TO THE LASTING MEMORY OF JOHN BONICA AND HIS ENDURING QUEST TO END NEEDLESS PAIN.

John and Emma L. Bonica

CONTRIBUTING AUTHORS

Janet Abrahm, MD
Associate Professor, Medicine
Harvard Medical School
Director, Pain and Palliative Care Program
Dana-Farber Cancer Institute and Brigham and Women's Hospital
Boston, Massachusetts

Ajit S. Ahluwalia, MD, MHA
Capital Hospice and Palliative Care
Falls Church, Virginia

Roger J. Allen, BS, BSPT, MS, PhD
Professor
Department of Physical Therapy
University of Puget Sound
Tacoma, Washington

Charles E. Argoff, MD
Professor of Neurology
Albany Medical College
Director, Comprehensive Pain Program
Albany Medical Center
Albany, New York

Paul M. Arnstein, RN, PhD
Clinical Nurse Specialist for Pain Relief
Director, MGH Cares About Pain Relief Project
Massachusetts General Hospital
Boston, Massachusetts

Wael F. Assad, MD
Department of Brain and Cognitive Sciences
Center for Learning and Memory
Massachusetts Institute of Technology
Boston, Massachusetts

Misha-Miroslav Backonja, MD
Professor of Neurology
University of Wisconsin
Madison, Wisconsin

Zahid H. Bajwa, MD
Director, Education and Clinical Pain Research
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, Massachusetts

Samir K. Ballas, MD, FACP, FASCP, DABPM
Professor of Medicine and Pediatrics
Cardeza Foundation for Hematologic Research
Department of Medicine
Jefferson Medical College
Philadelphia, Pennsylvania

Andrew Baranowski, MBBS, FRCA, MD, FFPMRCA
Honorary Senior Lecturer
The Institute for Neurology
University College London
Consultant in Pain Medicine
The Pain Management Centre
The National Hospital for Neurology and Neurosurgery
London, England

David Barnard, PhD, JD
Professor of Medicine
Director, Institute to Enhance Palliative Care
Director of Palliative Care Education, Center for Bioethics and Health Law
University of Pittsburgh
Pittsburgh, Pennsylvania

Allan J. Belzberg, MD, FRCSC
Associate Professor of Neurosurgery
Johns Hopkins School of Medicine
Attending Neurosurgeon
Johns Hopkins Hospital
Baltimore, Maryland

Charles B. Berde, MD, PhD
Sara Page Mayo Chair in Pediatric Pain Medicine
Chief, Division of Pain Medicine
Department of Anesthesiology, Perioperative and Pain Medicine
Children's Hospital
Professor of Anaesthesia (Pediatrics)
Harvard Medical School
Boston, Massachusetts

Prabhat K. Bhama, MD
Resident
Department of Otolaryngology—Head & Neck Surgery
University of Washington School of Medicine
Seattle, Washington

Andrew R. Block, PhD
Director of Pain Programs
Texas Back Institute
Plano, Texas

Nikolai Bogduk, MD, PhD
Conjoint Professor of Pain Medicine
University of Newcastle
Head, Department of Clinical Research
Royal Newcastly Centre
Newcastle, New South Wales
Australia

William S. Breitbart, MD
Chief, Psychiatry Service
Memorial Sloan-Kettering Cancer Center
New York, New York

Gary J. Brenner, MD, PhD
Assistant Professor
Harvard Medical School
Program Director, MGH Pain Medicine Fellowship
Department of Anesthesia, Critical Care and Pain Medicine
Massachusetts General Hospital
Boston, Massachusetts

Shane E. Brogan, MB, BCh
Assistant Professor
Department of Anesthesiology
University of Utah Health Sciences Center
Salt Lake City, Utah

David L. Brown, MD
Professor and Chair
Institute of Anesthesiology
Cleveland Clinic Foundation
Cleveland, Ohio

Stephen P. Bruehl, PhD
Department of Anesthesiology
Vanderbilt University School of Medicine
Nashville, Tennessee

Luis F. Buenaver, PhD
Department of Psychiatry & Behavioral Sciences
Center for Mind-Body Research
Johns Hopkins University School of Medicine
Baltimore, Maryland

Asokumar Buvanendran
Associate Professor of Anesthesiology
Department of Anesthesiology
Director, Orthopedic Anesthesia
Rush University Medical Center
Chicago, Illinois

Cynthia Campbell, MD
Swedish Medical Center
Seattle, Washington

Claudia M. Campbell
Department of Psychiatry & Behavioral Sciences
Center for Mind-Body Research
Johns Hopkins University School of Medicine
Baltimore, Maryland

James N. Campbell, MD
Professor of Neurosurgery
Department of Neurosurgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Jacqueline Casillas, MD, MSHS
Assistant Professor of Pediatrics
Division of Hematology/Oncology
Department of Pediatrics
David Geffen School of Medicine at UCLA
Los Angeles, California

Douglas G. Chang, MD, PhD
Chief, Physical Medicine and Rehabilitation
Department of Orthopaedic Surgery
University of California, San Diego
San Diego, California

C. Richard Chapman, PhD
Professor and Director
Department of Anesthesia
Pain Research Center
University of Utah
Salt Lake City, Utah

Ming L. Cheng, MD
Department of Neurosurgery
Rhode Island Hospital
Brown Medical School
Providence, Rhode Island

Gary P. Chimes, MD, PhD
Assistant Professor
Department of Physical Medicine and Rehabilitation
Director, Jackson T. Stephens Spine Clinic
Assistant Residency Program Director
University of Arkansas for Medical Sciences
Little Rock, Arkansas

Roger Chou, MD
Oregon Health & Science University
Associate Professor of Medicine
Department of Medicine and Department of Medical Informatics and Clinical Epidemiology
Portland, Oregon

Michael R. Clark, MD, MPH
Associate Professor and Director
Chronic Pain Treatment Programs
Department of Psychiatry & Behavioral Sciences
Johns Hopkins Medical Institutions
Baltimore, Maryland

Daniel J. Clauw, MD
Professor of Anesthesiology and Medicine
Associate Dean for Clinical and Translational Research
The University of Michigan
Ann Arbor, Michigan

Steven P. Cohen, MD
Associate Professor
Department of Anesthesiology & Critical Care Medicine
Johns Hopkins School of Medicine
Baltimore, Maryland
Associate Professor
Department of Anesthesiology
Uniformed Services University of the Health Sciences
Colonel, US Army
Walter Reed Army Medical Center
Washington, DC

Doris K. Cope, MS, MD
Professor and Vice Chairman of Pain Medicine
Department of Anesthesiology
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Alberto Cortes-Ladino, MD
Chief Fellow, Department of Psychiatry and Behavioral Sciences
Memorial Sloan-Kettering Cancer Center
Weill Cornell Medical College
New York, New York

Michele Curatolo, MD, PhD
Professor
Department of Anaesthesia
Division of Pain Therapy
Bern University Hospital
Bern, Switzerland

Elaine S. Date, MD
Associate Professor
Division Head and Program Director
Physical Medicine and Rehabilitation
Department of Orthopaedic Surgery
Stanford University
Stanford, California

Richard A. Deyo, MD, MPH
Kaiser Permanente Professor of Evidence-Based Family Medicine
Director, OCTRI Community and Practice-Based Research
Departments of Family Medicine and Internal Medicine
Oregon Health & Science University
Portland, Oregon

Jan Dommerholt, PT, MPS, FAAPM
Bethesda Physiocare, Inc/Myopain Seminars, LLC
Bethesda, Maryland

Michael J. Dorsi, MD, FRCSC
Neurosurgical Resident
Department of Neurosurgery
Johns Hopkins Hospital
Baltimore, Maryland

Robert H. Dworkin, PhD
Professor of Anesthesiology, Neurology, Oncology, and Psychiatry
Vice-Chair for Clinical Research, Department of Anesthesiology
Director, Anesthesiology Clinical Research Center
University of Rochester School of Medicine and Dentistry
Rochester, New York

Elon Eisenberg
Director, Pain Relief Unit
Rambam Medical Center
Haifa, Israel

Joyce M. Engel, PhD, OT
Professor
Department of Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington

Joel B. Epstein, DMD, MSD, FRCD(C)
Professor and Head
Department of Oral Medicine and Diagnostic Sciences
Director of Interdisciplinary Program in Oral Cancer
Chicago Cancer Center
College Medicine
University of Illinois at Chicago
Chicago, Illinois

Emad N. Eskandar, MD
Assistant Professor
Harvard Medical School
Director of Stereotactic and Functional Neurosurgery
Massachusetts General Hospital
Boston, Massachusetts

Ronnie Fass, MD
Professor of Medicine
Section of Gastroenterology
University of Arizona School of Medicine
Head, Neuroenteric Clinical Research Group
Southern Arizona VA Health Care System
University of Arizona Health Sciences Center
Tucson, Arizona

Roger B. Fillingim, PhD
Professor
University of Florida College of Dentistry
Staff Psychologist
Malcom Randall VA Medical Center
Gainesville, Florida

Ezekiel Fink, MD
Clinical Instructor
Departments of Neurology and Physical Medicine and Rehabilitation
University of California
Los Angeles, California

Scott M. Fishman, MD
Professor of Anesthesiology
Chief, Division of Pain Medicine
Department of Anesthesiology and Pain Medicine
University of California, Davis School of Medicine
Sacramento, California

Dermot R. Fitzgibbon, MB, BCh
Associate Professor of Anesthesiology
Adjunct Associate Professor of Medicine
University of Washington School of Medicine
Director of Pain Services
University of Washington Medical Center
Director, Cancer Pain Services
University of Washington Medical Center and Seattle Cancer Care Alliance
Seattle, Washington

Rollin M. Gallagher, MD, MPH
Clinical Professor of Psychiatry and Anesthesiology and Critical Care
University of Pennsylvania
Director of Pain Management
Philadelphia Veteran Affairs Medical Center
Philadelphia, Pennsylvania

Gregory C. Gardner, MD, FACP
Professor of Medicine
Division of Rheumatology
Adjunct Professor of Orthopaedics and Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington

Robert J. Gatchel, PhD, ABPP
Professor and Chairman
Department of Psychology
College of Science
University of Texas at Arlington
Arlington, Texas
Clinical Research Director
Eugene McDermott Center for Pain Management
University of Texas Southwestern Medial Center at Dallas
Dallas, Texas

Gerald F. Gebhart, PhD
Director, Center for Pain Research
University of Pittsburgh
Pittsburgh, Pennsylvania

Youssef Ghabrial
Area Director
Department of Orthopaedics
Newcastle Bone and Joint Institute
Newcastle, New South Wales
Australia

Christopher Gilligan, MD, MBA
Staff Physician
Center for Pain Medicine
Massachusetts General Hospital
Instructor in Anaesthesia and Emergency Medicine
Harvard Medical School
Boston, Massachusetts

Aaron M. Gilson, MS, MSSW, PhD
Associate Director for US Policy Research
Pain and Policy Studies Group
Paul P. Carbone Comprehensive Cancer Center
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Peter J. Goadsby, MD, PhD, DSc, FRACP, FRCP
Professor of Neurology
Headache Group, Department of Neurology
University of California
San Francisco, California

Michael S. Gold, PhD
Associate Professor
Department of Anesthesiology
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Douglas L. Gourlay, MD, MSc, FRCPC, FASAM
Centre for Addiction and Mental Health
Toronto, Ontario
Canada

Jayantilal Govind†, MBChB, MMed, FAFOM
Director and Senior Staff Specialist
Occupational and Pain Medicine
Canberra Hospital and Australian National University
Canberra, Australian Capital Territory
Conjoint Senior Lecturer
University of Newcastle
Newcastle, New South Wales
Australia

Christine Greco, MD
Department of Anesthesiology, Perioperative and Pain Medicine
Children's Hospital
Boston, Massachusetts

Joel D. Greenspan, PhD
Professor
Department of Biomedical Sciences
University of Maryland Dental School
Program in Neuroscience
University of Maryland
Baltimore, Maryland

Robert S. Griffin, MD, PhD
Department of Anesthesia and Critical Care
Massachusetts General Hospital
Boston, Massachusetts

Narasimha R. Gundamaraj, MD
Assistant Professor of Clinical Anesthesiology
Keck School of Medicine
University of Southern California
Staff Physician
University of Southern California Pain Clinic
Los Angeles, California

Neil A. Hagen, MD, FRCP
Head, Division of Palliative Medicine
University of Calgary
Calgary, Alberta
Canada

R. Norman Harden, MD
Associate Professor
Northwestern University
Director, Center for Pain Studies
Rehabilitation Institute of Chicago
Chicago, Illinois

Michael Hauck
Department of Neurophysiology and Pathophysiology
University Medical Center Hamburg-Eppendorf
Hamburg, Germany

Jennifer A. Haythornthwaite, PhD
Professor
Department of Psychiatry & Behavioral Sciences
Center for Mind-Body Research
Johns Hopkins University School of Medicine
Baltimore, Maryland

Michael L. Hearndon, DO
Department of Physical Medicine and Rehabilitation
University of Arkansas for Medical Sciences
Little Rock, Arkansas

Howard A. Heit, MD, FACP, FASAM
Assistant Clinical Professor of Medicine
Georgetown University School of Medicine
Washington, DC

†Deceased

Jeanne Hernandez, PhD, MSPH
Assistant Professor
Department of Anesthesiology
University of North Carolina
Director of Behavioral Medicine
Anesthesia Pain Clinic
Spine and Pain Center, UNC Hospitals
Chapel Hill, North Carolina

Keela A. Herr, PhD, RN, FAAN, AGSF
Professor and Chair, Adult and Gerontology
RWJ Executive Nurse Fellow
College of Nursing
University of Iowa
Iowa City, Iowa

Stanley A. Herring, MD
Clinical Professor
Director, UW Medicine Spine Center
University of Washington
Seattle, Washington

Anita H. Hickey, MD, CAPT, USN
Head, Pain Research
Department of Anesthesiology
Naval Medical Center San Diego
San Diego, California

Robert W. Hurley, MD, PhD
Associate Professor
Chief of Pain Medicine
Department of Anesthesiology
University of Florida
Gainesville, Florida

Charles E. Inturrisi, PhD
Professor
Department of Pharmacology
Weill Cornell Medical College
New York, New York

Gordon A. Irving, MBBS, MSc, MMed, FFA(SA)
Clinical Associate Professor
Department of Anesthesia
University of Washington School of Medicine
Medical Director, Swedish Pain and Headache Center
Seattle, Washington

Kenneth C. Jackson II, BSc Pharmacy, PharmD
Associate Professor
Pacific University School of Pharmacy
Hillsboro, Oregon

