposed to handle patients."*
CLINICIAN: *"I am sorry that you are upset, but we are doing this for her own safety. We try and take the greatest care with all our patients. Although your mother has been experiencing some of the effects of the medication, she will be fine."*

Main issues: It is important to be reassuring and matter of fact without reacting in a negative way. By acknowledging how the person may be feeling and checking to see if this is accurate, you allow the person to share his or her feelings. Helping the person to get some understanding of what is happening and why things are done according to protocol can also be valuable.

Scenario No. 6

A middle-aged man develops an infection following the implantation of a device. His goal was to decrease his opioid medication. Now he has more pain, is taking more opioids, and is very angry at the outcome. He returns with his wife and demands to know what will be done for his pain.

PATIENT: *[Noticeably angry and upset] "I am a lot worse off now since that failed procedure. What are you going to do about my pain?"*
CLINICIAN: *"I know that you had hope that this would help your pain, and it must be frustrating that you are experiencing more pain. Having a set-back like this is difficult for all of us. We need to work together to get you back to a better state."*

PATIENT: *"But things are even worse now than ever."*
CLINICIAN: *"I wish we could be 100% successful every time, but unfortunately that is not the case. I am afraid that this did not work out as we expected, but we will keep working on this and hopefully we will be able to turn this around soon."*

Main issues: In this case, underneath the anger, the patient is worried that he will be abandoned, and acknowledging this fear and worry as well as offering some reassurance is important. At first, allowing the patient to vent and express anger without becoming defensive or being angry in return can set the stage for greater partnership in the treatment process. It is important to speak slowly and calmly and to clarify expectations of treatment and limitations in the treatment process. Spending time with an angry patient despite levels of discomfort and helping to get the patient to commit to maintaining a mutual relationship in the treatment process are also important.

Scenario No. 7

A 42-year-old man was referred for treatment of his chronic back pain. He had two back surgeries following a work-related injury and has been taking opioids for his pain. His primary care provider has been prescribing his medication, and he was referred because he had been running out of his medication early and had an abnormal urine toxicology screen. This patient was seen on follow-up after having completed a comprehensive set of screening questionnaires, a structured interview with a psychologist, and a toxicology screen.

PATIENT: *"My doctor referred me to you because she no longer wants to write for my pain medication. She thinks that you should take over writing for my pain medication since you are at a pain center."*
CLINICIAN: *"Your interview and questionnaire information suggest that you are at high risk for having problems with opioids. This means that we will need to be very cautious. So, if I manage your medication I am going to have to require that you see me every 2 weeks, sign an opioid contract, give a urine screen once a month, and participate in substance compliance counseling. We may also find in the end that you are not a good candidate for opioids to treat your pain."*
PATIENT: *"You are just punishing me for being truthful about my drug history. Don't you realize that I have real pain and I need pain medication?"*
CLINICIAN: *"If you have heart problems I would not be giving you treatments that would cause problems for your heart. Your test results suggest that these medications can be a problem for you, and as a result we need to be very careful—for your sake and ours."*

Main issues: The physician does not talk down to the patient or accuse him of being a drug abuser, but instead educates him about the best course of treatment for someone with his risk factors. The suggestion is that there must be an up-front doctor–patient agreement and that cooperation will be needed. Ultimately the physician is expressing the final authority to decide what will be the best course of treatment.

SUMMARY AND CONCLUSIONS

Many things can contribute to patient conflicts when treating chronic pain: personality disordered patients, a busy work schedule, and ever-demanding regulations all can create problematic encounters. Despite the many patient factors that contribute to doctor–patient conflicts, some clinicians know how to recover from difficult patient interactions without long-term repercussions. Much is due to their skills in interpersonal relations and the effects these skills have on patients' perception of their caregiver. Certain patients are difficult because of issues of psychiatric comorbidity and a substance use disorder, but the doctor's use of tested interpersonal communication skills can help to prevent the escalation of conflicts. It is important to have access to mental health professionals who can assist in working with the most difficult patients. Increased coordination and adequate communication among the other providers is also important. Ultimately, the employment of positive communication strategies can improve doctor–patient relations and minimize conflicts within a pain management practice.

ACKNOWLEDGMENT

Special thanks are extended to Kathleen Gordon and Edith Mariano from the Patient Family Relations Triaging Program, Brigham and Women's Hospital, for their invaluable assistance, and to the patients and staff of the Pain Management Center, BWH, Boston for their inspiration and support. Thanks also to Jaylyn Olivo for reviewing an earlier draft of this chapter.

CHAPTER 34 ■ JOINT PAIN

GREGORY C. GARDNER

This chapter contains a discussion of the common causes of joint pain encountered in clinical practice. These are osteoarthritis (OA), rheumatoid arthritis, the spondyloarthropathies (ankylosing spondylitis, psoriatic arthritis, and reactive arthritis), and crystalline forms of arthritis (gout, pseudogout). In addition, there will be a brief discussion of two other types of rheumatologic disorders that present as joint pain: septic arthritis and polymyalgia rheumatica.

BASIC CONSIDERATIONS

Problem in Perspective

Data from the Centers for Disease Control and Prevention (CDC) indicate that, as of 2003, 43 million U.S. adults were affected by some form of arthritis (21% of the population) and it was the leading cause of disability in the U.S.[1] Self-reported arthritis is least common in Hawaii (17.9% of the survey sample) and highest in West Virginia (37.2%). By 2030, 67 million adults in the United States will be affected representing 20% of the projected population.[2] Women are more likely to report a musculoskeletal problem and are more often limited by its presence. The overall cost of musculoskeletal disease to the U.S. economy was estimated to be $86 billion in 2003 but numbers as high as $254 billion have been used as well.

Musculoskeletal disease is a worldwide phenomenon. In recognition of this, the Bone and Joint Decade was proposed by the United Nations in 1999 and formally launched on January 13, 2000, in Geneva, Switzerland, at the headquarters of the World Health Organization. The aim of the initiative is to raise the awareness of the increasing societal impact of musculoskeletal injuries and disorders; empower patients to participate in decisions about their care; increase funding for prevention activities and research; and promote cost-effective prevention and treatment of musculoskeletal injuries and disorders worldwide.[3] The official Bone and Joint Decade in the United States is from 2002 to 2011.

Joint Anatomy

Joints in the extremities are synovial (diarthrodial) joints that permit movement over a wide range[4] (Fig. 34.1). The joint is held together by a capsule of dense fibrous tissue and ligaments, and gains further support from overlying muscle and tendons. The inner surface of the joint capsule is covered by synovium, which consists of an intimal layer of specialized cells called *synoviocytes*, and an outer layer of highly vascularized connective tissue. Synoviocytes comprise one to three cell layers and are of two basic types, A and B. Type A synoviocytes are active in phagocytosis and type B cells synthesize hyaluronate, which is responsible in large part for the high viscosity of normal synovial fluid. Synovial fluid in a normal joint lubricates the surfaces of synovium and cartilage. The synovium is folded along the inside of the joint capsule and does not cover the load-bearing surface of articular cartilage. The connective tissue layer of synovium blends with periosteum, which does not cover the bone within the joint. The synovium has a rich network of capillaries, venules, and lymphatics and it is innervated by sympathetic nerve fibers. The knee and the sternoclavicular and radiocarpal joints contain discs of fibrocartilage that help to stabilize these joints when they rotate. The intervertebral facet joints are diarthrodial joints and are covered by synovium.

Amphiarthrodial joints are only slightly movable and include the symphysis pubis and the joints between vertebral bodies. The joint surfaces are separated by intervertebral discs. The sacroiliac joint has elements of both a diarthrodial and an amphiarthrodial joint.

Articular cartilage is composed of type 2 collagen and proteoglycans. Type 2 collagen is unique to joints and provides cartilage with form and tensile strength. Proteoglycan molecules are linked noncovalently to a long chain of hyaluronic acid and are interwoven within the network of collagen fibers. Proteoglycan molecules bind most of the water present in cartilage, which represents approximately 70% of the total weight of articular cartilage. The proteoglycan molecules are constrained within the meshwork of collagen fibers and are responsible for the resiliency of cartilage. Chondrocytes secrete collagen, proteoglycans, and enzymes that degrade the cartilaginous matrix. The process of remodeling and degradation is kept in balance unless the microenvironment of these cells is altered. Joints normally contain a small amount of synovial fluid, which is viscous, clear, and does not clot spontaneously. Normal synovial fluid contains fewer than 200 cells per cubic millimeter; most of these cells are mononuclear.

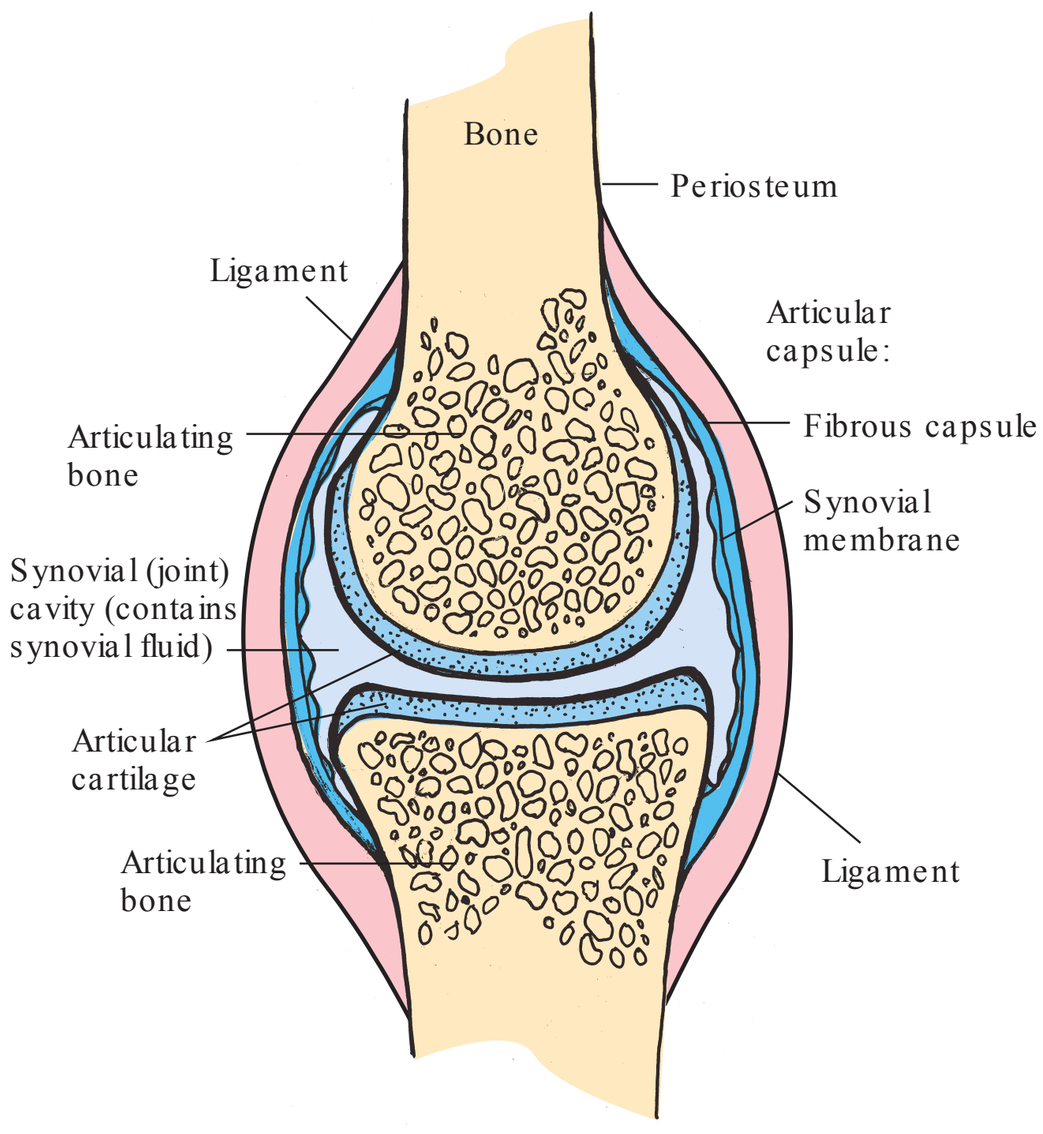

FIGURE 34.1 Schematic diagram of the anatomic features of a typical synovial joint seen in a section cut across the middle of the joint. (From Oatis CA. Kinesiology. *The Mechanics and Pathomechanics of Human Movement*. Baltimore: Lippincott Williams & Wilkins, 2003.)

Nerve and Blood Supply

Joints are supplied partly by articular nerves, which are branches of major peripheral nerves, and partly by branches of nerves supplying adjacent muscles as well as vasomotor sympathetic fibers. Nerve endings are distributed in the interstitial and perivascular tissue located in the subsynovium fibrous capsule, articular fat pads, and in the adventitial sheaths of arteries and arterioles supplying the joints. The periosteum is innervated, but articular cartilage and subchondral bone are not and, thus, not a direct source of pain in arthritis.

There are four types of receptors that supply joints.[5] Type I receptors are ovoid corpuscles with a thin connective tissue capsule and each is supplied by a small myelinated nerve fiber (5–8 mm in diameter) that arborizes within the capsule. The type I receptor occurs almost exclusively in the fibrous joint capsule, acts as a slowly adapting mechanoreceptor (stretch receptor), and resembles both structurally and functionally the Ruffini endings in the dermis. The type II receptor is approximately twice as large as the type I receptor and is supplied by a somewhat thicker myelinated fiber (8–12 mm in diameter) that usually ends as a single terminal within a rather thick laminated capsule. These receptors, which resemble the pacinian corpuscles, occur only in the fibrous joint capsule and have been shown to be rapidly adapting mechanoreceptors (acceleration receptors) that are sensitive to rapid movements. Type III receptors, which are the largest, are supplied by thick myelinated fibers that branch profusely. These receptors, which resemble the Golgi organs, are present in extrinsic and intrinsic ligaments (and not in the joint capsule) and adapt slowly and at high thresholds. Type IV receptors are represented by plexuses of fine unmyelinated fibers that occur in the fibrous joint capsules, ligaments, and subsynovial capsules and fat pads; they are considered to be the joint nociceptors.

An anastomotic plexus of blood vessels called the *periarticular anastomosis*, together with these nerves, surrounds the capsule and its branches penetrate the capsule. The periarticular anastomosis is fed by branches of arteries passing the joint and is the source of blood to the capillary bed in the synovial membrane and also to the epiphysis.

CLINICAL APPROACH TO JOINT PAIN

A variety of disorders, both systemic and local, cause joint pain. A history and a careful physical examination should be performed on each patient that will guide the clinician in developing a differential diagnosis and help in selection of appropriate laboratory and radiographic studies to help confirm a diagnosis.

History

The musculoskeletal history is composed of three parts: determining the pattern of joint complaints, determining the number of joints involved, and ascertaining the presence of other features that might help in developing a differential diagnosis.

Patterns of Complaints

There are three basic patterns to joint pain common to the rheumatologist. These are inflammatory, mechanical, and fibromyalgic. Inflammatory conditions, such as rheumatoid arthritis, are characterized by joint stiffness in the morning lasting at least 30 minutes but often several hours. Patients generally feel better after activity as the fluid accumulated during inactivity is pumped out of a swollen, stiff joint by the lymphatics, thus reducing the sensation of stiffness. The presence of inflammatory cytokines such as interleukin-1 (IL-1) or tumor necrosis factor (TNF) may cause fatigue, anorexia, or a loss of the sense of well-being. Joints may initially be stiff and painful but invariably become swollen. There is a subtype of inflammatory pain caused by the presence of bacteria, blood, or crystals. These conditions have an acute or subacute onset and cause severe pain. The affected person keeps the joint at 30 to 40 degrees of flexion and resists movement. This is the position of maximum joint volume and attempts to flex or extend the joint leads to decreased joint volume and, thus, increased joint fluid pressure. Pain is typically severe in these forms of arthritis.

Mechanical joint pain, typified by osteoarthritis, generally causes only 5 to 10 minutes of morning stiffness but affected joints become progressively more painful with activity. There may be discomfort for some period of time following use. Swelling may or may not be present or only present following stress. There are no systemic symptoms in patients with mechanical forms of arthritis.

Fibromyalgic pain is characterized by all over morning stiffness or pain, a period of loosening up late morning or early afternoon, followed by fatigue and increased pain as the afternoon progresses. Sleep is poor, memory may be reported to be poor, and activity and exercise are poorly tolerated and in fact patients will report being in bed for 1 or 2 days following a strenuous physical or even emotional event. Doing household chores may exacerbate the discomfort. Patients often describe their pain in dramatic terms such as hot pokers or ice picks being driven into a particularly painful area.

With experience, the clinician can with some ease categorize a patient's joint complaints into one of these three major types.

Number of Joints Affected

The next step in developing a differential diagnosis is determining the number of joints involved. There are three categories in joint number as well and include monoarthritis, pauciarthritis (2–5 joints affected), and polyarthritis (6 or more joints). Tables 34.1 to 34.3 give a general differential diagnosis based on inflammatory or mechanical joint pain pattern and number of joints involved. It is important to recognize that these are general guidelines because a polyarticular condition such as rheumatoid arthritis might initially present with less than six affected joints but progress over time to be polyarticular in character. Once a disease has been established for several weeks/months, these patterns tend to be more fixed.

Systemic Features of Arthritis

A variety of systemic or demographic features of illness also provide clues to the underlying diagnosis and will be discussed with the individual conditions.

Physical Examination

When evaluating a patient with musculoskeletal complaints, it is important to determine whether the joint complaint is articular, periarticular, or radiating from elsewhere. Joints should be examined for evidence of synovial proliferation, fluid, and bony enlargement. Tenderness, warmth, and any limitation of range of motion should be noted. Pain on passive motion of a joint suggests the possibility of inflammation in the joint or periarticular structures. Even though a patient may complain of a particular joint or joints, make sure to examine all joints. Milder abnormalities that may be present could provide useful information to make a diagnosis. Comparing an affected to a nonaffected joint often confirms the presence of swelling or deformity. Remember that "joint pain" may be the result of tendon, ligament, muscle, bone, or nerve abnormalities.

Examination of Synovial Fluid

Examination of the joint fluid is helpful in patients who have undiagnosed arthritis. Diagnosis of infectious or crystal-induced arthritis is established only by examination of joint fluid. Characteristics of the joint fluid in various rheumatic conditions are shown in Table 34.4. In inflammatory effusions, the cell count is usually elevated, with predominantly neutrophils. The fluid is cloudy, has reduced viscosity, and forms a fibrin clot. Normal joint fluid does not spontaneously clot because it contains no fibrinogen. Viscosity is reduced in inflammatory arthritis because of the breakdown of hyaluronate. A rough assessment of viscosity

TABLE 34.4

JOINT FLUID CHARACTERISTICS IN VARIOUS FORMS OF ARTHRITIS

Diagnosis	Appearance	Mucin clot[a]	White blood count (per mm^3) leukocytes	% Neutrophils
Normal	Clear, straw colored	Good; firm	<200	<25
Osteoarthritis	Straw colored	Good; firm	<2000	<25
Rheumatoid arthritis	Yellow	Fair to poor; friable	5000–25,000 or greater	>65
Gout or pseudogout	Yellow, slightly cloudy	Fair to poor; friable	2000–75,000	>70
Spondylo-arthropathies	Yellow, slightly cloudy	Fair to poor; friable	2000–75,000	>50
Bacterial arthritis	Cloudy to purulent	Poor; friable	10,000, often >100,000	>75

[a]Mucin clot correlates with viscosity except with grossly purulent fluid.

can be made by forcing a drop of fluid through the end of the syringe. Fluid with poor viscosity drops like water. In normal joint fluid or noninflammatory conditions, a string trails the drop; the longer the string, the higher the viscosity.

Normal joint fluid usually contains fewer than 200 white cells per cubic millimeter and these cells are predominantly mononuclear. Cell counts greater than 75,000 per cubic millimeter and in which the cells are predominantly neutrophils suggest an infectious arthritis, but cell counts of this magnitude are also seen in noninfectious inflammatory joint diseases such as reactive arthritis or urate gout.

CLINICAL CONSIDERATIONS

Osteoarthritis

Osteoarthritis (OA) is characterized by progressive loss of articular cartilage leading to joint pain and limitation of movement. Weight-bearing and frequently used joints are most often affected. The disease is divided into a primary (idiopathic) form in which no predisposing factors are apparent and a secondary form that is associated with trauma, a metabolic disorder, or a congenital abnormality. Primary OA is the more common form but pathologically, the two forms are indistinguishable.

Epidemiology and Pathophysiology

OA is the most common form of arthritis worldwide and is the leading cause of disability in seniors.[6] The disease occurs in all races and geographic areas. Prevalence and severity increase with age. Under age 55 years, the frequency and joint distribution of OA in men and women are approximately the same. After age 55 years, OA of the knee is more common in women and OA of the hip in men.[7] OA can be demonstrated radiographically in almost all persons over the age of 75.[8] Weight-bearing joints such as the hips, knees, feet, and cervical and lumbosacral joints are most often affected. The distal and proximal interphalangeal (PIP) joints of the hands are also commonly involved. Certain occupations have been shown to predispose a person to OA. In coal miners, for example, OA of the shoulders and knees is more frequent, presumably because of the forces placed on these joints during work. Prize fighters are more likely to develop OA of their metatarsophalangeal joints, football players of their knees, and ballet dancers of their ankles. Hereditary factors also exist: Heberden's nodes (osteophytic deformity of the distal interphalangeal joints) are twice as frequent in mothers of affected persons and three times more frequent in sisters.[9] A single point mutation in the cDNA coding for type II collagen was found in family members with an inherited form of OA associated with a mild chondrodysplasia.[10,11] Previous major trauma and repetitive use of a joint increase the risk of developing OA. Age alone is a risk factor, with the prevalence of OA increasing after age 45 years. Obesity has been shown to be a definite risk factor for developing OA of the knees.[12,13]

The process of OA in the joint is well known. The cartilage initially shows fissuring and pitting, which eventually progress to erosions and denuded areas. The proteoglycan content of cartilage and the number of chondrocytes decrease in proportion to the degree of disease. Subchondral bone becomes thickened and has an eburnated, or ivory-like, appearance. Cysts appear in the subchondral bone, and the formation of new bone at the joint margins produces osteophytes or spurs. The synovium is thickened and contains a modest infiltration of lymphocytes, plasma cells, and an occasional multinucleated giant cell. The joint capsule and ligaments are hypertrophied. Figure 34.2 shows the progressive nature of OA in the knee via arthroscopy.

For many years treatment approaches to OA have focused on cartilage. To date no chondroprotective agent has been approved by the U.S. Food and Drug Administration even though several, such as doxycycline, have shown promise in animal studies. There is no data in human trials that they make an impact on the disease course. As one can imagine, such trials are difficult to do from a time perspective given the slowly progressive nature of the disease. Recently it has been argued by Felson and Kim that what is needed is a shift in our thinking about the approach to OA in general.[14] To successfully solve the problem of OA, a more global approach will be needed; that is, focus on intra- as well as extraarticular processes such as joint alignment, muscle strength, and other issues that influence loading forces across the joint.

Symptoms and Signs

OA may be limited to one or two joints or may occur in a generalized form involving many joints. Involved joints are stiff for 30 minutes or less in the morning and after periods of inactivity and pain develops with use. The involved joints often ache at night, and the ache can keep the patient awake. Night pain is caused in part by increased intraosseous venous pressure. As the disease progresses, pain becomes a constant feature of physical activity and can persist for several hours afterward. Eventually, restricted motion and joint deformities develop.

Primary OA most frequently affects the distal interphalangeal joints, the first carpometacarpal (CMC) joint, the scaphotrapezoid joint, the hips, knees, and first metatarsophalangeal (MTP) joint. The spine may also be affected, particularly the cervical and lumbar areas. *Heberden's nodes* usually develop after age 40 and are associated with OA of the distal interphalangeal joints. Similar nodes, called *Bouchard's nodes*, appear at the PIP joints (Fig. 34.3). At times, these nodes become red and painful to touch. Bony enlargement, small effusions, restricted motion, and angulation can be seen on physical examination. Radial subluxation of the first CMC joint gives a square appearance to this joint (shelf sign). A form of OA, referred to as *primary generalized OA*, appears most often in middle-aged women and affects the distal interphalangeal and proximal interphalangeal joints of the hand, the first CMC joint, knees, hips, and the first MTP joint. Episodes of inflammation are characterized by warmth, pain, and swelling of these joints.

OA of the hip is usually unilateral, but the opposite side is also affected in approximately 20% of patients.[15,16] Congenital or developmental abnormalities such as slipped capital femoral epiphysis, Legg-Calvé-Perthes syndrome, or hip dysplasia underlie many of the cases. OA follows avascular necrosis, which can be related to deep-water diving, glucocorticosteroid therapy, alcohol, or sickle cell disease. Hip pain is experienced in the groin, over the greater trochanter, in the buttock, or down the anterior and inner thigh. Pain might be referred to the distal thigh and upper knee because the obturator nerve and its branches supply both hip and knee. Hip disease can be mistaken for knee arthritis or trochanteric bursitis because hip pain can be referred to those locations. The pain of hip disease is often described as dull and aching and is initially experienced with physical activity. Later, night pain is also experienced. Patients might limp and have difficulty rising from a sitting position. Functional shortening of the leg caused by adduction and flexion contractures causes the patient to walk with a shuffling gait. Examination of the hip shows initially decreased internal rotation that is followed later by decreased extension, abduction, and flexion, as well as a flexion contracture.

The cause of OA of the knee is not known in most patients. Previous injury such as a torn meniscus or ligament predisposes the knee to secondary OA. The presence of an alignment abnormality such as genu varum (bow legs) or genu valgum (knock

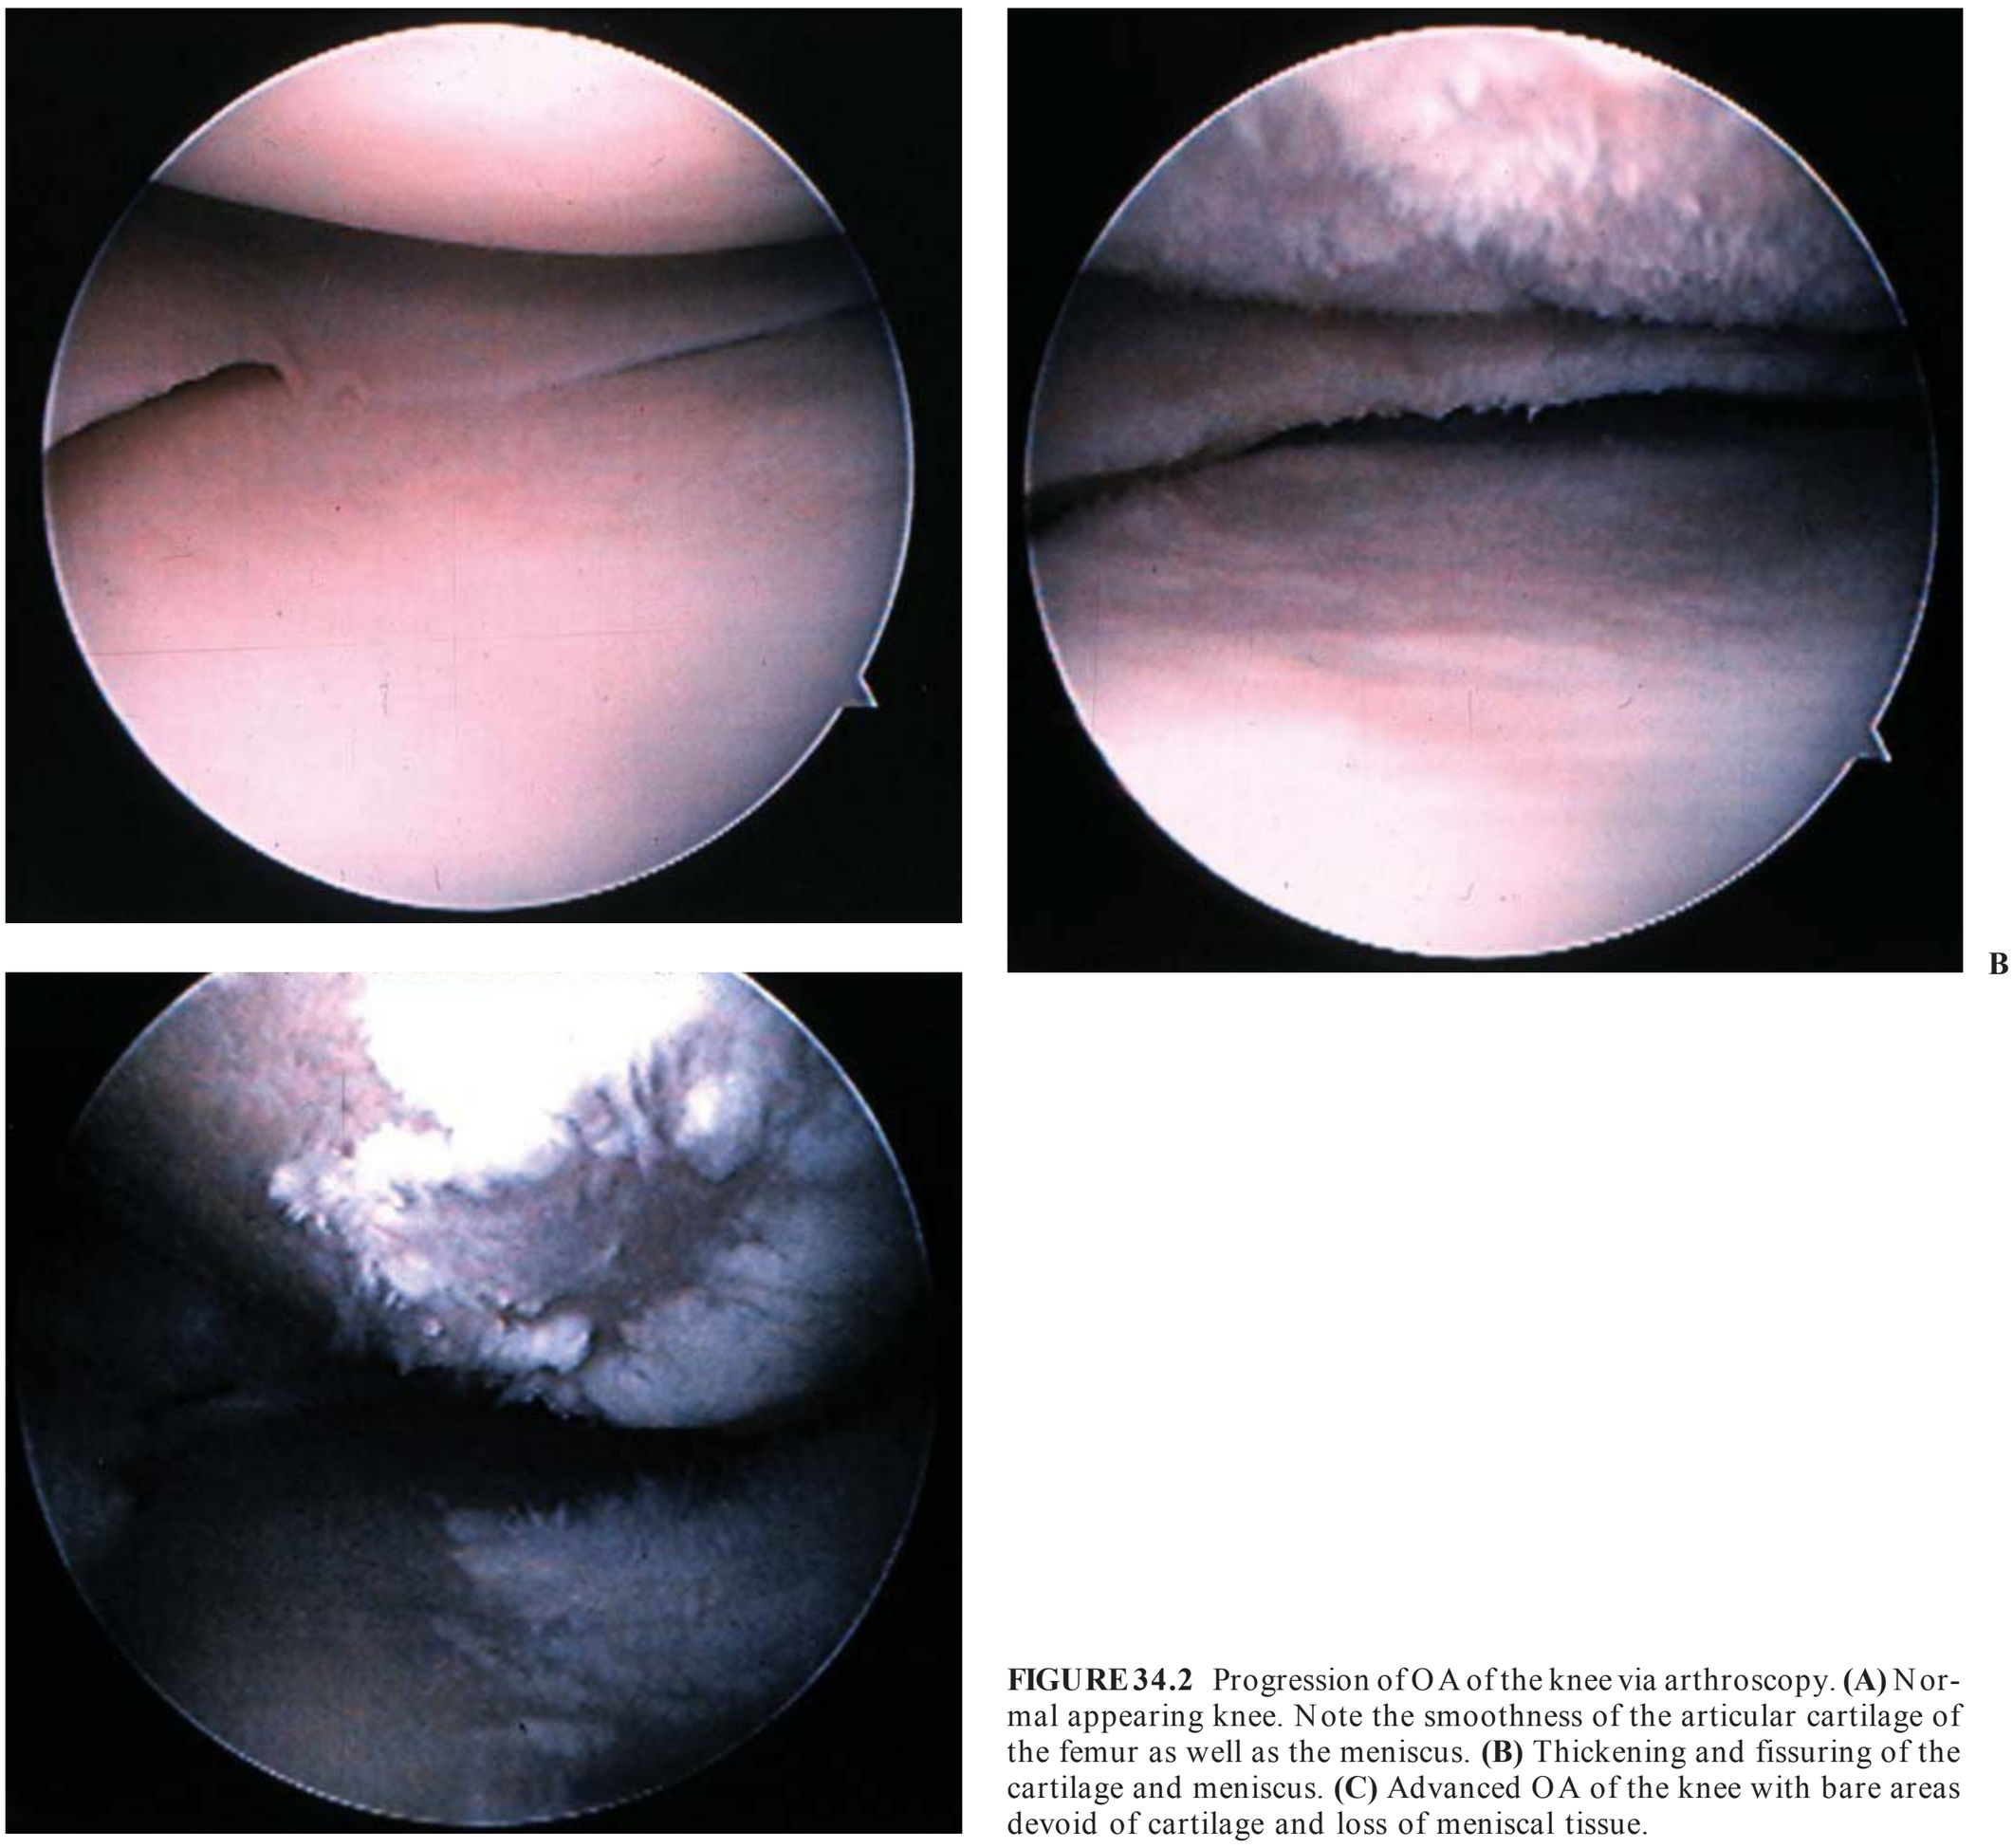

FIGURE 34.2 Progression of OA of the knee via arthroscopy. **(A)** Normal appearing knee. Note the smoothness of the articular cartilage of the femur as well as the meniscus. **(B)** Thickening and fissuring of the cartilage and meniscus. **(C)** Advanced OA of the knee with bare areas devoid of cartilage and loss of meniscal tissue.

knees) increases the force directed through either the medial or lateral side of the knee and can lead to OA. These deformities are also acquired in OA as a result of destruction of either the medial or lateral articular cartilage. Obesity predisposes the knees to OA by the additional weight and by the thigh thickness, which places the legs in a genu varus position and increases the pressure on the medial compartment. Pain also can be localized to either the medial or lateral aspect of the joint depending on which compartment is primarily involved. Stiffness lasting less than 30 minutes is present in the morning or after prolonged rest during the day. Stiffness improves with activity but might return later in the day. Atrophy and weakness of the quadriceps muscle develop with progression of the arthritis. Crepitus might be noted with bending of the knee as well as an effusion. With more severe disease, a contracture may be present which increases the energy required to stand upright. With loss of ligamentous and muscle support, the knee becomes unstable, and the patient may be hesitant to walk on uneven surfaces. The knee might suddenly give way because of a pain reflex. A loose cartilaginous fragment, sometimes referred to as a *loose body*, can prevent the joint from being fully extended.

FIGURE 34.3 Osteoarthritis of the hands. Note Heberden's nodes (DIP joints) and Bouchard's nodes (PIP joints) in this patient with classic hand OA.

Patellofemoral arthritis occurs alone or in conjunction with arthritis of the other knee compartments, especially in older patients. The term *chondromalacia patellae* is often used interchangeably with patellofemoral arthritis, although some restrict this term to a self-limiting disorder occurring in adolescents and young adults. Patellofemoral arthritis is caused in some patients by improper tracking of the patella through the patellofemoral groove (trochlea). The patella is pulled to the lateral margin of the groove by a tight lateral patellar retinaculum or a relative weakness of the vastus medialis compared with the vastus lateralis of the quadriceps muscle. Lateral subluxation of the patella can also be caused by rotational malalignment of the femur and tibia.

In the spine, intervertebral discs and apophyseal (facet) joints are sites for OA. Involvement of intervertebral discs is referred to as *spondylosis*, whereas disease in the apophyseal joints is considered true OA. OA also affects the joints of Luschka (uncovertebral joints), which are located in the cervical spine between the superior process of one vertebral body and the inferior process of the vertebral body above it.

Symptoms of spine involvement are localized pain and stiffness, referred or dermatomal pain, and radicular pain from nerve root compression. Nerve root involvement produces paresthesias, decreased sensation, loss of muscle strength, and diminished or absent deep tendon reflexes. OA of the cervical spine causes either localized pain or pain referred to the occiput, shoulder, interscapular area, or arm, depending on the level affected. With upper cervical disease the pain tends to be referred to the occiput, and with lower cervical involvement it is referred to the shoulder, upper arm, or interscapular area. Neurologic manifestations are also caused by compression of the spinal cord by posteriorly directed osteophytes and by occlusion of the anterior spinal artery by a herniated disc. Cervical spine diseases are discussed in Chapter 67; lumbar spine in Chapters 71 through 75.

Secondary Osteoarthritis

OA can develop in joints that have been damaged. A torn knee meniscus or ligament can lead to incongruity of the joint surfaces resulting in OA. In addition, ligaments contribute to proprioceptive input and injury to these structures may increase the risk of developing OA.[17] OA may follow joint damage produced by infectious arthritis or an inflammatory arthritis such as rheumatoid arthritis. Neuropathic joint disease is a severe form of OA resulting from the loss of pain sensation, proprioception, or both.[17,18] Without these protective mechanisms, joints are subjected to repeated trauma, leading to progressive cartilage damage. Diabetes is the most common cause of neuropathic joint disease. Other causes include tabes dorsalis, syringomyelia, amyloidosis, meningomyelocele in children, and leprosy.

OA occurs in patients with excessively hypermobile joints. Patients with Ehler-Danlos syndrome, a hereditary disorder of connective tissue, develop OA of their hands, shoulders, knees, and ankles usually before age 40 years.[19] Debate exists regarding whether patients with idiopathic joint hypermobility are at risk of developing premature OA.[17]

Several metabolic disorders are associated with the development of OA. These include hemochromatosis, ochronosis, and acromegaly. Arthritis occurs in 20% to 50% of patients with hemochromatosis and may appear before other overt clinical manifestations.[20,21] Hands, knees, and hips are most commonly affected. A particularly characteristic finding is involvement of the second and third metacarpophalangeal (MCP) joints, which are rarely affected in primary OA. Ochronosis is a rare disorder caused by a hereditary deficiency of homogentisic acid oxidase, leading to accumulation of homogentisic acid in connective tissue. Deposits of homogentisic acid impart a blue-black hue to the sclerae and external cartilage of the ears. Arthritis appears in middle age and involves most often the knees, shoulders, hips, and spine.[22] Approximately 60% of patients with acromegaly develop OA, which most often involves the spine, knees, hips, shoulders, and, occasionally, ankles.[23] The increased growth of articular cartilage causes joint surface incongruity and abnormal wear.

Laboratory Findings

Routine laboratory work is normal in patients with primary OA. If OA is found in unusual locations (MCP joints) or unusually early, unusual metabolic diseases or trauma may well be the case. In particular check for parathyroid hormone abnormalities with a PTH level and for hemochromatosis with iron studies (TIBC and FE with saturation level). The synovial fluid in OA is straw colored and has good viscosity. The cell count is usually less than 2000 white cells per cubic millimeter and the cells are predominantly mononuclear. Radiographs in early OA are usually normal, but as the disease progresses joint space narrowing, subchondral bone sclerosis, subchondral cysts, and osteophytes are observed (Fig. 34.4). Erosive OA is characterized by erosions on the joint surface, sclerosis of subchondral bone, and later by bony ankylosis. Radiographic abnormalities do not always correlate with clinical symptoms.

Treatment

Think about the treatment of OA as a program especially when the weight-bearing joints are involved. Basically the program consists of three parts: physical modalities, medications, and surgery. The goal in OA should not necessarily be 100% pain relief as no pain in a biomechanically abnormal joint may not be a good thing. The goal should be to reduce pain to a level that promotes quality of life and activity.

Physical modalities include education, weight loss if needed, joint protective aerobic exercises, range of motion exercises especially focusing on reduction of contractures, muscle strengthening exercises, assistive devices such as a cane, and attempts to affect alignment with off-loading knee braces or patellar taping if needed. The Arthritis, Diet, and Activity Promotion Trial demonstrated the benefit of promoting both exercise and weight loss in an 18-month program that examined both together versus either one alone.[24] The control group was healthy lifestyle. The combination group lost more weight than the weight loss group alone (5.7% of body weight vs. 4.9%) and the combination group had a 24% improvement in physical functioning and a 30% decrease in knee pain over the study period. The exercise group only showed improvement in walk time while the weight loss group showed no significant improvement in any of the variables related

FIGURE 34.4 Osteoarthritis of the hip. The features of OA are well illustrated in this x-ray including joint space narrowing, subchondral cysts, osteophytes, and subchondral sclerosis (thickening of the bone where cartilage has been lost)

to the arthritis. Correct use of a cane can off-load a joint by up to 24% and has been shown to reduce pain in OA of the hip or knee. There is evidence for a modest benefit with the use of an off-loading knee brace designed to realign either a varus or valgus knee disalignment.[25]

The first-line pharmacologic therapy for OA is over-the-counter analgesics (e.g., acetaminophen, 1000 mg four times a day, or even less if it is effective). If the patient remains symptomatic after 2 to 4 weeks, low-dose ibuprofen or nonacetylated salicylates are indicated. If the response is still inadequate after 2 to 4 weeks, the patient should be placed on a full dose of a nonsteroidal drug. In the patient with risk factors for upper gastrointestinal (GI) bleeding or ulcer disease, a proton pump inhibitor should also be provided. There is one COX-2 inhibitor currently marketed in the United States (celecoxib) that could be used for patients at significant risk of GI bleeding if other options do not work. Because of a concern for cardiac toxicity from the COX-2 agents, use the recommend dose of no more than 200 mg per day. There was for a time some excitement about glucosamine based on a European trial published in *the Lancet* in 2001.[26] The data suggested not only a clinical benefit over placebo but also a possible disease modification of OA. A more recent U.S. five arm trial (glucosamine, chondroitin, combination, NSAID, and placebo) did not demonstrate an impressive effect of either nutraceutical in OA although the placebo response was impressive.[27]

Intra-articular corticosteroid injections are effective in OA and can be used as part of the overall program. How often can injections be given? For many years these were limited due to the concern about the development of Charcot joints. Again, the comments about not being too effective in controlling pain completely should be remembered. Data suggested that corticosteroid injections can be given every 3 months for at least 2 years with clinic benefit but no structural change. In the absence of data, injections should probably not be given more frequently than this.[28] Injectable hyaluronic acid is approved for use in OA of the knee. A recent meta-analysis of data on hyaluronic acid injections in knee OA suggests a small benefit especially for the higher molecular weight compounds.[29] Treatment with hyaluronic acid requires 3 to 5 injections and can be used in patients who fail more conservative therapy.

When a joint is severely damaged and painful, joint replacement should be considered. Total hip replacement has provided dramatic relief of pain and improvement of function. Placement of a knee or shoulder can also be quite helpful. Correction of a valgus or varus deformity by osteotomy of the knee improves weight distribution and extends the functional life of the joint. Rebuilding the first CMC joint and replacement of the PIP joint with a prothesis are now possible. Surgery is generally suggested for patients with a level of pain that is not controlled with physical modalities or medications and the patient is willing to endure a period of hospitalization and physical therapy.

Rheumatoid Arthritis

Rheumatoid arthritis is an inflammatory polyarthritis of unknown etiology and typically involves peripheral joints in a symmetric distribution. The worldwide prevalence varies from 0.097 to 2.900 per 1000.[30] In the United States, the prevalence is 1% to 2%.[31] Women are more commonly affected; the average ratio is 3:1. An association also exists with HLA-DR4, the prevalence being 48% to 59% in persons with this genetically determined antigen compared with 8% to 16% in the general Caucasian population.[32,33] Even though there is a genetic association, only 15% of the disease process is placed on genes as opposed to factors from the environment.

Etiology and Pathophysiology

Even though the etiology of rheumatoid arthritis remains unknown, significant advancements have been made in the understanding of the inflammatory events leading to joint injury and extraarticular manifestations. The hallmark of rheumatoid arthritis is the proliferation of synovium, which spreads over the articular surface as a pannus and damages cartilage, bone, and joint capsule. Harris has classified the pathophysiology of rheumatoid arthritis into four phases.[34] Stage I is characterized by the presentation of an as yet unknown antigen or antigens to T cells. In stage II, proliferation of T and B cells, as well as synovial angiogenesis, occurs. In stage III, synovial hypertrophy begins and neutrophils accumulate within the joint in response to chemotactic factors produced by the fixing of complement and the production of cytokines by macrophages and synoviocytes such as tissue necrosis factor-α, interleukin-1 (IL-1) and -6, and granulocyte macrophage cell-stimulating factor. Of interest, cytokines from macrophages and synoviocytes are present in abundance in the rheumatoid joint but typical T-cell cytokines such as IL-2 and interferon-γ are notably absent in established disease. Finally, stage IV is characterized by pannus formation and joint destruction.

B cells in the synovium have been shown to synthesize immunoglobulins, some of which have anti-IgG (rheumatoid factor) activity. Immune complexes consisting of IgG and anti-IgG form in the joint fluid and activate the complement system, which results in the formation of vasoactive and chemotactic factors. Polymorphonuclear white cells attracted to the joint by chemotactic factors phagocytize these immune complexes and secrete proteolytic enzymes within the synovial fluid. The most common form of rheumatoid factor is an IgM molecule directed against the *Fc* portion of IgG. IgG and IgA rheumatoid factors can also be found in patients with rheumatoid arthritis, and IgA rheumatoid factors in particular have been noted to be associated with more severe disease.[35]

The etiology of rheumatoid arthritis is uncertain, but research for many years has focused on the possibility of an arthrotropic infectious disease either triggering the inflammatory cascade or persisting in some form in the joint. An interesting piece of evidence is that rheumatoid arthritis was rare in the Old World before European exploration of the New World and seems to have appeared in Europe after this period.[36] Rheumatoid arthritis has been diagnosed via skeletal remains in certain Native American populations antedating the age of exploration, leading some to speculate that the disease is a New World phenomenon that was transmitted back to the Old World.

Symptoms and Signs

The typical patient with rheumatoid arthritis is a young to middle-aged woman who presents to her physician with a history of 2 to 3 months of joint pain and stiffness in her hands. Constitutional symptoms of fatigue, weight loss, and low-grade fever might also be present. The hands and other involved joints are stiff on arising in the morning. Stiffness might last from 30 minutes to 2 hours or longer. In severe disease, the patient might remain stiff most of the day.

Patients with involvement of the hands and wrists might have difficulty performing tasks such as lifting pots, washing their hair, and opening jars or doors. A firm handshake can be quite painful. Tingling and numbness of the thumb and index and middle fingers, which often occur at night, indicate compression of the median nerve by synovial tissue in the carpal tunnel (carpal tunnel syndrome). At times, the carpal tunnel syndrome produces pain radiating up the forearm and down into the hand. Rheumatoid arthritis can begin in the feet in the MTP joints. It is not unusual for a patient to attribute metatarsalgia to improperly fitting shoes before seeking medical attention.

On physical examination, the joints are swollen, tender to palpation, and warm but not hot. The combination of synovial proliferation and fluid gives the joint a boggy sensation on palpa-

FIGURE 34.5 Example of rheumatoid arthritis of the hands. DIP joints are spared while the MCP and PIP joints are swollen. There is beginning to be some early ulnar deviation on the left hand.

tion (Fig. 34.5). Synovial proliferation in the flexor tendons of the fingers fills in the palm, giving it a flat appearance. The skin over the small joints often has a bluish discoloration resulting from venous engorgement. The hands may be cool and clammy. The range of joint motion is initially limited by pain and later by contractures. Ulnar deviation of the fingers at the metacarpal phalangeal joint is a common deformity in established disease and results from radial deviation of the wrist and slippage of the extensor tendons to the ulnar side of the MCP joints. Another common deformity of the hand that develops in chronic disease is the swan-neck deformity. This appearance results from flexion of the distal interphalangeal joint and MCP joint with hyperextension of the PIP joint. The boutonniere deformity is caused by avulsion of the extensor hood over the PIP joint, leading to a flexion deformity of this joint and hyperextension of the distal interphalangeal joint. In advanced disease, subluxation and flexion deformities are common and involve the knees, ankles, elbows, wrists, shoulders, hands, and feet.

The course of rheumatoid arthritis is highly variable. Fifteen percent of patients have complete remission, whereas 10% or less go on to destructive disease that responds poorly to all forms of therapy. Most patients fall between these two groups with variable periods of remission and relapse. Some patients experience significant disability, whereas others respond to treatment and function quite well throughout their lifetimes. Prognostic factors for more severe disease include the presence of high titers of rheumatoid factor, elevated cyclic citrullinated peptide (CCP) (see next section), presence of HLA-DR4, and more joints initially involved.

Laboratory Findings

Patients often have a normocytic normochromic anemia and an elevated erythrocyte sedimentation rate (ESR). Approximately 80% of patients have a positive rheumatoid factor test result. In the last several years, the CCP has emerged as an important diagnostic and prognostic test. It detects the presence of antibodies to citrullinated peptides and is 75% sensitive and 96% specific for rheumatoid arthritis. The higher levels are correlated with more erosive disease and may appear before overt arthritis has appeared.[37] Radiography in early disease reveals only juxtaarticular osteopenia and soft tissue swelling. In more advanced disease one finds narrowing of joint spaces, erosions at the margins of the joint, and eventually subluxation (Fig. 34.6). The synovial fluid usually has a white blood cell count that varies from 5000 to 25,000 cells per cubic millimeter (most of the cells are neutrophils), decreased viscosity, and a low glucose level although this is rarely measured anymore (see Table 34.4).

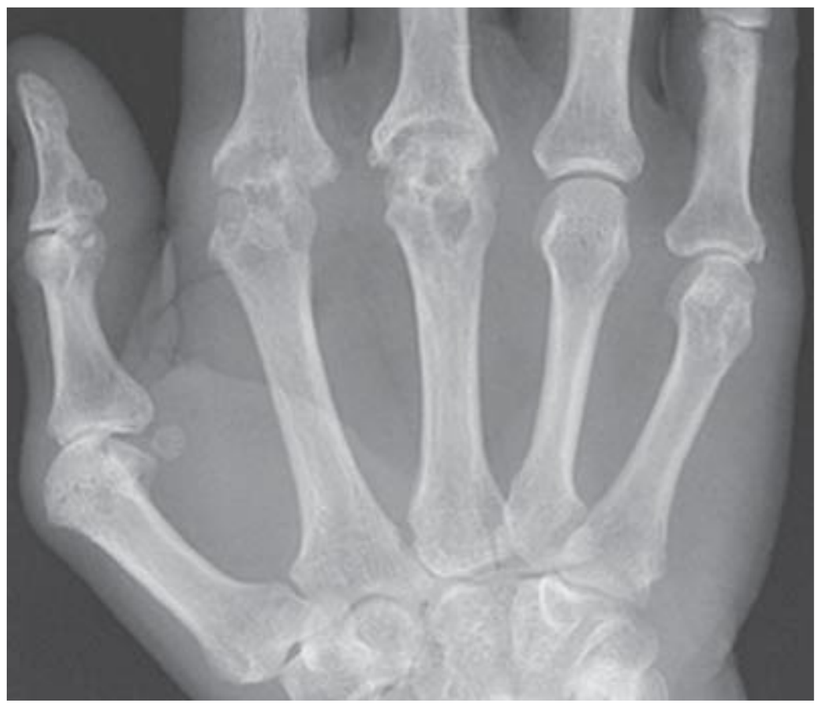

FIGURE 34.6 X-ray of rheumatoid arthritis of the right hand. Note the erosions and joint space narrowing at the second and third MCP joints.

Treatment

The treatment of rheumatoid arthritis has undergone considerable rethinking over the years. The time-honored approach to the treatment of rheumatoid arthritis has been based on the *pyramid*, in large part because of the philosophy that rheumatoid arthritis was a disabling but otherwise benign disease. Via the treatment pyramid, patients would receive nonsteroidal anti-inflammatory drugs (NSAIDs) or salicylates along with education and physical and occupational therapy and, as the disease progressed, more aggressive therapy with immunomodulating drugs known as DMARDs (disease modifying antirheumatic drugs) of increasing toxicity would be used. In 1965, up to 120 months would pass before a DMARD would be started.[40] A majority of patients with rheumatoid arthritis develop erosions after 2 years of disease and it has been found not to be the benign disease it was once thought to be. It has been suggested that we invert the pyramid; that is, begin with aggressive therapy up front to prevent erosive changes to joints that are generally not reversible and thus prevent the disability and potentially the mortality caused by unchecked rheumatoid arthritis.[39–41] Currently, most rheumatologists start a DMARD as soon as the diagnosis of rheumatoid arthritis is made and medication-induced remission rates in rheumatoid arthritis are now approaching 50% with the combination of methotrexate and anti-TNF biologics that will be discussed later.

Current Management of Rheumatoid Arthritis

Disease-Modifying Agents. Current therapy of rheumatoid arthritis is early diagnosis and early aggressive therapy especially for patients that have factors indicative of a poor prognosis—namely, high titer rheumatoid factor (or CCP) and a high number of joints involved at presentation. Patients with features that suggest more severe disease are typically started on methotrexate while patients without such features may be started on less potent DMARDs such as hydroxychloroquine or sulfasalazine. If after 3 to 6 months of therapy there is incomplete control of the disease, other agents are added to the regimen in particular the antitumor necrosis factor-α (anti-TNF) biologics.

Patients with early mild synovitis could be started on hydroxychloroquine.[42] This agent takes 8 to 12 weeks before it begins

to affect the synovitis. Its mechanism of action is thought to be on the basis of increasing the pH of the vacuoles in antigen-presenting cells and gently disrupting the interaction of the major histocompatibility complex, with antigen thus affecting the way antigen is presented to T cells.[43]

Hydroxychloroquine is dosed by weight at 6.5 mg per kg per day in divided doses. Doses higher than this increase the risk for ocular toxicity. Common side effects include diarrhea, GI upset, and rash. Serious side effects are listed in Table 34.5 as well as a monitoring schedule. Improvement in morning stiffness and pain, as well as a decrease in the number of tender and swollen joints, and a reduction in acute-phase reactants (i.e., ESR or C-reactive protein [CRP]) are measures of success. Patients with more significant synovitis may be candidates for either sulfasalazine or methotrexate as single agents.

Sulfasalazine is another DMARD used for less severe disease. It is a combination of sulfapyridine and 5-aminosalicylic acid, which is cleaved by gut bacteria into two compounds. It is thought that the sulfapyridine moiety is the active one in rheumatoid arthritis.[42] It is dosed generally at 2000 mg in two divided doses and monitored as noted in Table 34.5. It takes 4 to 8 weeks for an effect to be apparent in most patients, and in some may be up to 12 weeks. Common side effects include GI upset, diarrhea, and rash. Severe agranulocytosis can occur and is idiosyncratic. Drug cessation resolves the cytopenias in most cases, but there have been a few cases requiring granulocyte colony-stimulating factor therapy. G6PD deficiency may lead to severe anemia in affected patients and should be checked before starting therapy if suspected.

Methotrexate is the current "workhorse" drug for rheumatoid arthritis. It is used by itself or, more and more frequently, in combination with other agents. In rheumatoid arthritis in particular, methotrexate plus something else seems to work better than either agent alone. The dose range and other characteristics are presented in Table 34.5. Methotrexate is a dihydrofolate reductase inhibitor. Its mode of action is uncertain but may be caused by an increase in adenosine, an anti-inflammatory compound.[44] Methotrexate has the advantage of being given once a week and can be given both orally and intramuscularly. Methotrexate begins to be effective generally in 3 to 8 weeks after initiation of therapy. Common side effects include stomatitis, nausea, GI upset, and mild hair thinning. Stomatitis in particular might respond to the addition of 1 mg of folic acid daily without affecting its activity in rheumatoid arthritis.

Leflunomide is a relatively new DMARD. The usual dose is 20 mg per day. Data indicate that it is similar to methotrexate in efficacy as well as toxicity. It has had, if you would, the misfortune to come to market at the same time as the anti-TNF biologic agents and thus has been somewhat overshadowed by the impressive results of these agents.

Biologic DMARDs. There are currently three anti-TNF DMARDs on the market with more on there way. Etanercept, infliximab, and adalimumab are anti-TNF agents that have been shown to be quite effective in not only controlling inflammation in rheumatoid arthritis but also preventing joint damage. In fact, data from the TEMPO study (Trial of Etanercept and Methotrexate with Radiographic and Patient Outcomes) indicates that the combination of methotrexate plus etanercept can prevent new erosion in 76% of patients over 3 years and even lead to filling in of previous erosions.[45]. The other anti-TNF agents have similar numbers. Etanercept is administered subcutaneously once or twice a week; infliximab is given intravenously at 0, 2, and 6 weeks, and then every 8 weeks thereafter; and adalimumab is given subcutaneously every 2 weeks. Side effects can include leukopenia, reactivation of latent tuberculosis (TB), multiple sclerosis–like disease, and there is a concern for an increased prevalence of lymphomas in patients who use these drugs. The latter issue is difficult to

TABLE 34.5

DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

Drug	Dose range	Route	Serious side effects	Monitoring
Hydroxychloroquine	200–600 mg/day	PO	Retinal toxicity, neuromyopathy	q 6–12 mo funduscopic and visual fields examination
Sulfasalazine	1000–3000 mg/day	PO	Leukopenia, sulfa hypersensitivity	CBC and platelets q 2–4 wk ∞ 3 mo, then CBC q 3 mo
Methotrexate	7.5–25.0 mg/wk	PO, IM, SQ	Bone marrow suppression, pneumonitis, hepatotoxicity	CBC, platelets, aspartate aminotransferase, albumin, and albumin q 4–8 wk
Leflunomide	10–20 mg/day after 100 mg/day for 3 days loading dose	PO	Hepatotoxicity, gastrointestinal distress, diarrhea, alopecia	LFTs q mo ∞ 6 mo, then every 3 mo. CBC would be reasonable early in course as well.
Etanercept	25 mg twice a week to 50 mg once a week	IM, SQ	Local injection site reaction, increased risk of infections, leukopenia, severe hepatitis in hepatitis B carriers, multiple sclerosis-like illness	Baseline CBC, LFT, hepatitis B, PPD; CBC, LFTs every 3–6 months
Infliximab	Initial dose: 3 mg/kg 2 wk: 5 mg/kg 6 wk: 5 mg/kg q 4–8 wk: 5–10 mg/kg	IV	Reactivation of TB, leukopenia, increased risk of infection, SLE-like disease, tumor risk uncertain, infusion reactions	Baseline CBC, LFT, hepatitis B, PPD; CBC, LFTs every 3–6 months
Adalimumab	40 mg	SQ	Similar to infliximab	Baseline CBC, LFT, hepatitis B, PPD; CBC, LFTs every 3–6 months

CBC, complete blood count; LFT, liver function test, PPD purified protein derivative.

ascertain as rheumatoid arthritis itself increases the risk of lymphomas. In addition to the anti-TNF biologics, two other biologic agents are now approved for rheumatoid arthritis. Rituximab, long used for treatment of lymphoma, is an anti-B cell agent, and abatacept is a molecule that inhibits T cell activation. These are currently used in patients who fail methotrexate plus an anti-TNF agent. In the next few years, there will be additional biologic agents for the treatment of rheumatoid arthritis.

Glucocorticoids. The anti-inflammatory mechanisms of glucocorticoids include altering leukocyte traffic and function, stabilizing lysosomal membranes of neutrophils and monocytes, and inhibiting the secretion of destructive enzymes including collagenase and elastase.[46] They also inhibit the products of arachidonic acid metabolism including prostaglandins and leukotrienes.

Studies have shown that low-dose glucocorticoids (defined as 7.5 mg or less of prednisone or the equivalent of another short-acting glucocorticoid) given in the morning by 10 AM reduces the progression of joint damage.[52] Also, the hypothalamic-pituitary-adrenal axis remains intact when low doses of prednisone are used. Low-dose prednisone treatment can be especially beneficial during initiation of treatment with a DMARD. Glucocorticoids are often used as bridge agents for patients diagnosed with rheumatoid arthritis; that is, 5 to 10 mg per day until the DMARD begins to work. In patients on corticosteroids, it is important to give calcium in the range of 1000 to 1500 mg per day and 400 units of vitamin D a day. Patients should be monitored closely for evidence of hypercalcemia and hypercalcinuria. A bisphosphonate (e.g., alendronate) may also reduce the bone loss of calcium in patients on corticosteroids.

Judicious intra-articular administration of corticosteroids can be quite useful in the treatment of rheumatoid arthritis. It is recommended that an individual joint be injected no more than three times at intervals of 6 months or longer. In a badly damaged joint or one that is soon to be replaced by a prosthetic joint, corticosteroids may be injected more frequently.

Surgery. Indications for orthopedic surgery in rheumatoid arthritis are twofold: pain unresponsive to medical management and loss of function. Synovectomy of selected joints provides alleviation of symptoms and improvement of function in the first year after operation, but may not provide a long-term effect. Removal of synovial tissue from the wrist and dorsal tendon sheath and resection of the ulnar head might prevent rupture of the extensor tendon. Patients with severely deformed hands can benefit from MCP arthroplasty. Patients with severe pain and loss of function can benefit from total joint replacement, especially the knee or hip. Metatarsal head resection can be of tremendous help in patients with painful metatarsal heads. Intermittent splinting of selected joints is beneficial.

Important Complications of Rheumatoid Arthritis Presenting with Pain

Carpal Tunnel Syndrome. Carpal tunnel syndrome is a common problem in rheumatoid arthritis caused by wrist synovitis that can lead to median nerve compression. Therapy is generally directed at the rheumatoid synovitis with DMARDs and anti-inflammatory agents. A wrist injection with corticosteroids may be helpful in many cases. Carpal tunnel release may be necessary in some cases.

Rheumatoid Vasculitis. This is a potentially life-threatening complication. Patients with long-standing, seropositive, erosive rheumatoid arthritis are generally at risk for this small to medium vessel vasculitis similar to polyarteritis nodosa. Patients may present with digital gangrene or symptoms of mononeuritis multiplex (i.e., footdrop). More serious complications include intestinal perforation or cardiac involvement. Kidneys are less commonly involved than in polyarteritis nodosa. Treatment is with cyclophosphamide and high-dose prednisone.

Cervical Spine Disease. The synovial portions of the cervical spine can be involved in rheumatoid arthritis. This can lead to C1–2 instability or subaxial instability. Symptoms may be caused by cord or vascular compression and may include neck pain, shocklike sensation up or down the spine, and intermittent loss of consciousness when vertebral artery compression occurs. Before surgery, all patients with long-standing rheumatoid arthritis should have a set of lateral flexion and extension views of the cervical spine taken to evaluate the cervical spine for C1–2 subluxation.

Septic Arthritis. Patients with rheumatoid arthritis are at increased risk of septic arthritis caused by abnormal joint architecture, use of immunosuppressive drugs, and skin breakdown over high-pressure, biomechanically abnormal sites such as the feet. Patients often present with one joint out of proportion to the others in terms of pain or swelling and may have a paucity of systemic symptoms typical in nonrheumatoid patients. Detection is imperative because of the high mortality in such patients (i.e., 20% mortality if a single joint is infected and over 50% in patients with multiple joints involved).[48]

The Spondyloarthropathies

Ankylosing Spondylitis

Ankylosing spondylitis is an inflammatory arthritis involving sacroiliac joints and the spine. Inflammation also occurs at sites of tendon and ligament insertions (enthesitis). Hips and shoulders can also be affected. Peripheral arthritis is less common. Onset of disease is usually in the second or third decade, and men are predominantly affected. The histocompatibility antigen HLA-B27 is found in 90% or more of patients, fulfilling clinical criteria for ankylosing spondylitis.[49] The normal frequency of HLA-B27 in the Caucasian population is approximately 7%.

Pathophysiology. Synovitis in the apophyseal and costovertebral joints of the spine and peripheral joints is characterized by synovial hyperplasia with focal accumulation of lymphoid and plasma cells. Inflammation also involves cartilaginous joints, which include the intervertebral discs, manubriosternal joint, and symphysis pubis. Ossification of the outer layers of annulus fibrosus of the disc and the inner layers of the longitudinal ligaments forms syndesmophytes that eventually interconnect to give the spine the appearance of bamboo.

In recent years the enthesis (insertion of tendons, ligaments, and joint capsule to bone) has become an important tissue in understanding the pathophysiology of spondyloarthropathies.[50] These are common sites of inflammation and it appears that inflammation may begin on the bone side at areas rich in fibrocartilage such as enthesis and extend to surrounding tissues. The knee has some 32 enthesis alone and the concept of enthesitis explains the clinic finding of dactylitis or sausage digits in the spondyloarthropathies (Fig. 34.7).

Symptoms and Signs. The onset of the disease is usually in the second and third decades. The patient initially notes low back pain and stiffness, especially on arising in the morning. The stiffness of the back lasts for several hours in the morning and occurs after periods of activity during the day. The pain might radiate into either buttock, extend down the back of the leg to the knee, and can be mistaken for the pain caused by herniated disc. The pain might alternate from side to side. Involvement of the hips and shoulders causes pain, stiffness, and decreased motion. Peripheral joints other than the hips or shoulders are affected

FIGURE 34.7 Classic example of dactylitis AKA "sausage digit" in a patient with a spondyloarthropathy (psoriatic arthritis in this case).

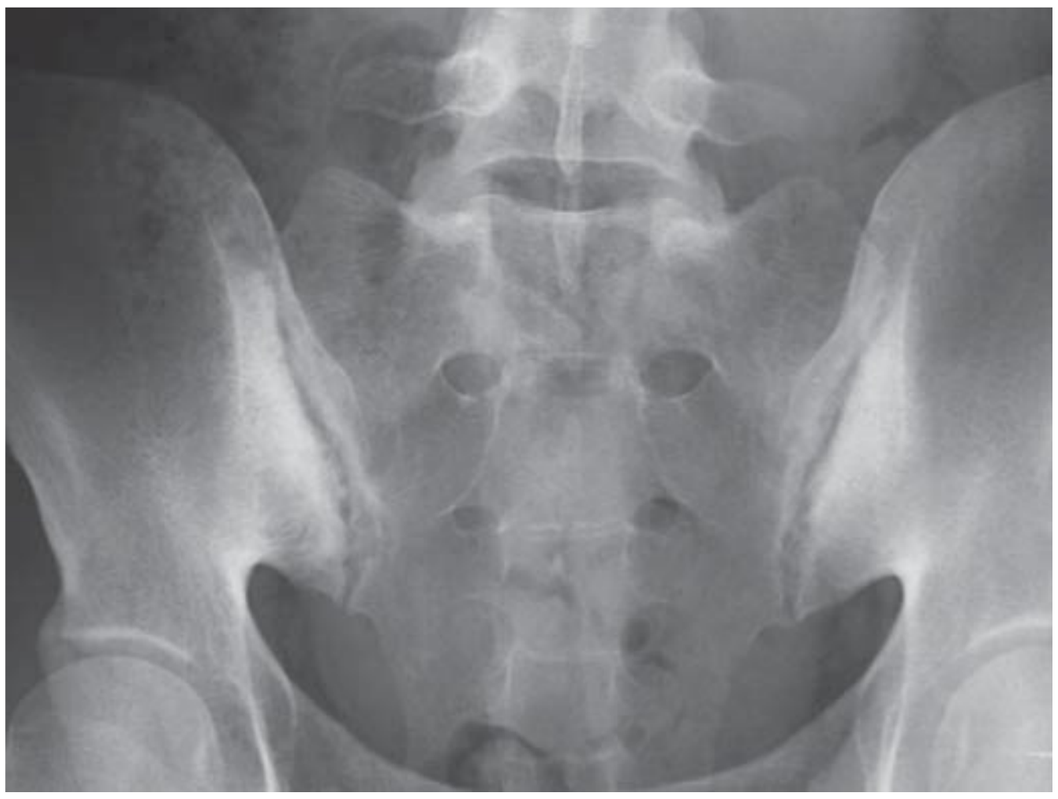

FIGURE 34.8 Ferguson view of the pelvis showing reactive bone changes around the SI joints as well as an indistinctness to the joints caused by erosions.

relatively infrequently. Costovertebral joint arthritis can cause chest pain similar to that of angina pectoris or pleurisy. The entire spine can become ankylosed. Ankylosis develops over several years, usually 10 years or more. The extent of involvement varies among patients and ranges from bilateral sacroiliitis to complete ankylosis of the spine. The spondylitis sometimes skips segments of the back. Atlantoaxial subluxation (with the potential danger of spinal cord compression) can occur, but this is observed less often in ankylosing spondylitis than in rheumatoid arthritis. The fused spine, especially the neck, is susceptible to fractures with trauma.

Acute iritis occurs in approximately one-third of the patients. A rare manifestation of ankylosing spondylitis is fibrosis of the upper lobes of the lung, which occurs late in the course of the disease. Also with long-standing disease dilatation of the proximal aorta may lead to insufficiency of the aortic valve and inflammation of the atrioventricular bundle can produce cardiac conduction abnormalities. Patients occasionally have significant constitutional symptoms of fever and weight loss.

On physical examination, sacroiliac tenderness is elicited by direct palpation or by maneuvers that stress the joint. A loss of normal lumbar lordosis occurs, giving the lumbar area an ironed-out appearance. Flexion is limited. Tenderness can be present over costovertebral joints, iliac crests, greater trochanter, and heels. Chest expansion is limited. In advanced disease the spine becomes rigid, fusing in varying degrees of flexion.

Laboratory Findings. The sedimentation rate or CRP can be elevated, and a mild hypoproliferative anemia can occur. The rheumatoid factor test result is negative and one would rarely mistake rheumatoid arthritis and ankylosing spondylitis. The synovial fluid is inflammatory (see Table 34.4). Radiography of the sacroiliac joints in early disease shows blurring and irregularity of the joint margins, followed later by subchondral erosions, sclerosis, and eventually fusion (Fig. 34.8). Bony spurs appear at tendinous insertions such as the sites of attachment of the Achilles tendon and plantar fascia. Radiography shows a straight lumbar spine, squared vertebrae, and syndesmophytes. Syndesmophytes extend along the outer aspect of the intervertebral disc and eventually form a bridge between adjacent vertebrae (bamboo spine).

Treatment. With the advent of the anti-TNF agents, the treatment philosophy has changed. There is now the hope of disease slowing or even remission similar to that seen with rheumatoid arthritis although it still remains to be seen whether that is indeed true. Most patients would still receive an NSAID initially but with partial response or evidence of radiographic progression most patients would now be put on an anti-TNF agent early in the course of the disease.

Nonsteroidal Anti-inflammatory Drugs. NSAIDs are especially useful in reducing inflammation and relieving pain, but they may not change the course of the disease. It is speculated, but not proven, that NSAIDs may encourage the patient to be more mobile and possibly lessen the chance of spine fusion. Preferred agents include indomethacin or a once-a-day agent such as piroxicam because of their anti-inflammatory activity. Any anti-inflammatory agent chosen usually needs to be dosed at an anti-inflammatory level (i.e., upper limit of dosing range) for benefit.

Disease-Modifying Antirheumatic Drugs. Sulfasalazine has been shown to be beneficial for the peripheral joint in ankylosing spondylitis, but not the spine.[51] Methotrexate has also been used for ankylosing spondylitis, but controlled trails are lacking. The anti-TNF agents have a significant impact on disease symptoms and also diminish both bone edema and enthesitis by serial MRI scan.[52,53] It has not been shown yet that they are definitive disease remitting agents yet but these medications have become important tools in the treatment of ankylosing spondylitis.

Physical Therapy. Physical therapy is directed at maintaining the erect posture of the patient. Patients should be encouraged to sleep in the prone position and to avoid using a pillow when sleeping on their backs. Anterior uveitis or iritis can be treated with topical or intraocular corticosteroids and in severe cases, methotrexate of the monoclonal anti-TNF agents such as adalimumab or infliximab can be used. Etanercept, a fusion protein, is not effective for uveitis. Patients with severe hip or shoulder disease can benefit from total shoulder replacement.

Important Complications of Ankylosing Spondylitis Presenting with Pain

Cauda Equina Syndrome. Patients with cauda equina syndrome generally have long-standing ankylosing spondylitis. The patient generally presents with progressive lower extremity weakness, pain, and loss of sensation in the lower extremities and perineum. Impotence and overflow incontinence are also frequently occurring problems. Radiographically, large dorsal arachnoid diverticula are seen on myelography or magnetic resonance imaging.[54]

Electromyography demonstrates multi-root involvement. Therapy with high-dose corticosteroids and surgery both have been disappointing.

Spondylodiskitis

Spondylodiskitis is a rare complication of long-standing ankylosing spondylitis. Patients have persistent mechanical-type back pain (pain with activity) rather than inflammatory low back pain (pain in the morning or with rest). It is caused by a mobile vertebral segment surrounded by fused segments. The focus of activity at the one segment may lead to significant inflammation and damage to the adjacent vertebral bodies, simulating infection. Infection generally needs to be ruled out and treatment is directed to immobilizing the segment either via brace and allowing it to fuse or refuse; occasionally it may need to be surgically fused.[55]

Vertebral Fracture. Vertebral segments connected by syndesmophytes are subject to fracture with even minor trauma.[55] The usual location for such fractures are the C5–7 vertebral segments; the fractures are typically caused by a hyperextension injury. Patients suspected of fracture should be evaluated by computed tomographic scan or bone scan to try to identify a potential fracture site, as plain radiography may not be able to demonstrate the fracture. Patients with such fractures have a relatively high morbidity and mortality even if identified, because of surgery or prolonged immobilization usually required for treatment. Only 40% of such patients return to their former level of activity.

Chronic Enthesitis. Enthesitis of Achilles tendon, plantar fascia, and occasionally the ribs can be a chronic source of pain and may be more resistant than spondylitis to usual therapies.[61] In such cases, indomethacin at maximum dose, use of a DMARD such as methotrexate, sulfasalazine, or an anti-TNF agent may be warranted. Refractory patients may benefit from low-dose radiation to the heel.[56]

Reactive Arthritis

Reactive arthritis (formally Reiter's syndrome) is defined as an asymmetric arthropathy involving predominantly joints of the lower extremities plus one or more of the following: urethritis or cervicitis, dysentery, mucocutaneous lesions, and inflammatory eye disease. It is also defined as an episode of arthritis lasting longer than 1 month that is associated with urethritis or cervicitis. The histocompatibility antigen HLA-B27 is present in approximately 80% of patients.[57] The reasons of the change in nomenclature for Reiter's to reactive arthritis is due to the involvement of Hans Reiter with the Nazi regime and the fact that the same syndrome had been described previously by others.

There appears to be a relationship between certain infections and a specific genetic background. Reactive arthritis can follow infections with *Shigella*, *Salmonella*, *Campylobacter*, or *Yersinia*.[58] An association also exists with urethritis associated with *Chlamydia* or *Mycoplasma* infections. In addition, reactive arthritis has been associated with human immunodeficiency virus (HIV) infection. Reactive arthritis develops in patients without these infections, however, and most patients with nonspecific urethritis do not develop this syndrome. The risk of an individual who has a positive result for HLA-B27 with nonspecific urethritis developing reactive arthritis is in the range of 20%. Up to 3% of individuals with nonspecific urethritis have been shown to develop a reactive arthritis. Reactive arthritis has a worldwide distribution and occurs more often in men. In postdysenteric reactive arthritis, the gender distribution is equal.

Symptoms and Signs

Arthritis affects several joints in an asymmetric fashion; knees and ankles are most often involved. Patients also experience pain in the feet and ankles secondary to inflammation at the insertion of the Achilles tendon and plantar fascia. Joints can remain swollen for several months. Swelling of two adjacent interphalangeal joints and adjoining tendon sheath results in a sausage digit or dactylitis. In approximately 20% of patients, spinal involvement occurs. Sacroiliitis is usually unilateral and spine involvement mild. Patients can also experience chest pain caused by inflammation at the tendinous insertions of the intercostal muscles.

The mucocutaneous lesions of reactive arthritis include oral ulcers, balanitis, and keratoderma blennorrhagica. The oral ulcers are shallow and irregular, and have a slightly erythematous base. These lesions are only present for several days. Balanitis usually begins as small painless vesicles that become hyperkeratotic. These lesions are painless and remain crusted in the circumcised patient. In the uncircumcised patient, lesions are moist and can become secondarily infected. Keratoderma blennorrhagica, a hyperkeratotic skin lesion similar to psoriasis, most commonly involves the feet. Sometimes it involves the hands, but it can be present almost any place on the body.

Conjunctivitis involves one or both eyes. Uveitis also occurs. Urethritis can precede or accompany the arthritis. Prostatitis is present in approximately 80% of patients.

As with ankylosing spondylitis, some patients may develop dilatation of the proximal aorta leading to aortic valve insufficiency.

The course of reactive arthritis is recurrent or persistent, with only an occasional patient experiencing transient, self-limited disease. In some patients, sexual intercourse with a certain partner appears to lead to an exacerbation of reactive arthritis. These patients should be advised to use a condom even though the benefit of this practice is questioned by some. No evidence exists that the use of an antibiotic prevents or alters the course of reactive arthritis.

Laboratory Findings

Routine laboratory test results are usually normal. The sedimentation rate is quite variable and does not correlate with disease activity. Synovial fluid shows an elevated white cell count ranging from 5000 to 50,000 cells per cubic millimeter, predominantly neutrophils. Radiography shows juxta-articular osteopenia, joint space narrowing, and bone erosions. Periostitis is present adjacent to the involved joints and at the insertion of tendons and fasciae. Erosions, sclerosis, and irregularity of the sacroiliac joint can be present and are usually unilateral. Changes of spondylitis are usually asymmetric, occur at various levels of the spine, and are similar to those seen in psoriatic arthritis. Testing for HLA-B27 is not necessary for diagnosis. This test should be reserved for patients who have asymmetric arthritis without other evidence of reactive arthritis.

Treatment

Treatment of reactive arthritis is similar to that of ankylosing spondylitis. NSAIDs are first-line therapy followed by sulfasalazine in refractory cases. Methotrexate or azathioprine can be used in more severe disease. Intra-articular corticosteroid can also be useful. The anti-TNF agents are less well studied in this condition but there is no reason to doubt their efficacy.

Complications of Reactive Arthritis Associated with Chronic Pain

Rare patients may have more persistent inflammatory eye disease requiring continuous ophthalmology care. Enthesitis can be severe in some cases of reactive arthritis. Chronic foot involvement can lead to erosive disease at the MTP.

Psoriatic Arthritis

Arthritis appears in 6% to 39% of outpatients with psoriasis depending on the population studied.[59] Hereditary factors play

a role. An increased prevalence of psoriatic arthritis occurs in first-degree relatives with psoriasis. An association with HLA-B27 is seen in psoriatic arthritis with spondylitis, but not in patients with peripheral arthritis. Onset of psoriatic arthritis is usually in the third or fourth decade, and the gender ratio is approximately equal. In most patients, psoriasis precedes the arthritis by several years. Most patients with psoriatic arthritis have only a few joints that are involved, and, overall, the prognosis tends to be better than in rheumatoid arthritis. Psoriatic arthritis has been noted in patients with HIV infection.

Symptoms and Signs

Several patterns of arthritis are observed in patients with psoriasis. The majority of patients have an asymmetric oligoarthritis involving the proximal joints of the hands and feet. In approximately 10% of patients, arthritis affects predominantly the distal interphalangeal joints and is usually accompanied by psoriasis of the adjacent nail. Other patients have a symmetric polyarthritis similar to that seen in rheumatoid arthritis. These patients usually have negative results for rheumatoid factor. If the rheumatoid factor test or the CCP result is positive, the patient may have both rheumatoid arthritis and psoriasis. Patients can also manifest sacroiliitis, and variable degrees of spondylitis. In some patients the spine becomes ankylosed. A few patients have a severe, destructive, and deforming polyarthritis referred to as *arthritis mutilans*.

Joints are swollen, warm, and tender, and a digit may have the appearance of a sausage (see ankylosing spondylitis). Contractures and ankylosis of joints occur with long periods of persistent joint inflammation. In most cases there appears to be no definite correlation between the degree of skin involvement and joint disease.

Laboratory Findings

Laboratory findings include an elevated sedimentation rate and a hypoproliferative anemia. The rheumatoid factor test result is negative. The synovial fluid shows evidence of inflammation with elevated white cell counts; the cells are predominantly polymorphonuclear. A somewhat characteristic radiographic finding is that of the pencil-in-cup deformity caused by osteolysis, or whittling of the distal end of the middle phalanx, which produces a pencil point that projects into a widened cup-like erosion in the adjacent surface of the distal phalanx (Fig. 34.9). Radiography shows joint space narrowing, erosions, osteolysis, and ankylosis, depending on the degree of clinical severity. The radiographic findings of the spine are similar to those found in patients with reactive arthritis.

FIGURE 34.9 X-ray of the left foot in psoriatic arthritis demonstrating fusion of the fourth MTP and a developing pencil in a cup deformity of the fifth MTP.

Treatment

Initial treatment of psoriatic arthritis is aspirin or other NSAIDs. In patients with progressive disease, methotrexate, cyclosporine, sulfasalazine, and even hydroxychloroquine have been used successfully.[69] Low-dose oral corticosteroids as well as intra-articular corticosteroids can also be used. The tapering of corticosteroids in patients who have been on moderate to large doses may exacerbate the skin disease. The anti-TNF agents have an impressive effect on both skin and joints in many patients and are generally used with failure of methotrexate.[60]

Important Complications of Psoriatic Arthritis Presenting with Pain

See Ankylosing Spondylitis for a discussion of chronic enthesitis. For a discussion of carpal tunnel syndrome, see Rheumatoid Arthritis.

Arthritis Associated with Inflammatory Gastrointestinal Disease

Both ulcerative colitis and regional enteritis (Crohn's disease) are associated with peripheral arthritis and spondylitis.[61] Peripheral arthritis occurs in approximately 10% to 20% of patients with inflammatory bowel disease. Onset of peripheral arthritis is usually in the third or fourth decades. Both genders are equally affected. The arthritis usually follows the onset of colitis by months to years and involves only one or two joints. Arthritis is acute, lasts several days to several weeks, and leaves no residual damage. The knees and ankles are most frequently affected.

Ankylosing spondylitis is also associated with inflammatory bowel disease. The gender distribution is equal, in contrast to the male predominance observed in primary ankylosing spondylitis. The majority (70%) of patients with spondylitis associated with inflammatory bowel disease has positive results for HLA-B27. Asymptomatic bilateral sacroiliitis can be found in up to 15% of patients with inflammatory bowel disease. Frequency of HLA-B27 is not increased in patients with only peripheral arthritis. Synovial fluid analysis shows an inflammatory effusion.

Treatment

Peripheral joint symptoms are managed with salicylates or other NSAIDs. NSAIDs, however, may lead to an exacerbation of the inflammatory bowel disease. Peripheral arthritis often disappears after colectomy. Treatment of the spondylitis is similar to that described for ankylosing spondylitis.

Arthritis Caused by Deposition of Calcium Pyrophosphate

Deposition of calcium pyrophosphate dihydrate in the joint produces both an acute and chronic form of joint disease. The acute or subacute form is referred to as *pseudogout* because of its similarity to gout. *Chondrocalcinosis* refers to calcium pyrophosphate deposits in articular tissue that are detectable radiographically and occur in the absence of inflammatory arthritis. Pseudogout affects persons over the age of 40, men predominately. The knee is the most frequent site of acute arthritis, but the hip, shoulder, ankle, wrists, and bursae can be affected. Approximately 3% to 5% of the adult population has calcium pyrophosphate deposits in knee joints at the time of death. This disorder is associated with OA.

Three forms of calcium pyrophosphate deposition disease (CPDD) are recognized: a hereditary form, CPDD associated with metabolic and other diseases, and an idiopathic form. The frequency of OA in CPDD varies from 40% to 70%. CPDD occurs in 41% of patients with hemochromatosis and in 5% to 15% with hyperparathyroidism.[62] An association is suspected in patients with diabetes mellitus, hypophosphatemia, Wilson's disease, ochronosis, and hypothyroidism.

Pathophysiology

The initial site of crystal formation is in articular cartilage. In idiopathic CPDD it is not clear whether the primary event is deposition of crystals in cartilage or whether the crystals develop as a consequence of disturbed cartilage metabolism. Increased inorganic pyrophosphate is found in the synovial fluid and probably reflects a local disorder of pyrophosphate metabolism leading to deposition of calcium pyrophosphate crystals in the joint.[63,64] Elevated levels are also found in patients with OA. Acute arthritis is brought on by shedding of crystals into the joint space. The mechanism for crystal shedding is the lowering of either calcium or pyrophosphate ions in synovial fluid.[65,66] The decreased concentration of ionized calcium results in movement of crystals from cartilage into synovial fluid. Crystals can also be shed into the synovial fluid as a consequence of mechanical disruption of cartilage. Attacks can follow trauma. In addition, crystals can be released as a result of degradation of cartilage by enzymes from polymorphonuclear white cells during episodes of bacterial arthritis or other forms of inflammatory arthritis. Increased enzyme activity is also present in OA.

Symptoms and Signs

Several patterns of joint disease are recognized.[62] In approximately 25% of patients, CPDD presents as an acute arthritis involving a single joint or a few joints at any given time. The clinical picture mimics that of acute gout, which accounts for the term *pseudogout*. The onset of joint swelling and pain is abrupt and severe and usually reaches a peak within 24 to 36 hours. An attack can last up to 14 days. The joint is swollen, red, and tender. The most common site of involvement is the knee, but attacks can involve other large joints such as the ankles, wrists, elbows, or hips. Also, the lumbar and cervical spine can be involved. Trauma, surgery, or severe medical illness can precipitate an attack. The same joint is often involved in subsequent attacks. Radiographic evidence of chondrocalcinosis may be present in affected joints.

Approximately 5% of patients with CPDD have a form of disease that mimics rheumatoid arthritis (*pseudorheumatoid disease*). Involvement of multiple joints, synovial proliferation, limitation of joint motion, and joint deformity can develop. Patients experience fatigue and morning stiffness. To further confuse the issue, calcium pyrophosphate deposition can occur in rheumatoid arthritis.

CPDD also occurs in a chronic form that is similar to OA. Multiple joints are involved and include the knees, wrists, MCP joints, hips, shoulders, elbows, and ankles. The disease involves middle-aged to elderly patients, predominantly women. CPDD can mimic neuropathic arthropathy and can also occur in patients with neuropathic joint disease.

The diagnosis of calcium pyrophosphate disease is established by identification of calcium pyrophosphate crystals in synovial fluid, both free and in polymorphonuclear white cells. The crystals appear as short rods, rhomboids, and cuboids and they have a sign of weakly positive birefringence under compensated polarized light. Radiography shows calcification in articular hyaline cartilage that is parallel to and separated from the subchondral bone. Calcifications in fibrocartilage are thick and irregular densities and are found in the menisci of the knee, symphysis pubis, annulus fibrosus, and the triangular cartilage of the wrist. Calcifications also occur in the Achilles, supraspinatus, and triceps tendons, but can involve any tendon. Changes in the joint are similar to those seen in OA with sclerosis of subchondral bone, joint space narrowing, and large subchondral cysts.

Treatment

The NSAIDs are effective in the treatment of acute and chronic joint disease. An NSAID is given for 10 to 14 days in patients with acute pseudogout. The drug can be continued indefinitely in patients with CCPD associated with OA. When an NSAID is contraindicated, another method of treatment for an acute attack is prednisone, starting with 40 mg the first day and gradually tapering over a 7-day period. Colchicine, 0.6 mg twice a day, is started on day 3 or 4 and continued for several weeks to avoid a flare of arthritis after prednisone is discontinued. Colchicine, 0.6 mg twice a day, can also be given prophylactically to reduce the number and length of attacks (see colchicine in section on gout). Aspiration of the involved joint followed by an injection of glucocorticoids reduces pain and swelling.

Urate Gout

Urate gout (as opposed to pyrophosphate gout or pseudogout) is characterized by elevated serum urate levels, recurrent attacks of acute arthritis involving a single joint or a few joints at any given time, and deposition of monosodium urate dihydrate (tophi) in and around joints, leading in some patients to a deforming and crippling arthritis. Renal stones also may form. These features are present in varying combinations.[67]

Recognized since ancient times, gout has been depicted in caricatures as affecting well-fed aristocrats overindulging in rich foods and wines. The disease has been referred to as the *king of diseases* and the *disease of kings*.[68]

The normal serum urate concentration is 5.1 ± 1.0 mg per dL in men and 4.0 ± 1.0 mg per dL in premenopausal women. After menopause, the level in women approximates that of men. The level in young boys is 3 to 4 mg per dL and increases to adult levels at puberty. Serum urate levels show a positive correlation with weight and surface area in various racial groups.[82] The prevalence of gout varies from 0.20 to 0.35 per 1,000.[69–71] The prevalence of gout increases with age and increasing levels of serum urate. In one study of men whose ages ranged from 35 to 44 years old, the prevalence was 15 per 1,000 men.[72]

Both genetic and environmental factors play a role in the expression of hyperuricemia and gout. For example, higher serum urate levels are found in Filipinos living in the United States compared with racially identical persons living in the Philippines. These persons are unable to excrete the greater uric acid load resulting from the higher purine content of the diet eaten in the United States.[73]

Etiology and Pathophysiology

Uric acid is a product of purine metabolism.[67] The serum urate concentration depends on the rate of uric acid production and excretion. Approximately two-thirds of uric acid is excreted in the urine and one-third into the gastrointestinal tract. Normally, uric acid is completely filtered through the glomeruli and completely reabsorbed in the proximal tubule. Secretion of uric acid occurs in the proximal tubule, followed by a second reabsorption in the proximal tubule.

Primary gout is defined by the absence of other diseases or conditions such as drugs that lead to hyperuricemia and gout. Approximately 90% of patients with primary gout have decreased renal clearance of uric acid resulting from reduced glomerular filtration, increased tubular reabsorption, reduced tubular secretion, or combinations of these factors. Evidence for a molecular renal defect is still lacking in the majority of patients.

Approximately 10% of patients are overproducers of uric acid. Overproduction is defined as the urinary excretion of more than 800 to 1,000 mg of uric acid in 24 hours while the patient is on a regular purine diet.

Two inborn errors of purine metabolism make up a small number of primary gout patients who are overproducers of uric acid. The first disorder is caused by a partial deficiency of the enzyme hypoxanthine-guanine phosphoribosyltransferase, which catalyzes conversion of hypoxanthine to inosinic acid and guanine to guanylic acid.[67] The second disorder is caused by increased 5-phosphoribosyl-1-pyrophosphate synthetase activity leading to elevated levels of intracellular 5-phosphoribosyl-1-pyrophosphate and overproduction of uric acid. These patients usually experience the onset of gouty arthritis in the second or third decade and have a high frequency of uric acid stones. Both diseases are inherited as an X-linked disorder, therefore affecting male subjects, with women as carriers. Some of these patients also have dysarthria, hyperreflexia, lack of coordination, and mental retardation. A severe form of the first disorder with almost a complete deficiency of this enzyme, referred to as the Lesch-Nyhan syndrome, is characterized by self-mutilation, choreoathetosis, and mental retardation.[74] This disorder is classified under secondary hyperuricemia or gout because the neurologic disorder is predominant.

Secondary gout is defined as gout or hyperuricemia occurring in patients with other disorders. Overproduction of uric acid results in hyperuricemia in patients with disorders associated with increased cell proliferation and turnover of nucleic acids. These disorders include myeloproliferative and lymphoproliferative diseases, multiple myeloma, polycythemia, pernicious anemia, hemoglobinopathies, and some carcinomas. The hereditary disorder glucose 6-phosphatase deficiency (von Gierke's glycogen storage disease) is also manifested by overproduction of uric acid. Secondary hyperuricemia can also result from renal failure or the effects of drugs or toxins on renal clearance of uric acid. Diuretic agents, low doses of aspirin (less than 2 g per day), alcohol, ethambutol, cyclosporine, and lead are some of the agents that decrease the clearance of uric acid and thereby raise the serum urate level.

Pathophysiology of Acute Gouty Arthritis

Acute gouty arthritis results from the inflammatory reaction to urate crystals that form in the joint space or are released into the joint from synovium or articular cartilage. Plasma becomes supersaturated with urate at concentrations of approximately 7 mg per dL.[67] This point has to be remembered when a laboratory "normal" level of uric acid is indicated to be 3 to 8 mg per dL. Factors in addition to supersaturation of plasma urate are necessary for crystal precipitation because most patients with hyperuricemia do not develop gout. The lower temperatures found in peripheral joints or tissues might contribute to urate precipitation at these sites. Urate is less soluble at 32°C, which is the temperature observed in a normal knee, compared with the core body temperature of 37°C.[75] Another mechanism for urate precipitation might be the faster reabsorption of extracellular fluid than urate from the joint space, resulting in a transient increased urate concentration and crystal formation.[76] Trauma or impact loading of a joint that breaks crystals loose from the joint surface is yet another possible mechanism and might explain the high frequency of gout at the base of the great toe, which is a joint subjected to great stress.

Urate crystals induce inflammation by several mechanisms.[67] Urate crystals activate Hageman's factor in joint fluid, leading to the formation of kinins that induce vasodilatation and increased vascular permeability. Urate crystals activate the complement system with the generation of leukocyte chemotactic factors and also stimulate the formation of leukotrienes from arachidonic acid. Furthermore, urate crystals can activate platelets, which secrete several inflammatory mediators including prostaglandins. Urate crystals can also stimulate synovial lining cells and macrophages that secrete prostaglandins and collagenase.

The key to urate-induced inflammation is the polymorphonuclear white cell. Urate crystals activate toll-like receptors on the surface of cells that lead to the release of inflammatory mediators such as IL-1.[77] Crystals also bind IgG, leading to their attachment to and phagocytosis by polymorphonuclear white cells.[67] This process mediates the production of superoxide anions, which damage tissue. In addition, ingestion of crystals results in the release of chemotactic factors from the polymorphonuclear white cells, thus attracting more polymorphonuclear white cells. On ingestion by polymorphonuclear white cells, crystals are incorporated into phagosomes, which fuse with lysosomes. The rupture of phagolysosomes inside polymorphonuclear white cells damages these cells. Lysosomal and cytoplasmic enzymes are released into the joint space, resulting in tissue inflammation and injury.

Gouty arthritis often develops with fluctuation of serum urate levels. A rapid increase in serum uric acid results in precipitation of crystals in tissue or fluid. A rapid decrease in serum urate brings about release of urate from the joint surface into the joint space.