Robert N. Jamison, PhD
Associate Professor
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Nora A. Janjan, MD, MPSA
Professor
Department of Radiation Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Mark P. Jensen, PhD
Professor
Department of Rehabilitation Medicine
University of Washington School of Medicine
Seattle, Washington

Kaj H. Johansen, MD, PhD
Clinical Professor of Surgery
George I. Thomas, MD, Clinical Professor of Surgery (Emeritus)
University of Washington School of Medicine
Swedish Heart and Vascular Institute
Seattle, Washington

David E. Joranson, MSSW
Distinguished Scientist
Director, Pain and Policy Studies Group
Paul P. Carbone Comprehensive Cancer Center
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

David A. Keith, BDS, FRDSCS, DMD
Professor
Department of Oral and Maxillofacial Surgery
Massachusetts General Hospital
Harvard School of Dental Medicine
Director, Dental/Oral and Maxillofacial Surgery
Harvard Vanguard Medical Associates
Boston, Massachusetts

Joel L. Kent, MD
Associate Professor
Department of Anesthesiology
Director, Division of Pain Management
University of Rochester School of Medicine and Dentistry
Rochester, New York

Kenneth L. Kirsh, PhD
Assistant Professor
Pharmacy Practice and Science
University of Kentucky College of Pharmacy
Clinical Psychologist
The Pain Treatment Center of the Bluegrass
Lexington, Kentucky

Nancy D. Kishino, OTR, CVE
Director, West Coast Spine Restoration Center
Riverside, California

Robert J. Klickovich, MD
Department of Anesthesiology, Pain and Perioperative Medicine
Brigham and Women's Hospital
Boston, Massachusetts

Ronald J. Kulich, PhD
Associate Professor
The Craniofacial Pain and Headache Center
Tufts University School of Dental Medicine
Lecturer, Department of Anesthesia and Critical Care
Division of Pain Medicine
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

Irfan Lalani, MD
Assistant Professor
Department of Anesthesiology and Pain Medicine
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Joseph C. Langlois, MD
Clinical Professor of Dermatology
University of Washington School of Medicine
Seattle, Washington

Frederick A. Lenz, MD
Professor of Neurosurgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Bengt Linderoth, MD, PhD
Department of Neurosurgery
Karolinska Hospital
Stockholm, Sweden

Arthur G. Lipman, PharmD
Professor, Department of Pharmacotherapy
College of Pharmacy
Adjunct Professor, Department of Anesthesiology
School of Medicine
Director of Clinical Pharmacology, Pain Management Center
University of Utah Health Sciences Center
Salt Lake City, Utah

Spencer S. Liu, MD
Clinical Professor of Anesthesiology
Director of Acute Pain Service
Hospital for Special Surgery
Weill Cornell Medical Center
New York, New York

David Loomba, MD
Assistant Professor
Director of Resident Education
Department of Anesthesiology and Pain Medicine
University of California
UC Davis Health System
Sacramento, California

Jürgen Lorenz, MD
Faculty of Life Sciences
Hamburg University of Applied Sciences
Human Physiology and Biology Lab
Hamburg, Germany

Raymond J. Maciewicz, MD, PhD
Director, PBS Medical Consulting
Boston, Massachusetts

Gagan Mahajan, MD
Assistant Professor
Director, Fellowship in Pain Medicine
Department of Anesthesiology and Pain Medicine
University of California, Davis School of Medicine
UC Davis Medical Center
Sacramento, California

Kenneth R. Maravilla, MD
Professor, Radiology
Neurological Surgery Director
MR Research Laboratory
University of Washington
Seattle, Washington

Martha A. Maurer, MSSW, MPH
Pain and Policy Studies Group
World Health Organization Collaborating Center for Policy and Communications in Cancer Care
University of Wisconsin School of Medicine and Public Health
Paul P. Carbone Comprehensive Cancer Center
Madison, Wisconsin

Emeran Mayer
Professor, Departments of Medicine, Physiology, Psychiatry, and Biobehavioral Sciences
David Geffen School of Medicine at UCLA
Director, UCLA Center for Neurovisceral Sciences & Women's Health
UCLA Division of Digestive Diseases
Los Angeles, California

Bill McCarberg, MD
Founder, Chronic Pain Management Program
Kaiser Permanente
Assistant Clinical Professor (voluntary)
University of California, San Diego
San Diego, California

Regina McConley, MA
Doctoral Graduate Student
Medical Psychology
University of Alabama at Birmingham
Birmingham, Alabama

Lance M. McCracken, PhD
Consultant Clinical Psychologist and Clinical Lead
Pain Management Unit
Royal National Hospital for Rheumatic Diseases
Visiting Fellow, Pain Management Unit
Department of Psychology
University of Bath
Bath, United Kingdom

Ellen McGough, PT, MEd
Lecturer
Department of Rehabilitation Medicine
University of Washington
Seattle, Washington

Brian E. McGuirk, MBBS, DPH(OH), FAFOM(RACP), FAFOM
Senior Staff Specialist, Occupational (Musculoskeletal) Medicine
Hunter New England Area Health Service
New Castle, New South Wales
Australia

James P. McLean[†], MD
Assistant Professor
Department of Physical Medicine and Rehabilitation
University of Kansas Medical Center
Kansas City, Kansas

Noshir R. Mehta, DMD, MDS, MS
Professor and Director
The Craniofacial Pain and Headache Center
Tufts University
Chairman
Department of General Dentistry
Tufts University School of Dental Medicine
Boston, Massachusetts

M. Stephen Melton, MD
Assistant Professor
Department of Anesthesiology
Duke University Medical Center
Durham, North Carolina

[†]Deceased

James R. Miner, MD, FACEP
Associate Professor of Emergency Medicine
University of Minnesota Medical School
Department of Emergency Medicine
Hennepin County Medical Center
Minneapolis, Minnesota

Asako Miyakoshi, MD
Assistant Professor of Neuroradiology
Department of Radiology
University of Washington School of Medicine
Seattle, Washington

Jane Moore, MBBS, MSc
Honorary Consultant Gynaecologist
Nuffield Department of Obstetrics and Gynaecology
John Radcliffe Hospital
Oxford, England

David B. Morris, PhD
University Professor
University of Virginia
Charlottesville, Virginia

SpineCare Medical Group
San Francisco Spine Institute
Daly City, California

Mark M. Schubert, DDS, MSD
Professor, Department of Oral Medicine
University of Washington School of Dentistry
Director of Oral Medicine
Seattle Cancer Care Alliance and Fred Hutchinson Cancer Research Center
Seattle, Washington

Steven J. Scrivani, DDS, DMedSc
Professor
The Craniofacial Pain and Headache Center
Tufts University
Research Associate
Pain and Analgesia Imaging and Neuroscience (P.A.I.N.) Group
Brain Imaging Center
McLean Hospital
Harvard Medical School
Boston, Massachusetts

Curtis N. Sessler, MD, FCCP, FCCM
Orhan Muren Professor of Medicine
Pulmonary and Critical Care Medicine
Virginia Commonwealth University
Medical Director
Critical Care, MRICU
Medical College of Virginia Hospitals
Richmond, Virginia

Jay P. Shah, MD
Staff Physiatrist
Rehabilitation Medicine Department
Clinical Research Center
National Institutes of Health
Washington, DC

Sam R. Sharar, MD
Professor
Department of Anesthesiology
University of Washington School of Medicine
Harborview Medical Center
Seattle, Washington

Donald C. Shields, MD, PhD
Department of Neurosurgery
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

Philip J. Siddall, MBBS MM (Pain Mgt), PhD, FFPMANZCA
Clinical Associate Professor
Pain Management Research Institute
University of Sydney
Royal North Shore Hospital
Sydney, Australia

Charles A. Simpson, DC, DACBO
Vice President, Medical Director
Complementary Healthcare Plans, Inc
Beaverton, Oregon

Howard S. Smith, MD
Associate Professor & Academic Director of Pain Management
Department of Anesthesiology
Albany Medical College
Albany, New York

Pamela L. Squire, MD, CCFP
North Vancouver, British Columbia
Canada

Steven P. Stanos, Jr, DO
Medical Director
Chronic Pain Care Center
Rehabilitation Institute of Chicago
Assistant Professor
Department of Physical Medicine and Rehabilitation
Assistant Program Director
Multidisciplinary Pain Fellowship
Northwestern University Medical School
Feinberg School of Medicine
Chicago, Illinois

Tatiana D. Starr, MA
Department of Psychiatry and Behavioral Sciences
Memorial Sloan-Kettering Cancer Center
New York, New York

M. Alan Stiles, DMD
Facial Pain Management
Department of Oral and Maxillofacial Surgery
Thomas Jefferson University
Philadelphia, Pennsylvania

Milan P. Stojanovic, MD
Spine & Pain Institute of New England
Dedham, Massachusetts

Mark D. Sullivan, MD, PhD
Department of Rehabilitation Medicine
University of Washington
Seattle, Washington

Kimberly S. Swanson, PhD
Licensed Clinical Psychologist
The Everett Clinic
Everett, Washington

Karen L. Syrjala, PhD
Member and Director of Behavioral Sciences
Clinical Research Division
Fred Hutchinson Cancer Research Center
Associate Professor
Department of Psychiatry and Behavioral Sciences
University of Washington School of Medicine
Seattle, Washington

Raymond C. Tait, PhD
Professor, Department of Neurology and Psychiatry
St. Louis University
St. Louis, Missouri

Ronald R. Tasker, MD, MSc, FRCS(C)
Professor Emeritus of Neurosurgery
University of Toronto
Division of Neurosurgery
Toronto Western Hospital
Toronto, Canada

Rajbala Thakur, MD
Associate Professor of Anesthesiology
Medical Director, Anesthesia Clinical Research Center
University of Rochester School of Medicine and Dentistry
Rochester, New York

Brian R. Theodore, MS
Department of Psychology
University of Texas at Arlington
Arlington, Texas

George I. Thomas, MD
Clinical Professor of Surgery
University of Washington School of Medicine
Seattle, Washington

Beverly E. Thorn, PhD, ABPP
Editor, Journal of Clinical Psychology
Professor of Psychology
University of Alabama
Tuscaloosa, Alabama

Knox H. Todd, MD, MPH
Professor of Emergency Medicine
Albert Einstein College of Medicine
Director, Pain and Emergency Medicine Institute
Beth Israel Medical Center
New York, New York

Rolf-Detlef Treede, MD
Professor of Neurophysiology
Center for Biomedicine and Medical Technology, Mannheim
Ruprecht Karls University, Heidelberg
Mannheim, Germany

Dennis C. Turk, PhD
John and Emma Bonica Professor of Anesthesiology & Pain Research
University of Washington
Seattle, Washington

Katy Vincent, MBBS, BSc
Pelvic Pain Fellow and Honorary Registrar
Nuffield Department of Obstetrics and Gynaecology
John Radcliffe Hospital
Oxford, England

Gary A. Walco, PhD
Director, The David Center for Children's Pain and Palliative Care
Hackensack University Medical Center
Hackensack, New Jersey
Professor of Pediatrics
University of Medicine and Dentistry of New Jersey—New Jersey Medical School
Newark, New Jersey

David Walk, MD
Associate Professor or Neurology
University of Minnesota
Minneapolis, Minnesota

Barbara B. Walker, PhD
Clinical Professor
Department of Psychological and Brain Sciences
Indiana University
Bloomington, Indiana

Anthony C. Wang, MD
Department of Neurosurgery

FOREWORD

This, the fourth edition of *Bonica's Management of Pain*, continues the tradition that John J. Bonica, M.D., started with the publication of the first edition in 1953. That was a herculean endeavor and monumental achievement, as no one had ever attempted to comprehensively describe all that was known about pain and how to diagnose and treat it. The first edition was almost exclusively the work of Dr. Bonica; only minor sections were contributed by his colleagues. It took him 30 years to bring out the second edition, which was the product of not only Dr. Bonica but also of a long list of contributors who, in fact, wrote more than half of the pages. This edition was characterized by extensive consideration of the anatomy and physiology underlying pain and by the discussion of multidisciplinary pain management and pain clinics.

The field of pain management, launched by Dr. Bonica's own practice and teaching and by his founding of the International Association for the Study of Pain, had flourished by the time of the second edition. The field of pain medicine developed rapidly, and Bonica knew that another edition of the *Management of Pain* would have to be written to keep his textbook current. Unfortunately, his health limited his ability to undertake this task. Shortly before he died, I promised him that there would be a third edition that I would edit with the help of colleagues at the University of Washington. The third edition was published in 2000, firmly based upon the format of the prior editions but expanding the content to keep up with developments in both basic science and clinical pain management.

Another decade has passed; the sciences basic to pain and clinical practice have continued to rapidly expand. It is time for a new edition of this great book; I am thrilled by the job that the new editors have done in assembling an all-star group of contributors to continue what Dr. Bonica began over 50 years ago. This latest edition of *Bonica's Management of Pain* will again set the pace for the coming decade of pain research, teaching, and patient care.

Whereas everyone active in pain research or patient care knew John Bonica in the last 30 years of the twentieth century, we now have spawned a generation or two of workers in this field who know him only through his publications or the occasional prophetic story. Although this is an understandable reality, it is unfortunate. Dr. Bonica was a truly great man whose efforts almost single handedly caused pain to be put on the road maps of both basic science and health care. As I wrote in his obituary published in *Pain*[1]:

"He cared about his patients for whom he tirelessly worked. He cared about the research that scientists undertook to understand the mechanisms of pain. He cared about those who suffered in far-away places; he wanted their doctors to learn about pain management. He cared about how governments impacted the delivery of pain management services. He cared about his students, trainees and colleagues. He really cared about those who attempted to continue what he had started. He cared about his children and his wife, although his career took time away from them." (p2)

More than an inscription on his gravestone, the continued life of *Bonica's Management of Pain* tells us of his accomplishments. It was a true privilege to have known him and his family, worked for and with him, and to have carried on the traditions that he launched. JJB, as he was known to all who worked alongside him, would have been gratified to see the advances that he inspired. His greatness will live on through the publication of this fourth edition.