Drinking of alcohol is also associated with the precipitation of gouty attacks. Metabolism of ethanol results in an increased concentration of blood lactate, which blocks the renal excretion of uric acid by inhibiting tubular secretion and raising the serum urate level. Alcohol consumption also leads to accelerated degradation of adenosine triphosphate to adenosine monophosphate with accumulation of adenine nucleotides that are degraded to uric acid and other purine metabolites.[78] Beers and ales in particular increase the risk of gout due to the amount of purines these contain. The drinking of moonshine whiskey is associated with gouty arthritis and is referred to as *saturnine gout*.[79] Moonshine whiskey is often distilled in automobile radiators containing a lead core. Lead reduces the excretion of urate and decreases its solubility. In addition, lead may affect renal mechanisms for handling urate, leading to elevated levels.

Gout follows periods of fasting. During fasting the increased plasma level of acetoacetate and β-hydroxybutyrate interferes with renal excretion of urate.[80] Overindulgence of food and wine has often been associated with gout. When a large protein- and purine-rich diet is ingested along with copious amounts of wine or other liquor, the uric acid serum concentration rises because of increased formation and decreased excretion of sodium urate. Acute gouty arthritis attacks occur when drugs increase or lower the serum uric acid level. Attacks are precipitated by allopurinol, which lowers the uric acid concentrations, and thiazides or low doses of aspirin, which raise the level. Cyclosporine interferes with the renal excretion of uric acid and induces hyperuricemia and gout.[81] An increased frequency of gout is seen in transplant recipients receiving cyclosporine and may affect atypical joints such as the hips, sacroiliac joints, or shoulders.

Symptoms and Signs

Gouty arthritis occurs mainly in middle-aged and older men and after menopause in women. Approximately one-fourth of the patients have a family history of gout. Nephrolithiasis precedes the first attack of arthritis in approximately 10% of patients. The first attack occurs most often in the MTP joint of the great toe (podagra). Subsequent attacks might be separated by several months or even years. The involved joint usually returns to normal between attacks. In untreated cases, the attacks become more frequent and involve other joints, such as wrists, elbows, olecranon bursae, and the small joints of the hand. Gouty arthritis can occur in distal interphalangeal joints already involved with OA

FIGURE 34.10 Tophaceous gout affecting the DIP joint.

and Heberden's nodes[82] (Figs. 34.10 and 34.11). Gout can be overlooked in these joints because acute inflammation can also occur with Heberden's nodes. Gouty arthritis of intervertebral joints, sacroiliac joints, and shoulders and hips is uncommon.

The typical attack of gout comes on acutely, often during the early hours of morning. Attacks also occur after surgery. Pain and swelling reach a peak within 24 hours. The joint is exquisitely tender, and overlying soft tissue is swollen and erythematous even to the degree that it could be mistaken for cellulitis. Pain is intense and throbbing. Patients are unable to tolerate even a light sheet touching the involved great toe. Jarring of the bed can make the patient wince with pain. The patient might even dread the landing of a fly on the involved toe. Both a low-grade fever and leukocytosis can accompany the attack, especially in polyarticular gout. An untreated attack of gout usually lasts for 1 to 2 weeks. Less severe attacks also occur that last only a few days.

Chronic tophaceous gout develops in some patients. Before the effective control of hyperuricemia, approximately one-half of the patients with episodes of gouty arthritis eventually developed deposits of monosodium urate dihydrate in and around joints as well as in other tissues. These deposits, referred to as *tophi*, usually become apparent at least 10 years after the onset of gouty arthritis. They develop in the olecranon, infrapatellar and prepatellar bursae, Achilles tendons, synovium, subchondral bone, and, infrequently, in the cartilage of the ear. Tophi can ulcerate and drain material that contains microscopic needle-shaped crystals of monosodium urate. Patients with tophaceous gout have frequent episodes of acute gouty arthritis. Joint deformity and disability can be quite severe in the untreated patient.

FIGURE 34.11 X-ray of same patient with tophaceous gout. Note erosions in the middle phalanx of the index finger caused by gout.

Significant renal disease secondary to gouty nephropathy is rare. Proteinuria, decreased concentrating capacity, and a decrease in creatinine clearance might be present. Small deposits of urate are observed in the interstitium of the renal medulla. Nephrosclerosis and hypertension are frequently associated with gout.

Treatment of patients with underlying myeloproliferative or lymphoproliferative disorders results in extremely high levels of serum urate that can precipitate in the renal tubules, producing obstruction and oliguria. Patients should be treated with allopurinol and colchicine before treatment of the blood dyscrasia.

Renal calculi develop in approximately 20% of patients with gout. Hypertension, diabetes mellitus, and hypertriglyceridemia occur more frequently in patients with gout.

Laboratory Findings

Radiography of the affected joint in acute gouty arthritis is usually normal. When the first MTP joint is involved, radiography might show underlying changes of OA. The typical erosion caused by urate deposition is sharply defined and has a thin shell-like overhanging edge at the margins of the erosion. The diagnosis of gout is established by demonstration of the characteristic crystal of monosodium urate monohydrate in the synovial fluid or from tissue deposits. Crystals are found both in the polymorphonuclear white cells and free in fluid. The crystals in joint fluid are usually rod shaped and 7 to 10 μm in length. They are identified by use of polarized microscopy. With use of a first-order red compensator, crystals have a sign of strongly negative birefringence.[83] Crystals from tophi are long and needle-shaped and are not usually found in white cells.

Treatment

Treatment of a patient with gout has two components: treatment of the acute gouty arthritis and treatment of hyperuricemia. Each is treated independently. Even though they are closely interrelated, the drugs used for each are different. In fact, the indiscriminate use of a drug to lower the uric acid can exacerbate or prolong an attack of gouty arthritis.

Anti-inflammatory Drugs. For the acute attack of gouty arthritis, the patient is given indomethacin, 200 mg in four divided doses (50 mg every 6 hours) the first 24 hours, followed by 150 mg every day for 7 to 10 days. Other NSAIDs can also be used. NSAIDs for the treatment of acute gout should be avoided or used with caution in patients with symptomatic heart failure, renal failure, oliguria, or peptic ulcer disease. Glucocorticoids are also quite effective in treatment of acute gout. Prednisone is given over a 7-day period with an initial dose of 40 mg as a single dose and then gradually tapered over a 7-day period. To avoid a flare of arthritis when prednisone is discontinued, the patient is started on 0.6 mg of colchicine or an NSAID beginning on day 3 or 4 of prednisone therapy and continuing for several weeks. Methylprednisolone can be given intravenously to patients unable to take oral medications. The dose schedule for oral prednisone is followed. Intra-articular corticosteroids can also be used to treat gout in a large joint such as the knee.

In patients who experience frequent attacks of acute gouty arthritis, 0.6 mg colchicine once or twice a day is quite effective in preventing attacks. Patients on this prophylactic regimen can abort an acute attack by taking colchicine, 0.6 mg every hour for four to six doses, when they experience the first twinge of joint pain.

Myopathy and polyneuropathy may occur on maintenance doses of colchicine in patients who have renal insufficiency.[84] Myositis manifests as proximal muscle weakness and serum creatine kinase becomes elevated. These abnormalities return to normal 3 to 4 weeks after stopping the drug. Polyneuropathy also disappears on discontinuing colchicine. In addition, agranulocytosis or aplastic anemia can occur in patients with renal insufficiency who are on regular doses of colchicine because the plasma drug levels in these patients greatly increase.

Antihyperuricemic Drugs. Treatment of hyperuricemia in patients with gout is directed at preventing the formation of tophaceous deposits. It is not uniformly agreed that all patients with elevated uric acids and gouty arthritis require medications to lower their uric acid. If the patient already has tophaceous deposits in joints or subcutaneous tissue, then the uric acid should be lowered. On the other hand, an elevated uric acid of less than 10 mg per dL in a patient without tophi or frequent gouty attacks might not require treatment. Whether they have gout or not, persons with uric acid levels above 10 mg per dL are usually treated because of their higher risk of developing gout.

The uric acid concentration can be lowered by probenecid, which is a uricosuric agent.[85] In patients with normal renal function and no renal stones, probenecid is an effective agent. The dose of probenecid is 1 to 3 g per day given twice a day. The urine should be alkalinized to prevent precipitation of urate in the urinary tract. Sulfinpyrazone is another uricosuric drug. The usual daily dose is 300 to 400 mg per day, administered in three or four divided doses.

Serum uric acid level is effectively reduced by allopurinol, which is a potent inhibitor of xanthine oxidase.[85] This drug blocks the conversion of hypoxanthine to xanthine and xanthine to uric acid. This leads to the accumulation of other oxypurines in the blood. The daily dose of allopurinol is 300 to 800 mg per day, which is regulated to reduce uric acid to a concentration below 6 mg per dL. Allopurinol administration can precipitate an acute attack of gout, presumably because of fluctuation of sodium urate between tissue and blood. To prevent an acute gouty attack, allopurinol is started in a low dose and gradually increased. Colchicine, 0.6 mg once or twice a day, is given along with the allopurinol to prevent an acute attack.

The most significant side effect of allopurinol is a rash that occasionally progresses to a severe life-threatening exfoliative dermatitis. Transient leukopenia and abnormalities of liver function are observed in some patients. In patients treated for many years, xanthine stones may occur. These tend to occur in patients who are overproducers and hyperexcretors of uric acid.

Allopurinol is the drug of choice in patients with renal insufficiency who are unable to excrete a uric acid load. This drug is also indicated in patients with uric acid renal calculi. Allopurinol is more effective than probenecid in reducing tophi in patients with severe tophaceous gout. The addition of probenecid, however, further enhances the lowering of serum acid level.

Allopurinol is also indicated in patients with gout who are overproducers and hyperexcretors of urate (urine acid excretion greater than 1000 mg for 24 hours) because these patients are at greater risk for developing renal stones. No clear evidence exists that treatment of asymptomatic hyperuricemia in a person who is not a hyperexcretor is beneficial.

Allopurinol potentiates the action of 6-mercaptopurine and azathioprine. The dose of the cytotoxic agent is usually reduced by at least one-third in patients on allopurinol.

Infectious Arthritis

Nongonococcal Bacterial Arthritis

Acute bacterial or septic arthritis is a serious problem that requires prompt treatment to avoid joint damage.[86,87] Bacteria usually reach the joint by hematogenous spread from a primary infection elsewhere. Often, however, no primary source of infection is found. An infection in the adjacent bone or soft tissue can extend directly into the joint. Acute bacterial arthritis is most often caused by *Neisseria gonorrhea*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Staphylococcus pyogenes*, or *Haemophilus influenzae*, with *Staphylococcus* spp. being the most common causative organisms. Gram-negative organisms include *Escherichia coli*, *Salmonella*, and *Pseudomonas* and are usually seen in patients who are immunosuppressed or use intravenous drugs.

Patients with diabetes mellitus or blood dyscrasias or those receiving glucocorticoids or immunosuppressive drugs are more susceptible to joint infection. Septic arthritis is more likely to occur in joints previously damaged by trauma or inflammatory arthritis. Patients with rheumatoid arthritis in particular have an increased risk of septic arthritis and an increased mortality rate.[88]

Pathophysiology. The synovium is edematous and infiltrated by neutrophils. As the disease progresses, small abscesses are present in the synovium and subchondral bone. Proteolytic enzymes from neutrophils damage the cartilage, bone, and joint capsule. Healing is manifested by proliferation of fibroblasts, which can lead to ankylosis.

Symptoms and Signs. The onset of bacterial arthritis is usually abrupt and associated with severe pain and fever. A shaking chill occasionally accompanies the onset. Any motion of the joint causes excruciating pain. The overlying skin is usually erythematous. In elderly patients and those who are on glucocorticoids, the symptoms can be less severe.

The joint affected most frequently by septic arthritis is the knee, which is involved in at least one-half of the cases. Other commonly involved joints are hips, shoulders, wrists, ankles, elbows, and sternoclavicular and sacroiliac joints. Involvement of the latter two joints has been noted in intravenous drug abusers. In the spine, the intervertebral disc space and adjacent vertebral bodies are infected. Infection in the hip is more difficult to recognize because swelling is less evident. Patients with hip infection might hold the thigh in adduction, flexion, and internal rotation. Pain is felt in the groin or thigh and is also referred to the anterior surface of the knee.

An overlying infected bursa or cellulitis can be mistaken for septic arthritis. It is important in aspirating a joint not to insert the needle through an infected bursa or cellulitis and possibly infect a normal joint.

Laboratory Findings. Joint fluid usually shows increased numbers of neutrophils ranging from 10,000 to greater than 100,000 per cubic millimeter. The white cell count in infected bursa fluid is not as high as observed in the joint. A peripheral blood leukocytosis might also be present. The synovial fluid glucose is usually less than 20% of a simultaneously drawn blood glucose when these two compartments are in equilibrium. Equilibrium is usually reached 6 hours after a meal. In gonococcal arthritis, however, the synovial fluid glucose is not significantly reduced. Gram stain performed on synovial fluid often shows bacteria except in gonococcal infections. Culture results of synovial fluid as well as blood are also often positive.

Radiography of the joint initially shows soft tissue swelling and distension of the joint capsule, followed later by juxta-articular osteoporosis and periosteal elevation. As the process continues, destruction of articular cartilage leads to joint space narrowing followed by bony erosions. Juxta-articular bone destruction might indicate osteomyelitis. In the spine, the initial change consists of narrowing of the disc space and proliferation of bone at vertebral margins. Osteolytic lesions in adjacent vertebrae are seen later. Radioisotope scans can be helpful in identifying infection in certain joints such as the hip, shoulder, spine, and sacroil-

iac joints, but inflammatory arthritides and degenerative joint disease also give a positive scan result.

Treatment. An infected joint requires immediate aspiration and rapid initiation of parenteral antibiotic therapy. It has been reported that joint outcome is best when patients are seen within 7 days of initial symptoms.[89] Joint fluid should be immediately cultured and a Gram stain performed. Vancomycin is the current suggested antibiotic for gram-positive infections (especially where methicillin-resistant *Staphylococcus aureus* [MRSA] infection is common) and generally a third-generation cephalosporin for gram-negative organisms. (The details of antibiotic therapy are beyond the scope of this text.) Antibiotics should be given intravenously for at least the first 2 weeks. A total of 6 weeks of antibiotic therapy is generally indicated but there is little evidenced based data with regard to length of therapy.[90] Antibiotics do not need to be infused into the joint. The joint should be adequately drained to prevent damage. Usually drainage can be accomplished with a large-gauge needle. Drainage reduces intraarticular pressure and removes pus, which is a source of proteolytic enzymes. Repeated aspirations are only necessary during the first few days of treatment. Surgical drainage is required when the joint cannot be adequately aspirated and irrigated by needle or when the cell count in the synovial fluid does not decline in spite of what appears to be adequate drainage. Surgical drainage via arthroscopy should also be considered in patients with underlying arthritis and those with prolonged symptoms (i.e., longer than 7 days).[88] During the first few days of treatment, splinting of the involved joint in extension makes the patient more comfortable and reduces the possibility of a flexion contracture. Daily physical therapy, once the acute process has resolved, improves the range of motion. In a severely damaged joint, bony fusion might be required.

Gonococcal Arthritis

Gonococcal arthritis is a frequent cause of bacterial arthritis in young adults. Women are more susceptible to gonococcal arthritis during menses and pregnancy. Persons who have a homozygous deficiency of complement component C5, C6, C7, or C8 are also susceptible to disseminated neisserial infections.[90] Patients with low complement levels caused by consumption of complement might also be more susceptible to disseminated neisserial infections.

Symptoms and Signs. Patients typically present with fever and migratory arthritis or arthralgias that evolve in several days into monoarticular arthritis. Patients also directly present with monoarticular arthritis. Wrists and knees are common sites of involvement, but any joint can be affected. Arthritis is manifested by swelling, erythema, and severe pain as in other bacterial arthritides. Skin lesions can accompany gonococcal arthritis. These lesions can be pustular, vesicular, or hemorrhagic and can ulcerate.

Laboratory Findings. Joint fluid shows increased numbers of polymorphonuclear white cells, but the white cell count might not be as high as in other bacterial infections. The joint fluid glucose is also not decreased to the low levels found in other bacterial joint infections.

Diagnosis. Gonococcal arthritis is suspected in a patient presenting with fever, typical skin lesions, and polyarthralgias or arthritis that evolves into monoarticular arthritis. Diagnosis is confirmed by positive culture results from synovial fluid or from blood, but culture results from these sites are positive in fewer than 50% of cases. Cultures from skin lesions are also usually negative. Gram stain or culture results from cervix, urethra, or rectum might be positive when joint, skin, and blood culture results are negative.

Treatment. The patient should be admitted to the hospital and receive parenteral antibiotics. Currently, the recommendation is to start a third-generation cephalosporin such as ceftriaxone since penicillin resistant strains are now widespread. The dose of ceftriaxone is 1 gram IV every 24 hours for 3 to 7 days. Most patients can be converted to oral antibiotic therapy in 48 hours. The patient is placed at bed rest for the first 2 days. Splinting of the affected joint provides pain relief. The infected joint should be immediately aspirated. The frequency of aspirations depends on the degree of inflammation. In most patients residual joint damage does not occur.

Polymyalgia Rheumatica

Polymyalgia rheumatica (PMR) is an inflammatory disease affecting people over the age of 50 years and typically those of Northern European ethnic background. Patients can generally remember the day or the week the symptoms began and the symptoms include marked stiffness of the shoulders and hip girdle regions, fatigue, and low-grade fever.[91] About 15% to 20% of patients may have joint swelling involving the wrists, finger joints, or the knees. Another feature that might be clue to PMR is a senior patient with bilateral "rotator cuff tendonitis." Patients my have rotator cuff signs and symptoms but it is unusual to have bilateral rotator cuff tendonitis. PMR is a synovitis and the tenosynovitis around the shoulder may lead to rotator cuff symptoms and signs. The general stiffness is often profound and a patient will describe significant difficulty getting out of bed. Patients will relate that they had to roll out of bed in order to get up. A related illness, giant cell arteritis (GCA), can present with manifestations of PMR but also includes headache and may include visual changes, jaw pain with chewing, and more pronounced systemic symptoms. It is important to recognize the difference between isolated PMR versus PMR plus GCA. If GCA is untreated it may lead to permanent visual loss in up to 50% or stroke in up to 10% of patients.

The laboratory hallmark of PMR is a markedly elevated ESR or CRP. A few patients (10% to 15%) may have normal levels and still have PMR, so the history is the key as well and the response to prednisone. Patients can also have mild anemia typical of other inflammatory diseases.

Treatment is, and has been for almost 50 years, prednisone. If suspected, an initial dose of 15 to 20 mg is sufficient in most patients with PMR, especially if a small portion is given in the evening. The initial dose is maintained for 4 to 6 weeks then slowly tapered. One taper regimen is to reduce the prednisone by 1 mg a week to 10 mg, 1 mg every 2 weeks to 5 mg, then 1 mg every month to 0 but there may be many small ups and downs on the prednisone dose. It must be recognized that the average length of disease duration is 24 months. If GCA is suspected, start the patients on high dose prednisone (40–60 mg per day) and refer to a rheumatologist. The patient will need to have temporal artery biopsy scheduled as soon as possible and may need additional therapy.

CHAPTER 35 ■ MYOFASCIAL PAIN SYNDROME

JAN DOMMERHOLT AND JAY P. SHAH

INTRODUCTION TO MYOFASCIAL PAIN SYNDROME

Muscle pain is a common manifestation of many chronic pain conditions and is described as a diffuse, difficult to pinpoint, aching pain that may refer to deep somatic structures.[1,2] Muscle pain is common in all age groups, but chronic muscle pain is more frequent in the elderly than in younger populations.[3,4] Kellgren[5] was one of the first researchers to explore the diffuse nature of muscle pain and particular-referred pain patterns. Muscle-referred pain involves nociceptive specific neurons in the spinal cord and in the brainstem.[6,7] Wall and Woolf[8] have shown that muscle nociceptive afferents are especially effective in inducing neuroplastic changes in the spinal dorsal horn. Muscle pain activates specific cortical structures, such as the anterior cingulate gyrus, which is also involved in the emotional, affective component of pain.[9–11] Muscle pain is inhibited strongly by descending pain-modulating pathways, and, under normal circumstances, there is a dynamic balance between the degree of activation of dorsal horn neurons and the descending inhibitory systems.[12] Prolonged input from muscle nociceptors can be misinterpreted in the central nervous system and eventually can lead to allodynia and hyperalgesia and an expansion of receptive fields.[13]

Although muscle pain is very common, there is considerable controversy regarding the nature and relevance of muscle pain. Some clinicians consider muscle pain to be a secondary phenomenon to other diagnoses, such as tendonitis, muscle strain, inflammation, degeneration, or injuries to joints and nerves.[14] Gunn has proposed that all muscle pain (or more precisely, all myofascial pain) is the result of peripheral neuropathy, defined by Gunn as "a condition that causes disordered function in the peripheral nerve."[15] Gunn's model is based on Cannon and Rosenblueth's Law of Denervation, which states that the function and integrity of innervated structures is dependent on the free flow of nerve impulses.[16] When the flow of impulses is restricted, all innervated structures, including muscles, would become atrophic, highly irritable, and supersensitive.[15] In spite of a few early scientific outcome studies and numerous case reports, there are no studies that support the notion that myofascial pain is indeed always indicative of neuropathic pain. Gunn's model was never developed beyond the hypothetical stage, although he has denied that his approach is even based on a hypothetical model.[17] According to Gunn, his model is a "description of clinical findings that can be found by anyone who examines a patient for radiculopathy."[17]

Another example of muscle pain is the delayed onset of muscle soreness after eccentric exercise[18] which typically resolves in a few days and is generally of little concern to clinicians. Others view persistent muscle pain primarily as a manifestation of a presumed somatoform disorder.[19] With the development of orthopedic and manual medicine, physicians, chiropractors, and physical therapists directed their attention mostly to articular dysfunction, although early manual medicine pioneers Drs. James Cyriax and John Mennell did include muscle dysfunction in their thinking.[20–22] In this context, it is noteworthy that, although skeletal muscle comprises nearly half of the body's weight, it is the only organ in the human body that is not linked to a particular medical specialty. This has led Simons to suggest that muscle is an orphan organ, as further evidenced by the fact that muscle research and the development of a knowledge base of muscle-specific ailments, pathophysiology, and diagnostic and treatment options have not evolved until fairly recently.[23] The literature on myofascial pain is scattered among the literature of many different disciplines. One could wonder why persistent muscle pain and dysfunction have largely been ignored by the medical professions, but such contemplations are outside the scope of this chapter.

BRIEF HISTORICAL OVERVIEW

Over the past centuries, several articles and books have been published about muscle pain and dysfunction.[24,25] For example, in the 16th century, French physician Guillaume de Baillou (1538–1616) described specific muscle pain syndromes. In 1816, British physician Balfour reported observing muscles with "nodular tumors and thickenings which were painful to the touch, and from which pains shot to neighboring parts."[26] Muscle pain has been described by many different terms, including fibrositis, interstitial myofibrositis, myogeloses, nonarticular rheumatism, myofascial pain, idiopathic myalgia, myofasciitis, perineuritis, myodysneuria, and fibromyalgia. The publications by Kellgren, describing referred pain patterns from muscles and other soft

tissues, strongly influenced physicians James Cyriax in England and Janet Travell in the United States. In 1942, Cyriax published his book *Massage, Manipulation and Local Anaesthesia* in which he devoted much attention to referred pain phenomena. Cyriax advocated treating nodules and taut bands of abnormal muscle tissue with deep friction massage.[27] Cyriax was very influential, and his work became a major aspect of modern manual medicine and manual therapy practice.[28]

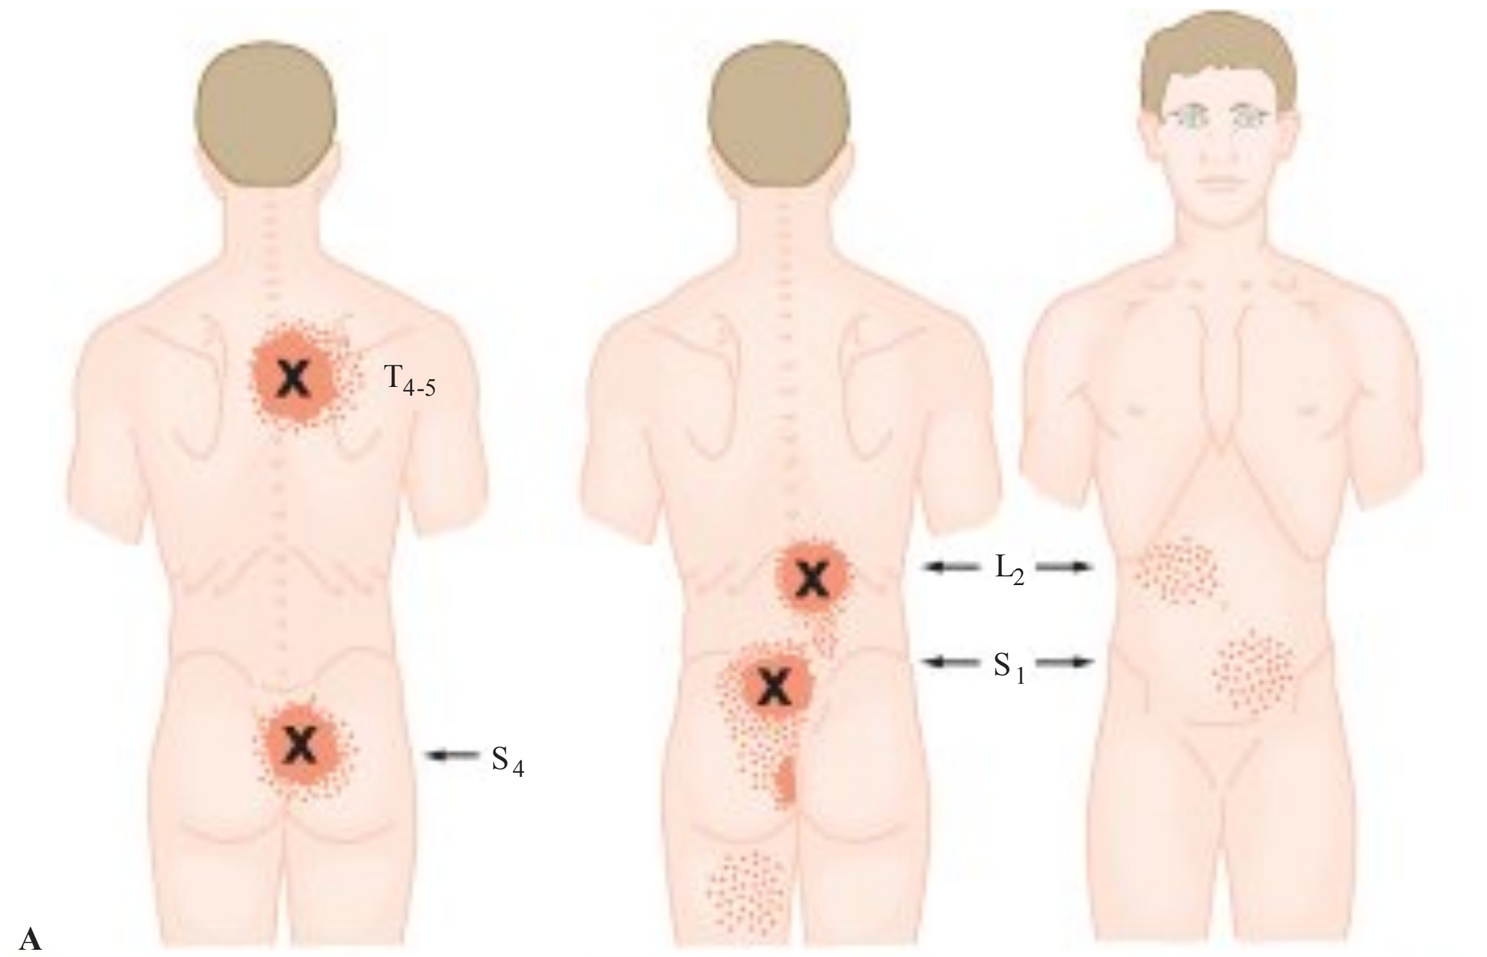
At the time of Kellgren's first publications, Travell was a cardiologist and researcher. Initially, she was mostly interested in the applicability of Kellgren's findings to cardiac pain, but she quickly became interested in musculoskeletal medicine.[29] In 1942, she coauthored the first of many articles about the diagnosis and treatment of muscle pain.[30] In 1952, Travell and Rinzler published an article of observed pain referral patterns of 32 muscles (Fig. 35.1).[31]

At that time, there was virtually no research on muscle pain, and many of Travell's writings were based on her empirical observations and ability to establish clinical correlations. For example, Travell and Rinzler observed that the fascia generated similar referred pain patterns as the contractile elements of the muscle; she subsequently modified her terminology to "myofascial pain" to encompass both the fibrous and contractile aspects.[31] Interestingly, the similarities between referred pain patterns of fascia and muscle and the mechanical relationships between fascia and muscle were not further investigated until only a few years ago.[32]

Travell's work eventually culminated in the publication of a two-volume textbook on myofascial pain, which she coauthored with Dr. David Simons.[33,34] These books became known as the Trigger Point Manuals and they have been translated in multiple languages. The term "trigger point" was introduced by Steindler in 1940 in a paper on muscle pain.[35] Travell and Rinzler introduced the terms "myofascial trigger point" and "myofascial pain syndrome,"[31] which are now intricately linked to a particular theoretical model, referred to as the "integrated trigger point hypothesis."[36] The terms "muscle pain" and "myofascial pain" are sometimes used interchangeably; however, "muscle pain" is really a descriptive term while "myofascial pain," as introduced by Travell, is much more specific.[37]

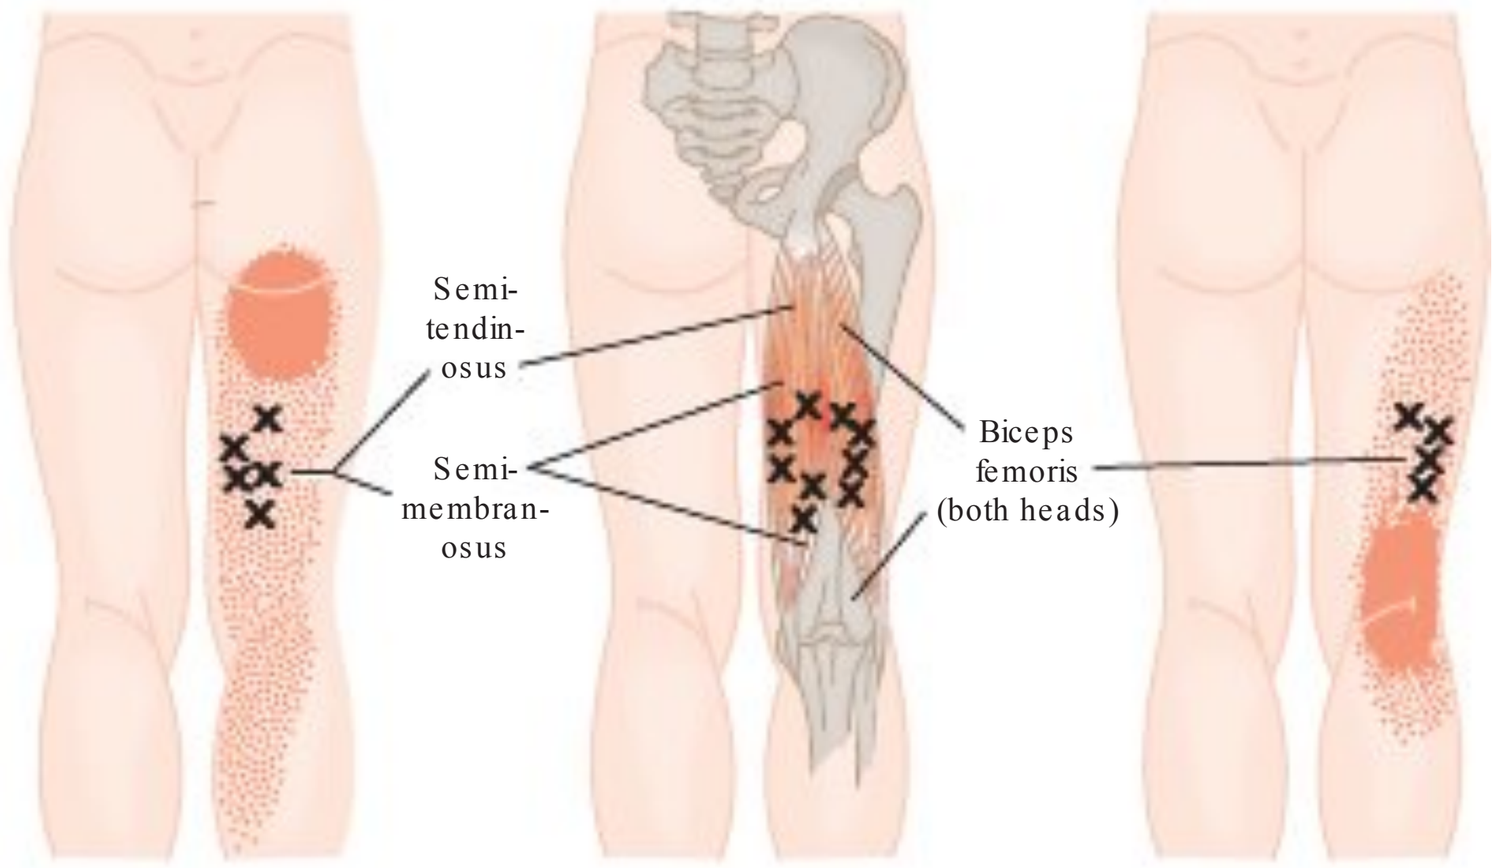
Travell's concepts of myofascial pain did not gain wide acceptance in the manual medicine world and are not uniformly accepted even today. She is rarely mentioned in the manual medicine literature and is mostly remembered for blocking the profession of physical therapy from membership into the North American Academy of Manipulative Medicine, an organization she founded in 1966 with Mennell.[28] Travell did gain some recognition in the pain management world, however. A growing number of pain management clinicians and researchers are integrating Travell's model in their practices and laboratories. A survey of physician members of the American Pain Society showed overwhelming agreement that myofascial pain is a distinct clinical entity.[38] A second edition of Volume 1 of the Trigger Point Manual was published in 1999.[39]

In 1981, Simons and Travell developed a hypothetical model explaining the phenomena they observed. This model became known as the "energy crisis hypothesis."[40] The energy crisis hypothesis postulates that direct trauma and subsequent damage to the sarcoplasmic reticulum or the muscle cell membrane leads to an increase in calcium (Ca^{2+}) concentration, increased activation of actin and myosin, a relative shortage of adenosine triphosphate (ATP), and an impaired calcium pump, which in turn would increase the intracellular calcium concentration even more, completing the cycle.[40] Under normal physiological conditions, the calcium pump is responsible for returning intracellular Ca^{2+} to the sarcoplasmic reticulum against a concentration gradient, which requires a functional energy supply. In 1999, the energy crisis hypothesis was integrated into the integrated trigger point hypothesis.[39] In turn, several recent publications have expanded the integrated trigger point hypothesis based on electrodiagnostic, histopathological studies, and other related fields.[36,41–44] This chapter provides an updated review of the etiology, mechanisms, pathophysiology, and clinical implications of myofascial trigger points, including the integrated trigger point hypothesis.



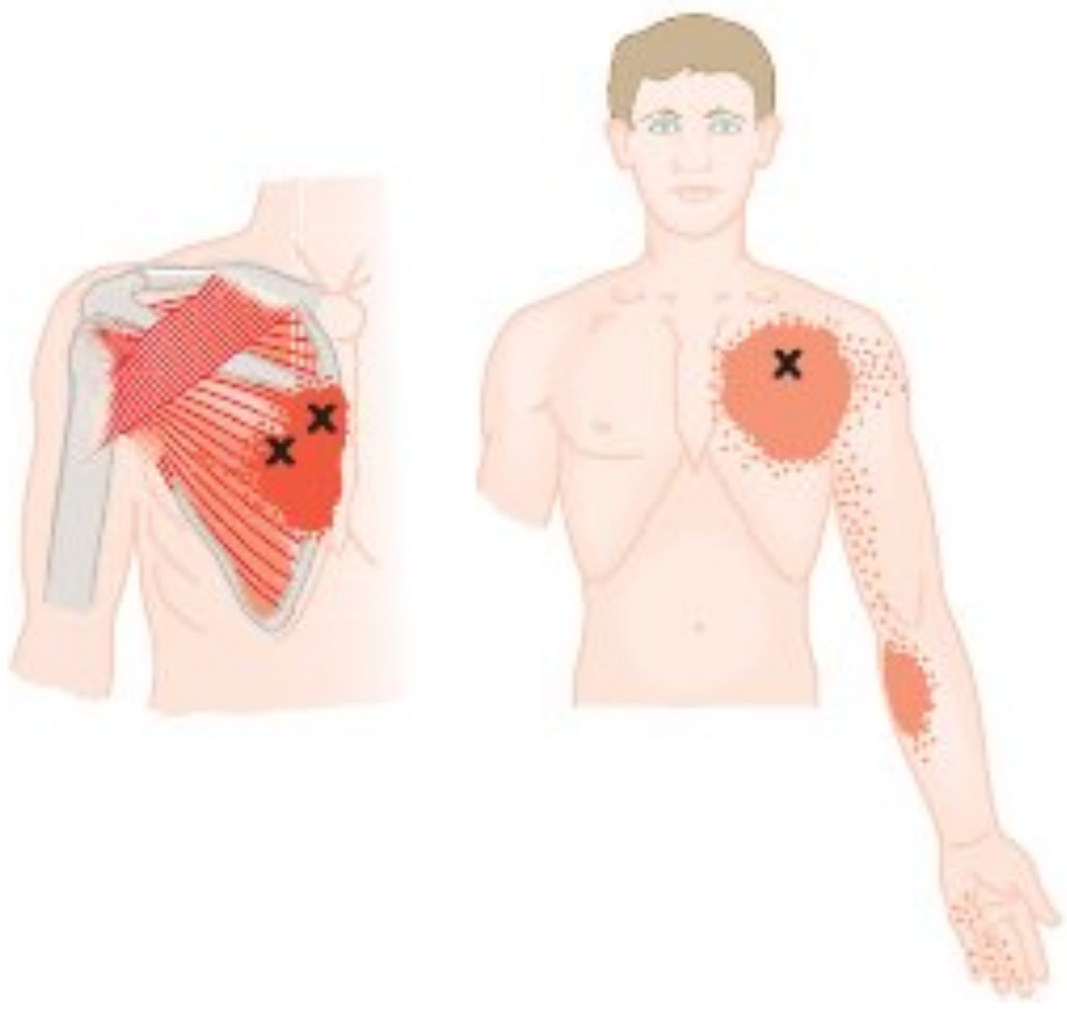
BASIC MYOFASCIAL PAIN CONCEPTS

During the past decade, research in the etiology, epidemiology, pathophysiology, diagnosis, and clinical management of myofascial pain has grown exponentially. Although the integrated trigger point hypothesis is not a perfect theoretical concept, it is the most comprehensive evidence-informed model currently available to explain the role of muscle tissue in acute and persistent pain conditions.[36] Researchers around the world are conducting basic trigger point research, prevalence studies, and clinical outcome studies. Their findings show that trigger points are associated with virtually all painful musculoskeletal problems, including migraines, tension-type headaches, craniomandibular dysfunction, epicondylalgia, low back pain, postlaminectomy syndrome, neck pain, disc pathology, carpal tunnel syndrome, osteoarthritis, radiculopathies, whiplash-associated disorders, fibromyalgia, postherpetic neuralgia, complex regional pain syndrome, etc.[41] Trigger points have also been associated with visceral dysfunction, including endometriosis, interstitial cystitis, irritable bowel syndrome, urinary/renal and gallbladder calculosis, dysmenorrhea, and prostadynia.[45–51] Although trigger points are reportedly the most common diagnosis responsible for chronic pain and disability, they are frequently overlooked in the clinic.[52] Trigger points have been reported in all age groups except infants.[3,39,53–56]



A trigger point is described as "a hyperirritable spot in skeletal muscle that is associated with a hypersensitive palpable nodule in a taut band."[39] By definition, trigger points are located within a taut band of contractured muscle fibers. Palpating for trigger points begins with identifying this taut band by palpating perpendicular to the fiber direction (Fig. 35.2).

Two recent studies confirmed the existence of taut bands using magnetic resonance elastography (MRE).[57,58] Taut bands are stiffer than relaxed muscle fibers, and the degree of stiffness can be assessed by phase-contrast analysis of vibration-induced cyclic shear waves.[57–60] Sikdar et al.[61] demonstrated that myofascial trigger points can be visualized using diagnostic ultrasound and sonoelastography. Myofascial trigger points are hypoechoic on two-dimensional ultrasound and appear stiffer than the surrounding muscle on vibration sonoelastography. An active trigger point produces symptoms, including local tenderness and pain, referral of pain or other paresthesia to a distant site, and peripheral and central sensitization. A latent trigger point is only painful when stimulated. Trigger points have characteristic motor, sensory, and autonomic features. Motor phenomena associated with trigger points include disturbed motor function, muscle weakness as a result of motor inhibition, muscle stiffness, and restricted range of motion. Nociceptive input can perpetuate altered motor control strategies and lead to muscle overload or disuse.[62,63] Lucas et al.[64] demonstrated that subjects with latent trigger points in several shoulder muscles featured altered shoulder abduction patterns when compared to healthy subjects. Autonomic aspects may include, among others, vasoconstriction, vasodilatation, lacrimation, and piloerection.[65]



To discuss the current research and the clinical implications of myofascial trigger points and the integrated trigger point hypothesis, a brief review of muscle physiology, the role of the motor endplate, muscle pain, dorsal horn, and central sensitization will be provided in the context of myofascial trigger points. The motor phenomena of trigger points are best explained by

A

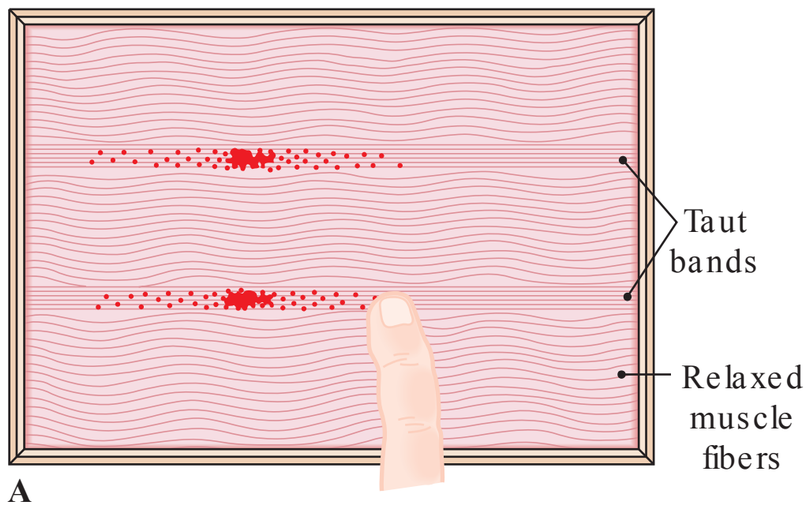

FIGURE 35.2 Palpation of trigger points. As the palpating finger of the examiner moves from normal areas of muscle (**A**) and encounters a painful trigger point (**B**), a local twitch response often occurs within the muscle surrounding the trigger point. (Redrawn after Simons DG, Travell JG, Simons LS. *Travell and Simons' Myofascial Pain and Dysfunction; The Trigger Point Manual*. 2nd ed. Baltimore: Lippincott Williams & Wilkins; 1999.)

understanding the functions and structure of the motor endplate and the sarcomere assembly.

MUSCLE PHYSIOLOGY

Skeletal muscles consist of groups of fascicles, which are made of muscle fibers and myofibrils, accountable for contraction and relaxation of the fiber. The myofibril is approximately 1 to 2 μm in diameter and is separated from surrounding myofibrils by the mitochondria, the sarcoplasmic reticulum, and the transverse tubular systems (T-tubules).

The T-tubules lie perpendicular to the long axis of the muscle fiber with two zones of transverse tubules to each sarcomere via the so-called dihydropyridine and ryanodine receptors. The main function of the T-tubules is to conduct impulses from the exterior to the interior of the muscle fiber with the release of Ca^{2+} from the sarcoplasmic reticulum, which is a store for the release and uptake of Ca^{2+}. Calcium is a prerequisite for muscle contractions. Muscle contractions occur after actin and troponin are activated by Ca^{2+}, allowing tropomyosin to shift its position and expose myosin-binding sites on actin, thus regulating the cross-bridge interactions between actin and myosin.[66] Myofibrils show a striated patterning when viewed under longitudinal electron micrograph scanning, which reflects the organization of thin actin and thicker myosin filaments. In addition to actin and myosin, there are several other important proteins, such as titin, nebulin, desmin, tropomyosin, troponin, and tropomodulin, among others, which together maintain the architecture and stability of the sarcomere (Fig. 35.3).[67–69]

Titin is the largest known vertebrate protein; it connects the Z-line with myosin filaments with cross-links from titin molecules of adjacent sarcomeres. Titin positions the myosin filaments at the center of the sarcomere as a spring.[70,71] One particular section of titin, the so-called PEVK domain or segment, is able to interact with actin filaments in close proximity to the Z-line, which may limit the degree of sarcomere contraction as the tip of the myosin filament may literally bounce back against a "viscous bumper" of the actin-titin interaction, similar to a dragnet.[72,73] Titin filaments are responsible for passive tension generation when sarcomeres are stretched, and provide muscle stiffness by virtue of its spring mechanism in the I-band. During sarcomere contractions, titin filaments are folded into a sticky gel-like structure at the Z-line.[68,70,71,74] Myofascial trigger points are thought to have a damaged sarcomere assembly; myosin filaments may have broken the actin-titin barrier and have literally gotten stuck in the sticky titin substance at the Z-line.[75]

Single molecules of nebulin span the full length of the actin filaments, and it is thought that nebulin actually dictates the architecture of actin with direct involvement of titin and the Z-line protein myopalladin.[76] Titin and nebulin interact at many levels, especially during myofibrillogenesis.[77] Nebulin connects to the proteins myopalladin and desmin in the Z-line.[78] Myopalladin binds to α-actinin, which in turn connects to actin and to titin.[78] Desmin filaments link adjacent Z-lines and interconnect the myofibrils with the sarcolemma, the nuclei, the T-tubules, the mito-

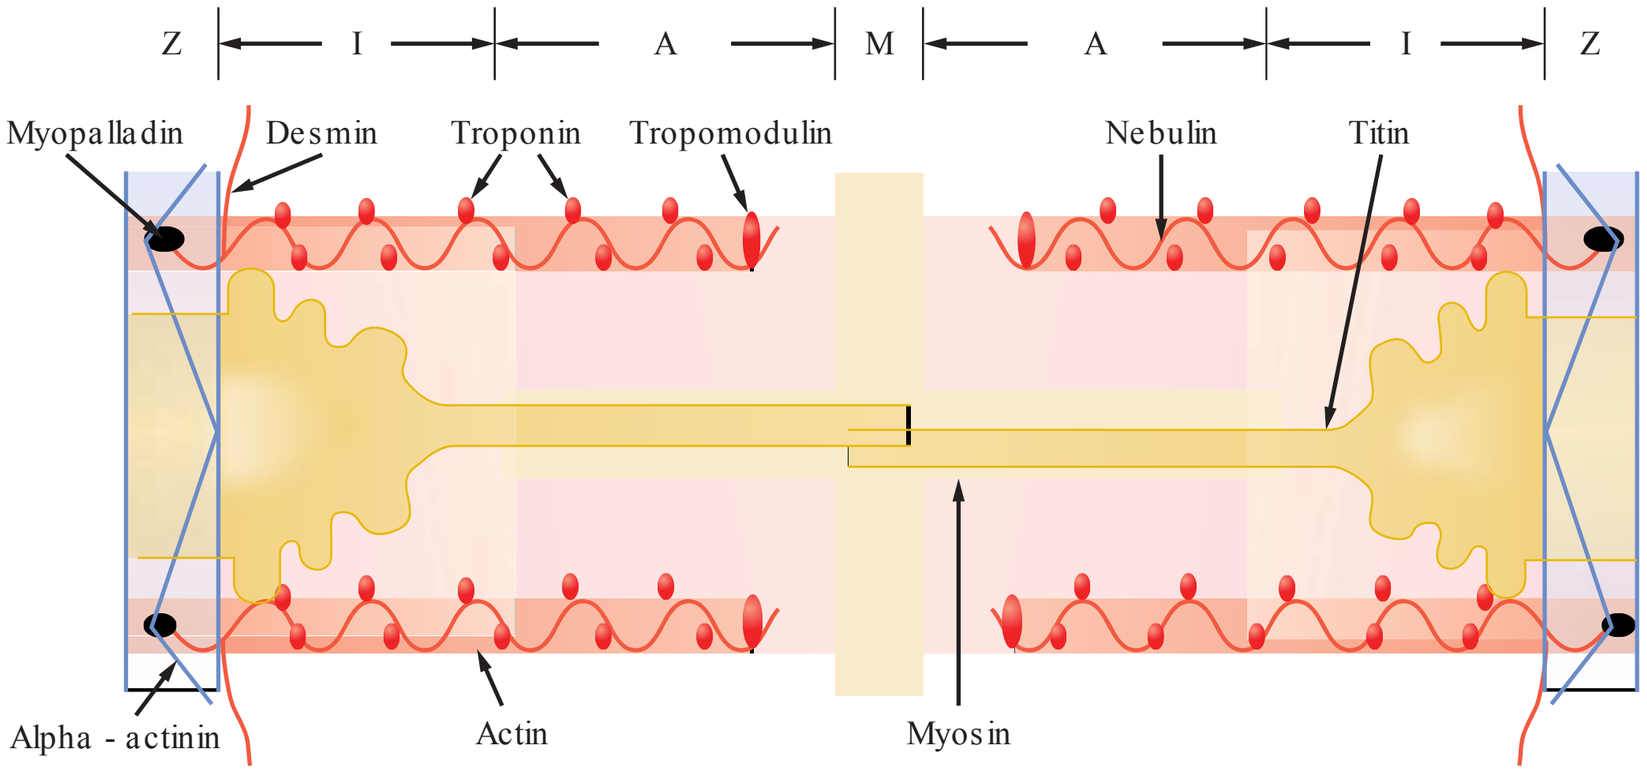

FIGURE 35.3 Sarcomere.

chondria, and possibly the microtubules.[66,79] Nebulin acts as a stabilizing structure through its specific binding sites at different places at actin, but also at tropomyosin, troponin, and tropomodulin.[66,77,80,81] Nebulin regulates muscle contractions by inhibiting the cross-bridge formation until actin is activated by Ca^{2+}.[77]

A key feature of the integrated trigger point hypothesis is the presence of excessive acetylcholine (ACh) at the neuromuscular junction, which stimulates voltage-gated sodium channels of the sarcoplasmic reticulum and continuously increases intracellular Ca^{2+} levels. This results in ongoing activation of nebulin, troponin, and tropomyosin, and causes persistent muscle contractures consistent with myofascial trigger points. The role of the neuromuscular junction or motor endplate will be reviewed in the next section.

THE MOTOR ENDPLATE

The terms neuromuscular junction and motor endplate are used interchangeably, although technically, the neuromuscular junction refers to function, while the motor endplate refers to structure.[43] A motor endplate is the synapse between the terminal ends of motor neurons and skeletal muscle. The terminal branches of a single motor neuron terminate in multiple presynaptic boutons, which each contain many ACh vesicles.[82]

When nerve impulses from an α-motor neuron reach the motor nerve terminal, voltage-gated sodium (Na^+) channels are opened, which trigger a Na^+ influx that depolarizes the terminal membrane. Voltage-gated Ca^{2+} channels are opened, which causes an influx of Ca^{2+} and a quantal release of ACh and other molecules, such as ATP, from the nerve terminal into the synaptic cleft (Fig. 35.4). When two ACh molecules bind to a nicotinic ACh receptor (nAChR) across the synaptic cleft, the nAChR opens a cation-specific pore, which facilitates a Na^+ influx and a potassium (K^+) efflux across the muscle cell membrane. Each single quantum of ACh will depolarize the postsynaptic cell and trigger a miniature endplate potential (MEPP). A sufficient number of MEPP's will produce a depolarization and an action potential, which travels along the T-tubules, triggers the ryanodine receptor in the sarcoplasmic reticulum, and causes a release of Ca^{2+} from the sarcoplasmic reticulum.

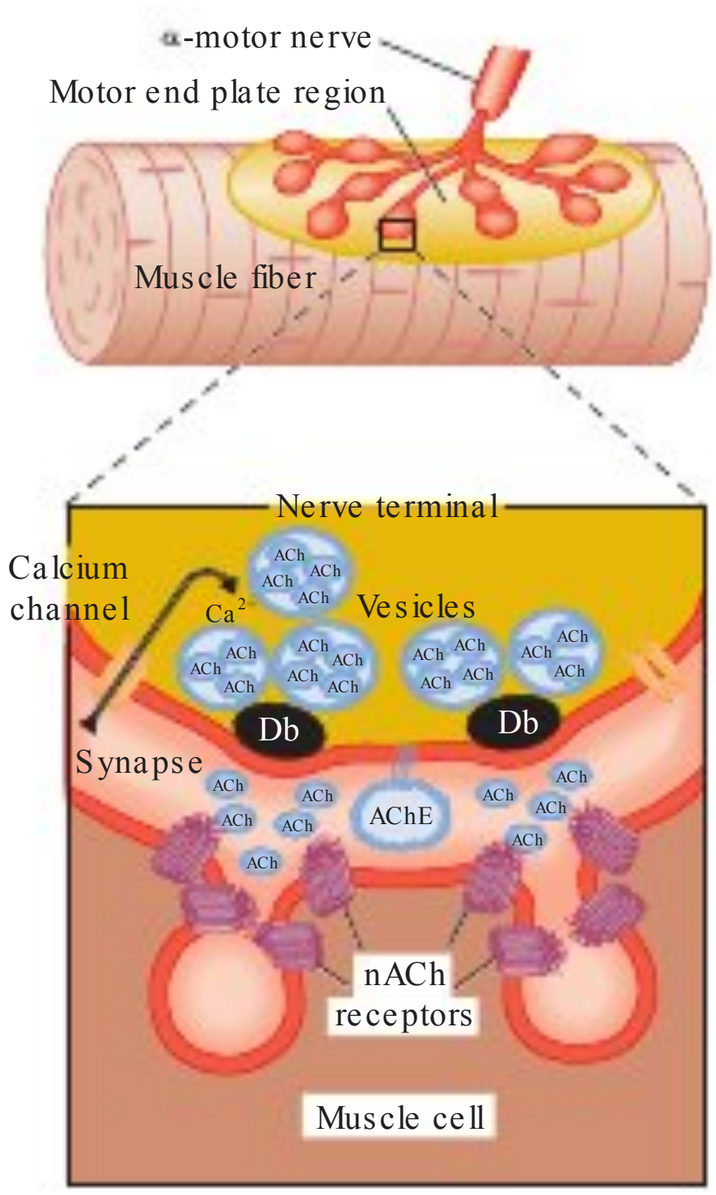

FIGURE 35.4 The motor endplate.

As stated, the release of Ca^{2+} triggers tropomyosin to shift its position and nebulin to allow cross-bridges to form between the actin and myosin filaments, resulting in a muscle contraction. The K^+ efflux restores the resting membrane potential. During the brief period before the actual muscle contraction, ACh is hydrolyzed by the enzyme acetylcholinesterase (AChE) into acetate and choline. Choline is reabsorbed into the nerve terminal, where it is synthesized into ACh by acetyltransferase by combining choline and acetyl coenzyme A from the mitochondria. ACh release is not only activated by motor nerve stimulation, but it is also modulated by the concentration of AChE. Inhibition of AChE will cause an accumulation of ACh in the synaptic cleft, which may stimulate motor nerve endings and tonically activate nAChRs.

A 1993 publication illustrating spontaneous electrical activity in myofascial trigger points initiated a new line of research into the role of motor endplates.[83] Initially, the electrical activity was assumed to be the result of dysfunctional muscle spindles, but soon multiple human, rabbit, and even equine studies confirmed that the activity was in fact abnormal endplate noise, related to an excess of ACh at the motor endplate.[36,84–91] Wang and Yu[75] postulated that in myofascial trigger points, the contractures resulting from excessive ACh may cause myosin filaments to get stuck in sticky titin gel at the Z-line, thereby damaging the sarcomere assembly. The persistent contractures will compromise local blood vessels, reducing the local oxygen supply, which will result in hypoxia, a lowered pH, and hypoperfusion, which all contribute to muscle pain and dysfunction.[92] There is evidence that the oxygen saturation in myofascial trigger points is far below normal values.[93]

The reduced oxygen levels in myofascial trigger points and an increased metabolic demand result in a local energy shortage and a local shortage of ATP.[44] Under normal physiologic circumstances, presynaptic ATP inhibits the release of ACh. Inversely, a decrease in ATP leads to an increased ACh release. Insufficient postsynaptic ATP results in a failure of the calcium pump, increased levels of Ca^{2+}, and a Ca^{2+}-induced Ca^{2+} release. An increase in the Ca^{2+} concentration will reinforce muscle contractures. The local energy crisis is likely related to the finding of abnormal mitochondria in the nerve terminal and ragged red fibers, which are an indication of structural damage to the cell membrane and the mitochondria.[94]

The presence of excessive ACh can be the result of AChE insufficiency, an acidic pH, hypoxia, a lack of ATP, certain genetic mutations, drugs and particular chemicals, such as calcitonin-gene related peptide (CGRP), di-isopropylfluorophosphate, or organophosphate pesticides, and increased sensitivity of the nAChRs.[42,44,95] Myofascial tension or muscle hypertonicity, as seen in trigger points, may also enhance the excessive release of ACh.[96,97] There are many possible vicious cycles capable of maintaining the resulting contractures and trigger points. For example, hypoxia leads to an acidic milieu, muscle damage, and an excessive local release of multiple nociceptive substances, including CGRP, bradykinin (BK), and substance P (SP).[98] Hypoxia may even trigger an immediate increased ACh release at the motor endplate.[95] CGRP stimulates the release of ACh from the motor endplate, decreases the effectiveness of AChE, and upregulates the nAChR. An acidic pH enhances the release of calcitonin gene-related peptide and down-regulates AChE and causes hyperalgesia.[42,99,100]

There are many similarities between the mechanisms and consequences of myofascial trigger points and eccentric loading or eccentric exercise. Eccentric training or exposure is frequently characterized by a certain degree of cytoskeletal muscle damage.

Even very short bouts of eccentric exercise can result in a disorganization of the A-band, streaming of the Z-line, and a disruption of several cytoskeletal proteins, including titin, nebulin, vimentin, fibronectin, and desmin.[101–106] By comparison, postmortem histological studies of myofascial trigger points showed pathologic alterations of the mitochondria, as well as an increased width of A-bands and decreased width of I-bands in muscle sarcomeres of trigger points in 102 biopsies of the trapezius, gluteus medius, and gluteus maximus muscles. The samples were taken in a time period of 4–48 hours following death.[107,108] A biopsy study of trigger points in a dog gracilis muscle revealed a similar pattern of severely shortened sarcomeres in the center and lengthened sarcomeres outside the immediate trigger point region.[109] The diagnosis of trigger points in animals is basically the same as in human subjects. While an animal cannot verbalize recognition of pain, skilled palpation combined with an analysis of dysfunctional movement patterns will direct the investigator or clinician to clinically relevant trigger points.

There are other similarities between eccentric loading and myofascial trigger points, such as hypoxia, an impaired local circulation, and local and referred pain. Gerwin, Dommerholt, and Shah[42] suggested that eccentric contractions in unconditioned muscle or unaccustomed eccentric contractions are likely sources of myofascial trigger point development, which was confirmed by Itoh et al.[110] who demonstrated that eccentric exercise facilitated the formation of taut bands and myofascial trigger points in exercised muscle.

Yet, there are other possible causes of trigger points. Patients commonly report an onset of pain associated with trigger points following either acute, repetitive, prolonged, or chronic muscle overload. Piano students developed significantly decreased pressure thresholds over latent trigger points after only 20 minutes of continuous piano playing.[111] Computer operators developed trigger points after as little as 30 minutes of continuous typing.[112] In other words, low-level muscle contractions can contribute to the development of trigger points, which is best explained by the so-called Cinderella hypothesis.[113] According to the Cinderella hypothesis, low-level muscle contractions follow stereotypical patterns, where smaller motor units are recruited before and derecruited after larger motor units, which means that smaller type 1 fibers may be continuously activated during prolonged low-level contractions.[114,115] Low-level contractions have been shown to lead to muscle fiber degeneration, an increase in Ca^{2+} release, energy depletion, and the release of various cytokines, which all have been associated with the formation of trigger points.[116–119] During low-level contractions, the intramuscular pressure increases considerably especially near the muscle insertions, which may impair the local circulation, cause hypoxia, and eventually lead to trigger point formation.[41,120] As noted, motor phenomena associated with trigger points include disturbed motor function, muscle weakness as a result of motor inhibition, muscle stiffness, and restricted range of motion.

SENSITIZATION AND ACTIVATION OF MUSCLE NOCICEPTORS

To better understand the sensory aspects of myofascial trigger points, including local and referred tenderness, pain, and other paresthesia, as well as peripheral and central sensitization, a brief review of the current understanding of muscle nociceptors, spinal cord mechanisms, and sensitization is indicated.

Muscle nociceptors are dynamic structures that can be activated mechanically by deforming the axonal membrane of the nerve ending, as for example, following a blow to a muscle. They are also very susceptible to chemical activation by pain producing substances released from the surrounding tissues and immune cells.[121] Matched receptors at the nociceptor exist for a variety of substances including BK, prostaglandins (PG), serotonin (5-HT), protons (H^+), ATP, glutamate, and others, including the so-called purinergic and vanilloid receptors. Purinergic receptors bind ATP and stimulate nociceptors accordingly. Vanilloid receptors are especially sensitive under conditions of lowered tissue pH and muscle ischemia. Pain during tension-type headaches, tooth clenching, and bruxism is mediated by the vanilloid receptor molecule.[121] BK, 5-HT, and PG interact at many levels at the vanilloid receptors.[122] A combination of substances may have a synergistic effect in terms of local muscle pain production. For example, when injected together into the temporalis muscle of normal volunteers, BK, and 5-HT produce more pain than when each stimulant is injected alone.[123]

Moreover, the mechanism of chemical activation is of clinically greater interest, especially in evaluating chronic pain states where there often is little gross swelling evident. Endogenous substances such as BK, PG, and 5-HT are not only very effective at sensitizing or activating muscle nociceptors, but also cause local vasodilation. Therefore, the release of these substances can also lead to mechanoreceptor activation by distorting the normal tissue relationships. A sensitized muscle nociceptor has a lowered stimulation threshold into the innocuous range, such that it will respond to harmless stimuli like light pressure and muscle movement.[124]

The nociceptor terminals contain neuropeptides, such as SP and CGRP. When these substances are released, they stimulate local vasodilation, plasma extravasation, and liberation of sensitizing substances from the surrounding tissue. The effects of these neuropeptides are integral to the nociceptive response. Upon activation by a noxious stimulus, the nociceptor releases the stored neuropeptides, which directly influence the local microcirculation by stimulating vasodilation and increasing the permeability of the microvasculature.[125,126] More importantly, the secretion of the neuropeptides in sufficient quantity leads to a cascade of events, including the release of histamine from mast cells, BK from kallidin, 5-HT from platelets, and PGs from endothelial cells.[127] The cumulative effect is the increased production and release of sensitized substances in a localized region of edema in the muscle tissue. Therefore, the muscle nociceptor is not merely a passive structure designed to record potentially noxious stimuli. Rather, muscle nociceptors play an active role in the maintenance of normal tissue homeostasis by sensing the peripheral biochemical milieu and by mediating the vascular supply to peripheral tissue. With tissue injury, the secretion of SP and CGRP increases, leading to the response outlined above that can alter the responsiveness of the nociceptor. Muscle tenderness is mainly due to the sensitization of muscle nociceptors by BK, PG, and 5-HT, which may account for the exquisite tenderness found when firm pressure is applied over an active trigger point.[128]

As noted before, the activation of a nociceptive terminal is not primarily due to a nonspecific damage of the nerve ending by a strong stimulus. Rather, the binding of specific substances, including BK, PG, and 5-HT to their paired receptors on muscle nociceptors, is more often responsible.[124] Receptor responsiveness is dynamic. For example, inflammation alters the population of BK receptors at the nociceptive terminal. In normal muscle tissue, the B2 receptor is more prevalent. With tissue inflammation, an additional BK receptor (B1) is synthesized in the cell body of the ending in the dorsal root ganglion and inserted into the nociceptor terminal membrane. Unlike the B2 receptor, which is constitutively expressed, the B1 receptor is inducible and is involved in sensitization of the peripheral nociceptor. Induction and binding of the B1 receptor can also lead to the production of proinflammatory mediators, including tumor necrosis factor-α (TNF-α) and interleukin-1 β (IL-1β). Stimulation of B2 receptors leads to only transient increases in the intracellular calcium concentration and, for this reason, sensitization of the nociceptor is less likely. Conversely, stimulation of the B1 receptor results in prolonged elevation of intracellular Ca^{2+} concentration, which

can lead to sustained peripheral sensitization.[129,130] If the conformational change of the BK receptor persists, even after the inflammation subsides, this maladaptive change may herald the transition from acute to chronic pain. Therefore, the degree to which muscle nociceptors in a trigger point become sensitized or activated will vary according to the balance of sensitizing substances in the muscle tissue and the threshold of their respective receptors. There may be a spectrum of nociceptor irritability based on this balance that distinguishes a normal muscle from a muscle with a latent or active trigger point.

CENTRAL SENSITIZATION

In addition to sensitization of the peripheral nociceptors, the pain and dysfunction induced by trigger points may also be due to alterations in the responsiveness of the dorsal horn. A chronic active trigger point may be the source of ongoing noxious input that sensitizes dorsal horn neurons and generates increased or referred pain to other spinal cord segments via central sensitization.[131,132] Conversely, a sensitized central nervous system may lead to a lowering of the activation threshold of the peripheral nociceptors in a trigger point, inducing the transition from a latent to an active trigger point. The latter may occur when trigger points develop secondary to referred pain from viscera, joints, or as a result of psychological stress. Giamberdino et al.[133] have established that visceral referred pain with hyperalgesia is usually associated with cutaneous hyperalgesia and with trigger points. Vecchiet et al.[134,135] measured significantly lower pain thresholds with electrical stimulation over active trigger points in the muscles, but also in the overlying cutaneous and subcutaneous tissues. With latent trigger points, the sensory changes did not involve the cutaneous and subcutaneous tissues.[134,135] Nociceptive input from the viscera may sensitize the central nervous system and indirectly lower the threshold for peripheral trigger point nociceptors. Because of this phenomenon, trigger points in the abdominal wall can be used for diagnostic purposes. Jarrell[51] found that the presence or absence of a trigger point in the abdominal wall helps to determine whether there is evidence of current or previously treated visceral disease. The presence of an abdominal wall trigger point predicted evidence of visceral disease in 90% of subjects. However, the absence of a trigger point was associated with no visceral disease in 64% of the subjects.[51,136] A recent cohort study of men with chronic pelvic pain syndrome found that abdominal pain or tenderness was present in 51% of patients, compared to only 7% of healthy controls.[137] Trigger points may be associated with joint dysfunction. Trigger points in the upper trapezius were found to correlate with cervical spine dysfunction at the C3 and C4 segmental levels, although a cause-and-effect relationship was not established.[138] A single spinal manipulation did induce changes in pressure pain sensitivity in latent trigger points in the upper trapezius muscle.[139] A brief review of basic muscle pain neurophysiology is useful to understand how central sensitization develops.

The primary peripheral sensing apparatus in muscle involves group III (thinly myelinated, low-threshold fibers) and group IV (unmyelinated, high-threshold fibers) afferent nerve fibers. These fibers cause aching, cramping pain when stimulated with microneural techniques. The central projections of these fibers share several important characteristics especially when compared to cutaneous nociception. First, a reduced spatial resolution because of a lower innervation density of muscle tissue will make it harder to localize muscle pain. Second, convergence of sensory input from skin, muscle, periosteum, bone, and viscera into lamina IV and V of the dorsal horn onto the wide dynamic range neuron can blur the identification of the origin of the pain. Third, divergence of sensory input into the dorsal horn-sustained noxious stimulation as demonstrated for example in group IV fibers in animal models can open previously ineffective synaptic connections in the dorsal horn, such that these fibers begin to respond to lower levels of stimulation, leading to mechanical allodynia and hyperalgesia.[124]

Compared to normal muscle and muscle with latent trigger points, a muscle with active trigger points is more tender and mechanically sensitive, suggesting that peripheral nociceptors are already sensitized. Once sensitized, the group IV afferent nerve fibers will fire at lower thresholds, even though they are normally high-threshold nociceptors. For example, in animal models, injection of BK into muscle will cause the group IV afferents to respond to much lower levels of stimulation, suggesting they have become sensitized.[140] Since muscle tenderness is mainly due to the sensitization of muscle nociceptors by BK, PGs, and 5-HT, peripheral sensitization by these substances presumably contributes to the tenderness seen in active trigger points and may contribute to the pain that individuals with active trigger points describe. Recent studies on the biochemical milieu of active trigger points in the upper trapezius muscle support this hypothesis.[141,142] Therefore, if an active trigger point in a muscle has elevated levels of these and other sensitizing biochemicals, any local muscle contraction that occurs with daily functional activities and postures may be sufficient to cause pain by activating the normally high-threshold nociceptors, which ordinarily do not respond to this type of mechanical activation.

Central sensitization is more readily induced as the activation threshold is lowered for peripheral muscle nociceptors. In animal models of pain, a nociceptive input from skeletal muscle is much more effective at inducing neuroplastic changes in the spinal cord than is input from the skin.[8] Experimentally induced myositis in animal models causes a marked expansion of the response of second order neurons beyond the muscle's target area of the dorsal horn. Hoheisel et al.[143] found that after a localized inflammatory reaction was created, noxious input from the gastrocsoleus (L5) muscle also activated second order neurons in the L3 segment. This segment would not ordinarily be activated by noxious stimulation of the gastrocsoleus in noninflamed muscle.[143] This study demonstrated an expansion of the receptive field in the dorsal horn as a result of a central sensitization. The L3 dorsal horn neurons became hyperexcitable after continuous nociceptive input from the inflamed L5 muscle. The sensitized surrounding segments caused the L3 segment to respond to previously ineffective afferent input.[143] This model of referred pain combines peripheral input and central processing and is known as the central hyperexcitability theory.[144] Supraspinal mechanisms contributing to referred pain have been explored by Niddam et al.,[9,10] who demonstrated that pain from myofascial trigger points involves enhanced activity in the somatosensory and limbic regions and suppressed hippocampal activity.

Expansion of the receptive field in the spinal cord with myositis-induced excitation is clinically relevant, helping to explain the unusual referral patterns seen in myofascial pain. For example, trigger points in the suboccipital muscles may refer to the frontal region of the head, and trigger points in the piriformis may cause pseudosciatica. In addition, central sensitization in animal models may explain the spread of muscle pain to other segments which become painful over time in patients with chronic myofascial pain. It may also explain the symptomatic hyperalgesia reported by many patients, as many of these neurons become hyperexcitable. It is likely that these myositis-induced changes in the spinal cord occur due to a rewiring of dorsal horn neurons in response to sustained peripheral drive from an irritable, sensitized muscle nociceptor, such as that found in an active trigger point.[132]

It is important to add that referred pain is not unique to muscle tissue or myofascial trigger points. All tissues, including fascia, intervertebral discs, internal organs, ligaments, and zygapophyseal joints are capable of referring pain.[5,14,133,144–148] Referred pain patterns from cervical zygapophyseal joints are very similar to those of trigger points in cervical muscles.[149] Clinically referred pain phenomena can be rather confusing, as patients frequently

complain of pain in an area of the body where the pain did not originate. For instance, pain in the elbow region, often considered a local problem (e.g., epicondylitis), may in fact be referred pain from shoulder muscles.[150] Another example may be upper arm or shoulder pain originating in the distant infraspinatus muscle. Hsieh et al.[151] demonstrated that inactivating trigger points in the infraspinatus muscle inactivated trigger points in the anterior deltoid muscle. Similarly, pain in the region of the masseter muscle can be resolved by treating trigger points in the trapezius muscle.[152] Headley[153] has suggested that trigger points in one muscle may inhibit other muscles, especially in the area of referred pain. In other cases, muscle pain and trigger points may be secondary to other, nonmuscular disorders, such as internal organ, joint, or disc pathology. This finding underscores the necessity of an excellent and comprehensive differential diagnostic process to uncover the nuances of referred pain. Patients with osteoarthritis of the hip or knee joint were found to have significantly higher numbers of trigger points in muscles crossing these joints than healthy controls.[154] The correlations between pathological conditions and an increased number of trigger points may partially explain why localized painful conditions can become more widespread.[37]

SYNAPTIC CONNECTIONS IN THE DORSAL HORN

There are at least two functional types of synaptic connections in the dorsal horn. One is an "effective" synapse, where action potentials arriving at the presynaptic portion of the synapse exert a strong influence on the postsynaptic or second order neuron. There are a much larger number of "ineffective" synapses between primary afferents and second order neurons. They are considered ineffective because under normal circumstances they do not influence the postsynaptic neuron in a way that will propagate the action potential. These ineffective synapses are multisegmental, and there is anatomical evidence that deep somatic afferents can ramify and enter the dorsal horn of up to 6–7 segments.

The excitatory amino acid glutamate is the presynaptic transmitter for nociceptive information in dorsal horn neurons and can act on *N*-methyl-D-aspartate (NMDA) and the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors at the postsynaptic site. Under normal conditions, only the AMPA receptor is active. Thus, when one sustains a blow to a muscle, a short train of nociceptive impulses from the injured muscle causes the presynaptic site in the dorsal horn to release glutamate. This glutamate release causes a brief activation of the AMPA receptor and postsynaptic neuron. Ineffective synapses limit sensation to specific areas. Though the train of impulses may reach segments of the dorsal horn normally thought to be outside the myotome of the injured muscle, ineffective synapses do not have AMPA receptors and the second order neurons will not fire at these levels. However, with an intense or sustained noxious input, SP is coreleased with glutamate. If this noxious barrage continues and sufficient quantities of SP are released, the NMDA receptor will release its magnesium plug and become responsive to glutamate. This allows the entry of Ca^{2+} ions into the cell of the second order neuron, leading to a cascade that results in the de novo synthesis of AMPA receptors at what were previously ineffective synapses. In this way, the release of SP in the dorsal horn in sufficient quantities will increase the efficacy of synaptic connections in the spinal cord, allowing the multisegmental spread of noxious input. This process explains how action potentials emanating from nociceptors in an L5 muscle can then excite neurons in the L3 segment.[124]

THE BIOCHEMICAL MILIEU OF MYOFASCIAL TRIGGER POINTS

Investigators at the U.S. National Institutes of Health (NIH) developed a clinical protocol to assess the local biochemical milieu of myofascial trigger points.[142] They designed, fabricated, and tested a novel 30-gauge microdialysis needle capable of the in vivo collection of small volumes (~0.5 μL) and subnanogram sizes (<75 kDa) of solutes from muscle tissue. The needle has the same size, shape, and handling characteristics of an acupuncture needle. Its features permit simultaneous sampling of the local biochemical milieu of muscle before, during, and after a local twitch response is elicited with the same needle (Fig. 35.5).

A local twitch response is an involuntary spinal cord reflex contraction of muscle fibers within a taut band, which can be elicited by manually strumming or needling of a taut band. Local twitch responses can be observed visually, recorded electromyographically, or visualized with diagnostic ultrasound.[155] When a trigger point is needled with a monopolar Teflon-coated electromyography needle, local twitch responses appear as high amplitude polyphasic discharges.[156,157] Eliciting local twitch responses is essential when using deep dry needling in clinical practice not only to accomplish optimal treatment results, but also to confirm that the needle is placed into a taut band, which is critically important when needling close to peripheral nerves or internal organs, such as the lungs.[158–160]

The microanalytical system allowed investigators to safely explore and measure the local biochemical milieu of muscle in subjects with and without pain and with and without trigger points at a standardized location in the upper trapezius muscle. In one study, 9 subjects were selected, and based on history and physical examination, classified into 3 groups:

- Group 1—*Normal* (no neck pain, no myofascial trigger point)
- Group 2—*Latent* (no neck pain, myofascial trigger point present)
- Group 3—*Active* (neck pain, myofascial trigger point present)

Samples were obtained continuously with the microdialysis needle at regular intervals, including at the time of needle insertion, elicitation of a local twitch response, and posttwitch.[142] The main outcome measures were pH and concentration levels of protons, SP, CGRP, BK, 5-HT, norepinephrine, TNF-α, and IL-

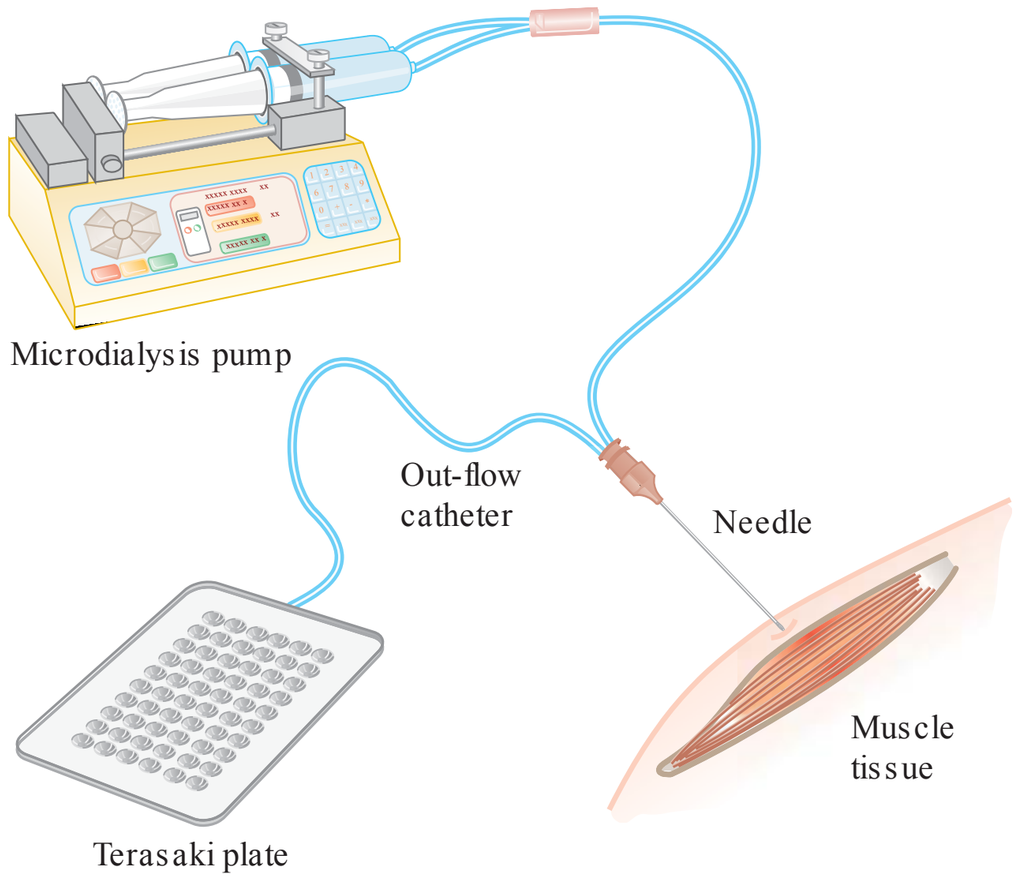

FIGURE 35.5 Schematic of perfusion pump and collection plate.

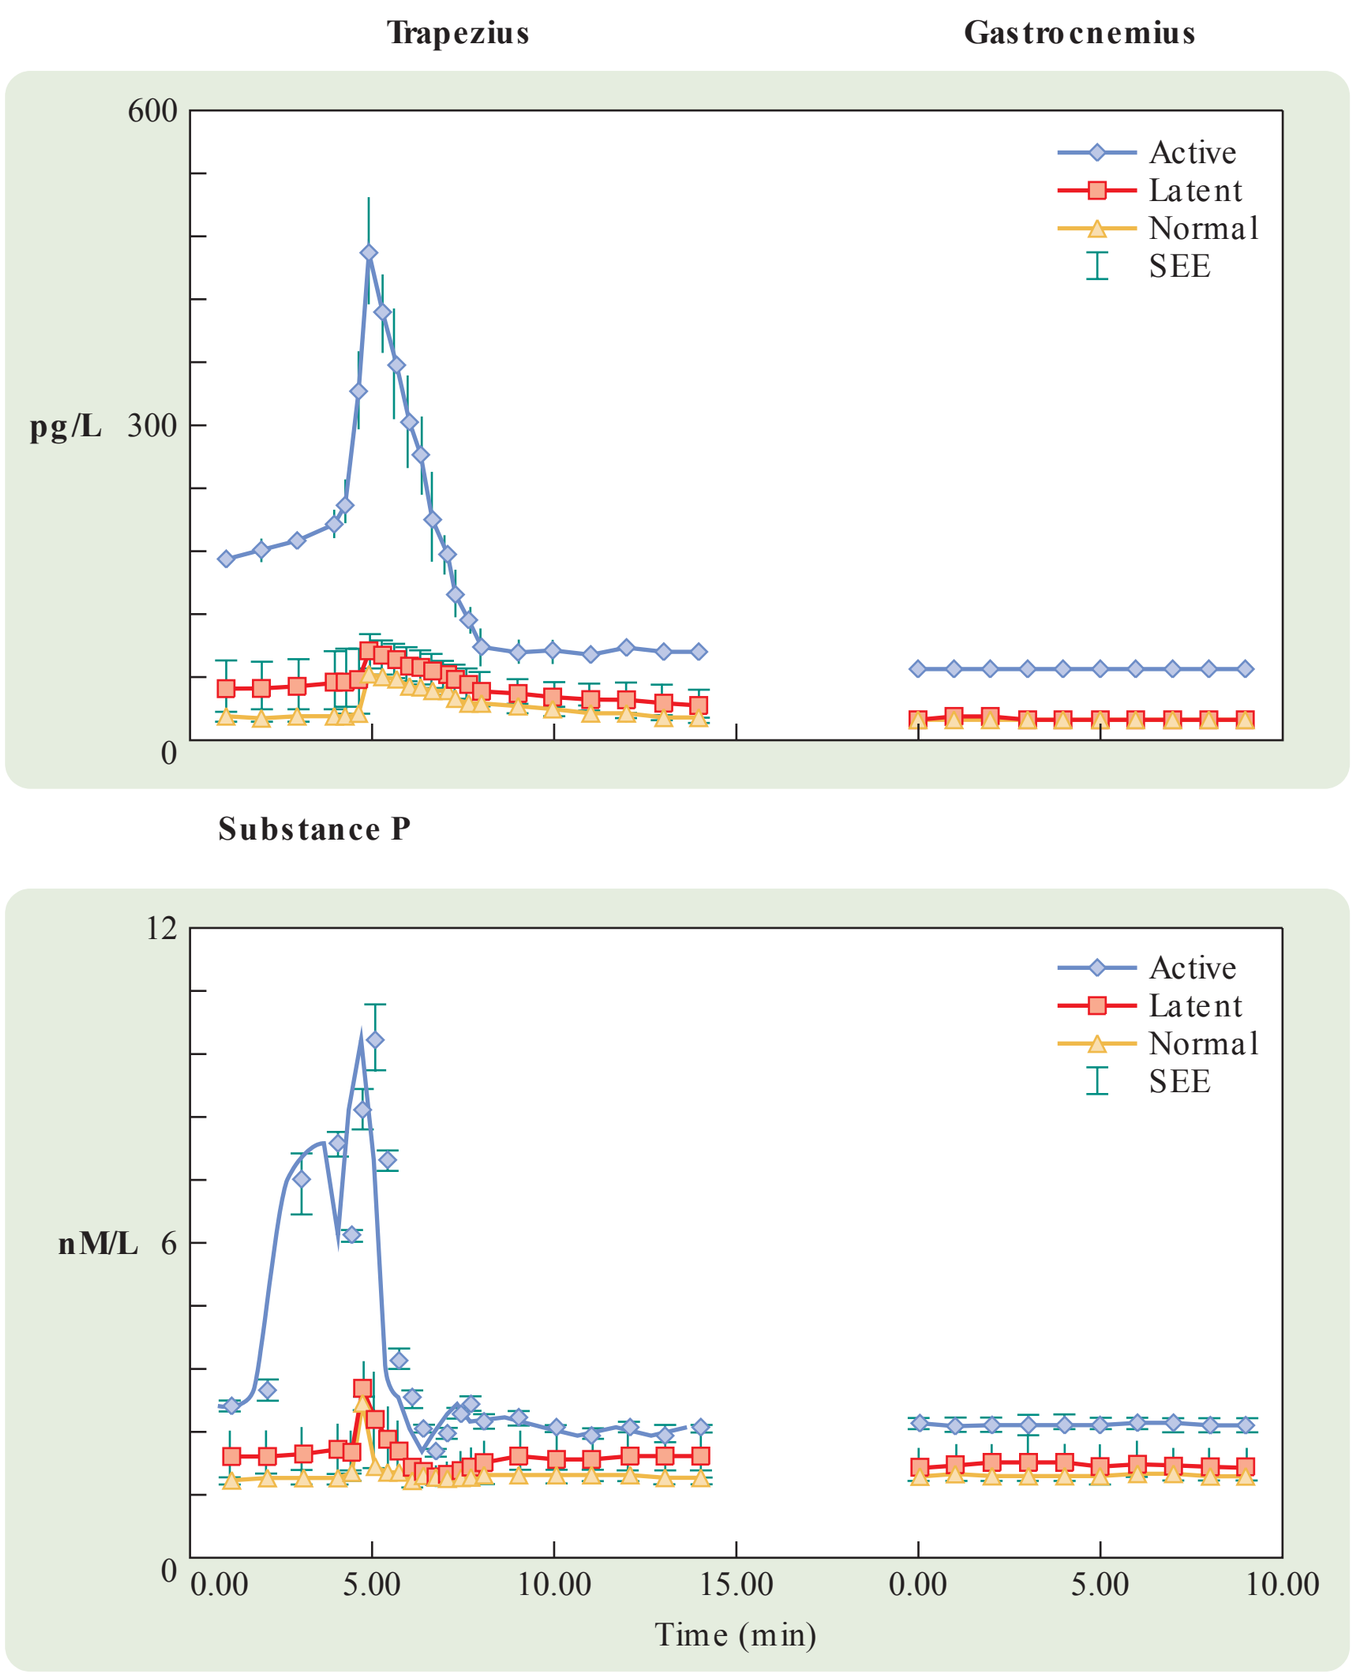
1β, determined by analysis of samples. Overall the amounts of SP, CGRP, BK, 5-HT, norepinephrine, TNF-α, and IL-1β were significantly higher in the *Active* group than either of the other two groups ($p < 0.01$). The pH was also significantly lower in the *Active* group than the other two groups ($p < 0.03$). In the *Active* group, the amounts of SP and CGRP were significantly lower at the end of sampling (posttwitch) than at baseline ($p < 0.02$) (Fig. 35.6).

In a second study, the previous findings were confirmed, demonstrating that biochemicals associated with pain and inflammation are elevated in soft tissue in the vicinity of active trigger points.[141] The concentrations of these biochemicals, including protons, BK, SP, CGRP, TNF-α, IL-1β, 5-HT, and norepinephrine differentiate the *Active* group from the *Latent* and *Normal* groups. Two additional analytes sampled, IL-6 and IL-8, were likewise significantly higher in the *Active* group.[141]

The second study also included sampling of analyte levels from the biochemical milieu of a remote uninvolved site in the upper medial gastrocnemius muscle. Like the previous study, subjects were classified into groups based on physical findings of active, latent, or no upper trapezius trigger points. The upper medial gastrocnemius was examined and selected as a remote uninvolved site, and none of the participants had active or latent trigger points at this site. Analyte levels from this remote site were compared to levels in the upper trapezius with active, latent, and no trigger points. In the *Active* group at needle insertion, analyte concentrations of the tested biochemical substances in the gastrocnemius were almost always lower than concentrations in the trapezius. The only exception was pH, which was the same in both muscles at needle insertion. Therefore, the biochemical milieu of an active trigger point in the upper trapezius differs quantitatively from a remote, uninvolved site in the gastrocnemius muscle.[141] They also found that subjects with an active trigger point in the upper trapezius have relatively elevated levels of these analytes in a remote, uninvolved muscle (the upper medial gastrocnemius) compared to gastrocnemius levels in latent and normal subjects (Fig. 35.7). This suggests that substances associated with pain and inflammation are not limited to local areas of trigger points or a single anatomical locus.[141] However, the elevated gastrocnemius concentrations in the *Active* group were lower than most analyte concentrations in the upper trapezius of the *Active* group.

Although there were no trigger points in the upper medial gastrocnemius for all subjects, analyte levels in this muscle were always significantly higher in the *Active* group than the *Normal* group and generally higher than analyte levels in the *Latent* group. This suggests that analyte abnormalities may not be limited to local areas of active (painful) trigger points in the upper trapezius, but are present in unaffected muscle remote from the active trigger points, albeit lower in concentration than in the



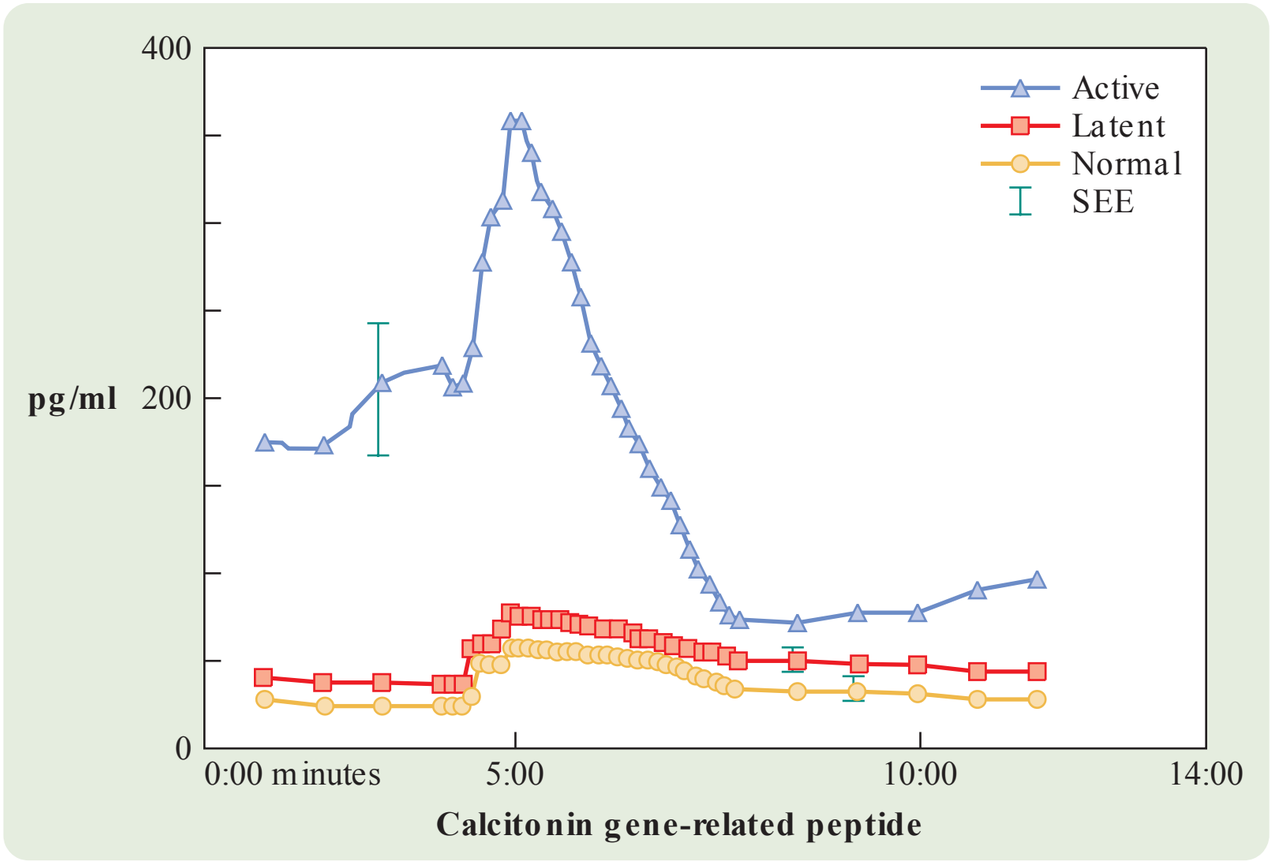


FIGURE 35.6 Analyte concentrations in trapezius compared to gastrocnemius, substance P, norepinephrine.

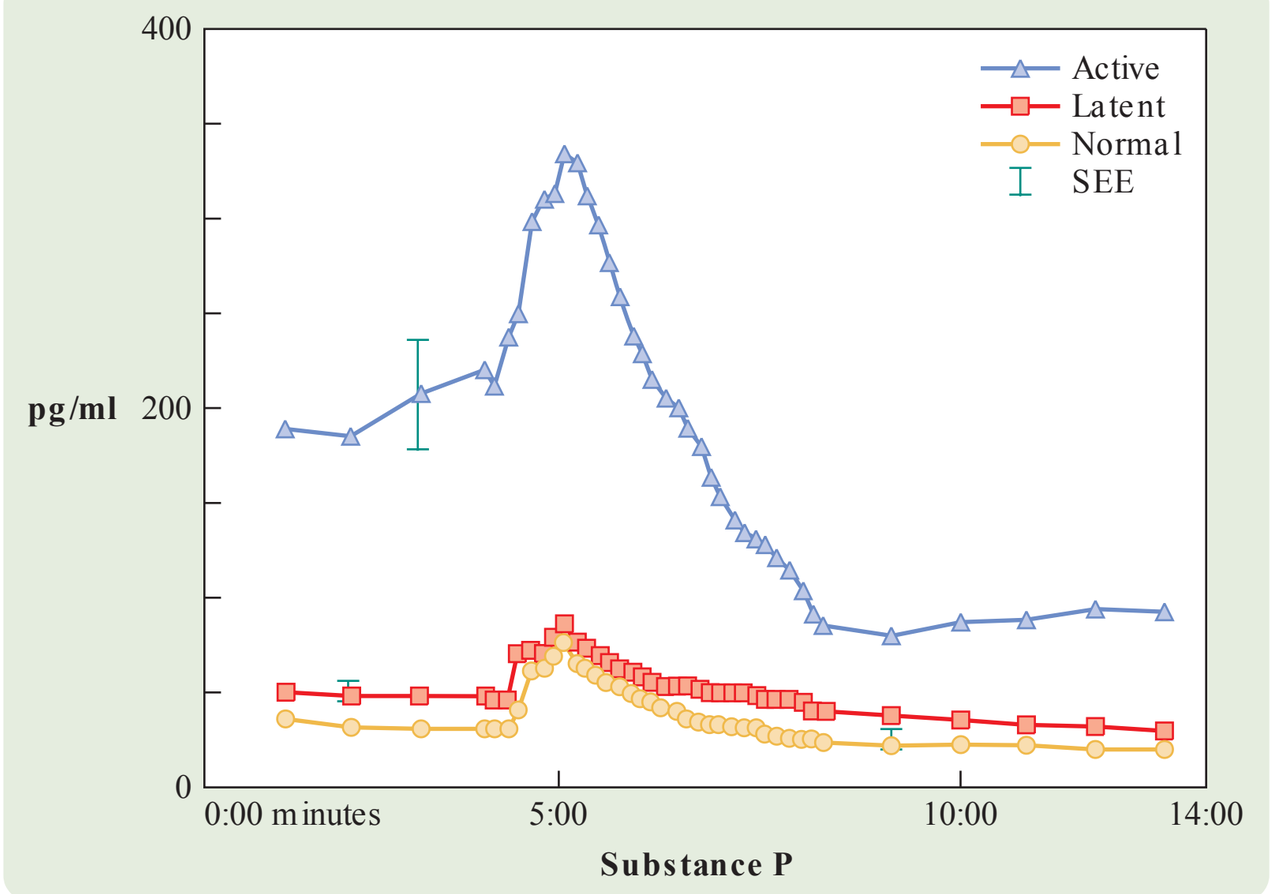

FIGURE 35.7 Concentrations of CGRP and SP across time. A local twitch response was elicited at 5 minutes.

trapezius. The slightly elevated analyte levels in the gastrocnemius may be a widespread phenomenon, possibly related to central sensitization in the *Active* group. There is a possibility that widespread elevation of analytes is a precursor to development of active (painful) trigger points. Conversely, individuals who are susceptible to developing active trigger points may have pre-existing elevated baseline levels of these analytes in muscles throughout their bodies. Further study of the natural history of this condition may elucidate whether the relatively elevated analyte levels in the gastrocnemius in the *Active* group follows the development of an active myofascial trigger point or if there is a baseline low-level elevation of these analytes that precedes the development of an active trigger point.

The NIH investigators demonstrated that it is possible to collect near real-time samples from soft tissue with minimal system perturbation and without harmful effects on subjects. They also showed proof-of-principle of the system's ability to distinguish among subjects who have clinically distinct soft tissue findings. In both studies, the microdialysis needle was used to elicit a local twitch response in the trapezius muscle of the *Active* and *Latent* groups. This caused dramatic changes in temporal sequencing of analyte levels with distinct curves observed among the three groups of subjects.[141,142] In clinical practice, eliciting local twitch responses while needling active trigger points is believed to be therapeutic.[158–160] Audette et al.[161] found that in 61.5% of active trigger points in the trapezius and levator scapulae muscles, dry needling an active trigger point elicited a local twitch response in the same muscle, but on the opposite side of the body. Needling of latent trigger points resulted in unilateral local twitch responses only.[161] The authors suggested that this phenomenon may be another indication that active trigger points represent a greater degree of central sensitization.[161]

Until recently, myofascial pain was characterized primarily by a physical finding and symptom cluster without demonstrable pathology. Microdialysis sampling revealed that a unique biochemical milieu of substances associated with pain and inflammation exists in the vicinity of active trigger points in the upper trapezius and includes elevated concentrations of protons, SP, CGRP, BK, TNF-α, IL-1β, IL-6, IL-8, 5-HT, and norepinephrine. Further sampling of these and other substances, such as anti-inflammatory cytokines or peripheral opioids, may lead to an improved biochemical characterization of trigger points and identify those who are at risk for developing persistent symptoms. Furthermore, discovering if and which measurable substances are predictive of pain could lead to focused therapies in the future. The relevance of the research by Shah et al. within the broader

context of the pain sciences will be illustrated in the following sections.

pH AND MUSCLE PAIN

A previous study demonstrated a positive correlation between pain and local acidity.[162] Sluka et al.[99] demonstrated that an acidic milieu without muscle damage is sufficient to cause profound changes in the properties of the "pain matrix" such that alterations in pH would be sufficient to modify the threshold sensitivity of the nociceptor. An acidic pH stimulates the production of bradykinin during local ischemia and inflammation; therefore, a local acidic milieu may explain some of the pain associated with an active trigger point. Mechanical hyperalgesia is a hallmark of a trigger point. However, ongoing nociceptive activity is not necessary to cause mechanical hyperalgesia. In a rat model, repeated injections of acidic saline boluses into one gastrocnemius muscle produced bilateral, long-lasting mechanical hyperalgesia of the paws.[99] Furthermore, the study showed that the persistent hyperalgesia was not caused by muscle tissue damage and was not maintained by continued nociceptive input from the site of muscle injury, demonstrating that secondary mechanical hyperalgesia may be maintained by neuroplastic changes in the central nervous system, such as spinal dorsal neurons and thalamic neurons.[99]

Investigators have identified specific acid sensing ion channels (ASICs) on muscle nociceptors that can be sensitized and activated by acidic pH. For example, ASIC3 knockout mice do not develop hyperalgesia following repeated bolus injections of acidic saline.[100] Hong et al.[157,163] suggest that an integrative mechanism at the spinal cord level in response to sensitized nociceptors plays a role in development of active trigger points, and should be considered in any pathogenetic hypothesis. In an expansion of Simons' integrated hypothesis, Gerwin et al.[42] propose that the acidic pH may also modulate the motor endplate by inhibiting AChE. This would result in increased concentration of ACh at the synaptic cleft, promoting sarcomere contraction and formation of the taut band characteristic of trigger points.[42]

NEUROPEPTIDES, INFLAMMATORY MEDIATORS, AND TISSUE INJURY AND PAIN

Significantly elevated levels of SP and CGRP were found in the vicinity of active trigger points. The orthodromic and antidromic release of these substances is greatly increased in response to nociceptor activation, for example by protons and BK binding to their matched receptors.[164] This dynamic phenomenon may lead to neuroplastic changes in the dorsal horn and profound changes in neuronal activity and the perception of pain. In the studies by Shah et al.,[141,142] SP and CGRP were the only two analytes in the *Active* group which had concentrations significantly below their original baselines in the recovery period following a local twitch response. These biochemical changes correspond with the commonly observed decrease in pain and local tenderness after the inactivation of a trigger point by dry needling.[159]

SP causes mast cell degranulation with the subsequent release of histamine, serotonin, and upregulation of both proinflammatory cytokines, including TNF-α and IL-6, and anti-inflammatory cytokines, including IL-4 and IL-10. TNF-α is the only cytokine prestored in the mast cell and is released immediately following mast cell degranulation. TNF-α may stimulate norepinephrine production. The finding of elevated levels of serotonin, BK, norepinephrine, and proinflammatory cytokines in active trigger points is consistent with biochemical pathways involved in tissue injury and inflammation.[141,142]

CATECHOLAMINES AND THE AUTONOMIC NERVOUS SYSTEM

Significantly elevated levels of 5-HT and norepinephrine were found in the vicinity of active trigger points, supporting the effect of the elevated TNF-α. The increased levels of norepinephrine may be associated with increased sympathetic activity in the motor endplate region of trigger points. In one study, sympathetic activity was recorded from rabbit myofascial trigger spots, which is a model of the human trigger point.[87] Intra-arterial injection of phentolamine, an α–adrenergic antagonist, decreased the spontaneous electrical activity from a locus of a myofascial trigger spot in rabbit skeletal muscle.[87] Conversely, the nicotinic ACh receptor antagonist curare had no effect on the spontaneous electrical activity. Elevated levels of norepinephrine in the local milieu of active trigger points suggest that the autonomic nervous system is involved in the pathogenesis of spontaneously painful trigger points. A study by Ge et al.[65] provided evidence of sympathetic facilitation of mechanical sensitization of trigger points. Gerwin et al.[42,92] have suggested that the presence of alpha and beta adrenergic receptors at the endplate provides a possible mechanism for autonomic interaction. Stimulation of the alpha and beta adrenergic receptors stimulated the release of ACh in the phrenic nerve of rodents.[165]

CYTOKINES AND PAIN

A unique cascade of cytokines is released following tissue injury and inflammation. For example, bradykinin stimulates the release of TNF-α which leads to the release of IL-1β and IL-6. These two cytokines stimulate the cyclooxygenase (COX) nociceptive pathway, which leads to the production of prostaglandins.[166] TNF-α also stimulates a separate nociceptive pathway via the release of IL-8, which mediates sympathetic pain by stimulating the liberation of sympathetic amines.[167]

As noted, Shah et al.[141,142] found elevated levels of TNF-α, IL-1β, IL-6, and IL-8 in the trapezius of subjects with active trigger points. A study by Schafers et al.[168] also documented the importance of cytokines in muscle pain. It was demonstrated that TNF-α produces a time- and dose-dependent muscle hyperalgesia within several hours after injection into the gastrocnemius or biceps brachii of a rat. The hyperalgesia was completely reversed by systemic treatment with the nonopioid analgesic metamizol.[168] Furthermore, TNF-α did not cause histopathological tissue damage or motor dysfunction. One day after injection of TNF-α, elevated levels of CGRP, nerve growth factor and prostaglandin E2 were found in the muscle. According to Schafers et al.,[168] TNF-α and other proinflammatory cytokines such as IL-1β may play a role in the development of muscle hyperalgesia, and the targeting of proinflammatory cytokines might be beneficial for the treatment of muscle pain syndromes.

In rat model studies, Loram et al. measured the tissue and plasma levels of cytokines following injection of carrageenan into the hind paw compared with intramuscular injection into the gastrocnemius muscle. They demonstrated, for the first time, that the initiation of primary muscle hyperalgesia is not associated with elevated levels in local muscle of TNF-α, IL-1β, or IL-6.[169] Loram et al.[169–171] also showed that IL-1β and IL-6 are elevated at a time interval when there is no hyperalgesia. One possible explanation, they suggest, is that elevated intramuscular levels of IL-1β and IL-6 induce central sensitization, but do not contribute to the initiation of hyperalgesia.[169]

Cytokines that lead to PG release via the COX pathway have been targeted for pharmacologic intervention because of their roles in the inflammatory response.[167] IL-1β is the major cytokine stimulus for central COX-2 expression during inflammation.

Loram et al. found that IL-1β was the only cytokine that reached a higher concentration in muscle than hind paw after carrageenan injection in the rat. Furthermore, IL-1β was significantly elevated 24 hours after inducing muscle inflammation at a time when secondary hyperalgesia was induced.[169] IL-1β also stimulates IL-6 production during muscle injury. Together, both cytokines are necessary for repair and regeneration of muscle.[172–174] In light of these cytokines' importance to muscle regeneration, Loram et al. suggest that pharmacologic interventions preferentially target action of IL-1β and not IL-6 in order to reduce secondary muscle hyperalgesia and still conserve the cytokines' regenerative qualities.[169]

Moreover, which cytokines and when to target them may depend on the time course of the muscle injury and inflammatory response. As mentioned, Schafers et al.[168] found that TNF-α produces a time- and dose-dependent muscle hyperalgesia within several hours after injection into rat muscle. On the other hand, Hoheisel et al.[175] found that injection of TNF-α into a rat's gastrocnemius muscle did not excite, but rather had a short desensitizing action on group IV muscle afferents. According to Hoheisel et al.,[176] the data suggest that TNF-α has a dual action when released intramuscularly. Specifically, "it suppresses neuronal excitability after release but contributes to neuronal hyperexcitability in a later phase."[176] Therefore, the elevated levels of TNF-α, IL-1β, and IL-6 found in active trigger points may mediate secondary hyperalgesia and central sensitization via the COX pathway.

A second distinct nociceptive pathway moderates the inflammatory hypernociception following tissue injury. Rat CINC-1 and its homolog in humans, IL-8, coordinate the sympathetic components of hypernociception. Loram et al.[169] demonstrated that of the four cytokines—TNF-α, IL-1β, IL-6, and CINC-1—measured in muscle after carrageenan injection, only levels of CINC-1 were elevated at the time of primary hyperalgesia. Moreover, CINC-1 and IL-8 induce a dose- and time-dependent mechanical hypernociception. Therefore, the elevated levels of IL-8 found in active myofascial trigger points may mediate inflammatory hypernociception, muscle tenderness, and pain via this pathway. Furthermore, this pathway is inhibited by β-adrenergic receptor antagonists, though not COX antagonists.[167]

CLINICAL MANAGAMENT

Trigger Point Diagnosis

As there is no medical specialty that has adopted muscle as its distinctive organ, the literature on the clinical management of patients with myofascial pain is scattered over multiple specialties and disciplines, including algology, physiatry, dentistry, otolaryngology, urology, neurology, osteopathy, orthopedics, gynecology, physical therapy, chiropractic, acupuncture, and massage therapy, among others. Because disciplines tend to have their own jargon, the term "myofascial pain" may have different meanings among different disciplines, which could potentially challenge understanding across disciplines. In dentistry, for example, the term "myofascial pain dysfunction syndrome" is commonly used for nonspecific muscle pain with or without limited mouth opening.[176] Each discipline will have to explore general and discipline-specific differential diagnoses, especially when trigger points may not be the primary dysfunction. General aspects of the differential diagnostic process may include a neurologic examination, a biomechanical assessment of posture and movement patterns, and an assessment of other possible contributing factors. Some trigger point-referred patterns are very similar to radicular pain patterns. Referred pain patterns of trigger points in the teres minor muscle or gluteus minimus muscle resemble a C8 or L5 radiculopathy, respectively.[177,178] The presence of myofascial trigger points does not rule out a radiculopathy and vice versa. Trigger points may be associated with lumbar disc lesions or contribute to symptoms of thoracic outlet syndrome.[178,180] Although much of the fibromyalgia literature suggests that myofascial pain is a regional issue, widespread pain may still be due to myofascial trigger points.[181] As part of the diagnostic process, clinicians should consider other diagnoses as well which may feature widespread pain, including but not limited to hypothyroidism, systemic lupus erythematosus, Lyme disease, babesiosis, ehrlichiosis, candida albicans infections, myoadenylate deaminase deficiency, herpes zoster, complex regional pain syndrome, hypoglycemia, parasitic diseases such as fascioliasis, amoebiasis, and *Giardia*, systemic side effects of medications, including any of the statin drugs or even glucosamine sulfate, and metabolic or nutritional deficiencies or insufficiencies of vitamin B12, vitamin D, and ferritin.[181] Having patients complete standardized pain questionnaires at the time of the initial examination allows for objective outcome measurements. Discipline-specific differential diagnoses support the notion of having a multidisciplinary approach as individual clinicians may not be familiar with diagnoses or patterns of dysfunction outside their own area or specialty.[182] Yet, the underlying mechanisms and principles of muscle dysfunction, described earlier in this chapter, apply to all disciplines.

Palpation is the criterion standard for identifying myofascial trigger points. However, there still are no research-validated criteria. Simons, Travell, and Simons[39,183–192] defined empirically-derived criteria, which have been applied to a number of interrater and intrarater reliability studies. The presence of a taut band and spot tenderness has been shown to be a reliable indicator of myofascial trigger points in one comprehensive study, while in a more recent study referred pain and a jump sign were the most reliable indicators.[183,185] The local twitch response is more difficult to elicit and has not been shown to be a reliable feature of trigger points. Occasionally, the concept of myofascial pain is challenged, because excellent interrater reliability was only achieved with experienced and well-trained clinicians. However, the fact that trigger point palpation has to be learned is no different than most other clinical skills and procedures. Palpation and, more specifically, trigger point palpation is not taught in the vast majority of medical, physical therapy, and chiropractic schools, and it should come as no surprise that clinicians do not necessarily master trigger point palpation without specific training.

Familiarity with referred pain patterns of trigger points is essential, as it will guide clinicians to clinically relevant muscles and trigger points. Recent studies have confirmed previously suggested referred pain patterns, especially in the head and neck region.[150,193–195] Other studies and case reports have described new patterns either directly from trigger points or from muscles in general.[196–198] Acupuncturists may recognize correspondences between trigger point-referred pain patterns and acupuncture meridian pathways.[199]

The physical examination for myofascial trigger points should be a standard component of the diagnostic process and does not exclude any other part of the standard examination process. In addition to trigger points, there are many other possible sources of pain. A detailed history is critical. There are several predisposing or perpetuating factors that need to be assessed in addition to possible medical diagnoses.

Mechanical perpetuating factors are relatively easy to identify by clinicians across disciplines and include forward head posture, which frequently contributes to migraines or tension-type headaches, neck pain, and upper thoracic pain,[200,201] decreased spinal mobility, structural misalignments, such as leg length discrepancies or pelvic torsions, or systemic or local hypermobility.[139,182,202–204] The combination of static and awkward postures, excessive force, and repetitive tasks predisposes a patient to the development of trigger points. Awkward postures may include prolonged wrist flexion and extension, ulnar and radial abduction, forearm supination and pronation, extended reaches beyond the

shoulder-reach envelope, pinch grips that are either too wide or too narrow, habitual postures during computer tasks, among others.[112,205] Ergonomic measures often play a vital role in correction and prevention of myofascial pain problems.[205]

Psychological arousal has a direct impact on the electrical activity of myofascial trigger points, while autogenic relaxation reduces the electrical activity.[206–208] Whether specific regions of the brain, such as the anterior cingulate gyrus, which has been linked to nociceptive input from muscles, and to depression, anxiety, and anger can explain at least part of the association of psychological factors and trigger points remains to be seen.[9–11,209,210] Depression, anxiety, anger, feelings of hopelessness and helplessness, and fear avoidance are common with many chronic pain syndromes and are not specific for myofascial pain.[211,212]

Any nutritional or metabolic condition that interferes with the energy supply of muscle tissue can contribute to the development of myofascial trigger points.[181] Laboratory levels can be within the "normal" range, yet be insufficient for a given individual, which makes it more difficult to diagnose, but no less important. Common nutritional and metabolic deficiencies or insufficiencies include vitamins B1, B6, B12, and D insufficiency states, iron, magnesium, and zinc insufficiency states, and thyroid deficiency states, among others.[181] The importance of metabolic and nutritional perpetuating factors is illustrated for vitamin D.

Vitamin D deficiency is commonly observed with chronic, nonspecific musculoskeletal pain.[213] Nearly 90% of 150 subjects with musculoskeletal pain had vitamin D levels less than 20 ng/mL and 28% had less than 8 ng/mL, where levels above 30 ng/mL are considered optimal.[213] Vitamin D deficiency in adults is defined as serum 25(OH)D levels below 20 ng/mL and vitamin D insufficiency as 25(OH)D below 30 ng/mL.[214–216] Vitamin D deficiencies are endemic in northern Europe and America[215,217,218] and are associated with muscle weakness, myofibrillar protein degradation, reduced muscle mass, osteoporosis, and decreased functional ability.[219,220] Although there are no randomized controlled studies examining the correlation between vitamin D deficiencies or insufficiencies and myofascial pain, empirical observations in a community pain management center suggest that vitamin D insufficiencies are very common among individuals with myofascial pain.[181] In the hierarchy of evidence-based medicine, clinical evidence is a valid parameter and should be included in the review of evidence.[221–223]

Physical Examination Technique

The physical examination of myofascial trigger points is performed with either a flat or pincer palpation technique. With the flat palpation technique, the taut band and trigger point are compressed in between a finger or thumb against the underlying tissue or bone (Fig. 35.8). With the pincer palpation technique, the taut band and trigger point are held in between the clinician's fingers and thumb (Fig. 35.9). The initial palpation focuses on the presence of taut bands as, by definition, trigger points are always located within a band of contractured muscle fibers. Palpation for trigger points is performed perpendicular to the fiber direction, which requires good anatomical knowledge of muscles and their fiber directions. Whether a muscle should be shortened, lengthened, or kept in a resting position depends entirely on the individual muscle, the tension in connective tissues and fascia, and available range of motion. The muscle needs to be placed in a position where the taut band can optimally be palpated. For patients with very tight and restricted muscles, the muscle may need to be placed in a relaxed position, while in hypermobile patients the muscle may need to be prestretched to be able to identify taut bands.[41] Prolonged pressure on trigger points for as long as 10–15 seconds may elicit referred pain patterns and the patient's familiar pain complaint. Local twitch responses may be elicited by strumming the taut band, but this has little utility as part of the diagnostic process. The minimum criteria for identification of an active trigger point are the presence of a taut band with exquisite spot tenderness and patient-recognized pain.

FIGURE 35.8 Flat palpation technique.

Magnetic resonance and ultrasound elastography may become useful technologies in the future, but have not yet been utilized in clinical practice.[57,58,61] Piezoelectric and electro-hydraulic shockwave emitters are being used especially in Germany for the identification and treatment of trigger points and their specific referred pain patterns.[224,225] Both types of shockwave emitters were able to reproduce patients' familiar referred pain patterns. As endplate noise was found to be characteristic of trigger points, electromyography has been used in research studies to confirm the presence of trigger points, but in clinical practice there is no advantage to using electromyography. The limited resolution of diagnostic ultrasound has restricted its use to visualizing local twitch responses with needle penetration, but improved technology may enable clinicians and researchers to identify trigger points.[61,155,226] At this point in time, palpation remains the primary tool for the identification of trigger points.

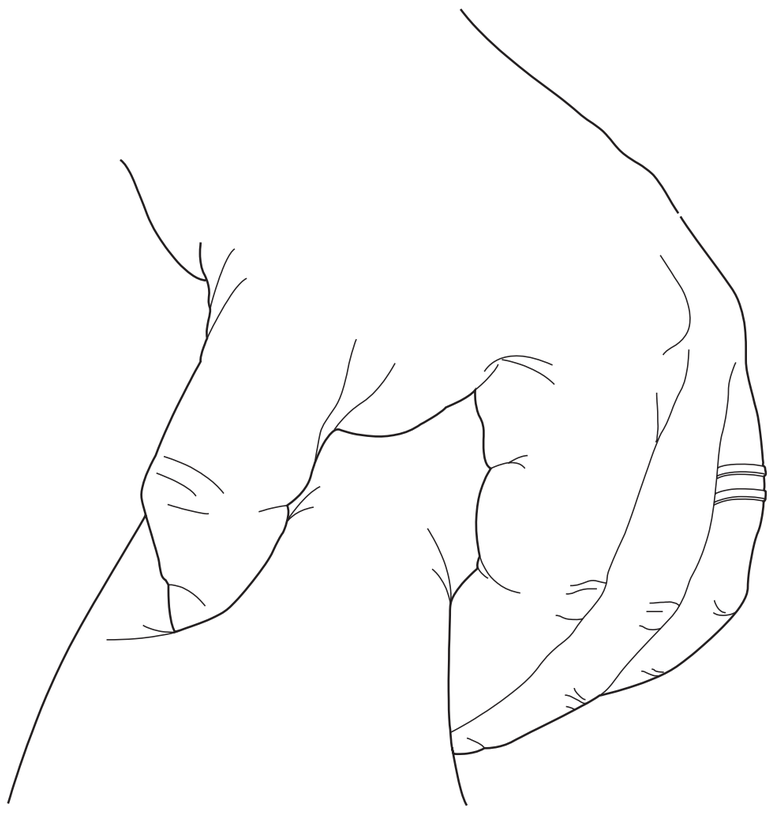

FIGURE 35.9 Pincer palpation technique.

Treatment Options

One of the first decisions to make after the initial examination is whether the patient's pain complaints have a significant myofascial component. A recent paper defined clinical prediction rules to assist in identifying patients with chronic tension-type headaches who are likely to benefit from trigger point therapy.[227] Patients with chronic tension-type headaches were examined and potential predictor variables were entered into a stepwise logistic regression model to determine the most accurate combination of variables to predict treatment success. Headache duration, headache frequency, bodily pain, and vitality were found to be predictive variables. As expected, patients with shorter and fewer headaches and those with less bodily pain were more likely to have successful outcomes. Interestingly, patients with lower vitality were found to be more responsive to intervention, which the authors could not explain based on the data or other theoretical models. If all four variables were present, the probability of success was 84%. Another interesting finding of this preliminary study was that the number of active trigger points and tenderness were not predictive of outcome.[227]

Patients with chronic pain problems may present with a combination of possible contributing factors. If metabolic or nutritional insufficiencies are suspected, additional testing may be required. It is unlikely that therapy will be successful unless such insufficiencies have been addressed adequately. The choice of treatment modalities is partially based on a clinician's bias, preferences, experience, and skills. A dentist treating a patient with facial pain and trigger points in the masseter muscle may decide to improve the patient's occlusion assuming that the muscle pain is secondary to the malocclusion. An orthopedic surgeon may manage a patient's complaint of radiating pain down the leg with epidural injections to reduce radicular pain, while a physician familiar with referred pain patterns of myofascial trigger points may decide to treat trigger points in the gluteus medius muscle with trigger point injections or myofascial release techniques. Many patients with chronic myofascial pain may benefit from a comprehensive pharmacologic management strategy, which may include nonsteroidal anti-inflammatories, opiates, antidepressants, and anticonvulsants, although these are not specific for myofascial pain.[228,229]

Patient Education

Following the initial examination, patients need to be educated about the nature and complexity of their pain. Studies have shown that patients with chronic pain gain much understanding and insight when the clinician explains the principles of peripheral and central sensitization rather than focuses on anatomical concepts such as spinal mechanics.[166,230] Excellent patient education can reduce disability and assist patients in making appropriate choices, overcoming counterproductive beliefs, and modifying dysfunctional behaviors by increasing physical activity and self-efficacy.[231,232] If the patient's pain complaint could easily be provoked by pressure on certain trigger points, it is likely that trigger point therapy will make significant improvements. However, clinicians should be cautious in promising total relief, especially for chronic pain conditions with multiple interacting aspects.

Physical Therapy

The role of physical therapy in pain management centers is often limited to instructing patients in proper stretching and strengthening exercises, stabilization programs, posture corrections, and maybe limited manual therapy interventions.[232] Relatively few physical therapists have received adequate training in pain management, and physical therapists are poorly represented in professional pain management associations.[233] It appears that few physical therapy schools have adopted a specific pain science curriculum.[234] As many as 96% of orthopedic physical therapists preferred to work with patients without chronic pain.[235] Physical therapists experienced in working with persons with chronic pain, including myofascial pain, work closely with physicians and other members of the interdisciplinary team. A comprehensive team approach may distinguish two distinct but overlapping phases. During the first phase, the emphasis is on reducing the nociceptive component of the pain problem with manual trigger point therapy, trigger point dry needling or trigger point injections, other manual therapy interventions, breathing exercises, relaxation therapy, electrotherapeutic modalities, early posture training, and physical conditioning.[206,234,236] According to Moseley, "any strategy that has an inhibitory effect on nociceptive input is probably appropriate in the short-term unless it simultaneously activates non-nociceptive threatening input."[237] During the second phase, the emphasis shifts to further improving physical functioning, cardiovascular endurance, and aerobic conditioning.

Patients need to learn self-pacing and setting appropriate and achievable goals, including physical goals, psychological goals, functional goals, and social goals.[238] An important variable is the degree of a patient's belief in their self-efficacy, which is defined as "the belief in one's capabilities to organize and execute the sources of action required to manage prospective situations."[231,239,240] Patients with a weak belief in their self-efficacy tend to avoid difficult tasks, have low aspirations, maintain a self-diagnostic focus, and emphasize personal deficiencies and adverse outcomes. They are more prone to depression and stress and give up quickly. Patients with a strong belief in their self-efficacy are more likely to set challenging goals, consider difficult tasks as challenges rather than as threats, and maintain a task-diagnostic focus. They usually are not depressed and increase their effort when faced with difficulties.

Needling Therapies

Invasive trigger point therapy can be divided into trigger point injections and trigger point dry needling. Trigger point injections are usually restricted to medical doctors and their professional support staff. The state of Maryland is the only jurisdiction in the United States where physical therapists are legally allowed to perform trigger point injections.[159] Physical therapists and physicians around the world utilize trigger point dry needling.[159] As Steinbrocker already suggested in 1944, the mechanical stimulation of trigger points is an important mechanism to explain the effects of needling therapies.[241]

Trigger point dry needling consists of superficial and deep dry needling based on the depth of needling.[159] The first comprehensive paper about deep dry needling was published in 1979 and reported that dry needling of trigger points caused immediate analgesia in almost 87% of the needle sites, which was referred to as "the needle effect."[242] In 1980, a prospective deep dry needling study of injured workers with low back pain showed that dry needling was an effective treatment for low back pain.[243] A recent Cochrane review supported the use of dry needling as an adjunct for the treatment of patients with chronic low back pain.[244] The technique used with deep dry needling is similar to the technique of trigger point injections and aims to elicit local twitch responses (Fig. 35.10).

The mechanisms and effectiveness of deep dry needling are comparable to trigger point injections.[158–160,244–249] Earlier studies suggested that dry needling would cause more postneedling soreness, but when injections are compared to dry needling using solid filament needles, there are no differences between the two methods.[224,246,249,250] Postneedling soreness occurs in most patients and can vary in duration from just a few minutes to as much as 2 days. Vasovagal reactions can occur with any needling procedure, but they are relatively rare. To avoid unnecessary

FIGURE 35.10 Trigger point dry needling of the trapezius muscle.

complications from possible vasovagal reactions, patients are needled only while lying down on the treatment table.

With the superficial dry needling technique, a solid filament needle is placed into the tissues overlying active trigger points at a depth of approximately 5–10 mm for 30 seconds. In case of any residual pain, the needle is inserted for another 2 or 3 minutes.[24,251] Local twitch responses are usually absent with superficial dry needling. The degree of available endogenous opioid peptide antagonists may determine how intensely a patient responds to the therapy. So-called weak responders may have excessive amounts of endogenous opioid peptide antagonists. A rodent model has shown that mice with deficient opioid peptide receptors did not respond well to needle-evoked nerve stimulation.[252]

Trigger point injections are administered with a variety of injectables (Fig. 35.11). Travell preferred procaine hydrochloride, which is no longer available everywhere.[30,253] The current recommendation is to use 0.25% lidocaine, which was found to be more effective than stronger concentrations.[254,255] Other anesthetics used with trigger point injections include ropivacaine, levobupivacaine, and mepivacaine, among others.[256,257] There is no scientific evidence that injections with steroids, vitamin B12, nonsteroidal anti-inflammatories, or bee venom would be beneficial, although these have been reported. Bee venom has some potential based on its antinociceptive and anti-inflammatory effects through activation of brainstem catecholaminergic neurons and activation of the alpha-2 adrenergic and serotonergic pathways of the descending inhibitory system.[258–260] Melitin, an active ingredient of bee venom, can suppress lipopolysaccharide-induced nitric oxide and the transcription of cyclooxygenase-2 (COX-2) genes and proinflammatory cytokines, including TNF-α and IL-1β in microglia.[261,262] Injections of bee venom into specific acupuncture points in several animal and human studies of knee arthritis were beneficial and reduced pain levels significantly, but there are no studies that demonstrate the effectiveness of trigger point injections with bee venom.[259,263,264] Trigger point injections with the serotonin antagonist tropisetron were found to be more effective than injections with lidocaine solution, but injectable serotonin antagonists are not available in all countries.[265,266]

There is a growing body of literature supporting the use of botulinum toxin in the treatment of myofascial trigger points, although this remains a controversial issue. Many botulinum toxin studies fail to demonstrate superiority of botulinum toxin over placebo.[267] Yet, clinicians familiar with myofascial trigger points support its use, based on the demonstrated mechanisms of botulinum toxin and empirical evidence.[268,269] Indeed, several studies have shown significant benefit of botulinum toxin injec-

FIGURE 35.11 Trigger point injection to the frontalis muscle.

tions in the treatment of myofascial trigger points and various pain states, including migraine, tension-type headache, low back pain, and phantom pain.[270–272] Potential problems with these studies relate to the use of different dosages, varying injection sites, and the degree of familiarity with myofascial trigger points. Botulinum toxin prevents the release of ACh from the presynpatic nerve terminal.[268,273,274] ACh is released in response to evoked stimulation of the nerve or spontaneously without axonal nerve activation.[95,275,276] Botulinum toxin also has an antinociceptive effect, which in part may be due to its ability to also block the release of CGRP from the nerve terminal.[273,277–279]

Trigger point needling therapies are always part of a much broader treatment approach and should not be offered as a stand-alone intervention. Extensive training is required to gain the necessary palpation skills and kinesthetic awareness, without which trigger point needling would become a random process. Anatomical knowledge is required prior to developing the sensory-motor skills needed to visualize the tip of the needle and the pathway the needle follows inside patients' bodies.[159] Clinicians should be able to visualize a three-dimensional image of the exact location and depth of the trigger point and accurately elicit local twitch responses. The needle should not be used as a search tool except in muscles that cannot be palpated directly, such as the subscapularis or lateral pterygoid muscles. Trained clinicians can almost always identify clinically relevant trigger points, except in obese patients where certain muscles may not be accessible to palpation.[159] Eliciting local twitch responses is thought to be essential with trigger point needling to reach optimal treatment results.[160] As noted, research by Shah et al.[141,142] demonstrated that eliciting a local twitch response facilitated a normalization of the neuropeptides SP and CGRP in the local biochemical milieu of active trigger points. Myofascial trigger point injections were the second most common procedure after epidural injections in a study of Canadian pain anesthesiologists, although the art of trigger point injections and trigger point palpation are not usually covered in medical schools, and there are no formal postgraduate training programs in Canada.[280] In clinical practice, patients commonly report never having experienced local twitch responses when they were treated with trigger point injections previously.

Robinson and Arendt-Nielsen[37] suggested limiting the number of injections to no more than six during an initial treatment program with additional injections offered only as maintenance therapy. However, based on published studies, case studies, and empirical evidence, there are multiple benefits to reducing pain levels significantly before starting rigorous exercise programs.[159] Dry needling and injections can eliminate or reduce trigger point pain often in just a few sessions with a skilled clinician allowing the patient to be more successful in the conditioning phase of the rehabilitation program.[64,131,242,281–283] Patients enrolled in a stroke rehabilitation program performed significantly better in multiple variables after trigger points in their painful shoulder were treated with dry needling, compared to patients who did not get the needling therapy.[283] There are many other clinical outcome studies confirming that needling therapies are effective in inactivating trigger points and in reducing pain levels.[243,284–286]

In spite of a rapidly increasing number of clinical outcome studies, the exact mechanisms of trigger point injections and dry needling are not known.[159] Deep dry needling and trigger point injections may destroy motor endplates and cause distal axon denervations, which may trigger changes in the endplate cholinesterase and ACh receptors as part of the normal muscle regeneration process.[287,288] It is likely that trigger point needling involves central pain mechanisms, including the limbic system, the subcortical gray structures, and the descending inhibitory system. Most needling procedures are painful, possibly stretch fibroblasts in connective tissues, and activate the enkephalinergic, serotonergic, and noradrenergic inhibitory systems associated with A-δ fibers through segmental inhibition.[289–291] Superficial dry needling is often explained in a similar fashion; however, superficial dry needling is a painless procedure, which would not activate A-δ fibers, unless the needling is combined with rotating the needle after it has been inserted.[24,159] A-δ nerve fibers are only activated by nociceptive mechanical stimulation for type I high-threshold A-δ fibers or by cold stimuli for type II A-δ fibers.[292] It is conceivable that the light stimulus of superficial dry needling activates mechanoreceptors coupled to slow conducting unmyelinated C fiber afferents and stimulates the anterior cingulate cortex with emotional and hormonal reactions representing a sense of progress, reduction of pain, and well-being.[293–295] There is also evidence that superficial dry needling may stimulate a central release of oxytocin.[295,297]

Noninvasive Treatment Options

Rickards and Fernández-de-las-Peñas et al.[298,299] published comprehensive systematic reviews of noninvasive treatment options for myofascial pain. It is beyond the scope of this chapter to describe all approaches and the reader is referred to these reviews and to a descriptive review by Dommerholt et al.[41] A wide variety of manual therapies are being used in the treatment of myofascial trigger points, such as spray and stretch, trigger point compression, muscle energy techniques, massage, etc. There is some evidence of the short-term effectiveness of manual therapies, but no conclusions can be made in relation to the medium- and long-term effectiveness.[298] Fernández-de-las-Peñas et al.[300] demonstrated that trigger point compression and transverse friction massage were equally effective in treating trigger points with a significant reduction in visual analogue scores and significant increase in the pressure pain threshold. Hou et al.[301] showed that trigger point compression reduced pain levels within minutes.

The spray and stretch technique became nearly synonymous with Travell and consists of a vapocoolant such as ethylchloride or fluoromethane sprayed over the skin overlying the muscle into the referral zone of the trigger point, followed by stretching of the muscle.[34,39,253] Because of its detrimental effect on the ozone layer, fluoromethane was recently replaced by a new "spray and stretch" product. The new product contains hydrofluorocarbons and is classified as a "volatile organic compound" and is a powerful greenhouse gas.[302] The new product's carbon dioxide equivalent or global warming potential is 1300, which means that the product has a 1300 times greater greenhouse effect than carbon dioxide.[303] Manual therapies are environmentally safe and have been shown to be more effective.[304]

Several modalities have been applied to trigger points, such as laser, ultrasound, and electrotherapy.[298,299] Laser proved to be an effective modality in most trials.[305–311] Ultrasound has mixed reviews. A recent study demonstrated a short-term decrease of the sensitivity of trigger points following ultrasound.[312] Another study of high-power static ultrasound was more beneficial than more traditionally applied ultrasound, while two other papers did not show any benefit of ultrasound.[313–315] Transcutaneous electrical stimulation is the most studied electrotherapy modality, but it remains difficult to draw any conclusions beyond short-term effects.[304,314,316–319] A prospective, randomized study of extracorporeal shockwave therapy in the treatment of athletes with acute or chronic shoulder pain, showed significantly improved isokinetic force production, a reduction in pain, and overall performance.[320]

SUMMARY

Myofascial trigger points are a very common cause of clinically observed local muscle pain, tenderness, and referred pain in patients with acute and chronic pain. However, they are also a common physical finding in asymptomatic individuals. This di-

chotomy challenges and behooves pain management practitioners to learn how to palpate the soft tissue and distinguish active from latent myofascial trigger points. Making this distinction is critical in order to adequately identify and treat a myofascial component of pain. Several independent and emerging lines of scientific inquiry, including histological, neurophysiological, biochemical, and somatosensory research into the nature of myofascial trigger points have revealed objective abnormalities. These findings suggest that myofascial pain consists of both motor and sensory abnormalities involving the peripheral and central nervous systems. Accordingly, active myofascial trigger points may be viewed as part of a complex series of changes in the peripheral tissue and central nervous system that occur with central sensitization, characteristic of a form of neuromuscular dysfunction. From this perspective, future clinical research studies should focus on identifying the mechanisms responsible for the pathogenesis, amplification, and perpetuation of myofascial pain syndrome. Successful treatment depends upon identifying and targeting these mechanisms and addressing the perpetuating factors that sustain this common pain syndrome.

CHAPTER 36 ■ FIBROMYALGIA

DANIEL J. CLAUW

INTRODUCTION

Clinical practitioners commonly see patients with pain and other somatic symptoms that they cannot adequately explain based on the degree of damage or inflammation noted in peripheral tissues. In fact, this may be among the most common predicaments for which individuals seek medical attention.[1] Typically, an evaluation is performed looking for a ''cause'' for the pain. If none is found, these individuals are often given a diagnostic label that merely connotes that the patient has chronic pain in a region of the body, without an underlying mechanistic cause (e.g., chronic low back pain, headache, temporomandibular disorder [TMD], etc.). In other cases, the label given alludes to an underlying mechanism that may or may not be responsible for the individual's pain (e.g., ''facet syndrome'').

Fibromyalgia (FM) is merely the current term for individuals with chronic widespread musculoskeletal pain, for which no alternative cause can be identified. Gastroenterologists often see the exact same patients and focus on their gastroenterological complaints, and often use the terms functional GI disorder, irritable bowel syndrome (IBS), nonulcer dyspepsia, or esophageal dysmotility to explain the patient's symptoms.[2] Neurologists see these patients for their headaches and/or unexplained facial pain, urologists for pelvic pain and urinary symptoms (and use labels such as interstitial cystitis, chronic prostatitis, vulvodynia, and vulvar vestibulitis), dentists for TMD, and so on.

Until recently, these unexplained pain syndromes perplexed researchers, clinicians, and patients. However, it is now clear that:

- Individuals will sometimes only have one of these ''idiopathic'' pain syndromes over the course of their lifetime. But more often, individuals with one of these entities, and their family members, are likely to have several of these conditions.[3,4] Many terms have been used to describe these coaggregating syndromes and symptoms, including functional somatic syndromes, somatization disorders, allied spectrum conditions, chronic multisymptom illnesses, medically unexplained symptoms, etc.[3,5–7]
- Women are more likely to have these disorders than men, but the sex difference is much more apparent in clinical samples (especially tertiary care) than in population-based samples.[8,9]
- Groups of individuals with these conditions (e.g., FM, IBS, headache, TMD, etc.) display diffuse hyperalgesia (increased pain to normally painful stimuli) and/or allodynia (pain to normally nonpainful stimuli).[10–14] This suggests that these individuals have a fundamental problem with pain or sensory processing rather than an abnormality confined to the region of the body where the person is currently experiencing pain.
- Similar types of therapies are efficacious for all of these conditions, including both pharmacological (e.g., tricyclic compounds such as amitriptyline) and nonpharmacological treatments (e.g., exercise, cognitive behavioral therapy). Conversely, individuals with these conditions typically do not respond to therapies that are effective when pain is due to damage or inflammation of tissues (e.g., NSAIDs, opioids, injections, surgical procedures).

Until perhaps a decade or ago, these conditions were all on somewhat equal (and tenuous) scientific ground. But, within a relatively short period of time, research methods such as experimental pain testing, functional imaging, and genetics have led to tremendous advances in the understanding of several of these conditions, most notably FM, IBS, and TMD. Many in the pain field now feel that chronic pain itself is a ''disease,'' and that many of the underlying mechanisms operative in these heretofore-considered ''idiopathic'' or ''functional'' pain syndromes may be similar whether the pain is present throughout the body (e.g., in FM) or localized to the low back, the bowel, or the bladder. Because of this, the more contemporary terms used to describe conditions such as FM, IBS, TMD, vulvodynia, and many other entities include ''central pain,'' ''neuropathic pain'' (when this term is used in this setting, it is meant to imply that the pain is coming from the nervous system rather than the periphery, rather than connoting that the pain is due to nerve damage), or ''nonnociceptive pain.''[15,16]

The review regarding fibromyalgia below focuses on our current understanding of this disorder as one of the prototypical ''central pain syndromes.''

HISTORICAL PERSPECTIVE

Although the term fibromyalgia is relatively new, this condition has been described in the medical literature for centuries. Sir William Gowers coined the term *fibrositis* in 1904. During the next half century, fibrositis (as it was then called) was considered by some to be a common cause of muscular pain, by others to be a manifestation of tension or psychogenic rheumatism, and by the rheumatology community in general to be a nonentity.

The current concept of fibromyalgia was established by

Smythe and Moldofsky in the mid-1970s.[17] The name change reflected the fact that there was increasing evidence that there was no *–itis* (inflammation) in the connective tissues of individuals with this condition, but instead *–algia* (pain). These authors characterized the most common tender points (regions of extreme tenderness in these individuals), and reported that patients with fibromyalgia had disturbances in deep and restorative sleep, and that selective stage 4 interruptions induced the symptoms of fibromyalgia.[18] Yunus and others then reported on the major clinical manifestations of patients with fibromyalgia seen in rheumatology clinics.[19]

The next advance in fibromyalgia was the development of the American College of Rheumatology (ACR) criteria for fibromyalgia, which were published in 1990.[20] These classification criteria require that an individual have both a history of chronic widespread pain (CWP) and 11 or more of a possible 18 tender points on examination. These ACR classification criteria were intended for research use, to standardize definitions of fibromyalgia. In this regard, the criteria have been extremely valuable. Unfortunately, many practitioners use these criteria in routine clinical practice to diagnose individual patients, and this unintended use has led to many of the current misconceptions regarding fibromyalgia, that are discussed later.

The finding of diffusely increased tenderness, as well as a lack of finding "–itis" in the muscles or other tissues of FM patients, caused the name of this entity to be changed from fibrositis to fibromyalgia. The diffuse nature of the pain and tenderness also led many groups of investigators that began to explore neural mechanisms to explain the underlying pathogenesis of these disorders.[21,22] In fact, major advances have only occurred in understanding individual syndromes within this spectrum once investigators concluded that this was not a condition caused by peripheral damage or inflammation and began to explore central, neural mechanisms of these diseases. Thus, the conditions we now understand best within this spectrum include FM, IBS (previously termed "spastic colitis" until the recognition that there was little –itis and that motility changes were not the major pathological feature), and TMD (previously termed temporomandibular joint disorder until it was recognized the problem was not largely within the joint).

EPIDEMIOLOGY

Chronic Widespread Pain

Epidemiological studies of the historical component of the ACR criteria for fibromyalgia, CWP, have been extremely instructive. CWP is typically operationalized as pain above and below the waist, involving the left and right sides of the body, and also involving the axial skeleton. Population-based studies of CWP suggest that 5% to 15% of the population has this symptom at any given point in time.[23–25] Chronic regional pain is found in 20% to 25% of the population. Both CWP and regional pain occur about 1.5 times as commonly in women than men.

Fibromyalgia

The ACR criteria for FM require that an individual has both a history of CWP, and the finding of 11 or more of 18 possible tender points on examination. Tender points represent nine paired predefined regions of the body, often over musculotendinous insertions.[20] If an individual reports pain when a region is palpated with 4 kg of pressure, this is considered a positive tender point. Between 25% and 50% of individuals who have CWP will also have 11 or more tender points, and thus meet criteria for fibromyalgia.[25,26] The prevalence of fibromyalgia is just as high in rural or nonindustrialized societies as it is in countries such as the U.S.[27–29]

Significance of Tender Points

At the time the ACR criteria were published it was thought that there may be some unique significance to the locations of tender points. In fact, a term *control points* was coined to describe areas of the body that should not be tender in fibromyalgia, and individuals were assumed to have a psychological cause for their pain if they were tender in these regions. Since then, we have learned that the tenderness in fibromyalgia extends throughout the entire body. Thus relative to the pain threshold that a normal nonfibromyalgia patient would experience at the same points, "control" regions of the body such as the thumbnail and forehead are just as tender as in fibromyalgia tender points.[30–32] Thus, to assess tenderness in clinical practice, the practitioner can apply pressure wherever he/she wishes, and as long as they perform this exam with the same pressure in a series of patients, they can get a good sense of the overall pain threshold of any individual patient.

The tender point requirement in the ACR criteria not only misrepresents the nature of the tenderness in this condition (i.e., local rather than widespread), but also strongly influences the demographic and psychological characteristics of FM. Women are only 1.5 times more likely than men to experience CWP, but are 10 times more likely than men to have 11 or more tender points.[23] Because of this, women are approximately 10 times as likely to meet ACR criteria for fibromyalgia as men. Yet, most of the men in the population that have CWP but are not tender enough to meet criteria for FM likely have the same underlying problem as the women who meet the ACR criteria for FM.

Another unintended consequence of requiring both CWP and at least 11 tender points to be diagnosed with FM is that many individuals with fibromyalgia will have high levels of distress. Wolfe has described tender points as a "sedimentation rate for distress" because of population-based studies showing that tender points are more common in distressed individuals.[33] Distress is usually considered as a combination of somatic symptoms and symptoms of anxiety and/or depression.[33] Until recently, many assumed that because *tender points* were associated with distress, that *tenderness* (an individual's sensitivity to mechanical pressure) was associated with distress. However, recent evidence suggests that this latter association is probably due to the standard tender point technique, which consists of applying steadily increasing pressure until reaching 4 kg. In this situation, individuals who are anxious or "expectant" have a tendency to "bail out" and report tenderness. Recently, more sophisticated measures of tenderness have been developed which give stimuli in a random, unpredictable fashion, and the results of these tests are independent of psychological status.[34,35] Since tender points are associated with high levels of distress, requiring 11 or more tender points in order to diagnose someone with CWP with fibromyalgia dramatically increases the likelihood that these individuals will be female and/or and distressed, compared to individuals with CWP and <11 tender points.[25]

In fact, population-based studies suggest that the primary symptom of fibromyalgia, CWP, is only modestly associated with distress, and distress is only weakly associated with the subsequent development of CWP.[36,37] There are far more psychologically "normal" individuals who develop CWP than distressed or depressed people that do, and most individuals with CWP do not have or subsequently develop distress or depression.

In summary, although many clinicians uniquely associate fibromyalgia with women who display high levels of distress, much of this is an artifact of: (1) the ACR criteria that require 11 tender points, and (2) the fact that most studies of FM have originated from clinical samples from tertiary care centers, where healthcare seeking behaviors lead to the fact that psychological and psychiat-

TABLE 36.1

"STRESSORS" CAPABLE OF TRIGGERING FIBROMYALGIA AND RELATED CONDITIONS

- Peripheral pain syndromes
- Infections (e.g., parvovirus, EBV, Lyme disease, Q fever; not common upper respiratory infections)
- Physical trauma (automobile accidents)
- Psychological stress/distress
- Hormonal alterations (e.g., hypothyroidism)
- Drugs
- Vaccines
- Certain catastrophic events (war, but not natural disasters)

ric comorbidities are much higher.[9] When all these biases are eliminated by examining CWP in population-based studies, a clearer picture of fibromyalgia can be gleaned, and CWP becomes much like chronic musculoskeletal pain in any other region of the body.

ETIOLOGY

Genetic Factors

Research has indicated a strong familial component to the development of fibromyalgia. First degree relatives of individuals with fibromyalgia display an eightfold greater risk of developing fibromyalgia than those in the general population.[4] Family members of individuals with fibromyalgia are much more tender than the family members of controls, regardless of whether they have pain or not. Family members of fibromyalgia patients are also much more likely to have IBS, TMD, headaches, and other regional pain syndromes.[3,38,39] This familial and personal coaggregation of conditions which includes fibromyalgia was originally collectively termed *affective spectrum disorder*,[40] and more recently *central sensitivity syndromes* and chronic multisymptom illnesses.[7,41] In population-based studies, the key symptoms that often coaggregate besides pain are fatigue, memory difficulties, and mood disturbances.[7,42] Twin studies suggest that approximately half of the risk of developing CWP is due to genetic factors, and half environmental.[43]

Recent studies have begun to identify specific genetic polymorphisms that are associated with a higher risk of developing fibromyalgia. To date, the serotonin 5-HT2A receptor polymorphism T/T phenotype, serotonin transporter, dopamine 4 receptor, and COMT (catecholamine *o*-methyl transferase) polymorphisms have all been noted to be seen in higher frequency in fibromyalgia.[44–47] All of the polymorphisms identified to date involve the metabolism or transport of monoamines, compounds that play a critical role in activity of the human stress response. It is likely that there are scores of genetic polymorphisms, involving other neuromodulators as well as monoamines, which in part determine an individuals' "set point" for pain and sensory processing.

Environmental Factors

As with most illnesses that may have a genetic underpinning, environmental factors may play a prominent role in triggering the development of fibromyalgia and related conditions. Environmental "stressors" temporally associated with the development of either fibromyalgia or chronic fatigue syndrome include physical trauma (especially involving the trunk), certain infections such as Hepatitis C, Epstein Barr virus, parvovirus, Lyme disease, and emotional stress (Table 36.1). The disorder is also associated with other regional pain conditions or autoimmune disorders[22,48,49] (Figs. 36.1 and 36.2). Each of these stressors only leads to CWP or fibromyalgia in about 5% to 10% of individuals who are exposed; most individuals who experience these same infections or other stressful events regain their baseline state of health.

An example of how illnesses such as FM might be triggered occurred in the setting of the deployment of troops to liberate Kuwait during the Gulf War in 1990 and 1991. The term "Gulf War illnesses" is now commonly used to refer to a constellation of symptoms developed by some 10% to 15% of the 700,000 U.S. troops deployed to the Persian Gulf in the early 1990s. The symptoms, which include headaches, muscle and joint pain, fatigue, memory disorders, and gastrointestinal distress,[7] were seen in troops deployed from the United Kingdom (UK) and other countries as well.[50] The panels of experts who examined potential causes for these symptoms and syndromes found that the sickness could not be traced to any single environmental trigger, and noted the similarities between these individuals, and those diagnosed with fibromyalgia and chronic fatigue. Furthermore, similar syndromes involving multiple somatic symptoms have been noted in veterans of every war the U.S. or UK has been involved in during the past century.[51] This suggests that war may be an environment where individuals are simultaneously exposed to a multitude of "stressors," triggering the development of this type of illness in susceptible individuals.[52]

The previously noted relationship between individuals with other chronic rheumatic or autoimmune disorders deserves special attention, because of the relevance to practicing clinicians. As many as 25% of patients correctly diagnosed with generalized inflammatory disorders such as systemic lupus erythematosus

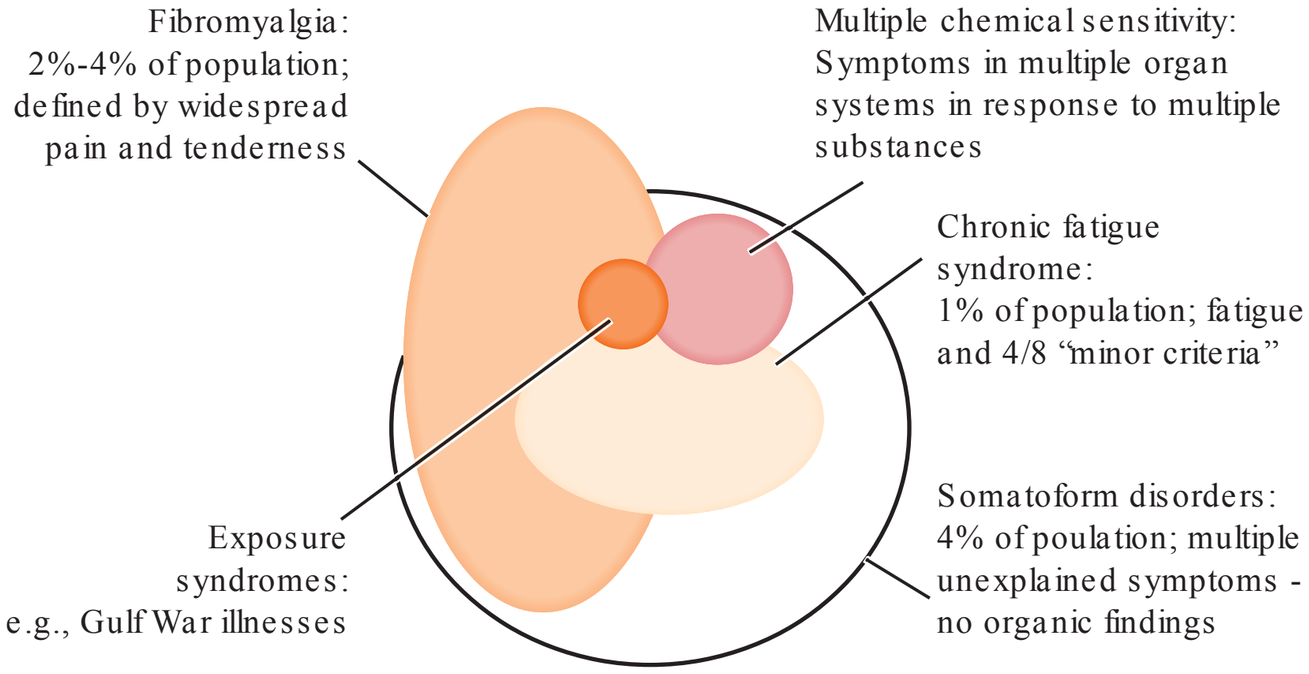

FIGURE 36.1 Regional or localized syndromes that overlap with fibromyalgia in prevalence, mechanisms, and treatment.

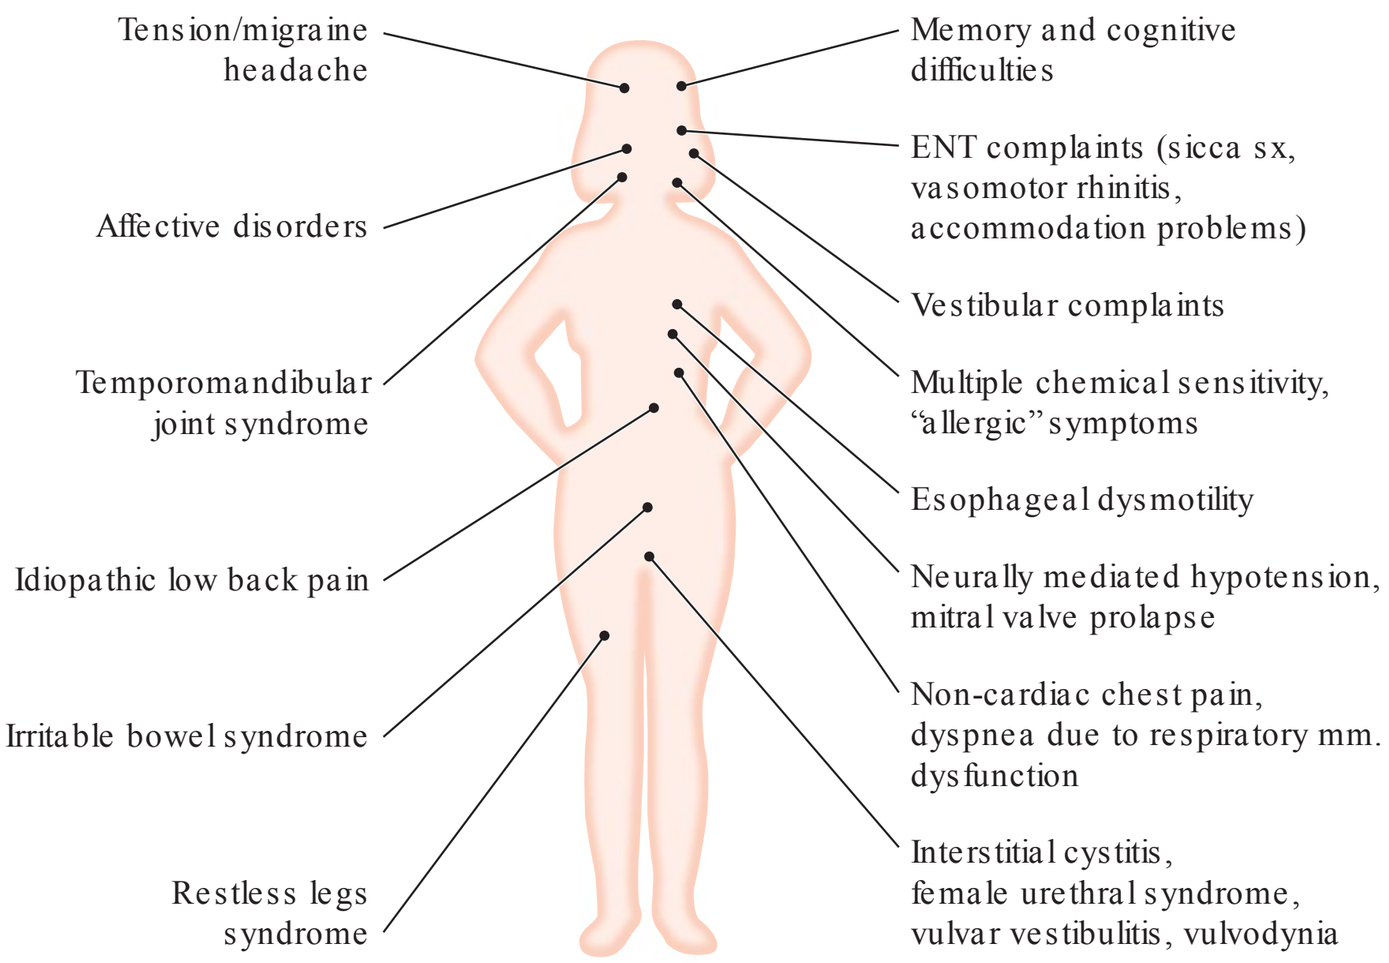

FIGURE 36.2 The "systemic" conditions that overlap with fibromyalgia.

(SLE), rheumatoid arthritis (RA), and ankylosing spondylitis will also fulfill ACR criteria for FM.[53] However, in clinical practice this coexpression may go unrecognized, especially when the FM develops after the autoimmune disorder or regional pain syndrome. In this setting, when comorbid fibromyalgia goes unrecognized, patients are often unnecessarily treated more aggressively with toxic immunosuppressive drugs.

PATHOGENESIS

Role of Stressors

Once FM develops, the mechanisms responsible for ongoing symptom expression are likely complex and multifactorial. Because of the fact that disparate "stressors" can trigger the development of these conditions, the human stress response has been closely examined for a causative role. These systems are mediated primarily by the activity of the corticotropin-releasing hormone (CRH) nervous system located in the hypothalamus and locus-ceruleus-norepinephrine/autonomic (sympathetic/LC-NE) nervous system in the brainstem. Recent research suggests that although this system in humans has been highly adaptive throughout history, the stress response may be inappropriately triggered by a wide assortment of everyday occurrences that do not pose a real threat to survival, thus initiating the cascade of physiological responses more frequently than can be tolerated.[54]

The type of stress and the environment in which it occurs also have an impact on how the stress response is expressed. Victims of accidents experience a higher frequency of fibromyalgia and myofascial pain than those who cause them, which is congruent with animal studies showing that that the strongest physiological responses are triggered by events that are accompanied by a lack of control or support, and thus viewed as perceived as inescapable or unavoidable.[55] In humans, daily "hassles" and personally relevant stressors seem to be more capable of causing symptoms than major catastrophic events that do not personally impact on the individual.[56]

Two studies performed in the U.S. just before and after the terrorist attacks of September 11th point out that not all psychological stress is capable of triggering or exacerbating fibromyalgia or somatic symptoms. In one study performed by Raphael and colleagues, no difference in pain complaints or other somatic symptoms was seen in residents of New York and New Jersey who had been surveyed prior to September 11th, and then just following the terrorist attacks on the World Trade Center.[57] In another study performed in the Washington, DC, region (near the Pentagon—the other site of attack) during the same time period, patients with fibromyalgia had no worsening of pain or other somatic symptoms following the attacks, compared to just before the attack.[58]

Recent reviews regarding the role that "stressors" (e.g., infections, physical trauma, and emotional stress) or catastrophic events may have in triggering the development of fibromyalgia or related conditions have identified a number of factors that may be much more important than the intensity of the "stressor" in predicting adverse health outcomes. Female gender, worry or expectation of chronicity, and inactivity or time off work following the stressor make it more likely to trigger the development of pain or other somatic symptoms.[49] Naturally occurring catastrophic events such as earthquakes, floods, or fires are much less likely to lead to chronic somatic symptoms than similarly stressful events that are "man-made" such as chemical spills or war.[59] Being exposed to a multitude of stressors simultaneously, or over a period of time, may also be a significant risk for later somatic symptoms and or psychological sequelae. Intensely stressful events can lead to permanent changes in the activity of both mouse and human stress response systems.[54,60]

To complete this vicious circle, these changes in baseline function of the stress response (i.e., of the autonomic and neuroendocrine systems—see later) that may occur following a stressor earlier in life have been shown to predict which symptom-free individuals without chronic pain or other somatic symptoms are more likely to develop these somatic symptoms. This has been noted both in population-based studies and in experiments where healthy young adults are deprived of regular sleep or exercise.[61,62]

This theoretical link between stress, changes in stress axis activity, and subsequent susceptibility to develop somatic symptoms or syndromes is also supported by studies showing that patients with fibromyalgia and related conditions may be more likely than nonaffected individuals to have experienced physical or sexual abuse in childhood.[63–66] Twin studies have recently supported a link between posttraumatic stress disorder (PTSD) and trauma, and CWP.[67] Just as a lack of or cessation of exercise following trauma seems to be associated with a higher likelihood of developing pain or other somatic symptoms, a recent study of

Israeli war veterans with PTSD showed that those who exercised regularly were much less likely to develop CWP or fibromyalgia.[68]

Role of Neuroendocrine Abnormalities

Because of this link between exposure to "stressors" and the subsequent development of fibromyalgia, the human stress systems have been extensively studied in this condition. These studies have generally shown alterations of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system in fibromyalgia and related conditions.[69–74] Although these studies often note either hypo- or hyperactivity of both the HPAl axis and sympathetic nervous system in individuals with fibromyalgia and related conditions, the precise abnormality varies from study to study. Moreover, these studies only find "abnormal" HPA or autonomic function in a very small percentage of patients, and there is tremendous overlap between patients and controls in many of these studies.

The inconsistency of these findings should not be surprising, since nearly all of these studies were cross-sectional studies that assumed that if HPA and/or autonomic dysfunction was found in fibromyalgia, it must have *caused* the pain and other symptoms. Data now suggest the opposite. As noted previously, there are better data suggesting that (especially HPA abnormalities) might represent a diathesis or be *due to* the pain or early life stress, rather than causing it. In fact in two recent studies examining HPA function in fibromyalgia, McLean showed that salivary cortisol levels covaried with pain levels, and that CSF levels of CRH were more closely related to an individual's pain level or a history of early life trauma than whether they were a fibromyalgia patient or control.[75,76] Since most previous studies of HPA and autonomic function in fibromyalgia failed to control for pain levels, a previous history of trauma, and PTSD or other comorbid disorders that could affect HPA or autonomic dysfunction, it is not surprising for these inconsistencies to exist.

Heart rate variability at baseline and in response to tilt table testing has been evaluated in patients with fibromyalgia as a surrogate measure of autonomic function. The consistent and reproducible finding of lower baseline heart rate variability in FM compared to controls makes it a more useful measure than tilt table testing.[73,74,77] An abnormal drop in blood pressure or excessive rate of syncope during tilt table testing has also been noted in most studies.[78–80] Moreover, recent findings also suggest that aberrations in heart rate variability may predispose to fibromyalgia symptoms,[61,62,81] possibly identifying patients at risk. Also, a recent study showed that heart rate variability was normalized following exercise therapy, suggesting that this finding might also be an epiphenomenon due in part to deconditioning.[82]

It is likely that these neurobiological alterations are shared with other syndromes that are known to be associated with HPA and/or autonomic function such as depression or PTSD. A model of susceptibility and development of these disorders, that takes into account both genetics and personality as risk factors, is illustrated in Figure 36.3. This recognizes the critical importance of stressors in "resetting stress response systems," as well as other factors including (1) the role of behavioral adaptations to these stressors such as cessation of routine exercise and (2) whether an individual is in an environment characterized by control or support.

Augmented Pain and Sensory Processing as a Hallmark of Fibromyalgia and Related Syndromes

Once fibromyalgia is established, by far the most consistently detected objective abnormalities involve pain and sensory

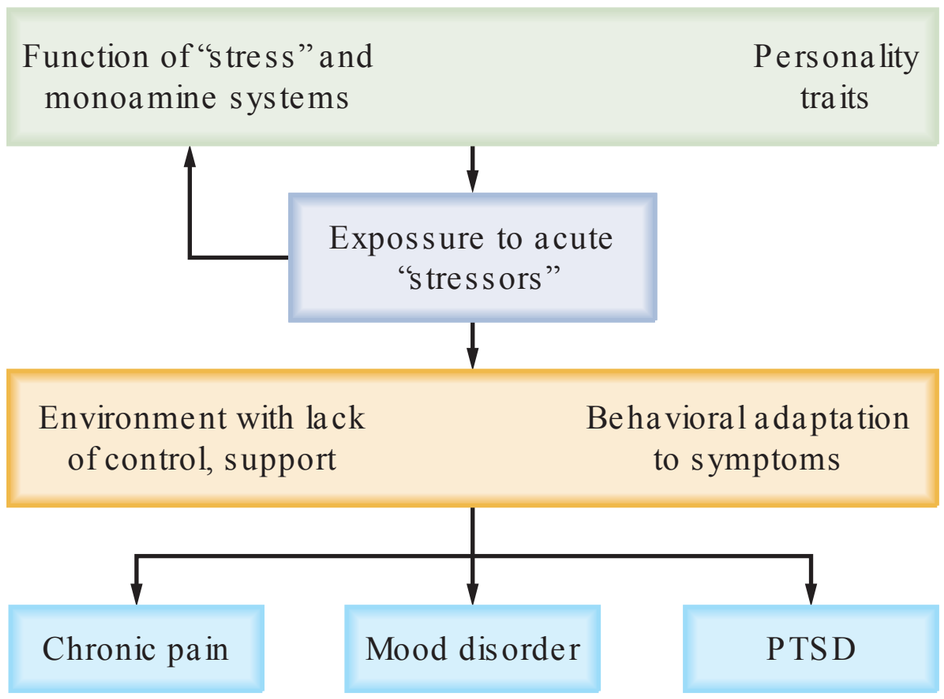

FIGURE 36.3 The hypothesized relationship between "stressors" and the development of syndromes such as fibromyalgia, PTSD, and depression.

processing systems. Since FM is defined in part by tenderness, considerable work has been performed exploring the potential reason for this phenomenon. The results of two decades of psychophysical pressure pain testing in fibromyalgia have been very instructive.

One of the earliest findings in this regard was that the tenderness in fibromyalgia is not confined to tender points, but instead extends throughout the entire body.[23,31] Theoretically, such diffuse tenderness could be either primarily due to psychological (e.g., hypervigilance, where individuals are too attentive to their surroundings), or neurobiological (e.g., the plethora of factors that can lead to temporary or permanent amplification of sensory input) factors.

Early studies typically used dolorimetry to assess pressure pain threshold, and concluded that tenderness was in large part related to psychological factors, because these measures of pain threshold were correlated with levels of distress.[23,33,83] Also, nuances such as the rate of increase of stimulus pressure, control by the operator versus by the patient, and patient distress have been shown to influence pain threshold when it is measured in this manner.[84,85]

To minimize the biases associated with "ascending" (i.e., the individual knows that the pressure will be predictably increased) measures of pressure pain threshold, Petzke and colleagues performed a series of studies using more sophisticated paradigms using random delivery of pressures.[30,35,86,87] These studies showed that: (1) the random measures of pressure pain threshold were not influenced by levels of distress of the individual, whereas tender point count and dolorimetry exams were; (2) fibromyalgia patients were much more sensitive to pressure even when these more sophisticated paradigms were used; (3) fibromyalgia patients were not any more "expectant" or "hypervigilant" than controls; and (4) pressure pain thresholds at any 4 points in the body are highly correlated with the average tenderness at all 18 tender points and 4 "control points" (the thumbnail and forehead).

Because of this close link between tenderness and fibromyalgia, this phenomenon has also been well studied as a potential relevant outcome in clinical trials of new fibromyalgia therapies. In a number of longitudinal randomized placebo-controlled trials of fibromyalgia, improvements in clinical pain have corresponded with a significant change in tender point counts or tender point index.[88] In contrast, other studies did not show a correspondence between improvements in clinical pain and tender point counts.[89–94] These discrepancies between previous studies could either be because these therapies did not improve tenderness, or

because tender points are not a good measure of tenderness. Two recent studies suggest the latter because, when individuals with fibromyalgia were simultaneously assessed using tender point counts, dolorimetry, and random pressure paradigms, the random pressure paradigms showed the most responsiveness to change.[95,96]

Heat, Cold, and Electrical Stimuli

In addition to the heightened sensitivity to pressure noted in fibromyalgia, other types of stimuli applied to the skin are also judged as more painful or noxious by these patients. Fibromyalgia patients also display a decreased threshold to heat,[86,97–99] cold,[98,100] and electrical stimuli.[101] Similar but somewhat attenuated decreases in pain threshold have also been noted in individuals with CWP without 11 or more tender points.[102]

Responses to Other Sensory Stimuli

Gerster and colleagues were the first to demonstrate that fibromyalgia patients also display a low noxious threshold to auditory tones, and this finding was subsequently replicated.[103,104] However, both of these studies used ascending measures of auditory threshold, so these findings could theoretically be due to expectancy or hypervigilance. A recent study by Geisser and colleagues used an identical random staircase paradigm to test fibromyalgia patients' threshold to the loudness of auditory tones and to pressure.[96] This study found that fibromyalgia patients displayed low thresholds to both types of stimuli and the correlation between the results of auditory and pressure pain threshold testing suggested that some of this was due to shared variance, and some were unique to one stimulus or the other. The notion that fibromyalgia and related syndromes might represent biological amplification of all sensory stimuli has significant support from functional imaging studies that suggest that the insula is the most consistently hyperactive region (see later text). This region has been noted to play a critical role in sensory integration, with the posterior insula serving a purer sensory role, and the anterior insula being associated with the emotional processing of sensations.[105–107]

Specific Mechanisms That May Lead to a Low Pain Threshold in Fibromyalgia

There are two different specific pathogenic mechanisms in fibromyalgia that have been identified using experimental pain testing: (1) an absence of descending analgesic activity, and (2) increased wind-up or temporal summation.

Attenuated Diffuse Noxious Inhibitory Controls in Fibromyalgia. In healthy humans and laboratory animals, application of an intense painful stimulus for 2 to 5 minutes produces generalized whole-body analgesia. This analgesic effect, termed diffuse noxious inhibitory controls (DNIC), has been consistently observed to be attenuated or absent in groups of FM patients, compared to healthy controls.[98,108–110] Wilder-Smith and colleagues have performed studies suggesting that in IBS there is a similar decrease in descending analgesic activity.[111] A point of emphasis is that this finding of attenuated DNIC is not found in all fibromyalgia or IBS patients, but is considerably more common in patients than controls.

The DNIC response in humans is believed to be partly mediated by descending opioidergic pathways and in part by descending serotonergic-noradrenergic pathways. In fibromyalgia, the accumulating data suggests that opioidergic activity is normal or even increased, in that levels of cerebrospinal fluid (CSF) enkephalins are roughly twice as high in FM and idiopathic low back pain patients as in healthy controls.[112] Moreover, positron emission tomography (PET) data show that baseline mu-opioid receptor binding is decreased in multiple pain processing regions in the brains of FM patients, consistent (but not pathognomonic) with the hypothesis that there is increased release of endogenous mu-opioid ligands in FM leading to high baseline occupancy of the receptors.[113]

The biochemical and imaging findings suggesting increased activity of endogenous opioidergic systems in FM are consistent with the anecdotal experience that opioids are generally ineffective analgesics in patients with FM and related conditions. In contrast, studies have shown the opposite for serotonergic and noradrenergic activity in FM. Studies have shown that the principal metabolite of norepinephrine, 3-methoxy-4-hydroxyphenethylene (MPHG), is lower in the CSF of FM patients.[114] Similarly, there are data suggesting low serotonin in this syndrome. Patients with FM were shown to have reduced serum levels of serotonin and its precursor, L-tryptophan, as well as reduced levels of the principal serotonin metabolite, 5-HIAA, in their CSF.[114,115] Further evidence for this mechanism comes from treatment studies, where nearly any type of compound that simultaneously raises both serotonin and norepinephrine (tricyclics, duloxetine, milnacipran, tramadol) has been shown to be efficacious in treating FM and related conditions.[94,116–118]

Increased Wind-up in Fibromyalgia. Experimental pain testing studies have also suggested that some individuals with fibromyalgia may have evidence of wind-up, indicative of evidence of central sensitization.[119,120] In animal models, this finding is associated with excitatory amino acid and substance P hyperactivity.[121–123] Just as with the findings regarding DNIC, these results of psychophysical pain testing are congruent with both levels of neurotransmitters in the CSF, as well as clinical trials of drugs. Four independent studies have shown that patients with FM have approximately threefold higher concentrations of substance P in CSF, when compared with normal controls[124–127] (Fig. 36.4). Other chronic pain syndromes, such as osteoarthritis of the hip and chronic low back pain, are also associated with elevated substance P levels, although chronic fatigue syndrome (which is not defined on the basis of pain) is not. Interestingly, once elevated, substance P levels do not appear to change dramatically, and do not rise in response to acute painful stimuli. Thus, high substance P appears to be a biological marker for the presence of chronic pain.

Another important neurotransmitter in pain processing, and one that likely is playing some role in FM, is glutamate. Glutamate (Glu) is a major excitatory neurotransmitter within the central nervous system, and CSF levels of glutamate are twice as high in FM patients than controls.[128] Not only are these levels elevated, but a recent study using proton spectroscopy demonstrated that the glutamate levels in the insula in fibromyalgia change in response to changes in both clinical and experimental pain when patients are treated with acupuncture.[129]

Nerve growth factor (NGF) and calcitonin gene-related peptide are additional neuropeptides that have been evaluated in FM. NGF was shown in one study to have increased levels in FM and not in FM/RA and therefore with inconclusive results.[130] CSF and serum CGRP have been studied and not found to be different in fibromyalgia patients and controls.[131,132]

Thus, a number of lines of evidence point to the fact that fibromyalgia is a state of heightened pain or sensory processing, and that this might occur because of high levels of neurotransmitters that increase pain transmission, and/or low levels of neurotransmitters that decrease pain transmission (Fig. 36.5).

Abnormalities on Functional Neuroimaging

Functional neural imaging enables investigators to visualize how the brain processes the sensory experience of pain. The primary modes of functional imaging that have been used in FM include functional magnetic resonance imaging (fMRI), single photon

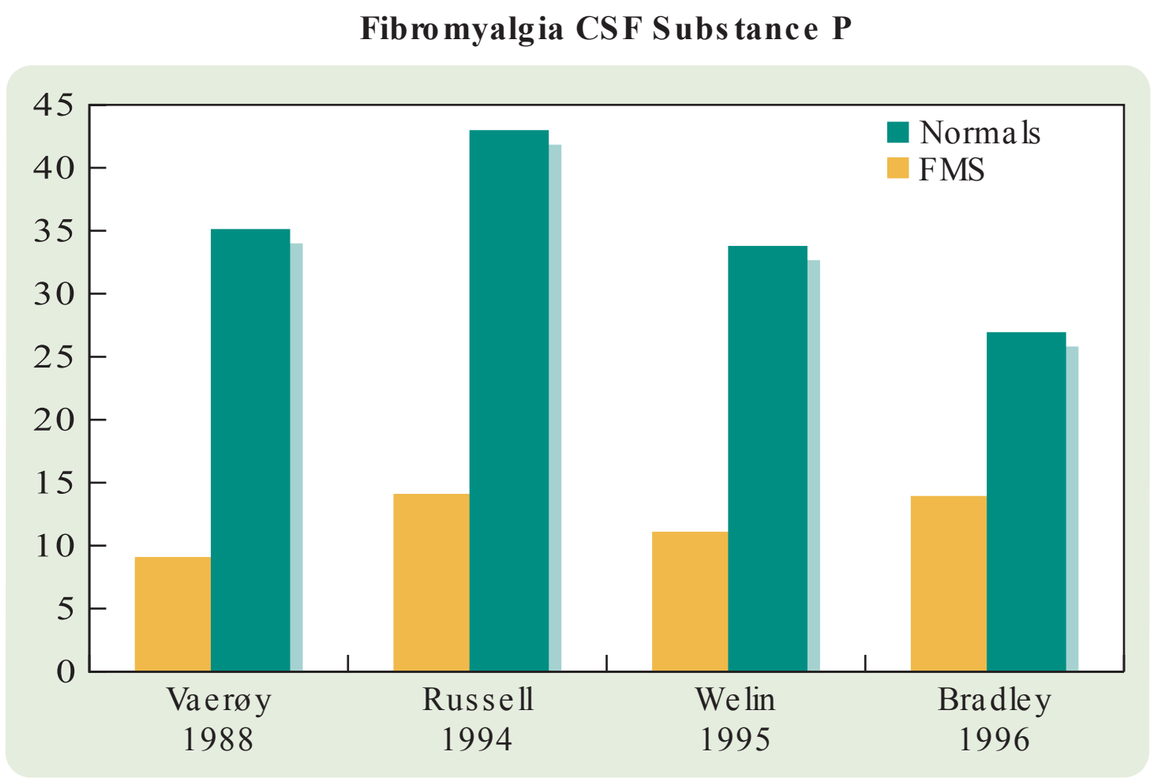

FIGURE 36.4 Levels of cerebrospinal fluid of substance P in four different studies of FM

emission computed tomography (SPECT), PET, and proton spectroscopy (H-MRS).

SPECT was the first functional neuroimaging technique to be used in fibromyalgia. SPECT imaging involves the introduction of radioactive compounds into the participant's bloodstream, which then decay over time giving a window for neural activity assessment. The first trial using SPECT imaging in FM patients was conducted by Mountz et al.[133] Their data from 10 FM patients and 7 age- and education-matched healthy controls indicated that both the caudate and the thalamus of FM patients had decreased blood flow. The findings by Mountz et al. were largely replicated in a second SPECT study by Kwiatek et al.[134] In a third SPECT trial, Guedj et al. reported a study using a more sensitive radioligand (99mTc-ECD) in FM patients and pain free controls.[135,136] Guedj et al. found hyperperfusion in FM patients within the somatosensory cortex and hypoperfusion in the anterior and posterior cingulate, the amygdala, medial frontal and parahippocampal gyrus, and the cerebellum. Finally, if these regional cerebral blood flow (rCBF) differences are relevant for fibromyalgia pathology, one could hypothesize that changes in rCBF should track with changes in pain symptoms over time. One longitudinal treatment trial used SPECT imaging to assess changes in rCBF following administration of amitriptyline within 14 FM patients.[137] After 3 months of treatment with amitriptyline, increases in rCBF in the bilateral thalamus and the basal ganglia were observed. Since the same two regions had been implicated previously, these data suggest that amitriptyline may normalize the altered blood flow thereby reducing pain symptoms.

fMRI is a noninvasive brain imaging technique that relies on changes in the relative concentration of oxygenated to deoxygenated hemoglobin within the brain. In response to neural activity, oxygenated blood flow is increased within the local brain area. This causes a decrease in the concentration of deoxygenated hemoglobin. Since deoxygenated hemoglobin is paramagnetic, this in turn causes a change in the magnetic property of the tissue. Unlike SPECT and PET which can measure baseline levels of blood flow, the fMRI BOLD signal originates from a difference between experimental conditions and does not assess baseline blood flow. Typically in fibromyalgia trials involving fMRI, evoked pain sensations are compared to "off" conditions that have either no pain or involve an innocuous sensation.

The first study to use fMRI in fibromyalgia patients was performed by Gracely et al. In this study 16 fibromyalgia patients and 16 matched controls were exposed to painful pressures during the fMRI experiment.[138] The authors found increased neural activations (i.e., increases in the BOLD signal) in patients compared to pain free controls, when stimuli of equal pressure magnitude were administered. Regions of increased activity included the primary and secondary somatosensory cortex, the insula, and the anterior cingulate—all regions commonly observed in fMRI

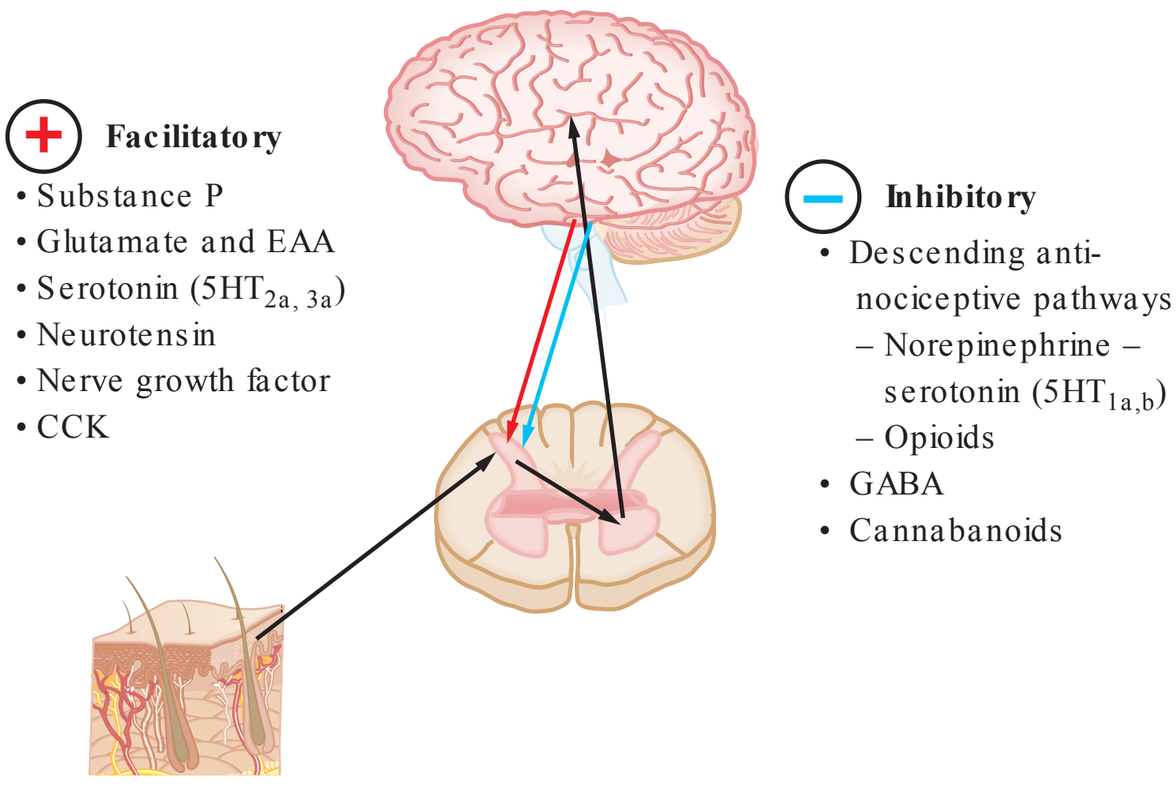

FIGURE 36.5 Neurotransmitters that are known to play either facilitatory (increase pain transmission) or inhibitory (decrease pain transmission) roles in the central nervous system.

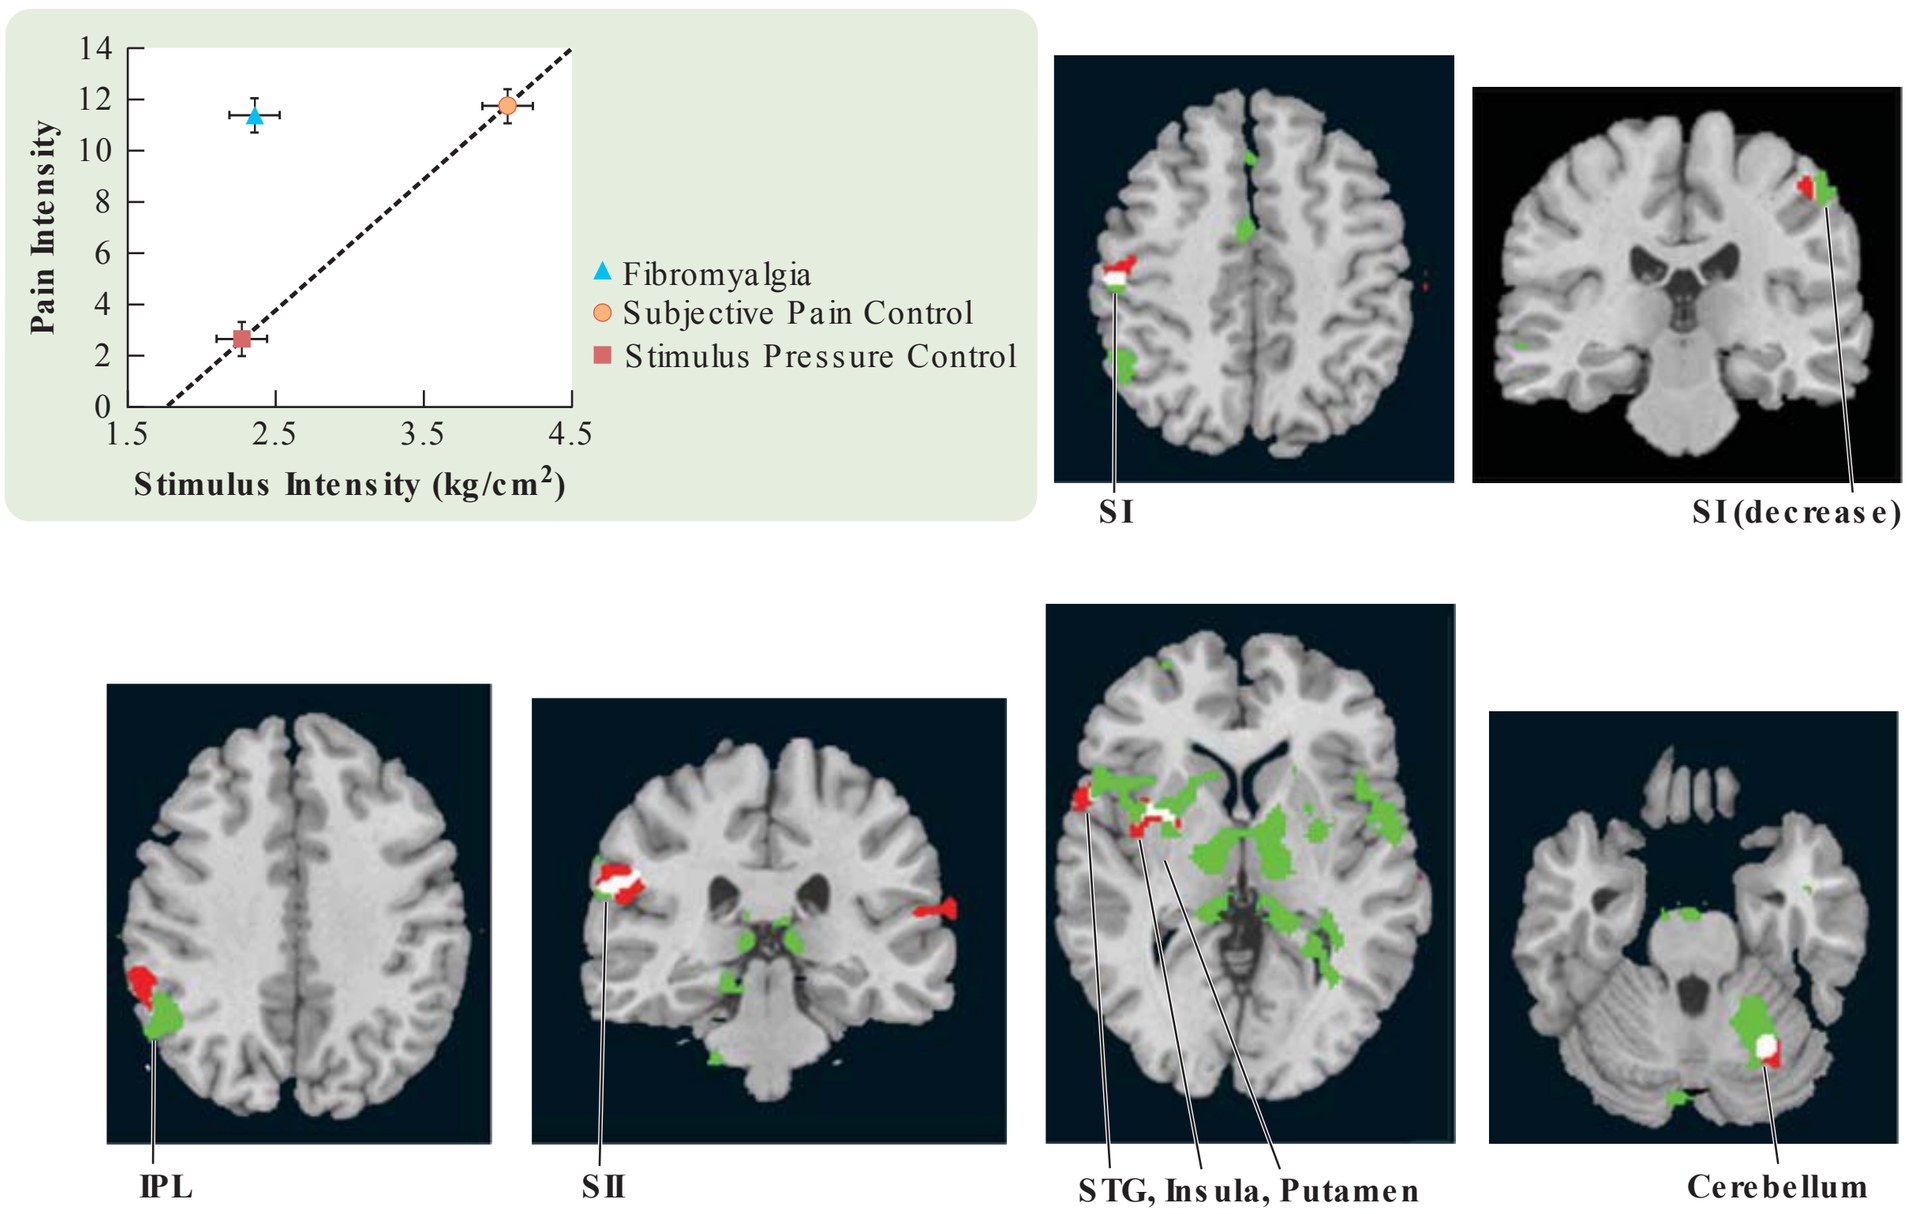

FIGURE 36.6 In *top left* panel, individuals with fibromyalgia (*red*) given a low pressure stimulus have similar levels of pain, and of neuronal activation in areas of the brain known to be involved in pain processing (*ends of arrows*) as controls given nearly twice as much pressure. Controls given the same low pressure that causes pain in fibromyalgia rate their pain as 2/20 instead of 12/20, and have no neuronal activation with this amount of pressure.

studies of healthy normal subjects during painful stimuli. Interestingly, when the pain free controls were subjected to pressures that evoked equivalent pain ratings in the FM patients, similar activation patterns were observed. These findings were entirely consistent with the ''left-shift'' in stimulus-response function noted with experimental pain testing, and suggest that fibromyalgia patients experience an increased gain or ''volume setting'' in brain sensory processing systems (Fig. 36.6). In a similar experiment, Cook et al. used painful heat stimuli during fMRI.[139] Similar to the Gracely et al. findings, the authors observed significant increases in the pain ratings of patients and augmented pain processing within the contralateral insula. fMRI has also proved useful in determining how comorbid psychological factors influence pain processing in fibromyalgia. For example, a recent study by Giesecke et al. explored the relationship between depression and enhanced evoked pain sensations in 30 patients with fibromyalgia.[140] The authors found that the anterior insula and amygdala activations were correlated with depressive symptoms, consistent with these regions being involved with affective or motivational aspects of pain processing. However, the degree of neuronal activation in areas of the brain thought to be associated with the ''sensory'' processing of pain (i.e., where the pain is localized and how intense it is) were not associated with levels of depressive symptoms, or the presence or absence of major depression. These data are consistent with a plethora of evidence in the pain field that there are different regions of the brain responsible for pain processing devoted to sensory intensity versus affective aspects of pain sensation, and suggest that the former and latter are largely independent of each other. In contrast, this same group showed that the presence of catastrophizing, a patient's negative or pessimistic appraisal of their pain, influences both the sensory and affective dimensions of pain on fMRI in fibromyalgia.[141]

PET has been used in several studies in fibromyalgia. In the first such study, Yunus and colleagues did not identify any differences in regional cerebral blood flow between fibromyalgia patients and controls.[142] However, Wood and colleagues used PET to show that attenuated dopaminergic activity may be playing a role in pain transmission in fibromyalgia, and Harris and colleagues showed evidence of decreased mu-opioid receptor availability (possibly due to increased release of endogenous mu-opioids) in fibromyalgia.

Event Related Potentials

Another technique that has been used to demonstrate abnormal neural responses to sensory stimuli in fibromyalgia is event related potentials. Cerebral potentials evoked by noninvasive stimulation provide a unique opportunity to investigate the functional integrity and magnitude of brain processing pathways. Expressing the ability of the human brain to discriminate, classify, and memorize the significance of exogenous stimuli, event related potentials (ERPs) have been used as a marker of cognitive function in patients with psychiatric and neurological disorders. The electrical waveforms generated can be divided into late and early components and are designated by their polarity and latency (timing of peak) after stimulus onset. Additionally, the amplitude, or the size of voltage difference between the component peak and a prestimulus baseline, is also quantified. In patients with fibromyalgia, auditory, somatosensory, and visual evoked potentials have been evaluated in a handful of studies.

Among the ERPs evaluated to date, the P300 potential (most commonly generated by an auditory consciously attended stimuli) appears to be the most promising to differentiate FM patients

from controls. The P300 wave is a late cortical neuropsychological event, the latency of which reflects information processing speed while its amplitude expresses memory functions. A reduced P300 amplitude during auditory discriminated task paradigm has been significantly noted in FM patients as compared to controls in three cross-sectional studies by two different groups.[143–145] All three studies also evaluated the P300 latency, but only the largest by Alanoglu et al. noted an increase in P300 latency, a finding that may have not been found in the prior studies due to lack of power. In one study by Ozgocmen et al., ERP was performed before after-treatment, and 8 weeks of sertraline treatment led to an increase in P300 magnitude. These studies generally failed to show an association between the ERP findings and symptom severity, although there was an association noted with the total myalgic score. Although the change in the P300 potential after sertraline treatment was attractive, the authors agreed that given the corresponding significant clinical improvement in pain, fatigue, or depression, the mechanism for the change remained unclear and acknowledged it may represent regression to the mean. Larger studies by different groups with an attention to standardizing methods are essential prior to mainstream use of this marker.

Other Serological and Biochemical Abnormalities

The search for representative autoantibodies is a predictable step for a disease like fibromyalgia, often evaluated by rheumatologists and coexisting with autoimmune diseases. Antiserotonin antibody, antiganglioside antibody, and antiphospholipid antibody have been shown to be different in patients and controls, but the applicability of these findings is not yet clear.[146] Antiserotonin antibody has been shown to be increased in FM in three cross-sectional studies by two different groups. Antiganglioside antibody and antiphospholipid antibody have each been shown to be increased in FM in two cross-sectional studies by the same group. A different group evaluating antiganglioside antibody in a third cross-sectional study was unable to reproduce the results. Antithromboplastin antibody, antipolymer antibody, anti-68/84, and anti-45kDa have each been evaluated in one cross-sectional study and have shown increased levels in FM. Review of the literature suggests that ANA, antithyroid antibodies, antisilicone antibodies, and antiglutamic acid decarboxylase are not informative in FM.

This inconsistent increase in antibodies to a number of antigens may be a nonspecific finding that arises from a subtle shift in immune function in this spectrum of illness. In the closely related chronic fatigue syndrome and Gulf War illnesses, investigators have noted a shift from a TH1 to TH2 immune response, which would be expected to lead to increased production of nonspecific antibodies. Thus, any antibody or autoantibody proposed as either a diagnostic test or biomarker of FM must be carefully tested using stringent controls to ensure its authenticity.

The amino acid tryptophan and the cytokine IL-8 have both been shown to be different in patients compared to controls in a couple of studies, but none have been evaluated in longitudinal studies.[147–150] Low tryptophan, a precursor for serotonin, has been found in two of three studies by three different groups.[115,147,151] IL-8 has been consistently demonstrated in three studies by two different groups.[148–150] Moreover, IL-8 has been shown to correlate with symptoms and not to be associated with depressed FM. IL-8 levels are closely tied to autonomic function and the findings of these increased levels could be due to the dysautonomia seen in fibromyalgia and related conditions.[152] Serum IL-6 was evaluated and found to be normal in FM.[150,153]

Structural Abnormalities in Fibromyalgia

Although a few studies have found mild abnormalities in the *skeletal muscles* of fibromyalgia patients (these findings have been inconsistent and may be due to de-conditioning rather than the illness itself[154–156]), there are a few studies that suggest there may be subsets of FM patients with damage to *neural* structures. P31-spectroscopy has been used to examine muscle metabolism in FM and the results are conflicting, with one study comparing sedentary controls to FM finding no differences, and the other finding lower ATP levels among FM patients.[157,158] Studies suggest that the tenderness in fibromyalgia is not at all confined to just the muscle, so in aggregate most investigators have concluded that primary muscle disease is not a likely cause of the pain associated with fibromyalgia.

There are recent data, however, suggesting that a subset of fibromyalgia patients may have abnormalities involving small sensory nerves in the skin, indicative of a small fiber neuropathy.[159,160] There are also emerging data suggesting that there may be subtle abnormalities in brain structure seen in fibromyalgia.[161,162] Thus, if there are structural abnormalities or damage to tissues in fibromyalgia the most evidence for this is involving neural tissues.

Sleep and Activity in Fibromyalgia

In addition to pain, other symptoms very commonly seen in fibromyalgia include disturbed sleep and poor physical function. One of the first biological findings in fibromyalgia was that selective sleep deprivation led to symptoms of fibromyalgia in healthy individuals, and these findings have subsequently been replicated by several groups.[18,163] However, the electroencephalography (EEG) abnormalities that were noted in this first study and initially thought to be a marker for fibromyalgia, so-called alpha intrusions, have subsequently been found to be present in normals and in individuals with other conditions.[164,165] More recent findings on polysomnography that occur more commonly in fibromyalgia include demonstration of fewer sleep spindles, an increase in cyclic alternating pattern rate, upper airway resistance syndrome, and/or poor sleep efficiency.[166–169] However, sleep abnormalities rarely are shown to correlate with symptoms in FM, and many investigators anecdotally feel as though even identifying and treating specific sleep disorders often seen in FM patients (e.g., obstructive sleep apnea, upper airway resistance, restless leg or periodic limb movement syndromes) does not necessarily lead to improvements in the core symptoms of FM.