John D. Loeser, M. D.
March, 2009

1. Loeser, JD: Obituary: John J Bonica, M.D., and Emma B. Bonica. Pain. 1994;59:1–3.

PREFACE TO THE FOURTH EDITION (2009)

This book was first introduced 56 years ago, a time that many believe marks the beginning of the multidisciplinary field of pain management. The idea for a clinical textbook devoted to the management of pain came from John Bonica, and in its first edition he wrote that the book offers a synthesis of information from disparate disciplines to form a complete discussion on pain and its management. Such a book, he believed, would strengthen the pain field by assimilating new insights and growing knowledge from many interested disciplines. Since the first edition in 1953, the purpose of the book has remained essentially the same, despite extraordinary growth in the science and practice of pain management, and the emergence of pain medicine as its own discipline. The book has remained a key reference for clinicians through all its editions, largely because of the high quality of the original book, and the ability to attract world-class experts to engage in his project, even years after Dr. Bonica's death in 1994. It was with trepidation and pride that we, the three chief editors, accepted the task of shepherding the next edition of this essential book to publication. We quickly realized that we were no match for Bonica, who formulated and wrote large parts of the original book himself and from the start, we solicited help from expert subeditors. As an editorial group, we made several key decisions: that we would keep the book near its original manageable size, that understanding anew the key role played by central mechanisms in pain, that we would shift the book's emphasis from its focus on peripheral (anatomically-based) mechanisms to one with a greater focus on neural (global) mechanisms, and that we would include new or updated chapters on issues that impact clinical pain management such as pain training, regulatory and political issues, and conducting clinical trials.

In his first edition, John Bonica tells us that he was called to write his book out of of the ". . . deep feeling for those who are afflicted with intractable pain, and by an intense desire to contribute something toward the alleviation of their suffering." This commitment originated from his experiences in treating wounded soldiers with intractable pain during the Second World War. It is sad and ironic that this fourth edition is now published at a time when undertreated pain is more widely recognized than ever and, in part, informed by wounded soldiers returning from the wars in Iraq and Afghanistan. In the year just prior to publishing this, the fourth edition, the U.S. Congress passed, and the President of the United States signed into law, two bills that aim to improve pain care for our active military personnel and veterans respectively. More than 50 years after Bonica began to raise awareness about the plight of those in pain, our society increasingly values safe and effective control of pain, and this trend echoes Bonica's vision of a world free of suffering from treatable pain.

The fourth edition of the textbook remains faithful to Bonica's original intent that his book should provide a comprehensive reference for practicing clinicians across all disciplines. In 1953, Bonica was one of few experts in the new field of pain medicine, and he almost single-handedly undertook the task of producing the first clinical textbook. Now, there are many experts with a remarkable depth of knowledge. It is a testament to Bonica that the many leading authorities contributing to the present edition as authors and section editors feel sincerely indebted to him, and they have willingly given of their time to maintain his legacy. Through its second and third editions, the book maintained a structure and organization similar to the 1st edition. In this new edition, every chapter has been revised, substantially rewritten, or represents a completely new chapter and or topic. With the addition of new material, there will undoubtedly be overlap between chapters. With a text of such broad scope, some degree of overlap is inevitable; indeed, we often allowed significant overlap, so that each chapter would stand on its own during independent perusal or study.

This book is divided into 6 parts: (1) Basic Considerations, (2) Economic, Political, Legal, and Ethical Considerations, (3) Evaluation of the Pain Patient, (4) Pain Conditions, (5) Methods for Symptomatic Control, and (6) Provisions of Pain Treatment. Basic Considerations offers an orientation to the history of pain management and the concepts and paradigms fundamental to this field, including taxonomy, basic science, anatomy, physiology, psychology, and social science. Economic, Political, Legal, and Ethical Considerations represents new content for this textbook, reflecting the emerging social impact of pain and pain management. Evaluation of the Pain Patient covers physical and psychological assessment, use of imaging and other technology-based testing, as well as special assessment for function, disability, addiction, and multidisciplinary care. Pain Conditions is the largest single part of the text, comprising 9 sections and 53 chapters. These sections include neuropathic pain syndromes; psychological contributions to pain; vascular, cutaneous, and musculoskeletal pain disorders; pain due to cancer; acute pain; pain in special populations; visceral pain disorders; regional pain; and low back pain. The section on pain in special populations addresses populations such as children, older persons, and those with pain and addiction. The regional pain section is a holdover from past editions and covers pain disorders that are associated with discrete parts of the body such as facial pain, cranial neuralgias, and pain syndromes associated with upper or lower extremities. Methods of Symptomatic Control is another large part of the text which is partitioned into the following 6 sections: pharmacologic therapies, psychological techniques, physical and other noninterventional modalities, implanted electrical stimulators, interventional pain management, and surgical approaches. Provision of Pain Treatment is the final part of this text, addressing systems for delivery of care and means for training pain specialists. Special areas of medicine in which pain has a prominent role are addressed, including primary care, end of life care, intensive care, and emergency care. The text concludes with a brief view toward the future of pain management.

This book would not be possible without the extensive contributions of the section editors and particularly the efforts of the chapter authors; the success of this work is directly attributable to these individuals. The editors are indebted to Brian Brown and Francis DeStefano of Lippincott, Williams &

Wilkins who served critical roles in shepherding this project into existence, and to Keith Donnellan of Dovetail Content Solutions who managed its development with skill and diplomacy.

As the field of pain medicine has evolved, so has this text. Despite much that is new or revised, the text remains incomplete, a reflection of an emerging field that awaits profound discoveries and development. Through the many chapters and pages of this new edition of his classic text, we hope that John Bonica's passion for an integrated, coherent, and compassionate field will live on. Like Bonica, our central purpose is to assist students and practitioners across all medical disciplines, advance their knowledge of pain medicine, and relieve suffering.

PREFACE TO THE FIRST EDITION (1953)

The purpose of this book is to present within one volume a concise but complete discussion of the fundamental aspects of pain, the various diseases and disorders in which pain constitutes a major problem, and the methods employed in its management, with special emphasis on the use of analgesic block as an aid in the diagnosis, prognosis, and therapy. Although several books dealing with certain phases of this problem are available, none is complete from the standpoint of the practitioner; for it is necessary for him to consult several texts in order to obtain information regarding the cause, characteristics, mechanisms, effects, diagnosis, and therapy of pain and management of its intractable variety with analgesic block and certain adjuvant methods. The present volume is the product of the author's desire to facilitate the task of the busy practitioner and to supply him easily accessible information with the conviction that this will induce more clinicians to employ these methods of diagnosis and therapy.

One need not elaborate on the reasons for writing on the management of pain, for reflection emphasized that this age-old problem is still one of the most difficult and often vexing phases of medical practice—a fact well appreciated by most physicians. This fact, as well as other reasons, are presented in the introduction and are emphasized throughout the book, particularly in Chapter 5.

I have been motivated to write this volume by a deep feeling for those who are afflicted with intractable pain, and by an intense desire to contribute something toward the alleviation of their suffering. The plan for its writing was germinated almost a decade ago during the Second World War, while I was Chief of the Anesthesia Section of a large Army hospital, where I was afforded the opportunity to observe and manage an unusually large number of patients with severe intractable pain. The gratifying results obtained with analgesic block in some instances impressed me with the efficacy of this method in selected cases. In addition, the fact that these procedures effected relief which frequently was not only dramatic, but outlasted by hours and days the transient physiochemical interruption of nerve impulses, fascinated me and aroused my interest. Perusal of the literature revealed a paucity of material on this subject—a situation which has not changed much since then and which clearly indicated an obvious need for a practical source of information about this perplexing phenomenon and the application of analgesic block to its management.

This book is composed of three parts. *The first part* includes a discussion of the fundamental aspects of pain. While some of the material, on superficial thought, might be considered too detailed or entirely unnecessary, it has been included because of my conviction that in order to manage pain properly its anatomical, physiological and psychological bases must be understood. As is true in all fields of endeavor, a thorough knowledge of fundamental principles is an essential prerequisite without which optimal results are precluded. In order to diagnose and treat it properly, the physician must know the course of pain from its place of origin to the apperception centers in the brain and must be well versed in all the essentials and components of which pain consists; he must know its causes, mechanisms, characteristics, varieties, its localizations and significance, and the mental and physical effects it produces.

The second part deals with methods and techniques of managing pain. It was originally planned to include only the method which is the central theme of the book—analgesic block. However, it was soon realized that while this important phase is, to be sure, here treated in a comprehensive manner, it does not present the complete story of the management of pain; because frequently other adjuvant methods are employed in conjunction with nerve blocking. To illustrate the point, trigeminal neuralgia is frequently treated with neurolytic blocks, but sometimes this does not afford sufficiently long relief, and neurotomy is resorted to. The pain associated with malignancy is managed with alcohol nerve block, but roentgen therapy is frequently employed as an adjuvant. Moreover physical and/or psychiatric therapy constitute integral phases of the management of pain without which optimal results cannot be hoped for. After careful consideration, it was decided to include another section in Part II in which are presented methods that are frequently employed in conjunction with analgesic block. It is hoped that such inclusion will give the book a wider scope and greater usefulness.

In the third part are presented various diseases or disorders with painful syndromes which have been and can be managed with analgesic block with or without the aid of other methods. The arrangement of this part is explained in detail on page 671. It is suggested that the reader refer to that page before proceeding further to read any on the pain syndromes. Though the material in this part mainly represents my observations, clinical impressions, and opinions, obtained or developed from experience with, and statistical analysis of, many thousands of cases, it also includes unpublished data of several outstanding authorities who have kindly placed them at my disposal. Moreover, it includes the published views and clinical experiences of others, with credit given where it is due.

In writing this comprehensive treatise, which has involved no small amount of time and effort, the one principle which has always been kept in mind and adhered to has been to present the fundamental considerations and principles of the problem before the practical aspects are discussed.

I have endeavored to make this book as complete as possible, and to this end have thoroughly searched the literature, both English and foreign, and have taken from it all that I thought might be valuable to the reader. In order to comply with the aim of completeness and still keep the book concise and within reasonable size, the material has been selected with care and discretion. In a field so vast and complex as pain, it is unavoidable that what might be thought sufficiently important to deserve detailed discussion is presented in an abbreviated manner or entirely omitted. In other instances, mere mention or omission represents a reluctant compliance with the requirements dictated by the size of the volume. Nonetheless, I believe thoroughness and important detail have not been sacrificed. The bibliography represents the most important references, and many excellent articles on each subject were also reluctantly omitted for that reason.

The book is intended for practitioners of every field of medi-

cine, because pain is universal and provides the main reason why patients seek the aid of the doctor. It is hoped that it will prove useful, not only to the anesthesiologist, neurologist, neurosurgeon, orthopedist, and physiatrist to whom especially is relegated the task of caring for patients with intractable pain, but also to the general practitioner, surgeon, internist, psychiatrist, and any other physician who may be confronted with this problem. It is especially intended for general practitioners, particularly those practicing in smaller communities where the services of a specialist in analgesic blocking are not available. With this aim in mind the techniques of analgesic block are presented in such a manner that most of them may be effectively accomplished by any physician, even though he may be a novice with regional analgesia. In order to facilitate the task of the busy reader, less relevant facts—material which has been included because of its academic importance, for the sake of completeness, or for consumption by students and those who wish to delve deeper into the problem—are presented in small type. These can be omitted without losing continuity of thought. In this manner, while completeness, detail, and thoroughness are not sacrificed, emphasis is laid on the practical aspects of the problem at hand.

The unusually large number of illustrations, many of which are original and composed from dissected material or clinical cases, have been included with the conviction that these frequently tell the story much better than words.

A book of this nature is made possible only by the contribution of many individuals. The information set forth in the first part of the volume represents the fruition of the joint effort of anatomists, physiologists, pharmacologists, neurologists, neurosurgeons, anesthesiologists, psychiatrists, and many other laboratory and clinical investigators who have spent untold time, labor, and effort to discover the mystery of pain. I am grateful for their elucidating knowledge. To clinicians who have reported their experiences, and to others who have placed at my disposal unpublished data, observations, and opinions, my sincere thanks. I am particularly obliged to General Maxwell Keeler, and Col. Clinton S. Lyter, of Madigan Army Hospital for their continuous cooperation in obtaining much of the clinical data embraced in this volume. I want to express my gratitude to Mr. Harold Woodworth for his friendship, sympathetic understanding and devotion to the cause of medicine. I also want to thank the other members of the Board of Trustees of Tacoma General Hospital, but particularly Mr. Alex Babbit, and Mr. Walter Heath and John Dobyns, Directors of the hospital. Their continuous cooperation has facilitated the activities of the Department of Anesthesia, Nerve Block Clinic, and Pain Clinic.

I am very grateful to Dr. Robert Johnson, Associate Professor of Anatomy of the University of Washington School of Medicine, for his encouragement and criticism of some parts of the manuscript; to Doctor Frederick Haugen for his assistance, criticism and suggestion.

My collaborators, Professor Robert Ripley, Doctors Wendell Peterson, Frank Rigos, John T. Robson, Col. Clark Williams, M.C., and Lieut. Col. Walter Lumpkin, M.D., have my heartfelt thanks for their contributions and cooperation.

My appreciation is extended to Miss Joy Polis, Miss Virginia Coleman, and other artists for the illustrations and to Mr. Kenneth Ollar for the photography; to Mrs. Louise Cameron for her cooperation in obtaining the roentgenograms; to Mrs. Katherine Rogers Miller, Miss Eleanor Ekberg and the late Mrs. Blanch DeWitt of Tacoma, Miss Bertha Hallam, Portland, and Mr. Alderson Fry, Seattle—all librarians whose cooperation has facilitated a difficult task, and to Mr. John Morrison for editorial work.

This preface would be incomplete if I did not acknowledge my indebtedness to my secretaries, Miss Katherine Stryker and Mrs. Dorothy Richmond, for the inestimable aid they have given me in the preparation of the manuscript.

My appreciation is extended to my publishers for their courtesy, cooperation, and considerateness throughout the preparation of this volume.

John J. Bonica
Tacoma, Washington

ACKNOWLEDGMENTS

Jane C. Ballantyne and James P. Rathmell thank Tina Toland for editorial assistance and Dr. Warren Zapol, immediate past Chair of the Department of Anesthesiology and Critical Care at Massachusetts General Hospital, for his encouragement and support.

Scott M. Fishman thanks Mureen Darrington, Marnie Livingston, and Katherine Chu for editorial assistance and the faculty of the Division of Pain Medicine and Dr. Peter Moore, Chair of the Department of Anesthesiology and Pain Medicine at the University of California, Davis, for encouragement and support.