Actigraphy

Actigraphy, a method of motion assessment that infers sleep and wakefulness from presence of limb movements, is increasingly being used as a surrogate marker for both sleep and activity. The actigraph typically combines a movement detector and memory storage on a watch-like device. The device can be worn on wrist or ankle continuously for long periods of time. Sleep-pattern measures available via actigraphy analyses include sleep latency, wake time after sleep onset, and total sleep time; sleep architecture cannot be measured as with polysomnography. However, compared to the polysomnography, actigraphy is less expensive, invasive, and more conducive to repeated measures, resulting in extensive use in intervention studies.[170]

Actigraphy is being increasingly used in FM and is increasing and appears promising, but has not yet proven to be adequately sensitive to stand alone in clinical evaluation or treatment trials.[171–173] As a measure of sleep quality, there have been inconsistent results, with one group noting increased levels of activity at night in FM (also noted in patients with major depression) and another noting no difference. Edinger et al. used actigraphy as an outcome measure in an intervention trial comparing cognitive

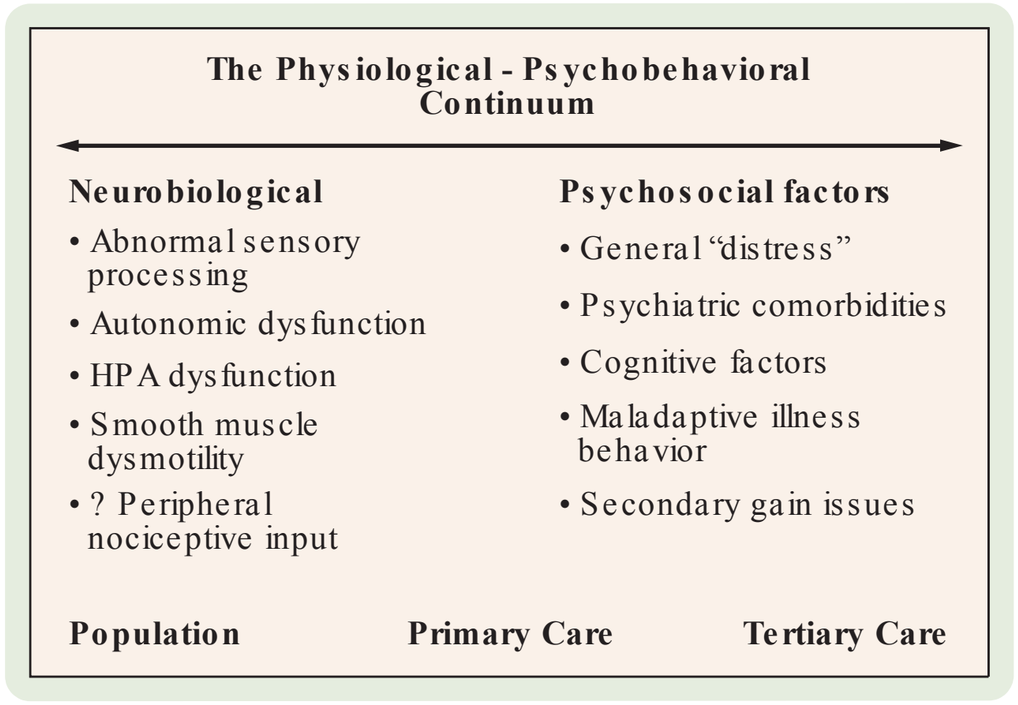

FIGURE 36.7 The relationship between neurobiological factors that initiate pain and other symptoms, and psychological and behavioral factors that either preexist or develop as a result of pain, and can perpetuate or worsen symptoms. These latter factors increase in frequency as one moves from examining pain patients in the population to those seen in tertiary care centers.

behavior therapy (CBT) intervention to sleep hygiene and usual care in the treatment of insomnia.[174] Deriving an actigraphic improvement criterion, the investigators showed a greater number of patients receiving CBT had clinically significant improvement in total wake time compared to sleep hygiene therapy. No statistical difference between CBT and usual care was able to be demonstrated, even though a statistical difference between the groups was shown using sleep log data in the same study.

As an objective measure of functional status, actigraphy might hold more promise as a surrogate outcome measure, because it allows the direct recording of activity levels, rather than counting on patient self-report.[175] Kop and colleagues demonstrated that although patients with FM have SF-36 score nearly two standard deviations below the population average, they have the same average activity level as a group of sedentary controls. However, the fibromyalgia patients had much lower peak activity levels, suggesting that the problems in function that fibromyalgia report might be more due to an inability to rise to the intermittent demands of day-to-day life than overall reduced function.

Behavioral and Psychological Factors

In addition to neurobiological mechanisms, behavioral and psychological factors also play a role in symptom expression in many FM patients. The rate of current psychiatric comorbidity in patients with FM may be as high as 30% to 60% in tertiary care settings, and the rate of lifetime psychiatric disorders even higher.[3,176,177] Depression and anxiety disorders are the most commonly seen. However, these rates may be artifactually elevated by virtue of the fact that most of these studies have been performed in tertiary care centers. Individuals who meet ACR criteria for FM who are identified in the general population do not have nearly this high a rate of identifiable psychiatric conditions[9,178] (Fig. 36.7).

As already noted, population-based studies have demonstrated that the relationship between pain and distress is complex and that distress is both a cause and consequence of pain. In this latter instance, a typical pattern is that as a result of pain and other symptoms of FM, individuals begin to function less well in their various roles. They may have difficulties with spouses, children, and work inside or outside the home, which exacerbate symptoms and lead to maladaptive illness behaviors. These include isolation, cessation of pleasurable activities, reductions in activity and exercise, etc. In the worst cases, patients become involved with disability and compensation systems that almost ensure that they will not improve.[179]

The complex interaction of biological, behavioral, and psychological mechanisms is not, however, unique to FM. Nonbiological factors play a prominent role in symptom expression in all rheumatic diseases. In fact, in conditions such as RA and OA, nonbiological factors such as level of formal education, coping strategies, and socioeconomic variables account for more of the variance in pain report and disability than biological factors, such as the joint space width or sedimentation rate.[180,181]

Because of the biopsychosocial nature of fibromyalgia, several groups have attempted to identify subgroups of individuals with this condition that may present differently or respond differentially to treatment.[182,183] One of these studies examined how differential degrees of depression, maladaptive cognitions, and hyperalgesia might interact to lead to different subgroups of patients. Three identified subgroups can be usefully identified (Fig. 36.8). The first comprises approximately half of the patients who have low levels of depression and anxiety, normal cognition re-

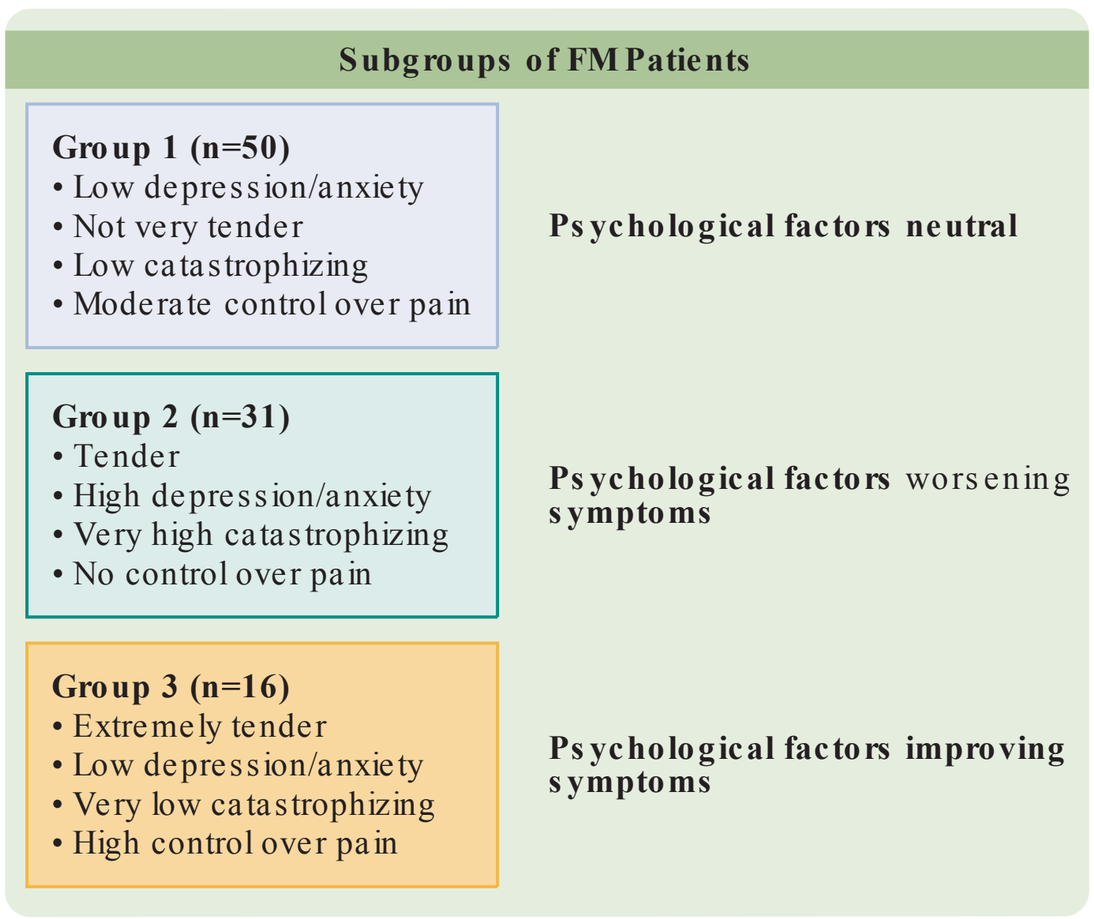

FIGURE 36.8 Subgroups of fibromyalgia patients based on grouping by psychological, cognitive, and neurobiological (degree of hyperalgesia) factors.

garding pain, and are mildly tender (although tender enough to meet the ACR criteria). The second subgroup, representative of a ''tertiary care'' fibromyalgia patient, is slightly more tender and also displayed high levels of depression. These patients also have cognitions associated with a poor prognosis in many pain conditions. These include an external locus of pain control, defined as feeling that they can do nothing about their pain, and catastrophizing, defined as having a very negative and pessimistic view of their pain. The third subgroup are the most tender, but with no negative psychological or cognitive factors. This suggests that in some ''resilient'' individuals, positive psychological and cognitive factor issues may actually ''buffer'' neurobiological factors leading to pain and other symptoms in FM.

Functional imaging studies have been instructive with regard to how these comorbid mood disorders or cognitions may be influencing pain processing in FM. Functional MRI undertaken on 30 fibromyalgia patients with variable levels of depression, with additional experimental pain testing, investigated how the presence or absence of depression influenced pain report.[140] This study found that the level of depressive symptomatology did not influence the degree of neuronal activation in brain regions responsible for coding for the sensory intensity of pain, the primary and secondary somatosensory cortices. As expected, the depressed individuals did display greater activations in brain regions known to be responsible for the affective or cognitive processing of pain, such as the amygdala and insula. Another study with similar methodology examined how the presence or absence of catastrophizing might influence pain report in FM.[141] In contrast to the results noted previously, the presence of catastrophizing was associated with increased neuronal activations in the sensory coding regions. These studies thus provide empirical evidence for the value of treatments such as cognitive behavioral therapy. This is especially the case if individuals exhibit cognitions such as catastrophizing which, independent of other factors, may be capable of increasing pain intensity.

THE EVALUATION OF INDIVIDUALS WITH CHRONIC WIDESPREAD PAIN

The evaluation of an individual with chronic pain is a complex process. In contrast to most other medical problems, simply arriving at a ''diagnosis'' is typically insufficient to guide treatment. This is because within any given pain diagnosis, there is tremendous heterogeneity with respect to the underlying causes and contributors to symptoms, and the most effective treatments. In particular, individuals with chronic pain can have greater or lesser peripheral nociceptive (i.e., tissue damage, inflammation) and central nonnociceptive (i.e., pain amplification, psychological factors) contributions to their pain. Therefore, the differential diagnosis of chronic pain involves identifying which of these factors are present in which individuals, so that the appropriate pharmacologic, procedural, and psychological therapies can be administered.

A careful musculoskeletal history and examination remains the most important diagnostic test for musculoskeletal pain. In other fields of medicine, advances in diagnostic testing have largely rendered a physical examination obsolete. However, in musculoskeletal medicine, technology confuses as much as it helps. For example, a high proportion of the healthy, asymptomatic population has a positive antinuclear antibody, positive rheumatoid factor, or abnormal results of imaging studies.[184–186] Worse yet, these diagnostic tests rarely tell us how ''severe'' the pain is, because there is typically a significant discordance between the results of laboratory or imaging studies, and the severity of pain and other symptoms that the individual is experiencing. Therefore, the musculoskeletal history and examination must allow the clinician to arrive at the diagnosis (or at worst a very narrow differential diagnosis) and then, if necessary, further diagnostic testing should be used to confirm these findings.

DIAGNOSIS

The diagnosis of FM is illustrated in Figure 36.9. The American College of Rheumatology criteria for fibromyalgia were never intended to be used as strict diagnostic criteria for use in clinical practice. Many individuals who clearly have fibromyalgia will not have pain throughout their entire body, or will not have 11 tender points. Moreover, pain and tenderness occur across a continuum in the population, and it is impossible to know where to ''draw the line'' between an individual with symptoms, and someone with an ''illness.''[187]

History

Pain

In clinical practice, one should suspect fibromyalgia in individuals with multifocal pain that cannot be explained on the basis of damage or inflammation in those regions of the body. In most cases, musculoskeletal pain is the most prominent feature, but because pain pathways throughout the body are amplified, pain can be perceived more generally. Thus chronic headaches, sore throats, chest pain, abdominal pain, and pelvic pain are very common in individuals with fibromyalgia, and patients with chronic regional pain in any of these locations are more likely to have fibromyalgia.

Because pain is a defining feature of fibromyalgia, it is helpful to focus on the features of the pain that can help distinguish it from other disorders. The pain of fibromyalgia is typically diffuse or multifocal, often waxes and wanes, and is frequently migratory in nature. These characteristics of ''central pain'' are quite different from ''peripheral'' pain, where both the location and severity of pain are typically more constant. Patients may complain of discomfort when they are touched or when wearing tight clothing, and may experience dysesthesias or paresthesias that accompany the pain.

Nonpain Symptoms

Aside from the pain, a number of seemingly nonrelated symptoms may develop and persist. These include fatigue, sleep difficulties, weakness, problems with attention or memory, unexplainable weight fluctuations, and heat and cold intolerance. ''Allergies'' are reported much more commonly in fibromyalgia patients, although these excess symptoms are better considered hypersensitivities rather than true IgE-mediated immunological reactions. These patients are also more prone to nonallergic rhinitis, sinus, and nasal congestion, and lower respiratory symptoms, all of which again may be primarily attributable to neural mechanisms. Distortions in hearing, vision, and vestibular symptoms are often reported, as are sicca symptoms (sometimes so prominent that these individuals will overlap with those with Sjögren syndrome).

''Functional disorders'' involving visceral organs have long been noted to be more common in fibromyalgia. These include noncardiac chest pain, heartburn and palpitations, and the frequent comorbidity of IBS. Thus, there are reports of increased echocardiographic evidence of mitral valve prolapse and esophageal dysmotility, and reduced static inspiratory and expiratory pressure on pulmonary function tests. The latter might be explained by pain in respiratory muscles. Syncope and hypotension are symptoms that may occur in FM, and in some cases will be accompanied by neurally mediated hypotension or postural orthostatic tachycardia. Pelvic complaints are common, including

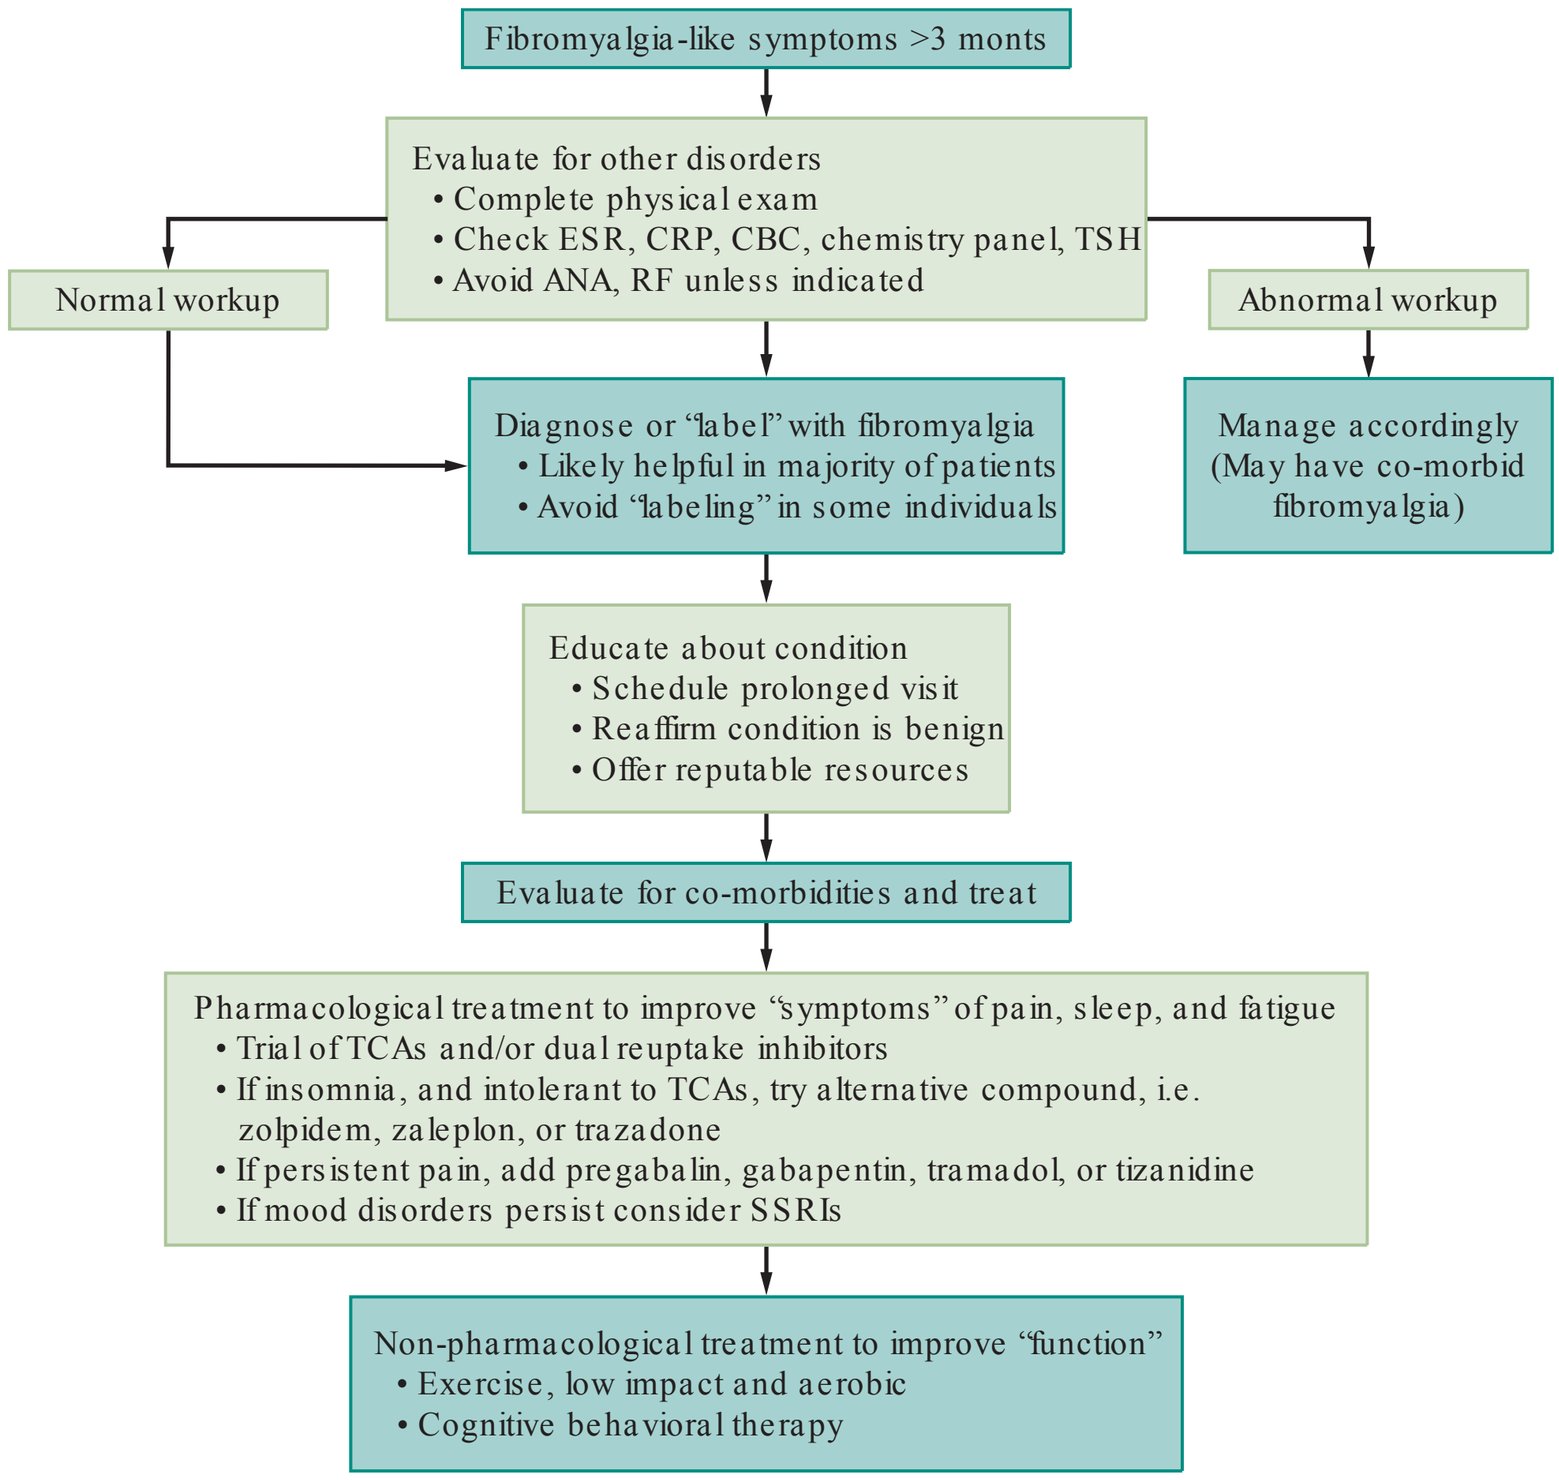

FIGURE 36.9 Algorithm for the diagnosis and treatment of fibromyalgia.

not only pain but also urinary frequency and urgency. In females the frequent comorbid diagnoses are dysmenorrhea, interstitial cystitis, endometriosis, and sensitivity disorders like vulvar vestibulitis and vulvodynia, whereas in males these same symptoms are sometimes diagnosed as chronic or non-bacterial prostatitis.

Physical Examination and Laboratory Investigations

Physical examination is often unremarkable, except for the presence of tenderness. As previously discussed, tenderness may be generalized and thus present anywhere in the body. Laboratory testing is generally not useful, except for the purpose of differential diagnosis. One factor that can help guide the intensity of the diagnostic workup is the length of time the patient has had symptoms. If the patient's symptoms have persisted for several years, minimal testing is required, whereas a more aggressive strategy should be employed for acute or subacute onset of symptoms. Simple testing should be limited to complete blood count and routine serum chemistries, along with thyroid-stimulating hormone (TSH) and ESR and/or CRP.

Serologic studies such as ANA and rheumatoid factor assays should generally be avoided unless there are historical features not seen in fibromyalgia, or abnormalities on physical examination. This represents a problem in clinical practice, because several autoimmune disorders share overlapping symptomatology with fibromyalgia. These include not only fatigue, arthralgias, and myalgias, but also such symptoms as morning stiffness and subjective swelling of the hands and feet. Certain dermatologic features commonly seen in fibromyalgia, including malar flushing, livedo reticularis, and Raynaud-like reddening of the hands, also mimic symptoms of autoimmune disorders. This sometimes results in patients with fibromyalgia being misdiagnosed as having an autoimmune disorder such as systemic lupus erythematosus.

Aside from the many comorbid conditions already discussed, fibromyalgia may present similarly to a number of disorders or concurrently with other disorders that may confuse the diagnosis. Table 36.2 shows conditions that often mimic or present concur-

TABLE 36.2
CONDITIONS THAT SIMULATE FIBROMYALGIA

Common
Hypothyroidism
Polymyalgia rheumatica
Early in course of autoimmune disorders, e.g., rheumatoid arthritis or SLE
Sjogren's syndrome
Less common
Hepatitis C
Sleep apnea
Chiari malformation
Celiac sprue

rently with fibromyalgia. Hypothyroidism and polymyalgia rheumatica can be differentiated from fibromyalgia by results of TSH and ESR. Sleep apnea and hepatitis C also simulate fibromyalgia, and tend to present more often in men than women.

TREATMENT

Progress in the understanding of fibromyalgia has led to more therapeutic options for patients with this condition. Investigators are examining the utility of newer medications as well as non-pharmacological interventions in controlled trials (Fig. 36.10). Clinical based evidence advocates a multi-faceted program emphasizing education, certain medications, exercise, and cognitive therapy.[188]

Diagnostic Labeling

Once a physician rules out other potential disorders, an important and, at times controversial, step in the management of fibromyalgia is asserting the diagnosis. Despite some assumptions that being "labeled" with fibromyalgia may adversely affect patients, a study by White et al. indicated that patients had significant improvement in health satisfaction and symptoms after being "labeled."[178] Nonetheless, in certain select individuals (i.e., adolescents or young adults, or overtly anxious persons) the preferred route may still be not to label. Regardless, diagnosis confirmation should be ideally coupled to patient education, an intervention shown to be effective in randomized controlled trials.[188]

Pharmacological Therapy

The majority of fibromyalgia clinical trials have involved antidepressants of one class or another (Table 36.3). Trials studying the oldest class of agents, tricyclic antidepressants (TCAs), are most abundant, though several recent studies have focused on selective serotonin reuptake inhibitors and "atypical antidepressants"—a class that includes dual reuptake inhibitors and monoamine oxidase inhibitors (MAOIs).

Tricyclic Antidepressants

The most frequently studied pharmacological therapy for fibromyalgia is low doses of tricyclic compounds. Most TCAs increase the concentrations of serotonin and/or norepinephrine (noradrenaline) by directly blocking their respective reuptake (Fig. 36.11). The effectiveness of TCAs, particularly amitriptyline and cyclobenzaprine, in treating the symptoms of pain, poor sleep, and fatigue associated with fibromyalgia is supported by several randomized, controlled trials.[94] Tolerability is a problem but can be improved by beginning at very low doses (e.g., 10 mg of amitriptyline or 5 mg of cyclobenzaprine), giving the dose a few hours before bedtime, and very slowly escalating the dose.

TABLE 36.3

PHARMACOLOGICAL THERAPIES

- **Strong evidence:** tricyclics (amitriptyline, cyclobenzaprine); dual-reuptake inhibitors (SNRI/NSRI—venlafaxine, duloxetine, milnacipran); alpha-2-delta ligands (pregabalin, gabapentin)
- **Modest evidence:** tramadol; selective serotonin reuptake inhibitors (SSRIs); dopamine agonists; gamma hydroxybutyrate (GHB)
- **Weak evidence:** growth hormone, 5-hydroxytryptamine, tropisetron, S-adenosyl-L-methionine (SAMe)
- **Not shown to be effective:** opioids, NSAIDs, corticosteroids, benzodiazepine and nonbenzodiazepine hypnotics, melatonin, guanifenesin, dehydroepiandrosterone

Selective Serotonin Reuptake Inhibitors

Because of a better side effect profile selective serotonin reuptake inhibitors (SSRIs) are frequently used in fibromyalgia. The SSRIs fluoxetine, citalopram, and paroxetine have each been evaluated in randomized, placebo-controlled trials.[188–191] In general, the results of studies of SSRIs in fibromyalgia have paralleled the experience in other pain conditions. The newer "highly selective" serotonin reuptake inhibitors (e.g., citalopram) seem to be less efficacious than the older SSRIs, which have some noradrenergic activity at higher doses.[192]

Since TCAs and high doses of certain SSRIs such as fluoxetine and sertraline that have the most balanced reuptake inhibition are the most effective analgesics, many have concluded that dual receptor inhibitors such as serotonin-NE and NE-serotonin reuptake inhibitors (SNRIs and NSRIs) may be of more benefit than pure serotonergic drugs.[192] These drugs are pharmacologically

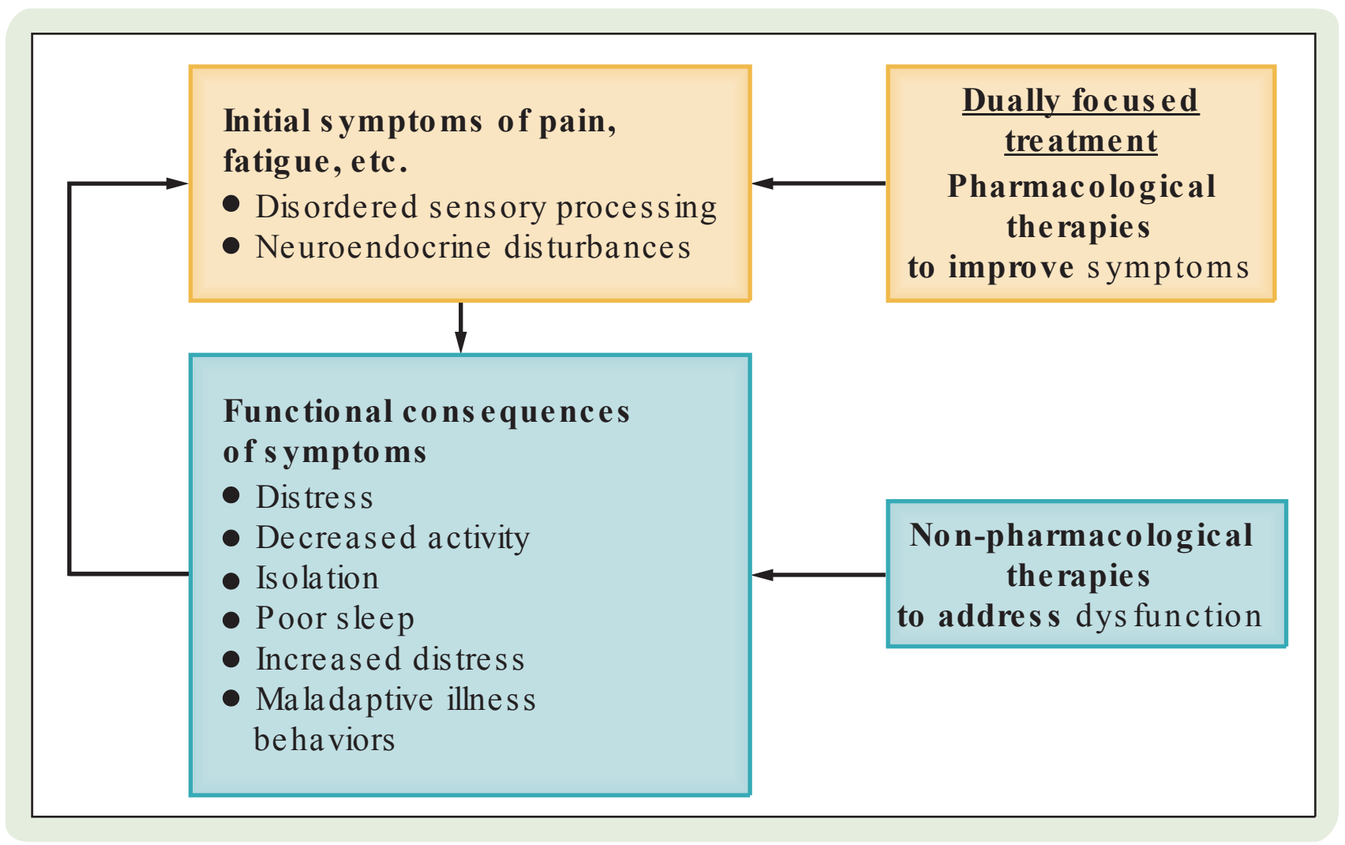

FIGURE 36.10 An example of dually focused treatment.

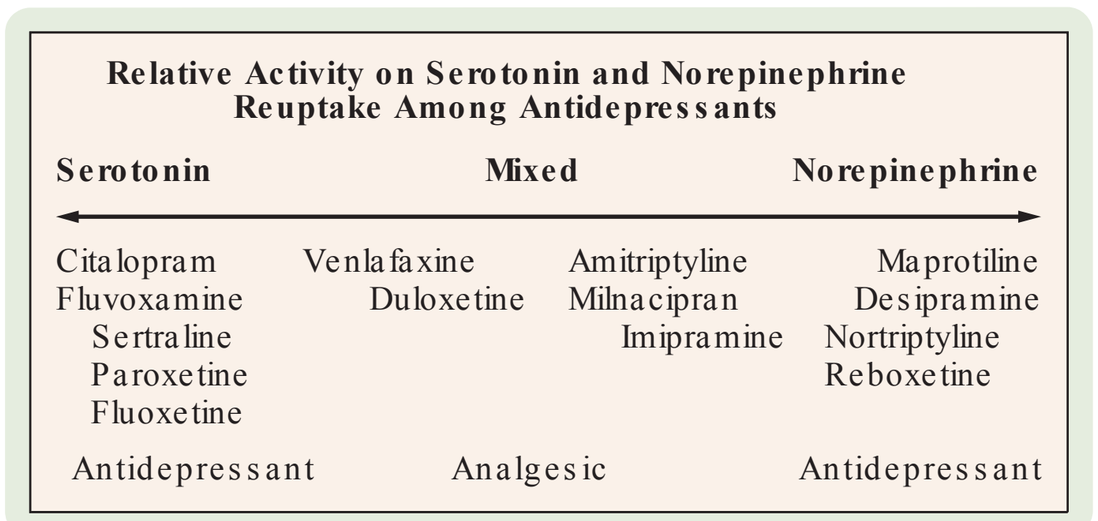

FIGURE 36.11 Relative activity on serotonin and norepinephrine reuptake among antidepressants.

similar to some TCAs in their ability to inhibit the reuptake of both serotonin and NE, but differ from TCAs in being generally devoid of significant activity at other receptor systems. This selectivity results in diminished side effects and enhanced tolerability. The first available SNRI, venlafaxine, has data to support its use in the management of neuropathic pain, and retrospective trial data demonstrate that this compound is also effective in the prophylaxis of migraine and tension headaches.[193] Two studies in fibromyalgia have had conflicting results, with the one using a higher dose showing efficacy.[188]

Two new SNRIs, milnacipran and duloxetine, have undergone recent multicenter trials and were shown to be effective in a number of outcome variables.[116,194] In the study evaluating milnacipran, statistically significant differences were noted in overall improvement, physical functioning, level of fatigue, and degree of reported physical impairment. In the trial of duloxetine compared to placebo, participants treated with duloxetine had decreased self-reported pain and stiffness and a reduced number of tender points. In both studies, benefits were shown to be independent of the drug effect on mood, thus suggesting that the analgesic and other positive effects of this class of drugs in fibromyalgia is not simply due to their antidepressant effects.

Other Central Nervous System Acting Drugs

Antiepileptic drugs are widely used in the treatment of various chronic pain conditions, including postherpetic neuralgia and painful diabetic neuropathy.[195] Pregabalin is a gamma-aminobutyric acid (GABA) analog and approved for the treatment of neuropathic pain. A recent randomized, double-blinded, placebo-controlled trial demonstrated efficacy of pregabalin against pain, sleep disturbances, and fatigue as compared to placebo.[196] Pregabalin is currently the only pharmacological agent approved by the Food and Drug Administration in the treatment of fibromyalgia. Gabapentin, a compound with similar pharmacology to pregabalin, is specifically indicated for the treatment of postherpetic neuralgia and studies support its use in the symptomatic treatment of a variety of pain states as well as headache prophylaxis.[195,197] Another antiepileptic compound, clonazepam, has demonstrated efficacy in treating temporal mandibular disorder and associated jaw pain and is useful in the treatment of restless leg syndrome[195] and may be of value in FM.

Sedative-hypnotic compounds are widely used by fibromyalgia patients. A handful of studies have been published on the use of certain nonbenzodiazepine hypnotics in fibromyalgia, such as zopiclone and zolpidem. These reports have suggested that these agents can improve the sleep and, perhaps, fatigue of fibromyalgia patients, though they had no significant effects on pain. On the other hand, gamma-hydroxybutyrate (also known as sodium oxybate), a precursor of GABA with powerful sedative properties, was recently shown to be useful in improving fatigue, pain, and sleep architecture in patients with fibromyalgia.[198] Note, however, that this agent is a scheduled substance due to its abuse potential.

Pramipexole is a dopamine agonist indicated for Parkinson disease that has shown utility in the treatment of periodic leg movement disorder.[199] Recent studies suggest that this compound may improve both pain and sleep in fibromyalgia patients.[200]

Tizanidine is a centrally acting alpha-2 adrenergic agonist approved by the Food and Drug Administration for the treatment of muscle spasticity associated with multiple sclerosis and stroke. Literature suggests that this agent is a useful adjunct in treating several chronic pain conditions, including chronic daily headaches and low back pain. A recent trial reported significant improvements in several parameters in fibromyalgia, including sleep, pain, and measures of quality of life.[201] Of particular interest was the demonstration that treatment with tizanidine resulted in a reduction in substance P levels within the CSF of patients with fibromyalgia.

Analgesics

There have been no adequate randomized controlled clinical trials of opiates in fibromyalgia, and many in the field (including the authors) have not found this class of compounds to be effective in anecdotal experience. Tramadol is a compound that has some opioid activity (weak mu-agonist activity) combined with serotonin/NE reuptake inhibition. This compound does appear to be somewhat efficacious in the management of fibromyalgia, as both an isolated compound and as fixed-dose combination with acetaminophen.[199].

A large number of fibromyalgia patients use nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen. Although numerous studies have failed to confirm their effectiveness as analgesics in fibromyalgia, there is limited evidence that patients may experience enhanced analgesia when treated with combinations of NSAIDs and other agents. This phenomenon may be a result of concurrent "peripheral" pain (i.e., due to damage or inflammation of tissues; e.g., osteoarthritis, rheumatoid arthritis) conditions that may be present, and/or that these comorbid peripheral pain generators might lead to worsening of "central" pain.

Nonpharmacological Therapies

The two best-studied nonpharmacological therapies are cognitive behavioral therapy and exercise (Table 36.4). Both of these therapies have been shown to be efficacious in the treatment of fibromyalgia, as well as a plethora of other medical conditions.[188,202] Both of these treatments can lead to sustained (e.g., greater than 1 year) improvements, and are very effective when an individual complies with therapy.

Alternative therapies have been explored by patients managing their own illness, as well as healthcare providers. As with other diseases, there are few controlled trials to advocate their general use. Trigger-point injections, chiropractic manipulation, acupuncture, and myofascial release therapy are among the more

TABLE 36.4

NONPHARMACOLOGICAL THERAPIES

- **Strong evidence:** cardiovascular exercise, cognitive behavior therapy, patient education, multidisciplinary therapy
- **Modest evidence:** strength training, acupuncture, hypnotherapy, biofeedback, balneotherapy
- **Weak evidence:** acupuncture, chiropractic, manual and massage therapy, electrotherapy, ultrasound
- **No evidence:** tender (trigger) point injections, flexibility exercise

commonly used modalities, which achieve varying levels of success. Two randomized, sham-controlled trial of acupuncture showed no difference between the two groups.[95,204] A usual-care comparison group was not studied. There is some evidence that the use of alternative therapies gives patients a greater sense of control over their illness. In instances where this sense of control is accompanied by an improved clinical state, the decision to use these therapies is between physicians and patients themselves.

PROGNOSIS

The prognosis of FM depends largely on where the individual falls on a continuum. One end of the continuum are individuals in the population with CWP, or individuals with FM that are seen in primary care, with the prognosis in these individuals being quite good.[205,206] On the other hand, individuals with FM seen in tertiary care settings do quite poorly.[207] In this latter study, there was little change in symptoms over time, and no significant change in health satisfaction, symptoms or functional disability.

With regard to function in FM, studies have reported varying disability rates from 9% to 44%.[206,208,209] Disability has been most strongly associated with functional and work status, pain, mood disturbances, coping ability, depression, pending litigation, and educational background.

General Considerations

Management strategies are similar to other chronic illnesses, where empathetic healthcare providers should develop a partnership with their patients. At one end of the continuum, there are some individuals with FM that respond to a single medication, or a graded, low-impact exercise program. At the other end of the continuum is the tertiary care patient with high levels of distress, who has no sense of control of their illness, little social support, and has looked toward disability and compensation systems to try to solve their problem. For this individual, and many in between, multimodal programs that integrate nonpharmacological (especially exercise, CBT) and pharmacological therapies are required.

CHAPTER 37 ■ PAIN OF DERMATOLOGIC DISORDERS

JOSEPH C. LANGLOIS AND JOHN E. OLERUD

INTRODUCTION

Pain is not as distinctive a feature of dermatologic disorders as is the related disorder of pruritus, which is beyond the scope of this discussion. It is well known that pruritus appears to be so intolerable that the act of scratching inflicts a transient pain with attendant structural damage to the skin. It is generally considered that the induced pain is subjectively more tolerable than the itching. Nonetheless, pain is a distinctive feature of certain dermatologic disorders and merits attention simply because of the great prevalence of skin disorders. Dermatologic disease of sufficient significance that it should be seen by a physician is present in 30% of the population in the United States. Half of all problems related to skin present to primary care physicians other than dermatologists. Of the 12 most common disorders of skin disease, only herpes simplex is attended by pain symptoms. Herpes simplex has a seroprevalence rate of 57% in a random sample of nonhospitalized U.S. civilians as reported in the NHANES data base for 1999–2004.[1] The effects of pain on the patient are best demonstrated by the impact of the persisting pain that sometimes follows herpes zoster, postherpetic neuralgia, which occasionally leads to suicide. This disease is discussed in Chapter 27, but this chapter focuses attention not only on the impact of pain but also on the need for appropriate recognition of the antecedent viral disease and on the value of immediate and appropriate treatment.

The diseases discussed in this chapter can be grouped into the categories of vasculitis, infections of viral and bacterial origin, inflammatory diseases of the subcutaneous space, and neoplasms. Some neoplasms, although benign, are specifically painful based on their neurovascular components. We discuss the causes and pathogenesis of the selected pain-related skin diseases, paying attention to symptoms and signs, methods of diagnosis, and preferred methods of treatment. For more comprehensive discussions of the individual diseases, refer to selected general textbooks of skin disease.[2–5] Because of space limitations, vasculitides and tumors are described in Table 37.1.

BASIC CONSIDERATIONS: ANATOMY AND PHYSIOLOGY OF THE SKIN

Human skin is a vast, sheet-like interface for the organism with its environment. It is adapted to the dryness of the atmosphere, resisting mechanical shearing and puncturing forces as well as the invasion of chemical and infective agents. This organ, which in aggregate covers an area of more than 2 m^2, has a mass greater than that of any other organ. It contains an extensive vascular and sweat gland system, essential for thermal regulation, and an even more extensive and finely attuned neuroreceptor network, including the varied transducers of pain and other sensations (Fig. 37.1).

The skin is covered by a thin, stratified epithelium, the epidermis, which is only 75 to 100 micrometers thick except on the palms and soles, where it is four to five times thicker. The bulk of the skin is fibroelastic dense connective tissue known as the *dermis*, which supports the extensive network of vessels and nerves as well as the specialized glandular structure of the sweat apparatus and keratinizing appendages, such as hair and nail. The subcutaneous space is a variably fatty connective tissue perforated by collagenous septa, continuous on the outermost aspects with the fibers of the dermis and continuous beneath the skin with fascial or periosteal attachments to the skeleton.

It is generally believed that the peripheral pain receptors are the finely arborized (penicillate) free nerve endings that ramify in the superficial aspects of the dermis. This network of fine C fibers has been shown to innervate the epidermis as well (see Fig. 37.1)[6–8] and has been referred to as the *cutaneous sensory nervous system*.[9] These fibers convey information from the skin to the central nervous system and thus have a sensory role. They also have an effector function in the skin, mediated by locally releasing neuropeptides. Sensory neurons express at least 17 different neuropeptides, including substance P and calcitonin gene–related peptide.[10] The cutaneous sensory nervous system appears to play an important role in the "communication" between the nervous system and the immune system, the vascular system, and the cells of the epidermis. Neuropeptides appear to participate in vital functions such as neuroinflammation and tissue repair.[6,11] They have important biological effects on a variety of cells in the skin, including keratinocytes, endothelial cells, fibroblasts, Langerhans cells, mast cells, macrophages, and smooth muscle cells.[9] It is easy to imagine how these effector functions may participate in the perpetuation of chronic skin conditions characterized by pain or itch.

The diagnosis of skin disease depends less on deductive logic than on direct observation. One should distinguish localized nodules resulting from small tumors of the skin from the large plaquelike swellings associated with acute edema and redness that mark inflammatory processes, and umbilicated small vesicles occurring in clusters on inflammatory bases that are characteristic of the herpetic viral infections. Subtle or marked defects in the integrity of the protective epidermal sheet should be noted, as manifested by denuded sites of bullae (erosions). Also to be noted are deeper defects in the integrity of the protective barrier that involve loss of the epidermis as well as of some dermis, leading to ulcer formation. Such lesions are inevitably attended by pain, unless associated with a neuropathy, which can best be explained by exposure of free nerve endings.

CLINICAL DISORDERS

Leukocytoclastic Vasculitis

Characteristic features of vasculitis are compared in Table 37.1.

Leukocytoclastic vasculitis (LV) is a common form of vasculitis that may be confined to the skin[21] or related to systemic vascu-

TABLE 37.1

CHARACTERISTICS OF CUTANEOUS VASCULITIDES

Type	Clinical signs	Pathologic features	Immunofluorescence findings	Granulomatous changes	ANCA[a]		Allergic rhinitis, asthma, eosinophilia	Pain	Comment	Treatment
					cANCA	pANCA				
Leukocytoclastic vasculitis	Palpable purpura on lower extremities	Infiltration and destruction of postcapillary venules by polymorphonuclear leukocytes with leukocytoclasis	Immunoglobulins and complement (C3) in small capillaries of the upper dermis (lesions <24 hr old)	–	–	–		Small lesions are usually asymptomatic; larger papules, nodules, and ulcers are often painful	Causative factors include infections, drugs, chemicals, serum, connective tissue diseases, and malignancy	No therapy for mild cases; antihistamines, NSAIDs, dapsone, colchicine, prednisone 7- to 10-day course starting with 60 mg/day
Polyarteritis nodosa	Tender nodules, livedo reticularis, ulcers, nodules along an artery	Leukocytoclastic vasculitis of small- and medium-sized arteries	Immunoglobulins and complement in vessel walls	–	–	–	Eosinophilia sometimes	Aching pain is characteristic of the cutaneous form, aggravated by physical activity or edema	Limited cutaneous form of polyarteritis nodosa rarely progresses to systemic polyarteritis nodosa	Prednisone 1 mg/kg/day Cyclophosphamide 2 mg/kg/day[12] For hepatitis B–related polyarteritis nodosa: corticosteroids plus plasma exchange plus interferon-α[12] or lamivudine[13]
Wegener's granulomatosis	Papules, papulonecrotic lesions, nodules with ulceration, subcutaneous nodules, ulcers, petechiae, ecchymotic lesions, vesicles, pustules	Necrotizing vasculitis of small arteries and veins; necrotizing granulomas	Usually negative	+	44%–90%	12%–20%	Eosinophilia sometimes	Lesions can be tender	Limited form does not have renal involvement	Prednisone 1 mg/kg/day plus oral cyclophosphamide 2 mg/kg/day[12] (higher initial intravenous doses in patients with aggressive disease)[14,15]

Allergic granulomatosis of Churg-Strauss	Cutaneous nodules usually on scalp and extremities Palpable purpura	Extravascular granulomas; necrotizing vasculitis of small- or medium-sized arteries and veins	Usually negative	+	As high as 70%–78% mostly pANCA	Allergic rhinitis, asthma, eosinophilia (virtually all)	Cutaneous nodules are usually tender	Serious renal involvement is infrequent; coronary arteritis and myocarditis are principal causes of death	Prednisone 1 mg/kg/day Cytotoxic drug added if needed[12]
Microscopic polyangiitis	Palpable purpura, ulcers	Necrotizing vasculitis of small vessels; sometimes small- and medium-sized arteries	Immune deposits absent (pauci-immune)	−	38%–57% (>80% overall)	Eosinophilia sometimes	Similar to leukocytoclastic vasculitis	Renal involvement frequent; pulmonary involvement common	For patients with major organ damage, prednisone 1 mg/kg/day plus oral cyclophosphamide 2 mg/kg/day[12] (higher initial intravenous doses in patients with aggressive disease)[14]
Rheumatoid vasculitis	Petechiae, palpable purpura, leg ulcerations, nail fold, and digital infarcts, gangrene	Vasculitis of small arteries, arterioles, capillaries, or venules	Immunoglobulins and complement in vessels reported in normal skin as well as in lesional skin in rheumatoid vasculitis	−	20% (rheumatoid arthritis) pANCA		Lesions are sometimes painful	Associated with relatively severe rheumatoid arthritis	For patients with severe disease: Prednisone 0.5–1 mg/kg/d combined with other agents.[16] Pulse IV cyclophosphamide and methylprednisolone[17]
Livedoid vasculitis	Livedo reticularis, purpuric macules, papules, ulcers, stellate scarring	Hyalinizing segmental vasculitis in middle and lower dermis	Immunoglobulins, complement, and fibrin in vessel walls	−			Pain may be severe		Treat coagulation defects. Aspirin 325 mg/day plus dipyridamole 50 mg tid.[18] Pentoxifylline 400 mg tid.[19] Danazol 50–100 mg bid. Therapeutic ladder as proposed by Callen[20]

[a]ANCA, antineutrophilic cytoplasmic antibodies; cANCA, ANCA of the cytoplasmic type; pANCA, ANCA of the perinuclear type; +, present; −, absent.
Modified from Braverman IM. The angiitides. In: Braverman IM, ed. *Skin Signs of Systemic Disease*. 3rd ed. Philadelphia: WB Saunders; 1998:311.

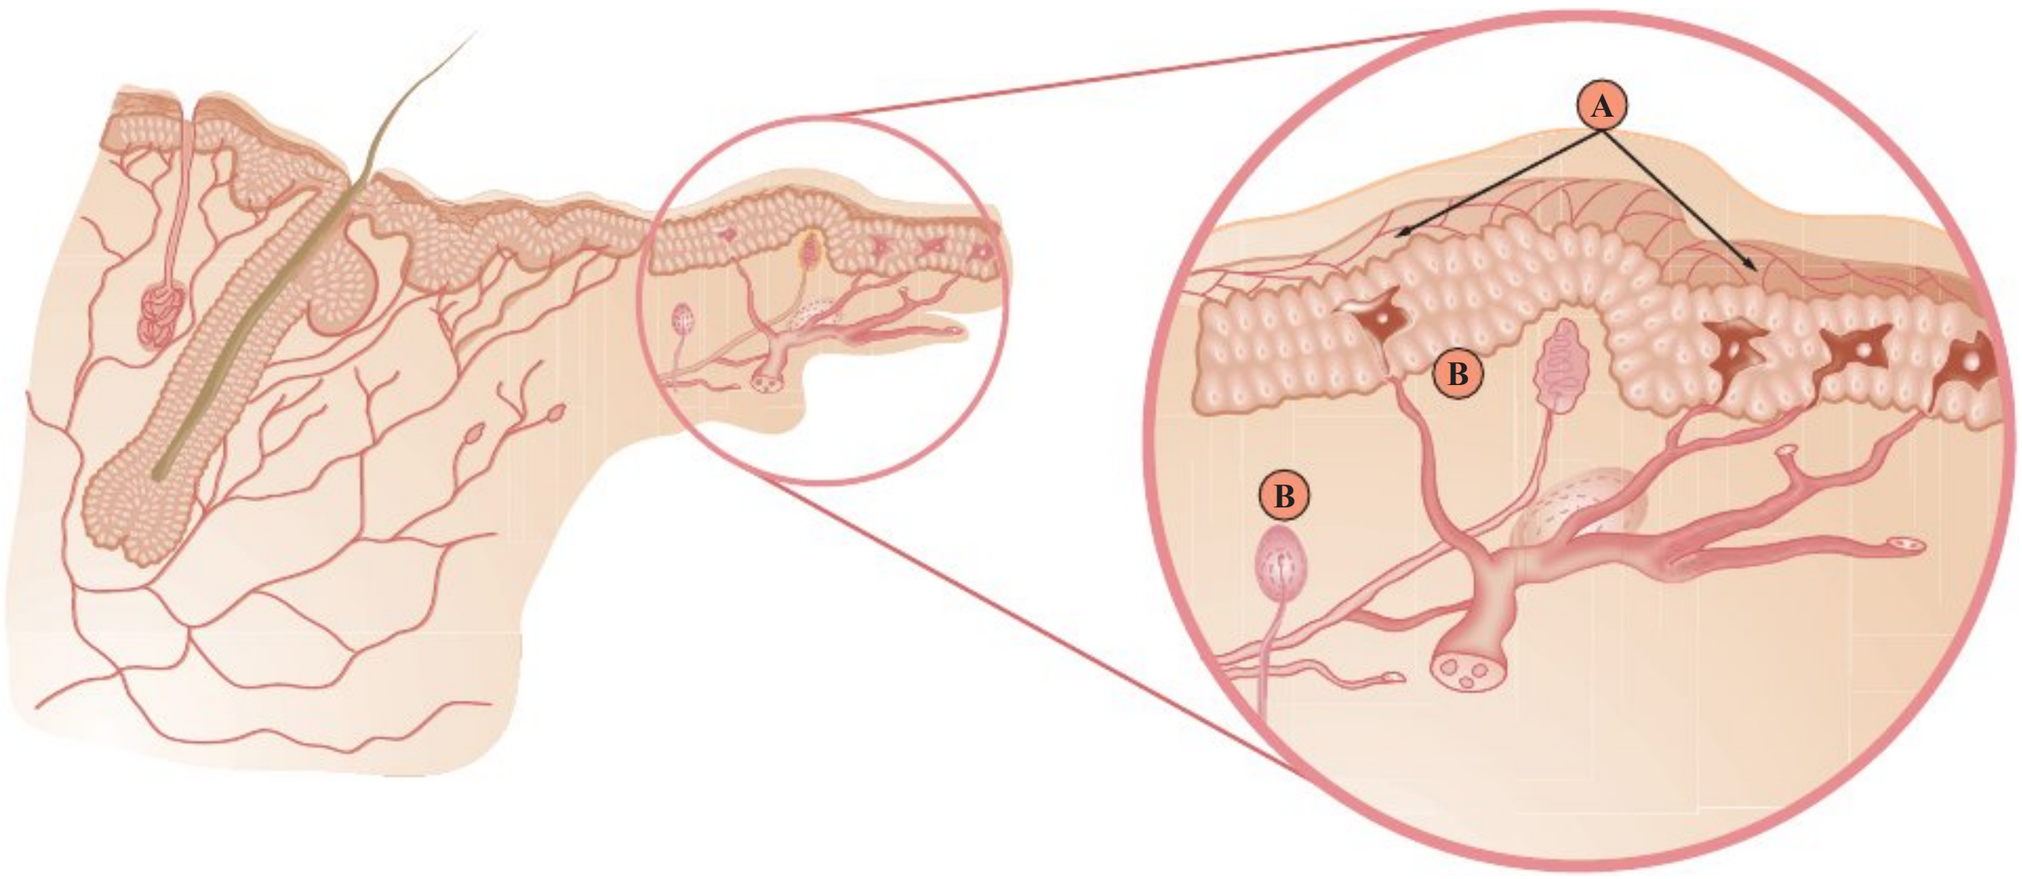

FIGURE 37.1 Schematic representations of sensory nerve formations (SNFs) for the cutaneous sensory nervous system. The SNFs depicted are the free nerve endings in the epidermis **(A)** and mechanosensors **(B)** in the dermis. Although nociception in the skin is mainly a function of free nerve endings composed of unmyelinated C fibers, more specialized SNFs for mechano- (baro-, preso-, osmo-) sensors, thermosensors, electrosensors, chemosensors, and nociosensors are also present. (Modified from Malinovsky L. Sensory nerve formations in the skin and their classification. *Microsc Res Tech* 1996;34:283–301.)

litis, connective tissue diseases, or malignancy.[22,23] LV typically affects postcapillary venules producing palpable purpura which are the clinical hallmark of the disease.[21] Although palpable purpura occurring in dependent areas (e.g., the legs and ankles in ambulatory patients and the back and sacral area in bedridden patients) is typical, a spectrum of other cutaneous lesions may occur such as papules, nodules, vesicles, bullae, pustules, ulcers, urticarial lesions, and livedo reticularis.[24,25] Purpuric lesions may often be associated with tenderness, burning, stinging, or pruritus.[21] The presence of painful skin lesions has been reported to be associated with a lower risk of systemic involvement.[26]

Histologic changes seen with LV consist primarily of infiltration of polymorphonuclear leukocytes within and/or around blood vessels and destruction of the vessel wall with fibrinoid necrosis whereas hemorrhage, nuclear dust (leukocytoclasis), endothelial changes, ulceration, necrosis, and eccrine gland necrosis are considered secondary changes.[27] The differential diagnosis of LV includes septic vasculitis and other causes of pseudovasculitis such as bacterial endocarditis, atrial myxoma with emboli, cholesterol emboli, antiphospholipid syndrome, warfarin-induced skin necrosis, calciphylaxis, and others.[28]

Etiology

Among the many reported etiologic factors associated with LV are infectious agents (e.g., streptococcus; hepatitis A, B, and C; and influenza), medications (e.g., penicillin, sulfonamides, beta-lactam antibiotics, phenothiazines, nonsteroidal anti-inflammatory drugs [NSAIDs], and streptomycin), serum sickness, anti-influenza vaccines, foodstuff allergens, chemicals (e.g., insecticides and petroleum products), connective tissue and inflammatory diseases (e.g., systemic lupus erythematosus [SLE], Sjögren's syndrome, rheumatoid arthritis, ulcerative colitis, and Behçet's disease), and malignancy (both lymphoproliferative and solid tumors).[21,24]

Pathogenesis

LV is felt to be principally caused by deposition of circulating immune complexes within the vessel walls of postcapillary venules, activation of complement, infiltration by neutrophils, and release of lysosomal enzymes.[24] Other factors involved in the pathogenesis include histamine release, inflammatory cytokines, adhesion molecules, thrombosis of vessels, fibrinolysis, and cell-mediated immune response (late stages).[24] Endothelial cell activation and expression of E-selectin may play a role in recruiting polymorphonuclear leukocytes to the site.[29] Immunoglobulins and complement can be detected in vessel walls by direct immunofluorescence in early lesions that are less than 24 hours old (preferably less than 4 hours).[25] Patients who develop leg ulcers from LV have been reported to have an increased incidence of hypercoagulability related to factor V Leiden and lupus anticoagulant.[30]

Patients who present with LV need to be evaluated for systemic involvement particularly for involvement of kidneys, joints, gastrointestinal tract, and pulmonary and nervous systems. They may need to be reclassified depending on the type of systemic involvement according to the Chapel Hill Consensus Conference nomenclature.[31] If no systemic involvement is found, patients need to be followed over time because some patients develop systemic involvement later.

Subsets or variants of LV include urticarial vasculitis, Henoch-Schönlein purpura, and cryoglobulinemic vasculitis. Hepatitis C is an important cause of mixed cryoglobulinemic vasculitis and is responsible for the majority of cases that have an infectious etiology.[32,33]

Treatment

Any underlying infections such as group A streptococcal infections should be treated, suspect medications stopped, and other potential etiologic agents avoided. Any associated connective tissue diseases should be treated and the patient evaluated for underlying malignancy if another etiology is not found.

Specific treatment for the vasculitis should be tailored to the severity of the disease. For patients who are asymptomatic or have mild disease, options include no treatment, antihistamines, and NSAID drugs. Dapsone and colchicine may be beneficial. A prospective randomized controlled trial of colchicine showed no overall significant benefit but a few individual patients may have

benefited.[34] A short course of systemic corticosteroids may be useful for an acute exacerbation of the disease. For patients with more severe and recalcitrant disease azathioprine, cyclosporine, IVIG, and plasmapheresis are considerations.[21] Tumor necrosis factor (TNF) inhibitors have been reported to both cause and treat vasculitis.[35] Rituximab has been reported to be effective in some cases but further studies are needed to determine its long term safety and effectiveness.[36]

Polyarteritis Nodosa

Polyarteritis nodosa is an uncommon form of vasculitis affecting small- and medium-sized arteries. Two forms of cutaneous involvement can occur: benign cutaneous and systemic.

Symptoms and Signs

Cutaneous polyarteritis nodosa characteristically is manifested by tender nodules, livedo reticularis, and ulcers. It may also be associated with myalgias, arthralgias, neuropathy, and fever.[37,38] Patients may have periodic flareups or exacerbations of their disease, but the long-term course of their disease is generally benign. Progression to systemic polyarteritis nodosa is rare, but has been reported. Patients need long-term follow-up to monitor for this possibility.[39]

Systemic polyarteritis nodosa may have cutaneous involvement in up to 60% patients manifested most commonly as palpable purpura, bullae, and ulcerations and less commonly as nodules, livedo reticularis, and gangrene.[37,40,41] Nodules can sometimes be palpable along the course of an artery.[42]

In both forms of polyarteritis nodosa, leukocytoclastic vasculitis affects small- and medium-sized arteries of the skin[37,38] with IgM, fibrin, or C3 demonstrable on direct immunofluorescence.[37] Angiogenic cytokines have been reported to be elevated in serum and tissue in some patients with systemic and cutaneous polyarteritis nodosa reflecting vascular injury and repair.[43]

Hepatitis B, hepatitis C, streptococcal infection, Crohn's disease, Takayatsu arteritis, tuberculosis, and relapsing polychondritis are reported associations with both cutaneous and systemic polyarteritis nodosa.[39,44,45] In addition, cutaneous polyarteritis nodosa has been reported in association with ulcerative colitis[46] as a reaction to minocycline[47] and in a single report as a reaction to conjugated estrogen.[48]

Treatment

The benign cutaneous form of polyarteritis nodosa usually responds to systemic corticosteroids alone. Response to other treatments is less predictable. Other treatments that have been used include NSAIDs, sulfapyridine, dapsone, azathioprine, colchicine, pentoxifylline, and hydroxylchloroquine.[37,38] Low dose methotrexate, cyclophosphamide, and intravenous immune globulin have also been used with variable response.[49] Patients with streptococcal induced cutaneous polyarteritis nodosa should be treated with penicillin and may need long-term prophylaxis, especially in children where streptococcal induced disease appears to be more common.[37,38,49,50] General supportive measures include rest, medications for pain, local wound care for ulcerated lesions, and antibiotics for secondary infection.

Severe systemic polyarteritis nodosa is treated with prednisone 1 mg/kg/day plus cyclophosphamide 2 mg/kg/day similar to the treatment for Wegener's granulomatosis while milder cases have been treated with prednisone alone.[12] Patients on cyclophosphamide and prednisone need to be closely monitored to keep the leukocyte count above 3000/μL and the absolute neutrophil count around 1500/μL. The prednisone is converted to an alternate day regimen after 1 month and then tapered over about 6 months. The patient is slowly tapered off the cyclophosphamide after being in remission for 1 year.[12] Close monitoring for side effects of treatment is essential. Potential side effects of cyclophosphamide include neutropenia, sepsis, hemorrhagic cystitis, hair loss, gonadal dysfunction, and neoplasia. Measures to prevent osteoporosis are also indicated. Pulse cyclophosphamide plus corticosteroids have been advocated to reduce the total dose and toxicity from cyclophosphamide.[51,52] Because of higher relapse rates in Wegener's granulomatosis with the same regimen, Sneller et al. strongly recommend oral daily cyclophosphamide rather than pulse therapy.[12]

Systemic polyarteritis nodosa related to hepatitis B is best treated with systemic corticosteroids in combination with plasma exchange to clear immune complexes and either interferon-α[12] or lamivudine.[13]

Wegener's Granulomatosis

Wegener's granulomatosis is an uncommon disease of unknown cause characterized by necrotizing vasculitis and granulomatous inflammation involving the upper and lower respiratory tracts, together with glomerulonephritis, although more limited forms of the disease without renal involvement may occur.[14,15] Approximately 90% of patients, when in the active stage of their disease, have antineutrophilic cytoplasmic antibodies (ANCA) of the cytoplasmic type (cANCA) directed at proteinase 3.[15] The pathogenesis of Wegener's granulomatosis is poorly understood. There is limited evidence that ANCA antibodies of the cANCA type are involved in the pathogenesis of Wegener's granulomatosis. Bacterial peptides from *Staphylococcus aureus* and other bacteria share homology with peptides of complementary proteinase 3 suggesting infection may initiate an autoimmune response.[53]

Symptoms and Signs

Cutaneous lesions occur in approximately 45% of patients and include palpable purpura, ulcers, vesicles, papules, nodules, necrotic papules, and pustules.[15,54] Pyoderma gangrenosum-like ulcerations may occur.[55] Papules, nodules, and ulcerative lesions may be tender or painful.[54,56,57] The upper airway is frequently affected and manifestations include oral ulcerations and gingival hyperplasia with petechiae.[54] Friable gingival hyperplasia with petechiae is said to be pathognomonic of Wegener's granulomatosis.[57–59] Saddle nose deformity occurs in some patients, but is a rare manifestation.[55] On biopsy of cutaneous lesions one may see small vessel vasculitis, granulomatous dermatitis, and, least commonly, granulomatous vasculitis. Not all changes may be seen in the same specimen.[60]

Treatment

The treatment of choice for Wegener's granulomatosis is daily oral cyclophosphamide, 2 mg/kg daily plus prednisone 1 mg/kg daily.[12,14,15] Some patients with aggressive disease have been given higher initial IV doses.[14,15] Daily prednisone is continued on a daily dosage for 2 to 4 weeks, then converted to an alternate-day regimen over several months and finally tapered off. Patients are kept on cyclophosphamide for 1 year after achieving remission and then tapered off in 25-mg decrements every 2 to 3 months.[15] Methotrexate and azathioprine are potential substitutes for cyclophosphamide when patients are in remission to diminish long-term toxicity from cyclophosphamide.[12] Patients on cyclophosphamide need careful monitoring to keep the leukocyte count above 3000 per μL and the absolute neutrophil count around 1500 per μL. Patients also need close monitoring for other potential side effects of cyclophosphamide including sepsis, hemorrhagic cystitis, hair loss, gonadal dysfunction, and neoplasia. The complications of prolonged corticosteroid use can also occur and measures should be implemented to prevent osteoporosis. Prophylaxis for pneumocystic pneumonia with trimethoprim-sulfamethoxazole is also recommended unless the patient is allergic to the medication.[12]

Pulsed IV cyclophosphamide has been used instead of daily oral cyclophosphamide to lower the total dose and toxicity of cyclophosphamide but there is a higher frequency of relapses[61,62] leading Sneller et al.[12] to strongly recommend daily oral cyclophosphamide over pulse therapy. For patients with milder disease on initial presentation, treatment with methotrexate and glucocorticoids may be considered.[63,12] Trimethoprim-sulfamethoxazole has been advocated by some for prevention of relapse,[64] but only felt to prevent upper airway relapse and not serious internal organ relapse by others.[12] Etanercept was found to be ineffective in maintaining remissions and was associated with increased risk of neoplasia.[65] Rituximab has shown promise in a prospective open label pilot study in inducing and maintaining remissions.[66]

Microscopic Polyangiitis

Microscopic polyangiitis is a systemic small vessel vasculitis commonly affecting the kidneys, lungs, and skin. The vasculitis affects arterioles, capillaries, venules, and sometimes small- and medium-sized arteries with few or no immune deposits evident on direct immunofluorescence (pauci-immune).[31] Positive ANCA, usually of the perinuclear type (pANCA), also referred to as myeloperoxidase-ANCA, has been reported in >80% patients.[14] There is experimental evidence to suggest that myeloperoxidase-ANCA may be involved in the pathogenesis of vasculitis.[53]

Microscopic polyangiitis as defined by the Chapel Hill Consensus Conference is distinguished from cutaneous leukocytoclastic vasculitis by the presence of systemic involvement and the absence of immune deposits on direct immunofluorescence.[31] Both of these distinguishing features are time dependent. Patients initially presenting with cutaneous leukocytoclastic vasculitis need to be followed over time to determine whether systemic involvement will occur and immune deposits in vessel walls of the skin in leukocytoclastic vasculitis typically disappear in lesions more than 24 hours old.[67]

Cutaneous involvement has been reported in 44% to 62% patients with microscopic polyangiitis.[40] Purpura is commonly reported but a variety of other cutaneous manifestations have been reported including purpuric macules and papules, vesicles, bullae, splinter hemorrhages, nodules, cutaneous necrosis, digital infarction, gangrene, pyoderma gangrenosum-like ulcerations, livedo reticularis, facial edema, urticaria, orogenital ulceration, and erythema elevatum diutinum.[40,68–73] Although not focused on specifically in reports, ischemic pain would be expected as in other forms of vasculitis, particularly with ulcers, infarction, and gangrene.

Treatment

Serious major organ involvement, such as pulmonary or renal disease, is treated with a combination of corticosteroids and cyclophosphamide similar to Wegener's granulomatosis.[12,14] Higher IV doses initially have been recommended for patients with aggressive disease.[14]

Allergic Granulomatosis of Churg-Strauss

Churg-Strauss syndrome is a rare syndrome characterized by allergic rhinitis, asthma, eosinophilia, granulomatous inflammation, and systemic vasculitis affecting small- to medium-sized arteries.[14,31] Pulmonary involvement and cardiac involvement are common with coronary arteritis and myocarditis being the principal cause of death whereas renal involvement is relatively less common and tends to be mild.[14,40] Histologically, one sees a vasculitis affecting small vessels, extravascular granulomas, tissue infiltration with eosinophils, and an absence of vascular immune deposits on direct immunofluorescence.[60] As high as 70% to 78% of patients have positive ANCA, usually of the perinuclear type (pANCA), directed at myeloperoxidase.[14,74] Two recent reports indicated a positive ANCA in about 40% cases.[75,76] There is some evidence that ANCA antibodies of the myeloperoxidase-ANCA (pANCA) type and less convincing evidence that antibodies of the cANCA type are involved in the pathogenesis of vasculitis.[53]

Symptoms and Signs

Cutaneous lesions occur in up to 75% of patients.[77] The most common cutaneous findings are palpable purpura on the lower extremities and skin nodules.[78] Among the many other reported cutaneous manifestations are papules, plaques, petechiae, ulcers, infarcts, bullae, wheals, and livedo reticularis.[79] More recently described variations include severe digital gangrene associated with antiphospholipid antibodies[80] and purpura fulminans.[81] Pain or tenderness is characteristic of the skin nodules[82] and also likely occurs on an ischemic basis in some vasculitic lesions as well.

Treatment

The treatment of choice for Churg-Strauss syndrome is corticosteroids which usually controls the disease. For patients who do not respond or present initially with fulminant disease the addition of daily cyclophosphamide is recommended based on its success in treating other serious vasculitic disorders.[83] Pulsed IV cyclophosphamide plus corticosteroids have been recommended by some to lower the total dose and toxicity of cyclophosphamide compared to daily oral cyclophosphamide.[51,74] Careful monitoring of patients for side effects and complications of corticosteroids and cyclophosphamide is essential. Pulsed IV cyclophosphamide plus corticosteroids has also been advocated as first line therapy in patients with one or more poor prognostic factors (proteinuria >1 gm/day, creatinine >1.58 mg/dL [>140 μmol/L], cardiomyopathy, gastrointestinal involvement, and central nervous system involvement) and as second line therapy in patients who relapse on corticosteroids.[77] Patients may be switched from cyclophosphamide to a less toxic steroid sparing agent (e.g., azathioprine, when in remission).[77] There is limited information on some other reported therapies such as IVIG, plasma exchanges, rituximab, interferon alpha, and mycophenylate mofetil.[16,84,85]

Rheumatoid Vasculitis

Rheumatoid vasculitis is a systemic vasculitis that may affect vessels of different sizes including capillaries and small- and medium-sized arteries. It tends to occur in patients with more severe rheumatoid arthritis of long standing duration and high titer rheumatoid factor.[16,85,86] The diagnostic criteria as originally proposed by Scott and Bacon[17] included rheumatoid arthritis (meeting ARA criteria) plus one or more of the following: (1) mononeuritis multiplex, (2) peripheral gangrene, (3) biopsy evidence of acute necrotizing arteritis plus systemic illness such as fever or weight loss, and (4) deep cutaneous ulcers or active extra-articular disease (e.g., pleurisy, pericarditis, scleritis) if associated with typical digital infarcts or biopsy evidence of vasculitis.[17]

Histologically, one finds a vasculitis that may be leukocytoclastic, granulomatous, or lymphocytic.[84,87] IgM and/or complement was found on direct immunofluorescence in vessel walls in 6 of 7 patients by Chen et al. consistent with immune complex mediated vasculitis.[84] Immunoglobulins and complement are also commonly found in the normal skin of patients with rheumatoid arthritis and have been found to correlate with more severe extra-articular disease, vasculitis, and circulating immune complexes.[88]

Cutaneous manifestations are one of the most common fea-

tures of the disease (up to 90% patients) and include petechiae, palpable purpura, hemorrhagic blisters, ulcerations, nailfold and digital infarcts, subcutaneous nodules, livedo reticularis, atrophie blanche, gangrene, maculopapular erythematous rashes, and, rarely, erythema elevatum diutinum and pyoderma gangrenosum.[16,84,85] Ulcerations and gangrene may by painful on an ischemic basis.

Treatment

Patients with isolated nailfold infarcts (Bywaters lesions) require no treatment. Patients with more severe disease are treated with systemic agents. The only placebo-controlled study to date conducted with azathioprine demonstrated no clinical benefit.[89] Prednisone 0.5 to1 mg/kg/day in combination with other agents is often used in patients with more severe disease.[16] IV pulse cyclophosphamide plus methylprednisolone was found to be more effective than other treatments in one study.[17] Patients need to be monitored closely for complications of treatment particularly neutropenia, sepsis, or both. TNF alpha inhibitors, as reviewed by Genta et al., have been reported to be effective in treating rheumatoid vasculitis but also may cause vasculitis.[16]

Livedoid Vasculitis (Livedoid Vasculopathy)

Livedoid vasculopathy is an uncommon disease characterized by livedo reticularis and purpuric papules and exquisitely painful ulcerations on the lower extremities that heal with white atrophic scars, telangiectasias, and surrounding hyperpigmentation.[25,90] Some patients have associated medical conditions. Among the most common in a recent series of patients were venous insufficiency, deep venous thrombosis, and connective tissue diseases.[90] A lengthy list of coagulation disorders have also been reported in some patients with livedoid vasculopathy and reviewed by Calamia et al.[91]

The histologic changes seen on biopsy of livedoid vasculopathy include intimal proliferation, hyalinization of the intima, fibrinoid material in the vessel wall or lumen, and varying levels of inflammation but no leukocytoclasis.[92] The histologic changes have been referred to as segmental hyalinizing vasculitis in the past.[93] Direct immunofluorescence usually demonstrates fibrin, C3, and IgM in vessel walls.[94]

A question arises as to how extensively to evaluate patients for underlying coagulation disorders. Hairston et al. recommend the following studies: complete blood cell (CBC) count, cryoglobulins, cryofibrinogens, homocyteine, ANA, anticardiolipin antibody, lupus anticoagulant, protein C and S levels, factor V Leiden gene mutation, prothrombin gene mutation (G20210A), and beta 2 glycoprotein 1 antibody.[90]

Treatment

General supportive measures for livedoid vasculopathy include avoidance of smoking, rest, antibiotics for secondary infection, local wound care for ulcerations, and pain control.

Any underlying coagulation disorders should be treated. In the absence of any specific defects a reasonable initial approach to therapy would be aspirin 325 mg/day plus dipyridamole 50 mg three times daily[18] and/or pentoxifylline 400 mg three times daily.[19] One of the authors has obtained good results with danazol 50 to 100 mg twice daily. Low-dose danazol was reported to be effective in two patients by Hsiao et al.[95] The literature on treatment of livedoid vasculopathy consists of case reports or small series with no controlled studies. Other treatments reported to be effective include low or minidose heparin,[96,97] low molecular weight heparin,[98] warfarin,[99] phenformin and ethylestranol,[100] tissue plasminogen activator,[101,102] nicotinic acid,[93] nicotinamide,[93] nifedipine,[103] PUVA therapy,[104] hyperbaric oxygen,[105] and intravenous immunoglobulin.[106] Treatment should be individualized. The concept of a therapeutic ladder as proposed by Callen with treatments with more potentially serious side effects higher on the ladder is a sound one.[20]

OTHER VASCULAR DISORDERS

Antiphospholipid Syndrome

The antiphospholipid syndrome (APS) is an uncommon syndrome characterized by thrombotic occlusion of arteries and/or veins, complications of pregnancy (miscarriage, spontaneous abortions, and prematurity), thrombocytopenia, and positive anticardiolipin and/or lupus anticoagulant antibodies.[107–109] The anticardiolipin and/or lupus anticoagulant tests should be positive on at least two occasions at least 6 weeks apart to exclude transiently positive tests. APS may occur as a primary disorder, as a secondary disorder in patients with lupus erythematosus, and also may occur in a subset of patients with Sneddon's syndrome (livedo reticularis and multiple cerebrovascular events). Antiphospholipid antibodies in themselves are not diagnostic of antiphospholipid syndrome because they occur normally in small percentage of the normal population and have been associated with multiple other conditions.[107,110] Histologically, skin biopsies demonstrate noninflammatory thrombosis of arteries and/or veins.

Symptoms and Signs

Cutaneous manifestations of APS are common. In a recent series of 200 cases they occurred in 49% of patients with livedo reticularis, digital necrosis, subungual splinter hemorrhages, and superficial venous thrombosis being the most common.[108] Multiple other cutaneous manifestations have been reported with APS including cutaneous necrosis and gangrene, cutaneous ulcers, painful skin nodules, lesions resembling vasculitis, necrotizing vasculitis, livedoid vasculitis, anetoderma, discoid lupus erythematosus, Degos-like lesions (malignant atrophic papulosis), progressive systemic sclerosis, cutaneous T cell lymphoma, erythematous macules, petechiae, purpura, and ecchymoses.[108,110,111] Livedo reticularis is the most common skin manifestation and reported to have irregular broken circles (livedo racemosa) as opposed to the unbroken circles of physiologic cutis marmorata.[108] The cutaneous lesions of APS may be painful on an ischemic basis, particularly areas of necrosis, ulcers, and gangrene.

Diagnosis is based on the presence of either a thrombotic vascular occlusive event or a qualifying complication of pregnancy (≥1 unexplained deaths of morphologically normal fetus ≥10 weeks' gestation, ≥3 consecutive spontaneous abortions <10 weeks' gestation, or ≥1 premature birth of a morphologically normal fetus ≤34 weeks' gestation) plus the presence of either anticardiolipin or lupus anticoagulant antibodies.[107] These criteria were based on the preliminary criteria for the classification of APS published in an international consensus statement in 1999 referred to as the Sapporo criteria for the city in Japan where the conference was held.[112] These criteria were designed primarily for research purposes. Proposed revisions of the criteria were published in another international consensus statement in 2006.[113] These consensus statements provide greater detail regarding the qualifying pregnancy morbidity criteria and laboratory methods needed to confirm the diagnosis of lupus anticoagulant antibodies. The latest international consensus statement published in 2006 is remarkable for the following proposed revisions: (1) increasing the interval between repeat antiphospholipid tests from 6 weeks to 12 weeks to exclude transiently positive tests, (2) the addition of anti-beta2-glycoprotein I antibody as a qualifying antibody test, (3) more quantification of qualifying medium or high positive anticardiolipin titers (i.e., >40 GPL [IgG phospholipid units] or MPL [IgM phospholipid units] or

>99th percentile of controls), and (4) exclusion of patients if less than 12 weeks or more than 5 years separate the positive antiphospholipid antibody test and the clinical event.[113] These changes are discussed in greater detail by Kriseman et al.[109] who favor the Sapporo criteria over the more recently proposed revisions.

Treatment

The patient should be treated for any risk factors for cardiovascular events including hypertension and hyperlipidemia and advised to avoid smoking and oral contraceptives.

APS patients with a history of prior thrombosis or initially presenting with thrombosis should be treated differently depending on whether the thrombosis is venous or arterial. There is agreement that patients with venous thrombosis should be treated with warfarin with a target INR 2.0–3.0.[114,115] Arterial thrombosis may be categorized as cerebral or noncerebral. Lim et al.[114] recommend warfarin (INR 1.4–2.8) or aspirin 325 mg/day for cerebral arterial thrombosis with APS and warfarin (INR 2.0–3.0) for noncerebral arterial thrombosis. Using a different approach with analysis of more inclusive data (cohort studies, subgroup analysis, and randomized control studies) Ruiz-Irastorza et al.[115] recommend that patients with arterial thrombosis (mainly cerebral) and patients with recurrent venous thrombosis (despite adequate warfarin therapy) be treated with warfarin with a target INR 3.0–4.0. Treatment should be for life or at least long-term.[107] Asymptomatic patients incidently found to have antiphospholipid antibodies with no history of thrombosis or pregnancy complications may be offered no treatment or low-dose aspirin.[114]

For catastrophic APS (an acute severe variant with widespread microvascular occlusive events), an algorithmic approach was developed in an international consensus statement where patients presenting with non–life-threatening disease are treated with IV heparin and high-dose steroids whereas patients presenting with life-threatening disease are treated with IV heparin, high-dose steroids, and IVIG and/or plasma exchange.[116] Other therapies are then added as needed such as cyclophosphamide (for SLE flare), prostacyclin, fibrinolytics, or defibrotide.[116] Careful monitoring to detect, treat, or prevent precipitating factors is also recommended including infections, surgery, trauma, invasive procedures, underlying malignancy, SLE flares, and obstetric complications.[116,117]

Treatment and prevention of APS in pregnancy is complicated by the fact that warfarin is teratogenic. Women with APS on warfarin with a prior history of thrombosis should be switched to unfractionated heparin (UH) or low molecular weight heparin (LMWH) at full therapeutic doses.[118] They should be switched back to warfarin after the pregnancy. Women with APS based on pregnancy complications such as ≥2–3 first trimester losses, ≥1 fetal deaths, or ≥1 premature births due to placental insufficiency should be treated with low-dose aspirin and prophylactic doses of UH or LMWH.[118] The UH or LMWH is continued for 6 weeks after delivery and low-dose aspirin is continued lifelong. Pregnant women who have been incidentally found to have antiphospholipid antibodies with no prior history of thrombosis or qualifying pregnancy complications for APS are treated with low-dose aspirin during pregnancy which is continued after delivery.[118]

Multiple clinical studies have shown antimalarials to have an antithrombotic effect in patients with SLE.[115] In a recent observational prospective cohort study of 232 patients with SLE, antimalarials were protective against thrombosis and increased patient survival.[119] The role of antimalarials in treatment of APS has yet to be elucidated especially outside the setting of SLE. Other therapies that may eventually prove useful include statins and agents to inactivate complement.[115] There have been case reports of APS responding to rituximab with improvement or complete disappearance of autoimmune hemolytic anemia, thrombocytopenia, antiphospholipid antibody titers, and thrombotic episodes.[120]

Some Clinical Considerations Related to Corticosteroids and Immunosuppressive Agents

Systemic corticosteroids, corticosteroids combined with cytotoxic agents and noncorticosteroid immunosuppressive agents alone, are sometimes prescribed for serious skin disorders such as vasculitis, immunobullous disorders, connective tissue diseases, and other skin disorders. Standard measures should be taken to prevent complications—measures to prevent osteoporosis with chronic corticosteroids and measures to prevent bladder toxicity from cyclophosphamide. Chronic corticosteroids and other immunosuppressive agents have been associated with pneumocystis pneumonia (PCP) in non-HIV patients, but clear preventive guidelines have not yet been established in some of the lower risk groups for this complication. For patients with serious vasculitis some authorities recommend prophylaxis with trimethoprim-sulfamethoxazole (TMS) for all patients on chronic therapy with a combination of corticosteroids and a cytotoxic agent.[12] A recent review and meta-analysis concluded that the benefits of TMS prophylaxis outweighed the risks of serious adverse reactions requiring discontinuation of the drug when the risk of PCP was >3.5%, as for example in Wegener's granulomatosis, allogeneic bone marrow and solid organ transplants, and certain malignancies.[121] Children have a lower risk of adverse reactions to TMS so prophylaxis can be considered at lower incidence levels of PCP.[121] Other authorities monitor for depressed CD4 levels on chronic immunosuppression in non-HIV patients and institute prophylaxis for a CD4 count <300/μL.[74,122] Until more information is available, a reasonable approach would be to use TMS prophylaxis for all patients in the higher risk categories with >3.5% incidence of PCP, as in Wegener's granulomatosis, and follow CD4 counts in the lower risk categories instituting TMS prophylaxis for a CD4 count <300/μL. Patients with connective tissue diseases, polyarteritis nodosa, pemphigus, pemphigoid, and other long-term corticosteroid treatment are considered to have a <3.5% incidence of PCP.[121] It should be kept in mind, however, that PCP has been reported in patients with a CD4 counts >300/μL, so the previously noted recommendations should not prevent starting prophylaxis in other patients on a case by case basis, particularly if lymphopenic.[123,124]

Coumarin Necrosis

Coumarin necrosis is a rare reaction to warfarin and other coumarin anticoagulant derivatives that causes painful skin necrosis typically on the breasts, abdomen, buttocks, and thighs of middle-aged, obese women.[125–127]

Pathophysiology

Warfarin induced skin necrosis is believed to be caused by a temporary hypercoagulable state that occurs on initiation of warfarin treatment.[126] Protein C is a vitamin K dependent natural anticoagulant whereas factors II, VII, IX, and X are vitamin K dependent clotting (procoagulant) factors. Because of shorter half lives of protein C and factor VII, there is a relatively rapid fall in protein C and factor VII when warfarin is begun, compared to factors II, IX, and X, leading to a transient hypercoagulable state.[128] Patients who have hereditary or acquired protein C deficiency, protein S deficiency, or antithrombin III deficiency are at greater risk.[126,129] Histologically, thrombi in capillaries and

venules is considered to be the primary process, but other changes related to necrosis and hemorrhage can be seen.[126,130]

Symptoms and Signs

Symptoms usually begin within the first 3 to 6 days of starting warfarin but delayed onset of warfarin induced skin necrosis has been reported.[131] One or more erythematous edematous plaques appear that develop petechiae on their surface followed by blue-black discoloration, hemorrhage, bullous formation, gangrene or necrosis, and, finally, eschar formation.[132] The lesions are very painful.

Treatment

Warfarin therapy should be discontinued and heparin substituted for warfarin. Protein C concentrate has been reported to be effective as adjunctive therapy in treating one patient with phenprocoumon (coumarin derivative) induced necrosis and, as a preventive measure, in allowing the patient to be restarted on the oral anticoagulant.[133] Avoidance of warfarin and other coumarin derivatives in the future is the most prudent approach. Restarting warfarin at low dosage under coverage of intravenous heparin has been done successfully. However, three of seven patients reported by Jillella et al.[129] experienced recurrences of their skin necrosis, so great care and caution are needed. LMWH has been recommended over chronic unfractionated heparin use if warfarin cannot be restarted because of less risk of osteoporosis, lower risk of thrombocytopenia, and there is no need to monitor partial thromboplastin time (PTT).[131]

Meticulous wound care and pain management is necessary. More than 50% of patients require surgical intervention in the form of debridement, grafting, and amputation.[130]

Calciphylaxis

Calciphylaxis is a potentially life threatening cause of painful ulcerations of the skin that occurs most commonly in patients with chronic end-stage renal disease but also rarely occurs in patients without renal failure.[134–136] It has a reported prevalence rate of 4.1% in patients undergoing hemodialysis.[137] Many but not all patients have secondary hyperparathyroidism with elevated parathyroid hormone, increased alkaline phosphatase, increased calcium, phosphorous, or calcium x phosphate ion product.[137,138] Other potential risk factors include protein C deficiency, protein S deficiency, and warfarin therapy.[139]

Histologically, there is calcification of small arteries, intimal hyperplasia, and noninflammatory thrombosis of vessels.[140] Calcification of arteries may be seen on x-rays, but is nonspecific.

Cutaneous manifestations may begin as a painful violaceous discoloration similar to livedo reticularis that evolves to indurated plaques, ulcerations, and eschar formation. Patients are at high risk for secondary infection and sepsis which is the principal cause of death. Gangrene requiring amputation may also occur.[141] Diagnosis requires clinicopathologic correlation. Preservation of pulses, proximal location of ulcers on extremities, and absence of neuropathy favors calciphylaxis over arteriosclerotic ulcers and diabetic ulcers although patients may have concomitant disease and calciphylaxis ulcers may occur on acral locations.[137]

Treatment

Measures should be taken to lower the serum calcium, serum phosphate, and calcium x phosphate product when elevated. These measures may include low calcium dialysate, noncalcium phosphate binders, and low phosphate diet.[136,142]

A number of treatments have been reported to be effective in case reports or small series. One of these is cinacalcet (Sensipar) which is a calcimimetic agent that acts by increasing the sensitivity of the calcium receptor to calcium and, thus, lowering parathyroid hormone levels.[143–145] Another agent is sodium thiosulfate—a salt that increases the solubility of calcium in the form of calcium thiosulfate.[146–148] Pamidronate, a bisphosphonate, was reported to be effective in one patient. It was tried because of experimental studies in animals where it prevented calciphylaxis and because of its anti-inflammatory properties.[149] Another bisphosphonate, etidronate, has also been reported to be effective in treating calciphylaxis.[150] Low-dose tissue plasminogen activator has been reported to be effective by relieving thrombotic occlusion of vessels.[151] Hyperbaric oxygen has also been reported to be effective by increasing the partial pressure of oxygen in ischemic tissues.[152]

Parathyroidectomy has been effective in some but not all patients. It is more likely to be beneficial in patients with marked hyperparathyroidism.[136,142]

Local wound care, pain management, and antibiotics for secondary infection are also essential. Amputation may be needed in some patients.

ULCERS

Ischemic Ulcers

Ischemic (arterial) ulcers are a cause of painful ulcerations on the lower extremities most often seen in patients with arteriosclerotic peripheral vascular disease. The ulcers typically have a dry punched out appearance and are located on the distal lower extremities at sites of trauma or pressure including the toes, feet, lateral malleoli, and pretibial areas.[153–155] There may be associated atrophic skin, loss of hair, delayed capillary filling pressure, and rubor with dependency (reactive hyperemia). The ulcer pain is worse at night and relieved by dependency. Patients also may have a history of intermittent claudication and rest pain if the obstruction is severe enough.

Histologically, arteriosclerosis affects medium and large arteries where one finds plaques with varying degrees of infiltrations with foam cells, smooth muscle cells, inflammatory cells, hemorrhage, platelets, thrombus formation, collagen deposition, and ulceration.[156] Patients may have ulcers with a mixture of venous and arterial disease. Diabetics may also have small vessel disease complicated by peripheral neuropathy leading to further trauma and injury at the site. Neuritis on an ischemic basis may also occur.

The patient should be examined for absent or diminished pulses and bruits over proximal arteries. The patient should be further evaluated with measurements to determine the ankle brachial index which consists of the ratio of the systolic blood pressure in the ankle to the systolic blood pressure in the arm as detected by hand held Doppler device. A normal ankle brachial index (ABI) is ≥ 1, < 1 is abnormal, and ≤ 0.5 is severe disease.[157] Patients with calcification of arteries have a falsely elevated ABI because of noncompressibility of vessels. Other noninvasive forms of evaluation include digital pulse volume recordings, Doppler flow volume wave form analysis, duplex ultrasound, transcutaneous oximetry, stress testing, computerized tomographic angiography, magnetic resonance angiography, and toe-brachial index (to evaluate noncompressible vessels).[157,158] Digital subtraction angiography is considered the gold standard.[158]

Treatment

Measures should be taken to treat underlying causes of arteriosclerosis including cessation of smoking, control of blood pressure, hyperlipidemia, and control of diabetes.[155] Elevation of the extremity, compression and debridement of ulcers are to be

avoided. Protection of the extremities from trauma with sheepskin and foot cradling devices is helpful. Patients with claudication may benefit from an exercise program when the ulcer has healed. Adequate pain relief, local wound care, and treating any secondary infection are important. When conservative measures fail, there are a variety of nonoperative and operative revascularization procedures that may be used, including percutaneous transluminal angioplasty, stent placement, atherectomy, and bypass procedures, depending on the individual patient.[157]

Stasis Ulcers

Stasis ulcers (venous ulcers) are a common cause of painful ulcerations on the ankles typically over the medial malleoli in patients with chronic venous insufficiency.[155,159,160] Associated skin findings may include hyperpigmentation from hemosiderin deposition, varicosities, pitting edema, scars from prior ulcerations, and fibrosis and induration of tissues (lipodermatosclerosis). There may also be associated stasis dermatitis, contact dermatitis from topical medications, and secondary infection. The ulcer itself is typically shallow with irregular borders and sloping edge.[155,160]

Venous ulcers occur in the setting of chronic venous hypertension due to incompetent venous semi-lunar valves in superficial veins, communicating veins, or deep venous system or with disease of the calf muscles which act as a pump to empty the deep venous system.[153,160] The valves may be damaged by prior episodes of thrombophlebitis or be congenitally absent.[160] Obesity and peripheral edema from other causes such as pulmonary, cardiac, hepatic, or renal disease may be contributory or exacerbating factors. Pain in the ulcers is presumably on an ischemic basis.

Treatment

Elevation of the legs and support stockings will help control peripheral edema. Unna boots and other compressive wraps speed wound healing. Compression should be avoided, however, in patients with concomitant arterial disease. Local wound care may include gauzes, films, hydrogels, hydrocolloid dressings, foams, alginates and hydrofibers, or antimicrobial dressings.[161] Occlusive dressings on the wound may also relieve pain. Surgical debridement may sometimes be needed. Cultures should be taken if secondary infection is present and the patient treated with antibiotics effective for *Staphylococcus aureus* and *Streptococcus pyogenes*. Dermatitis from stasis dermatitis or contact dermatitis is treated with topical steroids and avoidance of responsible contactants. Surgical management with grafting may be necessary in refractory cases. Weight reduction and diuretics may be helpful in some obese patients. Optimization of therapy for any associated systemic conditions causing peripheral edema such as congestive heart failure or pulmonary insufficiency may also be helpful.

PAINFUL INFECTIONS

Many infections of the skin are painful. Common or selected skin infections are discussed here. For more comprehensive coverage of the topic the reader is referred to a general textbook of dermatology such as Fitzpatrick's *Dermatology in General Medicine*.

Herpes Zoster

Herpes zoster is a painful eruption caused by reactivation of the varicella virus in a dermatomal distribution.[162,163] The topic is presented and discussed in detail in Chapter 27.

Signs and Symptoms

Herpes zoster (HZ) is a painful vesicular cutaneous eruption in a dermatomal distribution that is often preceded by a 2 to 3 day prodrome of pain, paresthesias, or burning sensation in the involved dermatome. The eruption begins as erythematous macules, papules, and plaques, often grouped within a dermatome, that rapidly develop clear vesicular lesions on the surface. Lesions may become hemorrhagic or necrotic. Rarely, patients may have pain without skin lesions (zoster sine herpete). The clear vesicular blister fluid becomes cloudy which is followed by crusting and healing. In uncomplicated HZ the disease runs its course over 2 to 4 weeks with healing of lesions and subsidence of pain. Immunosuppressed patients may have delayed healing and an atypical appearance to the rash with persistent ulcerative or verrucous lesions as well as possible acyclovir resistance.[163]

Diagnosis

In the prodromal phase the disease may mimic a variety of acute medical conditions, but once the eruption appears the diagnosis becomes more straightforward. The diagnosis is confirmed by direct fluorescent antibody testing of scrapings from early vesicular lesions. Cultures can be done, but they take 2 weeks and may be negative. Postherpetic neuralgia is a serious complication of the disease that increases with age and is discussed in Chapter 27.

Treatment

Supportive care includes Burow's compresses, analgesics, and antibiotics for secondary infection when present. Antiviral therapy is indicated for all immunocompetent patients greater than 50 years old, all immunocompromised patients, and patients less than 50 years of age who have moderate to severe HZ (pain or rash), nontruncal involvement, ophthalmic zoster, Ramsay Hunt syndrome, motor nerve involvement, other neurologic involvement, or disseminated HZ. Antiviral therapy should preferably be started within the first 72 hours. Valacyclovir 1000 mg three times per day for 7 days and famciclovir 500 mg three times per day for 7 days are felt to be more effective than acyclovir 800 mg five times per day for 7–10 days because of higher blood levels and better compliance with dosing, but any of the three regimens may be used. Dosages of the medications need to be adjusted for renal insufficiency if present. For immunosuppressed patients, IV acyclovir 10 mg/kg three times per day may be needed. Valacyclovir in high dosages in immunosuppressed patients has been associated with thrombotic thrombocytopenic purpura and is best avoided under those circumstances. A 3-week course of systemic corticosteroids may provide some symptomatic relief in severe HZ if no contraindications and the patient is also receiving an antiviral agent. On May 25, 2006, the Food and Drug Administration (FDA) approved a live attenuated virus vaccine (Zostavax, Merck) for prevention of HZ in persons 60 years of age or older.[164] The vaccine was demonstrated to reduce the incidence of HZ and postherpetic neuralgia. Treatment of postherpetic neuralgia is dealt with in Chapter 27.