PART I ■ BASIC CONSIDERATIONS

Chapter 1 **Intellectual Milestones in our Understanding and Treatment of Pain** 1
Doris K. Cope

Chapter 2 **Pain Terms and Taxonomies of Pain** 13
Dennis C. Turk and Akiko Okifuji

Chapter 3 **Peripheral Pain Mechanisms and Nociceptor Sensitization** 24
Michael S. Gold and Gerald F. Gebhart

Chapter 4 **Substrates of Spinal Cord Nociceptive Processing** 35
Timothy Ness and Alan Randich

Chapter 5 **Modulation of Spinal Nociceptive Processing** 48
Alan Randich and Timothy Ness

Chapter 6 **Supraspinal Mechanisms of Pain and Nociception** 61
Jürgen Lorenz and Michael Hauck

Chapter 7 **Psychological Aspects of Pain** 74
Dennis C. Turk, Kimberly S. Swanson, and Hilary D.Wilson

Chapter 8 **Individual Differences in Pain: The Roles of Gender, Ethnicity, and Genetics** 86
Roger B. Fillingim

Chapter 9 **Functional Neuroanatomy of the Nociceptive System** 98
Robert S. Griffin, Ezekiel Fink, and Gary J. Brenner

Chapter 10 **Clinical Trials** 120
Roger Chou and Richard A. Deyo

PART II ■ ECONOMIC, POLITICAL, LEGAL, AND ETHICAL CONSIDERATIONS

Chapter 11 **Sociocultural Dimensions of Pain Management** 133
David B. Morris

Chapter 12 **Ethical Issues in Pain Management** 145
Ben A. Rich

Chapter 13 **Ethical Issues in the Care of Dying Patients** 153
David Barnard

Chapter 14 **Laws and Policies Affecting Pain Management** 166
Aaron M. Gilson

Chapter 15 **Litigation Involving Pain Management** 183
Ben A. Rich

Chapter 16 **Opioid Policy, Availability, and Access in Developing and Nonindustrialized Countries** 194
David E. Joranson, Karen M. Ryan, and Martha A. Maurer

PART III ■ EVALUATION OF THE PAIN PATIENT

Chapter 17 **Medical Evaluation of the Chronic Pain Patient** 209
Gordon A. Irving and Pamela L. Squire

Chapter 18 **Electrodiagnostic Evaluation of Acute and Chronic Pain Syndromes** 223
Douglas G. Chang and Elaine S. Date

Chapter 19 **Diagnostic Imaging of Pain** 234
Asako Miyakoshi and Kenneth R. Maravilla

Chapter 20 **Measurement of Pain** 251
Mark P. Jensen

Chapter 21 **Psychological and Psychosocial Evaluation** 270
Tatiana D. Starr, Lauren J. Rogak, Kenneth L. Kirsh, and Steven D. Passik

Chapter 22 **Disability Evaluation in Painful Conditions** 279
James P. Robinson and Raymond C. Tait

Chapter 23 **Multidisciplinary Assessment of Patients with Chronic Pain** 288
Dennis C. Turk and James P. Robinson

PART IV ■ PAIN CONDITIONS

SECTION A ■ NEUROPATHIC PAIN SYNDROMES

Chapter 24 **Painful Neuropathies** 303
David Walk and Misha-Miroslav Backonja

Chapter 25 **Complex Regional Pain Syndrome** 314
R. Norman Harden and Stephen P. Bruehl

Chapter 26 **Phantom Pain** 331
Howard S. Smith, Irfan Lalani, and Charles E. Argoff

Chapter 27 **Herpes Zoster and Postherpetic Neuralgia** 338
Rajbala Thakur, Joel L. Kent, and Robert H. Dworkin

Chapter 28 **Central Pain States** 357
Joel D. Greenspan, Rolf-Detlef Treede, Ronald R. Tasker and Frederick A. Lenz

SECTION B ■ PSYCHOLOGICAL CONTRIBUTIONS TO PAIN

Chapter 29 **The Psychophysiology of Pain** 375
C. Richard Chapman

Chapter 30 **Pain and Learning** 388
Robert J. Gatchel, Brian R.Theodore, Nancy D. Kishino, and Carl E. Noe

Chapter 31 **Psychiatric Illness, Depression, Anxiety, and Somatoform Pain Syndromes** 393
Ajay D. Wasan, Mark D. Sullivan, and Michael R. Clark

Chapter 32 **The Psychology of Addiction** 418
Lauren J. Rogak, Tatiana D. Starr, Kenneth L. Kirsh, and Steven D. Passik

Chapter 33 **The Doctor-Patient Relationship in Pain Management: Dealing with Difficult Clinician-Patient Interactions** 423
Robert N. Jamison

SECTION C ■ VASCULAR, CUTANEOUS, AND MUSCULOSKELETAL PAINS

Chapter 34 **Joint Pain** 431
Gregory C. Gardner

Chapter 35 **Myofascial Pain Syndrome** 450
Jan Dommerholt and Jay P. Shah

Chapter 36 **Fibromyalgia** 471
Daniel J. Clauw

Chapter 37 **Pain of Dermatologic Disorders** 489
Joseph C. Langlois and John E. Olerud

Chapter 38 **Pain Due to Vascular Causes** 512
Kaj H. Johansen

Chapter 39 **Pain Due to Thoracic Outlet Syndrome** 520
Kaj H. Johansen, Cynthia Campbell, and George I. Thomas

Chapter 40 **Pain Following Spinal Cord Injury** 526
Philip J. Siddall and Paul J. Wrigley

SECTION D ■ PAIN DUE TO CANCER

Chapter 41 **Epidemiology, Prevalence, and Cancer Pain Syndromes** 537
Neil A. Hagen

Chapter 42 **Mechanisms, Assessment, and Diagnosis of Pain Due to Cancer** 559
Dermot R. Fitzgibbon

Chapter 43 **Cancer Pain: Principles of Management and Pharmacotherapy** 582
Dermot R. Fitzgibbon

Chapter 44 **Interventional Pain Therapies** 605
Shane E. Brogan

Chapter 45 **Pain Caused by Cancer of the Head and Neck and Oral Mucositis** 618
Joel B. Epstein, Mark M. Schubert, Prabhat K. Bhama, and Ernest A. Weymuller, Jr.

Chapter 46 **Cancer-Related Bone Pain** 629
Janet Abrahm, Edgar Ross, and Robert J. Klickovich

Chapter 47 **Cancer-Related Visceral Pain** 635
Janet Abrahm, Edgar Ross, and Robert J. Klickovich

Chapter 48 **Radiotherapy and Chemotherapy in Cancer Pain Management** 644
Ajit S. Ahluwalia, Nora A. Janjan, and Cameron Muir

Chapter 49 **Cancer Pain in Children** 669
Jacqueline Casillas and Lonnie K. Zeltzer

SECTION E ■ ACUTE PAIN

Chapter 50 **Acute Pain Management in Children** 681
Christine Greco and Charles B. Berde

Chapter 51 **Acute Pain in Adults** 699
Robert W. Hurley, Steven P. Cohen, and Christopher L. Wu

Chapter 52 **Regional Anesthesia Techniques for Acute Pain Management** 723
M. Stephen Melton and Spencer S. Liu

Chapter 53 **Burn Pain** 754
Sam R. Sharar and David R. Patterson

SECTION F ■ PAIN IN SPECIAL POPULATIONS

Chapter 54 **Persistent Pain in Children** 767
Neil L. Schechter, Tonya M. Palermo, Gary A. Walco, and Charles B. Berde

Chapter 55 **Pain in the Older Person** 782
Paul M. Arnstein and Keela A. Herr

Chapter 56 **Obstetric Pain** 791
Cynthia A. Wong

Chapter 57 **Pain and Sickle Cell Disease** 806
Samir K. Ballas

Chapter 58 **Pain in Human Immunodeficiency Virus Disease** 827
William S. Breitbart and Alberto Cortes-Ladino

Chapter 59 **The Treatment of Chronic Pain in Patients with History of Substance Abuse** 846
Howard A. Heit and Douglas L. Gourlay

Chapter 60 **Compliance Monitoring in Chronic Pain Management** 854
Douglas L. Gourlay and Howard A. Heit

SECTION G ■ VISCERAL PAIN

Chapter 61 **Headache** 860
Peter J. Goadsby

Chapter 62 **Noncardiac Chest Pain** 876
Ronnie Fass

Chapter 63 **Abdominal, Peritoneal, and Retroperitoneal Pain** 899
Emeran Mayer and Heng Yu Wong

Chapter 64 **Pelvic Pain in Females** 925
Katy Vincent and Jane Moore

Chapter 65 **Pelvic Pain in Males** 941
Andrew Baranowski

SECTION H ■ REGIONAL PAIN

Chapter 66 **Cranial Neuralgias** 953
Anita H. Hickey, Steven J. Scrivani, and Zahid H. Bajwa

Chapter 67 **Facial Pain** 972
Steven J. Scrivani, Noshir R. Mehta, David A. Keith, M. Alan Stiles, Raymond J. Maciewicz, and Ronald J. Kulich

Chapter 68 **Neck and Arm Pain** 1000
Anita H. Hickey and Zahid H. Bajwa

Chapter 69 **Chest Wall Pain** 1042
Narasimha R. Gundamaraj and Steven Richeimer

Chapter 70 **Lower Extremity Pain** 1069
Gagan Mahajan and David Loomba

CHAPTER 1 ■ INTELLECTUAL MILESTONES IN OUR UNDERSTANDING AND TREATMENT OF PAIN

DORIS K. COPE

In order to treat something we first must learn to recognize it.
—Sir William Osler[1]

Through the ages, pain and suffering have been the primary reason that patients have sought medical care. What is pain? It is both a personal emotional experience as well as the result of complex physiological adaptations of molecular and biological function. This chapter will discuss this duality of concepts, the familiar mind-body dilemma in the context of how our mental constructs shape our understanding, and then treatment of this complex phenomenon we call pain. The chapter will close with a discussion of how the medical subspecialty is evolving within the broader context of medical specialization and thoughts for future development.[2]

PAIN UNDERSTOOD AS PART OF A LARGER PHILOSOPHY OR WORLD VIEW

Since the beginning of time, humans are born through a painful process and the experience of suffering remains universal. The meaning of pain reflects the contemporary spirit of the age and, therefore, has changed over recorded history with changing world views. Among the earliest systems of pain management, dating back to the Stone Age, was Chinese acupuncture, theoretically based on the philosophy of imbalances of between yin and yang affecting qi and blood flow. Thousands of years ago, Egyptians considered the experience of pain to be a god or disincarnate spirit afflicting the heart, which was conceptualized as the center of emotion. Galen, and later Aristotle (Fig. 1.1), described pain as an emotional experience, or "a passion of the soul."[3]

An important concept dating from antiquity that persisted until the 19th century was the theory of importance of the four humors. This world view was espoused by Greek philosophers in approximately 400 BC and later applied to medicine by Hippocrates (Fig. 1.2) who described humors as related to one of the four constitutions, shown in Table 1.1. Seasonal changes evoked pain and certain disorders, such as migraine, were associated with specific humors (e.g., excessive cold humors thought to result in a mucus discharge requiring application of "hot effusions" to the head).

Consistent with this ideology was the custom of treating pain by applying "opposites" such as hot applications to the head to counterbalance and evacuate "cold" humors of headaches.[5] Again, based on the humor theory and treatment via "opposites," was the technique called cupping. Warm suction cups were applied to the skin that on cooling resulted in raised reddened welts thought to "draw out" any unbalanced humors.[6]

Later, during the Middle Ages, coincident with the spread of Christianity, pain, not surprisingly, was explained in a spiritual, religious context. Medieval life has been described as short, cheap, and brutish, especially for the lower classes, with pain accepted as the universal lot of mankind. Little is known of how pain was actually treated during this period, but a suffering Christ, martyred saints, and the concept of physical pain in purgatory originated around the 12th century AD.[6,7] Commonly revered was the iconography of tortured saints with ecstatic faces depicting pain as a spiritual discipline bringing the saints closer to God, relieved primarily by prayer and meditation. A clear example of pain as ennobling was St. Ignatius Loyola's habit of wearing ropes and chains cutting into the skin and encouraging other humiliations of the flesh to enhance his spiritual development.[3]

An interesting example of pain as a function of the sociological concepts of the day is the rise and fall of the diagnosis of hysteria, common in the 17th century and virtually nonexistent today. Thomas Sydenham (Fig. 1.3), in 1681, wrote, "Of all chronic diseases hysteria—unless I err—is the commonest."[8] The one cardinal symptom of this condition was unexplained pain. In mid-19th century Europe and America, hysteria was virtually