Herpes Simplex

Herpes simplex virus (HSV) infection is a common often painful DNA viral infection presenting as grouped vesicular lesions on an erythematous base that may be preceded by a 1 to 2 day prodrome of burning, tingling or itching.[165–168] The early clear vesicular lesions progress through stages of clouding, crusting, and then healing.

Symptoms and Signs

Primary HSV infection (no antibodies to HSV in acute phase serum) may potentially be the most severe, painful, and protracted and is often accompanied by fever, malaise, tender regional adenopathy, and a higher rate of complications.[165] "First

episode" HSV may be primary infection or may be recurrent HSV where the primary infection was asymptomatic.[166] Between episodes the virus remains latent in sensory nerve ganglia and may periodically reactivate. Recurrent episodes are generally milder than the original episode and tend to become less frequent with time. Fever, stress, ultraviolet light, and certain surgical procedures may trigger reactivation of the virus (e.g., dermabrasion or laser resurfacing).

HSV infection may present in multiple clinical forms with orolabial (herpes labialis) and genital HSV being the most common. Keratoconjunctivitis, herpetic sycosis (beard area), herpetic whitlow, herpes gladiatorum, eczema herpeticum, recurrent lumbosacral HSV, and neonatal HSV are other clinical forms of the disease. HSV may also trigger recurrent episodes of erythema multiforme where HSV virus DNA can be detected in the lesions of erythema multiforme by polymerase chain reaction (PCR).[169] Immunosuppressed patients tend to have more severe and slower healing HSV infections with atypical clinical appearance such as persistent crusts, erosions, ulcerative, or vegetative lesions. Less commonly, visceral infection may occur affecting the esophagus, lungs, liver, and other organs.[165] Neonatal HSV may occur in utero, at the time of the delivery, or in the immediate few weeks after delivery. Patients may have involvement of the skin, eyes, and mouth (SEM), central nervous system (CNS), or disseminated disease. Most patients with neonatal HSV (68%) have vesicular skin lesions but a significant percentage of patients especially with CNS or disseminated disease have no skin lesions.[166]

Diagnosis

The diagnosis is most readily established by direct fluorescent antibody testing of scrapings from early vesicular lesions. Cultures should also be taken when possible from early vesicular lesions and will usually grow out within 48 to 72 hours. PCR for HSV DNA may be more sensitive than culture especially for demonstrating HSV in CNS.[165] Tzanck preparation has the advantage of obtaining immediate results but is more dependent on the experience and skill of the interpreter. It will not distinguish between HSV and herpes zoster virus. Skin biopsy will show ballooning degeneration of keratinocytes and multinucleate giant cells in the epidermis.

Treatment

Treatment with analgesics for pain, wet compresses with Burow's solution, and antibiotics for secondary infection are helpful supportive measures.

The principal antiviral medications for treatment of HSV are acyclovir, valacyclovir, and famciclovir. Valacyclovir and famciclovir have an advantage of less frequent dosing and greater bioavailability, but they are more expensive than acyclovir. Severe episodes of HSV are treated with IV acyclovir. The dosages of the medications need to be adjusted in patients with renal failure. Valacyclovir has been associated with thrombotic thrombocytopenic purpura at high dosages in immunocompromised patients and is best avoided under those circumstances. Representative treatment schedules are presented below for HSV.[165–168] A wider range of acceptable schedules and dosing is available.

First episodes of either orolabial or genital HSV infection may be treated with acyclovir 200 mg five times per day, valacyclovir 1 gm twice per day, or famciclovir 250 mg twice per day, all for 7 to 14 days.[165,166] Recurrent genital HSV may be treated with acyclovir 200 mg five times per day for 5 days, valacyclovir 500 mg twice per day for 3 to 5 days, or famciclovir 125 mg twice per day for 5 days. There is limited clinical benefit from treating recurrent orolabial HSV with intermittent topical antiviral therapy or intermittent oral antiviral drugs, although sun protective measures may be helpful on a preventative basis. If antiviral agents are used they should be initiated during the prodrome if possible.

For chronic suppression of recurrent genital HSV acyclovir 400 mg twice daily, valacyclovir 500 mg daily, valacyclovir 1 gm daily (for >9–10 recurrences per year), or famciclovir 250 mg twice daily may be used.[165,166] For chronic suppression of orolabial HSV infection, acyclovir 400 mg twice daily is usually recommended.[166] Prevention of reactivation of orolabial HSV infections with surgical procedures may be accomplished by giving valacyclovir 500 mg twice daily or famciclovir 250 mg twice daily 24 to 48 hours prior to the surgical procedure and continuing for 10 to 14 days.[165,166]

IV acyclovir 5 mg/kg every 8 hours is used for patients with severe disease in either immunocompetent patients or immunosuppressed patients. If oral antiviral agents are used in immunosuppressed patients, higher than usual doses and/or longer duration of treatment are usually recommended for initial episodes, recurrent disease, as well as for chronic suppression.[165,168] Acyclovir resistance is more likely to be encountered in immunosuppressed patients and treatment with intravenous foscarnet 40 mg/kg every 8 hours is an alternative agent that may be useful.[165]

Neonatal HSV infection is treated with IV acyclovir 60 mg/kg/day for 14 days for skin, eyes, and mouth involvement and 21 days for CNS involvement or disseminated disease.[166] Some authorities recommend oral acyclovir for 3 to 4 months following IV therapy.[165]

Erysipelas and Cellulitis

Both erysipelas and cellulitis are soft tissue infections that cause erythema, edema, warmth, and pain often on the lower extremities but other areas as well. Erysipelas is distinguished from cellulitis in being more superficial in the dermis and sharply demarcated from the surrounding normal skin, whereas cellulitis typically affects deeper tissues and is more indurated and poorly circumscribed.[170–173] Both may be associated with fever, chills, lymphangitis, and localized lymphadenopathy. Bullous formation may occur with erysipelas and rarely with cellulitis (e.g., vibrio vulnificus).[171,173] Group A streptococcus (streptococcus pyogenes) is the principal cause of erysipelas but may also cause cellulitis. Cellulitis may be caused by many other organisms as well. A break in the skin or portal of entry may sometimes be found (e.g., trauma or fissuring between the toes from tinea pedis).

The diagnosis is often made clinically before lab tests are available. Distinguishing erysipelas from cellulitis may be difficult at times. Culturing any breaks in the skin or ulcers may be helpful in recovering the organism. Culturing aspirates from the rash or skin biopsies are typically low yield procedures. Blood cultures, when positive, provide a definitive diagnosis.

Treatment

Erysipelas responds to treatment with intramuscular (IM) benzathine penicillin G or oral penicillin VK. Because *Staphylococcus aureus* may be difficult to exclude clinically, treatment with cephalexin or dicloxacillin pending culture results is prudent.

Cellulitis of the skin is often caused by *Staphylococcus aureus* and *Streptococcus pyogenes* and coverage with oral cephalexin or dicloxacillin for milder cases of infection is usually sufficient. Initial therapy is highly dependent on the history of exposure to any unusual organisms, underlying illnesses of the patient, toxicity of the patient, clinical setting (e.g., diabetic foot ulcer), and likelihood of methicillin-resistant *Staphylococcus aureus* (MRSA) which would dictate other antibiotic coverage. Seriously ill patients may need hospitalization, IV antibiotics, and infectious disease consult.

Elevation of the extremity if no arterial insufficiency is present, moist compresses (e.g., sterile saline or Burow's compresses) for any ulcers, and antifungal cream for tinea pedis are important adjunctive measures.

Furunculosis and Carbuncle

Furuncles and carbuncles are painful staphylococcal infections in hair bearing areas that begin as a folliculitis. A furuncle occurs when infection extends down the hair follicle to the subcutaneous tissue with abscess formation producing an erythematous, painful nodule with a superimposed follicular centered pustule. A carbuncle occurs when infection spreads to multiple adjacent contiguous follicles by subcutaneous extension resulting in a larger, erythematous, painful mass with superimposed follicular pustules. Culture and sensitivity taken from the pustules should guide antibiotic therapy.[174]

Treatment

Fluctuant abscesses should be incised, drained, and cultured. Milder cases may respond to incision and drainage and moist heat alone,[175] but careful follow-up is necessary if oral antibiotics are not given. If antibiotics are needed dicloxacillin or cephalexin 250 to 500 mg four times per day for 7 to 10 days should be used to treat methicillin-sensitive *Staphylococcus aureus* (MSSA). If MRSA is suspected treat with trimethoprim-sulfamethoxazole (TMP-SMX) one double strength tablet twice daily or doxycycline 100 mg twice daily for 7 to 10 days or minocycline 100 mg twice daily for 7 to 10 days, but it should be kept in mind that these agents will not treat Group A streptococcus infection.[176] If the MRSA is resistant to erythromycin and sensitive to clindamycin, a "D test" must be done to exclude inducible clindamycin resistance before clindamycin may be used. More seriously ill patients may need hospitalization and treatment with IV antibiotics.

In patients with recurrent furunculosis, elimination of nasal staphylococcal carriage and skin colonization may be helpful although the information on efficacy is limited. Regimens include intranasal mupirocin ointment twice daily for 5 days per month, rifampin 600 mg per day for 10 days plus dicloxacillin 250 to 500 mg four times per day for 10 days for MSSA; and rifampin 600 mg per day plus either TMP-SMX one double strength tablet twice daily for 10 days or doxycyline 100 mg twice daily for 10 days or minocycline 100 mg twice daily for 10 days for MRSA.[174–176] Rifampin should never be used alone because of rapid development of resistance. Chlorhexidine may be used to cleanse the skin. Some authorities recommend an infectious disease consult before eradication of the carrier state is attempted[176] and limiting systemic antimicrobials in this situation to patients with active infection.[177]

Good hygienic measures may be helpful for patients in preventing recurrences and spread of infection to others such as frequent handwashing, keeping wounds cleanly bandaged, regular laundering of clothing in contact with the wound, regular bathing with soap, avoiding shared towels and other shared items, and cleansing of equipment and surfaces in contact with wound drainage.[177,178]

Erysipeloid

Erysipeloid is an acute painful infection of the skin caused by *Erysipelothrix rhusiopathiae*, a gram-positive rod. It is an occupational hazard of fishermen and butchers and occurs domestically in those who handle raw fish, poultry, and meat products.[179,180]

The organism gains entrance through a break in the skin to cause what has been referred to as an erysipeloid rash. A painful violaceous red, warm, raised, lesion develops usually on the hand or finger, spreads peripherally, and clears centrally. There is no ulceration or scaling. Usually the infection remains localized, but systemic infection may occur.

The treatment of choice is penicillin 2 to 3 million units daily, orally or IM for 7 to 10 days. Higher doses are needed if systemic infection occurs.[179,180]

INFLAMMATIONS

Panniculitis

Erythema Nodosum

Erythema nodosum is a common cause of septal panniculitis that typically affects young adults between 20 and 30 years of age, with M:F ratio of 1:6, although any age may be affected.[181,182] Erythema nodosum usually presents as bilateral tender, poorly circumscribed erythematous nodules, 1 to 10 cm in diameter, on the anterior tibial areas but more widespread involvement may occur.[182] The lesions typically heal over a few weeks without scarring although new lesions may continue to appear. Some patients have constitutional symptoms such as fever, malaise, arthralgias, headache, cough, abdominal pain, vomiting, or diarrhea.[181] Associated lab abnormalities may include leukocytosis and elevated erythrocyte sedimentation rate.[182]

There have been many reported causes of erythema nodosum including infections (bacterial, viral, fungal, and protozoan), medications (e.g., penicillin, sulfonamides, oral contraceptives, iodides, and salicylates), malignancy, sarcoidosis, inflammatory bowel disease, and pregnancy.[181–184] Sarcoidosis and streptococcal infections are among the most frequent causes. They were reported in 11% to 28% and 6% to 28% of cases, respectively, in two recent series.[183,184] Streptococcus infection is an important cause of erythema nodosum in children—reported in 49% cases in one series.[185] In 35% to 55% cases no etiology may be found.[183,184] Uncommon, but important, causes to exclude are mycobacterium tuberculosis, deep fungal infections (histoplasmosis, coccidioidomycosis, and blastomycosis), and malignancy (lymphoma, leukemia, and solid tumors).[181]

The pathogenesis of erythema nodosum is poorly understood and felt to be a hypersensitivity reaction to etiologic agents. Histologically, one finds inflammation of the septae between fat lobules that evolves from acute inflammation to granulomatous change followed by fibrosis. The presence of Miescher's radial granulomas with aggregates of histiocytes and neutrophils around central clefts is a characteristic feature.[186]

Treatment

Any underlying diseases or infections should be treated. Medications that are a potential cause should be discontinued. Bed rest and NSAIDs may be sufficient. In patients with more persistent or recalcitrant disease, potassium iodide 400 to 900 mg daily may be helpful. Potassium iodide is contraindicated in pregnant women, should be avoided in renal insufficiency (risk of hyperkalemia), and used cautiously, if at all, in patients with thyroid disease (risk of hyper- or hypothyroidism).[187] It should be kept in mind that both aspirin and iodides have been reported as both causing and treating erythema nodosum. A short course of systemic corticosteroids may be helpful if any underlying infectious diseases have been excluded.

Weber-Christian Disease

Weber-Christian disease, also referred to as relapsing febrile nonsuppurative nodular panniculitis, is a disease characterized by recurrent episodes of fever and crops of painful subcutaneous nodules that may be erythematous and rarely discharge oily material.[188–192] The nodules may occur on the face, trunk, and extremities but are most common on the extremities, particularly the thighs. The nodules may eventually heal with atrophy. Patients may have associated arthritis, arthralgias, myalgias, ab-

dominal pain, and hepatosplenomegaly. Lab abnormalities described include elevated sedimentation rate, anemia, leukopenia, leukocytosis, thrombocytopenia, and circulating immune complexes. Visceral fat involvement may occur affecting the omentum, mesentery, and mediastinum, and perivisceral or intravisceral fat of the heart, kidneys, adrenals, pancreas, bone marrow, and joints. The disease may be fatal.

Histologically, one finds a lobular panniculitis with initial degeneration of fat cells and acute inflammation followed by infiltration with macrophages, foam cells, and extracellular lipid and, eventually, fibroblasts and chronic inflammatory cells corresponding to the stage of atrophy.[186]

Some of the cases of Weber-Christian disease reported in the past would be classified under different diagnostic categories today, such as cytophagic histiocytic panniculitis or alpha$_1$-antitrypsin deficiency and, possibly, lupus profundus or pancreatic panniculitis. Whether there remains a residual subset of patients with Weber-Christian disease is controversial. Some consider the Weber-Christian disease a nonspecific reaction pattern or another term for idiopathic and advise that the term be abandoned for more specific diagnoses.[193]

Treatments reported in the past to be effective include tetracycline, sulfapyridine, corticosteroids, thalidomide, antimalarials, NSAIDs, and immunosuppressive agents. Antimalarials and corticosteroids were the most effective in one series.[189]

Dercum's Disease

Dercum's disease is a rare condition of painful lipomas of the skin on the trunk and extremities in obese postmenopausal women as originally described by Dercum in 1892 who proposed the term adiposis dolorosa.[194] The condition has less frequently been reported in men. Subsequent reports also describe associated weakness, fatigue, and emotional and psychological disturbances.[195,196] Most cases are sporadic, but familial cases with autosomal dominant inheritance pattern have also been reported.[197] Histologically, one typically finds a lipoma with no distinguishing features from an ordinary lipoma.

Treatment

Weight reduction and analgesics may be helpful. Excision of individual painful tumors may also be helpful but new painful tumors may continue to appear.[198] Liposuction has also been reported to be of benefit.[199,200] Intravenous lidocaine may provide pain relief lasting from hours to months.[195,201,202]

Oral mexiletine, an oral derivative of lidocaine and antiarrythmic agent, has also been reported to be partially or completely effective.[202,203] Interferon alfa-2b was reported to provide pain relief in two patients with Dercum's disease who were being treated for hepatitis C.[204] Corticosteroids have been reported to both cause[205] and treat[206] Dercum's disease.

The pain in Dercum's disease has been characterized as both nociceptive (localized pain in lipomas aggravated by palpation) and neuropathic with allodynia (light touch perceived as painful), so approaches to management similar to other chronic pain syndromes may be beneficial.[207] With that in mind, the patient in the report was successfully treated with amitriptyline, a voltage-gated sodium channel blocker.[207]

Hidradenitis Suppurativa

Hidradenitis suppurativa is a chronic disease where recurrent painful nodules and abscesses occur in apocrine gland areas, typically the axillae, inguinal areas, and perineum, but the inframammary areas and buttocks may also be involved.[208,209]

Etiology

The etiology of hidradenitis suppurativa is felt to be follicular hyperkeratosis and occlusion, leading to acute suppurative inflammation and granulomatous changes that secondarily engulfs and destroys apocrine glands and other appendages.[210] The disease usually first appears at puberty, suggesting hormonal factors, and may occur as a part of a follicular occlusion triad of hidradenitis suppurativa, acne conglobata, and perifolliculitis capitis abscedens et suffodiens.

Symptoms and Signs

Early on, patients experience recurrent painful erythematous nodules that suppurate and eventually break down to form sinus tracts and scarring. The sinus tracts may form an extensive interconnecting network in the subcutaneous tissue with multiple openings. The disease process may be circumscribed or more diffuse. Secondary bacterial infection may occur. In addition to being physically painful, the disease may be psychologically debilitating, especially in patients with long standing disease.[211] Squamous cell cancer and amyloidosis are rare complications in patients with chronic hidradenitis suppurativa.[209]

Diagnosis

Initially, the disease appears similar to furuncles or an inflamed epidermal cyst. However, when the erythematous nodules are recurrent and lead to sinus tracts and retracted scars, the diagnosis becomes clear.

Treatment

Systemic antibiotics are often used as initial treatment such as tetracycline 250 to 500 mg four times per day or minocycline. Topical clindamycin may also be helpful. Culture and sensitivity may detect secondary bacterial infection that needs other antibiotic therapy.

When disease is limited to one or a few acutely painful erythematous nodules, intralesional triamcinolone acetonide 2.5 to 5.0 mg/mL will often relieve the pain and inflammation within a few days. If lesions are widespread or numerous, a short course of prednisone 40 to 60 mg/day tapered over 1 to 2 weeks will often cause the lesions to subside at least temporarily.

Weight reduction in obese individuals and cleansing the affected areas with antibacterial soaps such as chlorhexidine may be useful. Limited benefit has been reported with oral isotretinoin. TNF inhibitors have been reported to be beneficial in some patients. Infliximab has been reported to be effective, but some patients do not respond or response is transient and it is not without risk of significant potential side effects.[212–214] Experience with adalimumab for treating hidradenitis suppurativa is more limited. There have been two reports of patients responding to adalimumab.[215,216]

Surgical excision, with repair by flaps or grafts as needed, remains the most definitive therapy available. Not all patients are candidates for surgery. Surgical excision works best if the disease is consistently confined over time to a localized area. Liposuction has been suggested for early disease to remove apocrine glands on a preventative basis before scarring occurs.[208]

Inflamed Epidermal Cyst

Epidermal cysts are very common and typically present after puberty as whitish, sometimes pigmented, well-defined, partially compressible, subcutaneous nodules with a semi-solid feel and often with a pore opening to the surface.[217,218] They may extrude a thick whitish material with a foul odor through the pore. Most are asymptomatic, but when they are traumatized and rupture

into the surrounding tissue, they incite an acute inflammatory reaction that mimics infection with pain, erythema, edema, warmth, and purulence. Initial management consists of hot compresses and incision and drainage. If secondary infection is suspected, culture and sensitivity should be done and the patient treated with an antibiotic effective for *Staphylococcus aureus* and *Streptococcus pyogenes* such as cephalexin or dicloxacillin pending culture results. Once inflammation subsides the residual cyst is excised. Some cysts are destroyed by the inflammation if severe enough.

Great care should be taken in excising previously inflamed cysts in certain locations because scar tissue may have entrapped important nerves or other structures—for example, the temporal branch of the facial nerve in the temple areas, the spinal accessory nerve in the posterior cervical triangle of the neck, or the parotid duct overlying the masseter muscle on the cheek. In these locations it may be more prudent to open the cyst, evacuate the contents, and scrape the wall of the cyst with a curette if treatment is felt to be necessary.

Although epidermal cysts typically develop after puberty, an accurate history regarding a particular cyst may not always be available. Cysts that could possibly have been present since birth should be a cause of greater concern, especially in certain locations such as the midline of the face, the midline of the scalp, or the midline of the back, since they may communicate with the central nervous system. Should one of these cysts become inflamed or infected, surgery should not be attempted without prior imaging studies such as computed tomography (CT) and magnetic resonance imaging (MRI). If a communication is found with the central nervous system, the surgery needs to be done by a neurosurgeon. Similarly, cysts present at birth on the lateral neck may be branchial cleft cysts that communicate with the pharynx. They may become infected in adult life simulating an inflamed epidermal cyst. Referral to an otolaryngologist is indicated for definitive treatment. Cysts presenting in childhood may be a sign of Gardner's syndrome, an autosomal dominant condition, associated with multiple benign tumors of the skin, osteomas, intestinal polyposis, and a high risk of colon cancer.[219] Ordinary epidermal cysts have a lining similar to normal epidermis with a granular layer, but cysts with Gardner's syndrome often have focal areas of pilomatrical differentiation.[219]

Bullous Dermatoses with Erosions

Pemphigus Vulgaris

Pemphigus vulgaris is a rare disorder and the most frequent member of a group of disorders referred to as pemphigus. Other members of the group include pemphigus foliaceous, pemphigus vegetans, pemphigus erythematosus, and paraneoplastic pemphigus. Paraneoplastic pemphigus will be discussed in the next section.

Pemphigus vulgaris is an autoimmune disorder that usually presents with painful blisters and nonhealing erosions in the mouth that eventually spread to the skin, producing flaccid blisters and bullae followed by oozing, crusted, painful erosions.[220,221] Lateral pressure on the skin adjacent to a bullous lesion causes the epidermis to shear and detach (Nikolsky sign). Uncommonly, patients may have an associated thymoma or myasthenia gravis. Drug-induced pemphigus has been reported with a variety of medications including penicillamine, rifampicin, captopril, enalapril, penicillin, and other drugs.[220,222] The bullae and blisters are caused by autoantibodies to desmosomal cadherin adhesion molecules, either desmoglein 3 with isolated mucosal pemphigus vulgaris or desmoglein 3 plus desmoglein 1 with mucocutaneous pemphigus vulgaris, whereas patients with pemphigus foliaceous have antibodies to desmoglein 1 only.[221] This leads to detachment of cells from one another (acantholysis) that is seen histologically as a suprabasilar split in the epidermis (suprabasilar acantholysis) in pemphigus vulgaris and subcorneal acantholysis in pemphigus foliaceous. The autoantibodies can be detected by direct immunofluorescence of perilesional skin, producing a netlike pattern on the surface of keratinocytes. Circulating autoantibodies are commonly present and detected by indirect immunofluorescence or enzyme-linked immunosorbant assay (ELISA) for antibodies to desmoglein 3 and desmoglein 1. Titers of circulating autoantibodies may correlate with disease activity but not always.

Treatment

The mainstay of treatment of pemphigus vulgaris are systemic corticosteroids often with initial starting doses of prednisone 1 mg/kg/day and increasing to 2 mg/kg/day (in divided doses), depending on response to treatment.[220] A steroid sparing agent is then added if needed, usually azathioprine or mycophenylate mofetil and, less commonly, cyclophosphamide and other agents. Pulse steroids and plasmapheresis with and without cyclophosphamide are other treatments that have been used. More recently intravenous immunoglobulin,[223,224] intravenous immunoglobulin combined with rituximab,[225] and rituximab without intravenous immunoglobulin[226–228] have shown promising results in the more treatment resistant cases. Patients need close monitoring for complications of therapy and preventive measures when possible (e.g., measures to prevent osteoporosis related to chronic corticosteroid use). Topical therapy and supportive measures for mucous membrane and cutaneous involvement are also needed.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is a rare autoimmune disorder associated with benign and malignant neoplasms. It causes a painful stomatitis similar to pemphigus vulgaris but a more polymorphic eruption on the skin.[229] The skin eruption may have features resembling pemphigus vulgaris, bullous pemphigoid, erythema multiforme, or a lichen planus-like (lichenoid) appearance. The polymorphic clinical pattern is reflected in the histology where one sees suprabasilar acantholysis, keratinocytes cell necrosis, and interface dermatitis. Direct immunofluorescence demonstrates IgG and C3 in a netlike pattern on keratinocytes similar to pemphigus vulgaris and, less frequently, a linear pattern along the epidermal basement membrane. Circulating antoantibodies detected by immunoprecipitation recognize a complex of proteins including desmoplakin I (250-kD), bullous pemphigoid antigen 1 (230-kD), envoplakin (210-kD), periplakin (190-kD), and a not further characterized 170-kD antigen.[230] Autoantibodies of paraneoplastic pemphigus can be distinguished from pemphigus vulgaris autoantibodies by their ability to react with transitional epithelium of rodent bladder, but the test is not as accurate as immunoprecipitation.[229] Paraneoplastic pemphigus associated tumors include non-Hodgkin lymphoma, chronic lymphocytic leukemia, Castleman's tumor, thymoma, spindle cell neoplasms, Waldenström's macroglobulinemia,[229] and, rarely, solid tumors including uterine carcinoma,[231] hepatocellular carcinoma,[232] bronchogenic squamous cell carcinoma,[233] and pancreatic carcinoma.[234] Mortality may be 90% or higher with some patients dying from respiratory involvement manifested as bronchiolitis obliterans.[235]

Treatment. Treatment of paraneoplastic pemphigus involves treating the underlying tumor which, in some cases, may clear the eruption but is less likely to if the tumor is malignant.[229] Variable response has been reported with prednisone alone or combined with other immunosuppressive agents. There are reports of patients responding to rituximab,[236] mycophenylate mofetil,[237] and tacrolimus topically for the stomatitis.[238]

Bullous Pemphigoid

Bullous pemphigoid is the most common of the autoimmune bullous diseases that typically affects elderly patients.[239–241] Tense bullae develop on normal or erythematous skin commonly distributed on the lower abdomen, axillae, groin, and flexor extremities. Transient oral lesions may also appear. Pruritus occurs in some patients and temporarily painful erosions after rupture of blisters and bullae. Peripheral blood eosinophilia is often an associated finding. Most cases of bullous pemphigoid are idiopathic but bullous pemphigoid-like drug eruptions have been reported with furosemide, penicillamine, nalidixic acid, sulfasalazine, captopril, penicillins, and other agents.[241]

Histologically, one finds a subepidermal bullous lesion with varying degrees of cellular infiltrate, often with eosinophils. Direct immunofluorescence demonstrates IgG and C3 in a smooth linear pattern at the epidermal basement membrane. Circulating antibodies to the epidermal basement membrane occur in approximately two thirds of patients that bind to the epidermal side of salt split skin. Two bullous pemphigoid antigens have been identified associated with the hemidesmosomal plaques at the dermal-epidermal junction. Bullous pemphigoid antigen 1 (230-kD) is an intracellular antigen and bullous pemphigoid antigen 2 (180-kD) is a transmembrane protein.[242]

Treatment. Milder cases of bullous pemphigoid or localized bullous disease may respond to high potency topical steroids alone (e.g., clobetasol 0.05% cream twice daily). Tetracycline or erythromycin 500 mg four times per day plus niacinamide 500 mg three times per day or tetracycline alone may be effective.[243,244] These treatments may also be considered in patients with more severe disease who are not good candidates for treatment with systemic corticosteroids or as adjunctive treatment with systemic steroids. Dapsone may also be effective in a subset of patients with an intense neutrophilic infiltrates on their biopsies.

Most patients with moderate to severe, generalized bullous pemphigoid are treated with prednisone 0.5 to 0.75 mg/kg/day and a steroid sparing agent is added if needed.[245] Azathioprine or mycophenylate mofetil are used most commonly. Azathioprine dosing is aided by checking thiopurine methyltransferase (TPMT) levels. Less commonly used agents are methotrexate and cyclophosphamide. For patients with severe or extensive disease, total body applications of clobetasol 0.05% cream twice daily has been shown to be superior to prednisone 1 mg/kg/day in terms of effectiveness and survival.[246] However, compliance with this regimen may be difficult in the frail elderly without assistance from family members or nursing services.[242] Topical therapy should seriously be considered in patients with extensive disease if feasible under their individual circumstances. Uncommonly used treatments for refractory disease include intravenous immune globulin, pulse steroids, and plasmapheresis.[241]

Epidermolysis Bullosa

Epidermolysis bullosa refers to a group of rare disorders that may be inherited or acquired. They all exhibit abnormal skin and sometimes mucous membrane fragility with minor trauma leading to blister formation, painful erosions, and, in some cases, scarring.[247–251] Scarring may manifest as milia or dystrophic nails or in more severe cases as pseudosyndactyly, esophageal strictures, and conjunctival scarring.

The different types of epidermolysis bullosa are differentiated from one another on the basis of whether inherited or acquired, inheritance pattern, level of split within, below or at the junction of the epidermis and dermis, distribution and severity of skin and mucous membrane involvement, scarring or nonscarring, and the affected protein and mutated gene. The inherited forms of epidermolysis bullosa demonstrate little if any inflammation on biopsy, whereas the acquired form, epidermolysis bullosa acquisita (EBA), may have an intense inflammatory infiltrate. Determining the level of the split within, below, or at the junction of the epidermis and dermis is an important part of the initial evaluation of the patient. This may be done with electron microscopy or immunofluorescent mapping with antibodies such as those to Type VII collagen, laminin, or bullous pemphigoid antigen.[252] In EBA, autoantibodies are bound in the basement membrane zone that are localized to the floor of the blister when detected by immunofluorescence on 1 molar sodium chloride (1M NaCl) split skin. EBA is often associated with other diseases such as malignancies, amyloidosis, diabetes, inflammatory bowel disease, SLE, and other autoimmune disorders, so workup of the patient for an underlying disease is indicated.[248,250]

Pathogenesis. Ultrastructural, immunohistochemical, and molecular biologic techniques have enabled the identification of affected proteins, point mutations, and corresponding ultrastructural findings in the inherited forms of epidermolysis bullosa.[252] For example, mutations in the keratins 5 and 14 are responsible for epidermolysis bullosa simplex, mutations in laminin 5 (genes LAMA3, LAMB3, and LAMC2) occur in junctional epidermolysis bullosa, and mutations in Type VII collagen (COL7A1 gene) occur in dystrophic epidermolysis bullosa.[251] EBA is an autoimmune disease with autoantibodies against type VII collagen leading to loss of or diminution of anchoring fibrils in the papillary dermis similar to the dystrophic epidermolysis bullosa phenotype.[249] Adults with EBA typically form autoantibodies to epitopes within the noncollagenous amino-terminus domain NC-1 of type VII collagen, whereas children with EBA form autoantibodies to epitopes on the NC2 or triple helical domains or both.[253]

Treatment. Avoidance of friction, pressure, trauma, and heat to skin and mucous membranes are important in the management of epidermolysis bullosa. Emollients, nutritional support, drainage of larger bullae, topical antibiotics, and nonadherent skin dressings are also important.[254] Some patients with the most severe forms of the disease may need surgical correction of pseudosyndactyly, esophageal dilation for stricture, ophthalmologic care for scarring, dental care, and monitoring for renal complications and complicating squamous cell cancer of the skin.[254] Genetic counseling is also needed with the inherited forms of the disease.

EBA is difficult to treat with no controlled studies and poor or variable response to a variety of agents. Mutasim[245] proposed an algorithm where milder cases are treated with dapsone initially followed by colchicine, then glucocorticoids, and finally cyclosporine if needed, whereas moderate to severe disease is treated initially with a combination of dapsone plus prednisone followed by cyclosporine if needed. Other treatments that have been used include other steroid sparing agents (azathioprine and mycophenylate mofetil), intravenous immune globulin, plasmapheresis, and extracorporal photochemotherapy.[245,250] Most recently, rituximab has been reported to be effective for EBA.[255,256] Childhood EBA is more responsive to treatment than in adults and will often respond to dapsone and low-dose prednisolone.[253]

Cutaneous Endometriosis

Cutaneous endometriosis is a rare condition that may cause tender nodules in the skin.[257,258] They may occur within surgical scars (e.g., cesarean section, episiotomy scars, or appendectomy scars), but also may occur as primary cutaneous endometriosis in which case they usually affect the umbilical area. Tenderness and bleeding may occur at times of menstruation. The histological appearance may correspond to different stages in the menstrual cycle but, in general, there is a poor correlation between histological appearance and the menstrual stage.[259] The range of histological findings in cutaneous endometriosis has recently been reviewed.[260] Simple surgical excision usually suffices for treatment and referral for gynecologic evaluation is also appropriate.[258]

DISORDERS OF CONNECTIVE TISSUE STRUCTURE (CARTILAGE DISORDERS)

Relapsing Polychondritis

Relapsing polychondritis (RP) is a rare, potentially life-threatening, episodic, sometimes febrile, systemic inflammatory disease affecting cartilage containing structures (e.g., ears, nose, joints, and respiratory tract) and proteoglycan rich tissues (e.g., eyes, inner ear, cardiovascular system, and kidneys).[261–264] Recurrent episodes of pain, erythema, and swelling of the ears is the most common feature of the disease occurring in up to 100% patients.[263] The earlobe is spared and eventually the ears may become ''floppy'' or have a ''cauliflower-like'' appearance as the cartilage is destroyed. Nasal chondritis may lead to a saddle nose deformity over time, sometimes without clinically apparent inflammation. Ocular involvement is common including scleritis, episcleritis, uveitis, and conjunctivitis. Proptosis, periorbital lid edema, and chemosis may simulate cellulites.[264] Other features of the disease include nonerosive polyarthritis, laryngotracheal and bronchial chondritis, cardiovascular disease (e.g., aneurysm formation, valvular heart disease, conduction abnormalities, and large vessel vasculitis), and renal disease. Pulmonary infections, systemic vasculitis, airway obstruction, and renal disease are the principal causes of death.[262] Associated diseases are not uncommon in RP including systemic vasculitis, hematologic disorders (e.g., myelodysplastic disorders, myeloma, lymphoma, and leukemia), connective tissue diseases, and other autoimmune disorders.[262] Autoantibodies to type II collagen and circulating immune complexes have been found in RP, suggesting an autoimmune pathogenesis.[265]

Cutaneous manifestations have been reported in from 17% to 50% patients.[261,266–268] In a recent series of 200 patients, 50% of patients overall were reported to have cutaneous findings.[268] When one excluded those patients with associated disease that would explain the cutaneous manifestations (e.g., psoriasis, SLE, or dermatomyositis), 35.4% of the remaining patients had cutaneous findings. Aphthosis (oral, genital, or both) was the most common manifestation. Nodules on the limbs were next in frequency that showed a septal panniculitis on biopsy in some cases and neutrophilic infiltrates suggestive of Sweet's syndrome in others. Purpura related to vasculitis, papules, pustules, superficial phlebitis, livedo reticularis, ulcerations on the limbs, and distal necrosis, in decreasing order of frequency, were also observed. Cutaneous manifestations were noted in 91% of patients with associated myelodysplasia.[268] Other reported cutaneous features of RP include urticaria, angioedema, erythema multiforme, and granulomas.[261,267]

Different sets of diagnostic criteria have been used in the published series on RP. The diagnostic criteria of McAdam et al.[266] are based on six clinical features: (1) bilateral auricular chondritis, (2) seronegative inflammatory polyarthritis, (3) nasal chondritis, (4) ocular inflammation, (5) respiratory tract chondritis, and (6) audiovestibular damage. When three or more of these criteria are present, plus histologic confirmation, the diagnosis is certain.[266] Modifications of the McAdam criteria were proposed by Damiani and Levine.[269] Under the modified criteria the diagnosis could be established with any one of the following three criteria: (1) at least three of the six clinical features of the McAdam criteria without histologic confirmation, (2) one or more of the McAdam clinical features plus histologic confirmation, or (3) chondritis in two or more separate sites with response to corticosteroids or dapsone. A third set of diagnostic criteria was used by Michet et al.[267] that included either (1) proven inflammation in the cartilaginous structures of the ear, nose, or laryngotrachea (at least two of the three sites); or (2) proven inflammation in the cartilaginous structures of the ear, nose, or laryngotrachea (just one of the three sites) plus two other manifestations (ocular involvement, seronegative arthritis, hearing loss, or vestibular involvement).

Treatment

Milder cases of RP may respond to dapsone, colchicines, and NSAIDs.[261,262,270] Acute flares and more serious involvement of vital structures are usually treated with systemic corticosteroids. Adjunctive steroid sparing agents are added if needed including azathioprine, methotrexate, or cyclophosphamide. Methotrexate was found to be the most effective in the series reported by Trentham et al.[261] Other agents that have been used include cyclosporine, penicillamine, plasma exchange, pulse steroids, anti-CD4 monoclonal antibody, and minocycline.[261,262]

Surgery and other intervention may be needed for complications of the disease including tracheostomy, cardiac valve replacement, aortic aneurysm repair, and placement of a cardiac pacemaker for conduction disturbances.[262,264] Survival has improved over time, with 94% survival in patients who have had their disease on average 8 years.[261]

Chondrodermatitis Nodularis Chronica Helicis

Chondrodermatitis nodularis chronica helicis is a common painful disorder where tender papules occur on the rim of the helix or the antihelix of the external ear.[271–273] The papules may have scaling, crusting, or ulceration suggesting the diagnosis of squamous cell cancer or basal cell cancer. Biopsy should be performed if the diagnosis is in doubt. Histopathological features may include ulceration with exudates, epidermal hyperplasia, fibrinoid dermal necrosis, mixed inflammatory cell infiltrate, thickening of the perichondrium, and degeneration of cartilage.[274] Neural hyperplasia has also been observed, on occasion, which has been suggested might explain the induction of pain by light pressure.[273]

Various treatments have been employed with different degrees of success for chondrodermatitis nodularis chronicus helicis. Injections of intralesional triamcinolone 2.5 to 5 mg/mL and surgical excision are among the most effective. If the patient sleeps habitually on one side, a pillow with a hole in it may be helpful in relieving symptoms. In one study, the results from a conservative approach by using a sponge or foam padding with a hole in it, held in place with a headband, compared favorably with surgical excision, leading the investigators to recommend this as the initial approach.[275]

NEUROVASCULAR CUTANEOUS DISEASE

Sensory Mononeuropathies

Sensory mononeuropathies are not uncommon and may affect the head, trunk, and extremities. They may manifest themselves as numbness, burning, itching, hyperesthesias, and, frequently, pain.[276] Among the more common are cheiralgia paresthetica (superficial branch of the radial nerve), meralgia paresthetica (lateral femoral cutaneous nerve), notalgia paresthetica (dorsal rami of T2-T6), and gonyalgia paresthetica (infrapateller branch of the saphenous nerve). A less common but important neuropathy to be aware of is mental nerve neuropathy which presents as unilateral numbness of the chin and lower lip (numb chin syndrome).[276–278] It is usually associated with malignancy, most commonly breast cancer or lymphoma, so thorough evaluation is needed.[277]

Notalgia paresthetica is a sensory neuropathy affecting the posterior rami of T2-T6. Patients usually complain of pruritus and less commonly pain (30%), paresthesias (28%), and hyperesthesia (12%) in a unilateral localized area on the upper back medial to the scapula.[279] Findings on examination may include hyperpigmentation and hypoesthesia.[276,280] Electromyographic evaluation may show evidence of paraspinal denervation in some cases.[281] In a study of 43 patients, 60.7% were found to have radiographic abnormalities of the spine corresponding to the nerves involved, suggesting impingement of spinal nerves.[279] Massey postulated the posterior rami of T2-T6 are subject to trauma because they traverse the multifidus spinal muscle at a right angle course.[276] A hereditary variant of notalgia paresthetica has been described and it has also been reported in MEN2A.[280] Histologically, one may find postinflammatory hyperpigmentation, lichenification, and, in some cases, macular amyloidosis possibly related to excoriation.[282]

Treatment

Treatment of notalgia paresthetica has met with variable success with such agents as topical anesthetics, capsaicin, and topical corticosteroids.[283] Oxcarbazepine (a derivative of the anticonvulsant carbamazepine with a better side effect profile) was reported to be partially effective in three of five patients treated with the medication.[284] A paravertebral block using a combination of bupivacaine and methylprednisolone led to complete resolution of symptoms for at least 1 year in one patient.[280] Recently, intralesional botulinum toxin A was reported to produce complete resolution of pruritus in two patients.[283] Gabapentin in a dose of 600 mg/day provided complete relief of symptoms in one patient with notalgia paresthetica.[285]

Fabry's Disease

Fabry's disease (FD) is a rare, X-linked recessive, lysosomal storage disease caused by deficiency of the enzyme alpha-galactosidase A, leading to accumulation of neutral glycosphingolipids, primarily globotriaosylceramide and digalactosylceramide, in endothelial cells and other cell types.[286–290] The deposits in the endothelial cells cause swelling and narrowing of the lumen that can eventually lead to ischemia, infarction, and pain.

Symptoms and Signs

Angiokeratomas are the characteristic skin lesion of FD that occur in a pattern referred to as angiokeratoma corporis diffusum (ACD) to distinguish them from other variants of angiokeratomas not associated with FD, such as isolated angiokeratomas, angiokeratomas of Mibelli on the dorsum of the fingers and toes, and angiokeratomas of the scrotum (Fordyce) that occur typically in elderly males. Individual angiokeratomas are reddish-blue to black 3 to 4 mm diameter papules that may be scaly, hyperkeratotic, or verrucous. In ACD, they are usually distributed between the umbilicus and the knees but may be widespread and affect mucous membranes as well. Angiokeratomas usually first appear in adolescence and increase in number with time.

Hypohidrosis with heat intolerance, peripheral edema, and asymptomatic eye findings are other features of the disease. The potential eye findings include tortuous retinal and conjunctival vessels, a characteristic whorled corneal opacity, and a posterior capsular cataract (Fabry cataract). The corneal opacities may be found in approximately 70% of female carriers as well and, less often, female carriers may have angiokeratomas.[291] Female carriers in general may be asymptomatic, have mild disease, or rarely severe disease manifestations.[291]

Episodic painful acroparesthesias of the hands and feet lasting from minutes to hours may be the first manifestation of the disease developing in childhood. They may be brought on by heat, cold, fatigue, exertion, or fever. Patients may be left with residual tingling or pain between attacks. Acute attacks of abdominal pain may occur simulating an acute abdomen but abdominal pain may also be chronic.[286,287]

The most serious complications of the disease relate to involvement of the kidneys, heart, and central nervous system. Untreated patients typically develop end-stage renal disease by the fifth decade. Patients may develop cardiac arrhythmias, conduction defects, left ventricular hypertrophy, transient ischemic attacks, and strokes.[286] Variants of FD have been reported that involve principally the heart or the kidneys.[286]

Histologically, ACD demonstrates dilated vessels in the papillary dermis with epidermal hyperplasia or acanthosis.[291] The abnormal lipid in the endothelial cells may be detected with a lipid stain or periodic acid-Schiff stain. Electron microscopy demonstrates membrane-bound, lamellar, or myelin-like inclusions. Examination of the urine with polarized light may show birefringent glycosphingolipids in cells with a Maltese cross appearance. The diagnosis is confirmed by finding diminished alpha-galactosidase A activity in plasma or peripheral blood leukocytes. Female carriers may have normal alpha-galactosidase A levels and, in the absence of any clinical manifestations, identification of the specific gene mutation is needed for confirmation of the diagnosis.[286]

The angiokeratomas found in FD are not unique to FD. Other storage diseases have been reported to have angiokeratomas. These include fucosidosis, mannosidosis, GM-1 gangliosidosis, aspartylglycosaminuria, sialidosis, galactosialidosis, and alpha-N-acetylgalactosaminidase deficiency.[292] Rarely, there have been reports of angiokeratoma corporis diffusum in patients without alpha-galactosidase A deficiency or other enzyme deficiencies.[293]

Treatment

Enzyme replacement therapy (ERT) with recombinant alpha-galactosidase A (agalsidase beta, Fabrazyme, Genzyme Corp.) was approved for treatment in the U.S. by the FDA in 2003.[294] ERT has been associated with improvement of neuropathic pain, relief of gastrointestinal symptoms, and stabilization of renal function and cardiomyopathy.[286] In patients with advanced disease, ERT slowed progression of renal, cardiac, and cerebrovascular disease, suggesting intervention should be early before irreversible damage occurs.[294]

Supportive therapy for cardiac, renal, neurologic and gastrointestinal symptoms is important, along with monitoring for complications in both affected males and female carriers. Genetic counseling is also important. There is no need to treat the angiokeratomas unless they are symptomatic which can be done with a variety of local destructive methods such as laser or liquid nitrogen. The angiokeratomas have not been found to be a useful surrogate marker to follow disease activity with ERT.[295]

NEOPLASMS

Both benign and malignant neoplasms may sometimes be painful because of ulceration, location on the body where they are repeatedly traumatized, or on pressure bearing surfaces such as the soles of the feet. Certain benign neoplasms are characteristically painful and bring to mind a differential diagnosis that has been reported under the acronym LEND AN EGG which includes leiomyoma, eccrine spiradenoma, neuroma, dermatofibroma, angiolipoma, neurilemmoma, endometrioma, glomus tumor, and granular cell tumor.[296] We advocate the use of the acronym ANGEL for the reasons summarized in the following text. Painful neuromas include traumatic neuromas and Morton's neuroma of the forefoot. A traumatic neuroma is a proliferative and hyperplastic reactive change to injury rather than a true neoplasm.[297] Morton's neuroma is a degenerative change in neural tissue related to chronic injury and not a true neoplasm.[298] Dermatofibromas

TABLE 37.2

CHARACTERISTIC FEATURES OF BENIGN PAINFUL CUTANEOUS NEOPLASMS

Tumor	Appearance	Usual location	Pathologic features	Comment
Glomus tumor[304,305]	Reddish-blue papule or nodule usually <1 cm in diameter	Hands and fingers especially subungually	Glomus cells with eosinophilic cytoplasm and round nuclei, blood vessels and nerve fibers	Paroxysms of pain on exposure to cold or pressure. Multiple glomus tumors (familial glomangiomas) are usually asymptomatic.
Leiomyoma[306,307]	Firm erythematous to brown intradermal papules and nodules.	Trunk and extremities.	Interlacing bundles of smooth muscle cells with cigar-shaped nuclei.	Pain on exposure to cold, pressure, trauma, emotion or may occur spontaneously. May be associated with a hereditary syndrome with renal cell cancer.
Angioleiomyoma[307,308]	Subcutaneous or deep dermal nodule or mass up to 4 cm in diameter.	Lower extremities.	Encapsulated tumor with interlacing bundles of smooth muscle cells and many small blood vessels.	Pain or tenderness with pressure. Some leiomyomas are associated with a hereditary syndrome with renal cancer.
Angiolipoma[309,310]	Subcutaneous 0.5 to 4.0 cm nodule with normal, bluish or reddish overlying skin.	Typically located on the forearm.	Encapsulated tumor with mature adipocytes, many small-caliber blood vessels, and microthrombi.	Frequently painful with pressure or when moved.
Neurilemmoma (schwannoma)[311]	2–4 cm diameter flesh-colored tumor.	Head and extremities (especially flexor) attached to a cranial or peripheral nerve.	Intraneural proliferation of schwann cells with Antoni type A or Antoni type B pattern.	Pain may be localized or radiate along the course of the nerve.
Eccrine spiradenoma[312,313]	0.3–5.0 cm firm intradermal nodule often with bluish overlying skin.	Most often on ventral surface of the skin.	Two populations of epithelial cells with eccrine differentiation. Fibrous capsule and ductal differentiation often present.	Usually tender or painful.

are common benign neoplasms that typically are not painful but pain may occur on occasion. They often exhibit the dimple sign that is elicited by exerting pressure from the sides. Cutaneous endometriosis was discussed earlier in this chapter. Endometriosis is an ectopic localization of endometrial glands that may occur by fallopian tube regurgitation, angiolymphatic invasion, transportation during surgery, or a result of local imitative metaplasia rather than a true neoplasm.[299,300] Granular cell tumors are only occasionally painful.[301] The remaining benign painful neoplasms may be remembered under the acronym ANGEL: angiolipoma, neurilemmoma, glomus tumor, eccrine spiradenoma, and leiomyoma. These tumors are all true neoplasms where pain is a characteristic feature. They are listed in Table 37.2 with their comparative features. Treatment when needed consists of complete excision which is usually curative.

Leiomyomas are deserving of further discussion because of their association with hereditary leiomyomatosis and renal cell cancer.[302,303] This is an autosomal dominant condition due to mutations in the enzyme fumarate hydratase that is associated with cutaneous leiomyomas, leiomyosarcoma (rarely), uterine fibroids (leiomyomas), and renal cell cancer. Most patients have multiple cutaneous leiomyomas but even a single leiomyoma may be a marker for the syndrome. When a patient with a cutaneous leiomyoma is encountered, a history should be taken for any personal or family history of cutaneous leiomyomas, uterine fibroids, early hysterectomy, and renal cell cancer.[303] If the history is suggestive, imaging studies of the kidneys and testing for fumarate hydratase mutations is indicated along with lifetime surveillance and examination of relatives if studies confirm the diagnosis.

Acknowledgments

The authors wish to acknowledge the contributions of Dr. George F. Odland to this chapter. He was the original primary author, and many of his touches and words remain part of the fabric of the chapter.

CHAPTER 38 ■ PAIN DUE TO VASCULAR CAUSES

KAJ H. JOHANSEN

INTRODUCTION

Pain in one form or another is a frequent manifestation of arterial, venous, or lymphatic problems. The nature and location of pain complaints may be virtually diagnostic of the underlying vascular condition. On the other hand, pain arising from nonvascular conditions may mimic that associated with various vascular conditions, thereby delaying or complicating diagnosis and therapy. This chapter explores the mechanisms and pathophysiology of vascular pain and its relief; it emphasizes basic neuroanatomy and neurophysiology relevant to vascular pain and includes a compilation of different vascular pain syndromes.

Because pain is a frequent presenting feature of vascular disease and its therapy, topics covered herein necessarily share an interface with numerous other chapters in this text. Information provided in this chapter is, however, intended to be supplementary or expansive upon material elsewhere rather than duplicative. For more detailed discussions of vascular pain the reader is referred to comprehensive sources on this subject.[1–4]

BASIC NEUROANATOMIC AND NEUROPHYSIOLOGIC CONSIDERATIONS

A review of the neuroanatomy and neurophysiology of vascular structures and the organs and parts they serve helps inform an understanding of the way vascular disease results in pain. This is further clarified by an understanding of how pain is stimulated peripherally and transmitted and experienced centrally.

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[5] The perception of pain is a consequence of many variables including past and current pain experiences, level of consciousness, and the patient's emotional state.

Nociceptive pain is an uncomfortable sensation associated with injurious stimulation, while *neuropathic* pain arises in the absence of such injury. From a teleologic perspective, pain's "purpose" is to signal the presence of (and presumably prevent) tissue damage and, thus, exists as one aspect of homeostasis. Only when it becomes chronic, or is a manifestation of the postoperative state, is pain unhelpful.

Pain can be characterized by its location, duration, quality, and severity or intensity. Qualities of pain include the descriptive terms "aching," "burning," "spasmodic," "radiating," "lancinating," "sharp," or "dull." Focal pain is noted at the site of injury, while diffuse pain is more characteristic of deep structures.

Radicular pain radiates along peripheral nerve pathways, not uncommonly in concert with motor or sensory neurologic deficits. Referred pain is perceived at a site remote from where the noxious stimulation is actually occurring and results from a misplaced cortical appreciation of pain. Referred pain generally follows spinal segmental innervation and must be differentiated from radicular pain, which generally follows specific dermatomal distributions. Visceral pain is dull, aching, and has an agonizing, "sickening" component.

Pain can result from numerous physical stimuli including pressure, puncture, squeeze, tension, and extreme heat or cold. Pain can also result from chemical effects such as those resulting from a marked change in pH or the presence of various mediators—histamine-like materials, serotonin, bradykinin, and other similar polypeptides. Endogenous prostanoids can lower the pain threshold as a consequence of certain stimuli; local acidosis can enhance perception of pain. Local mediators such as substance P are released at sites of injury and the neural stimulation which results can be interpreted as pain.

Nociceptive receptors are usually free nerve endings and pain is transmitted from them in the small unmyelinated A-delta and C nerve fibers. These afferent nerves' cell bodies are located in the dorsal root ganglia and their axons enter the spinal cord through the dorsal roots. These axons synapse in the dorsal grey of the cord with second-order neurons. Most pain is transmitted centrally via the crossed lateral spinothalamic tract up the cord to third-order neurons in the thalamus. The spinothalamic tract, including the periaqueductal grey region of the brainstem, is relevant to more diffuse, longer-lasting pain and, probably, neuropathic pain. Interestingly, the precise central nervous system (CNS) location for pain perception remains obscure.

Large- and medium-sized *arteries* have two types of innervation: afferent (sensory) nerves and autonomic (sympathetic) nerves. Pain is the primary sensation transmitted via nociceptive afferents in arteries and veins; position, temperature, and other such sensations do not appear to be transmitted via the innervation of blood vessels. In large- and medium-sized arteries these receptors appear to be stimulated by direct trauma (e.g., an arteriography needle), stretch (as noted with balloon dilatation or stent placement), or shear (as in arterial dissection).

Nociception in large- and medium-sized *veins* is due to pain receptors in the venous adventitia which appear to respond primarily to stretch (as in venous distention or engorgement, perhaps the consequence of downstream thrombosis or other obstruction).

Classic neuroanatomic research by Pick[6] demonstrated that sympathetic and sensory fibers enter the arterial (and venous) adventitia to form an intrinsic neural network ("adventitial plexus"), mostly composed of sensory afferents. From this plexus bundles of nonmyelinated fibers (mostly sympathetic) approach the media ("border plexus"), and extensions of this network ramify within the media ("muscular plexus").

The basis for neuropathic pain, and how it is sustained, remain obscure. Neuropathic pain also appears to be transmitted by sensory afferents but, unlike nociceptive pain, it has autonomic (sympathetic nerve) components as well. This results in the well-established (although poorly understood) role of sympathetic modulation for neuropathic pain by pharmacologic or anesthetic blockade or by sympathectomy. Recognition, diagnosis, and management of various forms of sympathetically mediated or sympathetically sustained pain (formerly termed causalgia or reflex sympathetic dystrophy [RSD] but now subsumed, by fiat of expert panels,[7] under the umbrella term *complex regional pain syndrome* [CRPS]) is discussed in detail in Chapter 25.

Most nociceptive pain is relieved when the underlying noxious stimulus is resolved. On occasion the presence or severity of nociceptive pain warrants consideration of more invasive procedures to effect pain relief. Analysis of these procedures' results, both in the near-term and chronically, has provided substantial insight into the way peripheral pain is transmitted and appreciated.

VASCULAR PAIN SYNDROMES

Pain in one form or another is a common manifestation of various vascular disorders and the location, quality, and natural history of such pain may be crucial to the diagnosis or treatment of the condition. For example, sudden tearing interscapular pain is virtually diagnostic of an acute type B thoracic aortic dissection; mitigation of this pain is a hallmark of satisfactory "medical" management of this condition by means of antihypertensive therapy with beta blockers. A compendium of the types of pain associated with various arterial, venous, and lymphatic conditions follows.

Intermittent Claudication

Claudication is one of the most common pain complaints seen by vascular specialists. The pathophysiology of arterial claudication is based on a reduction of arterial perfusion to a degree that is inadequate to meet the needs of working muscles. The most common cause is arterial occlusive disease due to generalized atherosclerosis, and the most common sites are shown in Figure 38.1. The clinical phenomenon is seen most commonly in the gastrocnemius/soleus muscle group distal to atherosclerotic occlusion of the superficial femoral artery, but can also be seen in more proximal thigh muscle groups with aortoiliac occlusive disease or in the upper extremities with chronic brachiocephalic arterial stenoses or occlusion (Fig. 38.2). Rarely, patients may note claudication of the gluteal or lumbar paraspinal muscles in association with pelvic arterial insufficiency. Claudication of the muscles of mastication is almost diagnostic of involvement of the external carotid artery by giant cell arteritis.[8]

The quality and pattern of the pain associated with intermittent claudication is stereotypical. It is absent at rest but appears following muscle exertion of a specific amount, disappearing quickly following cessation of exercise. That the phenomenon is a consequence of inadequate perfusion to working muscles is demonstrated by the parallel course of the development of symptoms and the decline in skeletal muscle perfusion as measured by Doppler arterial pressure ankle/arm indices (AAIs) during treadmill walking and by symmetrical improvement in symptoms and AAI when treadmill walking is halted (Fig. 38.3).

The pain associated with the claudication of arterial insufficiency is localized to the working muscles and is characterized as "burning," "cramping," or "aching." The muscles are not particularly tender and, because basal blood supply is adequate, no distal trophic lesions occur. At the cellular level, claudication pain likely results from a combination of ischemic neuropathy (particularly of small unmyelinated A-delta and C sensory fibers) and a localized lactic acidosis resulting from the anaerobic metabolism of ischemia, perhaps heightened by elaboration of substance P.

Several types of intermittent *pseudo*claudication exist and contribute to an important differential diagnosis among patients presenting with walking-related extremity pain. The most important and commonly seen of these alternative diagnoses is that of *neurogenic claudication*, resulting from one form or another of lumbosacral neurospinal compression syndrome—spinal stenosis, herniated disc, arachnoiditis, spondylolisthesis, and the like. Initially such patients' complaints may appear to be very similar to those of subjects with arterial insufficiency, to the extent that

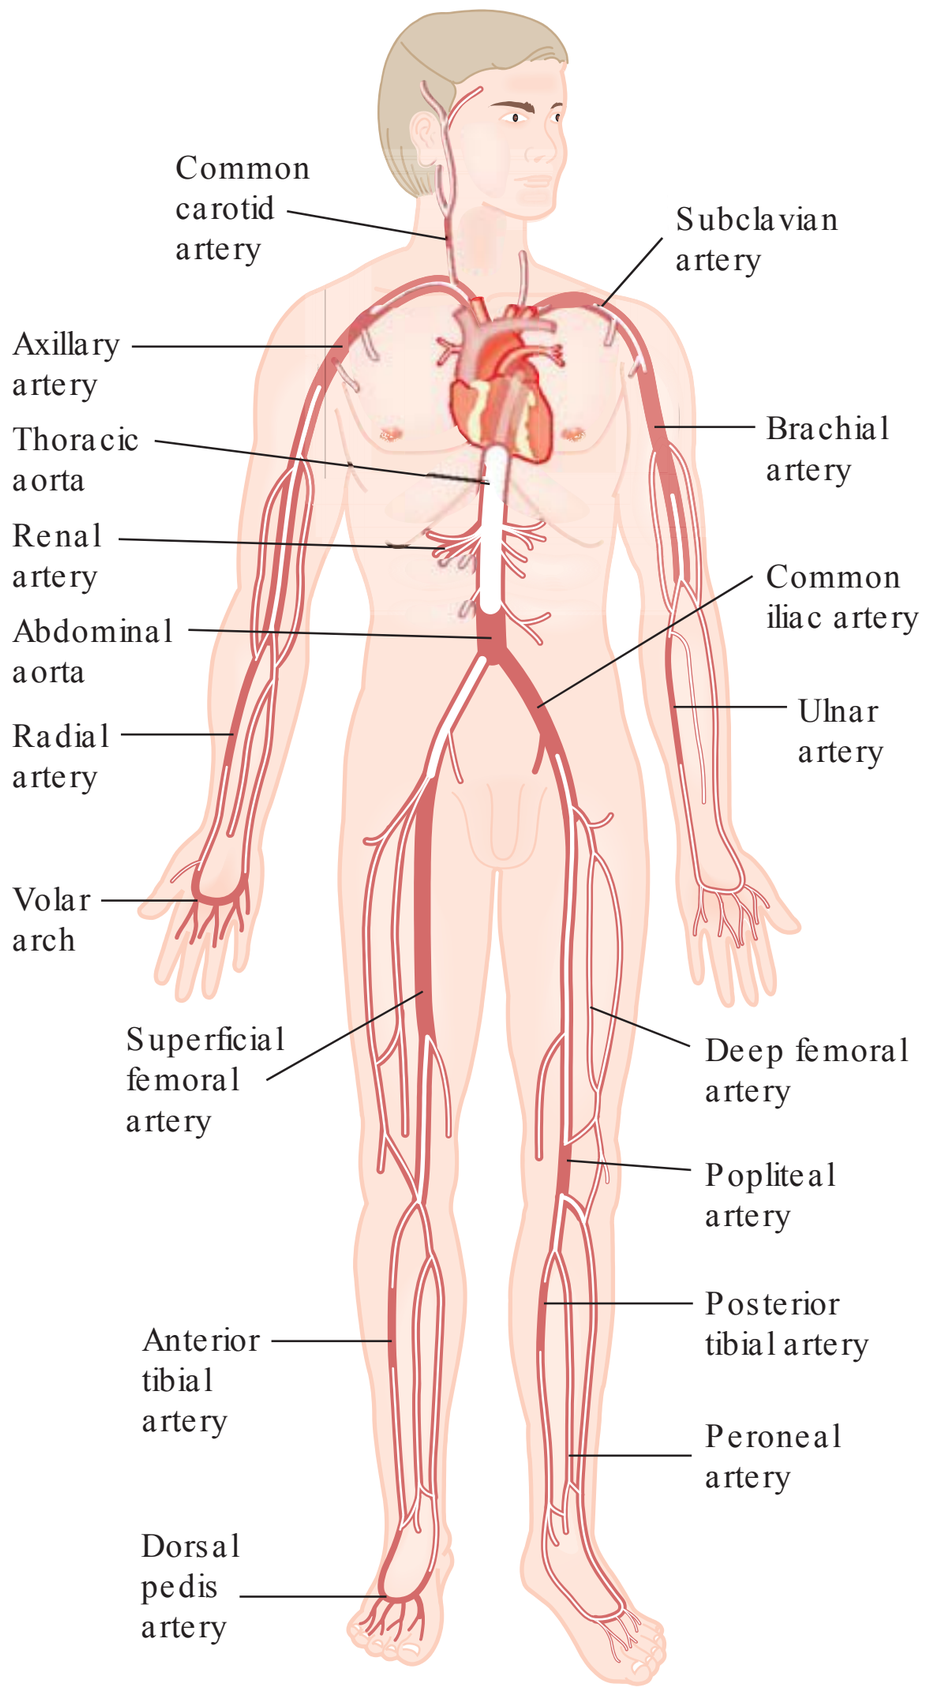

FIGURE 38.1 The most common sites for atherosclerotic occlusive arterial disease in peripheral arteries. The extent, degree, and pattern of the obstructive lesion vary considerably at each site.

they are occasionally subjected to surgical revascularization when they actually need a laminectomy (or vice versa!).

Fortunately, a careful history will frequently solve this diagnostic conundrum. Because the basis for neurogenic claudication involves compression of nerve roots by a diffuse fibrotic or inflammatory process in the region of the lower spinal cord or the cauda equina, neurogenic claudication is more commonly bilateral than that associated with arterial insufficiency. Further, the pain of neurogenic claudication is more diffuse, frequently extending from buttocks to feet, and often has a deeper, more aching or burning quality, not infrequently associated with distal paresthesias or numbness.

The subject with neurogenic claudication frequently finds relief from his/her steadily worsening symptoms by bending over while walking; when hip and leg pain forces the subject to halt, symptom relief commonly results only with sitting. Unlike the individual with arterial claudication who can walk the same distance on the level or on the treadmill over and over again with equal interspersed rest periods, the individual with neurogenic claudication who attempts to walk very far achieves shorter and shorter walking distances at the expense of longer and longer periods of sitting. Neurospinal compression may result in pain or numbness just with standing, once again and relieved by sitting.

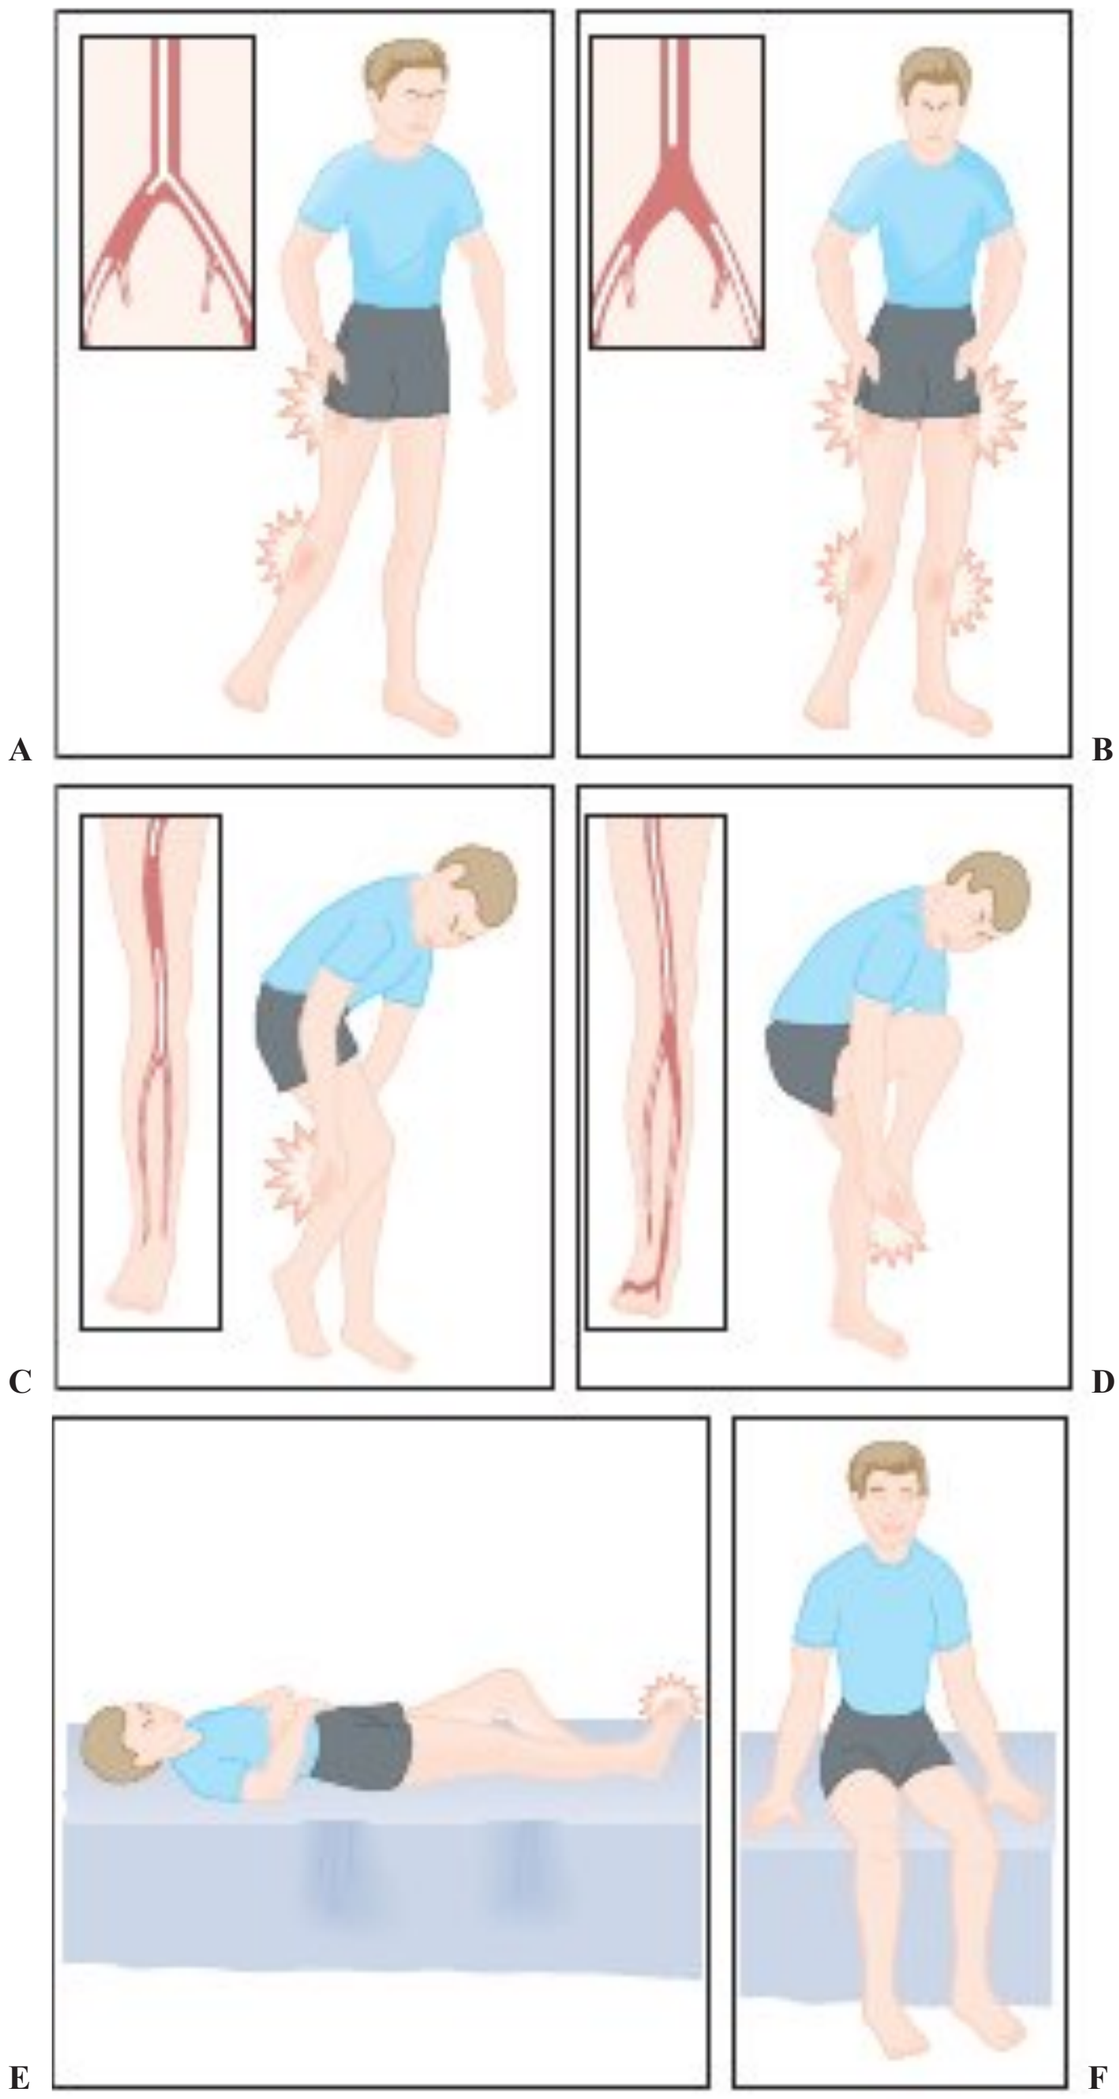

FIGURE 38.2 Sites of pain (radiating lines) caused by atherosclerotic occlusive arterial disease in different parts of the arteries of the lower limbs. **(A)** Obstruction in the right common iliac artery, which produces pain in the right hip, buttock, thigh, and calf. **(B)** Obstruction in both common iliac arteries and the lower aorta, which produces pain in both hips, buttocks, thighs, and calves—the so called "Leriche syndrome." **(C)** Obstruction of the superficial femoral artery, which produces severe and incapacitating intermittent pain in the calf. **(D)** Obstruction of the popliteal and tibial arteries (and dorsal pedal arterial arch), produces pain in the foot. This foot pain can occur at rest in the distal part of the foot **(E)** when the patient lies in bed and **(F)** the rest pain is often relieved when the limb is dependent.

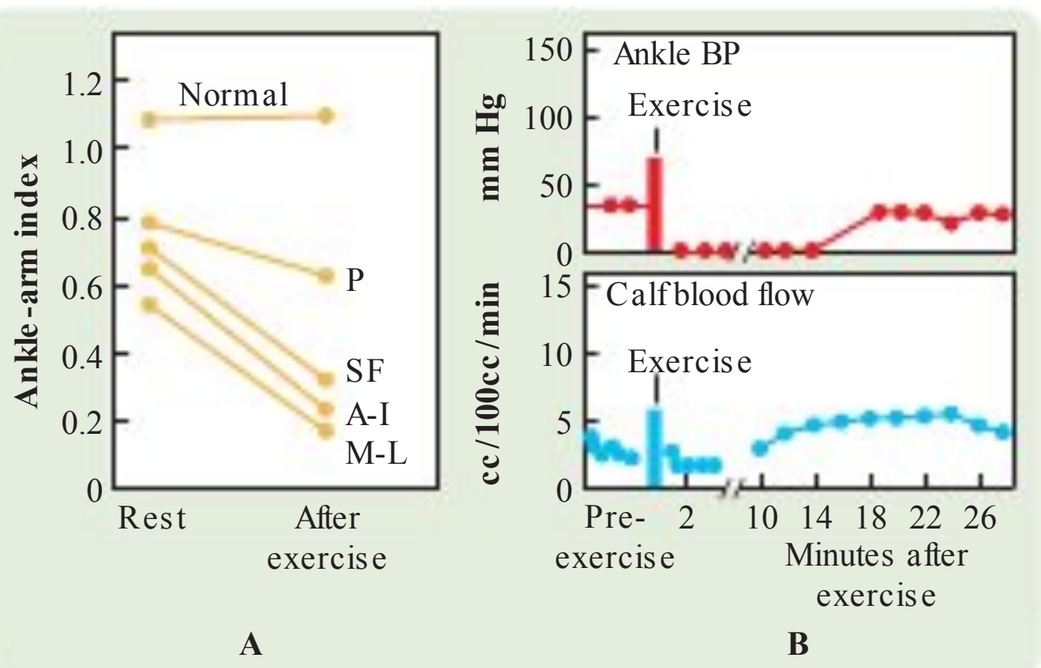

FIGURE 38.3 **(A)** Mean ankle–arm indices (ankle systolic blood pressure divided by arm [brachial] systolic blood pressure) at rest and after exercise in normal subjects and subjects with atherosclerotic occlusive disease. The location of the occlusion is indicated by the letters: *P*, popliteal artery below the knee; *SF*, superficial femoral artery; *AI*, aorta and iliac arteries; *ML*, multilevel. **(B)** Ankle pressure and calf blood flow before and after exercise in a patient with occlusion of the iliac, common femoral, and superficial femoral arteries. This patient had severe claudication and moderate rest pain. (BP, blood pressure). (Modified from Sumner DS. Practical approach to vascular laboratory testing in occlusive arterial disease. In: Rutherford RB, ed. *Vascular Surgery*, 2nd ed. Philadelphia: WB Saunders, 1984:45–56.)

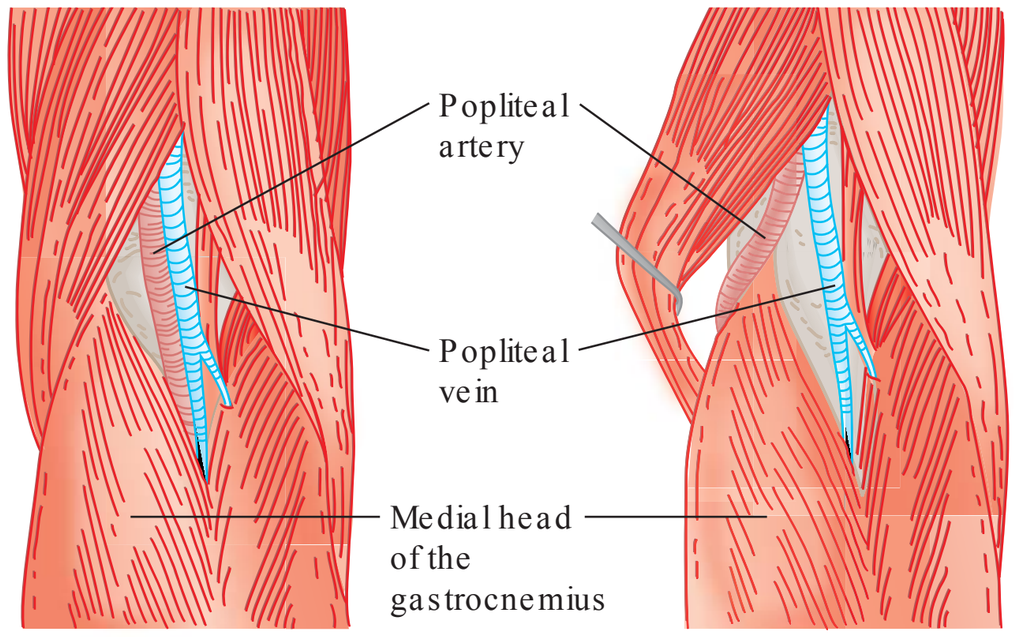
The pain of neurogenic claudication is felt to result from both ischemia and reactive swelling of nerve roots at their site of compression, an impression confirmed by studies utilizing intrathecal fibroscopy during treadmill walking in patients with neurogenic claudication.[9] Temporary relief of the pain of neurogenic claudication by various postural changes such as sitting appears to result from the fact that flexion of the hip and back relieves lumbosacral nerve root "stretch" and allows deconges-

tion of the epidural veins in the region.[9]



Substantial diagnostic confusion can result from the fact that older patients with lower extremity claudication may have *both* atherosclerotic arterial occlusive disease *and* degenerative lumbosacral spine disease. Minimal or no change in Doppler AAI in the presence of development of lower extremity symptoms during treadmill exercise excludes arterial occlusive disease as a cause of the patient's lower extremity symptoms.

Other much less common causes of intermittent claudication include the following: proximal venous occlusive disease of the lower extremities, resulting in a characteristic sense of "bursting" discomfort and engorgement of the exercising extremity ("venous claudication")[10] as well as various forms of myositis, the most common of which is an iatrogenic muscle inflammation and necrosis which results from the administration of various statin medications to treat hyperlipidemia.[11]

Lower extremity claudication in younger individuals should bring to mind two diagnoses—*popliteal entrapment syndrome* and (when exercise-induced pain is localized to the anterolateral aspect of the leg) *chronic compartment syndrome*. The intermittent claudication seen in young people (often athletes or military recruits) associated with popliteal artery entrapment syndrome (Fig. 38.4) has the same pathophysiologic mechanism as that associated with atherosclerotic lower extremity arterial occlusive disease.[12] The cellular basis for the anterior muscle compartment pain associated with chronic compartment syndrome is ischemia resulting from diminution of the intramuscular arteriovenous pressure differential due to venous congestion and compartment tissue hypertension.[13]

Aortic and Other Large Artery Pain

A substantial number of pain receptors populate the media of large- and medium-sized arteries. As noted previously, these re-

(a) Normal **(b)** Anomalous

FIGURE 38.4 **(A)** The normal relationship of the popliteal artery and the two heads of the gastrocnemius muscle. **(B)** The most common anomaly, which causes popliteal artery entrapment syndrome. The popliteal artery is looped medially around and then under the medial head of the gastrocnemius. The medial hamstring muscles have been retracted for clarity. During strenuous exercise of the leg, the muscle compresses the artery, with consequent ischemia and intermittent claudication.

ceptors can respond to direct stimulation, for example by a needle or other penetrating instrument; they also may respond to stretch or shear. Sensory nerve fibers do not appear in or near the arterial intima, perhaps explaining why atherosclerosis, even when it is "inflammatory,"[14] is not painful. Chronic slow dilatation of arteries, such as occurs with abdominal aortic aneurysm (AAA), does not appear to stimulate intra-arterial pain fibers; while palpation of an AAA occasionally results in a diffuse deep sickening ache, in the author's experience this occurs with equivalent frequency following deep palpation of normal nonaneurysmal aortas. Stimulation of periaortic autonomic fibers by such palpation may contribute to this characteristic sensation.

The pain associated with aortic aneurysmal rupture, usually into the peritoneal cavity, the retroperitoneum or (rarely) the pleural space, is generally described as sudden, steady, burning, and penetrating in nature. Such pain likely arises as a consequence of nociception at several levels, including stimulation of pain fibers in the torn aorta, in the stretched or torn peritoneum or pleura and as a consequence of extravasation and hematoma expansion in an enclosed pleura or retroperitoneum (tellingly, free rupture of an AAA into the abdominal cavity is commonly characterized only by transient pain followed by rapid loss of consciousness as the patient expires from hypovolemic shock).

Pain—characteristically "tearing," "ripping," or "boring" and located in a substernal or interscapular location—is a hallmark of aortic dissection. Similar burning pain in the lateral neck characterizes extracranial carotid arterial dissection. Shearing of nociceptive receptors in the aortic or carotid media by progression of the pulsatile hematoma within the media is the likely explanation for this pain. Except for patients with Marfan or Ehlers-Danlos syndromes, whose aortic or arterial dissections may occur asymptomatically, pain is a constant consequence of arterial dissection. As previously intimated, relief of such pain with hypotensive therapy is felt to indicate satisfactory control of an aortic dissection, while persistent pain suggests that such therapy is inadequate, obligating either that such therapy be augmented or be replaced by a more invasive intervention (operation or endovascular repair).

Vasculitic inflammatory involvement of large- and medium-sized arteries is uncommon but not rare. The most common such involvement of the aorta is the development of an inflammatory aneurysm, usually of the abdominal aorta. While the pathophysiology of this process remains obscure, its presentation is stereotypically as a thickened "rind" of chronically inflamed fibrofatty perianeurysmal tissues, frequently with an adhesive involvement of the ureters or the duodenum which can significantly complicate open aneurysmal repair. Patients with inflammatory AAAs commonly complain of diffuse aching mid-back discomfort and their aneurysms are dully tender to palpation.

Besides the jaw claudication often associated with giant cell arteritis,[8] such patients' inflammatory vasculitis can be associated with diffuse pain and tenderness over the affected arteries—especially the superficial temporal artery; biopsy (or duplex scanning)[15] of which may be diagnostic of the underlying condition. As for inflammatory AAA and other large- and medium-sized vessel arteritis, the diffuse and poorly localized pain seen in this condition is likely due to inflammatory involvement of nociceptors found both in the arterial media and adventitia as well as in periarterial connective tissue. That the pain associated with this condition is inflammatory is borne out by its resolution following administration of anti-inflammatory agents (particularly corticosteroids).

Rest Pain, Ulcers, and Gangrene

Advanced or critical arterial insufficiency—usually in the lower extremities—displays characteristic symptoms and signs which signal impending limb loss. Indeed, all patients with rest pain, ischemic ulcers, or gangrene will require an operative intervention—either an amputation or a procedure to reestablish vascular supply to the affected area. Such patients' arterial occlusive disease is severe and multilevel ("tandem") and their mortality rate exceeds 50% over the next 5 years as a consequence of premature, aggressive coronary artery disease.

Rest pain is characterized by a diffuse, ill-localized aching or burning pain in the distal foot (occasionally the heel). It is generally initially present at night when the patient is recumbent or the leg and foot are elevated. Symptoms dissipate if the leg is hung over the edge of the bed or the subject rises and walks around. The pathophysiology of rest pain is likely that of an ischemic neuropathy, with positional malperfusion of small sensory nerves in the distal foot. The symptoms of rest pain (or other advanced arterial insufficiency) necessarily develop in the most distal small arteries, those farthest away from the heart. Thus, pain at rest does not occur proximal to the foot (with one cardinal exception: rest pain may develop with severe ischemia in the stump of a patient with a below- or above-knee amputation).

Arterial ulceration in the nondiabetic is characterized by a shallow, pallid, nonhealing erosion of the skin in the distal foot, in a similar location as that for rest pain. The pain of such ulcerations is unremitting and severe, occasionally refractory even to high-dose oral narcotic analgesic agents, and is treated only by urgent revascularization or by amputation. The pain of such ulcerations is described as aching or burning, and arises not only from the same severe ischemic neuropathy which gives rise to ischemic rest pain but also to actual necrosis of sensory nerves in the skin at the site of the arterial ulcer.

Gangrenous changes of the toes or heel are indications that tissue death has occurred. Associated pain complaints are thus a summation not only of ischemic neuropathy but of actual necrosis of sensory nerve as well as the consequences of skin and subcutaneous tissue infarction, osteomyelitis, and ascending infection. As for patients with arterial ulceration, such patients' pain may be severe and unremitting; on the other hand, in certain such patients, necrosis of sensory nerves may actually make such gangrenous distal feet insensate and anesthetic, paradoxically resulting in less pain than would be anticipated from the degree of tissue destruction present.

Atheroembolism, usually to the toes or distal foot ("blue toe syndrome"[16]) occurs because of digital or distal branch artery occlusion from debris (clot, atheroma) which has embolized into the distal circulation from a proximal source (e.g., an aortoiliac

or popliteal aneurysm or an ulcerated atherosclerotic plaque). The syndrome occurs only with patent proximal arteries, and the distal limb is usually not ischemic. Pain is therefore uncommon until digital ischemia is severe enough to result in sensory nerve damage.

The diabetic foot is a special circumstance in which chronic nonhealing lower extremity and foot ulceration and toe gangrene may occur, yet the underlying pathogenesis revolves not around ischemia but rather diabetic neuropathy, foot structural changes, and diabetics' inability to combat bacterial infection. Indeed, most diabetic foot lesions are *not* ischemic[17] and revascularization is uncommonly required as part of their management. Widespread loss of distal foot and even lower leg sensation in diabetics consequent to diabetic neuropathy makes pain due to ulceration, gangrene, or infection relatively uncommon among diabetics. On the other hand, neuropathic pain is frequent (see later text).

Pain Syndromes Following Stroke

Pain is uncommon in association with cerebrovascular accident (CVA), except for patients whose cerebrovascular ischemia results from intracranial hemorrhage or tumor. Stroke survivors sometimes experience what appears to be a centrally mediated pain ipsilateral to the neurologic deficit.[18] Dejerine and Roussy first described excruciating pain involving the contralateral half of the body in a patient who had suffered a thalamic stroke and termed the condition "thalamic syndrome."[19] Similar symptoms can arise following injury anywhere along the course of the spinothalamic tracts, and this syndrome has been termed central poststroke pain (CPSP).[20]

CPSP occurs after ischemic or hemorrhagic stroke. Patients report burning or lancinating pain associated with sensory abnormalities in the painful region. Sensory abnormalities include decreased perception of sharpness and temperature, often accompanied by allodynia and hyperalgesia.[21] The pain is often constant, but may occur in paroxysms and it is usually limited to an area that is smaller than the area affected by sensory deficits. The pain is often worsened by stress and relieved by relaxation, and the pain can present an enormous burden to the patient, causing severe depression.[22]

Following thalamic stroke, CPSP is not uncommon. In a series of 100 patients with thalamic hemorrhage, 9% developed CPSP.[23] In a prospective study of 267 consecutively admitted stroke patients, CPSP occurred in 8% of the patients during the first year, with more than half of those with pain reporting moderate to severe pain.[24] In 63% of the patients, pain onset was within 1 month after stroke.

CPSP is a difficult condition to treat, and pain reduction rather than pain relief has to be the goal of the treatment. Conventional analgesics and opioids have been noted to be ineffective.[25] Numerous other types of drugs have been tried in the treatment of CPSP, but large controlled trials are lacking, and the treatment is far from being standardized. Treatment of CPSP has been reviewed in detail elsewhere.[26]

Pain Associated With Diseases Involving Small Arteries

Numerous regional or systemic disorders include involvement of small arteries. In the extremities, such conditions commonly manifest coolness, pallor, numbness, cyanosis, and pain—manifestations of Raynaud's syndrome.[27] Often such symptoms and signs result simply from abnormal arterial reactivity, such as occurs in its benign form, termed Raynaud's *disease* (seen primarily in young and middle-aged women, or as a consequence of chronic vibratory tool use, primarily in young male laborers). Dull aching digit pain is noted by such patients during periods of extreme vasoconstriction; with the hyperemia of digital reperfusion, when vasoconstriction is replaced by vasodilatation, this dull aching pain is commonly replaced by a burning "fiery" pain as the digits are suffused via vasodilated digital arteries.

A more ominous form of small-artery involvement associated with Raynaud's syndrome (termed Raynaud *phenomenon* in this setting) results from digital arterial occlusions resulting from one or another form of various rheumatoid conditions—especially scleroderma.[28] To these individuals' diffuse pain syndrome, resulting from digital vasoconstriction and then vasodilatation, is added intractably painful fingertip ulceration or necrosis. Such patients' distal digital pain is frequently severe and unremitting, not uncommonly refractory even to large doses of opiate analgesic medications, and may require amputation for pain relief. Pathophysiologically these lesions are similar to those of advanced chronic lower extremity arterial insufficiency.

A rare form of small-artery involvement resulting in severe pain is that associated with Buerger's disease (thromboangiitis obliterans [TAO]), a condition most commonly seen in young male tobacco addicts. TAO is a nonatherosclerotic necrotizing condition of arteries, veins, and nerves themselves primarily in the extremities.[29] Because only the tibial arteries in the lower extremity, or the distal radial and ulnar arteries of the upper extremity, are commonly involved in Buerger's disease these patients have excellent arterial inflow but inadequate collateralization (Fig. 38.5), and their ability to heal refractory ulcerations or areas of gangrene is poor. These patients' foot or hand pain is described as severe, unremitting, aching, burning, and agonizing; amputation is commonly the best management.

Pain Associated With Venous Disorders

Venous disease is common and is frequently undiagnosed. This occurs in part because one major component of venous disease—deep venous thrombosis (DVT)—commonly occurs in a relatively vegetative, bland fashion associated with only minimal inflammation. Such patients' first symptom may be painless lower extremity edema or, on occasion, chest pain and cardiorespiratory collapse associated with pulmonary embolus. Pain is only inconsistently associated with superficial venous disease. Patients with primary or secondary venous varicosities may note diffuse aching or burning pain associated with their venous varicosities, a discomfort likely secondary to stretch stimulation of nociceptors in and around the venous adventitia and media or in the surrounding soft tissue.

Patients who have suffered a prior lower extremity DVT often display symptoms and signs of the postphlebitic (postthrombotic) syndrome. This condition is characterized by chronic lower extremity edema, secondary venous varicosities, and characteristic skin changes including stasis pigmentation and eczema, subcutaneous atrophy, and, in advanced stages, skin breakdown and chronic nonhealing ulcerations around the medial and lateral malleoli. These stasis ulcerations, usually relatively small and shallow but occasionally circumferential and extending from ankle to mid-leg, are, in the author's experience, notably *nonpainful*, often manifesting only mild itching or burning. When significant pain occurs in a stasis ulcer, a secondary diagnosis should be entertained—invasive infection (usually streptococcal) or (rarely) malignant transformation, ischemia, or osteomyelitis.

Superficial phlebitis generally results from chemical irritation of the intima of peripheral veins as a consequence of intravenous infusions of various agents, sterile inflammation secondary to indwelling catheters or other foreign bodies, or bacterial infection. Such phlebitis is characterized by marked localized tenderness with overlying cellulitis, a palpable "cord" along the course of the vein and, rarely, systemic toxicity. Pain is characteristically well-localized along the vein and is burning in nature, resulting

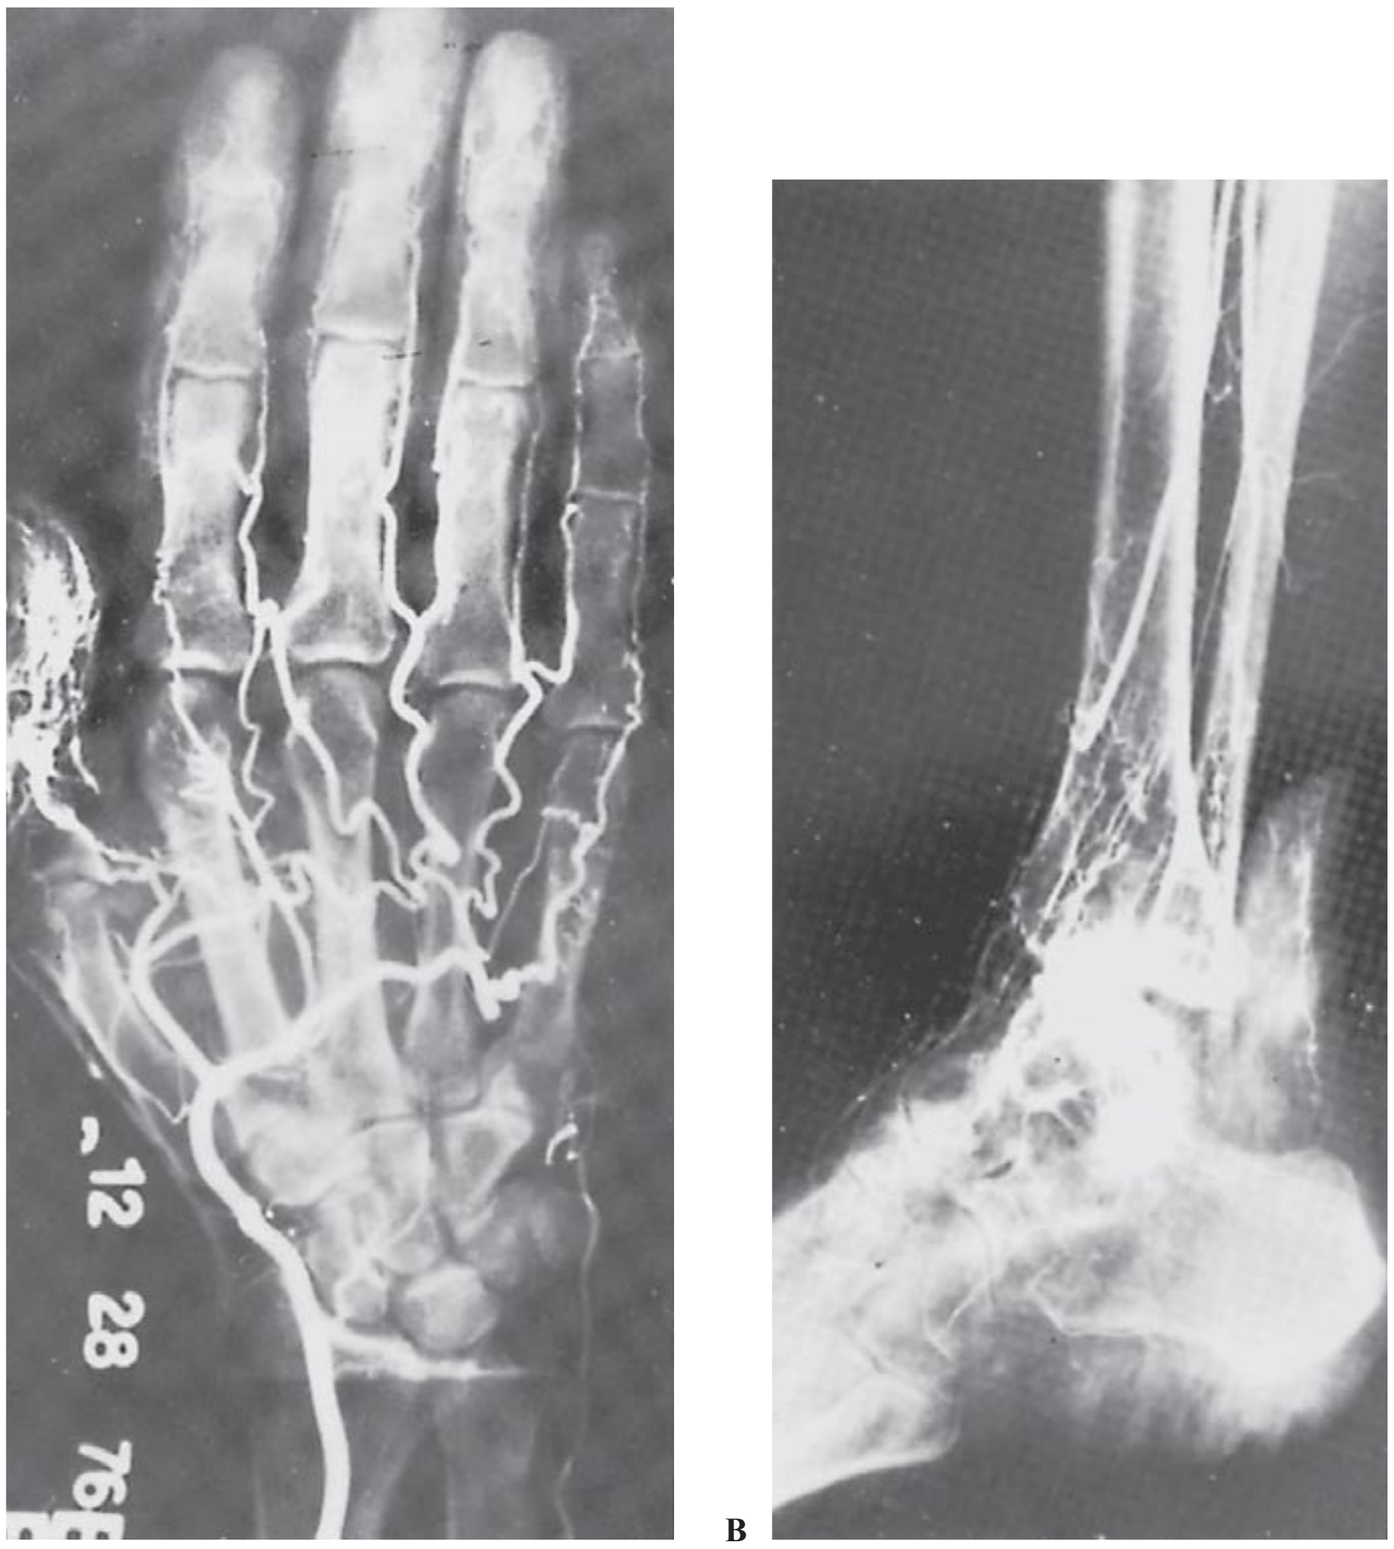


FIGURE 38.5 Angiograms of patients with thromboangiitis obliterans (Buerger's disease). **(A)** Angiogram of the hand of a patient showing lack of filling of the ulnar artery, characteristic tortuous, corkscrew-like arteries in the hand, and "skipped" areas where no contrast enters the digital arteries. **(B)** Angiogram of the distal part of the leg of a patient with thromboangiitis obliterans. The anterior and posterior tibial arteries appear normal until their abrupt occlusion at the ankle. (From deWolfe VG. Chronic occlusive arterial disease of the lower extremities. from stimulation of vein–wall nociceptive receptors. In addition, perivenous inflammation results in elaboration of acidic inflammatory or infectious mediators which stimulates perivenous nociceptors.