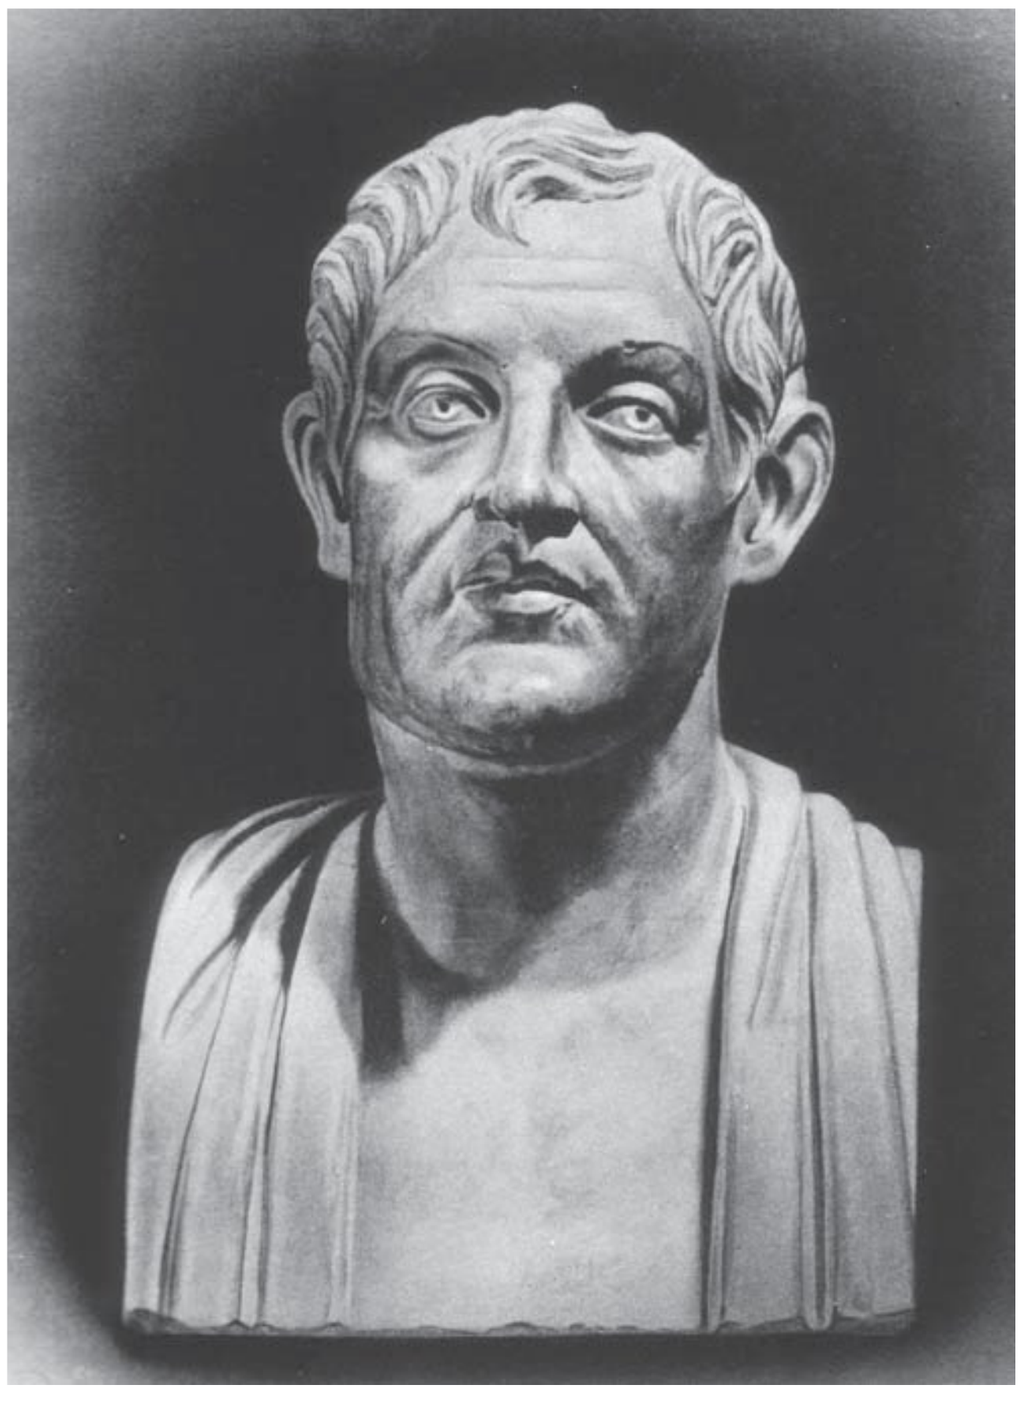

FIGURE 1.1 Aristotle. (Courtesy of the National Library of Medicine.)

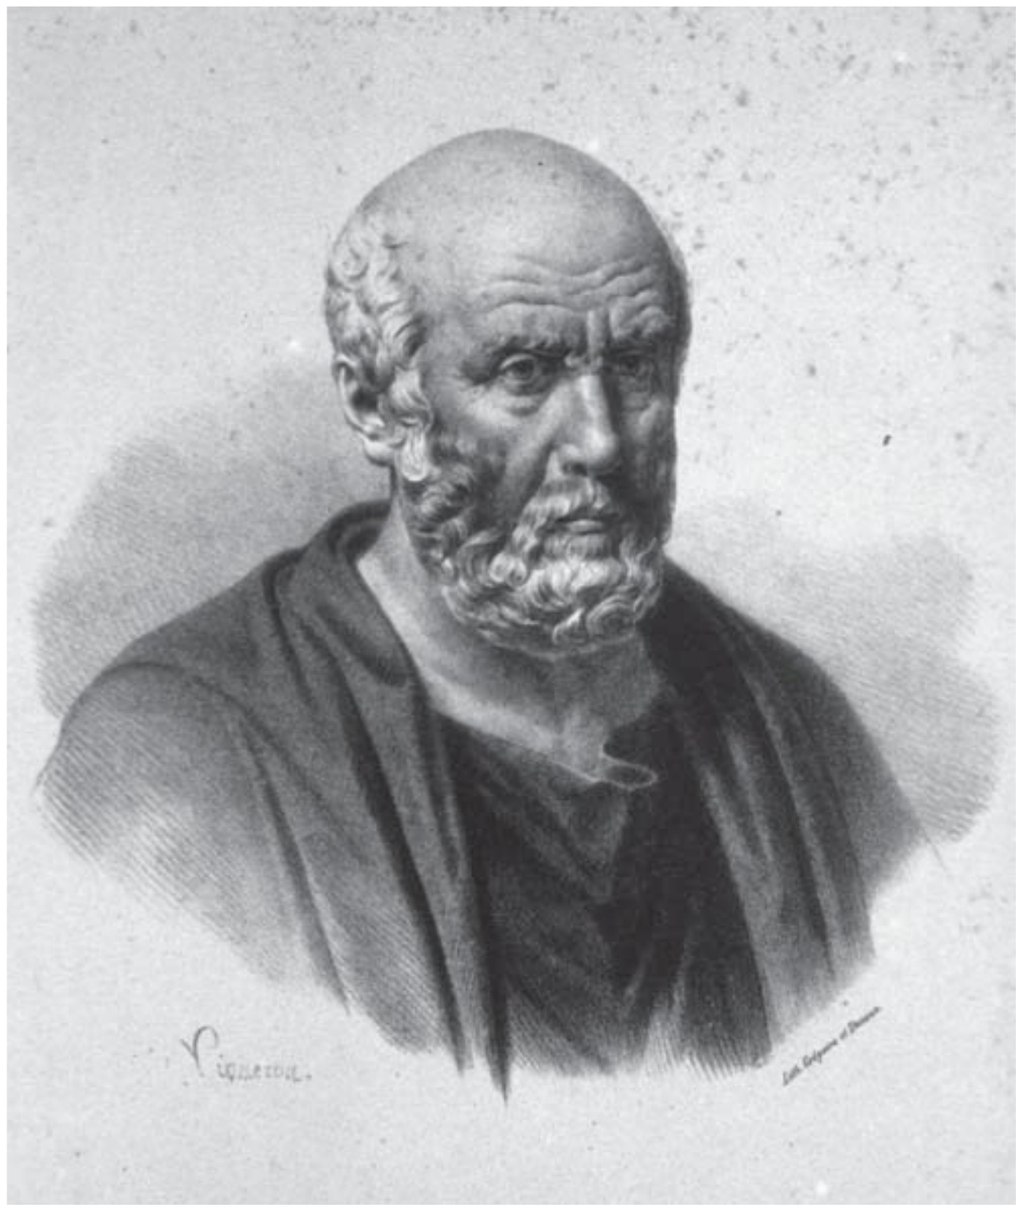

FIGURE 1.2 Hippocrates. (Courtesy of the National Library of Medicine.)

everywhere, found in every community. Invalids, mostly females, filled homes, spas, and convalescent facilities at the turn of the 19th century. This mysterious syndrome, afflicting only middle and upper class females, was treated by complete social isolation, bed confinement, and a total prohibition on any form of intellectual activity, even sewing or reading.[9] As the social situation and educational opportunities for women improved, this disorder almost totally disappeared, a public health success on the order of magnitude of the eradication of influenza or yellow fever. In the 21st century, fibromyalgia, while a commonly diagnosed condition in western countries, interestingly enough, is either underreported or not significantly present in Asian and developing country populations.

Another very clear link between mental state and the perception and control of pain can be seen in the work of the German physician Franz Anton Mesmer (Fig. 1.4). In 1766, he published his doctoral dissertation entitled "On the Influence of the Planets on the Human Body," describing animal (or life spirit) magnetism as a force to cure many ills.[10] He used iron magnets to treat various diseases, amplifying the magnetic fields with room-sized Leyden jars. His demonstrations of his technique, combining hypnotism with spectacle, included the wearing of brightly colored

robes in dimly lit ritualistic séances, with soft music playing from a glass harmonium. He invoked magnetic power with poles either held or waved over the patient and his techniques were an early rival to ether anesthesia as a way to relieve pain during surgical procedures.[11] Mesmerism was such a common form of pain therapy during his day that Robert Liston (Fig. 1.5) reportedly exclaimed after the successful administration of ether anesthesia in an early above-knee operation, "This Yankee Dodge beats mesmerism hollow."[12] Mesmerism was based on the larger, generally accepted, vitalism theory which posited that every part of a living thing was endowed with sensibility. The energy or force which animated a living organism was capable of being stimulated or consumed. In disease, pain was necessary to produce a "crisis" which rid the patient of original pain by stimulating the diminishing energy.[13]

A further development of the link between mind and body and the understanding of pain was the landmark development of Freudian theory in understanding the subconscious influences on pain perception and behavior. The link between the unconscious mind and physical sensation in hysterical conversion disorders was posited as an explanation for psychogenic pain and continues to be influential today. This conceptual paradigm was expanded in the 1970s by the psychiatrist George L. Engel (Fig. 1.6) who demonstrated the link between chronic pain and psychiatric illness.[14] Later psychiatrists, psychologists, and social scientists, including Thomas Szasz (Fig.1.7),[15] Allan Walters,[16] and Harold Merskey (Fig. 1.8),[17] explored social situations, psychological character traits, and the effects of past life experiences in understanding chronic pain in patients. Depression, stress, and personality, in addition to physiological mechanisms, have proved to be critical grounds for investigation and therapy. From these early studies investigating the mind-body interface of pain grew the cognitive-behavioral school of pain therapy in the 1980s that is widely employed today, emphasizing the development of

coping mechanisms to deal with chronic pain as a basic component of interdisciplinary pain programs. The concept of pain, not only as a physiological, mechanical, neurochemical response to stimuli but as a more complicated construct, incorporating a social, behavioral, psychological response to unpleasant stimuli, is an intellectual milestone that has inspired a wealth of investigations and patient treatment options. New areas of investigation now include pain in relationship to social setting, gender, national, ethnic, and racial background, as well as differences in coping ability and psychiatric comorbidities. Considerations of vocational and legal environment as well as family and interpersonal dynamics are also relevant to the understanding and care of individual patients.

This global philosophy of pain as only part of an entire life experience can best be summed up in the words of Alexander Pope in his *Essay on Man*, 1733:

> Say what the use, were finer optics giv'n,
> T' inspect a mite, not comprehend the heav'n?
> Or touch, if tremblingly alive all o'er,
> To smart and agonize at ev'ry pore?
> Or, quick effluvia darting thro' the brain,
> Die of a rose in aromatic pain?[18]

MECHANISTIC VIEWS OF PAIN

In counterpoint to the holistic philosophical consideration of pain was mechanism, the philosophical mind set suggesting that the human body functions as a simple machine with pain being the result of its malfunction.[19] This viewpoint is clearly seen in Descartes' *Passions of the Soul* in 1649 where he compares a human being to a watch:

> [T]he difference between the body of a living man and that of a dead man is just like the difference between, on the one hand, a watch or other automaton (that is, a self-moving machine) when it is wound up and contains in itself the corporeal principle of the movements for which it is designed . . . ; and, on the other hand, the same watch or machine when it is broken and the principle of its movement ceases to be active.[20]

How did the mechanistic view of the body develop and even supersede traditional theological and philosophical explanations for pain? Early anatomical studies were conducted beginning

FIGURE 1.9 Avicenna. (Courtesy of the National Library of Medicine.)

with Galen of Pergamum (130–201 AD) and Avicenna (Fig. 1.9), the Persian Muslim polymath (980–1037), forming an intellectual basis for pain as an actual physical sensation rather than as a mental, spiritual dilemma. Later, in the 14th through 17th centuries, the Renaissance cultural movement questioned the basis of all knowledge including ideas about the human body and the experience of pain. Empiricism and the development of scientific inquiry with direct observation into the mysteries of life became the basis for advances in both medical understanding and treatment, including the now commonly accepted neurological basis of pain. Extended wars on the continent between France and Spain resulted in bullet and musket ball injuries, with bullets and musket balls tearing the skin, forcing surgical removal and amputation. Wounds were bound and foreign bodies extracted, originally posited to prevent leakage of the "vital force" or to inhibit the entrance of animal spirits into the injured body. Gradually, direct observation of the circulation of the blood by William Harvey (Fig. 1.10) in 1628[21] and the direct anatomical studies of Descartes (Fig. 1.11) in 1662[22] elucidating sensory physiology became the theoretical basis for further exploration in the 18th and 19th centuries.

In this era of scientific discovery, mechanism based theories of pain (e.g., specificity theory, pattern theory, summation theory, and gate control theory) developed.

Specificity Theory

While there were many very important milestones leading to this transformation, the work of Charles Bell (Fig. 1.12) in Scotland in 1811 was a significant turning point. The specificity theory, the seminal concept that pain had a truly physical basis that could be dissected out by individual sensory nerves which are special-

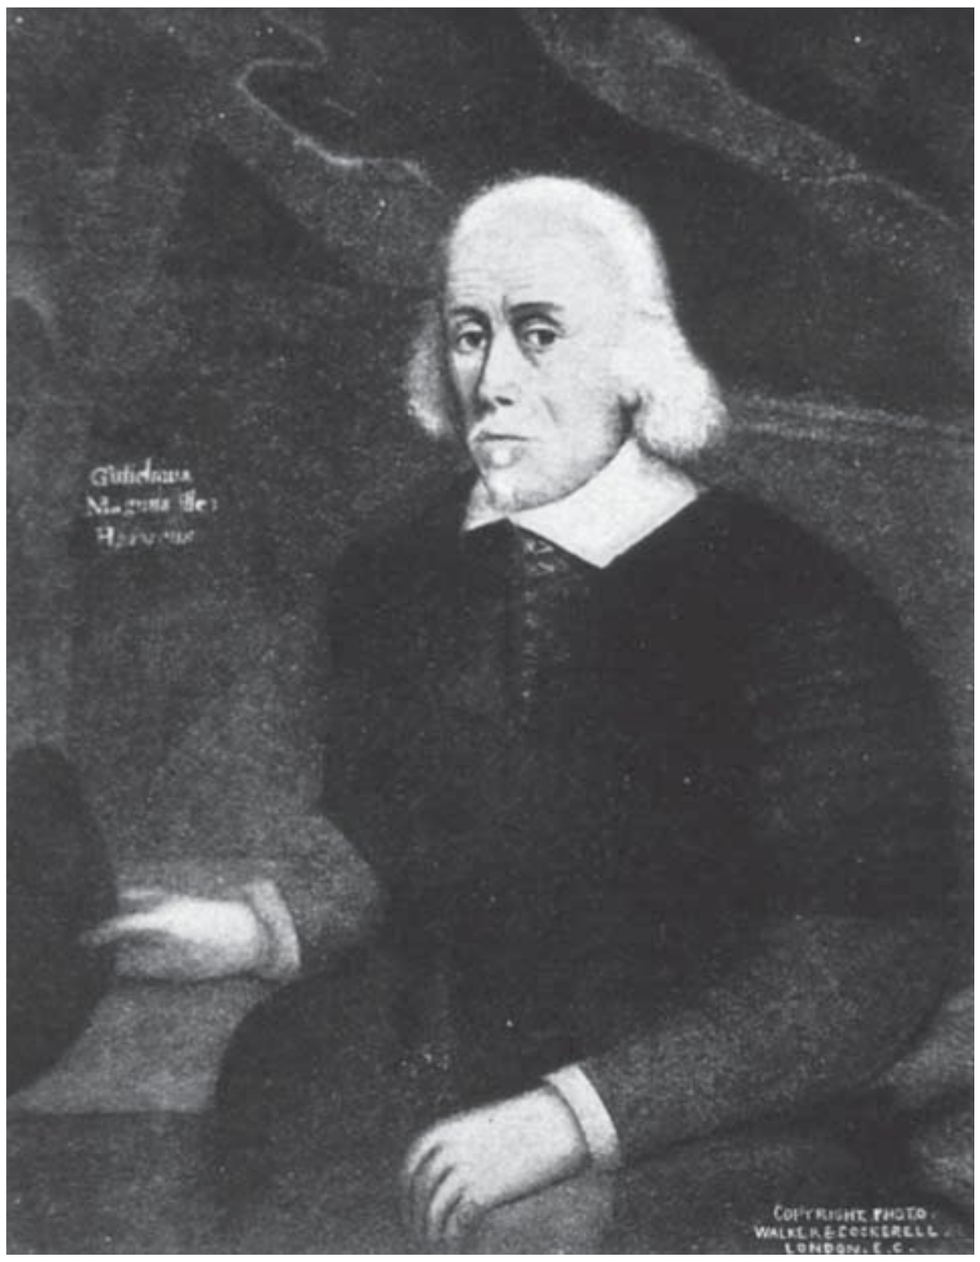

FIGURE 1.10 William Harvey. (Courtesy of the National Library of Medicine.)