Pain Associated With Lymphatic Diseases

The most common lymphatic disorder is *lymphedema praecox*—idiopathic, bland nonvenous swelling, usually of a lower extremity. Other forms of lymphedema are either iatrogenic (consequent to lymphadenectomy or irradiation) or result from infections of various sorts. The lymphatics are not innervated so most forms of lymphedema are painful only when cellulitis or lymphangitis—an unfortunately common complication of lymphedema—supervenes.

Pain Associated With Amputation

Commonly performed because of intractable pain in a nonsalvageable limb, amputation itself often results in pain of various types. These can be classified as being either acute—at the time of the amputation—or chronic—occurring weeks, months, or even (upon occasion) years following the initial procedure.

Acute postamputation pain may be related to the surgical procedure itself or to incompletely understood central or neuraxial phenomena arising from the patient's preoperative pain status. Acute postamputation pain may result from the obligatory section of major nerves during limb amputation. The incisional and wound pain that results from transtibial or transfemoral amputation commonly resolves within a week or so following amputation—sooner in many surgeons' experience if a rigid dressing is applied to the residual limb.[30]

Other relatively straightforward amputation pain issues occurring early in the postoperative period include those related to stump hematoma or ischemia or actual muscle necrosis because the amputation was performed too far distally, resulting in thrombosis of the stump's residual arterial blood supply. The latter complication generally requires re-amputation at a higher level.

Early postamputation pain problems unrelated to the wound itself include the development of diverse neuropathic phenomena, including phantom limb *sensation* or *pain*. Virtually all amputees experience the sense that the amputated limb is still present, for example, that it itches and needs to be scratched. Phantom limb *sensation* is generally considered to be benign and self-limited. Phantom limb *pain*, on the other hand, can frequently be severe and, on occasion, even incapacitating, although patients can be reassured that the phenomenon generally diminishes or disappears within months to a year following amputation. Treatment with antiseizure medications, tricyclic antidepressants, regional sympathetic blockade with long-acting local anesthetic agents, cutaneous electrical stimulation units, sympathectomy, spinal cord stimulation,[31] or even rhizotomy or distal reentry zone sectioning[32] may be of use for persistent or severe phantom limb pain.

Late postamputation pain most commonly results from a

poorly fitted limb prosthesis, and an experienced prosthetist's opinion is invaluable in this setting. Other less common but important causes of late postamputation stump pain can include progressive stump ischemia, DVT, progressive autonomic dysfunction (e.g., CRPS), or neuroma formation—the last problem best prevented by assuring that large nerves sectioned at the time of the original amputation are buried in muscle, well away from cut bone ends and the skin flap.

DIFFERENTIATING VASCULAR FROM NONVASCULAR PAIN

It is clinically self-evident that a large overlap occurs between the pain syndromes arising from vascular and nonvascular diseases. The not infrequent misdiagnosis of a ruptured AAA as ureteral or biliary colic, of an aortic dissection as a myocardial infarction or gastroesophageal reflux, or of lower extremity ischemic pain as lumbar spinal stenosis, all point to the importance of considering the entire constellation of diagnostic possibilities present in patients presenting with various forms of pain.

The scope of this chapter precludes an exhaustive discussion of those disease states in which the misdiagnosis of vascular for nonvascular disease (or, as important, the converse) can occur; the reader is referred to seminal general surgical differential diagnostic texts for further details.[33–35] Those intent on formalizing the divergence of vascular surgery from general surgery,[36,37] both in the context of resident training and as a separate specialty, must make every effort to ensure that future vascular surgeons and their general surgery colleagues experience a shared body of clinical knowledge and judgment in this context.

THE RELIEF OF VASCULAR PAIN

The relief (or at least the mitigation) of pain is the *sine qua non* of the rationale for many vascular interventions, to the extent that an ability to achieve pain relief may be tantamount to failure—either of the original diagnosis or of the intervention itself. The patient who continues to experience calf claudication after a technically successful femoral–popliteal bypass may well have needed more preoperative attention paid to the status of his lumbosacral nerve roots. The return of claudication after a period of pain-free walking suggests the progressive deterioration of the original revascularization.

Relief of several types of aortic pain can take both "medical" and surgical forms. As previously intimated, the presence of tearing central truncal pain is a hallmark of aortic dissection. All type A aortic dissections require immediate referral to a cardiothoracic surgeon for urgent intervention. However, Type B aortic dissections' natural history, as well as their indications for operative or endovascular intervention, are heavily dependent on the relief of this lesion's characteristic pain by pharmacologic therapy—specifically, the administration of beta-blocker agents, whose effect is to halt the medial hematoma's dissection by lowering systolic and mean blood pressure as well as left ventricular dV/dt.[38]

The pain associated with an expanding, leaking, or ruptured abdominal or thoracic aortic or iliac aneurysm is relieved by successful graft interposition, either by open or stent-graft means. Graft repair of aneurysms eroding into the spine commonly relieves the pain from such bony erosion. Similarly, and for obscure reasons, graft repair of inflammatory AAAs tends to resolve the characteristic inflammatory "rind" around the aorta and, with it, the diffuse, poorly localized, boring mid-abdominal-to-mid-back ache these patients commonly note. Interestingly, the use of corticosteroids, administered systemically or by injection, can also diminish the pain associated with an inflammatory aneurysm,[39] although such therapy theoretically increases the risk of aneurysm expansion and rupture.[40]

A preponderance of pain resulting from vascular disease arises from inadequate tissue oxygenation, most commonly with exertion or other increased nutritive blood flow demands but also in basal blood flow states in which tissue viability itself is threatened. Many vascular interventions focus on restoring tissue perfusion to (or toward) normal—not only various revascularization procedures, either by open or endovascular means (Fig. 38.6), but also pharmacologic or hygienic measures as simple as the encouragement of smoking cessation or aerobic exercise or the administration of hemorheologic medications. While such inter-

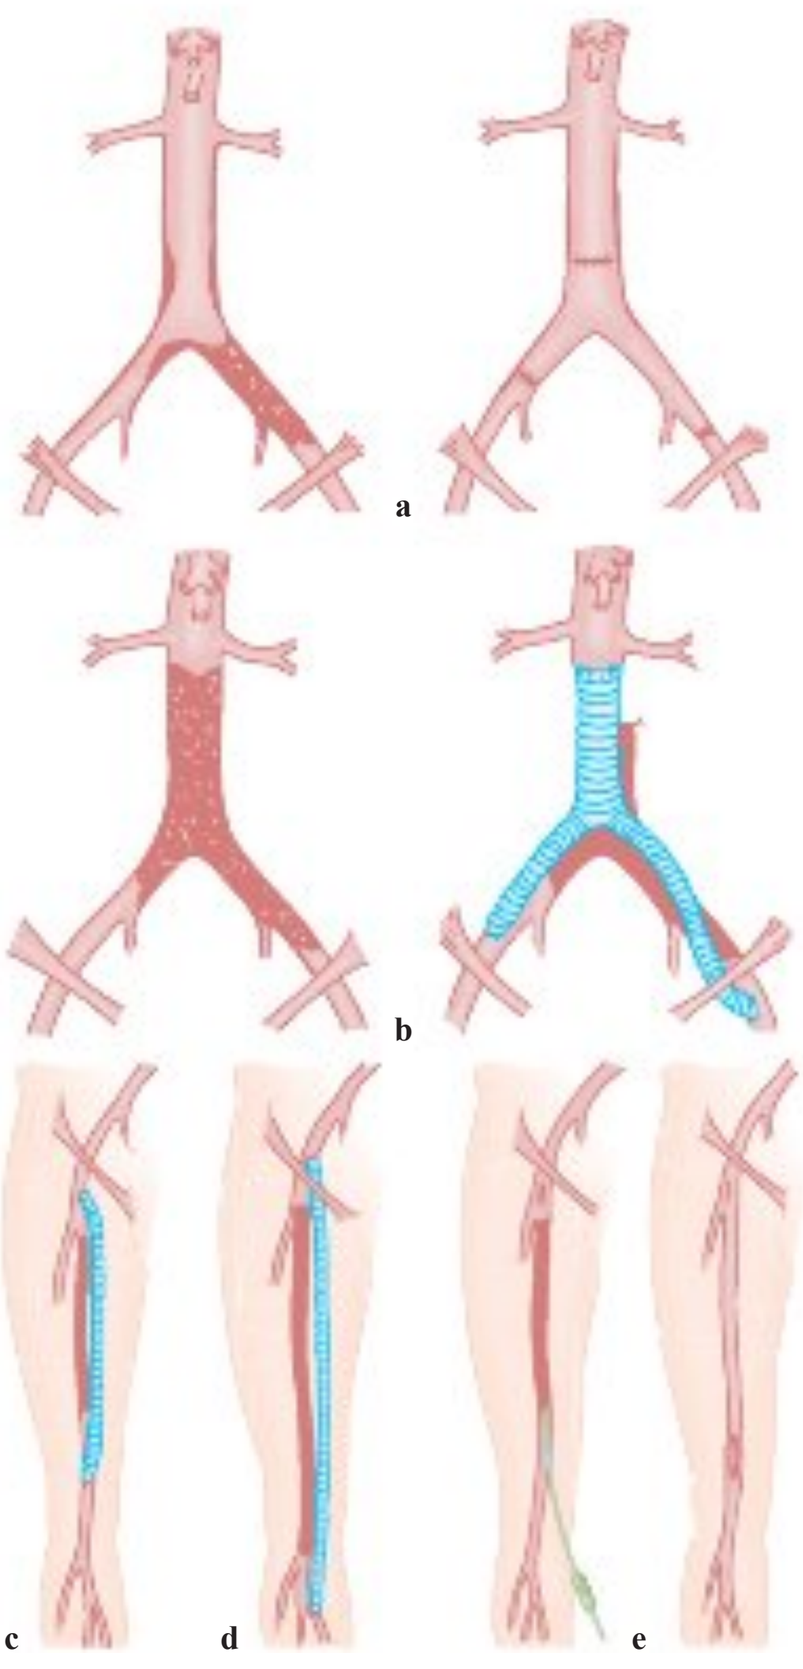

FIGURE 38.6 Various types of surgical procedures to achieve arterial revascularization. **(A)** Aortoiliac endarterectomy, which is especially useful in younger individuals with minimal deterioration of the arterial wall. This is accomplished through a transverse incision in the aortic and iliac arteries, removing the atheromatous and thrombotic cast, with subsequent reanastomosis of the iliac arteries and closure of the transverse incision in the aorta. **(B)** Endarterectomy of the proximal aorta, end-to-end aorta-graft anastomosis with oversewing of the distal aorta, and bypass graft to right external iliac artery and to the left common femoral artery. **(C)** A prosthetic bypass connecting the external iliac with the lower portion of the femoral artery. **(D)** The lower end of the prosthesis in **C** is grafted to the posterior tibial artery. **(E)** Endoluminal endarterectomy with vein patch arterioplasty. (Modified from Hollier LH. Principles and techniques of surgical treatment of occlusive arterial disease of the lower extremities. In: Spittell JA Jr, ed. *Clinical Vascular Disease*. Philadelphia: FA Davis, 1983:37–48.)

ventions are most commonly carried out for the symptomatic consequences of lower extremity atherosclerotic occlusive disease, the principle of relieving vascular pain by improving tissue nutrition can be relevant for nonatherosclerotic diseases of the upper extremities as well—for example, the salubrious effects seen with the administration of cilostazol in patients with various small-artery occlusive phenomena of the digits[41] or the relief of dialysis access-associated rest pain of the hand by the performance of distal revascularization/interval ligation.[42]

In unusual circumstances revascularization by conventional operative or pharmacologic means may not be feasible or may not provide tissue reperfusion adequate to relieve pain or other ischemic manifestations. In certain limited circumstances the observation, initially popularized by Leriche,[43] that sympathectomy can increase skin perfusion may offer a therapeutic alternative. Ipsilateral lumbar sympathectomy (most effectively by operative excision, although a therapeutic effect can result from phenol or absolute alcohol ablation) can heal shallow ischemic skin lesions and relieve associated ischemic rest pain, probably by the combined effects of increased skin blood flow and interruption of afferent pain fibers traveling within the lumbar sympathetic chain.[44,45] Patients subjected to such therapy have a 10% risk of developing a sometimes debilitating although transient burning pain termed postsympathectomy neuralgia.[46]

Revascularization to treat severe ischemia may not be possible, or, even if technically feasible, may not be successful in relieving pain. When tissue loss—advanced ischemic ulceration or gangrene—supervenes, amputation is indicated. However, in that subset of patients with far-advanced, refractory ischemia in which significant tissue loss has not yet developed but in which pain is severe and unremitting, Jacobs and colleagues have extensively investigated the possibility that spinal cord stimulation (SCS) might relieve pain and forestall the need for amputation as a pain-relief measure. Initial enthusiasm for this approach, based on nonrandomized studies demonstrating improved microcirculatory blood flow in subjects with advanced nonreconstructible lower extremity arterial disease,[47] has waned with publication of less favorable results of more recent prospective trials of SCS.[48] At the current time, the role of SCS in the management of subjects with advanced chronic limb ischemia appears to be restricted to those with relatively preserved microcirculatory skin perfusion.[48]

Pain associated with venous disease of various sorts is ubiquitous although rarely severe or incapacitating. The central role of vein wall distention as the proximate cause of lower extremity venous symptoms associated with saphenous or deep venous insufficiency is perhaps best demonstrated by the almost universal symptomatic improvement associated with such ''low-tech'' maneuvers as limb elevation or the donning of elastic support stockings. The ''swollen'' or ''bursting'' sensations associated with significant large-vessel lower extremity venous obstruction (''venous claudication'') may only be effectively treated by venous bypass or by endovascular relief of proximal venous occlusions.[49] The pain associated with acute venous thrombosis, either deep or superficial, is both congestive and inflammatory and is optimally treated with limb elevation and/or compression plus anti-inflammatory medications.

The management of acute pain is central to the cultural identity of most medical specialties. Unfortunately, published research has repeatedly documented that most medical professionals have inadequate training, experience, or understanding of the proper management of acute or chronic pain. Ballantyne and Mao have recently discussed this problem as well as recent research findings which could inform a more appropriate approach to the medical management of pain.[50] Pharmacologic (or other) management of chronic or severe pain of any origin is increasingly the domain of pain specialists, frequently with an anesthesiology background, in a multidisciplinary pain clinic setting.

CONCLUSION

How best to manage the manifold types of vascular pain is a vast and incompletely illuminated topic. Vascular pain's multifactorial nature confounds simple or stereotypical prescriptions for its relief. In a large majority of cases restoration to (or toward) normalcy of the underlying arterial or venous condition will resolve or improve associated vascular pain. Chronic vascular pain is closely allied with neuritic or neuropathic abnormalities, the management of which warrants involvement of specialist consultants in chronic pain.

CHAPTER 39 ■ PAIN DUE TO THORACIC OUTLET SYNDROME

KAJ H. JOHANSEN, CYNTHIA CAMPBELL, AND GEORGE I. THOMAS

INTRODUCTION

An important and incompletely understood cause of upper extremity pain is subsumed under the rubric of "thoracic outlet syndrome" (TOS). This condition arises from compression of neurovascular structures as they enter/exit the neuraxis and the mediastinum at the base of the neck. Particularly in cases involving chronic compression of the brachial plexus, TOS can be a complicated and frustrating condition to manage, due to ongoing controversy about the underlying pathophysiology, how the diagnosis is best made, and disputes about proper and effective treatment. Many of the problems regarding TOS revolve around the uncertain natural history of the condition with and without intervention. In this chapter we discuss the various types of TOS with a particular emphasis on the neurogenic type—by far the most common, the most disputed, and also the most likely to result in pain.

ANATOMY AND PATHOPHYSIOLOGY

The thoracic outlet is the aperture through which the subclavian artery and trunks of the brachial plexus pass as they exit the neuraxis and the upper mediastinum at the base of the neck. In normal anatomic circumstances the thoracic outlet is bound by several musculotendinous and bony structures including the anterior and middle scalene muscles and, inferiorly, the first rib (Fig. 39.1). In pathologic circumstances, compression of the neurovascular bundle at the thoracic outlet is most commonly the consequence of abnormalities of the scalene muscles and/or the first rib. However, neurovascular compression can also result from the presence of a cervical rib, abnormal fibrous bands, callus from a clavicular fracture, scarring from prior trauma or radiation therapy, or (rarely) a superior sulcus (Pancoast) tumor of the lung.

Because the subclavian vein lies anterior to the anterior scalene muscle it does not actually pass through the thoracic outlet. It is, however, located beneath (and can be compressed by) the subclavius muscle and between the clavicle and the first rib in its course toward the mediastinum.

In normal circumstances arm elevation or abduction results in a functional reduction in the caliber of the thoracic outlet aperture because of posterior rotation of the clavicle and contracture of the scalene muscles. The space between the clavicle and the first rib narrows, and below the shoulder the pectoralis minor muscle contracts.

Trauma, particularly cervical hyperextension ("whiplash") or chronic repetitive use of the upper extremities (particularly in an out-front or overhead position) may, over time, result in chronic spasm and contracture of the scalene muscles, producing both thickening of the anterior and middle scalene muscles as well as microstructural changes in muscle fiber type.[1,2]

Provocative maneuvers of the arm may result in compression of the subclavian artery and vein in up to 30% of normal individuals.[3] Reduction in the caliber of the thoracic outlet by pathophysiologic circumstances can result in extrinsic compression of the subclavian artery or vein in more than 90% of patients with TOS.

A cervical rib, abnormal bands, or residua from a clavicular fracture can result in subclavian *arterial* stricture. This may result in development of a poststenotic subclavian artery dilatation or even a subclavian artery aneurysm, mural thrombus from which may embolize into the arterial circulation of the wrist or hand.

Extrinsic compression of the subclavian vein in the costoclavicular space, perhaps involving the tendon of the subclavius muscle, can in concert with repetitive use of the upper extremity result

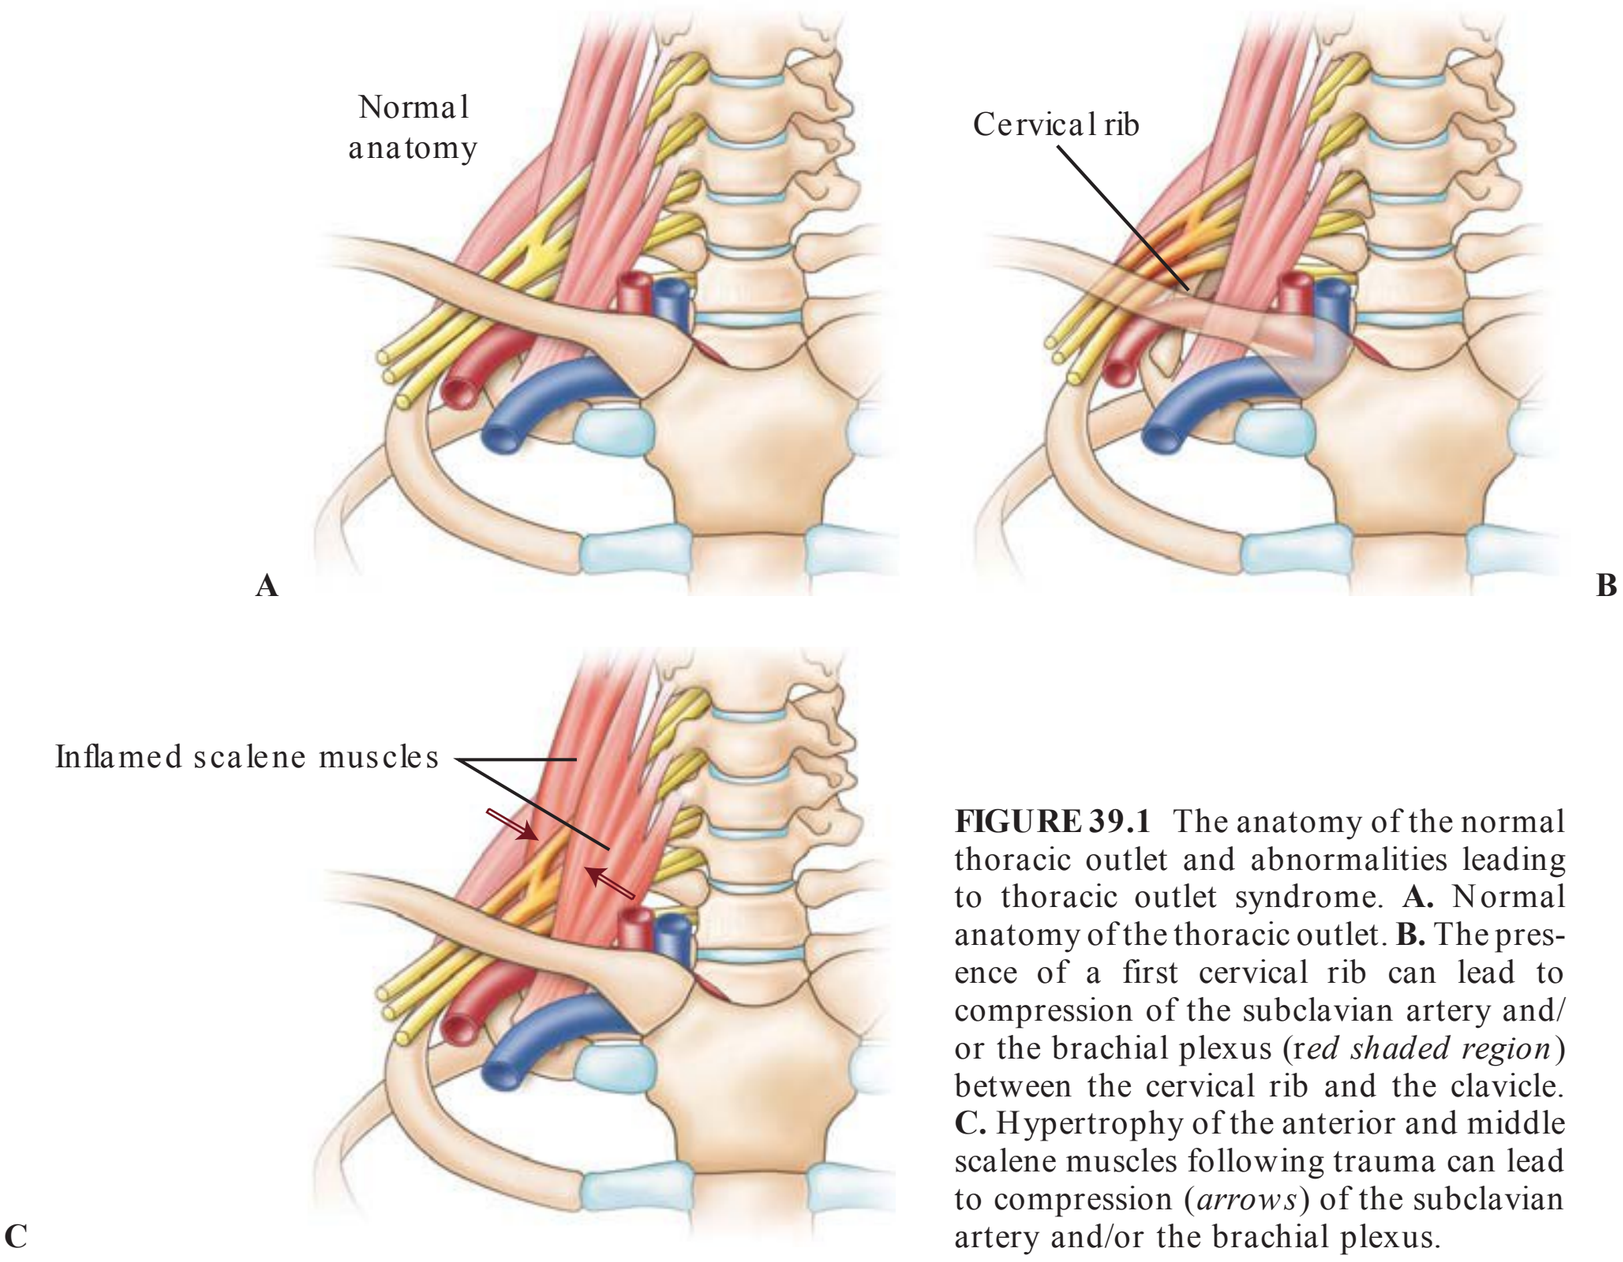

FIGURE 39.1 The anatomy of the normal thoracic outlet and abnormalities leading to thoracic outlet syndrome. **A.** Normal anatomy of the thoracic outlet. **B.** The presence of a first cervical rib can lead to compression of the subclavian artery and/or the brachial plexus (r*ed shaded region*) between the cervical rib and the clavicle. **C.** Hypertrophy of the anterior and middle scalene muscles following trauma can lead to compression (*arrows*) of the subclavian artery and/or the brachial plexus.

in axillosubclavian *venous* thrombosis likely due to intimal damage and venous stasis.

CLINICAL PRESENTATION

Arterial TOS is extremely uncommon, comprising less than 1% of the totality of any TOS practice, and almost always presents as forearm or hand claudication (or other upper extremity ischemic symptoms) or evidence for distal upper extremity embolization. Physical examination demonstrates diminished or absent wrist pulses; vascular laboratory examination may show occlusion of the radial and/or ulnar arteries or their palmar or digital branches. On occasion patients may present with rest pain or gangrene of the fingers due to far-advanced ischemia from repetitive distal arterial embolic occlusion.

Physical findings in patients with *arterial* TOS are primarily those of absent or diminished pulses and/or the manifestations of distal upper extremity ischemia.

Involvement of the upper extremity venous circulation by compression of the subclavian vein at the thoracic outlet comprises approximately 5% of a TOS practice. Patients with such *venous* TOS (also termed Paget-Schroetter syndrome or "effort" thrombosis of the axillosubclavian vein) may present with aching pain distributed diffusely throughout a swollen, ruborous upper extremity. In more chronic circumstances pain and swelling may be less prominent.

Patients with *venous* TOS manifest arm swelling and discoloration; in later stages, prominent veins can be seen over the upper arm and around the shoulder.

By far the most common presentation–the overwhelming majority of the patients seen in a TOS practice–results from compression of elements of the brachial plexus, that is, *neurogenic* TOS. Patients with neurogenic TOS almost always have a prior traumatic event—a cervical hyperextension ("whiplash") injury, a fall on an outstretched arm, an object falling on the head or the shoulder—or alternatively have a history for a repetitive stress injury, usually due to exigencies of employment. Occupational risk factors for neurogenic TOS include sustained effort with the upper extremity(s) out-front or overhead and may be seen in drywall hangers, dental hygienists, beauticians or hairdressers, grocery checkers, shelf-stockers, or clerical workers engaged in prolonged keyboarding.

Such injury- or workplace-related postures and stresses have been demonstrated to result in chronic contracture and spasm of the suspensory muscles in and around the shoulder girdle—among them the anterior and middle scalene muscles. Obesity, sedentary lifestyles and maladaptive postures—in neurogenic TOS, characterized by the head flexed on the neck and the shoulders down and forward—exacerbate chronic scalene muscle spasm.

Patients with neurogenic TOS may have few or no symptoms with the arms in a neutral position. However, they will quickly note the onset of pain and paresthesiae with the arms placed in an out-front, overhead, or abducted posture. Indeed, this presentation is so stereotypic that we do not seriously entertain the diagnosis of neurogenic TOS in the absence of a subject's indication of worsened symptoms with the arms in such provocative postures.

Symptoms characteristically evoked in neurogenic TOS patients include elevational arm aching, particularly proximally around the shoulder, the axilla and the upper arm, associated variably with numbness and tingling out the arm, distal weakness, and a limitation in range of motion of the affected upper extremity. Paresthesiae are found predominantly in a C8-T1 distribution, appropriate to impingement on the lower aspects of the brachial plexus. Indeed, 80% of patients with neurogenic TOS demonstrate pain and paresthesias radiating along an ulnar nerve distribution often into the small and ring finger as a consequence. This presumably results from upward traction on the first rib by the scalene muscles, thus selectively impacting the inferior aspects of the brachial plexus.

A significant proportion of patients with neurogenic TOS have significant headaches, primarily occipital.[4] They also may note symptoms of facial or jaw pain or pain around the ear.

Muscle pain is commonplace in neurogenic TOS, particularly around the neck and the shoulder, the scapula, and the upper arm. It is frequently difficult to discern whether such symptoms arise from neurogenic TOS itself or from concurrent soft-tissue injuries (e.g., the paraspinous or periscapular muscles: the rotator cuff in the shoulder) suffered at the same time as the injury causing the neurogenic TOS.

Patients with neurogenic TOS frequently display a series of symptoms associated with activities of daily living which, in the aggregate, strongly indicate the presence of neurogenic TOS. The presence of a strongly positive clinical template has been in our experience as predictive of the diagnosis of neurogenic TOS as the use of various provocative tests (e.g., Adson, Roos, Wright). during physical examination. Elements of our clinical template are shown in Table 39.1.

In *neurogenic* TOS objective physical findings are sparse. Such individuals have limited range of motion of the affected upper extremity and manifest diminished spontaneous (adventitial) movements of the extremity as well as an unwillingness to place (or maintain) the affected limb in various provocative postures. Muscle tenderness over the anterior and lateral neck is commonplace, as is neck muscle tightness or contracture. In the supraclavicular fossa tenderness can be elicited with palpation over the brachial plexus, often resulting in radiation of neuritic sensations into the axilla or out the arm. Occasionally a cervical rib can be palpated. Tenderness over the pectoralis minor tendon attachment at the coracoid process below the shoulder is commonplace.

More peripherally in the upper extremity, tenderness may be elicited with palpation deep in the axilla. Tenderness of the arm or forearm muscles or tendons, or evidence for peripheral nerve compression at the carpal or cubital tunnels, may be present; this is not, however, a primary manifestation of neurogenic TOS but, rather, of the concurrent upper extremity injury that may accompany neurogenic TOS ("double crush" syndrome).[5] Rarely, intrinsic hand muscle atrophy may be observed, a so-called Gilliatt hand.[6]

A series of provocative tests are commonly performed which, individually or in the aggregate, are thought by many to demonstrate the presence of neurogenic TOS. The *Adson test* is carried out with the affected arm held downward and backward: the ipsilateral wrist pulse is palpated as the head is turned toward this arm while the subject undertakes a sustained inspiration. A positive test, suggesting the presence of neurogenic TOS, results when the wrist pulse is obliterated.

The *military* or *shoulder brace position* involves retraction of the shoulders backward and downward, resulting in pulse obliteration at the wrist.

The Roos or *abduction/external rotation* (*AER)* ("*hands-up*") *test* involves, as described, the arms held at 90 degrees at the shoulders, the elbows flexed 90 degrees, and the hands then contracted repeatedly. A positive test involves rapid fatiguing and pain in the affected upper extremity.

Recently Sanders and colleagues have reported the high positive and negative predictive value of the *brachial plexus tension test*.[7] Here the arms are held horizontally with the elbows and wrists straight and the neck is laterally flexed *away* from the affected arm: both wrists are then extended. A positive test is characterized by a sense of tightness and pain in the ipsilateral neck as well as neuritic symptoms radiating out the affected arm.

While not a provocative test for neurogenic TOS, the *Spurling* test is important in evaluation of this condition. Because an important alternative diagnosis may be cervical radiculopathy, development of characteristic symptoms with lateral flexion of the neck *toward* the affected extremity makes neurogenic TOS less likely and neuroforaminal compression due to herniated disc, scar, or arthritis more probable.

The aforementioned provocative tests are commonly performed as part of an evaluation for neurogenic TOS. Skeptics point out that, while the sensitivity of each of these tests may be high, their specificity is very low (e.g., more than 30% of the asymptomatic population may have a positive Adson test[3]). Similar results hold for the military (shoulder brace) position. The AER ("hands-up") has a high sensitivity and much better specificity for NTOS. Experienced clinicians' view is that patients ultimately demonstrated to have neurogenic TOS will be strongly positive for many or most of these tests, individually or in the aggregate.

TABLE 39.1

CLINICAL ELEMENTS THAT SUGGEST NEUROGENIC THORACIC OUTLET SYNDROME

Inability to drive with the hands elevated in the normal 10 o'clock/2 o'clock position on the steering wheel
Problems with grooming (shampooing the hair or use of a hair-dryer)
Awakening at night with pain or numbness in the affected arm(s)
"Drop attacks": the tendency to drop things, often without recognizing that grip strength has diminished
Inability to carry out sustained overhead activities, for example, changing multiple light bulbs in the ceiling
Loss of handwriting legibility (with involvement of the dominant upper extremity)
Inability to remove a tight jar lid

DIAGNOSTIC TESTS

In patients with *arterial* TOS, chest roentgenography will frequently confirm the presence of a cervical rib or callus from a clavicular fracture. A noninvasive upper extremity vascular laboratory examination will confirm the absence of (or reduction in) arterial flow at the hand and wrist level, not uncommonly in a pattern consistent with thromboembolic occlusion. Duplex scanning of the subclavian artery may demonstrate aneurysm formation with mural thrombus within. Computed tomography (CT) scan or catheter-directed arteriography may demonstrate sharp angulation of the subclavian artery over a cervical rib or around a clavicular fracture callus (Fig. 39.2); such imaging studies may also document the specific distribution of distal forearm arterial or palmar arch occlusions.

In *venous* TOS, noninvasive vascular laboratory examination will demonstrate partial or complete axillosubclavian venous thrombosis.[8] Enlarged venous collaterals around the shoulder may be displayed. Not uncommonly, upstream (arm) venous tributaries such as the basilic vein may demonstrate partial or complete thrombosis as well.

In *neurogenic* TOS chest roentgenography may demonstrate a cervical rib. We commonly perform an apical lordotic view because, with a standard chest roentgenogram, on occasion a cervical rib may be hidden as it overlies the first rib (Fig. 39.3). A chest roentgenogram may also, as for arterial TOS, demonstrate a clavicular fracture; it may also document the presence of a superior sulcus tumor causing the patient's symptoms.

Arteriography may demonstrate extrinsic narrowing or occlusion of the subclavian artery by the aforementioned anatomic stricture, particularly when the affected arm is maintained in an abducted/externally rotated posture. Imaging studies such as magnetic resonance imaging (MRI) or CT may demonstrate hypertrophied or inflamed scalene muscles, or edema or inflammation of the brachial plexus.[9,10]

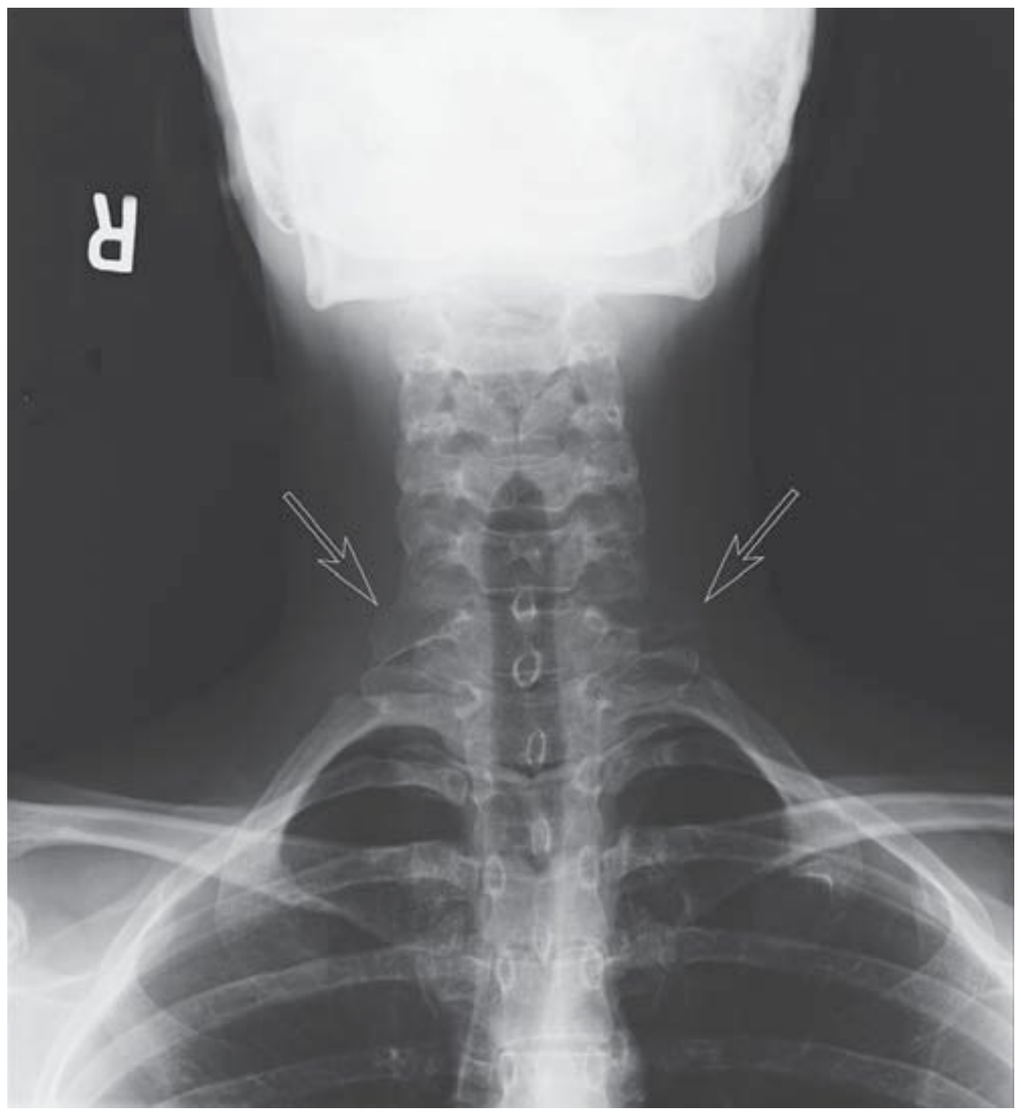

FIGURE 39.3 Chest x-ray demonstrating presence of cervical rib (*arrows*) in a patient with symptoms of thoracic outlet syndrome. (Image courtesy of Dean Donahue, MD, Division of Thoracic Surgery, Massachusetts General Hospital, Boston, MA.)

Electrodiagnostic testing is commonly performed in patients thought to have neurogenic TOS. For patient with "true" neurogenic TOS (a rarely seen condition which results from direct brachial plexus trauma, for example, a stab or gunshot wound), specific electrodiagnostic criteria have been established—primarily, reduction in median motor and ulnar sensory nerve amplitude. In patients with the much more common "nonspecific" or "disputed"[11] neurogenic TOS, standard electromyography (EMG) or nerve conduction velocity testing is almost always normal.[12] This is not because nerve compression is not present but, rather, as demonstrated by Tender et al.,[13] because such compression occurs much more centrally, at the level of the nerve roots and proximal brachial plexus trunks—an area that is difficult to assess via nerve conduction testing.

Recently Sanders has indicated the possibility that electrodiagnostic evaluation of the median antebrachial nerve may provide useful diagnostic information in neurogenic TOS.[14]

Most significant in the diagnostic evaluation of neurogenic TOS in our practice has been the use of temporary scalene muscle inactivation, carried out by EMG-guided intrascalene injection of either bupivacaine[15] or botulinum toxin A (Botox).[16] Scalene muscle block has been demonstrated to have a sensitivity *and* specificity >90% for the presence of neurogenic TOS.[15] After installation of one of these agents into the scalene muscle, the patient with neurogenic TOS commonly notes a reduction in pain and paresthesias as well as an improvement in flexibility and range of motion in the affected arm. Headache is frequently relieved and the dysautonomic symptoms (blueish discoloration, constant aching pain, moist skin) that accompany neurogenic TOS in up to 10% of patients are relieved.

Not infrequently, after a positive block, patients become emotional and burst into tears with such novel and unanticipated relief of their symptoms (sometimes having been told by prior

examiners that they are delusional or are malingerers). The effects start within a few minutes with bupivacaine injection and last from 15 minutes to several hours; with Botox administration (which we utilize both diagnostically and as a treatment maneuver) the onset of relief of symptoms (which occurs in more than 95% of patients who have had a positive bupivacaine block) occurs within 48 to 72 hours and lasts for 1 to 4 months.[16,17]

DIFFERENTIAL DIAGNOSIS

A number of alternative conditions present with symptoms and signs similar to those of various forms of TOS, thus complicating the diagnosis. This is most particularly true for neurogenic TOS, although on occasion arterial TOS may be written off for a time as Raynaud syndrome (or phenomenon) or some sort of dysautonomic disorder such as complex regional pain syndrome (CRPS). Venous TOS may be misdiagnosed as lymphedema or, again, some variety of sympathetic dystrophy.

In neurogenic TOS a wide range of conditions in the central nervous system or the neuraxis, most particularly multiple sclerosis but also such exotic disorders as syringomyelia, have masqueraded for a time as neurogenic TOS. Impingement on the cervical spinal cord or its nerve roots by herniated disc, arthritis, or cervical spinal stenosis can commonly present with neck, supraclavicular, shoulder, axillary, or upper extremity symptoms. Involvement of the shoulder or the scapula is a common concomitant of the injury which may initially have led to the neurogenic TOS itself. Cubital tunnel compression of the ulnar nerve in the elbow, or even carpal tunnel compression of the median nerve at the wrist, may manifest upper extremity symptoms which, on occasion, may be difficult to distinguish from those of neurogenic TOS.

Migraineurs may sometimes experience facial, jaw, or neck pain. Generalized shoulder girdle pain is a commonplace manifestation of fibromyalgia. Polymyositis, temporal (cranial) arteritis and polymyalgia rheumatica are connective tissue disorders which variably present with pain and tenderness of the muscles of the head, neck, and shoulder girdle.

The initial trauma (e.g., the "whiplash" injury suffered in a motor vehicle crash) commonly results in aches and pains and tenderness in the neck and out one or both upper extremities; it may even result in radicular symptoms which worsen with provocative postures of the arm. Such symptoms are not, however, those of neurogenic TOS, which we consider to be the consequence of *chronic* contracture of the scalene muscles. Indeed, we assert that the diagnosis of neurogenic TOS should not be invoked until at least 3 to 6 months after the initial traumatic event.

MANAGEMENT

In patients with *arterial* TOS two separate treatment goals must be met: relief of distal limb ischemia and eradication of the more proximal embolic source that resulted in the distal extremity ischemia. While repair of the proximal subclavian arterial lesion is relatively straightforward (usually aneurysmorrhaphy with a short segment of prosthetic graft material or of reversed saphenous vein), restoration of distal arterial flow is often difficult because the embolization that has occurred is chronic. The fact that the occlusion is longstanding often stymies efforts at catheter-directed thrombolysis or open arterial thrombectomy. Fortunately, if pulsatile flow can be restored to the level of the palmar arch then more distal digital tissue loss is generally avoided.

Conventional management of *venous* TOS should include systemic anticoagulation (this is, after all, a form of deep venous thrombosis and pulmonary emboli have certainly occurred as a consequence[18]) and, particularly if the onset of symptoms is recent, an attempt at catheter-directed axillosubclavian vein thrombolysis. If venous thrombus is thus relieved a stricture is often identified within the subclavian vein at the costoclavicular junction. Balloon angioplasty may frequently be carried out[19]; however, it is generally agreed that venous stenting should not be performed at this site because of the high likelihood of stent fracture between the "hammer" and "anvil" formed by the clavicle and first rib.[20]

Because of concerns about recurrent axillosubclavian venous thrombosis and chronic postthrombotic symptoms, conventional management has also commonly included not only thrombolysis and anticoagulation but staged operative thoracic outlet decompression.[21,22] Such an approach is designed to resolve the structural mechanism which led to the initial venous damage (also, by removing the costoclavicular "anvil," later stenting of the stenotic subclavian vein can be carried out if this is deemed necessary).

However, several recent natural history studies have suggested that recurrent axillosubclavian venous thrombosis is in fact quite uncommon and that the natural history of this condition is benign—enough so that thoracic outlet decompression may only rarely be warranted.[23,24] These authors argue that, far from preventing further complications, the magnitude of the dissection required for first rib resection is such that collateral vein disruption around the damaged axillosubclavian vein might paradoxically lead to worsening of the patient's venous congestive symptoms.

Early and mild-to-moderate *neurogenic* TOS should be treated by aggressive physiotherapy emphasizing postural training, abdominal breathing, and emphasis on stretching and relaxing the scalene muscles. Unfortunately, physiotherapy attempted in the early stages of neurogenic TOS is frequently misdirected, emphasizing resistance exercises; these, of course, tend only to exacerbate further scalene muscle contracture. Soon the scalene muscles are thickened and scarred, such that it is difficult to imagine much benefit from physiotherapy. Histologic studies of scalene muscle removed at this stage further support this conclusion: the muscle fibers are found to have changed from type II to type I and are interwoven with abundant fibroblasts.[1,2]

For these and other reasons, we believe that, once established, neurogenic TOS is effectively managed only by thoracic outlet decompression. Two means—chemodenervation with botulinum toxin A[16,17] or open surgical decompression of the thoracic outlet—are practiced and each has advantages and disadvantages.

Botulinum toxin, administered intramuscularly under EMG- or ultrasound-guided control, relieves symptoms of neurogenic TOS in the vast majority of subjects who have previously responded positively to a diagnostic scalene muscle block with local anesthetic. Such patients' symptoms are relieved for 1 to 4 months (mean 3 months).[17] A substantial proportion of such individuals can undergo repeat intrascalene botulinum toxin administration with attainment of another equivalent period of symptom relief.

However, scalene muscle chemodenervation, while temporarily affective at relieving symptoms of neurogenic TOS, does not appear to alter the underlying natural history of neurogenic TOS. Even when vigorous physiotherapy has been pursued during the period of time of scalene muscle denervation, durable improvement in the underlying condition is rarely detected. Tachyphylaxis to botulinum toxin is demonstrable in a substantial number of patients. The use of botulinum toxin for the treatment of thoracic outlet syndrome is not approved by the U.S. Food and Drug Administration, thus there is limited availability of this treatment. While a few of our surgery-averse patients have continued to undertake repeat botulinum toxin chemodenervation, a majority have ultimately opted for operation.

Surgical decompression of the thoracic outlet has historically been based on partial or complete excision of the first rib. The operative rationale is transparent—because the first rib is located at the bottom of the anatomic "triangle" forming the thoracic outlet and serves as the site of insertion of the anterior and middle

scalene muscles which comprise the remaining two sides of the "triangle," first rib removal should effectively open this orifice. Because the short, wide first rib plays no significant role in chest wall dynamics and the scalene muscles (developmentally archaic accessory muscles of respiration) serve no significant functional role, dismantling of the musculoskeletal bounds of the thoracic outlet should have minimal impact. Large series of patients undergoing first rib resection by transaxillary,[25,26] supraclavicular,[27] or posterior[28] approaches have demonstrated significant improvements in their prior neurocompressive symptoms 75% to 90% of the time.

Patients with symptoms of neurogenic TOS who have cervical ribs have generally done well simply with resection of the cervical rib as well as the tight adhesions ("bands of Roos"[29]) commonly associated with these extrathoracic ribs.

However, based on neurogenic TOS patients' stereotypic response to bupivacaine or botulinum-mediated chemodenervation, we have rethought our operative strategy for neurogenic TOS. Because a positive response to scalene muscle block is an obligatory part of our indications for operative intervention for neurogenic TOS (a positive block has a >90% positive predictive value for a favorable outcome of operative intervention[15]), we have concluded that the pathophysiology of this condition resides in the scalene muscles and not the first rib. We now consider the rib a *victim* of the condition rather than its *cause*. Others[30,31] have reasoned similarly.

We have thus ceased performing resection of the first rib and now focus our operative efforts on radical excision of the anterior and middle scalene muscles. We have carried out more than 200 consecutive thoracic outlet decompression procedures without excising the first rib: our results (90% "excellent" or "good" results) are equivalent to those we recorded with rib excision plus total scalenectomy, but patients in whom rib salvage has occurred appear to rehabilitate substantially more rapidly than those in whom subtotal first rib resection had taken place.

We have come to believe that a separate site of brachial plexus compression, in addition to the well-accepted interscalene and costoclavicular locations, occurs beneath the pectoralis minor tendon attachment to the coracoid process, a site where tendinous impingement on the upper aspect of the axillary nerve can occur. It has long been our practice to decompress this area by dividing the pectoralis minor tendon via a small vertical infraclavicular incision separate from the supraclavicular approach through which we decompress the brachial plexus. Sanders has likewise recently adopted this approach.[32]

OUTCOMES

Patients with *arterial* TOS are generally diagnosed and managed in timely fashion due to the sensitivity of finger, hand, and upper extremity neurovascular function. Even when chronic thrombotic occlusion of distal vessels is present, upper extremity arterial collateralization is generally robust enough to maintain distal hand and finger tissue viability and function.

For *venous* TOS, the long-term outcome following first rib resection appears to be good.[21,22] However, the natural history of this condition *without* first rib resection also appears to be excellent,[23,24] leading to recent skepticism regarding whether excision of the first rib in such patients really is in fact an obligatory part of management of this condition.[33]

Published data suggest that, while thoracic outlet decompression rarely completely resolves symptoms of *neurogenic* TOS, the vast majority of patients undergoing surgical thoracic outlet decompression appear to improve and to do well. Even among a high-risk group of workmen's compensation patients undergoing surgery for neurogenic TOS following prolonged administrative delays, the vast majority felt themselves to be improved and indicated they would undergo operation again if confronted by the problem.[34]

Approximately 5% to 10% of patients who have initially undergone decompressive surgery for neurogenic TOS will display persistent or recurrent neurogenic TOS symptoms. Such individuals may be found to have a missed cervical rib, a residual stub of first rib impinging on the brachial plexus or, most frequently in our experience, adherence of scar and unresected scalene muscle to the brachial plexus.[35] In such circumstances reoperative surgery, while associated with increased risk of peripheral nerve or brachial plexus damage, may be helpful in relieving symptoms. EMG-guided scalene muscle block may be highly useful in demonstrating the presence of adherent residual scalene muscle as the inciting problem in such patients.[35]

CHAPTER 40 ■ PAIN FOLLOWING SPINAL CORD INJURY

PHILIP J. SIDDALL AND PAUL J. WRIGLEY

INTRODUCTION

Pain presents a major challenge to those with spinal cord injury (SCI) and to those involved in their healthcare. Pain following SCI arises from a complex array of mechanisms. In addition, pain has a broad impact on physical, emotional, cognitive, and social functioning that needs to be evaluated and addressed in any management plan. Long-term sequelae involving other nonspinal musculoskeletal and visceral structures often coexist.

This chapter will provide an overview of the different types of pain presenting in people with SCI. It will examine the extent of SCI-associated pain in the community and the potential impact on the individual. The mechanisms underlying specific pains, assessment, and current treatment will also be explored.

EXTENT OF THE PROBLEM

Figures for the prevalence of pain in people with spinal cord injury vary depending on the method of survey and the way that pain is evaluated. Postal and community surveys have generally reported a prevalence of around 75% to 85%.[1–3] The figure for prospective, longitudinal studies is slightly lower. However, even these studies consistently demonstrate that around 65% of people with SCI pain have ongoing pain.[4,5] Furthermore, approximately one third of these people with pain report that the intensity of pain is severe or excruciating, indicating the importance of pain in these individuals.

The above studies address the general prevalence of pain following SCI. A few have investigated the prevalence of specific types of pain. There are several types of pain that can occur following SCI including musculoskeletal pain, visceral pain, and two distinct types of neuropathic pain that occur at and below the level of SCI. When these specific types of pain are identified, the most commonly occurring is musculoskeletal pain (58% of people at 5 years following injury) then at-level neuropathic pain (42%) and below-level neuropathic pain (34%).[5]

IMPACT OF PAIN

Loss of mobility is often considered the most serious consequence of SCI. It is interesting to note, however, that people with SCI consistently rate pain as one of the most difficult problems to manage, despite the presence of other problems that interfere with daily life.[1] Although it is sometimes difficult to attribute causality, there are a number of studies that clearly demonstrate the strong relationship between pain and poorer physical, psychological, and social functioning.[3,4,6,7] Pain may directly affect sleep and participation in activities of daily living, as well as contributing to functional disability beyond that attributable to the loss of mobility.[8–10] Pain also directly contributes to disability by limiting participation in rehabilitation and return to work.[2,10–12] Not surprisingly, these effects on functioning flow through to more global indicators of health such as reduced quality of life[13–15] and life satisfaction.[16]

The long-term prognosis for pain resolution following SCI is often poor. Many people with SCI report that despite trying a wide range of strategies, including different types of pain medications, complementary therapies, and physical therapy, their pain persists.[17] Pain may continue or worsen following injury.[3] It has also been observed that those reporting neuropathic pain 3–6 months following injury are likely to continue experiencing pain at 3–5 years.[5]

PREDISPOSING FACTORS FOR PAIN

Biological Factors

As described above, pain is a relatively common problem for people following SCI. Despite this, a clear understanding of the predisposing biological factors likely to result in pain has not been achieved. Contradictory evidence exists regarding the relationship between pain and the severity of injury (including completeness), the level of the injury, and the specific spinal cord tracts injured.[2,6,7,18–20]

Whether a complete or an incomplete injury occurs, the bulk

of clinical evidence strongly suggests that damage to the spinothalamic tracts is an important ingredient in the development of neuropathic pain following SCI. Several studies suggest that damage to spinothalamic tracts is a necessary, although not sufficient, condition for the development of neuropathic SCI pain.[21–23]

Psychological Factors

Studies have also investigated the relationship between pain and psychological factors. Indeed, some have suggested that psychosocial rather than biological factors are more closely associated with the presence and severity of pain.[4,6] These psychosocial factors include changes in mood and cognitions and social or environmental factors. Mood dysfunction is often correlated with the presence of SCI pain. Although it is often difficult to attribute causality in cross sectional studies, the presence of chronic SCI pain is consistently associated with significantly higher levels of perceived stress and depressive symptoms.[1,15,24,25]

Cognitive factors, such as catastrophic thinking about pain, self-efficacy beliefs, and acceptance, have also been demonstrated to influence pain and disability. Catastrophizing has consistently been found to be predictive of pain intensity and disability among people with SCI-related chronic pain.[25–27] Self-efficacy has also been demonstrated to be a powerful predictor of ability to perform physical tasks in people with SCI and pain.[28] One conceptualization of acceptance, re-evaluation of life values following injury, has been examined in a number of studies in SCI.[29,30] When specifically applied to those with chronic SCI-related pain, significantly lower levels of acceptance of injury as well as higher levels of helplessness were reported.[25]

Social and Environmental Factors

Comparatively little research has been done examining the contribution of social and environmental factors to the experience of pain following SCI. It has been demonstrated that social support has a positive effect on people after SCI.[27,31] However, perceived negative responses from friends, carers, and relatives may have a negative effect. Studies examining the influence of perceived responses to pain of significant others suggests that the perception of punishing responses was particularly important in the report of pain severity,[7,32] whereas negative or distracting responses were associated with increased pain-related disability.[33]

CLASSIFICATION OF PAIN FOLLOWING SPINAL CORD INJURY

Before moving on to assessment and treatment, it is important to consider the classification of SCI pain. A large number of SCI pain classification systems can be found in the SCI literature[34–37] causing confusion among researchers and clinicians. International pain and SCI associations are currently working to achieve consensus in this area. Some years ago, the Spinal Cord Injury Pain Task Force of the International Association of the Study of Pain (IASP) proposed a taxonomy of pain that attempts to provide a structure for systematically identifying the different types of SCI pain (Table 40.1).[38] This taxonomy is widely used and will therefore be employed in this chapter.

The IASP taxonomy proposes a tiered system in which pain types are firstly classified as nociceptive (musculoskeletal or visceral) or neuropathic (above-level, at-level, or below-level). The second tier classification (musculoskeletal, visceral, above-level neuropathic, at-level neuropathic, and below-level neuropathic) outlines the common types of pain encountered following SCI and is the most relevant for clinical purposes. The third tier attempts to identify the underlying pathology. Where the term ''neurological level of injury'' is used, this refers to the most caudal segment of the spinal cord with normal sensory and motor function bilaterally.[39]

Musculoskeletal Pain

In the acute setting following injury, nociceptive pain arises from damage to musculoskeletal structures including bones, ligaments, muscles, intervertebral discs, and facet joints. The pain is generally located in the region of preserved sensation close to the site of spinal injury although it may radiate in a somatic referred pattern. People with incomplete injuries also experience musculoskeletal pain below the neurological level. Chronic musculoskeletal pain may occur with overuse or abnormal use of structures, such as the arm and shoulder.[40,41] For mobility reasons, this type of nociceptive pain is very common in people with paraplegia and much less common in tetraplegia.[42] Pain associated with muscle spasm is another type of musculoskeletal pain commonly reported by people with incomplete injuries.

TABLE 40.1

PROPOSED CLASSIFICATION OF PAIN RELATED TO SPINAL CORD INJURY[38]

Broad type (Tier 1)	Broad system (Tier 2)	Specific structures/pathology (Tier 3)
Nociceptive	Musculoskeletal	Bone, joint, muscle trauma or inflammation
		Mechanical instability
		Muscle spasm
		Secondary overuse syndromes
	Visceral	Renal calculus, bowel, sphincter dysfunction, etc.
		Dysreflexic headache
Neuropathic	Above level	Compressive mononeuropathies
		Complex regional pain syndromes
	At level	Nerve root compression (including cauda equina)
		Syringomyelia
		Spinal cord trauma/ischemia
		Dual level cord and root trauma
	Below level	Spinal cord trauma/ischemia

Visceral Pain

Pathological processes occurring in visceral structures, such as urinary tract infection, bowel impaction, and renal calculi, also cause nociceptive pain. The level of SCI will influence the likelihood of developing these problems and the characteristics and presentation of the pain. People with thoracic injuries may experience visceral pain that is identical to those who have no spinal cord damage. However, people with cervical injuries may experience less well defined, generalized unpleasant symptoms that are difficult to localize and interpret. Despite this, pain may provide a warning for impending medical conditions, and responses to the pain by healthcare personnel can help avoid severe complications such as autonomic dysreflexia.

Above-level Neuropathic Pain

Neuropathic pain can occur above the neurological level of injury and includes pains that are not specific to SCI such as complex regional pain syndrome (previously referred to as reflex sympathetic dystrophy, causalgia, or shoulder-hand syndrome) and pain due to peripheral nerve injury (Fig. 40.1A). Although these types of pain are present in the general population, people with SCI may be more susceptible because of activities associated with wheelchair use and transfers.

At-level Neuropathic Pain

At-level neuropathic pain is defined as pain with typical neuropathic features (burning, aching, stabbing, or electric shocks) in a band within 3 dermatomes below the neurological level of injury (Fig. 40.1B). This type of pain has also been referred to as segmental, transitional zone, border zone, end zone, and girdle zone. At-level neuropathic pain is often associated with allodynia (pain from a normally non-painful stimulus) or hyperalgesia (an exaggerated pain response) in the affected dermatomes.

At-level neuropathic pain may arise from damage to spinal nerve roots (including the cauda equina) or the spinal cord itself. At times, the character of the pain may help in identifying the underlying cause. For example, unilateral pain exacerbated by spinal movement is more typical of nerve root damage than direct spinal cord injury. The origin of the pain may be difficult to distinguish on the basis of descriptors alone. However, when possible, this allows a more specific treatment pathway to be pursued.

Direct damage to the nerve roots may occur during the initial injury or at a later date secondary to spinal column instability, degeneration or disease (e.g., facet or disc impingement). Syringomyelia (cyst formation within the spinal cord) must always be considered in the person who has delayed onset of at-level neuropathic pain especially where there is a rising level of sensory loss. Loss of pain and temperature sensation is typical, but all sensory and motor functions can be affected during syrinx formation. People typically describe a constant, burning pain that may be associated with hypersensitivity (allodynia or hyperalgesia).

Below-level Neuropathic Pain

Below-level neuropathic pain is defined as pain with typical neurological features distributed diffusely below the neurological level of SCI (Fig. 40.1C). In contrast to at-level pain, below-level pain typically begins at least 4 dermatomes levels below (caudal to) the neurological level of injury; however, the region immediately below the neurological level of injury may also be involved. This type of pain may develop many months and even years following injury, and is the most likely type of SCI pain to be described as severe or excruciating.[5] It is also referred to as central dysesthesia syndrome, central pain, SCI phantom pain, or deafferentation pain. At-level and below-level neuropathic pain may both be present and at times are difficult to separate.

Below-level neuropathic SCI pain is typically constant, varying with mood or attention and is usually unrelated to position or movement. Pain may be triggered by sudden noises or physical jarring and exacerbated by other pathology such as urinary tract infections or disturbance of bowel function. Differences in the nature of below-level neuropathic pain may be apparent between those with complete and incomplete spinal cord lesions. Incomplete injuries are more likely to have an allodynic component due to sparing of tracts conveying touch sensations.

Psychological Aspects of Pain

Some classification systems have included psychological or psychogenic as types of pain that occur following SCI. However,

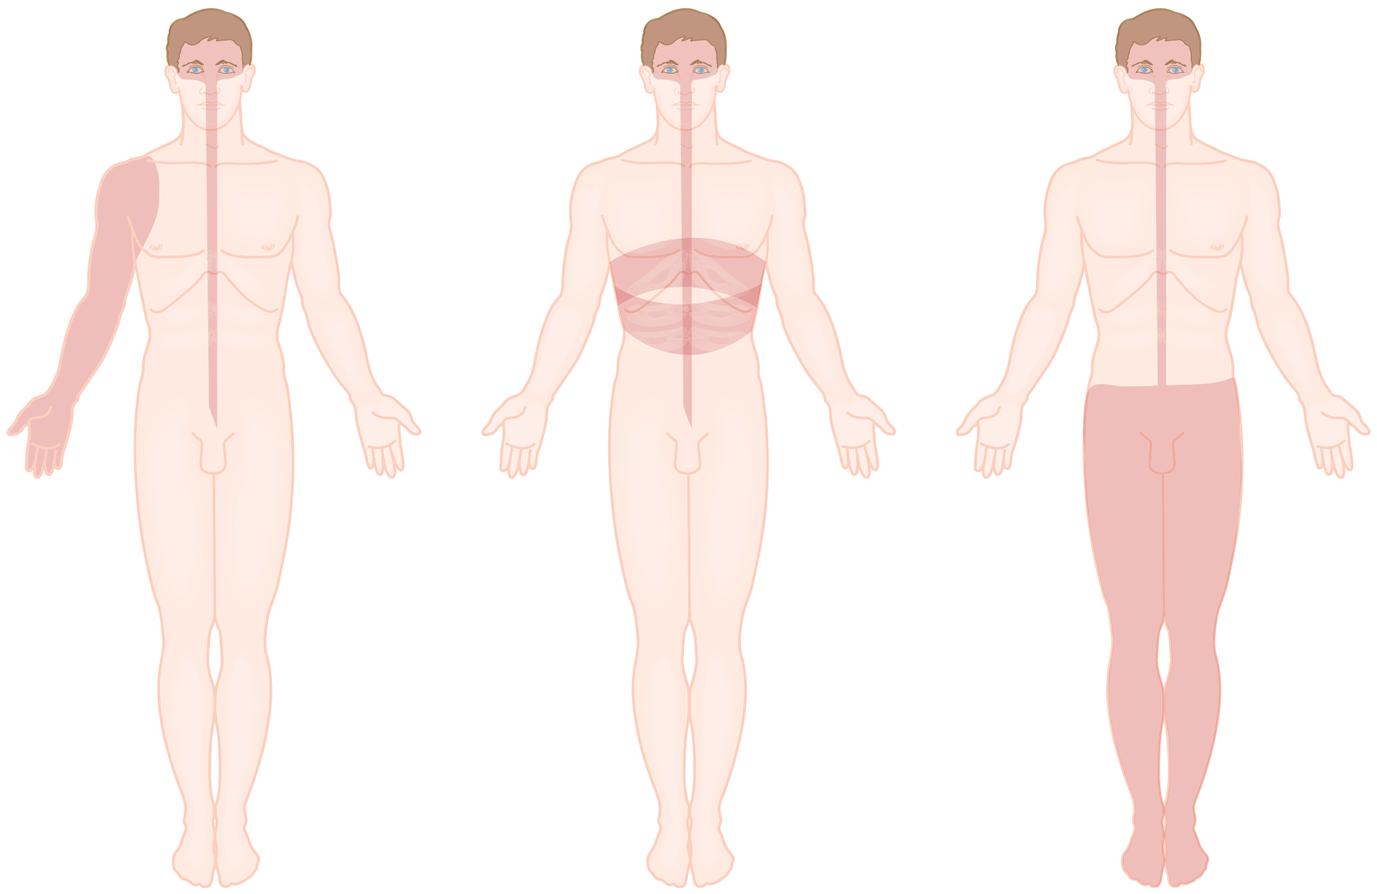

FIGURE 40.1 Typical patterns of **(A)** above-level and **(B)** at-level and **(C)** below-level neuropathic pain following a mid thoracic spinal cord injury.

applying a psychological label to the pain may be unhelpful. Pure psychogenic pain is extremely rare. On the other hand, it is well known that psychological factors such as mood and cognitions have a major influence on the pain experience.[6,43,44] Determining the contribution of psychological factors is an important aspect of management and will be discussed in more detail in the section on assessment.

MECHANISMS UNDERLYING PAIN IN PEOPLE WITH SPINAL CORD INJURY

Musculoskeletal Pain

Acute nociceptive pain arises from damage to structures such as bones, ligaments, muscles, intervertebral discs, and facet joints. Peripheral nociceptive mechanisms are responsible for the pain due to inflammatory mediator release, with both peripheral and central sensitization. Chronic musculoskeletal pain may occur with overuse or ''abnormal'' use of structures, such as the arm and shoulder and muscle spasm arising from a heightened reflex arc below the level of injury.

Visceral Pain

Pathological processes occurring in visceral structures, such as infection, impaction, and calculi formation, will generally give rise to nociceptive pain, though the quality of pain will be affected by the level of injury. As with musculoskeletal pain, visceral pain arises from afferent nociceptor activation and generally involves inflammatory processes.

Neuropathic Pain

Neuropathic pain following SCI has several clinical presentations that may reflect different underlying mechanisms. The specific mechanisms underlying at-level and below-level neuropathic pain remain unclear and therefore will be grouped together. Neuropathic pain may be due to changes occurring in the periphery, spinal cord, and brain.

Periphery

The degree to which peripheral changes influence neuropathic SCI pain remains uncertain, particularly in those with clinically complete injuries. Impingement of nerve roots may result in primary afferent functional and structural changes in a similar manner to peripheral nerve injury. People with clinically complete injuries may have residual sensory transmission through the cord that is not detectable using standard physical examination techniques (a ''sensory discomplete'' lesion). In this subgroup of clinically complete lesions, pain may be influenced by transmission of nociceptive impulses arising in the periphery via these residual pathways. This certainly seems to be the case in people with clinically complete injuries who report pain in the region of absent sensation that is strongly related to joint position or other nociceptive generators.

Spinal Cord

Some of the earliest investigations into SCI pain noted that blockade of the spinal cord using spinal administration of a local anesthetic immediately above the level of injury resulted in relief of pain in some people.[45] From these observations, it was proposed that neuropathic SCI pain may be due to the presence of an ''irritated focus'' or ''neural pain generator'' which was close to the rostral end of the SCI. This was supported by the finding that dorsal horn neurons immediately above the level of SCI demonstrated abnormal spontaneous neuronal activity.[46]

More recently, animal and human studies have confirmed that there are changes in the properties of nerve cells close to the site of SCI.[47] These changes include increased responsiveness to peripheral stimulation, an increase in the level of background activity and prolonged firing following a stimulus.[48–50] Further studies have demonstrated a number of changes in neurotransmitters and receptors which may lead to an increase in excitation or a reduction in inhibition and may result in the change in firing properties of these spinal neurons. These include changes in *N*-methyl-D-aspartate (NMDA), non-NMDA, and metabotropic glutamate receptors, sodium channels, and GABAergic, opioid, serotonergic, and noradrenergic function. In addition, SCI results in glial activation and increased cytokine and prostaglandin release as well as structural reorganization of inputs in the dorsal horn of the spinal cord.[23,51,52]

Brain

Despite the evidence supporting the concept of an ''irritated focus'' in the spinal cord close to the site of damage, neuropathic pain may continue despite removal of a section of the spinal cord above the level of injury.[53] This raises the question as to whether changes in the brain may also contribute to the development of pain. A number of studies in animals and humans have demonstrated brain changes associated with the presence of neuropathic pain. The precise link between these changes and the development of pain remains a matter of debate.[54] The brain changes described include alterations in thalamic neuronal firing,[55–58] expression of sodium channels,[59] biochemical changes,[60] and changes in thalamic perfusion or activity.[61,62]

Multilevel Effect

Before concluding this section on mechanisms, it is important to note that neuropathic SCI pain may be due to a combination of changes at a number of nervous system levels. For example, it has been observed that a higher proportion of patients with below-level neuropathic SCI pain have at-level sensory hypersensitivity than pain-free SCI patients.[63] When this specific group of patients were examined using magnetic resonance imaging (MRI), larger grey matter lesions were noted at the rostral end of the lesion compared to pain-free SCI patients.[64] In these patients, below-level neuropathic pain may be due to a combination of supraspinal neuroplastic changes in response to a spinothalamic lesion together with neuronal hyperexcitability at the rostral end of the injury.[23]

PATIENT ASSESSMENT

The perception and expression of pain is influenced by many factors including past experience, culture, environmental influences, and genetic makeup.[65,66] A thorough pain assessment therefore involves consideration of contributing biological, psychological, and environmental factors. An understanding of the patient's biopsychosocial system allows the clinician to develop a rational assessment of the causal links involved in the pain problem. This facilitates the development of a prioritized problem list and goal-oriented management plan. Such an approach leads to better long-term outcomes compared to unimodal treatment approaches.[67]

As is common to most clinical practice, a pain assessment first involves a careful history, followed by a focused physical examination and appropriate investigations or diagnostic procedures. The categories biological (nociceptive and neuropathic), psychological, and social can be used to summarize findings in a diagnostic framework and management template.[67]

Biological Contributors

Nociceptive. Musculoskeletal pain is suggested by descriptors such as dull and aching pain that is made worse by activity or

position. If musculoskeletal pain is present, physical examination (e.g., site of tenderness, limitation of movement, muscle tone) will help to determine the structures that may be affected and the presence of inflammation or muscle spasm. In the acute phase, if skeletal damage is suspected, investigations such as radiographs, computerized tomography (CT) scan, and MRI may help to identify pathology such as a fracture, dislocation, spinal misalignment, or instability. In the chronic phase, pain and restriction in range of movement of the upper limb may suggest an overuse syndrome. The pain is described as aching and is worse with use of involved joints or pressure on the part.

Visceral pain may arise from structures in the thorax, abdomen, and pelvis. It is generally poorly localized and often described as dull, aching, and cramping. The presence of visceral pain requires a standard diagnostic approach similar to that used in the person without SCI. However, in the person with SCI, particular attention should be paid to common conditions such as urinary tract infection, obstruction from ureteric calculi, and bowel impaction. Other relatively common conditions include cholelithiasis and esophagitis.

Physical examination and appropriate investigations will help to identify the pathology that may be giving rise to the pain. However, diagnosis is often difficult when sensory inputs from visceral structures are disturbed. If investigations fail to find evidence of visceral pathology, and treatments directed at visceral pathology do not relieve the pain, consideration must be given to classifying the pain as neuropathic rather than visceral. The onset of headache and raised blood pressure in a person with an upper thoracic or cervical SCI should alert the clinician to the possibility of a visceral disturbance such as bladder distension or bowel impaction producing autonomic dysreflexia.

Neuropathic. Above-level neuropathic pain is located in the region above the neurological level of injury. Assessment depends on the description of the pain, the use of physical examination to detect the nature of any sensory disturbance, the presence of other features such as autonomic dysfunction, and the use of diagnostic techniques such as nerve conduction studies, CT scan, and MRI.

At- and below-level neuropathic pains are differentiated by their location in relation to the level of neurological injury. The value of differentiating these two types of pain lies in highlighting potentially different underlying mechanisms and, therefore, treatment approaches. As previously mentioned, at-level neuropathic pain is located adjacent to the neurological level of injury and below-level neuropathic pain is located diffusely below the neurological level of injury (see Fig. 40.1). Both types of pain are usually reported using typical neuropathic pain descriptors such as shooting, electric, and burning with tingling and allodynia. Although not definitive, nerve root pain may be suggested by a unilateral distribution.

Diagnosis is assisted by radiographic, CT, or MRI evidence of nerve root compression in the foramen by bone or disc that correlates with the location of the pain. If investigations fail to find evidence of a peripheral nerve lesion, the pain is most likely due to central changes. If there has been a recent change in the location or characteristics of the pain, MRI may be useful to determine the formation or progression of a syrinx.

Psychological and Environmental Contributors

Psychological contributors may include mood dysfunction such as depression and anxiety and maladaptive coping strategies such as fear avoidance and catastrophizing. Environmental contributors may be social or physical. Social reinforcers may arise in relationships with family, friends, or at work. Compensation issues, either financial or social (e.g., receiving an apology), may also influence pain and recovery. Physical contributors such as wheelchair use, seating, and workplace ergonomics are also important to consider.

Obtaining a psychosocial history entails careful observation and listening, obtaining input from family, friends, and other team members. It may also require assistance from other professionals with formal training in psychological or psychiatric medicine. Psychological questionnaires may also be used to obtain baseline measures and monitor progress.

MANAGEMENT OF PAIN IN PEOPLE WITH SCI

Musculoskeletal Pain

Trauma to musculoskeletal structures may result in both pain and instability. Stabilization is the most effective treatment for pain arising from spinal instability. In this situation, pain usually resolves as healing occurs but symptomatic relief of pain may be required during the tissue healing phase.

Chronic inflammatory musculoskeletal pain may result from abnormal posture, abnormal gait, and overuse related to transfers and wheelchair use. These factors may be addressed via education, retraining, and environmental modifications, such as adaptive equipment and modification of seating. These approaches may be sufficient to eliminate the problem. In the short term, or if it is not possible to completely address the causative factors, symptomatic treatment may also be required.

In addition to correcting abnormal mechanical stresses, managing active disease processes, and modifying unhelpful psychosocial contributing factors, symptomatic pharmacological treatment of inflammatory musculoskeletal pain may be indicated. Similar principles can be used as those employed in the treatment of other degenerative and inflammatory joint conditions. Pharmacological management includes the use of simple analgesics, non-steroidal anti-inflammatory drugs (NSAIDs), local corticosteroid injections, and occasionally opioids.

Several considerations regarding the use of analgesics and NSAIDs apply in the person with SCI. NSAIDs may cause gastric erosion which is more prevalent and harder to detect in those with high spinal cord lesions. Therefore, acetaminophen is the safest first step in the treatment of musculoskeletal pain associated with SCI. If there is no response to acetaminophen, the use of "weak" opioids, such as tramadol, may be considered. While the use of "strong" opioids for acute inflammatory pain is reasonable, continued use in persistent pain remains controversial.[68] Case-by-case consideration for long term opioid therapy is reasonable, along the lines of published guidelines.[69] Opioid analgesics are known to exacerbate bowel dysfunction, and long-term use can be complicated by tolerance and dependence (both physical and psychological).

Spasticity is a common problem following SCI and has different features from muscle spasms that may occur in people who are neurologically intact. SCI results in major disruption to descending inhibitory controls with a resultant hyperreflexia and spasticity affecting muscle groups below the neurological level of injury. In addition to impairing motor function, spasticity associated with SCI may also cause pain. Spasm may be due to underlying pathology maintaining a heightened reflex arc. If so, this needs to be treated appropriately. More commonly in people with SCI, there is no underlying pathology that can be addressed and treatment once again focuses on symptomatic relief. At present, there is insufficient evidence to guide clinicians in a rational approach to the treatment of spasticity following SCI.[70] A number of approaches are traditionally used. Oral baclofen may be sufficient to control the symptoms and is the first line approach. Diazepam is an alternative approach although consideration must be given to the side effects associated with benzodiazepine use. Injection

of botulinum toxin has also been suggested as an effective treatment for localized spasticity.[71] If oral agents fail to provide sufficient relief, evidence supports consideration of intrathecal baclofen administration via an infusion device.[72,73]

Visceral Pain

Identification of symptomatic urinary tract infection requires treatment with antibiotics. Obstruction from ureteric calculi may require surgical removal or lithotripsy. Bowel impaction may require disimpaction in the short term and adjustment of bowel routine in the long term. The presence of autonomic dysreflexia may constitute a medical emergency and requires immediate blood pressure reduction and treatment of the underlying trigger.

Above-level Neuropathic Pain

If there is evidence of nerve root or peripheral nerve compression, surgical decompression may be indicated. Syringomyelia may require drainage and shunting or a detethering procedure. Complex regional pain syndromes can present a difficult management problem and a more comprehensive overview of treatment is described elsewhere in this volume. Sympathetic blockade may provide complete relief of pain in some individuals but effectiveness is unpredictable.[74] Physical rehabilitation may also be helpful in some people.

At-level and Below-level Neuropathic Pain

Management of a syrinx and surgical decompression of a compromised nerve root are the two available treatments aimed at the cause of at- and below-level neuropathic pain. Most available treatments, therefore, are symptomatic in nature and aim to reduce the impact of ongoing pain. Unfortunately, there are few controlled trials examining the efficacy of treatments for at-level and below-level neuropathic pain. Available studies often have small numbers and therefore conclusions may not be reliable. Treatment is often based on findings derived from other neuropathic pain conditions. A summary of the current treatments for at- and below-level neuropathic pain is listed below according to treatment category.

Pharmacological Options

A wide range of treatment options, including anticonvulsants, tricyclic antidepressants, opioid medications and more invasive procedures, such as intrathecal drug administration, are used for the treatment of neuropathic pain following SCI.[75,76] Adequate pain control is often difficult to achieve with available treatments only providing around one third of people with a 50% reduction in their pain.[76]

Opioids. During inpatient assessment of a person with SCI, parenteral drugs may be useful in the management of pain while investigations and longer term treatments are explored. Two randomized controlled trials involving intravenous morphine[77] and alfentanil[78] have been conducted. These studies demonstrated a short-term reduction in neuropathic pain following SCI. Intravenous morphine failed to relieve spontaneous pain but reduced brush-evoked allodynia.[77] Although effective in the short term, parenteral opioid treatment is not suitable for the long term management of neuropathic SCI pain. If used, slow release opioids are preferred. Evidence for the short-term (less than 2 months) efficacy of a number of opioids has been demonstrated in other neuropathic pain states.[79] However, the evidence for use of specific oral opioids in the treatment of neuropathic SCI pain is very limited. Tolerance, dependence, and side effects such as constipation also need to be considered.

Anticonvulsant Drugs. Anticonvulsant drugs are widely used in the treatment of neuropathic pain conditions and have a broad range of actions including sodium channel blockade, enhancement of GABAergic inhibition, reduction of glutamate release, and an action on the $\alpha_2\delta$ subunit of dorsal horn voltage-gated calcium channels. This broad mix of effects may explain the different responses obtained by using members of this group. Gabapentin is widely used in the treatment of neuropathic SCI pain and anecdotally there is good support for its effectiveness in some patients. There are, however, only two small short-term controlled studies that confirm this.[80,81] In a subgroup of patients, the effectiveness of gabapentin does appear to be sustained in the longer term.[82]

Pregabalin is a newer anticonvulsant that, like gabapentin, acts via the $\alpha_2\delta$ subunit of dorsal horn voltage-gated calcium channels. A recent multicenter study of 137 people with complete and incomplete injuries examined the efficacy of pregabalin in the treatment of neuropathic pain following SCI.[83] This study demonstrated a significant positive treatment effect when compared to placebo with a mean dose after stabilization of 460 mg/day and a number needed to treat for 50% relief of 7.1. A smaller study of 33 subjects also including people with neuropathic central poststroke pain found a significant positive analgesic response to pregabalin with a lower number needed to treat of 4.0. There was no difference in relief between the brain and spinal cord injuries groups.[84]

Lamotrigine has been used and trialed for the treatment of neuropathic SCI pain as well as other neuropathic pain conditions. It has a membrane stabilizing action via inhibition of voltage-dependent sodium channels in addition to inhibiting glutamate release. In a group of subjects with neuropathic SCI pain, lamotrigine 200–400 mg daily had no statistically significant pain relieving effect. However, a subgroup of patients with incomplete injury and evoked pain demonstrated relief of spontaneous pain.[85]

Topiramate is another anticonvulsant that acts on sodium and calcium channels, potentiates GABAergic inhibition, and inhibits glutamate receptors. One randomized controlled trial has been performed in people with neuropathic SCI pain but numbers were small.[86] The efficacy of topiramate 800 mg daily in four different neuropathic pain diagnoses was examined with 9 patients receiving topiramate and 4 receiving placebo. Topiramate was significantly better than placebo in the final 2 weeks of treatment, but only on one of the two primary outcome measures (present pain index) and not on the other primary outcome measure (pain visual analog scale).

Valproate has been used for some time in the treatment of neuropathic SCI pain. However, the only published controlled trial using this drug at doses of 600–2400 mg/day failed to demonstrate any significant difference from placebo.[87] Once again, the numbers in the study were relatively small raising the possibility of a false negative result.

Carbamazepine has also been used for many years for the treatment of neuropathic SCI pain but evidence to support its use is very limited.[88] More recently, oxcarbazepine has become available and may present another alternative. However, neither of these drugs have been the subject of controlled trials for neuropathic SCI pain.

Antidepressants. Like anticonvulsants, antidepressants are widely used in the management of neuropathic pain conditions. Traditionally, the analgesic mechanism of action for tricyclic antidepressants has been thought to be due to norepinephrine and serotonin reuptake inhibition. It may be possible, however, that other actions including NMDA-receptor antagonism and sodium channel blockade also contribute.

Despite their widespread use, there is little direct evidence for the effectiveness of tricyclic antidepressants in the treatment of neuropathic SCI pain. At present, only one well designed study has been performed. This study examined a group of people with

combined musculoskeletal and neuropathic SCI pain.[89] Amitriptyline at a dose of 10–125 mg/day was found to be no better than placebo. Further studies examining neuropathic SCI pain are needed to allow definitive conclusions to be made. Despite the lack of positive evidence, a trial of tricyclic antidepressants appears to be reasonable in clinical practice given supportive evidence from other neuropathic pain conditions. Tricyclic antidepressants may have a number of side effects including sedation, constipation, dry mouth, increased spasticity, and disturbance of bladder function.[89]

Selective serotonin reuptake inhibitors have now been available for some time. Although they are effective antidepressants and have a more favorable side effect profile, there remains little evidence to demonstrate superiority over tricyclic antidepressants for the treatment of neuropathic pain. The serotonin reuptake inhibitor and 5HT receptor antagonist, trazodone, has been shown in one randomized controlled trial to be no better than placebo.[90] There is increasing evidence to support the use of mixed serotonin and noradrenaline reuptake inhibitors, such as venlafaxine and duloxetine, in other neuropathic pain states. However, as yet, there is no evidence to support these agents specifically in the treatment of neuropathic SCI pain.

Drug Combinations. There are reports that combinations of anticonvulsants and tricyclic antidepressants are more effective than either administered alone.[88,91] Therefore, if a single agent is ineffective, a combination of an anticonvulsant with either a tricyclic antidepressant or an opioid may produce additional relief. However, some combinations, such as the use of tramadol and a tricyclic antidepressant, may present problems because of their combined effect on serotonin. In practice, many patients will require judicious use of a combination of agents to obtain optimum relief of pain.

Local Anesthetics. Parenteral administration of the sodium channel blocker lidocaine has been shown to reduce neuropathic SCI pain in higher doses (5 mg/kg).[92–95] Reductions in spontaneous ongoing pain, brush-evoked allodynia, and static mechanical hyperalgesia have been described. Although there is one report of long-term effectiveness with the use of lidocaine,[96] parenteral administration is generally not practical as an ongoing treatment. This interferes with its translation to long-term treatment. Mexiletine, an oral congener of lidocaine with a similar action, was not shown to be effective at a dose of 450 mg/day although, once again, the number of subjects was small (n = 11).[97]

NMDA Antagonists. Parenteral administration of the NMDA-receptor antagonist ketamine was demonstrated to be more effective than placebo and similar to fentanyl in reducing below-level neuropathic SCI pain.[78] As with lidocaine, long-term administration remains problematic and there are no effective oral alternatives available.

Propofol. The anesthetic agent and $GABA_A$-receptor agonist propofol is another parenteral agent that has been used for the treatment of neuropathic SCI pain. A subhypnotic dose of propofol, injected as a single intravenous bolus (0.2 mg/kg) provided less than one hour relief of spontaneous pain and allodynia in approximately half of 44 patients with SCI and poststroke pain.[98] Whether this effect would be sustained in an ongoing infusion is yet to be determined. The use of propofol would require special monitoring and a higher level of care.

Spinal Drug Administration. If oral administration fails to provide adequate analgesia, spinal administration may be considered. Evidence of efficacy is confined to case series and limited controlled trials. The approach is inherently invasive and should not be considered until more conservative measures have been thoroughly trialed. In a case series, spinal administration of morphine and clonidine[99] was found to be effective in some individuals. Combinations of morphine or clonidine with baclofen in those with spasm may provide additional benefit.[100]

In a controlled study, combined intrathecal administration of morphine and clonidine was found to be effective in a group of people with chronic at-level and below-level neuropathic SCI pain.[101] A positive response was associated with adequate drug availability above the level of SCI. People with significant scarring around the cord and cerebrospinal fluid block at the site of injury responded poorly to agents administered below the level of SCI. This study revealed a short-term reduction in pain and the long-term effectiveness of this treatment strategy remains to be established.

As mentioned previously, intrathecal baclofen is effective in managing spasticity and spasm-related pain secondary to SCI. However, the effect of baclofen on neuropathic SCI pain is less clear. Conflicting results have so far been obtained in controlled trials.[73,102]

Spinal anesthesia with subarachnoid lidocaine may also provide analgesia in SCI neuropathic pain.[103] The effect of spinal anesthesia is of course only temporary, limiting its clinical usefulness. Response to regional blockade suggests pain "generators" lie within the spinal cord or peripheral nervous system. Regional blockade has been suggested as part of the workup for techniques such as spinal cord stimulation which are more effective in peripheral neuropathic pain.[103]

Neurostimulation

Stimulation techniques, such as transcutaneous electrical nerve stimulation (TENS) and acupuncture, may be effective for some people with neuropathic pain.[17] However, positive evidence of efficacy is limited, particularly with below-level neuropathic pain.[104,105] Most studies also report a decline in efficacy over time.[76]

Other stimulation techniques are very invasive with limited evidence of efficacy. Spinal cord stimulation may provide relief although a greater effect is obtained in those with at-level neuropathic pain and incomplete lesions.[106] Deep brain stimulation seems not seem to provide long term pain relief in SCI pain.[76] Transcranial and epidural motor cortex stimulation have been tested in a few SCI pain patients with varying results.[107] A recent study using transcranial direct current stimulation (tDCS) demonstrated short-term reduction in pain following a 5 day treatment trial.[108]

Physical Approaches

Physical approaches may help to improve chronic musculoskeletal pain and may indirectly influence neuropathic SCI pain. Abnormal posture, gait, and overuse may all contribute to pain and may be addressed by physiotherapy, exercise,[109] retraining, and environmental modifications, such as the use of specialised adaptive equipment, wheelchair adjustment, and positioning. Regular exercise in people with SCI has also been demonstrated to result in improvements in both pain and mood.[110]

Surgical Approaches

Surgical approaches usually relieve pain by reversing structural problems. For example, surgery may be used to address nerve root or peripheral nerve compression, tethering of nerve roots, and syrinx formation. However, repair of a neurological lesion may not result in pain relief and may at times increase pain.

If it is not possible to address a structural problem, surgical approaches attempt to deal with the pain by destroying or disconnecting the site of abnormal neuronal activity. Several uncontrolled studies have been performed to examine efficacy of surgical approaches but have resulted in variable results. Cordotomy or cordomyelotomy have been used to a limited extent and some

reports suggest effectiveness in a subgroup of patients.[111,112] Dorsal root entry zone (DREZ) lesioning, a procedure that aims to destroy hyperactive nerve cells in the dorsal horn close to the level of injury, may provide relief of neuropathic pain, although best results are obtained in those with at-level neuropathic pain.[113] DREZ lesioning guided by intramedullary recordings of spontaneous and C-fiber evoked electrical hyperactivity is suggested to be effective in relieving both at- and below-level neuropathic pain.[114,115]

Psychological and Environmental Management

Coming to terms with a spinal injury requires a huge adjustment in relationships, lifestyle, vocation, and self-image. All of these issues need to be addressed and, not surprisingly, people with a severe SCI often have significant psychological distress particularly in the acute post injury period.[7] The presence of chronic pain may be an additional factor that prevents expected rehabilitation and return to employment and function in domestic life.[10,13,15,116] Anxiety and depression are both normal responses to injury and often improve with time and the implementation of the person's inherent coping skills. In these people, formal intervention may not be required. However, for the minority who experience severe or chronic mood dysfunction impacting on their ability to function, more formal intervention should be offered.

A variety of approaches are available for managing psychological and environmental contributors to pain and distress. Pharmacological strategies such as anxiolytic and antidepressant therapy and nonpharmacological strategies such as cognitive-behavioral therapy may be used.[117,118] The effectiveness of a cognitive-behavioral approach in the management of neuropathic SCI pain has been examined with significant improvements in mood, though not pain.[118]

Relaxation and desensitization techniques are suggested to be of benefit in SCI pain and may alter the patient's attitude toward pain. More recently, the effect of movement imagery as a component of a management program for SCI neuropathic pain has been examined. In one study (using a visual illusion of walking), a reduction in neuropathic pain was noted in people following cauda equina injury.[119] In contrast, a study using imagined lower limb movements following complete SCI found an increase in pain and unpleasant phantom sensations.[120] The difference in findings appears to be related to the level and completeness of injury, with the positive responders having incomplete cauda equina injuries. The use of cognitive strategies such as movement imagery, however, may be helpful in a certain subgroup of patients and provides an interesting noninvasive alternate strategy.

Treatment Summary

Treatment guidelines need to take into consideration a broad range of issues including pain type, other medical and psychological issues, personal preference, side effects, treatment availability, and cost. As mentioned, the evidence to support many interventions in the management of SCI pain is limited, making definitive recommendations difficult to formulate. It would not be wise to provide a prescriptive approach to the management of SCI pain. However, guidelines are available that provide a general approach that may be tailored to the individual (Figs. 40.2 and 40.3).[75]

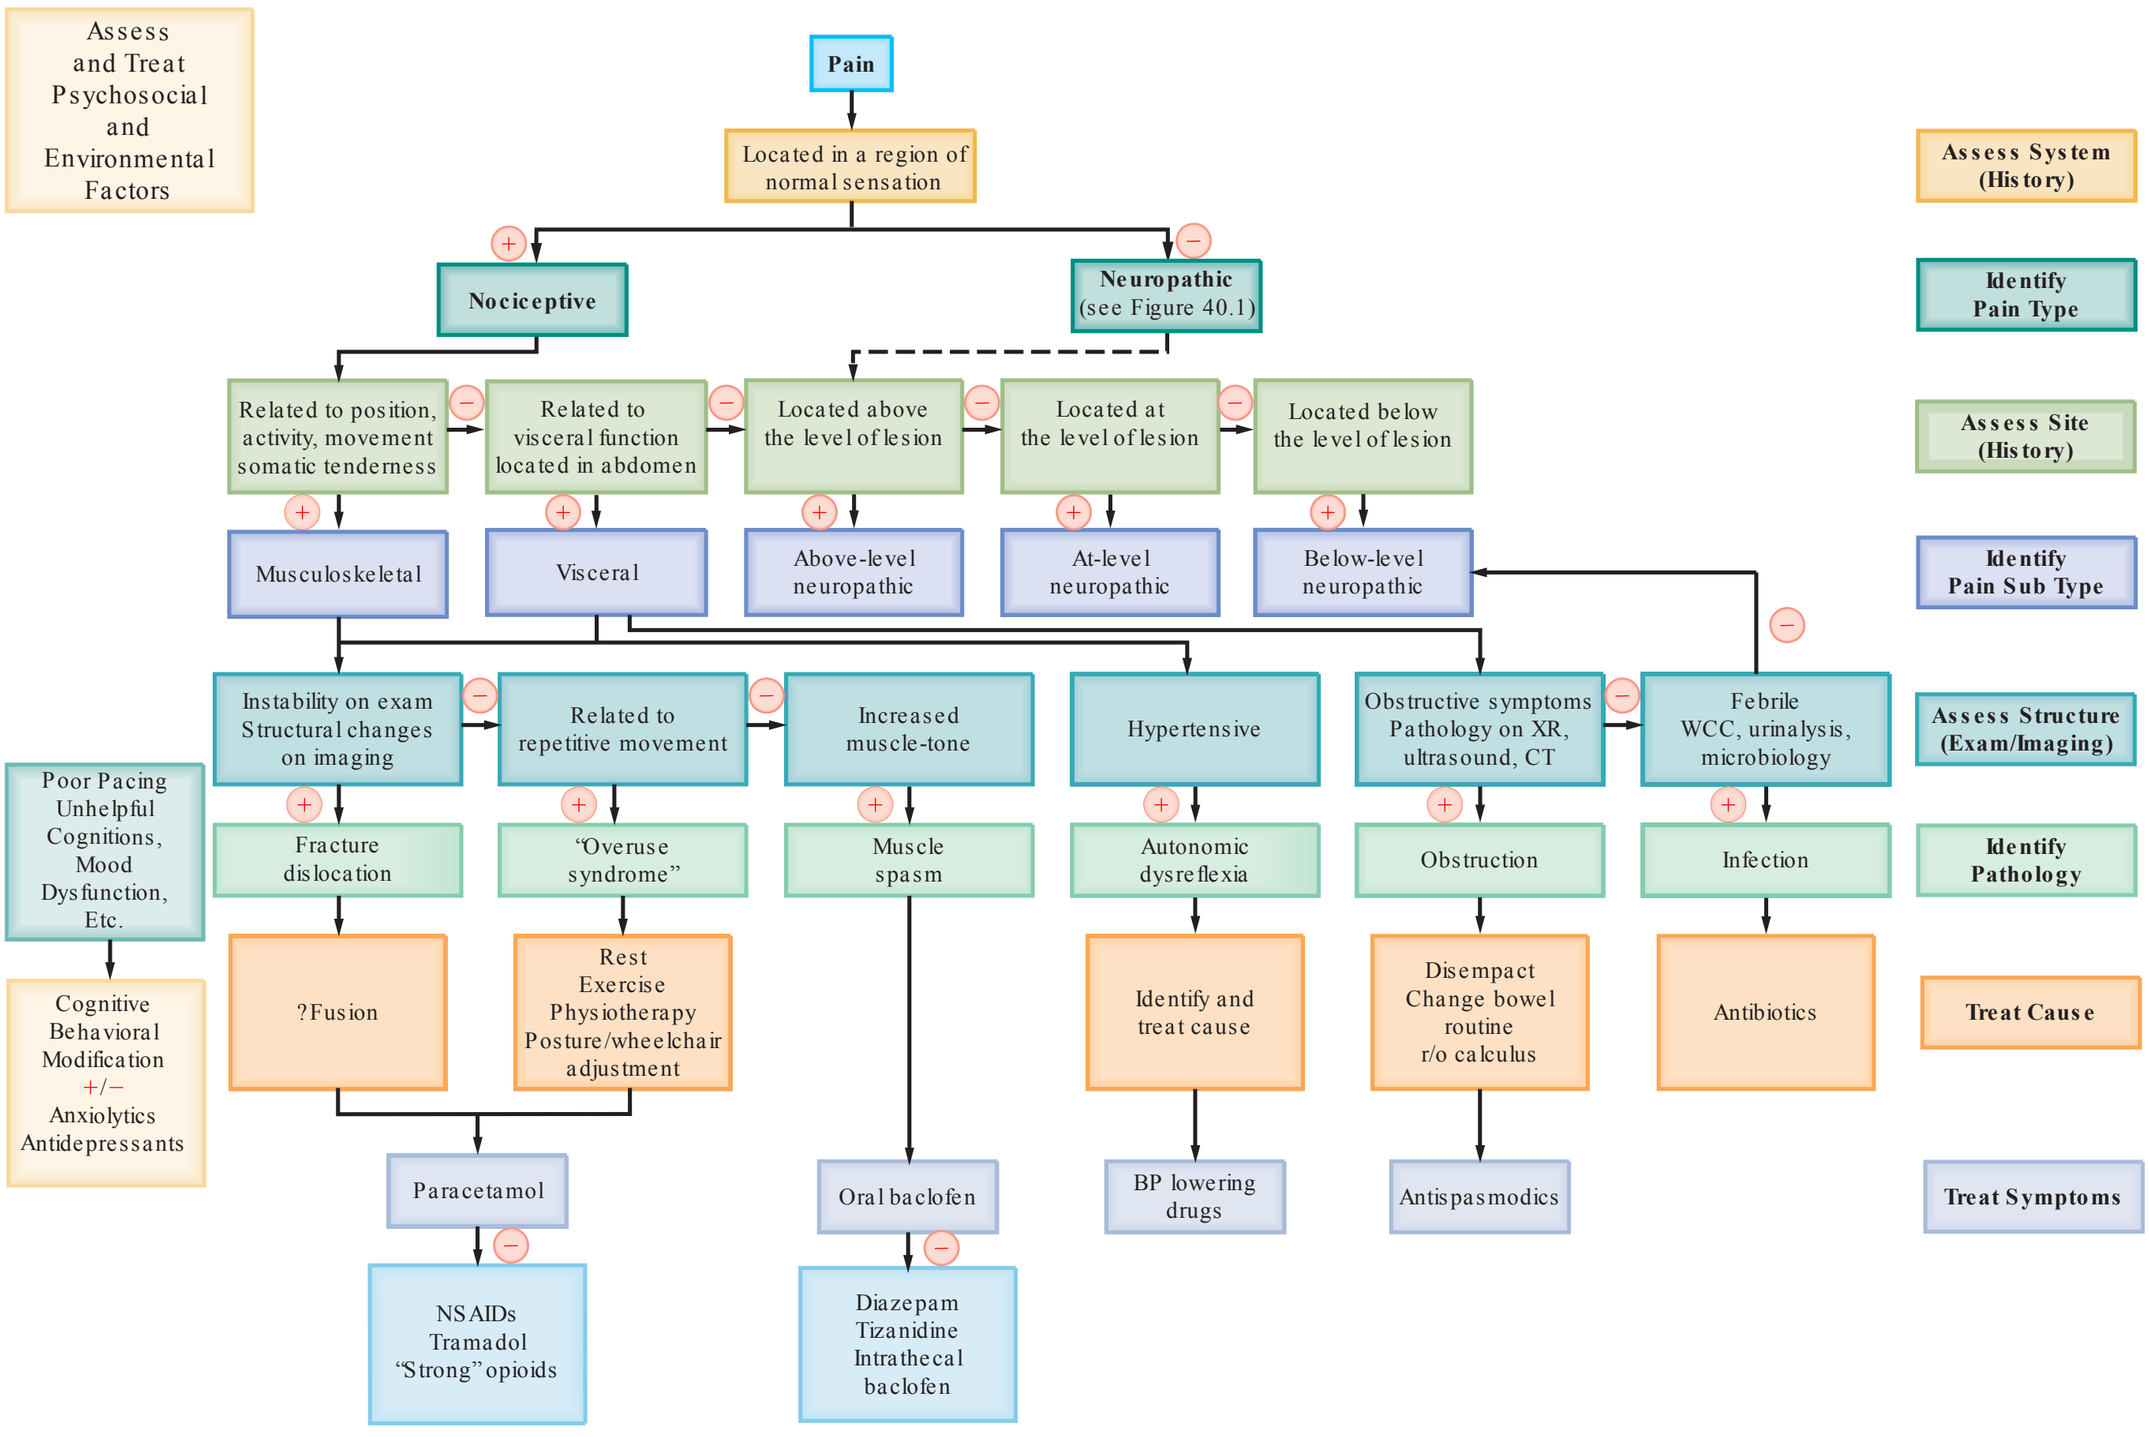

FIGURE 40.2 Assessment and treatment algorithm for the management of nociceptive pain following spinal cord injury. (Modified from Siddall PJ, Middleton JW. A proposed algorithm for the management of pain following spinal cord injury. *Spinal Cord* 2006;44:67–77.)