FIGURE 1.12 Sir Charles Bell. (Courtesy of the National Library of Medicine.)

FIGURE 1.11 René Descartes. (Courtesy of the National Library of Medicine.)

ized to perceive and transmit information from an individual stimulus type, opened the way for much more subsequent experimentation.[23] Although, in the early 1800s, anatomical dissection was still considered distasteful to Charles Bell, later anatomists expanded on his theoretical anatomical deductions by their own direct observations. For example, Charles Bell's discovery of ventral root stimulation controlling muscle contraction led the way for François Magendie's (Fig. 1.13) 1882 demonstration of sensory function via stimulation of dorsal nerve roots based on his experiments on puppies where surgically sectioning posterior nerve roots resulted in paralysis and insensibility of the corresponding limbs.[23,24] In 1839, Johannes Müller (Fig. 1.14) advanced the important idea of specialization of nerve fibers linked to the idea of vitalism. For example, he considered the sensation of sound to be the "specific energy" of the acoustic nerve, as the sensation of light the particular "energy" of the visual nerve.[25] Charles-Édouard Brown-Séquard (Fig. 1.15) and Sir William Richard Gowers (Fig. 1.16) expanded these concepts and, in this investigative climate, the physiological study of pain flourished. As Galen, Avicenna, Descartes, and Müller had theorized, specificity advanced the idea of specific pathways and specific receptors for pain.

In 1858, Moritz Schiff demonstrated that particular lesions of the spinal cord produced a reproducible loss of tactile and painful sensation. It was over 50 years later that a surgeon in Philadelphia applied these findings with the introduction of spinal cordotomy in a human patient.

Max von Frey (Fig. 1.17) continued investigations based on the specificity model, expanding Müller's concept of specific receptors, by defining specialized end organ receptors to detect cold and warmth. In 1896, he used horsehairs of various diameters and described "pain spots" in human patients observing sensitivity in a wider distribution than the injured site alone.[26] This ex-

FIGURE 1.18 Dr. Alfred Goldscheider. (Courtesy of the National Library of Medicine.)

perimental determination of painful skin receptor areas continues today with von Frey filaments still used in animal and human models.

Other important findings demonstrating specific receptors of pain were the microscopic anatomical observations of the corpuscles of Pacini and Meissner-Wagner, the demonstration of free nerve endings, and the later discovery of the bulbous corpuscles of Krause in 1860 and Golgi-Mazzoni.[27]

Pattern Theory

The origin of the another dominant pain theory, the pattern theory, was introduced in 1894 by Alfred Goldscheider (Fig. 1.18), a German army physician, who posited that certain patterns of nerve activation were produced by the summation of sensory input from the skin in the dorsal horn. Before his research, the skin had been commonly regarded as an organ endowed with only one kind of sensation. He demonstrated that skin contains instead a number of different perceptive organs, being a mosaic of a complicated pattern, in which each item represents a particular kind of sensibility. He found three kinds of sensitive areas in the skin (pressure, warmth, and cold) and was able to prove that each localized point reacted only to the appropriate stimulus and each point had a specific function.[28] Nafe further formalized this theory by expanding the concept that all sensation is the result of patterns spatially and temporally of nerve impulses rather than the result of individual or specific receptors of pathways.[29] In 1955, Sinclair and Weddell expanded the pattern concept emphasizing that all fiber endings, except those innervating hair follicles, are similar and it is only the pattern that is important in sensory discrimination.[30,31]

Summation Theory

William K. Livingstone, J. D. Hardy, and H. G. Wolff demonstrated the importance of interactions between various neurons and internuncial activity, the sympathetic nervous system, and the somatic nervous system in developing secondary hyperalgesia, a forerunner to the later concept of central sensitization. They based their ideas on their observations of discontinuous pain fields, which were not adequately explained by the earlier theories. They clinically noted the exacerbation of pain with repeated stimuli (hyperalgesia). Pressure sensation over time resulted in painful sensation and pressure points responded differently to stimulation than adjacent areas.[32] Thus, a summation theory was proposed to explain these clinical phenomena. Another clear milestone in the understanding of pain as a science was the work of Dr. Charles S. Sherrington, often described as the father of pain physiology. In 1932 he was awarded the Nobel Prize in Medicine for developing the concept of the motor-unit, comprising receptor, conductor, and effector. This theoretical framework of transmission integrated earlier findings as explained in his book, *The Integrative Action of the Nervous System*, published in 1906. His further experiments in noxious stimulus in skin re-

sulted in the novel and still relevant concepts of nonselective (polymodal) receptors and selective excitability.[33]

Gate Theory

The complexity of pain, however, could not be explained as simply a specific pathway, pattern, or summation of stimuli with a behavioral response; rather, it is a more complex interaction between the central and peripheral nervous systems. At least partial resolution of somewhat conflicting paradigms was reconciled to a degree in 1965 by the groundbreaking published theories of the Canadian psychologist Ronald Melzack (Fig. 1.19) and the British physiologist Patrick Wall (Fig. 1.20).[34] This challenge to the specificity theory gave at least a theoretical, conceptual framework to meld the old mind-body dichotomy with pain considered as an intersection between both physiology and psychology. Melzack and Wall introduced the theory that the information coming in over C fibers is modulated through presynaptic inhibition from incoming beta-fibers in the substantia gelatinosa. This "gating" mechanism depends on the relative quantity of information coming in over the larger fibers versus the smaller fibers. Two major pathways in which pain "gets through" the gate is either through damage to the beta-fibers, allowing spontaneous pain or activation of the C fibers by excessive stimulation through inflammation of pressure on the C fibers. While many specifics of the gate control theory have been since discounted, the importance of pain modulation by central mechanisms and competing stimuli at the spinal cord level has allowed a more complex understanding of pain.

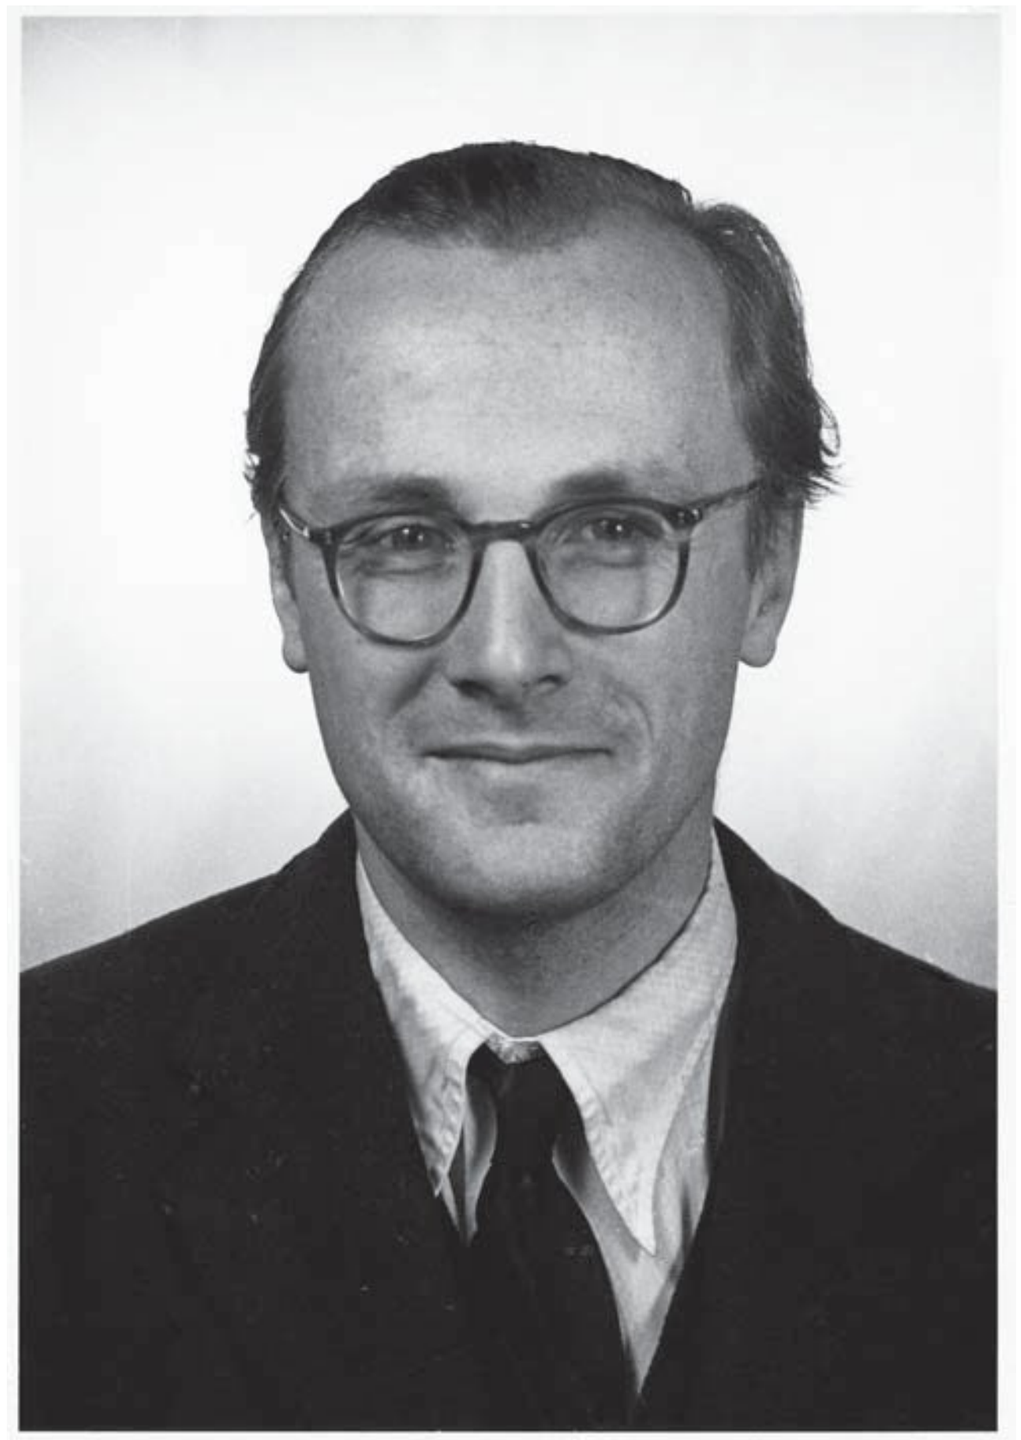

FIGURE 1.20 Patrick D. Wall, MD. (Courtesy MIT Museum.)

NEURAL PLASTICITY AND CENTRAL SENSITIZATION

More recently, the explosion of research into the transmission and transduction of pain has focused on molecular, biochemical, and genetic alterations. A key tenet and basis for many of these studies has been the concept of neural plasticity and hyperexcitability in the spinal cord early elucidated by Clifford Woolf (Fig. 1.21). He defined neural plasticity as "the capacity of neurons to change their structure, function, or chemical profile via activation, modulation, and modification . . . contributing to pain hypersensitivity."[35] Many more advances, primarily in cellular biology, have described various neuroactive proinflammatory cytokines, a variety of growth factors, microglial cells, and even changes in genetic transcription as active participants in the pain response, further explored in the later chapters of this textbook.

TREATMENTS FOR PAIN

The rationale for choosing one form or pain treatment over another more often reflects the philosophical world view of the physician more than the patient's presenting condition. Physicians who are focused on the patient's adaptation to life might focus on issues of lifestyle, stress, and emotional upheaval and assist the patient to work toward more adaptive behavioral responses to their pain. Physicians who see pain in mechanistic terms most likely will look for the anatomic foci of pain and be confounded if the source of the suffering is unclear. In the first

FIGURE 1.21 Clifford Woolf, MD, PhD. (With permission from Clifford Woolf, MD, PhD.)

older, historical paradigm, pain is a part of an entire life and the enhancing adaptation to life is also needed to manage painful conditions. In the second, a specific anatomical or physiological lesion is sought with therapy specifically directed toward the underlying pathology.

COGNITIVE TREATMENT FOR PAIN

The fundamental significance of the word "pain" in English is derived from the Latin word *poena*, meaning punishment, and its relief was through prayer.[36] This reflects the supposed cause of the pain being harm inflicted by the powers above for putative wrongdoing. Prior to the 18th century, nonspecific therapies were employed for many types of pain, including acupuncture, the application of humoral opposites, bloodletting, purging, topical and oral herbal compounds, and distraction by creating a competing, more severe pain. To better define why patients experienced pain and, presumably, how to treat it, physicians attempted classification by causes. However, treatment options were still limited. During the Roman emperor Trajan's time, a noted physician recorded 13 causes of pain. Avicenna, a noted Muslim healer in the early 11th century, described 15 separate causes. And Hahnemann, the founder of homeopathy, listed 75.[37] However, nonspecific treatments such as mesmerism and hypnotism, and even general anesthetics, were based on a whole body cure rather than a mechanistic view of pain. Later, cognitive behavioral therapy and palliative care focused on the care of the whole person as a human being in need of adaptive coping skills. Early work in the 1950s by Engel, based on Freud's theoretical ideals, explored the link between suffering from pain and psychiatric diagnosis. Merskey and Spear, in the mid 1960s, confirmed that chronic pain patients also often had coexisting psychiatric morbidity.[38] Henry Beecher, in the battlefields of World War II, observed that seriously wounded soldiers reported less pain than civilian patients in the Massachusetts General Hospital recovery room. Their injury may have been subjectively interpreted as a cause of removal from harm and their return home as a war survivor. Later, however, these same patients would complain loudly about a minor insult such as venous puncture, causing Beecher to conclude that the experience of pain was derived from a complex interaction between physical sensation, cognition, and an emotional reaction.[39]

FIGURE 1.22 Dr. John J. Bonica. (Courtesy of the Wood Library-Museum of Anesthesiology.)

Dame Cicely Saunders, mother of the hospice movement in Great Britain and throughout the world, championed the idea of "total pain" emphasizing the holistic concept of patient-centered pain management.[40] John Bonica (Fig. 1.22) also treated World War II veterans with complex multifocal persistent pain and organized an early multidisciplinary conference in Seattle, attended by 300 clinicians and researchers of various disciplines, which eventually became the International Association for the Study of Pain.[41]

PHARMACOLOGICAL TREATMENT OF PAIN

The development of pharmacology as a science parallels the treatment of painful conditions by medications. Alcohol and mor-

phine were proven antidotes to pain. In the mid-17th century, Thomas Sydenham concocted laudanum, the ubiquitous mix combining sherry, wine, opium, saffron, cinnamon, and clove and used to treat everything from dysentery to hysteria and gout. In South America, cocoa leaves were in common use, both as an orally chewed remedy for altitude sickness and physical pain and as a topical treatment. The alkaloid cocaine was isolated by Albert Niemann in his 1860s auto-experimentation and was originally touted as a cure for alcohol and morphine addiction.[42] Carl Koller, in 1884, demonstrated the local anesthetic effects of cocaine in reducing corneal movement during eye surgery.[43]

As chemical analysis became more sophisticated, opium, a long known treatment for pain, was studied by the pharmacist Serturner who isolated "the soporific principle" from the compound in 1806. Despite being well-known to herbalists, the first scientific report of the power of willow derivatives was reported in a paper to the Royal Society of Medicine in London in 1763 by the Reverend Edmund Stone from Chipping Norton, Oxfordshire.[44] The overuse of quinine in the early 19th century led to a shortage of the Peruvian cinchona trees and, therefore, there were increased efforts to isolate, characterize, and then commercially synthesize pain-relieving compounds. In 1829, the French pharmacist Henri Leroux extracted the active compound in willow leaves and bark that had been used in application to painful joints.

Later, in 1873, Charles von Gerhardt prepared salicylic acid by combining sodium salicylate with acetyl chloride to produce acetylsalicylic acid or aspirin. The benefit of adding the acetyl group was decreased irritation to mucous membranes of the mouth, esophagus, and stomach and avoidance of the bitter alkaloid taste.[45] Clinically, the benefits of this newly synthesized product were reported in treating acute rheumatism by Thomas J. Mac Lagan in 1876, over a century after Rev. Stone's first report.[46]

Two other landmarks that marked clear leaps forward in the pharmacological treatment of pain were the development of the hypodermic needle by Rynd[47] and the syringe by Wood,[48] permitting injection of analgesics and anesthetics. Morton's 1846 landmark demonstration of ether anesthesia, following Crawford Long's earlier application of ether anesthesia in 1843, marked a new era of surgical anesthesia.

ANATOMICALLY SPECIFIC TREATMENTS FOR PAIN

In contrast, the majority of the treatment options for pain in the last two centuries have been inspired by specificity theory and its refined derivatives. Surgical cures have been employed for pain relief by interruption of specific sensory tracts in neurotomies, division of the anterolateral column of the spinal cord, dorsal roots excision, thalamectomy, mesencephalic lesioning, psychosurgical lobotomies, and other procedures that specifically alter the anatomy of the central nervous system. This paradigm shift developed over time, paralleling the scientific advances in understanding the mechanisms of pain transmission.

As knowledge of the importance of the central nervous system in the transmission of pain increased, cures based on this new science proliferated. An early treatment, neurocompression, was developed by James Moore, a Glasgow-born London surgeon. He demonstrated that compression of specific nerves provided anesthesia in patients via clamps in both upper and lower limbs inducing reversible neurapraxia to anesthetize a limb.[49]

Before his time, Ambroise Paré (Fig.1.23) (1510–1590), the great French surgeon of the Renaissance and "physician to the kings of France," linked observable injury to the development of chronic pain. He not only sustained a prolific medical practice but wrote 10 books of surgery (*Dix Livres de la Chirugie*). These

FIGURE 1.23 Ambroise Paré, MD. (Courtesy of the National Library of Medicine.)

books were based on his extensive experience in treating gun and sword wounds and the pain that attended them.[50] He was the first to describe pain after the amputation of limbs, 300 years before the conceptualization of "phantom limb pain" was ever expressed. Remarkably, contrary to the current philosophy of his time, he resisted the prevailing wisdom that pain was either inevitable and to be passively tolerated or in some way the will of God to be accepted by man as a path to holiness by actively treating pain in his suffering patients. Some of his innovations included the development of prosthetic devices for missing limbs, a steam bath chair for urethral stone pain, and combinations, called "allodynes," of opium and other drugs to treat the symptoms of pain.[51]

Other compassionate physicians observing their tormented pain patients, primarily as a result of catastrophic war injuries, continued to develop options to treat pain out of necessity. The U.S. Civil War resulted in untold numbers of soldiers who suffered damaged nerves after amputation and injury, with resultant chronic "nerve" disease. The persistent burning pain long after the initial injury was first called *reflex paralysis* by Silas Weir Mitchell (Fig. 1.24) in 1864. Dr. Mitchell, born in Philadelphia as the seventh physician within three generations, was told at an early age by his physician father, "you are wanting in nearly all the qualities that go to make a success in medicine." Despite this, he graduated from Jefferson Medical College in 1848 and, at the outbreak of hostilities in 1861, was placed in charge of Turner's Lane Hospital in Philadelphia, a 400-bed hospital for nervous diseases. With colleagues, William Williams Keen, Jr. (Fig. 1.25) and George Read Morehouse (Fig. 1.26), he personally transported railroad cars full of wounded soldiers from the Gettysburg battlefield and undertook their care. Based on daily patient observation and review of literally thousands of pages of careful clinical notes, he described causalgia for the first time in 1864 in the work *Gunshot Wounds and Other Injuries of Nerves*.[52–54]

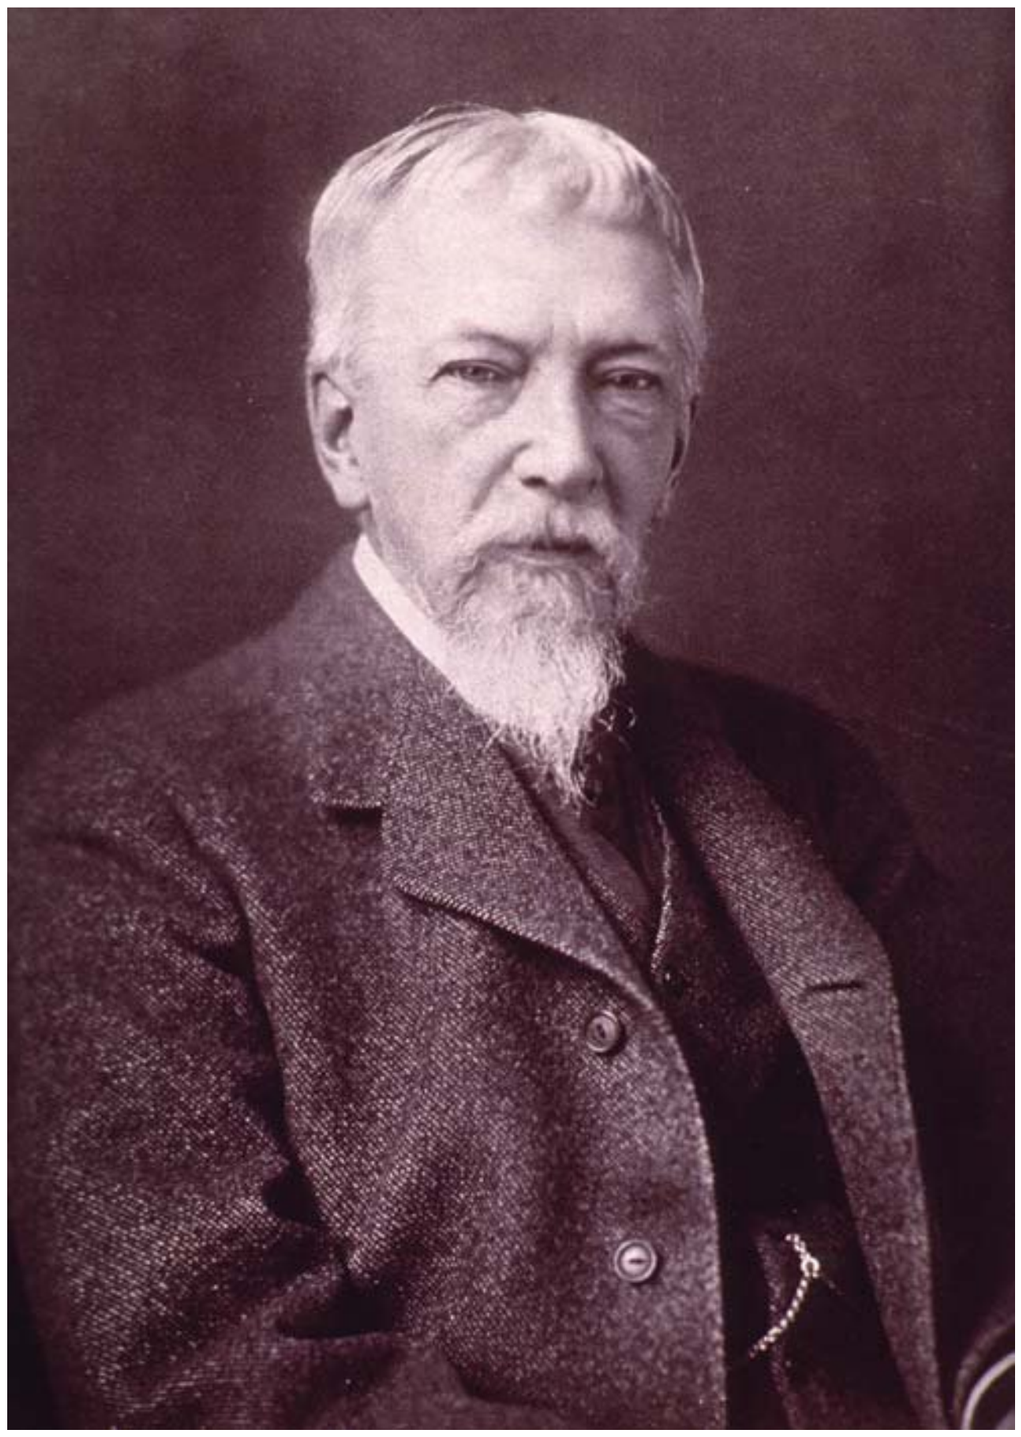

FIGURE 1.24 Silas Weir Mitchell, MD. (Courtesy of the National Library of Medicine.)

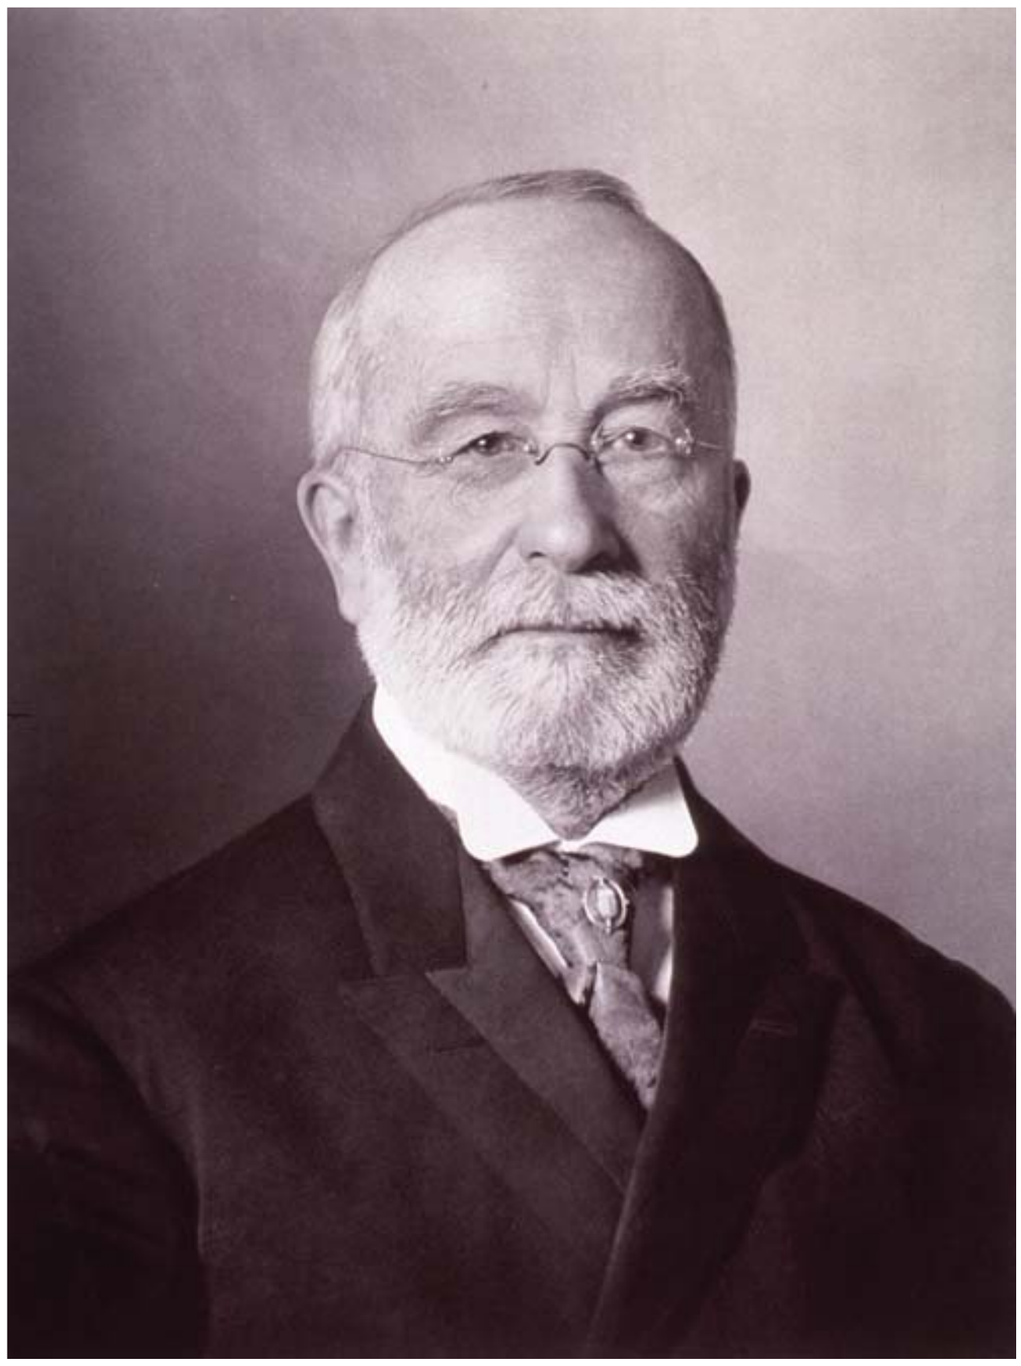

FIGURE 1.25 William Williams Keen, Jr., MD. (Courtesy of the National Library of Medicine.)