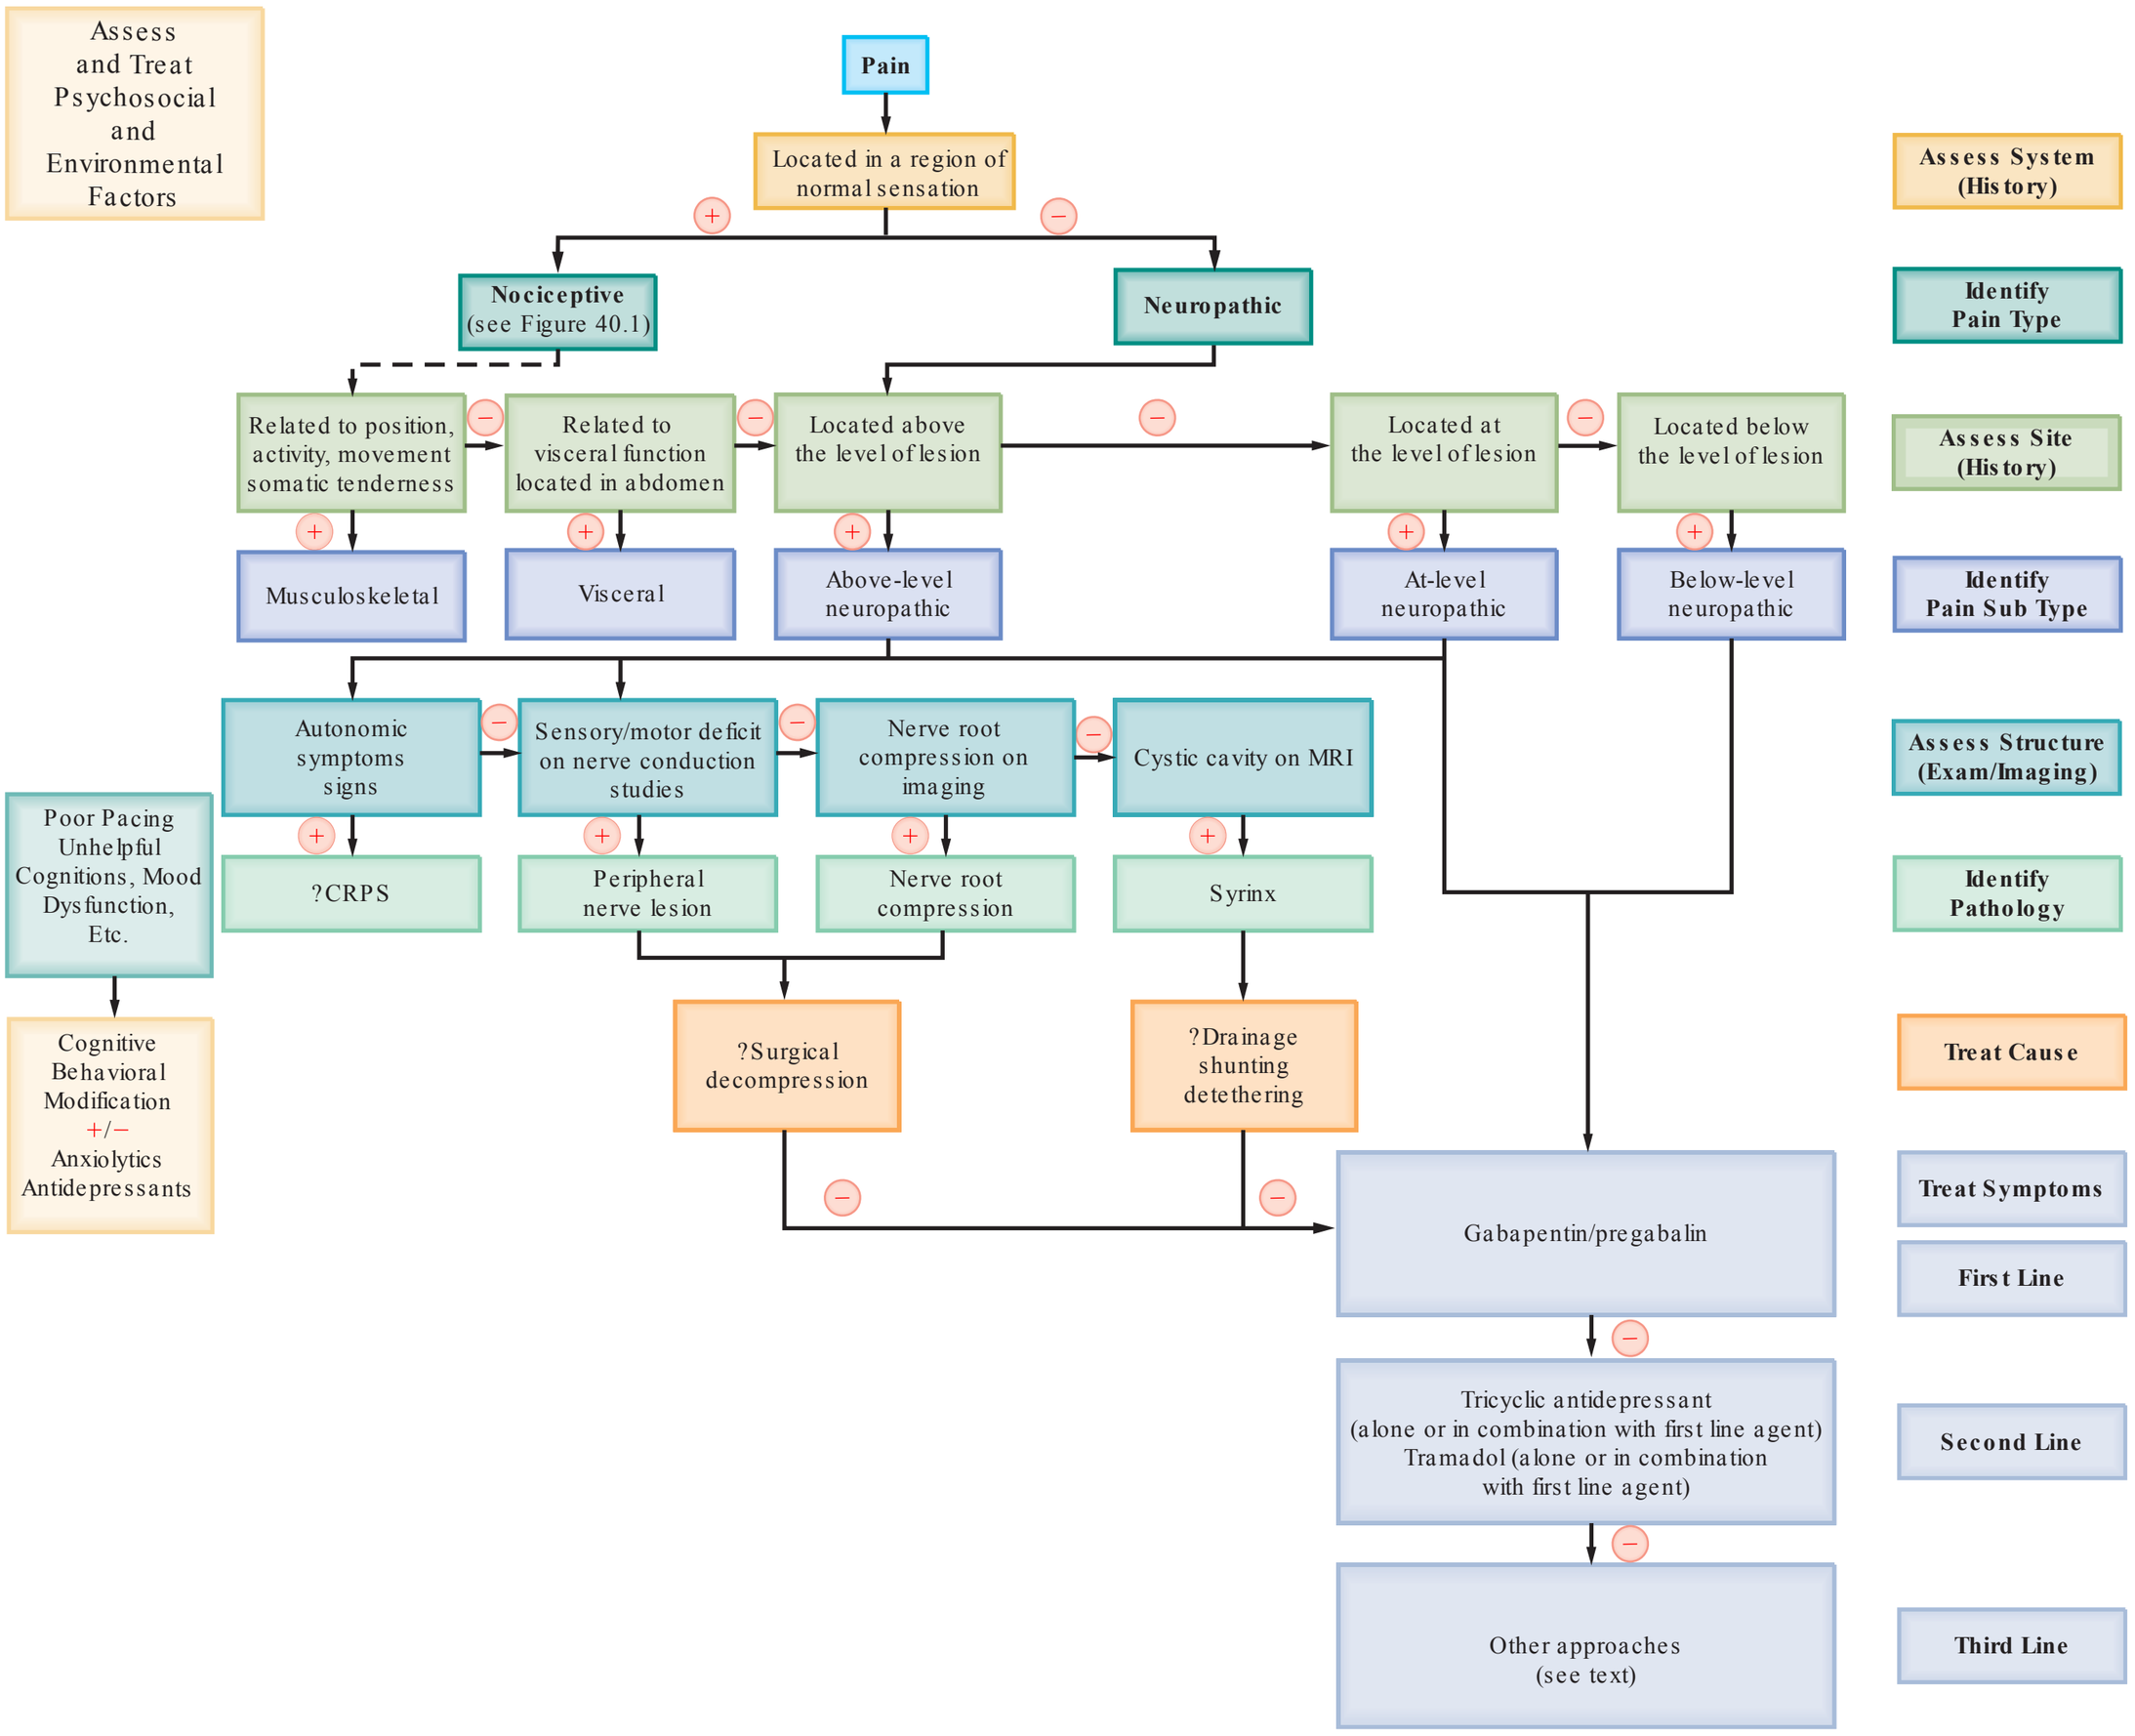

FIGURE 40.3 Assessment and treatment algorithm for the management of neuropathic pain following spinal cord injury. (Modified from Siddall PJ, Middleton JW. A proposed algorithm for the management of pain following spinal cord injury. *Spinal Cord* 2006;44:67–77.)

In this algorithm, a tri-level approach to the management of at- and below-level neuropathic SCI pain is suggested. First line treatments are those that have been validated in SCI pain; second line treatments have been validated in other neuropathic pain states; and third line treatments are limited by side effect profile, invasiveness, or lack of efficacy data. In the acute, inpatient setting, parenteral lidocaine is suggested as a first line agent and gabapentin in the subacute or chronic setting. With the recent evidence for the efficacy of pregabalin,[83] this provides an alternative to gabapentin. As a second line treatment, the use of a tricyclic antidepressant, such as amitriptyline or nortriptyline, or a weak opioid, such as tramadol, is suggested. The combination of an anticonvulsant with either a tricyclic antidepressant or an opioid may produce additional relief. However, the use of combination polypharmacy does expose the patient to greater risk. Third line treatments include many of the other treatments described above. If there is inadequate response to first and second line treatments, third line treatments may be considered. However, the likelihood of benefit must be weighed against possible adverse side effects of the treatment. In parallel with these treatments which largely focus on the biological aspects of the pain, consideration should also be given to treatment of psychosocial issues such as mood, cognitions, and environmental factors which may be contributing to both pain and disability.

CONCLUSION

Pain provides an additional challenge to the person with SCI. It is associated with poorer physical, psychological, and social functioning. Clinicians involved in the care of people with SCI pain also face the challenge of a limited therapeutic armamentarium, particularly for neuropathic pain. Despite this, many positive treatments are available for this group. Treatments should target causative factors where possible, which may be possible in musculoskeletal and visceral pain. The majority of treatments for neuropathic pain are symptomatic in nature.

Although the current therapeutic armamentarium is limited, increasing research efforts are underway to identify better treatments, particularly for neuropathic SCI pain. Optimal management depends on systematic assessment, identification of the specific type of pain, and utilization of validated treatment options.

A carefully devised biopsychosocial assessment and treatment plan can also assist a person with SCI pain to reduce the way persistent pain interferes with their quality of life and function.

CHAPTER 41 ■ EPIDEMIOLOGY, PREVALENCE, AND CANCER PAIN SYNDROMES

NEIL A. HAGEN

INTRODUCTION

Cancer is a highly prevalent and serious public health issue. It most commonly affects the elderly—the average cancer patient is aged 65 at first diagnosis—and cancer is more likely to occur in particular clinical settings, such as a life-long smokers, in obesity, and with certain environmental and heritable risks. However, there is no one who is immune from the disease, regardless of age. In North America, about 1 in 3 adults will develop cancer in their lifetime, with about a 50% fatality rate. Cancer is sufficiently prevalent that some individuals will develop more than one type of malignancy, either sequentially or concurrently. Cancer is often painful, with pain presenting as a common heralding manifestation of the disease. For example, about two thirds of women have pain at the onset or recurrence of ovarian cancer.[1] As cancer progresses, it is more likely to be associated with pain, and the pain is more likely to be severe. A range of epidemiological studies in several countries and practice settings suggests that pain from a wide variety of cancers is present in about one third of patients receiving cancer treatment and in 60% to 90% with advanced illness.[2]

Cancer treatment can also cause pain, and cancer pain is commonly classified as being either due to the underlying disease or due to its treatment. In pediatric malignancies, pain due to treatment is more common than pain from the underlying disease.[3] Cancer patients can also have pain from non–cancer-related conditions, and the causes and prevalence are similar to pain in patients without a cancer diagnosis.

There is an array of factors that contributes to the likelihood of pain being present, its severity, and the best approach to its management. Thus, in order to understand the wisest approach to the cancer patient who presents with cancer pain, the situation is best appreciated within the perspective of where the patient is in the disease trajectory and what other clinical factors are likely to be at play.

The intention of this introductory chapter is to provide a clinical context of the individual patient and to bring into focus the extensive information that follows in subsequent chapters where more detailed approaches to assessment and management will be elaborated. This chapter is divided into six sections:

- Summary of the epidemiology of cancer pain
- How to perform a cancer pain history
- How to perform a physical examination of a cancer pain patient, including bedside provocative maneuvers to help identify potential underlying pain-sensitive structures
- Problem formulation
- Constructing an analgesic strategy
- Managing pain in specific clinical situations

EPIDEMIOLOGY OF CANCER PAIN

Epidemiology is "the study of the relationship of the various factors determining the frequency and distribution of diseases in a human community."[4] The epidemiology of cancer pain refers to cancer pain within the population, and its delineation provides insight into the likeliest factors at play within an individual patient.

Pain Related to Extent of Disease: The Cancer Disease Trajectory

Commonly, patients with solid tumor malignancies present with an asymptomatic mass; less than 15% of patients with nonmetastatic disease describe pain from their cancer.[2] Cancer can present clinically in a wide variety of ways, including dyspnea, nausea, urinary symptoms, weakness, numbness, weight loss, and other signs and symptoms. When pain is the first symptom of cancer, there is a tendency for the cancer to be more advanced and perhaps for this reason, pain can be an independent predictor for poorer survival.

The clinician can use this information to suspect the underlying cause of pain. For example, imagine a patient with a diagnosis of melanoma who presents with a 3 day history of new onset of headache. It could be due to a benign cause (e.g., migraine) or due to malignancy (e.g., brain metastasis). Stage of cancer predicts the risk of brain metastases. In this example, the likelihood of central nervous system metastasis is much lower in the patient who has recently undergone resection of a primary melanoma in the leg, with regional lymph nodes negative, compared to the patient who has known liver and lung metastases from melanoma. About 90% of patients with melanoma have central nervous system metastases at the time of autopsy, and the report of any headache in a patient with known metastatic melanoma is ominous. If imaging studies of the brain are negative in a patient with metastatic melanoma and a new headache, the possibility of meningeal disease should be considered, along with a diagnostic dural puncture for cerebrospinal fluid analysis.

Special Needs of Particular Age Groups: Pediatric, Young Adult, Adult, Geriatric

Pain is a subjective experience, and the pain of cancer can be foreign and puzzling for the patient. Pediatric patients can lack the language and the sophistication of adults in communicating their inner world. While cancer can result in an overwhelming sense of threat at any age, the pediatric age group requires special skills and support. For instance, pediatric patients and their families become the "unit of care," far more so than with adult oncology, and specialized assessment tools must be used for this population (see Chapter 49).

Cancer pain is prevalent at all ages. However, there are several remarkable features of cancer pain within the pediatric population. First, pain from cancer treatment is highly prevalent, in part related to the high prevalence of procedures to manage hematological malignancies and other malignancies typical of this age group. Particular attention needs to be taken to diminish the fear of pain from procedures and treatment. Painful procedures include placement of intravenous catheters, repeated spinal taps, bone marrow biopsies, extensive cancer surgery, and others. Second, young patients are often proficient at managing their pain once taught an appropriate technique. Patients as young as 5 years can safely and effectively use a patient controlled analgesia device, with the overall outcome of good pain control and poten-

tially less risk of nausea or respiratory depression compared to continuous opioid infusions.[5]

Sarcoma and hematological malignancies are common in the 16–21 age group. Rarely, young adults can present with what looks clinically to be depression, but in fact the patient has uncontrolled pain. Particular attention needs to be placed on supporting the patient to be as active and have as normal a life as possible despite the potentially disfiguring effects of cancer treatment, difficulty with cancer pain, and the many challenges of cancer treatment.

Working-aged adults with cancer pain face their own unique complexities. A need to generate income or fulfill parenting roles despite illness, financial obligations, fear of addiction, and the challenges of managing emotional distress, are all issues that need to be consciously addressed in order to provide comprehensive symptom control. Young adults often choose or have indications for more aggressive or prolonged cancer treatments. For example, aromatase inhibitors are commonly used in the adjuvant treatment of breast cancer over the course of several years; almost half of these patients describe joint pain or stiffness. Usually symptoms are mild or moderate, but nearly one quarter of patients rate their symptoms as severe.[6]

The geriatric population often has medical comorbidity, such as underlying heart, lung, renal, or cognitive impairment, and may be on a variety of medications that interact with analgesic medications. Dosages of medications such as opioids may need to be lowered because the metabolism of medication can be much slower with advanced age or underlying organ impairment. An important, emerging concept within the geriatric population is that of frailty. Factors that promote return to health or maintenance of good health—resilience—are powerful in the pediatric and young adult population; with advancing years, the ability to maintain homeostasis becomes less. Frailty is a term that describes what has become an area of intense research in the geriatric community and is a key factor in analgesic care in the older cancer population.[7] Changes in medications should generally be made more slowly and with smaller dosing increments. Attention needs to be paid to drug–drug interactions, and the clinician should be vigilant for the appearance of early signs of cognitive impairment. Because of the high prevalence of delirium in the medically ill geriatric oncology population and the difficulty in making an early diagnosis, some clinicians have advocated for the routine use of delirium screening tools.[8]

Special Needs of Particular Ethnic Groups: Communication Styles, Common Preferences, and Managing Taboos

Some ethnic groups are particularly vulnerable to specific health issues. About 90% of cancer patients in the Middle East present with advanced, incurable illness. The commonest malignancy in women in the Middle East is gynecological cancer, although cancers associated with tobacco use are increasing rapidly. Hepatoma and nasopharyngeal cancer are highly prevalent in patients who originate from Pacific Rim countries, and the higher risk persists for decades after moving to a Western country. There are some First Nations communities in North America where diabetes mellitus has reached epidemic proportions, with more than half of all adults being afflicted; cancer care can be greatly complicated by underlying diabetes. Every culture and ethnic group has a unique set of medical issues that are of particular concern.

Some countries, or parts of countries, have a lengthy history of violence and social upheaval in association with the licit or illicit drug trade, and the medical use of opioids is greatly frowned upon. Some religious cultures are believed to hold the experience of suffering to be of spiritual value. Others are commonly believed to place a taboo on disclosure of a cancer diagnosis to the patient, relegating the burden of that knowledge and the decision making on cancer care to the eldest son.

There are approximately 6900 discrete languages spoken in the world[9] and uncountable distinct ethnic, religious, and other cultures. How is the clinician to be alert to all possible areas where culture can have a major influence on patient preferences and on patient assessment?

Basic knowledge of common beliefs within certain cultures is inarguably important, such as the prevalence of modesty as a dominant value in the Muslim faith community. Beliefs common to many cultures are complicated by the tendency in Western society for a shift in immigrant families, with increasing orientation toward secular values from one generation to the next. So when the patient who is thought to belong to a particular culture is in the physician's office along with their spouse and their adult children, which is likely to be the dominant culture? The clinician is wise to not make assumptions about what are the beliefs, values, and preferences of the patient or their family. Instead, it is far better to ask, since these issues will all have an impact on the patient's pain experience and treatment. There are many variations of beliefs within broad cultural groups, and it has been recommended in the clinical realm to instead focus on the patient and the family unit as having their own culture. It is the task of the clinician to understand and respect that culture.

If there is a taboo against disclosing a life-threatening diagnosis to the patient, the family will almost invariably make this wish abundantly clear to the clinician at an early stage. There is an emerging ethical construct that supports the clinician to respect such a request, if it is the explicit wish of the patient. If the patient indicates that another family member is to be the receiver of medical information and is to make all treatment and other decisions on the care of the patient, the patient has duly exercised their autonomy. The family, or a specific individual within the family, becomes the unit to which the authority of informed consent is conferred.[10] It is legitimate for the clinician to periodically confirm what is the preferred communication style and to whom the patient has conferred decision-making authority. Fortunately, taboos in disclosure of diagnostic information rarely interfere with obtaining information directly from the patient regarding their experience of pain and the effect of analgesic interventions.

Comorbidities Associated With Specific Cancers: Lung Disease, Liver Disease, Renal Disease, and Neurological Disease

Lung cancer is about 30 times as prevalent in life-long smokers as life-long nonsmokers. Patients with lung cancer commonly have clinically significant chronic obstructive lung disease, ischemic heart disease, or symptomatic peripheral vascular disease. If patients have pre-existing carbon dioxide retention, there is a risk the carbon dioxide retention will worsen with the use of opioids, especially with concurrent benzodiazepine use when anxiolysis is needed. Other than in the situation of life-threatening carbon dioxide retention, where very careful titration under monitored conditions may be indicated, opioids are generally not contraindicated by the presence of lung disease, and should be titrated to effect with monitoring for toxicity, similar to patients without known lung disease.

Premorbid liver disease is also prevalent in patients with specific cancer types, such as hepatoma and esophageal cancer. The major clinical features of liver disease relate to portal hypertension, with an elevated risk of episodes of gastrointestinal (GI) bleeding, ascites, and malnutrition. The capacity of the liver to metabolize medications is often less affected than other aspects of liver function, and the dose of medications commonly used in cancer pain such as opioids should not routinely be reduced.

Instead, medications should be titrated to effect. Acetaminophen should be used with caution, however, particularly in the setting of cirrhosis. The clinical presentation of liver metastases is often pain and jaundice; it is rare to encounter metabolic liver failure until almost all of the liver is replaced by cancer.

Renal disease is becoming much more prevalent in Western society, and many cancer treatments, such as platinum-based chemotherapy, are nephrotoxic. Cancer patients are at risk to accumulate medications or their active metabolites in the presence of even mild underlying renal impairment.[11] Doses of some medications used for neuropathic pain, such as gabapentin, are routinely reduced in the setting of renal impairment, but opioids are not. Instead, opioids should be titrated to effect, recognizing that a reduction in dose or increase in dosing interval may be required. In the face of end-stage disease with near-complete or total kidney failure, renally-cleared opioids (or those with active metabolites such as morphine) should be administered on an as-needed basis rather than around-the-clock.

About half of cancer patients are aged 65 years and older, an age group that has a particularly high prevalence of comorbid neurologic illness. Also, cancer and its treatments are associated with neurologic illness, such as stroke, meningitis, and other conditions. Concurrent cancer and neurologic disease affects pain management in several ways, but two deserve particular mention. First, pain assessment largely depends on an intact cognition. The widespread use of pain assessment tools such as the numeric rating scale has helped to bring some quantification to what is otherwise a subjective and often silent experience. But what if the patient is confused, and provides the wrong numbers? There is then a risk of overmedication or undermedication. The Brief Pain Inventory documents several discrete domains of the pain experience: average pain in the past 24 hours, worst pain in the past 24 hours, least pain in the past 24 hours, and so on. Study of the psychometrics of pain tools have revealed that the present pain intensity is the most reliable domain in the setting of cognitive impairment, and is the measure that should be used if there is any question of cognitive impairment. Also the information should be confirmed by other direct questions by the clinician, such as "is the pain bad, or not bad right now?" Further, cognitive impairment in cancer patients generally arises because of many contributing factors. Families are often quick to blame the pain medications. Only uncommonly are analgesics the sole or the major cause. However, in the absence of other obvious causes for delirium, rotating to a different pain medication, along with hydration and other general supportive measures, can reverse an episode of delirium even when other contributing factors are not correctable.

Cancer Pain and Substance Abuse

"Abuse" is a somewhat pejorative word, but its use has been widely accepted. Abuse has been defined in a variety of ways, but is generally taken to mean use of a recreational drug despite harm to self or others. "Addiction" is taken to be a far extreme in the spectrum of abuse, where there is an overwhelming focus on obtaining a supply, craving, and social disintegration.[12] About 15% of adult men in Western societies abuse alcohol, and only about half that proportion of adult women. A smaller proportion of the population abuses other substances, such as cocaine, methamphetamine, or cannabinoids. Some cancer patients are actively abusing psychoactive substances, and others have a past but not current history of abuse. Some active abusers are open about their lifestyle choices, and others keep it a secret.

Pain management is challenging in patients who have a prior history of substance abuse; they have more symptoms, more interference from pain, have more distress, and have more problematic drug-related behaviors than cancer pain patients who do not have a history of substance abuse.[13] Pain is common in the street-connected opioid abusing population, with about a third of patients in methadone maintenance programs describing moderate to severe chronic noncancer pain.[14] Pain can be difficult to reliably assess in cancer patients who have pre-existing chronic pain, a history of abuse of pain medications or other psychoactive compounds, and a coping strategy that has included the use of chemicals ostensibly to help them cope. There is a clash of cultures when the clinician, who believes that the pain is what the patient describes it to be, becomes aware that there may be reasons to not fully trust the patient's description. The clinician should carefully document the patient's description of her/his pain experience and obtain collateral information whenever possible. There is a role for greater reliance on diagnostic imaging to confirm clinical assessment. All patients deserve adequate pain control and to be treated with respect. However, the situation of a cancer patient with active substance abuse requires an approach that will protect the patient and their environment from things that can get in the way of successful pain management. An overall strategy for managing cancer pain in the addict is described at the end of this chapter.

Cancer Pain in Inmates

The incarcerated population has unique cancer risks, in part related to demographics.[15] Most inmates are men, are from ethnic minorities, and are less likely to be in the geriatric age group compared to the general population. Cancer risk factors are known to be highly prevalent in inmates, including smoking, drug and alcohol use, and AIDS-related illnesses. About 30% to 40% of U.S. inmates are infected with hepatitis C, and HIV infection rates are much higher than the national average.[16,17] High rates of human papillomavirus infection have been found in women inmates. A large study on the epidemiology of cancer in the incarcerated population found that the incidence of lung cancer, non-Hodgkin's lymphoma, head and neck cancers, and cervical cancer were two to three times more frequent than expected compared to age-matched controls, and death from hepatoma was more than three times the rate of controls. Survival was significantly poorer in incarcerated cancer patients compared to controls, with median survival of 21 months versus 55 months, and 5-year survival of 37% vs. about 48%.[15] In summary, compared to the general population, inmates are more likely to be affected by cancer, more likely to have cancers that are characterized by difficult to manage symptoms, and are more likely to have a past history of substance abuse or viral infection.

Inmates with cancer have been found to have a high prevalence of pain and to be undermedicated for cancer pain.[18] Drug misuse, actual drug diversion, fears held by prescribers of potential drug diversion, and lack of patient credibility have been identified as barriers to cancer pain management.

COMPONENTS OF THE COMPREHENSIVE MEDICAL EVALUATION OF A PATIENT WITH CHRONIC CANCER PAIN

An enormous amount of information is available to guide the clinician in assessing a patient with chronic cancer pain. Pain assessment tools have been extensively validated in a range of clinical settings, languages, and in different ages and disease states (see Chapter 20).

However, cancer patients are often systemically ill, and in addition to pain usually have low energy and may have a range of other symptoms. Clinicians need to find a balance between the wish to complete a comprehensive assessment and yet respect the

constraints of patients' abilities to tolerate such a comprehensive evaluation. Cancer patients and their families are not always able to endure lengthy clinic visits with use of extensive bedside assessment tools, detailed psychosocial evaluations, and evaluation of other important domains.

Cancer patients and their families have many needs that compete for their time and attention. In addition to symptom control, they also are keen to learn about cancer treatment options, meet the needs of their family members such as children, and fulfill other social obligations related to their employment, completing required insurance forms, and competing financial imperatives, such as purchasing food and prescriptions. Likewise, clinicians need to attend to their many professional roles despite the constraints of competing demands for their time: they must not only assess patients but also discuss treatment options and facilitate decision-making, coordinate care, provide treatment, communicate with other team members, and attend to many other patients and other professional responsibilities. Difficulty managing the complexities of time management can not only lead to patient-related problems, such as pushing palliative and supportive care issues into the background, but also result in professional stress and burnout.

How does a clinician decide on the level of assessment of the cancer pain patient? Pragmatically, it is wisest to comprehensibly evaluate a patient at the first encounter, to the extent he/she is able to tolerate it. If necessary, the evaluation can be completed with more than one encounter. After that point, it should only be necessary to comprehensively re-evaluate if there is a major change in the clinical presentation.

The complete bedside evaluation of the patient with cancer pain includes five major components: history, physical examination, bedside provocative maneuvers, diagnosis formulation, and construction of an overall analgesic strategy.

PAIN HISTORY

Definition of Pain

Pain is defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[19] Pain is always a subjective experience. Most nociception is mediated by nociceptors that are pain receptors found within visceral and somatic tissues. Nociceptors are present in most tissues in the body. There are some striking exceptions including most parts of the parenchyma of the central nervous system. Also, certain modalities of nociception cannot be sensed in certain parts of the body; for example, the stomach can sense stretch as an unpleasant sensation whereas when cauterized there is no pain sensation that results.

Presumably, all receptors within certain body parts will have been activated many times during a person's lifetime, such as nociceptors found in the nondominant thumb: pretty much everyone has hit their thumb with a hammer or some other blunt object, many times. Oddly, the majority of nociceptors throughout the body will never actually be activated during the entire lifetime of the individual. It should come as no surprise that patients describe their pain experience in a way that reflects their own uniqueness as a person and often, their unfamiliarity with the new pain experience.

Imagine the situation of a patient who has metastasis at the left C3 facet. Most people will never experience left C3 facet pain. The experience of nociceptors being discharged for the first time in a person's life can be puzzling, unpleasant, and difficult to describe. When experiencing a new, unfamiliar pain, patients may want to not use the word "pain" but instead use alternative descriptive words such as "discomfort," "unpleasant,","hurt," and others. The clinician should recognize that any unpleasant sensation may in fact be pain and should at all times support and legitimize the patient's experience.

Further, the pattern of pain referral may have gone unnoticed by the patient, particularly if the referred pain is less severe than the primary site of pain. If recognized, patterns of referral can greatly assist the identification of the underlying pain sensitive structure. Studies have evaluated the referral pattern in a range of tissues in many parts of the body, particularly nerves, connective tissues and ligaments, and muscles; mapping out the distribution of the resultant pain has resulted in construction of somatotopic maps. Clinicians are generally most familiar with the distribution of referred neuropathic pain along the corresponding dermatomes. *Sclerotomal pain* refers to the pattern of referred pain when the pain sensitive structure arises in connective tissues and ligaments. Stimulation of various muscles has resulted in similar although distinct patterns of referred pain, known as *myotomal pain*. Going back to the previous example of left C3 facet pain, this is a kind of sclerotomal pain and has a characteristic pattern of referral, felt draped laterally across the ipsilateral neck and projected rostrally toward the occipitonuchal junction.

Definition of Suffering

Suffering, as a human experience, needs to be distinguished from pain, per se, although the two are often interdependent: suffering is commonly present with pain and often increases as pain increases. There have been many insightful approaches to understanding suffering within the medical domain. One of the most widely accepted approaches describes suffering as a perceived threat to an individual's sense of intactness as a complete person.[20] If suffering is in part caused by pain, this definition speaks to the meaning that the person attributes to their pain. For example, at childbirth, intensity of labor pains commonly reaches 8 out of 10 or greater, and is often described as "horrible" on the McGill Categorical Scale. The sense of threat to a person's intactness as a human being during labor is generally believed to be less than the situation of pain of a similarly severe intensity caused by a life-threatening illness such as advanced cancer.

In Western countries, patients often conceptually link "pain and suffering" and may use the words interchangeably. In a comprehensive assessment of a patient with cancer pain, it is incumbent on the clinician to have an approach that is respectful of the patient's current circumstance. The clinician should not make assumptions about how much of the patient's distress is due to pain and how much is due to suffering. Remaining curious and empathic, the clinician works within the limitations of the comprehensive assessment in order to discover along with the patient as to how much of each is present, and how they might be related. There may be early clues about exigent pain as a major component of suffering: pain descriptors with a high affective component, such as "suffocating pain," have been found to predict the presence of suffering.[21]

Validated Assessment Tools

Many clinicians routinely use validated tools to support assessment of cancer patients, particularly to distinguish pain and suffering. There are several outstanding and widely used tools available. Some selected examples of the most largely used are as follows:

The Edmonton Symptom Assessment Scale, commonly referred to as the ESAS, includes 10 items: pain, tiredness, nausea, depression, anxiety, drowsiness, appetite, well-being, shortness of breath, and "other problem" (Fig. 41.1). Like many successfully applied clinical tools, it is short and has been extensively validated in a variety of countries and practice settings.

FIGURE 41.1 (*continued*).

The ESAS has several strengths: it is not overly burdensome to fill out, it is an effective screening tool to identify distress due to symptoms, and it identifies symptom clusters (see below) which, if present, can make pain more difficult to manage.

The Edmonton Classification System is a tool that helps characterize pain prognosis (Fig. 41.2).

The Brief Pain Inventory, widely referred to as the BPI, delineates several aspects of the pain experience, including: worst pain in the past 24 hours, average pain in the past 24 hours, least pain in the past 24 hours, physical functioning, and emotional functioning. The BPI holds several advantages: it has been extensively validated, it assesses several specific dimensions of the pain experience, and it has been used for both research outcomes and for clinical care (Fig. 41.3).

Edmonton Classification System for Cancer Pain

Patient Name: _____

Patient ID No: _____

For each of the following features, circle the response that is most appropriate, based on your clinical assessment of the patient.

1. Mechanism of Pain

No **No** pain syndrome
Nc Any **noc**iceptive combination of visceral and/or bone or soft tissue pain
Ne **Ne**uropathic pain syndrome with or without any combination of nociceptive pain
Nx Insufficient information to classify

2. Incident Pain

Io No incident pain
Ii Incident pain present
Ix Insufficient information to classify

3. Psychological Distress

Po No psychological distress
Pp Psychological distress present
Px Insufficient information to classify

4. Addictive Behavior

Ao No addictive behavior
Aa Addictive behavior present
Ax Insufficient information to classify

5. Cognitive Function

Co No impairment. Patient able to provide accurate present and past pain history unimpaired
Ci Partial impairment. Sufficient impairment to affect patient's ability to provide accurate present and/or past pain history
Cu Total impairment. Patient unresponsive, delirious or demented to the stage of being unable to provide any present and past pain history
Cx Insufficient information to classify.

FIGURE 41.3 (*continued*)

There are several other widely used screening tools to support assessment of cancer pain patients (see Chapter 20).

Types of Pain

Throughout the pain history, the clinician is looking for clues as to the underlying mechanism of pain. Because pain can be a foreign experience, it can be difficult to characterize in words. Patients sometimes appreciate being offered choices of words that might help describe their pain, such as burning, achy, dull, sharp, deep, and so on. Broadly, pain can be thought of as somatic, visceral, or neuropathic. The words the patient uses to describe their pain experience can guide the clinician to make inferences regarding the underlying mechanism.

Somatic pain arises from bone, muscle, ligament, subcutaneous tissue, or skin. It is often experienced as sharp or dull and is typically well localized by the patient. Less commonly, it can be referred to cutaneous sites characteristic of the tissue of origin, such as sclerotomal (connective tissue in origin) or myotomal (muscle) referred pain, as described above.

Visceral pain arises from organs such as lung, liver, or bowel and is broadly understood to arise from tissue that is embryologically mesodermal in origin. It is characteristically described as dull and achy and is usually poorly localized; typically the patient will use their entire hand to describe the location of the pain. Visceral pain is often also referred to distant sites, such as liver pain being experienced in the ipsilateral shoulder. Examination of the shoulder does not reproduce this pain.

Neuropathic pain is generally described as dull, achy, itchy, or burning. The skin can be sensitive to light touch (“allodynia”)[19] and there may be brief stabbing episodes of neuralgic pain. The burning may be superficial as in the experience of scalded skin or can be deep, as if there is a feeling of having been burned deep inside. The spontaneous use of the word “burning” by the patient predicts the presence of neuropathic pain. However, the clinician should be cautious: several other pains can also be experienced as an unpleasant, burning sensation, such as muscle spasm pain—a kind of somatic pain.[22] Combinations of words, such as “burning numbness,” and clinical findings such as hypesthesia, anesthesia, hyperalgesia, or allodynia in a segmental pattern within an area of pain, are of greater value in making the clinical diagnosis of neuropathic pain. For example, neuropathic pain should be diagnosed if there is significant clinical evidence such as a description of burning numbness along with tingling experienced in a distribution consistent with damage to a particular part of the nervous system; there may also be signs of motor dysfunction such as the loss of deep tendon reflexes (e.g., ankle or knee jerks) or muscle weakness; there may be bedside provocative maneuvers that reproduce the pain, such as the presence of a Tinel’s sign or a positive straight leg raise maneuver. The clinician should be wary of making a diagnosis of neuropathic pain based solely on the patient’s description of “burning pain,” although this is an important clue to initiate further investigations.

Mixed pain is the clinical situation where there is both nociceptive (i.e., somatic and/or visceral) and neuropathic pain. A common example is chest wall pain from lung cancer; there may be poorly localized deep ache consistent with visceral (pleural) pain, sharp and well-localized somatic pain from contiguous rib invasion, and burning numbness of the overlying skin due to invasion of intercostal nerves. The term *mixed pain* has less commonly been applied to the situation of multiple mechanisms of somatic pain in the same patient—for example, painful metastasis to the humerus with contiguous muscle spasm and shoulder joint articular changes because of immobility of the painful limb. Mixed pain may benefit greatly from multiple modalities of analgesic intervention, such as simple analgesics (acetaminophen or antiinflammatories), opioids, adjuvant analgesics in specific pain syndromes, and nondrug interventions such as heat, cold, stretch, massage, or orthotic interventions such as a joint-immobilizing splint.

Teasing out the many components of pain in the region of the body where the patient is experiencing pain will help the clinician to develop a more comprehensive approach to managing the pain and is therefore an essential part of the comprehensive pain assessment.

Presenting Complaint

The presenting complaint of the pain should contain four elements: onset, progression, focality, and accompaniments. Once the patient assessment has been completed, these four elements can be summarized in a single sentence and often represent a thumbprint of the underlying mechanism of pain.

Pain Onset

Patients are understandably often keen to tell you how long the pain has been severe. In order to characterize the nature of the underlying process, however, it is critical to also delineate the onset of pain: the time from when the pain first ever began until it became as bad as it was going to get (Table 41.1). Broadly, cancer pain unfolds in three different ways: it may have an onset of less than a day, days to weeks, or months in duration. Be wary of the tendency of pain to fluctuate, with good days and bad days, or good weeks or bad weeks; behind this background noise is the true onset of how the pain developed over time. As a guideline, pain that takes less than one day to become as bad as it is going to get is often vascular in origin. An example of this is an acute thigh hematoma from trauma to the leg or pain from hemorrhage into a site of metastasis. Pain that takes between a day and a month to reach its peak often has an inflammatory mechanism, such as a subcutaneous abscess, with each day being worse than the previous. Pain that is worse month after month, pain that is chronic, progressive, and focal, is most consistent with a diagnosis of cancer. These are only general guidelines, and there are many exceptions. However, delineating the onset of the pain, the time from when it began until it reaches its peak, can be an important clue regarding the nature of the underlying diagnosis.

Pain Progression

There are only a few common patterns of how cancer pain progresses over time. Once it has commenced, cancer pain is typically progressive and usually this progression occurs over months. A second pattern of pain is fluctuating, such as pain that is worse with standing because of metastasis to weight-bearing bone, pain worse with bladder emptying due to cancer invading the detrusor muscle, and pain that is worse at night and relieved by pacing, a classical description of pain experienced with epidural spinal cord compression. Back pain that gets worse with lying down is especially cause for concern about neuraxial tumor involvement. A third pattern of pain progression is pain that is improving: it began, peaked, and is now getting better or has resolved. This temporal profile is consistent with an underlying mechanism of pain that has been effectively treated, such as successful radiation treatment of an area of metastasis. A fourth temporal profile is intermittent episodes of pain. This temporal profile of pain can be incapacitating and can often be effectively managed with specific interventions. One example is a patient with neuropathic pain who has constant, deep, achy pain in the affected dermatome and also has superimposed spells of brief stabbing episodes of neuralgic pain. This pain is characteristically electrical in character, peaks instantly, and lasts seconds. Neuralgic pain commonly improves dramatically with anticonvulsant agents such as gabapentin, pregabalin, or carbamazepine. Another example of intermittent episodes of pain is the patient with baseline achy neuro-

TABLE 41.1

FORMULATING A PAIN PRESENTING COMPLAINT

Domain	Onset of symptoms	Progression	Focality	Accompaniments
Description	Time until peak of symptoms	Pattern of unfolding over time	Right or left; what region of the body	Symptoms that suggest what system is involved
Categories and examples	Less than a day —typically a vascular process —bleeding into a tumor —arterial embolus Between 1 day and 1 month —typically an inflammatory process —infected cancer wound —shingles pain More than 1 month —chronic, progressive and focal: likely cancer. Example: progressive neck pain due to bone metastasis —chronic, progressive and diffuse: likely toxic or degenerative. Example: peripheral neuropathy pain	Sudden and unchanging —typical of trauma Began, peaked, and now improving or resolved: —a typical monophasic course of a painful area successfully treated, such as following radiation therapy Relapsing and remitting: —a relapsing and remitting condition such as multiple sclerosis or change in lymphoma pain with steroids; Spells: —neuralgic pains are brief, electrical stabs of pain lasting seconds —seizures	Head and neck Chest Shoulder and arm Abdomen Pelvis Back Buttock and leg	Cardiac (palpitations); Pulmonary (shortness of breath, cough); Upper GI (nausea or pain on eating); Urinary (cardiac or pulmonary); Small or large bowel diarrhea or constipation Urinary (hematuria) Neurologic (confusion) Endocrine (hypoglycemia)

pathic pain with superimposed brief episodes of burning pain in the skin precipitated by light touch: allodynia.[19] Allodynia is a strong predictor of the presence of underlying neuropathic pain, and once the diagnosis is made, there are several analgesic interventions that can be effective.

Focality

In what region of the body is the pain being experienced? The medical approach to the cancer patient involves a systems approach, such as the respiratory system, the cardiac system, and so on, but it is also important to assess where pain is experienced because of referral sites away from the organ involved or due to the presence of painful distant metastases. There are several ways to classify regional pains. A simple approach is to describe seven regions of the body: head and neck, chest, shoulder and arm, abdomen, pelvis, back, and the buttock and leg region. There is commonly overlap, such as the patient who has back pain, buttock pain, and leg pain. In considering the patient who has pain in a certain region of the body, it encourages the clinician to be mindful of all potentially pain sensitive structures that could result in the experience of pain in that part of the body. The following pain history exemplifies this phenomenon.

> A 47-year-old premenopausal woman presented to her oncologist with a 3 month history of progressive back pain. Two months ago, the pain progressed down the right leg into the foot, in association with tingling and loss of sensation in a distribution similar to the pain. She had a prior history of breast cancer with 3 of 12 nodes positive, treated with surgery followed by radiation therapy, chemotherapy, and was currently on aromatase inhibitors.
> The regional pain exam revealed marked local spine tenderness including paraspinal muscle spasm that reproduced her back pain. Also, there were signs of active right L5 radiculopathy, including an unequivocally positive ipsilateral straight-leg raise maneuver (neuropathic pain in the right leg below the knee). An MRI of the spine revealed evidence of a large right lateral herniated L4–L5 disc and no evidence of cancer.

The presenting complaint of this cancer patient helped focus the rest of the history and the regional pain examination toward diagnoses—cancer and noncancer—that can cause chronic, progressive back pain and unilateral neurologic trouble in a leg.

Symptoms That Accompany Pain

Are there other symptoms that accompany the pain? They can be a strong indicator of the underlying disease process. Typical examples could be chest pain with breathlessness and cough, episodes of chest pain associated with palpitations, or deep achy chest pain associated with nausea after eating, a 30 pound weight loss, and dysphagia over 3 months (see Table 41.1). The symptoms that accompany the pain are a clue as to the underlying system that is involved in the disease process. Often, these other symptoms will unfold in a similar temporal profile of the underlying pain.

Formulating the Presenting Complaint

Integrating these four elements of the pain presenting complaint together within a single sentence—pain onset, progression, focality, and accompaniments—can bring clarity to an otherwise complex clinical presentation, even if the clinician has never encountered the situation previously.

> A 68-year-old man presented with a 1-year history (onset) of progressive (progression) left lateral abdominal wall and flank (focality) deep ache, burning numbness of overlying skin, and a 30 pound weight loss (accompaniments).

This pain syndrome is neuropathic and potentially also visceral. This perplexing presenting complaint suggests cancer of the left flank area, as the pain is chronic, progressive, and focal. The differential diagnosis includes diabetic abdominal wall neuropathy, a rare diabetic neuropathy typically encountered in adults with early onset, mild diabetes. There are other possible causes of this presenting complaint, but postherpetic neuralgia is

not likely if the presenting complaint is accurate: being inflammatory, shingles pain typically has a subacute onset, becoming maximal within days of its first appearance. This particular patient was not known to have cancer, and all investigations at the time of presentation were negative. Pain was controlled with opioids and adjuvant analgesics, and he was given appointments for follow-up computed tomography (CT) scans of the abdomen every 3 months for a year. At 9 months, he developed CT findings consistent with a left adrenal metastasis and retroperitoneal lymphadenopathy, and after biopsy demonstrating metastatic adenocarcinoma, palliative radiation therapy was effective to relieve pain. This is an example of a presenting complaint that was strongly suggestive of the underlying mechanism of pain.

Details of the Pain History

Since pain is a subjective experience, it is essential to obtain from the patient a description of the experience of pain, including the amount of pain. There is strong evidence that estimates of a patient's pain are often inaccurate; health care providers tend to underestimate pain,[23] and family caregivers often overestimate pain.[24] The input of surrogates should take second place to direct input of the patient's own experience. Estimating how much pain a patient is in, based on their facial expression or other indicators, should be approached with great caution, although behavioral cues may be the only way to assess pain in a non–self-reporting patient.

Further, extensive research evidence has indicated that there are ways to inquire of a patient that are more likely than others to get a response from the patient that is valid, reliable, and reproducible. A widely used approach is to ask the patient how much pain they are experiencing on a scale of 0 to 10, if 0 is "no pain" and 10 is the "worst pain possible." This approach has been broadly adopted within health care institutions. The clinician needs to be wary of the uncommon circumstance where the numeric rating scale turns out to be less reliable. One is delirium, a syndrome of fluctuating encephalopathy commonly encountered in cancer patients before death or in association with concurrent acute illness. When delirium is known to be present, it is appropriate to ask the patient how much pain they are experiencing using the 10 point numeric scale and record their answer, but also one should record that they have delirium. In this setting and any other settings where there is any doubt of the reliability of the patient's description, an additional method to quantify pain intensity should be used to confirm their description. A highly reliable, valid, and reproducible scale is the McGill categorical scale.[21] One asks the patient if they would describe their pain as none, mild, discomforting, distressing, horrible, or excruciating. If there is any question to the reliability of the patient's description, it is best to keep the questions simple and dichotomous, for example, "Is your pain bad, or not bad?" The more ways one poses the question, the more confident the clinician can be about the interpretation of the patient's response.

A detailed description of the many facets of the pain experience is described in detail in Chapter 20. In cancer pain, clinicians often ask the patient about their present pain intensity (on a scale of 0–10), the worst pain experienced in the past 24 hours, the least pain experienced in the past 24 hours, and the average pain.

If the patient is struggling to find words to describe their pain, the clinician should be supportive and encouraging, offering words to the patient such as burning, sharp, or crushing. If the patient spontaneously offers a word with a strong affective component, such as "suffocating" pain, the clinician should inquire about comorbidities such as concurrent dyspnea, but also recognize the possibility that such affectively loaded words may signal a more global sense of suffering. This requires further inquiry and evaluation.[21]

After delineating the intensity of the pain and the description of the pain, the clinician should find out, in detail, what part(s) of the body are affected and what the characteristics of the pain are throughout these locations. A differential description of discrete pains within the same region of the body can give a clue to as to the underlying mechanism. For example, patients with malignant brachial plexopathy often describe several different pains. There is often a deep achy, poorly localized discomfort draped over the ipsilateral shoulder, with burning pain and tingling in the ipsilateral lateral hand. There can also be pain with light touching of the area of numbness in the affected arm (allodynia), and superimposed spontaneous episodes of brief stabbing electrical pain in the arm, experienced as single jabs or brief trains (volleys) of pain. If present for several months, patients can develop pain from frozen shoulder or other articular or myofascial complications of immobility of the affected shoulder girdle region. All of these discrete pains can be elicited and described by the patient during the pain history.

The clinician then focuses on the experience of pain over time: what makes it better and what makes it worse. In particular, one seeks a description of the change of pain over time with medication (i.e., pharmacodynamics). Typically, one would expect there would be relief of pain beginning about one half hour after swallowing a short-acting opioid, peaking at approximately 60–90 minutes, and then it would wear out sometime thereafter. If the duration of analgesia is too brief (in this case less than 4 hours after taking a short acting opioid), the patient probably has end of dose failure. Identifying this phenomenon can guide the clinician to estimate the extent to which the patient is undermedicated.

Next, construct a detailed list of all prescription and nonprescription medications the patient has taken; the patient or family should be encouraged to look through the medication cabinet for all pills. The list should include the names of medications, the maximum dose that was taken, the duration that the maximum dose was taken, with what effect and what toxicity (Table 41.2). The goal is to be as confident as possible that the patient has completed an adequate trial of each of these medications and if they did not have an adequate trial, one then can consider reembarking on a trial of that medication in a more thorough manner. By the end of this description, the clinician should have a clear understanding what sequential trials of analgesics and combination of analgesics the patient has had over time.

Depending upon the patient's past history and current social circumstances, it may be appropriate to apply certain chemical misuse/abuse/dependency risk tools, such as the CAGE (Table 41.3)or the Opioid Risk Tool (ORT). Stratifying risk allows for a structured approach to pharmacotherapy that is tailored to each patient's particular circumstances.

The clinician should also seek information about other risk factors for poor pain prognosis. This includes any history of psychiatric disorder, the presence of breakthrough pain, neuropathic pain, other psychosocial stressors, use of high dose opioids without satisfactory pain control or excessive adverse effects, and the presence of significant interference of function by pain. Interference of function refers to pain interfering with physical functions such as sleep, activities of daily living, work and social functioning, such as a parenting role, sexual relations, and emotional functioning, such as ability to engage meaningfully with those around them and ability to cope.

The clinician then embarks on a detailed medical and psychosocial history. The medical history involves a review of systems such as respiratory, cardiovascular, GI, genitourinary, musculoskeletal, dermatological, neurological, and endocrine. There is a high risk of comorbidity with particular patterns of systems dysfunction in specific cancers. An example is the high prevalence of underlying respiratory disease in a patient who has a tobacco-related malignancy or a lengthy history of tobacco use.

The elements of a psychosocial history have been described elsewhere in this book (Chapter 21).

TABLE 41.2

LIST OF MEDICATIONS TAKEN FOR PAIN

Patient name _____

Today's date _____

Name of Medication	Start Date	End Date	Maximum Daily Dose (in milligrams)	What Benefit	Side Effects	Comments

PHYSICAL EXAMINATION

The pain physical exam includes a general physical exam, a regional pain exam, more specific neurological examination guided by history, and bedside provocative maneuvers.

General Physical Examination

The general examination of the cancer patient includes a brief screening physical exam including vital signs, head and neck, respiratory system, cardiovascular system, the abdominal exam, genitourinary exam including rectal exam (as appropriate to the clinical circumstance), musculoskeletal exam, peripheral vascular exam, neurologic exam, and dermatologic exam. Particular attention is paid to document the extent of underlying malignancy; patients presenting with cancer pain may have a greater extent of disease than was previously suspected, so the clinician needs to examine the patient with a view toward stigmata of underlying organ disease.

The Regional Pain Physical Examination

The clinician approaches the regional pain examination as guided by the pain history. This approach complements but does not replace the more traditional systems approach to the physical examination described above. Seven regions of the body are: head and neck, chest, shoulder girdle and arm, abdomen, back, pelvis, and buttock and leg (Table 41.4). For example, if the patient describes pain in the head and neck, a regional pain exam is done of that part of the body. The clinician pays particular attention to look for evidence of underlying disease in that region, which may be vascular, infectious, or neoplastic in origin. The clinician looks for evidence of degenerative neck disease, with reduced range of motion of the neck, neurologic disease with ptosis suggesting ipsilateral cancer in the low cervical spine, vascular disease such as carotid artery or vertebral artery bruit, palpable muscle spasm, and other signs of an underlying pathological process.

TABLE 41.3

CAGE TEST TO SCREEN FOR ALCOHOLISM

Please check the one response to each item that best describes how you have felt and behaved over your whole life.
1. Have you ever felt you should *cut* down on your drinking? 2. Have people *annoyed* you by criticizing your drinking? 3. Have you ever felt bad or *guilty* about your drinking? 4. Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (*eye-opener*)?

Bedside Provocative Maneuvers

The bedside provocative maneuvers are an important part of the pain physical exam. The goal is to gently reproduce the patient's pain complaint(s). If the clinician successfully reproduces the pain, the patient may be relieved, having their subjective complaints validated. As described above, since pain is a subjective experience, often patients have the sense that others do not appreciate how serious their pain is. If the clinician is able to reproduce the pain, the patient may believe that the clinician has confirmed that it exists. Further, if the clinician is able to localize, or "touch" the pain, the patient may have greater confidence the pain can be relieved. For the clinician, being able to reproduce the pain provides insight into the underlying mechanisms or pain-sensitive structures.

For each of the seven regions of the body, there is a list of regional bedside provocative maneuvers (Table 41.5). For example, in the situation of a patient who presents with head and neck pain, the clinician would first do a general physical exam and then a regional pain exam in order to look for underlying disease processes. After this time, the clinician would systematically embark on bedside provocative maneuvers. This would include neck range of motion in six directions, including an evaluation for meningismus, palpation of the skin, assessing for allodynia, and deep palpation of underlying tissues. One continues to palpate more deeply trying to identify areas of myofascial pain or muscle spasm. One looks at typical tender points[25] and also areas that commonly develop muscle spasm in response to disease, such as the paraspinal muscles. Muscle tenderness can be sought throughout the neck, the face, the jaw, and other areas. The clinician

TABLE 41.4

A REGIONAL APPROACH TO THE PAIN PHYSICAL EXAMINATION

Region	Syndrome	Examples of pain sensitive structures
Head and neck	somatic visceral neuropathic	paraspinal muscles focal neck myofascial pain occipitonuchal junction dentition sinuses periorbital area bone: base of skull, facial carotids orbits cervical radiculopathy
Shoulder and Arm	somatic visceral neuropathic	shoulder joint ligamentous muscle axilla apex of lung radicular pain referred from neck brachial plexus
Chest	somatic visceral neuropathic mixed pain	parietal pleura vertebral body visceral pleura thoracic nerve root chest wall: rib, muscle, nerve intradural lesion
Abdomen and Flank	somatic visceral neuropathic	flank muscle rib referred from vertebral body intra-abdominal: liver, hollow viscus, peritoneum kidney, adrenals retroperitoneal structure: pancreas intercostals nerve or intradural lesion
Back and Buttocks	somatic visceral neuropathic	bone: vertebral body, sacrum, bony pelvis paraspinal muscle cauda equina; nerve root; plexus presacral region, peritoneum cauda equina, nerve root, plexus, intercostals nerve
Pelvis	somatic visceral neuropathic	bony pelvis introitus ovaries, uterus plexus, pudendal nerve
Leg and Foot	somatic visceral neuropathic	bone: pelvis, femur, tibia muscle: gluteus, obturator ligament: insertion of biceps joint: hip, sacroiliac presacral area cauda equina, nerve root, plexus, nerve

should put on a glove and palpate the masseter musculature as well as posterior pharyngeal examination of the pterygoid muscles. Following this, bone structures should be systematically examined by palpation and percussion, including the orbit, the skull, the occipital condyle, and then down the cervical spine. Next palpate the carotid arteries (gently), the orbits, and the sinuses. Other bedside provocative maneuvers can be performed based on the clinical situation. The clinician should approach bedside provocative maneuvers as a sleuth, looking for evidence that will rule in or rule out various pain sensitive structures as being the source of the pain. Further detail on pain caused by cancer of the head and neck and oral mucositis is covered in Chapter 45.

Specific Bedside Provocative Maneuvers and Their Role in Pain Diagnosis

Spurling's Test

Spurling's test of the cervical spine is performed if there is concern the patient might have active cervical nerve root compression. It

TABLE 41.5

EXAMPLES OF BEDSIDE PROVOCATIVE MANEUVERS

Region	Structure	Provocative maneuver	Finding
Head and Neck	skin	wave hand over skin	allodynia
	paraspinal muscle	pinprick	hyperpathia
	bone	cold temperature	cold allodynia
	occipitonuchal junction	gentle palpation	palpable paraspinal spasm
	neck range of motion	gentle palpation of spinous processes; deeper palpation over vertebral bodies	tenderness
	Spurling's maneuver	gentle palpation	tenderness
		patient moves neck in six directions	pain; limited range of motion
		patient laterally flexes or laterally flexes and laterally rotates neck (see Fig. 41.4)	neuropathic pain or other neuropathic symptoms or signs
Shoulder and Arm	shoulder girdle	active range of motion of shoulder	pain
	brachial plexus	passive range of motion of shoulder	tenderness; reduced range of motion (e.g., frozen shoulder)
	axilla	examination for tender areas	bicipital tendonitis
		gentle percussion over Erb's point in the supraclavicular fossa	Tinel's sign positive tenderness
		palpation	
Chest	subcutaneous tissue	gently pinch skin	unilateral lymphedema
	spine	palpation; percussion	tenderness
Abdomen and Flank	organs	gentle then deep palpation, at rest then with inspiration	tenderness
	abdominal wall	Carnett's Maneuver	worse with tension of abdominal muscles (see Fig. 41.6)
	retroperitoneal structures (e.g., pancreas)	Retroperitoneal stretch maneuver (Fig. 41.5)	thoracic spine is not tender but back pain arises with retroperitoneal stretch
Back	vertebral body	spine palpation and percussion	tenderness
	sacroiliac joint	gently press thumb into sacroiliac joint	tenderness
	hips	flexion, abduction, internal then external rotation; palpate hip joint; palpate trochanteric bursae	tenderness; limited range of motion
Pelvis	pelvic organs	internal examination	tenderness
	rectum	rectal examination	tenderness
Buttock and Leg	low lumbar and sacral nerve roots	straight leg raise maneuver	ipsilateral neuropathic pain below the knee with other neurologic symptoms
	upper and mid lumbar nerve roots	crossed straight leg maneuver	ipsilateral neuropathic pain below the knee with other neurologic symptoms
		reverse straight leg raise maneuver	ipsilateral neuropathic pain in the anterior thigh with other neurologic symptoms

is analogous to the straight leg raise maneuver that detects active lumbosacral radiculopathy (see below). Spurling's test consists of gentle lateral flexion of the neck for about 1 minute toward the side of the pain, followed by lateral flexion of the neck for about 1 minute away from the side of the pain. A variation is lateral flexion plus lateral rotation of the neck (''throw your ear over your shoulder''), for 1 minute to one side and then to the other. The test is positive if it results in neuropathic pain, tingling, or numbness below the elbow or loss of a previously present arm reflex such as a triceps reflex. The side and nerve root distribution of the arm pain or other neurologic impairment localizes the site of the mass that is pushing on the thecal space. Some reports have recommended axial loading be undertaken at the same time as lateral flexion and rotation (the examiner pushes down on the top of the head).[26] We do not recommend that approach for cancer patients as there may be bone destruction and the test could be dangerous. Spurling's test can be particularly helpful to distinguish malignant brachial plexopathy (in which case the maneuver is almost invariably negative) from spinal cord compression in the cervical spine (in which case the maneuver is often positive) (Fig. 41.4). The procedure should not be undertaken if baseline pain is severe until radiographs or other imaging studies confirm that the neck is mechanically stable. Positive and negative predictive values for the test have been described for active cervical radiculopathy from benign disease but not for cancer.[26]

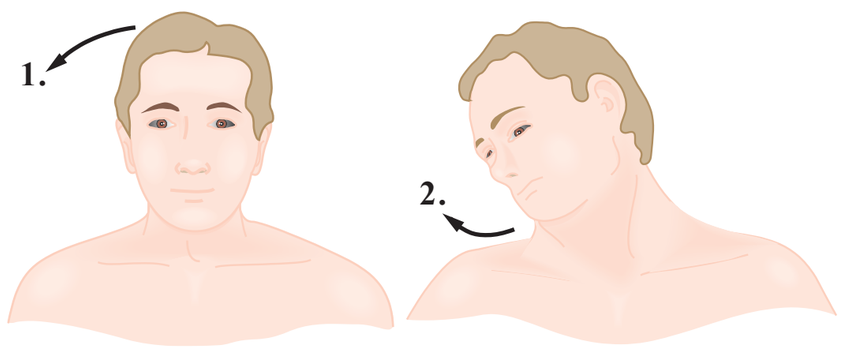

FIGURE 41.4 Spurling's test.

Dermatomal Pain

At some point, the clinician is likely to encounter an area of tenderness with pain referred to a distant site. Clinicians are familiar with dermatomal pain or radicular pain, such as L5 nerve root pain cause by a herniation of the L5–S1 disc. This pain can be provoked by a straight leg raise maneuver. The straight leg raise maneuver is a validated bedside provocative maneuver that has been carefully tested in a range of clinical situations, disease types and ages, and with a range of specific techniques to perform the test.[27] L5 radicular pain is felt down the ipsilateral buttock into the posterior part of the thigh and down the posterolateral leg into the dorsal or dorsolateral foot.

Sclerotomal Pain

There are other mechanisms for pain that may appear strikingly similar to dermatomal pain, including sclerotomal pain. A common example of sclerotomal referred pain is pain referred from the sacroiliac joint. The bedside provocative maneuver is to gently place the thumb in the sacroiliac joint and press with a few kilograms of pressure. The positive maneuver reproduces the ipsilateral paraspinal and low back pain the patient has been having. Referred sclerotomal pain goes down the ipsilateral posterior buttock and lateral leg into the ipsilateral ankle. L5 radicular pain and ipsilateral sacroiliac pain can occur in the same patient. This confusing clinical scenario may arise in a patient with active lumbosacral radiculopathy due to disc protrusion. Presumably the sacroiliac pain is a consequence of biomechanical changes that occur in a patient who is limping because of pain from the active radiculopathy. Eventually, the stress on the ipsilateral sacroiliac joint is such that it too starts to hurt. The patient may ultimately have a surgical procedure to remove herniated disc material. However, the sacroiliac pain can persist, leaving the patient with a wrong impression that the surgery was a failure. This clinical situation raises the complexity of regional pain, whereby there can be several interdependent mechanisms of pain in the same region of the body. Teasing out the various components of that regional pain will allow the clinician to direct therapeutic interventions at each.

Myotomal Pain

A third kind of referred pain is myotomal pain: pain that arises from muscles. Referred myotomal pain is generally not a great distance from the irritated muscle. One example of myotomal pain that is diagnosed based on a bedside provocative maneuver is pyriformus syndrome. In cancer patients, myotomal pain is generally not a major direct cause of referred pain, but it can occur in a similar manner as sclerotomal pain resulting from secondary mechanical dysfunction.

Myofascial Pain: How Hard Should You Press?

Myofascial pain is a term that can be used to describe specific myofascial tender point sites[25] or can be used as a more generic term for regional pain of muscular origin that is not due to primary pathology in the muscle. Myofascial pain is common in cancer pain patients, and it can mimic other types of pathology. Identifying its presence can lead to specific therapeutic interventions, such as heat, stretch, cold and massage, trigger point injections, or regional blockade, and it is therefore important to make the diagnosis when possible. Separate from regional myofascial pain, rheumatologists have defined the systemic condition fibromyalgia in part by a series of bedside provocative maneuvers palpating for tenderness in specific areas, applying an amount of pressure that would not normally be uncomfortable. All patients experience muscle tenderness if the examiner presses hard enough. Research in muscle tenderness has identified that most commonly muscles do not hurt when the examiner presses with up to 4 kilograms of pressure using the thumb. The clinician can use a baby weigh scale to become familiar with what represents 4 kilograms or can use a bedside dolorimeter, which is a bedside tool meant to gauge how hard one is pressing. Fibromyalgia is defined through the patient's history and testing for myofascial tenderness using a standardized methodology, with the finding of at least 11 of 18 typical tender point sites. The bedside diagnosis is accurate, with a sensitivity of 88.4% and a specificity of 81.1%.[25] The bedside exam of the cancer patient, looking for regional myofascial pain unrelated to fibromyalgia, is best undertaken with a similar technique.

Back Pain

In approaching the bedside examination of the patient with back pain, the clinician needs to pay particular attention to be gentle. In examining the spine, one would first palpate in the area where the patient describes the worst pain. Push very gently, with less than a kilogram of pressure on the palpating finger on the area of the worst pain and the broad area around it, looking for paraspinal muscle spasm. If negative, one can palpate with more pressure. There are some situations where a patient appears to have severe back pain and yet the regional pain exam demonstrates that the spine is completely aligned and there is neither spinal tenderness nor palpable paraspinal muscle spasm. How can there be severe back pain but not back tenderness? Retroperitoneal tumor can cause lumbar or thoracic regional pain where there is no tenderness with even deep percussion. There may be a suggestion that the patient has a retroperitoneal cause of back pain based on the patient's posture as you enter the examination room: the patient may have adopted a so-called pain-relieving posture, such as sitting on the bed with the knees folded up into the chest. This posture results in lumbar kyphosis and subsequent relief of pain from a retroperitoneal pain-sensitive structure.

Retroperitoneal Pain Stretch Maneuver

In order to diagnose a retroperitoneal source of back pain, have the patient sit upright in the bed with the legs stretched out. This is best done in a bed in which the back of the bed can be elevated. Place a pillow into the small of the back so there is moderate thoracolumbar lordosis, and have the patient lay back down in the bed. Gently lower the back of the bed so the patient goes toward a supine direction (Fig. 41.5). Retroperitoneal tumor can cause severe back pain and is reproduced with this maneuver. Oddly, it can take a few minutes for the pain to become fully apparent as the bed is lowered and the spine is extended. The history will commonly give a suggestion that this sign may be present because the patient may describe back pain upon laying flat, with the patient having thereafter sought sleep in a recliner.

Abdominal Wall Pain

The abdominal wall is frequently a source of pain and how to examine it has been less clearly defined than examination of underlying abdominal structures. Abdominal wall pain is a common mechanism of severe idiopathic abdominal pain.[28,29] It also can be a long term sequela of abdominal surgery such as hernia repair,

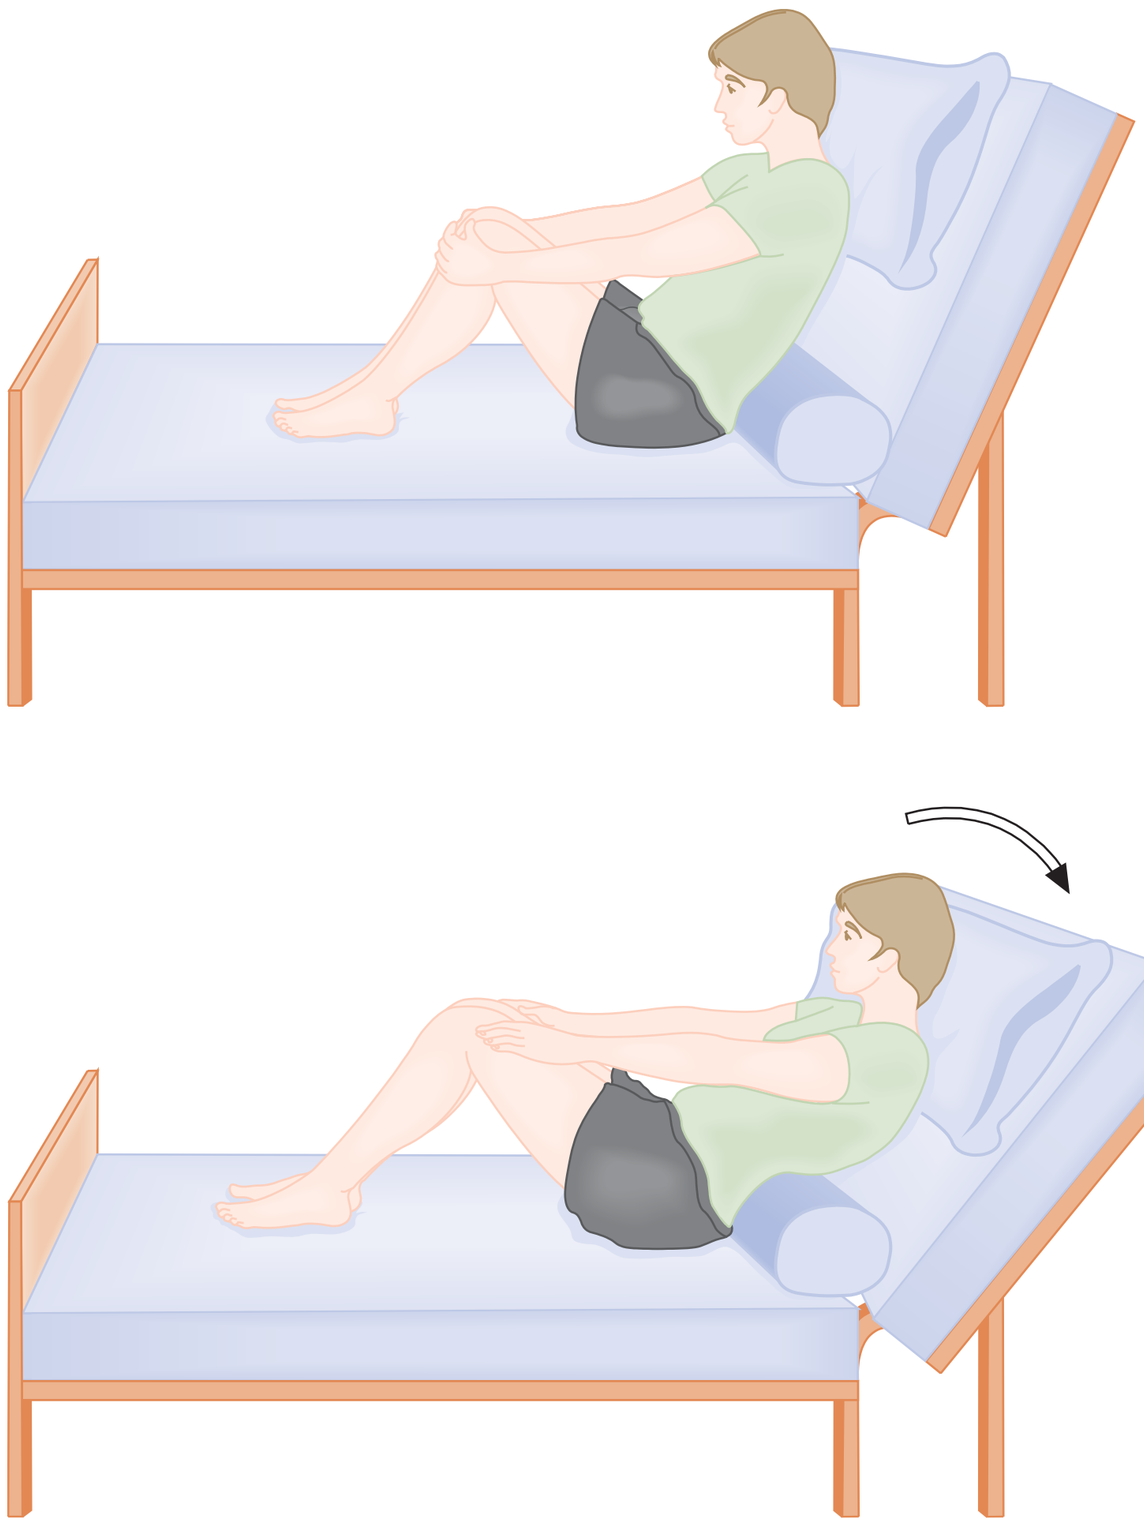

FIGURE 41.5 Retroperitoneal stretch maneuver.

open cholecystectomy, etc.[30] The distinction between an underlying and medically serious intra-abdominal source of pain from a benign abdominal wall source of pain is made through a bedside provocative test, Carnett's maneuver.

Carnett's maneuver: The patient is found to be tender upon gentle palpation, typically in the left or right lower quadrant (Fig. 41.6). If the patient tenses the abdominal wall, such as by lifting both legs a few centimeters in the air or lifting the shoulders off the bed, an inflamed visceral organ is protected from the palpating hand. Alternatively, if the pain-sensitive structure is within the abdominal wall, such as caused by a myofascial trigger point, a neuroma, a hematoma, or some other cause, pain becomes markedly worse with tensing of the abdominal wall during palpation.

Another cryptic cause of abdominal wall pain can be neuropathic pain. This can be caused by cancer invading intercostal muscles, from retroperitoneal tumor, from diabetic abdominal wall neuropathy, shingles, and other mechanisms. There are several bedside provocative maneuvers that can diagnose abdominal wall neuropathic pain. First, gently touch the normal side and then the abnormal side with a cold object, then a piece of cotton, then a pin (see Table 41.5). If any of these normally non-noxious stimuli results in pain, the patient likely has abdominal neuropathic wall pain. Sensitivity to temperature, touch, or pinprick can be one of the most dramatic bedside signs in the pain physical examination and is strong evidence of the presence of underlying neuropathic pain. The abnormal sensation can linger for up to a minute or longer, so called "after sensation." Abdominal wall neuropathic pain can be accompanied by numbness or loss of abdominal wall muscle tone.[31]

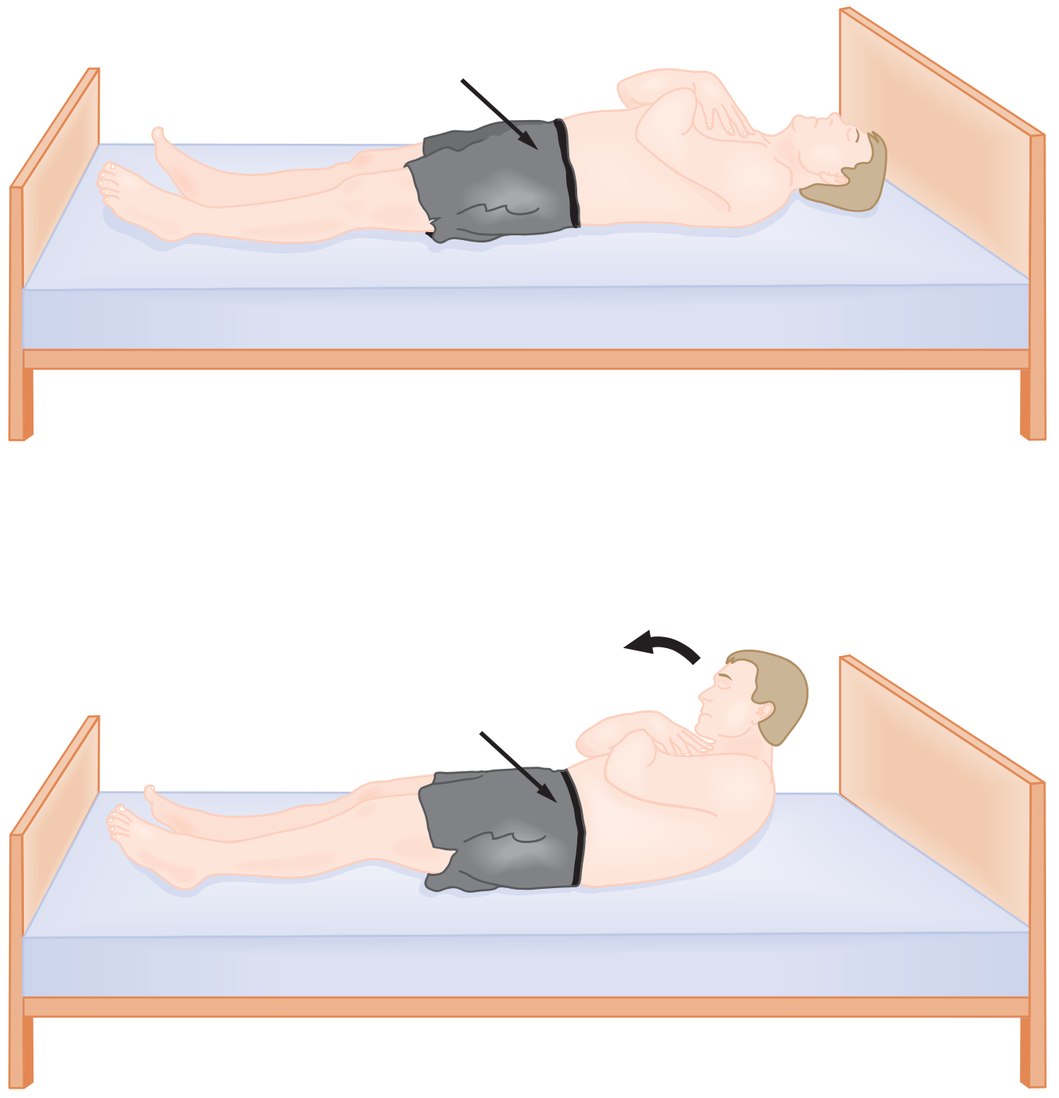

FIGURE 41.6 Carnett's maneuver.

FORMULATING A CANCER PAIN DIAGNOSIS

Syndrome Diagnosis

While it can be tempting for the clinician to make a specific diagnosis as to the underlying cause of the pain, it may be wiser to begin with a more general syndrome diagnosis. Broadly, pain can be classified into somatic, visceral, neuropathic, or mixed syndromes. Diagnosing the pain syndrome based on the characteristics, the pattern of referral, the accompaniment, and the provocative maneuvers can make it more likely that the clinician will consider a broad differential diagnosis.

The use of the taxonomy of somatic, visceral, and neuropathic pain syndromes can be challenged by closer scrutiny of their pathophysiologic basis. For example, some peripheral nerves are themselves pain sensitive structures, being innervated by nociceptors. In addition, other aspects of neuropathic pain can be non-nociceptive, that is, pain generated by a damaged nervous system. Thus, when the peripheral nervous system is invaded by cancer, there can be both nociceptive and non-nociceptive pain. A common clinical scenario is malignant brachial plexopathy. The nociceptive component generated by nociceptors within the brachial plexus is pain draped over the ipsilateral shoulder; the non-nociceptive component of the pain is commonly burning pain in the ipsilateral, numb hand. An example of a central generator of neuropathic pain is poststroke thalamic pain. Central pain caused by brain metastases is extraordinarily uncommon and may relate to the long period of time it takes for central pain to develop. However, the taxonomy remains of clinical value, and a more complex version is described in Table 41.6.

There are other causes of pain which appear nociceptive in characteristic but have a non-nociceptive mechanism. Pain purely or mostly of psychologic origin (often inappropriately termed psychogenic pain) is extraordinarily rare in the cancer population and must be used cautiously as it can either take the focus away from other equally or more important causes of pain or might stigmatize the patient as being less than genuine, truthful, or trustworthy. For this reason, the term psychogenic pain is usually avoided. An example of pain of psychologic origin would be a patient who feels pain as part of a psychotic sensory hallucination. Likewise, factitious pain is uncommon and is due to a compulsive need for unwarranted health care (different than malingering). Idiopathic pain is pain for which the cause is not evident after a detailed history, physical exam including bedside provocative maneuvers, and referral for appropriate diagnostic imaging, laboratory tests, and consultation as needed. Commonly, idiopathic pain in cancer patients turns out to be due to metastatic disease that was not evident despite extensive investigations. A wise approach to the cancer patient with idiopathic pain is to complete investigations and then see the patient in follow-up on a regularly scheduled basis such as every 3 months. Diagnostic imaging can be repeated at that time along with a repeat clinical assessment.

The role of bedside provocative maneuvers in formulating a pain diagnosis has been described.[32] In one prospective study of 50 patients, all or much of the pain that brought the patient to the clinical venue was reproduced by a positive maneuver in 47 of 50 patients. Most commonly, pain was somatic but it could also be visceral, neuropathic, and about half the time it was mixed pain. Myopathic pain or muscle spasm pain was present in about half of all patients and allowed a broader approach to overall pain control strategies.

Pathophysiologic Diagnosis

The temporal profile of how the pain progressed over time will commonly reveal the underlying mechanism of pain (see Table 41.1). Vascular events are usually as bad as they are going to get within less than a day. An example of a vascular event is a spontaneous bleed within a tumor bed, exemplified by a patient with a vascular neoplasm, such as choriocarcinoma or melanoma, who develops a headache and accompanying neurologic symptoms that become fully established in less than a day. An inflammatory process typically takes between 1 and 30 days to be as bad as it is going to get. An example would be a tumor-related skin or deep tissue abscess. When pain takes more than a month to become as severe as it is going to get, is focal and is progressive, it is usually due to a growing mass. Needless to say, in a patient with known cancer, severe pain should be considered to be progression of malignancy in that region of the body until proven otherwise.

COMPLEMENTARY CLINICAL PERSPECTIVES IN THE CARE OF CANCER PATIENTS

Acute pain is a symptom and not a diagnosis. Chronic pain can be a symptom of ongoing tissue injury or a disease process in and of itself as previously discussed. The overall approach to a pain management strategy, therefore, is greatly shaped by the underlying pain mechanisms involved and the overall goals of care. The medical approach focuses on disease diagnosis and disease cure, the palliative approach aims to relieve, suppress, or mask pain to the greatest extent possible, the rehabilitative approach (an approach widely employed by chronic noncancer pain clinics) focuses on improved function and adaptive coping, and

TABLE 41.6

PAIN MECHANISMS

Nociceptive pain	Somatic	bone metastasis
	Visceral	liver pain
	Neuropathic	brachial plexopathy
	Mixed	Pancoast tumor
Non-nociceptive pain	neuropathic with peripheral generator	neuroma
	neuropathic with central generator	thalamic pain
	pain of psychological origin	psychosis presenting as pain
	factitious	compulsive need for health care
	idiopathic	advanced but cryptic cancer

the anesthetic approach has the objective to diagnose and block, such as a combination of "medical" and "palliative" approaches. With each of these perspectives, however, the goal is to relieve pain as quickly as possible, with the least toxicity possible. These various, but not mutually exclusive, approaches can be exemplified in a clinical case.

> A 53-year-old man, who was previously healthy, developed a gradual onset of epigastric pain. He began to develop nausea and heartburn; symptoms worsened after eating. He developed weight loss. He seeks care from his physician 4 months after the onset of these symptoms.

The Medical Model: Pain is a Manifestation of Disease

In the medical model, pain is seen as a manifestation of an underlying illness. The general orientation is that of a systems approach, whereby the clinician focuses on the affected system. Using a rule in/rule out method, the clinician considers GI disease such as erosive esophagitis, gastritis, duodenal ulcer, and upper GI malignancy, cardiovascular disease such as a descending aortic aneurysm, and ischemic heart disease, and other neoplastic disease such as an intrathoracic malignancy with referred pain. Diagnostic tests are ordered to rule in or rule out each of these conditions. In this situation, pain is helpful in that it alerts the patient that something is wrong and needs to be investigated.

Palliative Model: Pain is Both Useless and Harmful

In this model, the underlying mechanism for pain is almost always known. The extent of underlying disease is also known and pain is both physiologically useless and potentially harmful to homeostasis. While controversial, there is some evidence that better control of cancer pain results in prolonged survival.[33,34] "Palliative" is an invented word based on the Latin for mask or cloak. The approach of the palliative model is to comprehensibly assess the whole patient, including their underlying disease, their social situation, their emotional state, and their spirituality, and then to mask or suppress the pain as much as possible. Other symptoms, such as anorexia, low energy, or nausea, should also be assessed and suppressed with medications or other approaches. Another closely related term commonly used to describe a whole-person approach to care of the cancer patient is "supportive care." An example of a palliative approach to cancer treatment is palliative chemotherapy or radiation therapy, and is discussed more fully in Chapter 48.

Rehabilitative ("Chronic Nonmalignant Pain") Model: Focus on Dysfunctional Pain Behavior and Pain-Related Deconditioning

A third model for pain diagnosis and treatment is the rehabilitation model for the management of the chronic pain syndrome and is applied in the setting of dysfunctional pain behaviors. In this scenario, pain has been investigated with findings of no underlying somatic, visceral, or neuropathic process to account for the pain or the underlying disease (e.g., arthritis) cannot be eradicated, so pain must be minimized in order to optimize quality of life. Either way, therapy is directed at reversing any chronic dysfunctional pain behaviors, and the client undergoes some form of behavior modification and functional restoration therapy.

Anesthetic Model: Diagnostic and Therapeutic Blocks

A fourth approach is the anesthetic model. In this approach, the patient undergoes a diagnostic procedure whereby local anesthetic is injected into or around suspected pain generator sites or regional blockade of sensory or autonomic nerves is performed. If the pain goes away, the patient may also undergo a series of such interventions, or in selected cases, a more definitive therapeutic block with a neurolytic agent such as phenol or alcohol. Interventional pain therapies are discussed in detail in Chapter 44.

All of the above are perspectives, and none should be adopted as the sole correct approach, but applied and integrated, depending upon clinical context. In the case history above of the patient with epigastric pain, the patient may present to his physician for assessment, and through the medical model, will have several conditions ruled out until a definitive diagnosis, such as pancreatic cancer, is made, during which time analgesics should be used to treat pain. He may undergo cancer treatment, but at the same time he may be started on long-acting opioids, with the plan of masking or suppressing the pain, or he may be referred for celiac plexus block. If this patient is having difficulty coping, or if he develops dysfunctional pain behaviors or aberrant medication use, a rehabilitative approach that focuses on behavior modification should be employed. Thus, the sage clinician can fluently move between different models of pain treatment and care depending on the clinical context and may in fact consider more than one model at the same time (Fig. 41.7).

MANAGEMENT OF PAIN IN SPECIFIC CLINICAL PRESENTATIONS

Bone Pain

Cancer-related bone pain is common. About 80% of patients who die from breast cancer will have bone metastases at the time of autopsy, and a similar prevalence has been observed in other kinds of cancer. Bone scintigraphy studies have revealed the surprising findings that bone metastases are far more numerous in any given patient than what would be expected by the pain history; about two thirds of bone metastases are painless. While the risk of pain correlates to an extent with the degree of bone destruction and whether or not the metastasis is in a weight-bearing bone, it can be difficult to predict based on imaging studies as to whether a metastatic lesion is painful or not. Oddly, bone pain can be transient and migratory; that is, very painful for several days and then appears to not be painful but other bone metastases become painful.

Typically, pain from bone metastases become worse over the course of months. However, at a point in time the pain may start to increase more quickly in a crescendo pattern, becoming worse each day. There is often severe muscle spasm in the contiguous muscles. This pattern of crescendo pain in bone metastasis predicts fracture. Crescendo back pain predicts collapse of a vertebral body; one should urgently investigate such patients for exigent or impending epidural cord compression to offer definitive treatment prior to developing their neurologic symptoms. Bone pain is described in more detail in Chapters 46 and 47.

Pain and Delirium

Delirium is a transient and potentially reversible disorder of cognition and attention.[35] Tools have been developed to assist the

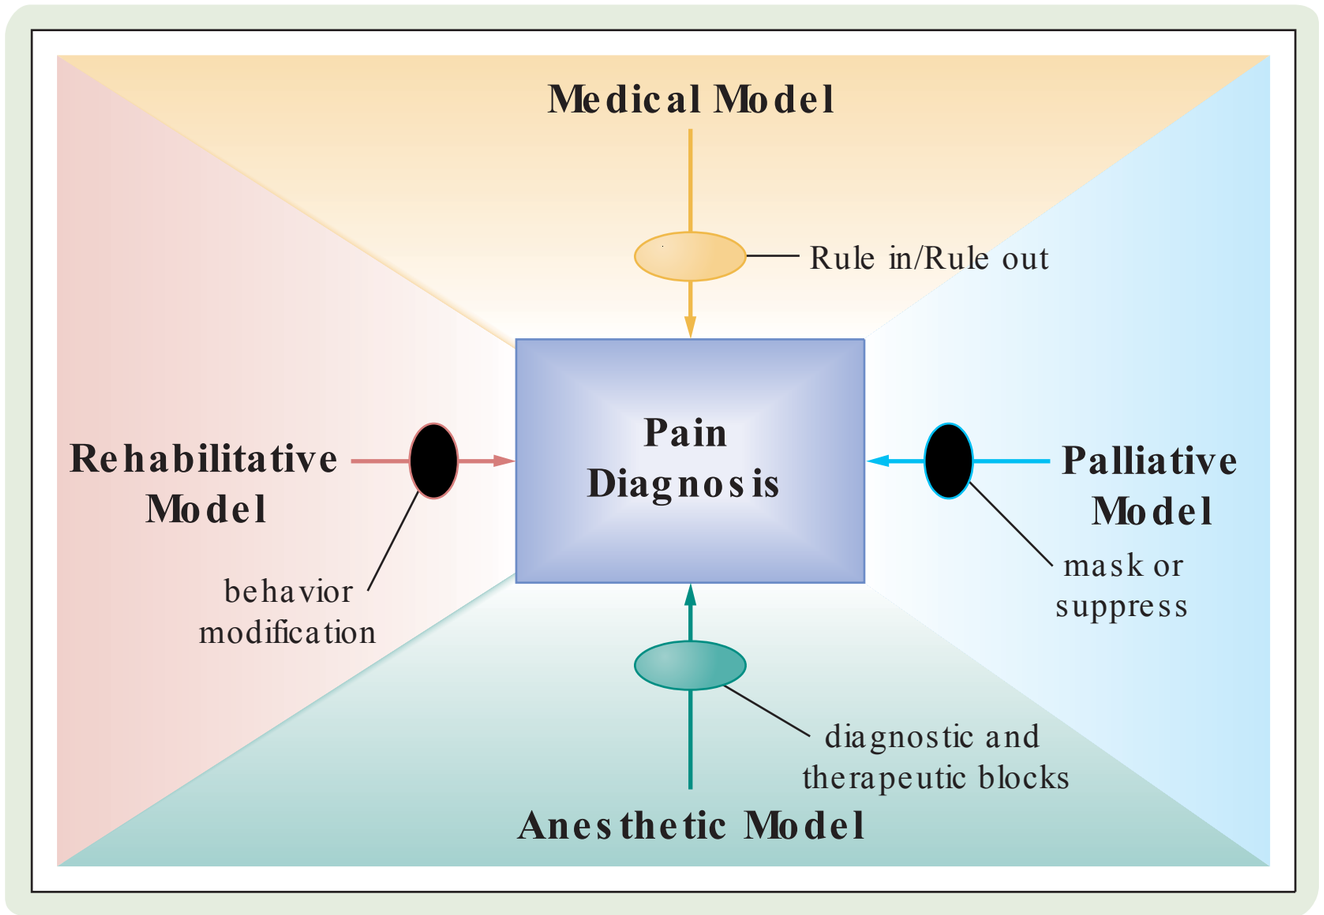

FIGURE 41.7 Complementary clinical perspectives in the care of cancer patients.

clinician to make the diagnosis as it has been found that delirium is common but the diagnosis is often delayed or missed. Since pain is a subjective symptom, there is a risk that the presence or severity of pain will be misunderstood if the diagnosis of delirium is not made.

Delirium can be caused by severe pain, pain medications, or can occur in a patient with advanced illness and organ failure who also happens to have pain. It can be challenging to distinguish between these different clinical scenarios. Almost invariably, delirium in the palliative setting is multifactorial in origin. In order to quantitate the pain, the patient's numeric rating of the pain should be dutifully recorded if possible, using tools that are intended for cognitively impaired individuals. Behaviors suggestive of pain should be sought, such as the patient grabbing the painful part of the body, the patient using other words to describe the pain, or the presence of a known destructive process in that region of the body.

Pain patients who develop delirium commonly describe a worsening of their pain, but the pain is often generalized to the whole body. In this situation, if all other potential causes of delirium have been ruled out or treated and opioids are being used, a trial of opioid dose reduction or rotation to a different opioid may be employed. Potentially reversible causes of delirium should be identified and treated, including a very wide array of possibilities such as hypercalcemia, along with hydration and other supportive measures to manage the delirium.[36] If there is clinical suspicion that the delirium may be caused by uncontrolled pain, a short-acting opioid should be considered as a test dose.

Pain and Nausea

Chronic nausea is a prevalent symptom in cancer patients, and opioids themselves can be emetogenic. Complicating this situation is the experience of patients who have both pain and nausea and are unable to take oral medications.

A wise approach to the presence of both pain and nausea is to assess each of them individually and treat any underlying cause. If there is any possibility that the opioid is causing or contributing to the nausea, this symptom should be treated aggressively and/or the patient should be rotated to a different opioid or to a nonopioid pain treatment strategy. As common as opioid-related nausea is, it is fortunate that this symptom is usually self-limiting, rarely necessitating discontinuation from opioid therapy. Alternative routes of administration, such as transdermal or injectable opioids, may need to be considered if the opioids are effective for pain but the patient cannot manage to take them by the oral route until habituation to this symptom occurs.

Pain and Anorexia/Cachexia/Asthenia

Anorexia/cachexia/asthenia is a common triad that accompanies many types of cancer, and when pain is also present, symptoms can be particularly difficult to manage. While fatigue is the most common symptom in cancer patients, affecting about 70% of patients, a large minority fulfill diagnostic criteria of anorexia with cachexia. Such patients may have difficulty tolerating opioids, may have concurrent nausea, or may not be able to tolerate oral opioids because of upper GI malignancy. Such patients require alternative routes of drug administration or other pain treatment strategies. Further, many interventions are available to support comprehensive assessment and management of anorexia, cachexia, and asthenia.

Pain and Bowel Disease

Slow-release opioids are about 50% absorbed in the large colon. Patients who have had a partial or complete colectomy may malabsorb slow-release opioids, as a function of the more rapid transit time. The clinician may be suspicious of this by the presence of end of dose failure of the opioid, occurring several hours before the medication would be expected to wear off. Patients may report seeing the "ghost" of slow-release tablets in their stool. Most patients who have a low colostomy (in the left lower quadrant on abdominal exam) only uncommonly malabsorb slow-release opioids, whereas patients with a right sided colostomy or ileostomy are at much higher risk. These patients should be considered for transdermal opioids or some other route of opioid administration.

Similarly, patients who have upper GI malignancy and pain can be anticipated to have nausea, obstruction, or other GI symptoms. At an early stage in their disease, they should be considered for another route of administration of analgesic medication.

Cancer Pain in the Addict

The overall strategy for pain management in the patient who carries an addiction diagnosis should be tempered according to

whether the history is that of remote addiction, recent addiction, or active addiction. It must be stated that use of controlled substances for any legitimate medical purpose requires vigilance and a risk management approach that considers diversion and abuse, irrespective of the patient's diagnosis or history. However, medical judgment must be used to determine the extent of such programs relative to the patient's individual circumstances. In all situations, the clinician will want to understand if the patient is in active recovery and/or maintenance therapy, communicate with the patient's addiction counselor/therapist, and look carefully for evidence of aberrant or problematic drug-taking behavior. The patient with a remote history of substance abuse and who currently has a stable social situation and a spouse or other close family member should be managed as any other cancer pain patient. However, these patients and their family members are oftentimes very concerned about rekindling addiction and may be highly opioid phobic. Long acting oral or transdermal opioids are the preference and the dose should be titrated upward to effect, with a structured management program (e.g., frequent follow-up visits, small supplies of medicine prescribed at any given time, urine drug screens) to provide sufficient support for the patient and family. A goal should be only one prescribing physician and, once stable analgesia is achieved, there should be sufficient confidence and evidence of compliance and increasingly longer periods of time between prescribing visits. To the patient who is a recent user and in recovery, the discussion needs to be more frank and the plan of care more structured. The clinician should outline the goals of care (improved comfort and improved function), but also inquire of the patient about their level of concern regarding opioids. The physician should warn the patient to not take the opioids for any reason other than relief of pain. Together, they should agree as to how often the medication prescriptions should be refilled and by whom. Comanagement with an addiction specialist is advised if the prescribing clinician is not strongly versed in addiction medicine. Unsanctioned dose escalation is not allowed, and if necessary, the medications may need to be controlled by the spouse or other family member.

Cancer patients who are actively abusing pose particular challenges. The patient and the clinician hope that the patient can achieve relief of pain but the prescribing physician will be particularly wary of causing harm. Harm includes the risk of drug diversion or overdosing because the patient is accustomed to a less potent source of drug. Also, there is the risk that the pain medication may be stolen by those around them because of the social circumstances that often accompany addiction. There needs to be a firm, concrete framework to support clinical care. In these situations, daily dispensing of pain medication is often required, along with observed ingestion. If transdermal fentanyl patches are prescribed, which may be useful in these circumstances, the patch should be replaced under observation and then either disposed of properly or the used patch may be brought to the next prescribing visit and disposed under observation of clinicians. Liquid methadone may also be preferable over other analgesics or formulations in this circumstance.

A written agreement delineates expected behavior and the consequences of nonadherence. The agreement (sometimes referred to as an "opioid contract") should include periodic unscheduled drug screening if the patient has committed to not use other drugs. In certain jurisdictions, the prescribing physician can benefit from a state computerized prescription network whereby it can be determined if the patient is obtaining prescription medications from another legitimate source. One should avoid high doses of opioids and should also consider nonpharmacologic interventions at an earlier stage (such as palliative radiotherapy or neural blockage).

Symptom Clusters

Cancer patients commonly have more than one symptom. A large survey of medical oncology inpatients and outpatients from a U.S. Veterans Affairs medical center revealed that most had several symptoms, including low energy (62%), pain (59%), dry mouth (54%), shortness of breath (50%), and sleeping difficulty (45%).[37] Patients with "moderate" intensity pain had a median number of 11 symptoms, and as the performance status fell, the number of intense symptoms increased.[37] Other studies have confirmed that cancer patients commonly have many distressing symptoms, and as the severity of disease increases so does the number and severity of symptoms.[38]

More recently, the concept of symptom clusters has emerged as an area of intense research. Symptom clusters have been defined as three or more concurrent symptoms that are related to each other but do not necessarily share the same etiology.[39] There is evidence that the coexistence of several symptoms in the same patient is associated with worse quality of life and potentially will benefit from specific, targeted therapeutic approaches. For example, it has been suggested that release of cytokines may result in a range of symptoms related to cancer and its treatment.[40] A wide array of specific clusters has been reported. Examples posited to date include fatigue-anorexia-cachexia cluster (easy fatigue, weakness, anorexia, lack of energy, dry mouth, early satiety, weight loss, and taste changes), upper GI cluster (dizzy spells, dyspepsia, belching, bloating), neuropsychologic cluster (sleep problems, depression, and anxiety), and others.[41] Further research is needed to confirm their existence as discrete nosological entities, to delineate their underlying pathogenesis and connectedness, and to explore mechanism-based approaches to their management.[3,42,43]

Pain at the End of Life

In the final hours of life, it may not be appropriate or there may not be sufficient time to obtain a detailed history, physical examination, and diagnostic studies in order to quickly obtain relief of distressing symptoms. The actual mechanism of pain becomes increasingly less relevant as death approaches. In the instance of severe pain, one would consider subcutaneous or intravenous opioids with rapid titration to effect. Severe regional pain such as abdominal, pelvic, or lower extremity pain can be managed with neuraxial (epidural, intrathecal) local anesthetics or opioids. In a pain crisis at the end of life, the patient may be a candidate for palliative sedation.[44] Palliative sedation is appropriate when the patient is aware that they are at the end of life, other interventions are not expected to relieve pain quickly enough, and the patient or family has given their informed consent. Assessment tools that have been developed to guide the depth of sedation, such as the Ricker scale, can be used.[45] These issues are discussed further in Chapter 108.

Cancer Pain Emergencies

Occasionally, patients will present to their physician with persistent, horrible cancer pain. A cancer pain emergency has been defined as pain that is severe or excruciating (8 out of 10 on a 0 to 10 scale), for more than 6 hours.[46] Such patients typically come to an emergency room in great distress. The patient may already be on large doses of opioids, and may be dehydrated due to limited oral intake during the previous days. Often the patient will not have slept at all during that time. In such cases, the patient assessment is greatly truncated. The physician examines the patient quickly to determine whether there is evidence of a ruptured viscous, subarachnoid hemorrhage, ischemic crisis, or other catastrophe. Vital signs and cognitive status are monitored, and an intravenous access is secured. Opioid is administered with rapid upward titration using a mini bolus technique until there is relief of pain. Intravenous protocols for cancer pain emergencies have been described for morphine[46] and fentanyl,[47] and

transdermal and other routes of administration of opioids have also been described.[48] Unlike conscious sedation, rapid upward titration of opioid in the setting of unrelieved cancer pain almost never results in serious toxicity. Patients appear to be able to leave the emergency room an hour or few hours after obtaining relief of pain. Only uncommonly will the cause of the cancer pain emergency be apparent. Typically the flare of pain arises in a place of known metastatic disease and the pain goes away as mysteriously as it came.

CONCLUSION

Cancer pain is common and, when present, is often severe. Fortunately, a great deal is known about its epidemiology, assessment, and management. An individualized approach to each patient offers the best opportunity to provide relief of pain and improve the quality of life at all stages of oncologic disease.

CHAPTER 42 ■ MECHANISMS, ASSESSMENT, AND DIAGNOSIS OF PAIN DUE TO CANCER

DERMOT R. FITZGIBBON

INTRODUCTION

Cancer is a major public health problem in the United Sates and other developed countries, and pain is a very common problem associated with cancer. This chapter will review the incidence, prevalence, etiologies, and assessment strategies in cancer-related pain syndromes.

One in four deaths in the United States is due to cancer. The lifetime probability of developing cancer is higher for men (45%) than for women (38%), but women have a higher probability of developing cancer before age 60 because of the relatively early age of breast cancer onset. Recent notable trends in cancer incidence and mortality rates include stabilization of the age-standardized, delay-adjusted incidence rates for all cancers combined in men from 1995 through 2003, a continuing increase in the incidence rate by 0.3% per year in women, and a 13.6% total decrease in age-standardized cancer death rates among men and women combined between 1991 and 2004.[1]

Among men, cancers of the prostate, lung and bronchus, and colon and rectum account for about 54% of all newly diagnosed cancers. Prostate cancer alone accounts for about 29% of incident cases in men. Based on cases diagnosed between 1996 and 2002, an estimated 91% of these new cases of prostate cancer are expected to be diagnosed at local or regional stages, for which 5-year relative survival approaches 100%. The three most commonly diagnosed types of cancer among women in 2007 were cancers of the breast, lung and bronchus, and colon and rectum, accounting for about 52% of estimated cancer cases in women. Breast cancer alone accounts for 26% (178/480) of all new cancer cases among women. Approximately 559,650 Americans die from cancer, corresponding to over 1,500 deaths per day. Cancers of the lung and bronchus, prostate, and colon and rectum in men, and cancers of the lung and bronchus, breast, and colon and rectum in women continue to be the most common fatal cancers. These four cancers account for half of the total cancer deaths among men and women. Lung cancer surpassed breast cancer as the leading cause of cancer death in women in 1987. Lung cancer accounts for 26% of all female cancer deaths in 2007. Lung cancer incidence rates are declining in men and appear to be reaching a plateau in women after increasing for many decades. Colorectal cancer incidence rates decreased from 1998 through 2003 in both males and females. Female breast cancer incidence rates leveled off from 2001 to 2003 after increasing since 1980, which may reflect the saturation of mammography utilization and reduction in the use of hormone replacement therapy. Death rates for all cancer sites combined decreased by 1.6% per year from 1993 to 2003 in males and by 0.8% per year in females from 1992 to 2003. Mortality rates have continued to decrease across all four major cancer sites in men and in women, except for female lung cancer in which rates continued to increase by 0.3% per year from 1995 to 2003.[1]

There have been notable improvements over time in relative 5-year survival rates for many cancer sites and for all cancers combined. This is true for both Caucasians and African Americans. Cancers for which survival has not improved substantially over the past 25 years include uterine corpus, cervix, larynx, lung, and pancreas. For all sites of cancer (excluding basal and squamous cell skin cancers and in situ carcinomas except urinary bladder) between 1996 and 2002, the relative survival rate was 66%.[1] A National Institutes of Health (NIH) Consensus Conference on symptom management in cancer estimated that approximately 60% of patients will survive at least 5 years after diagnosis.[2] As the number of cancer survivors continues to grow, the need to address persisting symptoms and impairments due to cancer and related treatments on individuals' lives becomes increasingly important.

Prevalence data of pain in patients with cancer range from 24% to 60% in patients on active anticancer treatment[3,4] and 62% to 86% in patients with advanced cancer.[5–7] Van den Beuken-van Everdingen et al.[8] reported pain prevalence in patients with cancer according to disease stage, treatment, and survival: 64% (confidence interval [CI] 58% to 69%) in patients with metastatic, advanced, or terminal disease, 59% (CI 44% to 73%) in patients on anticancer treatment, and 33% (CI 21% to 46%) in patients who had been cured of cancer.

Some important differences exist between cancer pain patients and those that experience acute pain and/or chronic noncancer pain. Although all types of persistent pain elevate psychological distress,[9–11] alter social life,[12] disturb sleep,[13] and compromise enjoyment of life,[14] end-of-life considerations and palliative care are rarely major issues for acute and chronic noncancer pain conditions. These concerns become extremely important for the cancer pain patient with advanced disease (see Chapter 108). The complexities that emerge from the medical and psychosocial aspects of the situation necessitate a multi- and/or interdisciplinary approach to care that requires skill and sensitivity to these issues. The oftentimes rapidly changing nature of cancer pain, either in response to treatments directed at the tumor and/or progression of the tumor, mandates vigilance and potential frequent alteration of treatment strategies for pain. In addition, cancer survivors face ongoing surveillance for the possibility of disease recurrence and therefore new or changing pain complaints in these patients require careful reassessment.

As cancer treatments continue to improve survival, many oncology patients face long-term pain management issues from aggressive treatment of their disease. Different treatment strategies need to be considered when life expectancy may be decades, rather than months or years. Comprehensive cancer care requires that many health care professionals become involved with the cancer pain patient at any specific time. Similarly, successful pain management requires that those involved in cancer care support an interdisciplinary approach.

There exist several medical, psychologic, social, and cultural issues that complicate cancer pain and its management. The interaction of pain and its treatment with other common cancer symptoms such as fatigue, weakness, dyspnea, nausea, constipation, and impaired cognition magnifies the negative impact of cancer pain.[15,16] Cancer patients treated on an outpatient basis frequently have pain that is inadequately controlled, with 67% of

outpatients (871 of 1308 patients) indicating that they had pain or had taken analgesic drugs daily during the preceding week, while 36% had pain severe enough to impair their ability to function.[17] Patients seen at centers that treated predominantly minorities were three times more likely than those treated elsewhere to have inadequate pain management[18] due to inadequate pain assessment, patient reluctance to report pain, and lack of staff time for pain management.[19]

ISSUES IN ASSESSMENT AND DIAGNOSIS OF CANCER PAIN

Studies from the 1990s documented inadequate treatment of pain in patients with cancer.[17,18,20,21] Despite the subsequent availability of effective pain treatments and various pain management guidelines, these deficiencies continue both in the United States and in other countries.[22–26] The most frequently identified barriers to effective management are physician underestimation of the patient's pain, inadequate pain assessment, and patient reluctance to report pain. Experienced physicians and professional organizations recognize a need for significant improvement in cancer pain assessment and treatment.[27,28] Lack of expertise by clinicians in assessing and managing cancer pain has been cited as an important cause of poor pain control.[29] Interviews of practicing physicians demonstrate knowledge deficits in the basic principles of cancer pain management.[30] Similar findings are demonstrated in nurses and nursing students.[20,31,32] Educational interventions can successfully improve cancer pain knowledge and attitudes of health care professionals.[33] However, medical education does not adequately prepare students and residents to provide adequate care for the cancer pain patient.[34,35]

In general, pain management requires a variety of assessment skills and the integration of knowledge about biobehavioral contributions to experience of pain, pharmacologic, and nonpharmacologic approaches to pain control. More specifically, safe and effective pharmacotherapy requires detailed knowledge of analgesic pharmacokinetics and pharmacodynamics, patient characteristics like individual variability and compliance with medications, side effects, and quality of life determinants. Cancer pain assessment also requires additional disease-specific knowledge of toxicities and likely outcomes of treatments. These skills must contribute to clinical judgment and decision-making, often requiring substantial individual experience.

Most studies concerning pain education of undergraduate medical students focus on knowledge, but little is known about their interviewing and pain evaluation skills. Leila et al.[36] suggested that formative assessment of both knowledge and communication skills is essential for the development of an effective pain curriculum for training medical students in pain management of chronic pain patients. Lasch et al.[37] demonstrated that for postgraduate nurses, day-long cancer pain education workshops were as effective as hands-on experience in improving cancer pain knowledge and changing attitudes. Computer simulation software may create a tool that can teach the principles and applied practice of cancer pain assessment and management, no less provide the ability to efficiently assist in the identification of specific errors in knowledge, judgment, and practice patterns of the individual.[38] Regardless of means, it can be concluded that significant improvements in pain assessment and management education are needed at all training levels and for those engaged in oncology practice in order to advance the field and assure quality care of cancer patients at all stages of disease.

PAIN AND THE CANCER PATIENT

Because pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage,[39] the sensory features and subjective qualities of pain vary, depending on its origin. Its emotional features depend in part upon the social and physical context in which pain occurs, associated cognition, and the meaning of tissue trauma for the individual, but they are almost always negative.

Sensory Component of Cancer Pain

From a sensory perspective, tumor-associated pain may be classified as nociceptive, neuropathic, or mixed. Pain is labeled nociceptive if the sustaining mechanism is believed to be related to ongoing tissue injury and is subdivided into somatic and visceral types. Pain is neuropathic if there is evidence that the pain is associated with injury to neural tissues and is sustained by aberrant somatosensory processing in the periphery or in the central nervous system. Caraceni and Portenoy[40] reported in an international survey of cancer pain characteristics and syndromes that pain inferred by the treating clinician to be nociceptive and due to somatic injury occurred in 71.6% of patients, nociceptive visceral in 34.7%, and neuropathic mechanisms occurred in 39.7%. Somatic nociceptive pain may be grouped into superficial (cutaneous) and deep. Most cutaneous pain is well-localized, sharp, pricking, or burning. Deep tissue pain usually seems diffuse and dull or aching in quality. Visceral pain is very diffuse, often referred to the body surface, perseverating, and frequently associated with a queasy quality that patients describe as "sickening."

The mechanisms of tumor involvement of the peripheral nervous system are heterogeneous and include local invasion, compression, direct infiltration, perineurial spread and rarely intraneural metastasis.[41] Compression and invasion of nerves by tumor results in the destruction of myelinated and unmyelinated fibers and of supporting tissue. Since peripheral nerves can usually evade pressure from a tumor on one side, infiltration by tumor tissue is the quintessential tissue trauma stimulus. In addition, indirect damage of unknown pathogenesis might also occur to peripheral nerves in the context of certain malignant conditions (e.g., paraneoplastic syndromes). Infiltration of tumor tissue into the perineural cleft is seen relatively often. However, this does not regularly lead to pain.[42] A massive and then painful entrapment of the nerve plexus or individual nerves occurs, especially in extensive breast carcinomas and their recurrences or in chest wall metastases of lung tumors. The perineural cleft widens tumor infiltration, and infiltration of the tumor into the nerve itself is common. Degenerative changes of the axis cylinders are sometimes visible with conventional histopathology screening methods. Primary tumors of the peripheral nerves themselves lead to painful destruction.

Compression regularly elicits pain when the affected nerve cannot give way, for example, a spinal nerve root. The process of tumor compression and invasion of nerves entails several degenerative, regenerative, and other pathophysiologic processes.[43] The whole afferent neuron is affected and goes through reactive, presumably reparative, biochemical changes. The neuron loses its neuropeptides,[44] atrophies, and may finally degenerate. This applies particularly to unmyelinated afferent neurons. The conditions in a nerve, when invaded or compressed by cancerous tissue, are probably similar to those after lesions of nerves induced by mechanical or other events. The process induces changes in the discharge properties of neurons (resting activity, response to mechanical and chemical stimulation).

Molecular Mechanism of Tumor Pain

In addition to cancer cells, tumors consist of different cell types including inflammatory cells and blood vessels that are often adjacent to primary afferent nociceptors. These cells include immune system cells such as macrophages, neutrophils, and T cells. These secrete various factors that sensitize or directly excite pri-

mary afferent neurons and include prostaglandins, tumor necrosis factor, endothelins, interleukin-1 and -6, epidermal growth factor, transforming growth factor, and platelet-derived growth factor. Receptors for many of these factors are expressed by primary afferent neurons. Endothelins (endothelin-1, -2, and -3) are a family of vasoactive peptides that are expressed at high levels by several types of tumor, including prostate cancer. Endothelins could contribute to cancer pain by directly sensitizing or exciting nociceptors as a subset of small, unmyelinated primary afferent neurons that express endothelin-A receptors.[45] Like prostaglandins, endothelins that are produced by cancer cells are also thought to be involved in regulating angiogenesis and tumor growth.[46] Consequently these factors and others from cancer and inflammatory cells, such as adenosine triphosphate, bradykinin, H^+, nerve growth factor (NGF), prostaglandins, and vascular endothelial growth factor excite or sensitize adjacent nociceptors.[47] Adjacent nociceptors such as vanilloid receptor-1 (VR1) detect extracellular H^+ and endothelin-A receptors detect endothelins released by cancer cells. NGF released by macrophages binds to the tyrosine kinase receptor TrkA.[48] Nociceptor activation results in the release of neurotransmitters, such as calcitonin gene-related peptide (CGRP), endothelin, histamine, glutamate, and substance P. Nociceptor activation also causes the release of prostaglandins from the peripheral terminals of sensory fibers, which can induce plasma extravasation, recruitment and activation of immune cells, and vasodilatation.

Other mechanisms, particularly tissue acidosis, may be involved in tumor-related pain. There are several mechanisms by which tumors could cause a decrease in pH. As inflammatory cells invade the neoplastic tissue, they release protons that generate local acidosis. The large amount of apoptosis* that occurs in the tumor environment also contributes to acidosis, as apoptotic cells release intracellular ions to create an acidic environment. This drop in pH can activate signaling by acid-sensing channels (including VR1) that are expressed by nociceptors. Tumor-induced release of protons and acidosis might be particularly important in the generation of bone cancer pain.[49] Finally, tumor-induced distention of sensory fibers may also be involved in tumor-associated nociceptive processes. Tumors are not highly innervated by sensory neurons.[50] Rapid tumor growth frequently entraps and injures nerves causing mechanical injury, compression, ischemia, or direct proteolysis. Proteolytic enzymes that are produced by the tumor cells can also cause injury to sensory and sympathetic fibers, causing neuropathic pain.

Muscle-Related Pain

Muscle-related pain may occur in a variety of settings and frequently occurs in oncology patients.[51] Because inactivity and deconditioning predisposes to muscle pain, the debilitated cancer patient may experience muscle pain. Myofascial pain syndrome (MPS) may occur independently of malignancy, or it may develop as a result of tumor-related tissue changes or treatment-related influences on soft tissues, for example, surgery and radiation therapy. The key is to identify and treat active trigger points and distinguish MPS from other pain mechanisms in the active and posttreatment cancer patient (see Chapter 35).

Muscle pain is generally described as aching and cramp-like. It can be difficult to localize and may be referred to other deep somatic structures. Muscle nociceptors are activated by tissue-threatening stimuli (pressure, ischemia), which can result in the release of local algesic substances such as bradykinin (BK), serotonin (5HT), and potassium (K^+). Kallidin found in plasma protein splits to form BK under pathological environmental changes such as ischemia, lowered pH, and blood clotting. Following vascular damage, 5HT is released and muscle damage releases K^+. C-nociceptors, when stimulated, release somatostatin, CGRP, and substance P in the dorsal horn resulting in substance P-mediated histamine release from mast cells, causing vasodilation and increased vessel permeability releasing more BK, 5HT, and prostaglandin E2. CGRP may inhibit degradation of substance P in muscle nociceptors.

Affective Processing and Suffering

Suffering, beyond—but amplified by—the sensory dimensions of the pain experience, is not unique to cancer patients (see Chapters 7, 29, 31, 81, and 83). Suffering related to cancer is inherently emotional, unpleasant, complex, and enduring. In some patients, it often has the additional existential (or spiritual) dimension of dealing with imminent mortality.

Treating clinicians must recognize that, although suffering may be a consequence of pain, it is separate from pain and not a synonym for it. It differs from pain in that it entails additional cognitive affective states. For example, perceived helplessness (inability to cope, bankruptcy of physical, psychological, or social resources) is a key element in the suffering of most patients with incurable disease. Similarly, grief can ensue when a cancer patient perceives the loss of a psychological or social resource, a body part or desired personal appearance, a prized employment status, or a physical capability for a treasured activity. Loss often equates with perceived threat to self. In addition, suffering in the cancer patient sometimes involves a sense of separation from social support or alienation. These factors, combined with the emotional distress, fatigue, and stress associated with prolonged pain and the rigors of oncologic treatment produce a complex state that differs from manifestations of chronic pain in other patient populations. For example, Wilson et al.,[52] in a study of 381 patients with advanced cancer, found that 25% of patients were suffering at a moderate to extreme level and concluded that suffering is a multidimensional experience related most strongly to physical symptoms, but with contributions from psychological distress, existential concerns, and social–relational worries.

Psychological Factors, Depression, and Fatigue

Somatization refers to patients who transform distress and global suffering into pain and symptom expression, and health care providers frequently view pain reported by cancer patients as primarily somatogenic, whereas chronic noncancer pain in patients who lack adequate objective physical pathology is viewed as psychogenic.[53] Consequently, providers tend to treat cancer pain with pharmacologic, medical, or surgical modalities. Psychological factors are considered to be of secondary importance.[54]

As stated above, regardless of cause, but especially when unremitting, pain is a complex experience entailing physiological, sensory, affective, cognitive, and behavioral components. The final individual perception of pain is dependent on nociceptive input and psychological modifiers such as fear, anxiety, anger, and depression (Fig. 42.1).

Turk et al.[53] classified the multidimensional nature of cancer pain. They compared the adaptation of cancer patients and chronic noncancer patients to persisting pain. The majority of the cancer patients, both with (81%) and without (84%) metastatic disease, as well as the noncancer chronic pain patients (85%), fit one of three psychosocial subgroups: dysfunctional (high levels of pain, perceived interference, affective distress, and low levels of perceived control and activity), interpersonally distressed (high levels of affective distress, negative responses from significant others, and low levels of perceived support), and adaptive copers (low levels of interference and affective distress, high levels of perceived control and activity).

* Apoptosis is a form of cell death necessary to make way for new cells and to remove cells whose DNA has been damaged to the point at which cancerous change is liable to occur.

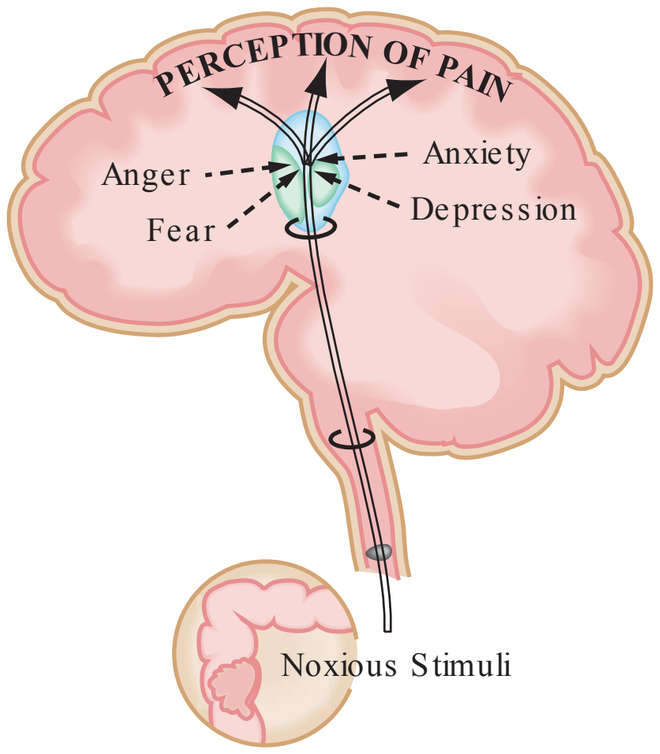

FIGURE 42.1 Individual perception of pain. Noxious stimuli are modified at supraspinal level by emotions such as anxiety, fear, and anger.

Substantial evidence suggests that psychological factors play an important role in exacerbating pain with clear origins of disease (see Chapters 29–33). For example, the belief that pain signifies disease, a commonly held belief among cancer patients,[55] is associated with elevated pain intensity.[14,56] Speigel and Bloom[56] also reported that the affective states of cancer patients, the belief that pain is an indicator for disease progression, and medication use all predict pain severity. Patients who attribute their pain to a warning of underlying disease report greater pain than patients with more nontumor-associated interpretations, despite comparable levels of disease progression.

Because of psychological factors, the relationship between pain severity and the extent of disease is rarely as linear as one might assume.[57] Research investigating the relationships between physical pathology and pain in cancer has shown inconsistent results. In one evaluative study, Twycross and Fairfield[58] reported that only 41 of 100 terminal-stage cancer patients reported pain due to disease, whereas Cleeland et al.[59] reported that the majority of patients with end-stage disease have pain of a severity that interferes with several aspects of the patient's quality of life. Front et al.[60] demonstrated that for many cancer patients, pain reports did not correspond to the presence or location of bone metastases. Turk et al.[53] found that patients with cancer-related pain reported a significantly higher level of perceived disability and inactivity due to pain than did those with pain of noncancer origin. Since the level of pain severity was comparable for the two patient groups, elevated disability may have been a consequence of the meanings patients attributed to their pain. The progression of malignant disease means further deterioration of health and impending death. Indeed, the patients with cancer-related pain appeared to be more fearful of pain and reported significantly higher levels of cognitive and behavioral fear-responses than did the patients with chronic pain not associated with cancer. These patients appeared to think and worry more about pain, avoid activities in order to prevent initiation of pain, and they generally felt more hopeless than the patients with noncancer-related pain.

The severity of depression is correlated with pain, anxiety, disease type, and other health-related quality of life issues.[61] The interactions between cancer pain, insomnia, fatigue, and depression/anxiety are complex, warranting treatment plans that focus not only on the relief of specific symptoms to improve quality of life but also on the impact of treatment on other related symptoms. Certain cancer types are highly associated with depression and include oropharyngeal (22%–57%),[62] pancreatic (33%–50%),[63] breast (1.5%–46%),[64] and lung (11%–44%).[65,66] A less high prevalence of depression is reported in patients with other cancers, such as colon (13%–25%),[67] gynecological (12%–23%),[68,69] and lymphoma (8%–19%).[70,71]

TABLE 42.1

CONSEQUENCES OF PAIN AND DEPRESSION IN CANCER PATIENTS

Impact	Comment
Suffering	Significant contribution particularly when major organic disease is present
Medical evaluation and decision-making	Depressive symptoms can complicate
Outcome and survival	Depressive disorders can adversely affect
Recovery and compliance	Depressed medically-ill patients tend to have slower recovery and poorer compliance
Suicide	Undetected and untreated depression can lead to suicide
Pain	Poorly managed pain is a common cause of reactive depression in patients with severe, life-threatening disease

It is important for the physician treating cancer pain to recognize and address depression (Table 42.1). Screening for depression should focus primarily on the cognitive/affective features of depression because these are not confounded with treatment-associated toxicities. In palliative care patients, several studies have found that the single question "Are you depressed?" was the screening tool with the highest sensitivity and specificity and positive predictive value.[72,73] Untreated, depression has a significant impact on patient quality of life, health care utilization, and even disease outcome.

SOURCES OF PAIN IN THE CANCER PATIENT

Most cancer pain results from one or more of three fundamental causes (Table 42.2):

TABLE 42.2

CAUSES OF PAIN IN PATIENTS WITH CANCER

Cause	Example
As a direct consequence of tumor	Involvement of bones Obstruction of hollow organs Compression of nerves
As an indirect consequence of tumors	By infections By metabolic imbalances By venous/lymphatic occlusion
As a consequence of tumor therapy	Following surgical intervention Following chemotherapy Following radiation therapy
Without relation to cancer	Migraine Diabetic neuropathy Myofascial pain problems

- direct tumor involvement
- cancer-directed therapy
- mechanisms unrelated to cancer or its treatment

Patients may present with complex patterns of pain that result from combinations of these categories, thus complicating the diagnosis. Factors influencing the pain complaint include the primary tumor type, stage of disease, tumor site, and mood factors (anxiety and depression).[11,74,75]

Many patients with advanced disease frequently have multiple pain complaints at different sites and were more common in patients with breast, lung, and prostate cancer compared with gastrointestinal cancers.[74] In a prospective study of 2266 cancer patients, Grond et al.[76] assessed localization, etiology, and pathophysiologic mechanisms of pain syndromes associated with cancer. Thirty percent of the patients presented with one, 39% with two, and 31% with three or more distinct pain syndromes. The majority of patients had pain caused by cancer (85%) or antineoplastic treatment (17%); 9% had pain related to cancer disease and 9% due to etiologies unrelated to cancer. These investigations classified pain as originating from nociceptors in bone (35%), soft tissue (45%) or visceral structures (33%), or of neuropathic origin (34%). Patients localized pain syndromes in the lower back (36%), abdominal region (27%), thoracic region (23%), lower limbs (21%), head (17%), and pelvic region (15%). Regions and systems affected by the main pain syndrome varied widely depending on the site of cancer origin, whereas the cancer site did not markedly influence the pain's temporal characteristics, intensity, or etiology.

Although a significant association exists between most cancer pain and the presence of metastases, certain tumor types are exceptions, notably breast and prostate cancers. Neither the prevalence nor the severity of pain among breast cancer patients varies directly as a function of metastatic sites of disease.[56,59] Palmer et al.[77] evaluated the sensitivity of pain as an indicator of bone metastases in patients with breast or prostate cancer. Pain was a common finding, whether or not metastatic disease was present, and it occurred in over half of the patients. Although most patients with bone metastases reported bone pain, 21% of breast and 22% of prostate patients were asymptomatic.

Cancer-directed therapy pain syndromes may result from chemotherapy and radiation therapy (see Chapter 48) or surgery. Steroid use is common in cancer care, and pain due to osteonecrosis is a well-described complication of steroid use. Morbidity is related to progressive joint damage, often leading to decreased range of motion, pain with movement, and arthritis. Weight-bearing joints are most commonly involved and the disease often requires joint replacement to restore function and relieve pain. The shoulder, elbow, wrist, hand, and vertebral bodies can also be involved. Osteonecrosis typically develops within 3 years of steroid treatment. Osteonecrosis or avascular necrosis may occur as a complication of either intermittent or continuous steroid treatment. It most commonly involves the femoral head and presents with pain in the hip, thigh, or knee that is worse with movement, with or without localized tenderness. Humeral head disease presents similarly with pain in the shoulder, upper arm, or elbow. It may occur in any bone in the body. Focal osteonecrosis may mimic bone tumor and may result from steroid therapy as well as radiation and chemotherapy. There is little correlation between the degree of bone involvement and the intensity of associated pain.

Cancer patients and, in particular, cancer survivors may experience chronic nontumor-related pain. The challenge for the treating clinician is to distinguish between tumor-associated and nontumor-associated pain. Many of the same interdisciplinary treatment paradigms apply to cancer survivors as apply to all chronic pain patients. These findings indicate that pain associated with cancer and its treatment poses a substantial management challenge for the physician. Pain can change over time, involve multiple sites, stem from several origins, involve several causes simultaneously, and may correspond loosely or not at all to the tumor.

Several schemata exist for classifying and evaluating pain in the cancer patient and are potentially useful for diagnosis and management; refer to Chapter 41 for additional perspectives.

Influence of Tumor Type

Factors influencing the pain complaint include the primary tumor type, stage of disease, tumor site, and mood factors such as anxiety and depression.[11,74,75] When metastatic disease appears, approximately 1 in 3 patients report significant pain. As discussed above, although pain tends to reflect the presence of metastases, this may not always be the case for certain tumor types, particularly for patients with breast or prostate cancers. The prevalence and severity of pain among breast cancer patients does not appear to vary directly as a function of metastatic sites of disease.[56,57]

Pain caused by tumor may occur at the onset of disease or at an advanced stage. Although pain can be one of the early indicators of the onset of disease, pain is not a significant problem for the majority of patients in the early stages of disease, with 5% to 10% of patients with solid tumors reporting pain at a level that interferes with mood and activity. However, when it does occur, pain is often the chief concern that prompts the patient to seek medical consultation. Vuorinen et al.[78] found that 28% of newly diagnosed cancer patients reported pain. Daut and Cleeland[14] found that pain was an early symptom of cancer in 40% to 50% of patients with cancer of the breast, ovary, prostate, colon, and rectum, and in about 20% of patients with cancer of the uterus and cervix.

Knowing the natural history of the disease facilitates an understanding of the pain process and is important in determining the nature and timing of treatment. Following are descriptions of the more common pain-producing malignant diseases.

Pancreatic Cancer. Over the past 20 years, the incidence of pancreatic carcinoma in Europe and North America has remained unchanged, with an estimated 9–10 cases per 100,000 and slightly increased male:female and black:white ratios. Pancreatic cancer currently ranks as the fifth most common cause of cancer-related deaths in western countries.[79] About 90% of pancreatic tumors are adenocarcinomas with a ductal phenotype. Neuroendocrine tumors and acinar cell carcinomas represent about 2% to 5% of all pancreatic tumors. Local tumor extension almost invariably involves the peripancreatic fat tissue through direct invasion of lymphatic channels and perineural spaces. Duodenum, stomach, gallbladder, and peritoneum are infiltrated by tumors located in the pancreatic head; body and tail tumors can invade liver, spleen, and left adrenal gland. Lymphatic spread to adjacent and distant lymph nodes seems to precede hematogenous spread, which affects, in descending order, liver, peritoneum, lungs, adrenals, kidneys, bones, and brain. Thirty to 60% of patients experience pain with early, relatively limited disease and over 80% of those with advanced disease have pain.[80,81]

A number of factors contribute to the generation and maintenance of pancreatic cancer pain. Pancreatic cancer is associated with extensive macrophage infiltration.[82] Macrophage infiltration is associated with upregulation of NGF which is associated with both the extent of perineural invasion of the tumor and pain intensity.[83] Given the massive increase in inflammatory and immune cells that are known to occur as pancreatic cancer progresses and that these cells contribute to a variety of pain states, it is likely that macrophages and other inflammatory or immune cells play a role in the initiation and maintenance of pancreatic cancer pain. A second group of mechanisms that may be involved in pancreatic cancer pain is the apparent sprouting (in precancerous and early stage pancreatic cancer) and then destruction (in

late stage disease) of sensory and sympathetic fibers that innervate the pancreas. With disease progression, there is a clear increase in the density of CGRP sensory fibers.[84] This increase in density of CGRP expressing fibers may represent NGF-induced sprouting, with the origin of NGF being the macrophages. With disease progression, the central area of head, body, and tail of the pancreas, where significant sprouting of CGRP fibers had previously richly innervated, gradually becomes necrotic, resulting in destruction of the distal ends of the sensory and sympathetic fibers that had innervated these regions of the pancreas.[84] As damage to even the distal ends of peripheral nerves can generate a significant neuropathic pain state, these processes of extensive sprouting and destruction of sensory and sympathetic fibers may contribute to the sensitization and activation of nerve fibers innervating the pancreas.

Pain due to pancreatic cancer is usually abdominal, typically referred to the epigastric region or the upper abdominal quadrants, but it can also involve the lower quadrants or be diffuse.[85] Back pain is associated with abdominal pain in 50% to 65% of cases, but only 5% to 10% of patients report it as their only complaint.[86] In one series, 67% of patients could not describe their pain location better than as over their "diffuse abdomen."[86] Direct infiltration of pancreatic afferent nerves, pancreatic duct obstruction with retention pancreatitis, biliary obstruction, or duodenal infiltration resulting in bowel obstruction can generate pain. Eating often aggravates the pain. Tumors of the head of the pancreas may cause epigastric pain with right flank radiation more often, whereas pain from tumors in the tail has left-sided radiation.[87] Back pain in the region of T10–L2 is very common and is the first symptom in 10% to 30% of cases. Lying flat typically exacerbates it and sitting relieves it. This pain probably comes from retroperitoneal tumor involvement, and it may not respond to celiac plexus block (see Chapter 44). It often merges with similar syndromes caused by nodal or other soft-tissue tumor involvement in the retroperitoneal region (Table 42.3). The impact of pancreatic pain can be profound. It is commonly associated with depressed mood and contributes to the rapid decline in function that characterizes this disease.[86,88]

Complete surgical resection is the only potentially curative treatment available. However, 5-year survival is only 10% to 20%. To be resectable, tumors must show no evidence of extrapancreatic disease or direct tumor extension to the celiac axis and superior mesenteric artery, but evidence of nonobstructive superior mesenteric-protal vein confluence does not always preclude tumor resection. Optimal symptomatic treatment has a prime role in the management of metastatic disease. This may require stenting or bypass surgery for obstructive jaundice or gastric outlet/duodenal obstruction.

Ovarian Cancer. The three categories of ovarian cancer are named for their cell of origin. Ninety percent of ovarian cancers arise from cells that make up the epithelial layer that covers the surface of the ovaries. The other 2 types are germ cell tumors and stromal tumors. Stromal tumors arise in the hormonally active elements within the connective tissue stroma of the ovary. Germ cell tumors and stromal tumors each account for approximately 5% of ovarian cancers. Epithelial cancer of the ovary is the most lethal gynecologic malignancy in the United States, with approximately 22,000 new cases and 16,000 deaths occurring annually. The lifetime risk of ovarian cancer in women with a germline mutation in the gene *BRCA1* approaches 40%, whereas in women with germline mutations in *BRCA2*, the lifetime risk ranges from 10% to 20%.The symptoms of ovarian cancer are fairly nonspecific and often occur when the disease is already spread throughout the abdominal cavity. Abdominal discomfort or vague pain, abdominal fullness, bowel habit changes, early satiety, dyspepsia, and bloating are frequent presenting symptoms. Occasionally, patients may present with bowel obstruction due to intra-abdominal masses or shortness of breath due to pleural effusion. Early-stage disease is usually asymptomatic, and

TABLE 42.3

PANCREATIC CANCER PAIN SYNDROMES

Pain due to tumor involvement	Pain due to cancer therapies
Visceral pain: Pancreatic gland infiltration Gastric infiltration Duodenal infiltration Liver metastases: capsule distention, diaphragmatic irritation Biliary tree distention Bowel obstruction (duodenal, peritoneal carcinomatosis) Ischemic abdominal pain due to mesenteric vessel involvement	Postoperative pain syndromes: Delayed gastric emptying Wound dehiscence or nonhealing
Somatic pain: Retroperitoneal involvement (direct, nodal) Parietal peritoneum and abdominal wall involvement Abdominal distention due to ascites Bone metastases	Biliary prosthesis complications
Neuropathic pain: Radiculopathy from retroperitoneal spread or bone metastatic involvement Lumbosacral plexopathy Epidural spinal cord compression	Postchemotherapy pain syndromes: Liver chemoembolization Mucositis Postradiation pain syndromes: Radiation enteritis

From Caraceni A, Portenoy RK. Pain management in patients with pancreatic carcinoma. *Cancer* 1996;78 (3 suppl):639–653. Copyright 1996 American Cancer Society. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

the diagnosis is often incidental, although such patients may occasionally present with dyspareunia or pelvic pain due to ovarian torsion. Serum CA-125 level has been widely used as a marker for a possible epithelial ovarian cancer in the primary assessment of a pelvic mass. In this setting, false-positive results may derive from several conditions, especially those associated with peritoneal inflammation, such as endometriosis, adenomyosis, pelvic inflammatory disease, menstruation, uterine fibroids, or benign cysts. Malignancies other than ovarian cancer can also increase CA-125 levels, but the most marked elevations (>1500 U/mL) are generally seen with ovarian cancer. Cytoreductive surgery is the cornerstone of the initial treatment of patients with advanced ovarian cancer. Although the majority of patients with ovarian cancer achieve a clinical complete remission with first-line chemotherapy, disease will recur in most. Overall, the 5-year survival rate for patients with advanced ovarian cancer is approximately 30%. Platinum-taxane combination chemotherapy yields responses in most patients with ovarian cancer. The issue of how many treatment regimens to use in patients with advanced ovarian cancer is an area of controversy. With low response rates with subsequent chemotherapies, patients need to decide whether to continue chemotherapy or receive supportive care only.

The prevalence of pain associated with ovarian cancer resembles the prevalence rates in populations with other solid tumors.[89] Ovarian cancer spreads by intraperitoneal, lymphatic, and locally invasive pathways. Lymphatic pathways may extend from the abdominal retroperitoneum to the groin via the inguinal/femoral canals or across the diaphragm to the pleural space. Intraperitoneal spread of tumor begins with extension of tumor through the ovarian capsule, allowing implantation of tumor throughout the abdomen. Intraperitoneal metastases show a predilection for the omentum and diaphragm, but no organ is spared, and concomitant ascites is frequent. Portenoy et al.[89] noted that pain, fatigue, and psychological distress were the most prevalent symptoms in patients with advanced (stage III or IV) ovarian cancer. Patients generally describe pain as occurring in the abdominopelvic or lower back region, as being frequent or almost constant, and moderate to severe in intensity. Patients with advanced disease may experience pain in the lower extremities either from invasion of the lumbosacral plexus by tumor or by lymphedema secondary to iliac vessel occlusion.

Cervical Cancer. Cancer of the cervix is a frequent cancer in women worldwide. There are several histologic subtypes of cervical carcinoma. Approximately 80% of cervical cancers are squamous cell, and 15% are adenocarcinomas. The cervix drains by preureteral, postureteral, and uterosacral routes into the following regional lymph nodes: parametrial, paracervical, hypogastric (obturator), common iliac, external iliac, internal iliac, sacral, and presacral. The common sites of distant spread include the aortic (para-aortic, periaortic), lateral aortic and mediastinal nodes, lungs, and skeleton. In patients with locally advanced disease (stages IIB to IVA), 24% have para-aortic disease.[90] Identification of para-aortic nodal status allows modification of therapy (usually extended-field radiation therapy) with improved survival.[91,92] Detection of para-aortic lymph node metastases may be difficult using standard imaging techniques such as abdominopelvic computed tomography (CT) scanning. The sensitivity of CT scanning for identifying para-aortic nodal metastasis may be only 34%.[90] Rose et al.[93] demonstrated that positron emission tomography (PET) scanning accurately predicts both the presence and absence of pelvic and para-aortic nodal metastatic disease. Magnetic resonance imaging (MRI) has been increasingly used to evaluate tumor volume and it is superior to CT in defining the extent of disease in the cervix and parametria, making it particularly useful in planning radiation treatment fields.[94] However, MRI is relatively inaccurate in assessing lymph nodes for the presence of metastasis. Recurrent cervical cancer is almost always incurable.

Prostate Cancer. Almost all prostate cancers (95%) are adenocarcinomas. The remaining 5% of cases consist of squamous cell carcinoma, signet-ring carcinoma, transitional carcinoma, neuroendocrine carcinoma, or sarcoma. Prostate adenocarcinoma may spread locally, by direct invasion of seminal vesicles, urinary bladder, or surrounding tissues, or distantly. Distant metastases can derive from an initial lymphatic spread or from hematogenous dissemination, mainly to the bones. The Gleason system is the most widely used grading system for prostate cancer (adenocarcinoma only). Prostate cancers are stratified into five grades (1–5) on the basis of the glandular pattern and degree of differentiation. The Gleason score is derived from the sum of the most represented grade (primary grade) with the second most represented grade (secondary grade) (e.g., 3 + 4 = 7); this correlates better with prognosis than the single Gleason grade. The Gleason system can be applied to biopsy and surgical specimens, but not to fine needle biopsy, which lack architectural data. Serum prostate-specific antigen (PSA), digital rectal examination, and transrectal ultrasonography constitute the three major diagnostic means for the detection of cancer. PSA is an organ-specific glycoprotein which originates in the cytoplasm of ductal cells of the prostate. It is responsible for liquefaction of seminal fluid. The greatest limitation of PSA is that it is tissue, and not tumor specific in the prostate. Elevated PSA levels may also be the sign of benign disorders such as benign prostatic hyperplasia or prostatitis because of the organ and not cancer specificity of this protein. Five-year relative survival varies with stage at diagnosis from 80% or more when malignancy is confined to the prostate to about 25% where bone metastases are present. The treatment of choice for advanced prostate cancer is androgen ablation, achieved via surgical (bilateral orchiectomy) or medical (LH–RH analogues) castration, which is effective, but not curative in 80% to 85% of cases. Patients progressing after hormone therapy can be treated successfully with second-line hormone therapy. Chemotherapy has a well-recognized role in the management of hormone-refractory prostate cancer. Chemotherapy combinations of taxanes plus estramustine have been tested with clinical results in the range of 33% to 46% (mean 43%) for paclitaxel and 17% to 50% (mean 32%) for docetaxel.[95] The relative role of radiotherapy in metastatic disease is to deal with isolated symptoms, which may persist despite systemic treatment.

Because of the predilection of prostate cancer to spread to bony sites, a significant proportion of patients with metastatic disease will have bone pain. Prostate cancer rarely spreads to vital organs and the disease tends to progress slowly. The only exceptions are spinal cord compression or ureteral obstruction secondary to retroperitoneal lymph node metastases.

Tumors of the prostate gland may produce local rectal, urethral, suprapubic, and penile pain as a result of expansion and inflammation of the prostate, pain referred to the back, lower extremities, and abdominal area resulting from tumor growth within the pelvis, and distant bone pain with associated neurologic dysfunction associated with long bone, vertebral, and skull metastases (Table 42.4). The regional lymph nodes of the prostate are the nodes of the true pelvis, which are the pelvic nodes below the bifurcation of the common iliac arteries. Distant lymph nodes are outside the confines of the true pelvis. They are the aortic (para-aortic, periaortic, lumbar), common iliac, inguinal, superficial inguinal (femoral), supraclavicular, cervical, scalene, and retroperitoneal nodes.

Clinical syndromes can be differentiated by the site of bony involvement, the coexistence of mechanical instability secondary to fractures, and the neurologic dysfunction caused by tumor infiltration of contiguous neurologic structures. Bone metastases to the hip and pelvis often produce local pain that is exacerbated by movement, especially during weight bearing. Local invasion of tumor from the pelvis into the sacrum may produce the syndrome of perineal pain. Patients with this syndrome complain of local and perirectal pain that is accentuated by pressure on the

TABLE 42.4

CAUSES OF PAIN IN PROSTATE CANCER

Causes of pain	Examples/clinical syndromes
Bone metastasis	Single metastasis of pelvis or long bone Vertebral body metastasis, spinal cord compression Base-of-skull metastasis, cranial nerve palsies Perineal pain syndromes
Soft tissue metastasis	Lumbosacral plexopathy Pelvic tension "myalgia"
Pelvic visceral pain	"Prostatitis" pain

From Payne R. Pain management in the patient with prostate cancer. *Cancer* 1993;71(3 suppl):1131–1137. Copyright 1996 American Cancer Society. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

perineal region, such as that caused by sitting or lying prone. In its most extreme form, the patient cannot sit or lie flat. Dysfunction of the parasympathetic sacral innervation to bladder and bowel impairs continence early in the course of this syndrome. Local spread of tumor from the prostate into other pelvic and abdominal structures often produces visceral and neuropathic pain. Tumor invasion of the lumbosacral plexus may occur.

Breast Cancer. Breast cancer is the most commonly diagnosed cancer and the second leading cause of cancer-related mortality among North American women. After primary treatment with breast-conserving surgery and radiation, 10% to 20% of patients will have local recurrence in the breast within 1 to 9 years. Between 10% to 25% of these will have locally extensive or metastatic disease. After radical surgery and postoperative radiation, loco-regional recurrences occur in $<10\%$.[96] Breast cancer is a heterogeneous disease. Breast cancers are derived from the epithelial cells that line the terminal duct lobular unit. Cancer cells that remain within the basement membrane of the elements of the terminal duct lobular unit and the draining duct are classified as in situ or noninvasive. An invasive breast cancer is one in which there is dissemination of cancer cells outside the basement membrane of the ducts and lobules into the surrounding adjacent normal tissue. Breast cancer consists of the following histologic types: carcinoma, ductal, lobular, nipple, and other (undifferentiated). Increasing tumor size and nodal involvement are well-established adverse prognostic factors for patients who have early-stage breast cancer. Therapeutic strategies for individual patients with breast cancer frequently depend upon the following prognostic variables: size of the primary neoplasm, the presence and extent of axillary lymph node metastases, pathological stage of disease after primary therapy, and the presence or absence of receptor (estrogen, progesterone) activity. The breast lymphatics drain via three major routes: axillary, transpectoral, and internal mammary. Intramammary lymph nodes are considered with, and coded as, axillary lymph nodes for staging purposes. Metastases to any other lymph node are distant. Hormone receptor status is a well-established prognostic and predictive factor. The role of estrogen receptor (ER) status as a prognostic factor was confirmed in a meta-analysis of seven cooperative group adjuvant therapy trials.[97] For women who had ER-negative tumors, there was a peak annual hazard of recurrence of 18.5% at approximately 1 to 2 years after surgery that declined rapidly thereafter to a rate of 1.4% in years 8 through 12. Most breast cancers, however, are ER-positive. The human epidermal growth factor receptor 2 (HER2) receptor is a member of the epidermal growth factor receptor family and is overexpressed in approximately 20% to 25% of human breast cancers. HER2 overexpression has historically conferred a worse prognosis compared with nonoverexpressing cohorts. HER2 status is also an important predictor of response to hormone therapy. For example, HER2-positive breast cancers are relatively resistant to tamoxifen therapy, presumably as a result of cross-talk between intracellular signaling pathways.[98] Hormone therapy with aromatase inhibitors, however, which have a unique mechanism of action compared with tamoxifen, has not demonstrated similar resistance patterns.[99]

PET scanning can be used to evaluate primary lesions, regionally metastatic, and systemic metastases of breast cancer. Combined fluorodeoxyglucose-PET (FDG-PET) and MRI provide useful treatment-planning data for patients clinically suspected of having recurrent axillary or supraclavicular breast cancer. FDG-PET helped confirm metastases in patients with indeterminate MRI findings and depicted unsuspected metastases outside the axilla.[100] FDG-PET is also superior to bone scintigraphy in the detection of osteolytic breast cancer metastases.[101]

Breast cancer can metastasize to any organ in the body: bone, lung, liver, and brain are frequent sites. Metastases usually appear within a few years but recurrence may occur, particularly in bone, many years later. Although metastatic disease may be asymptomatic, the most common site of metastases, bone, typically hurts. Between 40% and 60% of patients with metastatic breast cancer will have bony disease, and in many of these patients, the involved bones (vertebrae, femoral and humoral shafts, and the acetabular area) are those that are involved with motion. Moreover, patients with metastatic breast cancer and bone involvement as their only site of metastatic disease may have median survival expectations of 27 to 29 months, during which time pain may be the chief manifestation of disease. Even patients with pulmonary metastases have median survivals of the order of 18 to 23 months,[102] and patients with only unilateral pleural involvement on the order of 44 months.[103] Metastatic breast cancer is currently an incurable yet treatable disease. While median survival is of the order of 18 to 24 months, survival ranges from a few weeks to several years. This biological variability means that for many women, metastatic breast cancer can be viewed as a chronic relapsing and remitting disease that may respond for a time to an array of cytotoxic and endocrine therapies. However, there is no consensus on the effects of these treatments on overall survival and quality of life, on the relative efficacies of chemotherapy and endocrine therapy, on the most appropriate duration and dosages of treatment, and on the merits of combined modality treatment.

The clinician will most likely have a long relationship with the patient with metastatic breast cancer and will have the opportunity to follow the course and progression of disease. The course of disease in patients with metastatic breast cancer fits one of two patterns: an indolent course that is not immediately life-threatening or one that is rapidly progressing or with extensive vital organ disease. Knowledge of the natural history of the disease is important in determining the nature and timing of treatment.

Table 42.5 lists some of the common causes of pain in patients with breast cancer.

Lung Cancer. Lung cancer is the most common cancer in the world and the leading cause of cancer-related deaths in Western countries. Non–small-cell lung cancer (NSCLC) constitutes between 80% and 85% of all lung cancers; small-cell lung cancer (SCLC) makes up the remaining 15% to 20%. Unfortunately, at the time of diagnosis, the majority of patients already have metastatic disease, and a systemic, palliative treatment is the primary therapeutic option. Each of the two major types of lung cancer further divides into subtypes, but these categories often blend into each other or coexist. SCLCs are relatively sensitive to cytotoxic chemotherapy and radiation therapy. They are usually

TABLE 42.5

CAUSES OF PAIN IN PATIENTS WITH BREAST CANCER

Etiology	Example	Example
Tumor-related	Bone metastases	
	Neural metastases	Brachial plexopathy Spinal cord compression Meningeal carcinomatosis Peripheral neuropathy secondary to tumor infiltration
	Visceral metastases	Pleural Liver Bowel Peritoneum
Anticancer therapy	Procedure-related pain in breast Postmastectomy syndrome Lymphedema-related Postradiation treatment Peripheral neuropathy Phlebitis Mucositis Chemical cystitis (e.g., secondary to cyclophosphamide) Osteoporosis or avascular necrosis	
Pre-existing conditions	Chronic nonmalignant pain	

centrally located, but can arise peripherally. Clinically, these tumors demonstrate a rapid growth rate and early metastatic dissemination.

Before the advent of systemic therapy, local surgical or radiation therapy alone produced poor median survivals, ranging from 8 to 17 weeks and 5-year survivals of less than 1%.[104] Effective chemotherapy has allowed the control of disseminated disease and improved the median survival of patients to 1 year or more, increasing the number of long-term disease-free survivors to between 5 and 10%.[105]

SCLC tumors express many neuroendocrine markers. Individual tumors may secrete up to 10 discrete hormones.[106] Histologically, SCLCs include small-cell anaplastic carcinoma, which includes the oat cell type. Small-cell anaplastic carcinoma is an aggressive and rapidly growing neoplasm and is limited to the thorax at the time of diagnosis in only 25% of patients. Metastases occur in regional lymph nodes, lung, abdominal lymph nodes, liver, adrenal gland, bone, central nervous system (CNS), and bone marrow.

NSCLSs are a morphologically diverse group that includes squamous cell carcinoma, adenocarcinoma, and large-cell anaplastic carcinoma. Squamous cell carcinoma is less likely to metastasize early. Adenocarcinomas have become the most frequent form of lung cancer in the United States.[107] Adenocarcinoma metastasizes widely and frequently to the other lung, liver, bone, kidney, and the CNS. Large-cell anaplastic carcinoma metastasizes in a pattern quite similar to adenocarcinoma with a predilection for mediastinal lymph nodes, pleura, adrenals, CNS, and bone.

For the purposes of prognosis and for analyzing data from clinical studies, SCLC is divided into limited and extensive disease categories. Limited disease is characterized by tumor that is clinically confined to the chest, mediastinum, and ipsilateral supraclavicular lymph nodes. Ipsilateral pleural effusion represents limited disease. All other sites of metastases are defined as extensive disease.[108] The median survival for patients with limited disease is approximately 12 to 18 months; for extensive disease, it approximates 9 months.[109] During the last 10 years, several new cytotoxic agents have become available; these include taxanes (paclitaxel and docetaxel), vinorelbine, gemcitabine, and topoisomerase 1 inhibitor irinotecan. Advances in lung cancer therapy have led to modest improvements in survival of patients with early or advanced disease.[110]

Lung cancers, particularly SCLC, often entail clinical paraneoplastic syndromes. Malignancy-associated hyponatremia is commonly associated with excessive production of arginine vasopressin by tumor cells and a large fraction of new cases of syndrome of inappropriate antidiuretic hormone secretion in elderly smokers are due to SCLC. About 10% of all lung cancer patients have hypercalcemia, and of these patients 10% to 15% do not have evident bone metastases. Humoral hypercalcemia of malignancy is more common in NSCLC, and especially squamous cell carcinoma. The neurologic syndromes associated with lung cancer are rare disorders and include subacute cerebellar degeneration, optic neuritis and retinopathy, subacute necrotizing myelopathy, and peripheral neuropathy.

Pain is a common and severe symptom in patients with all types of advanced lung cancer.[111,112] Chest pain is the most common site of pain in patients with small-cell cancer. The pain complaint is often poorly localized, dull in character, may radiate to the neck or back, and exacerbates with coughing. Mercadante et al.[111] reported that patients with advanced lung cancer commonly reported chest wall (including ribs and shoulder blade) pain, followed by lower extremities and lumbar regions, then abdomen and upper extremities, and the head area. Apical lung tumors (so-called Pancoast tumors) are notorious for causing brachial plexopathy with associated neuropathic pain.[39]

Renal Cell Cancers. Renal cell carcinoma (RCC) comprises a histologically diverse group of solid tumors, together making up only about 3% of all adult neoplasms,[113] but mortality from RCC may be increasing.[114] Clear-cell and papillary RCC are the most common histologic subtypes. More than half of RCCs now present as incidental radiographic findings discovered during

workup of unrelated conditions.[115] Currently, no effective serum tumor markers for diagnosis of RCC exist. Twenty-five to 30% of patients have overt metastases at the time of diagnosis. Frequent sites include the lung (50% to 60% of patients with metastases), bone (30%–40%), liver (30%–40%), and brain (5%). Unusual sites of metastases characterize renal cancer, however, and may involve virtually any organ site, including the thyroid, pancreas, skeletal muscle, and skin or underlying soft tissue. Common metastatic sites include bone, liver, lung, brain, and distant lymph nodes. The regional lymph nodes of the kidney are renal hilar, paracaval, aortic (para-aortic, periaortic, lateral aortic), and retroperitoneal. Papillary RCC are less likely to metastasize than clear cell RCC, but metastatic lesions may have a worse prognosis than clear cell metastases.

Surgical resection remains the cornerstone of treatment for RCCs. Radical nephrectomy involves resection of kidney, perirenal fat, and ipsilateral adrenal gland. The extent and benefit of lymphadenectomy is controversial. In 10% to 20% of patients, nodal involvement is found at surgery without clinically evident distant metastases.[116,117] Virtually all such patients later relapse with distant metastases despite lymphadenectomy.[117] The benefit of lymphadenectomy is limited to the prognostic information it provides, rarely providing a cure. Though RCC is extremely radioresistant, palliative radiation therapy is appropriate for brain and bone metastases. Compared to other cancers, chemotherapy is rather ineffective for RCC. Many agents have been tested with most showing response rates of less than 10%. High dose cytokine therapy with interlueukin-2 is used for advanced cases of RCC but is associated with significant toxicity. Pegylated interferon is also used for advanced cases. The most important determinant of survival is the anatomical extent of the tumor (i.e., the pathologic stage). Patients with organ-confined disease that is resected completely generally have better outcomes than those with nodal involvement or distant metastases. Twenty to 30% of patients with localized tumors relapse after radical nephrectomy. Less than 5% have local recurrences, whereas lung metastases are the most common sites of distant relapse, occurring in 50% to 60% of patients.[118,119] The median time before a relapse after nephrectomy is 15 to 18 months, and 85% of relapses occur within 3 years.[118,119] Pain is common due to bone and other metastatic spread and the poor prognosis with this disease points toward the importance of palliative care planning early on.

Colorectal Cancer. Colorectal cancer is one of the most common malignancies in the Western world and accounts for about 10% of all cancer deaths in both Europe and the United States.[113] The vast majority of these tumors are adenocarcinoma (>90%) and, to a lesser degree, carcinoid tumors, leiomyosarcomas, and lymphoma. Spread to regional lymph nodes generally correlates to depth of invasion by the primary tumor and the grade of differentiation. Nodal spread occurs in 10% to 20% of tumors confined to the bowel wall. Hematogenous spread is usually to the liver via portal venous transmission.

The liver is the prime organ for metastatic spread (65%); extra-abdominal metastases in lung (25%) and brain and bone (10%) are much less common. Most recurrences appear within 2 years (about 70%) and almost all (90%) within 5 years.

Surgery is the primary modality of treatment. There is no well-defined role for radiation treatment in colon cancer. The response rates to chemotherapy (usually 5-FU) in recurrent and metastatic cancer remain poor and of limited duration. In addition to staging systems, independent prognostic factors include histologic type, histologic grade, serum carcinoembryonic antigen (CEA) level, and extramural venous invasion. Elevated CEA levels are found in a variety of cancers other than colonic, such as breast, lung, pancreas, stomach, and ovary. Ten years ago, the treatment of metastatic colorectal cancer was based on one drug only, 5-FU. With the development of drug combinations, the response rate and median overall survival have doubled, approaching 50% and 20 months, respectively.[120] Patients with nonresectable, potentially curable disease may benefit from neoadjuvant chemotherapy with the aim of inducing tumor shrinkage to the point that the disease becomes resectable. Combining CT with biologic agents might additionally improve survival in this setting. Pain is commonly caused both by local effects (e.g., obstruction) and metastatic disease (e.g., to liver).

Tumor Markers. Genomics, proteomics, and metabolomics are being used to develop molecular signatures for disease diagnosis, prognosis, and therapeutic efficacy. Tumor-associated antigens discovered by these methods are used to develop passive (humoral) as well as active immunotherapy strategies to stimulate the immune system. Development and validation of biomarkers in parallel with therapeutics can speed development times by accurate screening of patient populations and substituting surrogate markers that correlate well with clinical outcomes. A tumor marker can be defined as a molecule that indicates the likely presence of cancer or that provides information about the likely future behavior of a cancer. Markers are potentially useful in screening for early malignancy, acting as a diagnostic or prognostic aid, predicting therapeutic efficacy, maintaining surveillance following surgical removal of the primary tumor, and monitoring therapy in advanced malignancy. Examples of prognostic tumor markers in malignancy are shown in Table 42.6.

One of the main uses of tumor markers is in the postoperative follow-up of patients diagnosed with malignancy. Examples of markers used for surveillance in this fashion are listed in Table 42.7.

Markers may be used to guide treatment decisions. For example, molecular biomarkers in breast cancer may dictate therapy. Patients who are ER-positive may receive hormonal therapy in the form of tamoxifen or anastrozole, HER2 positive patients may receive immunotherapy as trastuzumab, and BRCA1 pa-

tients chemotherapy as anthracyclines or taxanes.[121] Markers are also frequently used to monitor treatment in patients with advanced disease. Consistently increasing levels may suggest treatment failure and the need to switch to alternative treatments.

Cancer Pain Syndromes

This section is intended to complement material presented in Chapters 41, 45, and 46.

NEUROPATHIC CANCER PAIN

Neuropathic pain is a common cause of severe and difficult to control pain syndromes in patients with cancer. The most common etiologies and syndromes are discussed.

Neuropathic Pain Secondary to Cancer-Related Pathology in Cranial Nerves

Painful cranial neuralgias may occur secondary to base of skull metastases, leptomeningeal metastases, or head and neck cancers.[122] Base of skull metastases produce several well-described pain syndromes[123] and are often associated with primary tumors of the breast, lung, and prostate. Constant localized aching pain from bone destruction and neurologic deficits from progressive cranial nerve palsies are cardinal manifestations.

The middle cranial fossa syndrome presents with facial numbness, paresthesias, or dysesthetic neuropathic pain in the distribution of the second or third divisions of the trigeminal nerve. Associated motor deficits include weakness in the masseter or temporalis muscles or abducens palsy.

The jugular foramen syndrome may present as glossopharyngeal neuralgia.[123] This pain is distributed over the ear or mastoid region and may radiate to the neck or shoulder. Associated deficits include a Horner's syndrome and paresis of the palate, vocal cords, sternocleidomastoid muscle, or trapezius muscle. Some attribute this syndrome to leptomeningeal metastases[124] and local extension of head and neck malignancies.[125] It is sometimes associated with syncope.[126]

A syndrome which clinically mimics classical trigeminal neuralgia can occur secondary to tumors in the middle or posterior fossa[127–130] or from leptomeningeal metastases.[131] This association between trigeminal neuralgia and tumor is uncommon, and cancer patients with a new onset of trigeminal neuralgia should have careful imaging of the base of skull.[128] Trigeminal neuralgia secondary to tumor usually presents as a constant, dull, well-localized pain related to the underlying pathology involving bone and other somatic structures associated with paroxysmal episodes of lancinating or throbbing pain.

Squamous cell carcinomas of the face, which commonly extend by perineural spread, are an important cause of complex trigeminal syndromes.[132] Perineural spread, when present, typically involves cranial nerves V and VII because of their extensive subcutaneous distributions.[133] Glossopharyngeal neuralgia commonly results from local nerve infiltration in the neck or base of skull. It typically produces throat and neck pain, radiating to the ear and mastoid, and is aggravated by swallowing. Occasionally, syncope accompanies severe pain.[134,135]

Cervical Plexopathy

Tumor infiltration of the cervical plexus can produce several pain syndromes, depending on the pattern of nerve involvement.[136] The upper four cervical ventral rami join to form the cervical plexus. The plexus lies close to C1–C4 vertebrae. The four cutaneous branches emerge from the posterior border of the sternocleidomastoid muscle into the posterior triangle of the neck. Because sensory afferents from the cervical plexus enter the spinal tract of the trigeminal along with the sensory afferents from cranial nerves V, VII, IX, and X, nociceptive referral patterns from the face and neck overlap. Symptoms usually include local pain with lancinating or dysesthetic components referred to the retroauricular and nuchal areas (lesser and greater auricular nerves), preauricular area (greater auricular nerve), anterior neck and shoulder (transverse cutaneous and supraclavicular nerves), and the jaw.[122] Associated findings include ipsilateral Horner's syndrome or hemidiaphragmatic paralysis. CT or MRI evaluation may be necessary to rule out associated epidural cord compression. Common clinical settings include local extension of a head and neck tumor or cervical lymph node metastases. In patients with head and neck tumors who have undergone radical neck dissection followed by radiation treatment, new onset or worsening pain includes a differential diagnosis of postradical neck dissection syndrome or tumor recurrence. Infections often complicate and exacerbate pain.

Tumor-Related Mononeuropathy

The most commonly described tumor-related painful mononeuropathy is intercostal nerve injury secondary to rib metastases with local extension. Patients with tumor invasion of the sciatic notch may present with symptoms resembling sciatica.

Radicular Pain/Radiculopathy

Radiculopathy is a pattern of pain corresponding to the dermatomal territory innervated by the dorsal spinal roots. Patients with cancer-related radiculopathy may present with pain on either or both sides of the midline. The pain tends to be unilateral in the cervical and lumbosacral regions and bilateral in the thorax. In cancer patients, radiculopathy typically results from epidural tumor mass or leptomeningeal metastases. Coughing, sneezing, recumbency, and strain exacerbate the pain, which often has dysesthetic qualities. Radiculopathy may also develop secondary to leptomeningeal metastases. Clinically, leptomeningeal metastases may produce multifocal neurologic signs and symptoms at a variety of levels, including cranial neuralgias. Most commonly, they produce a generalized headache with radicular pain in the low back and buttocks.[137]

Leptomeningeal Metastases

Leptomeningeal metastasis is defined as the appearance of tumor cells in the leptomeninges or cerebrospinal fluid (CSF) distant from the site of a primary tumor. It is also known as carcinomatous meningitis, neoplastic meningitis, neoplastic meningosis, leukemic meningitis (for leukemia), lymphomatous meningitis (for lymphoma), and meningeal carcinomatosis (for carcinoma). Oncologists and neurologists have increasingly reported diffuse leptomeningeal metastases of extracranial malignant tumors.[137–139] This complication occurs most commonly with adenocarcinoma of the lung and breast, lymphomas, and melanomas.

Leptomeningeal involvement occurs in 5% to 8% of solid tumors, 5% to 29% of non-Hodgkin's lymphomas, and 11% to 70% of leukemias.[140] Meningeal involvement was once a common complication of acute lymphoblastic leukemia, prior to the advent of CNS prophylaxis. Now this problem occurs in fewer than 5% of patients. Leptomeningeal metastases develop in 1% to 8% of patients with systemic cancer,[141] and has a poor prog-

nosis with a median survival of 3 to 6 months.[142] Untreated, the prognosis is dismal with an average survival of 6 weeks.[143]

Tumor cells may reach the leptomeninges by several mechanisms including hematogenous spread, direct extension, transport through the valveless venous plexus, extension along nerves, perineural/perivascular lymphatics, escape from choroid plexus or subependymal metastases, and iatrogenic causes. Leptomeningeal tumors can encase the spinal and cranial nerves or may directly invade them and produce demyelination and axon destruction. The major mechanism of dissemination once tumor cells reach the leptomeninges is via exfoliation into the CSF space. Leptomeningeal metastases can cause symptoms by direct compression of brain structures (by meningeal nodules causing focal symptoms), irritation of adjacent brain (seizures), blocking of CSF pathways (leading to hydrocephalus and raised intracranial pressure), ischemia, or stroke (by constriction of pial arteries), cranial and peripheral nerve palsies (by direct nerve involvement), metabolic derangements (by decreasing available glucose for brain by rapidly growing tumor cells), and by causing meningeal fibrosis.

The hallmark of the clinical presentation of leptomeningeal metastases is the simultaneous occurrence of symptoms and signs at more than one area of the neuraxis. The clinical presentation of leptomeningeal metastasis is pleomorphic and commonly affects the cerebral hemispheres, cranial nerves, or spinal cord and its roots. It is best to describe the symptoms by their location along the neuraxis. Symptoms are usually multifocal and more diffuse than one discrete lesion allows. Symptoms include headache, back and radicular pain, multiple cranial and spinal nerve involvement, and change in mental status. Pain may occur in 30% to 76% of cases.[137,144] Table 42.8 lists the frequency of spinal cord symptoms and signs in patients with leptomeningeal metastases. The most common symptom is pain (80%) and patients may report a diffuse headache (25%) or pain in a spinal, radicular, or meningeal pattern (>50%). Localizing symptoms include cranial neuropathies, mononeuritis, radiculopathy, urinary incontinence, and visual disturbance.

The diagnosis rests on finding malignant cells on CSF examination or on characteristic gadolinium-enhanced MRI findings in the appropriate clinical context. The diagnosis should ideally be based on a combination of CSF studies and neuroimaging. Careful neurologic examination is required to demonstrate multifocal involvement of the CNS, cranial nerves, and spinal roots, which constitute the clinical hallmark of the disease. CSF analysis is almost always abnormal but only a positive cytology or demonstration of intrathecal synthesis of tumor markers is diagnostic. T1-weighted gadolinium-enhanced sequence of the entire neuraxis (brain and spine) plays an important role in supporting the diagnosis, demonstrating the involved sites and guiding treatment (Fig. 42.2). MRI images typically show enhancing nodular lesions.

FIGURE 42.2 MRI of 50-year-old man with metastatic renal cell carcinoma. Patient presented with urinary retention and symptoms suggestive of cauda equinae syndrome. Lumbar spine (sagittal view) demonstrated diffuse leptomingeal carcinomatosis. Nodular contrast is noted particularly in the cauda equinae nerve roots (*yellow arrows*). There is also evidence of diffuse metastatic disease throughout the lumbar spine.

Brachial Plexopathy

Most tumors involving the brachial plexus originate from the lung or breast and, as a result, invade the lower plexus. This syndrome can present from either compression or tumor infiltration of the brachial plexus from contiguous structures, such as axillary or supraclavicular nodes, or by tumors in the apex of the lung. Neuropathic pain due to tumor infiltration of the brachial plexus usually stems from lymph node metastases from breast carcinoma or lymphoma, or direct extension from lung carcinoma (i.e., Pancoast tumor). The designation of "Pancoast" tumors relates to the symptom complex or syndrome caused by a tumor arising in the superior sulcus of the lung that involves the sympathetic nerve trunks, including the stellate ganglion. Superior pulmonary sulcus syndrome associated with a Pancoast tumor is defined as progressively intense pain in the shoulder and ulnar side of the arm, associated with sensory and motor deficits and Horner's syndrome due to tumor.[39]

In brachial plexopathy, pain is usually the first symptom in 85% of patients and often precedes neurologic deficits.[145,146] The key features of malignant plexopathy are the neuropathic nature of the pain, with numbness, paresthesias, allodynia, and hyperesthesias. Typically, the pain begins in the shoulder girdle where it is often described as pressure-like or aching and may radiate to the elbow, medial forearm, and fourth and fifth fingers. It may also appear to localize at the posterior arm or elbow. The patient may report a burning quality to the pain, with hyperesthesia along the ulnar aspect of the forearm.

Involvement of the lower plexus (C7, C8, and T1) occurs when tumor arises from the lung apex; associated pain and dysesthesias involve the elbow, medial forearm, and fourth and fifth fingers. Upper plexus involvement (C5, C6), if it occurs alone, will usually

TABLE 42.9

DIFFERENTIATING FEATURES OF BRACHIAL PLEXOPATHY INDUCED BY TUMOR INFILTRATION, RADIATION FIBROSIS, AND REVERSIBLE RADIATION INJURY

	Tumor infiltration	Radiation fibrosis	Reversible radiation injury
Incidence of pain	89%	18%	40%
Typical location of pain	Shoulder, upper arm, elbow, radiating to fourth and fifth fingers	Shoulder, wrist, hand	Hand, forearm
Nature of pain	Dull aching in shoulder; Lancinating pain in elbow and ulnar aspect of hand; Occasional dysesthesias, burning, or freezing sensations	Aching shoulder pain; Paresthesias in C5, C6 distribution in hand	Aching shoulder pain; Paresthesias in hand and forearm
Severity of pain	Moderate to severe (severe in 98% of patients)	Mild to moderate (severe in 35% of patients)	Mild
Course	Progressive neurologic dysfunction; atrophy and weakness with C7–T1 distribution; persistent pain; Homer's syndrome	Progressive weakness with C5, C6 distribution; stabilizing pain with appearance of weakness	Transient weakness and atrophy affecting C6–C7, T1; complete resolution of motor findings
CT scan findings	Circumscribed mass with diffuse infiltration of tissue planes	Diffuse infiltration of tissue planes	Normal
EMG findings	Segmental slowing; no myokymia	Myokymia	Segmental slowing; no myokymia

Modified from Foley KM. Brachial plexopathy in patients with breast cancer. In: Harris JR, Hellman S, Henderson IC, Kinne DW, eds. *Breast diseases*. Philadelphia: JB Lippincott Co, 1987.

develop into a panplexopathy. Upper plexus pain typically involves the shoulder girdle, with burning pain in the tips of both the index finger and thumb. Lung tumors can also present with pain involving the axilla and upper chest wall in the distribution of the intercostobrachial nerve.[147]

In more than 75% of patients, neurologic signs follow the appearance of dysesthesias. These signs include focal weakness, atrophy, and sensory changes in the distribution of C7, C8, and T1 roots.[146] There is usually early loss of the triceps reflex. Associated findings can include Horner's syndrome and adjacent vertebral disease. Such patients are at high risk for concurrent epidural extension.[144,148] For patients with brachial plexopathy secondary to tumor, imaging the contiguous epidural space prior to radiation treatment so that the radiation oncologist can include this area in the treatment field is recommended. A Spurling's maneuver (see Figure 41.4) can help to identify the spinal canal as the site of pathology.[149] Paraspinal involvement may help to predict epidural extension of tumor.

Neuroradiologic evaluations of choice for brachial plexopathy are CT and MRI. However, Ahmad et al.[150] demonstrated that FDG-PET scanning is a useful tool in evaluation of patients with suspected metastatic plexopathy, particularly if other imaging studies are normal. It may also be useful in distinguishing between radiation-induced and metastatic plexopathy. Electromyography (EMG) can also help distinguish malignant brachial plexopathy from radiation-induced brachial plexopathy or cervical radiculopathy (Table 42.9). In patients with brachial plexopathy, EMG usually shows fibrillation potentials and positive waves (evidence of denervation) in affected muscles. Radiation-induced brachial plexopathy is discussed below.

Lumbosacral Plexopathy

Direct tumor infiltration from adjacent soft tissues or lymph nodes or by compression from metastases in the adjacent bony pelvis can damage the lumbosacral plexus. Most lumbosacral plexopathy reflects local extension or nodal metastases from colorectal and other pelvic tumors (cervix, uterus, bladder, prostate), sarcomas, and lymphomas, but it may also occur with metastases from breast or lung cancer or melanoma (Table 42.10).[136] Saphner et al.[151] found lumbosacral plexopathy caused by retroperitoneal lymph node metastases the most common neurologic complication in patients with advanced cervical cancer.

The cardinal clinical feature of carcinomatous plexopathy is severe, unrelenting pain.[152] The distribution of pain varies and may localize in the pelvis, low back or hip, or refer in a radicular or nonradicular pattern into the leg. The local pain is pressure-like or aching in quality. The referred pain varies with the site of plexus involvement and can be burning, crampy, or lancinating. Weeks to months after pain begins, sensory symptoms of numbness and paresthesias, as well as weakness and leg edema usually develop. A "hot and dry foot" syndrome may result from lumbo-

TABLE 42.10

COMMON NEOPLASMS BY LOCATION OF PLEXOPATHY

sacral plexopathy and may reflect sympathetic fiber dysfunction.[153] The most common clinical findings on examination include leg weakness (86%), sensory loss (73%), reflex loss (64%), and leg edema (47%). Positive straight leg raising tests and sciatic notch tenderness are often present.[154]

Lumbosacral plexopathy may cause different clinical syndromes depending on the level of nerve involvement. Infiltration of the upper plexus occurs in approximately one third of patients who present with pain in the back, lower abdomen, flank, iliac crest, or anterolateral thigh. This syndrome has associated L1–L4 distribution neurologic deficits. Involvement of the lower plexus occurs in approximately one-half of patients, and presents with pain in the buttocks and perineum, with referral to the posterolateral leg and thigh. Examination may reveal associated L4–S1 neurologic deficits, leg edema, and bowel or bladder dysfunction. Sacral plexopathy can signal direct bony extension of a bony sacral lesion or a presacral mass. Numbness of the dorsal medial foot and sole with associated weakness of knee flexion, ankle dorsiflexion, and inversion is typical of lumbosacral trunk extension. Involvement of the coccygeal plexus results in sphincter dysfunction and perineal sensory loss. Panplexopathy occurs in one fifth of patients, and pain may refer anywhere in the territory of the plexus. Associated leg edema is relatively common.[153]

Jaeckle et al.[152] studied 85 cancer patients with lumbosacral plexopathy and documented pelvic tumor by CT or biopsy. They discerned three clinical syndromes: lower (L4–S1), 51%; upper (L1–L4), 31%; and panplexopathy (L1–S3), 18%. Seventy percent of patients had the insidious onset of pelvic or radicular leg pain, followed weeks to months later by sensory symptoms and weakness. The quintet of leg pain, weakness, edema, rectal mass, and hydronephrosis suggests plexopathy due to cancer. CT showed pelvic tumor in 96%. On myelography, epidural extension, usually below the conus medullaris, occurs in 45%. With treatment, only 28% of patients had objective responses on CT and 17% on examination.

In previously treated patients, the main differential diagnostic consideration is radiation-induced plexopathy (see below). Taylor et al.[155] found that MRI was more sensitive than CT for diagnosing cancer-induced lumbosacral plexopathy. Thus, MRI is the choice for the diagnostic work-up of patients with clinical and electrophysiologic evidence of plexopathy and suspected systemic cancer. Studies should include the L1 vertebral body through to the true pelvis. Neurologic findings include leg weakness, sensory loss, reflex asymmetry, focal tenderness (in the lumbar region in an upper plexopathy, sciatic notch and sacrum in a lower plexopathy, and lumbosacral region in pan-plexopathy), rectal mass, decreased sphincter tone, and positive direct and reverse straight leg raising signs.

Tumor Infiltration of the Sacrum and Sacral Nerves

Pain in a sacral distribution occurs usually as a result of the spread of bladder, gynecologic, or colonic cancer. There is dull aching midline pain and usually burning or throbbing pain in the soft tissues of the rectal or perineal region. Sitting or lying usually exacerbates the pain. With bilateral involvement, sphincter incontinence and impotence are common. There may be tenderness over the sacrum and in the regions of the sciatic notches. Sometimes there is limitation of both direct and reverse straight leg raising. Involvement of S1 and S2 roots will produce weakness of ankle plantar flexion, and the ankle jerks may be absent. There is usually sensory loss in the perianal region and in the genitalia, and this may be accompanied by hyperpathia.

Spinal and Radicular Pain

Patients perceive radicular pain as arising in a limb or thoracoabdominal wall. The cause is ectopic activation of nociceptive afferent fibers in a spinal nerve or its roots or other neuropathic mechanisms. The pain is lancinating in quality and travels along a narrow band. It may be episodic, recurrent, or paroxysmal according to the causative lesion or any superimposed aggravating factors. While patients may experience radicular pain as a deep tissue pain, it also has a cutaneous quality in proportion to the number of cutaneous afferent fibers ectopically activated. Radicular pain differs from nociception in the axons stimulated along their course; their peripheral terminals are not the site of stimulation. Ectopic activation may occur as a result of mechanical deformation of a dorsal root ganglion, mechanical stimulation of previously damaged nerve roots, inflammation of a dorsal root ganglion, and possibly by ischemic damage to the dorsal root ganglia. Acute spine pain may be described as cramping or knife-like, but may also be merely dull or aching. It is worse with movement. Chronic spine pain without a radicular component is generally aching, dull, or burning, or any combination of these three features. It also tends to be made worse with movement.

Central Pain Syndromes Caused by Cancer

Central pain syndromes are relatively infrequent in the cancer population. While epidural spinal cord compression is almost always painful, central pain is not the predominant symptom; nociceptive input from progressive bony destruction by metastases is the usual cause of pain, with or without concurrent radicular pain from nerve root compression. Radiation myelopathy is also a possible cause of central pain syndrome.

Paraneoplastic Peripheral Neuropathy

Clinically significant peripheral neuropathy in cancer patients is common but only a small minority is paraneoplastic in origin (Table 42.11). Paraneoplastic syndrome refers to a group of disorders (caused by, or associated with, cancers) that are neither direct effects of the primary tumor mass or metastatic to the involved organs. These disorders can affect virtually any portion

TABLE 42.11

PERIPHERAL NEUROPATHY IN CANCER PATIENTS

Causes	Examples

Unrelated to cancer	Diabetes mellitus Vitamin B12 deficiency

From: Darnell RB, Posner JB. Paraneoplastic syndromes affecting the nervous system. *Semin Oncol* 2006;33(3):270–298.

of the nervous system. Most paraneoplastic syndromes stem from an autoimmune reaction to an "onconeural" antigen shared by the cancer and the nervous system.[156] The immune reaction may slow growth of the cancer, but it also damages the nervous system. Autoantibodies found in individual patients with paraneoplastic syndromes are usually associated with specific tumors. Neurologic disorders, clinically and pathologically identical to paraneoplastic syndromes, may occur in some patients without cancer, but these patients do not have paraneoplastic antibodies. Diagnosis of a paraneoplastic syndrome depends on its increased incidence in patients with cancer, the occasional response of the neurologic syndrome to treatment of the underlying cancer, or the presence of specific autoantibodies.

Antibodies as clinical markers for a paraneoplastic etiology have been available for just over 15 years, starting with the description of anti-Hu in 1985.[157] Four series totaling about 500 patients have been reported.[158–161] The most common symptoms were sensory neuronopathy, paraneoplastic limbic encephalitis, and paraneoplastic cerebellar degeneration. Cancers were diagnosed in 80% to 90% of patients and were preceded by the neurologic symptoms in 70% to 100%. The associated cancers tend to be limited and show no metastases (other than to mediastinal lymph nodes). Anti-Hu (at low titer) is also present in about 16% of patients with SCLC without neurologic symptoms.[162]

Four types of polyneuropathy constitute most of the cases of paraneoplastic peripheral neuropathy: motor, sensory, sensorimotor, and autonomic. Most paraneoplastic peripheral neuropathies are sensorimotor and axonal. A pure sensory neuronopathy, such as pathology in the dorsal root ganglion, strongly suggests a paraneoplastic syndrome associated with the anti-Hu antibody. A pure motor neuropathy subacutely developing could be the Guillain-Barré syndrome associated with Hodgkin's disease or a multifocal motor neuropathy with conduction block associated with plasma cell dyscrasias. An autonomic neuropathy is sometimes associated with the anti-Hu syndrome. Paraneoplastic disorders of the autonomic nervous system usually arise in the setting of encephalomyelitis. However, autonomic symptoms may predominate or rarely be the only symptoms or signs of a paraneoplastic neuropathy. The most common symptom is pseudoobstruction of the bowel but anhidrosis, orthostatic hypotension, hypoventilation, sleep apnea, and cardiac arrhythmias can also present either alone or, more commonly, as part of a more widespread autonomic neuropathy. Most autonomic neuropathies are associated with SCLC and the anti-Hu syndrome. Mononeuritis multiplex suggests a vasculitis, possibly paraneoplastic in origin.

The classic paraneoplastic polyneuropathy is sensory neuropathy. Typically, patients with this disorder initially have an asymmetrical and painful sensory neuropathy, which evolves into complete loss of proprioception. The pseudoathetotic movement of the hands and severe sensory ataxia is very severe in most cases. Motor neuropathies may be acute or chronic, progressive or remitting, demyelinating, axonal or neuronal. Clinically, they are indistinguishable from the more common nonparaneoplastic motor neuropathies, unless they resolve after treatment of the cancer or are associated with a paraneoplastic antibody. These disorders include the Guillain-Barré syndrome, which occurs more frequently in patients with Hodgkin's disease than in the general population, a remitting and relapsing polyneuropathy resembling relapsing chronic inflammatory demyelinating polyneuropathy, and a subacute motor neuronopathy affecting patients with Hodgkin's disease or other lymphomas. The sensory neuropathies include a subacute pansensory neuropathy and a predominantly distal sensory neuropathy.

Paraneoplastic peripheral neuropathies are important because they may be the first sign of an otherwise occult cancer and/or because they may substantially disable the patient even when the cancer itself is asymptomatic. In about two thirds of cases, patients with paraneoplastic neurologic disorders present to the neurologist without a known tumor.

Neuropathic Pain Secondary to Therapeutic Interventions

Many pain syndromes occur in the course of or subsequent to treatment of cancer with surgery, chemotherapy, or radiation therapy. In most cases, there is injury to the peripheral nervous system or spinal cord, with pain as a major and often presenting complaint. In some cases, these syndromes occur long after the therapy is implemented, resulting in a difficult differential diagnosis between recurrent disease and a complication of therapy. Post radiation and chemotherapy pain mechanisms and syndromes are discussed in Chapter 48.

Postsurgical Neuropathic Pain

1. *Postmastectomy*: Pain can be a prominent postsurgical finding in breast cancer patients. It tends to appear in the postmastectomy period, a consequence of the disruption of normal neural pathways, or it may follow the development of lymphedema or the presence of metastases. In most situations, however, pain occurs primarily as a result of persistent restrictions in range of motion of the shoulder girdle in the region of surgery with findings of tender or trigger points in the associated muscle groups. Chronic neuropathic pain after mastectomy occurs primarily in patients whose surgery included axillary dissection,[163] although the problem can occur in women who undergo any surgical procedure on the breast from lumpectomy to radical mastectomy.[164] Postaxillary dissection pain is probably a more appropriate name than the usual postmastectomy pain for this syndrome.[165] The pain pattern typically involves paroxysms of lancinating pain against a background of burning, aching, tight constriction in the axilla, medial upper arm, and/or chest. Hyperesthesia, dysesthesia, hyperalgesia, allodynia, or hypoesthesia in the intercostobrachial nerve distribution may occur. The exact cause is unclear but various theories include dissection of the intercostobrachial nerve, intraoperative damage to axillary nerve pathways, and pain caused by neuroma formation. The intercostobrachial nerve is a cutaneous sensory branch of T1 and T2. The nerve is highly variable in size and distribution, making it difficult to avoid in these surgical procedures. Usually the pain develops shortly after surgery, but it can emerge months after surgery. Late-onset should prompt a search for other causes such as recurrent chest wall disease or bone metastases. The postmastectomy pain syndrome differs from metastatic or radiation-induced brachial plexopathy in which there is a different pattern of sensory loss, lymphedema, and usually more severe pain.
2. *Neck dissection* (also see Chapter 45): A large spectrum of surgical procedures is available for treatment of cervical lymph nodes.[166] These may be classified as radical neck dissection (RND), extended RND, modified RND, and selective neck dissection. RND for head and neck cancers can result in an iatrogenic syndrome characterized by ipsilateral face and neck pain with associated paresthesiae. Pain usually emerges weeks to months after surgery, consequent to injury to the cervical plexus or cervical nerves.[122] The most relevant functional sequel from RND is impairment of shoulder function due to sectioning the spinal accessory nerve and to the ensuing denervation of the upper trapezius muscle. Nahum et al.[167] coined the term "shoulder syndrome" to describe a clinical picture consisting of pain and limited abduction of the shoulder, full passive range of motion, and anatomic deformities such as scapular flaring, droop, and protraction. Pain is attributed to strain placed on other supporting muscles, such as the rhomboids and levator scapulae, as a consequence of shoulder drooping. A frequent ancillary sign of shoulder syndrome is sternoclavicular joint hypertrophy because of the abnormal

torque-like forces applied to the medial head of the clavicle, potentially complicated by stress fracture of the middle third of the clavicle. Recurrent tumor can also be a cause of pain that occurs or escalates after neck dissection.

3. *Thoracotomy*: Shortly following thoracotomy, a neuropathic pain can develop in the distribution of one or several intercostal nerves near the thoracotomy scar. The pain may remain stable after onset and gradually decrease over a period of months or years. Dajczman et al.[168] evaluated the prevalence and functional significance of long-term postthoracotomy pain in 56 patients who were at least 2 months postsurgery. Thirty patients (54%) with a median follow-up of 19.5 months had persistent pain; 26 others were pain-free at a median of 30.5 months postthoracotomy. Twenty-four of 44 patients (55%) who were more than 1 year after surgery, 13 of 29 patients (45%) more than 2 years, 6 of 16 (38%) more than 3 years, and 3 of 10 patients (30%) greater than 4 years postthoracotomy reported pain. Pain intensity was low, but 13 patients stated that pain "slightly" or "moderately" interfered with their lives. Five of 56 patients had sufficiently severe chronic pain to require daily analgesic use, nerve blocks, relaxation therapy, acupuncture, or referral to a pain clinic. Pain that increases with time or which first appears more than 3 months after surgery may signal recurrent tumor and should prompt further investigation. Maguire et al.[169] found two distinct patterns of nerve injury after thoracotomy and also demonstrated differences between surgical techniques. Thoracotomy with rib resection resulted in more detectable nerve damage than cautery along the top of the rib and pericostal closure. However, intercostal nerve damage at the time of operation was not associated with chronic pain or altered cutaneous sensation at 3 months postoperatively, suggesting that either the amount of intraoperative nerve damage is not indicative of long-term nerve damage or that there is a more significant cause for chronic pain other than intercostal nerve injury. In my experience, many patients experience chronic pain in the shoulder girdle region following thoracic surgical procedures not primarily from intercostal nerve damage but from a persistent inability to normally range the shoulder girdle region. In effect, these patients demonstrate persistent myofascial tenderness in the muscles of the shoulder girdle region (pectorals, trapezius, rhomboids, and deltoid).
4. *Phantom Pains*: Phantom pain disables a significant number of patients undergoing amputation of different body parts for malignancy.[170] It can have continuous or paroxysmal qualities, a burning or shooting character, and frequently invokes dysesthesias. The incidence of phantom limb pain is greater in cases where pain was present in the body part prior to amputation.[171] Phantom breast pain occurs in 13% of patients up to 1 year following mastectomy.[172] Phantom rectal pain occurs in up to 18% of patients after surgery for rectal carcinoma.[173] The reappearance or worsening of pain a long while after amputation can indicate tumor recurrence. The clinician must carefully distinguish among phantom pain, nonpainful phantom sensations, neuropathic stump pain, and nonneuropathic stump pain (see Chapter 26).

STEPWISE APPROACH TO PAIN ASSESSMENT

Assessing cancer pain is more than quantifying pain with a tool and recording it. A stepwise approach to cancer pain assessment begins with data collection and ends with a clinically relevant diagnosis which will require a thorough understanding of the various components contributing to the pain complaint. At a minimum, this involves determining the etiology of the pain and forecasting its future trajectory. It also involves determining the number of sites from which pain originates and the probable mechanisms involved. Assessment must include evaluation of the impact of pain on sleep, functional capability, activity level, and psychological well-being. In addition, the clinician must determine the nature, course, and impact of the cancer on the patient. A thorough evaluation will allow the clinician to obtain a basis for evaluating therapeutic intervention and determining the long-term goals of the patient and/or the patient's family.

The goals of the pain-related history are listed in Table 42.12. Optimal assessment includes a detailed description of these goals and classification by both pain syndrome and likely underlying mechanisms (see below).

TABLE 42.12

GOALS OF THE PAIN-RELATED HISTORY

Define the features of the pain
Outline the anatomical extent of the disease
Determine responses to previous disease-modifying and analgesic therapies
Clarify the impact of the pain on activity of daily living, psychological state, and familial and professional function
Determine the presence of associated symptoms that may modify the perception of pain

Features of Pain History (also see Chapter 41)

Table 42.13 lists the key components to assessing the characteristics of the pain complaint.

Location

Many patients with advanced disease have multiple pains at different sites. Multiple pain complaints are more common in patients with breast, lung, and prostate cancer compared with gastrointestinal cancers.[74] Pain of tumor origin may be characterized by its location. For example, somatic pain resulting from bone metastases tends to be well-localized, while visceral pain tends to be diffuse and is often referred. Neuropathic pain may be radicular in location.

Intensity

Guidelines from the Agency for Health Care Policy and Research,[174] the American Pain Society,[175] and the American Society of Anesthesiologists[176] recommend the regular use of pain rating scales to assess pain severity and relief in all patients who commence or change treatments. These recommendations urge

clinicians to teach patients and families to use assessment tools in the home to promote continuity of pain management in all settings. Assessment tools for determining the intensity of pain are discussed above.

Quality

Tumor-associated pain can be nociceptive (somatic or visceral structures) or neuropathic in origin. Each source of pain has distinguishing qualities. For example, patients tend to describe pain that is neuropathic in origin as burning, shock-like, or shooting in quality, while they often describe pain originating from somatic structures as aching, nagging, throbbing, or sharp.

Timing