An early example of injecting specific nerves to produce analgesia was the work of Schloesser in 1903. He injected alcohol to produce long-lasting interruption of neural conduction in patients with convulsive facial tics, obtaining paralysis that lasted from days to a month. He recommended lytic injections for the patients with clinical supraorbital neuralgia and tic douloureux.[55]

Later, war injuries in World War I soldiers inspired a practical surgeon, René Leriche, to study pain and its treatment in various forms of pathology. He identified patients with sympathetic nerve injuries—his "pariahs of pain"—that he treated by injecting the local anesthetic procaine and surgical sympathectomy, which later became standard therapy in the 1930s. He was a clinician's clinician, describing pain from direct personal observation: "Physical pain is not a simple affair of an impulse, traveling at a fixed rate along a nerve. It is the resultant of a conflict between a stimulus and the whole individual."[56]

Following the theory of pain arising from specific nerve injuries, surgeons in the 1920s performed nerve ablation procedures for chronic unexplained pain syndromes. Following this model, anesthesiologists experimented with various local anesthetic nerve blocks to provide analgesia for surgery. The first nerve block clinic for pain relief was started by Emery Rovenstine (Fig. 1.27) at Bellevue Hospital in New York City, New York, in 1936.[57] Eleven years later, the first nerve block clinic in the UK was established at University College Hospital in London in 1947.[58]

Current therapies based on central nervous system plasticity modulating input from peripheral nerves include spinal cord stimulation, sympathetic nerve blocks, radiofrequency modulation

(both pulsed and lesioning), and cognitive therapies and are now commonly available in modern pain practice.

THE SPECIALTY OF PAIN MEDICINE

How did pain as a medical specialty and physicians specializing in the diagnosis and treatment of pain conceive of chronic pain as an original and new field of clinical practice? A sociologist, Isabelle Baszanger, observed two clinics in Paris that had very different constructs of pain and pain treatment, which she described as the two poles of pain. The first "curing through techniques" considers pain as a function of physiological abnormalities, with diagnosis aimed at confirming the pathology and using medication and technical therapies to treat it. As more technological possibilities develop, the treatments become more focused and sophisticated. The second pole is "healing through adaptation," which considers pain a poorly adaptive behavior and, therefore, behavior and cognitive therapies are necessary to alleviate pain and suffering.[59]

Earlier, in 1936, Emery A. Rovenstine (1895–1960) set up one of the first outpatient clinics devoted to the treatment of chronic pain in Bellevue Hospital in New York City.[60] However, the founding father of interdisciplinary pain care was John J. Bonica (1917–1994), who established the first multidisciplinary clinic in Seattle in 1947 to treat the pain problems of wounded World War II veterans. He published the first edition of his comprehensive textbook, *Management of Pain*, in 1953.[61] His clinical practice increased and gained support after aligning with the University of Washington in Seattle in 1960. As his reputation grew, he encouraged other centers to recognize and treat pain as an integral part of health care.[62] He then proceeded to work internationally to foster the study and treatment of pain. He was the prime mover in hosting the first International Symposium on Pain in Issaquah, Washington, on May 21–26, 1973, and the subsequent establishment of the International Association for the Study of Pain as their first president. This association currently represents over 60 scientific disciplines in active research and clinical practice in a wide variety of pain related fields. The journal, *Pain*, supported by this organization, foreshadowed the numerous peer reviewed scholarly publications now focused on all levels of pain research.[63] The American Board of Anesthesiology (ABA) approved a Certificate of Added Qualification in Pain Management in 1991, followed by subspecialty certification from the American Board of Psychiatry and Neurology (ABPN) and the American Board of Physical Medicine and Rehabilitation (ABPMR) in 2000.[64]

It is an exciting time for the study and treatment of pain. Many scientific investigations are now possible with the probes of molecular biology for microneurographic stimulation and the ability to elucidate genetic codes. Newly developing technologies to study pain, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), and more sophisticated constructs of neural plasticity will result in ever more intriguing questions and hypotheses being developed. Advances in understanding of the interactions between the peripheral and central nervous system, the thalamus and cerebral cortex, and the limbic system continue to increase our understanding of pain processing. Enhanced imaging techniques such as PET and fMRI allow in vivo, real time investigation of information processing evoked by pain stimuli. Identification of newer molecular receptors for opioid compounds and genetic variability in pain expression provide the hope more pain syndromes can be defined and treated in a much more specific manner. And the role of cognition, personality, and memory in descending modulation of spinal mechanisms of pain affords better and more holistic treatment of the patient in pain. The complexity of the field is fertile ground for the ingenuity and persistent questioning of future pain scientists and clinicians. Therefore, the history of pain as science and pain medicine as a focused clinical specialty is only beginning to be written.

CHAPTER 2 ■ PAIN TERMS AND TAXONOMIES OF PAIN

DENNIS C. TURK AND AKIKO OKIFUJI

INTRODUCTION

The inherent subjectivity of pain presents a fundamental impediment to increased understanding of its mechanisms and control. The language used by any two individuals attempting to describe a similar injury and their pain experience often varies markedly. Similarly, clinicians and clinical investigators commonly use multiple terms that at times have idiosyncratic meanings. Needless to say, appropriate communication requires a common language and a classification system that is used in a consistent fashion. Thus, we have two primary goals in this chapter: (1) to provide definitions for many commonly used terms in the pain literature, in an effort to bring about consistency and thereby improve communication, and (2) to describe and discuss different classification systems or taxonomies that have been used or proposed, in an attempt to improve communication and bring consistency to research and treatment of patients reporting pain.

DEFINITION OF COMMONLY USED PAIN TERMS

Discussions of pain involve many terms. The meaning and connotation of these different terms may vary widely. For example, some authors use the term "pain" to relate to a stimulus, others to a thing, and still others to a response. Such inconsistent usage creates difficulties in communication. As Merskey[1] noted, it would be most convenient and helpful if there were some consensus on technical meanings and usage. Based on this belief, the editors of the two editions of the International Association for the Study of Pain (IASP) Classification of Chronic Pain included a set of definitions of commonly used pain terms[2,3] (note that a third edition is currently in preparation). In the second edition of this text, Bonica reproduced a list of the terms and in some cases provided annotations. We adopt a similar strategy. We follow the convention of IASP; we begin with the definition of pain and then proceed alphabetically. Terms preceded by an asterisk come directly from the IASP descriptions of pain terms.[3]

**Pain*: An unpleasant sensory *and* emotional experience associated with *actual or potential* tissue damage, or described in terms of such damage (emphasis added).

Pain, acute/chronic[1]: Definitions of acute, chronic, recurrent, and cancer pain are not specifically included in the IASP list of pain terms. We believe, however, that it is important to clarify these because they are commonly used in the literature.

Traditionally, the distinction between acute and chronic pain has relied upon a single continuum of time, with some interval since the onset of pain used to designate the onset of acute pain or the transition point when acute pain becomes chronic. The two most commonly used chronological markers used to denote chronic pain have been 3 months and 6 months since the initiation of pain; however, these distinctions are arbitrary.

Another criterion for chronic pain is "pain that extends beyond the expected period of healing." This is relatively independent of time because it considers pain as chronic even when it has persisted for a relatively brief duration. Unfortunately, how long the expected process of healing will (or should) take is ambiguous.

Some hold that pain that persists for long periods of time in the presence of ongoing pathology should be considered an extended "acute" pain state. In this case, treatment targets the underlying pathology. This is not to encourage a Cartesian dualistic perspective of pain that treats mind and body as independent entities with distinctive functions. Historically, such distinction led to a faulty assumption of acute pain as "real" whereas chronic pain without known pathology was suspect and viewed as being merely "functional." As the IASP definition clearly states, any pain, acute or chronic, regardless of the presence of identifiable tissue damage, is an unpleasant experience, inherently influenced by various cognitive, affective, and environmental factors. We hold that the weighing of psychological and environmental factors is often greater in chronic pain than acute pain, and the importance of these factors escalates over time, contributing to the experience of pain and associated disability.

We propose conceptualizing acute and chronic pain on two dimensions: time and physical pathology. Figure 2.1 schematically depicts this two-dimensional conceptualization of acute and chronic pain. From this perspective, any case falling above the diagonal line (short duration or high physical pathology) is acute pain; whereas cases falling below the diagonal line (low physical pathology or long duration) suggest chronic pain. The perspective presented in Figure 2.1 leads to the following definitions of acute and chronic pain.

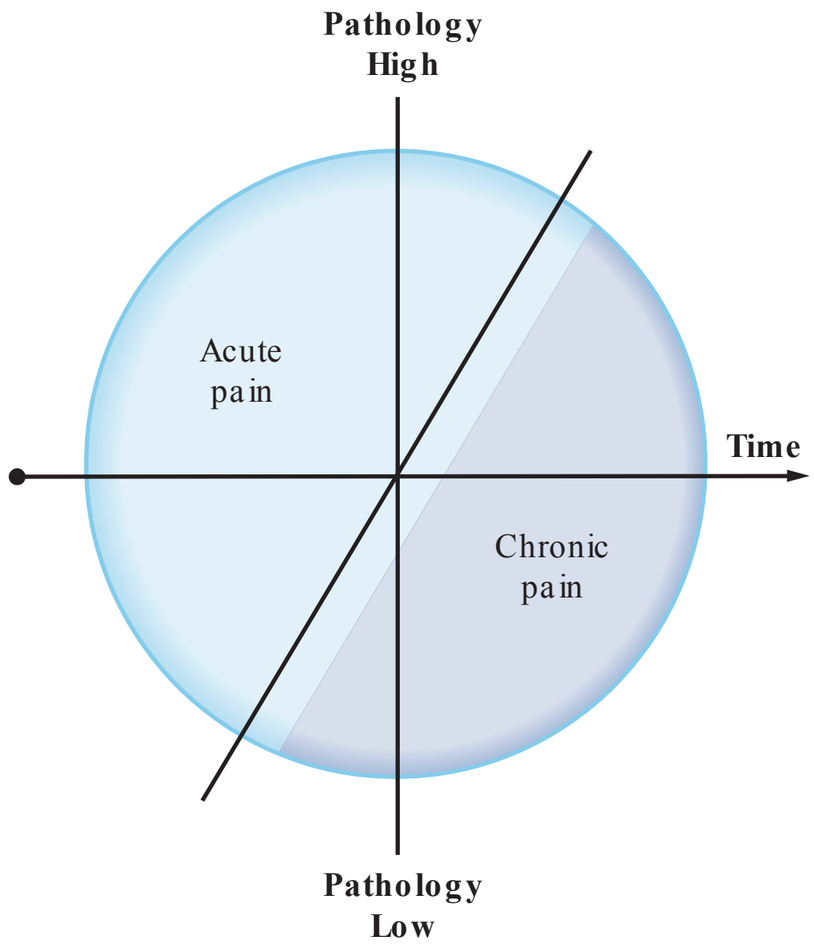

FIGURE 2.1 Pictorial representation of acute and chronic pain.

Acute pain: Pain elicited by the injury of body tissues and activation of nociceptive transducers at the site of local tissue damage. The local injury alters the response characteristics of the nociceptors and perhaps their central connections and the autonomic nervous system in the region. In general, the state of acute pain lasts for a relatively limited time and remits when the underlying pathology resolves (however, see definition of central sensitization below). This type of pain often serves as the impetus to seek health care and it occurs following trauma, some disease processes, and invasive interventions.

Chronic pain: May be elicited by an injury or disease but is likely to be perpetuated by factors that are both pathogenetically and physically remote from the originating cause. Chronic pain extends for a long period of time and/or represents low levels of underlying pathology that does not explain the presence and extent of pain (e.g., mechanical back pain, fibromyalgia syndrome [FM]). Recently, there have been suggestions that chronic pain in the apparent absence of pathology may be attributable to modification of nerves and sensitization of the peripheral or central nervous system. There have also been suggestions that genetic factors and prior life experiences might predispose some to develop chronic pain problems following an initiating insult that resolves in others who do not have the predisposition. Just as the brain is modified by experience, especially in early life, the brain may alter the way noxious information is processed to reduce or augment its impact on subjective awareness.

Chronic pain frequently is the impetus for people to seek health care. Currently available treatments are rarely capable of totally eliminating the noxious sensations and thereby "curing" chronic pain. Because the pain persists, it is likely that environmental, emotional, and cognitive factors will interact with the already sensitized nervous system, contributing to the persistence of pain and associated illness behaviors (see

[1]The discussion describing the distinction between acute and chronic pain reflects on deliberations among the editors of the previous edition of this volume.

description of pain behaviors below). It is also possible that, just as the brain is modified by experience, especially in early life, the brain may alter the way noxious information is processed to reduce or augment its impact on subjective awareness.

Cancer pain: Pain associated with cancer includes pain associated with disease progression as well as treatments (e.g., chemotherapy, radiotherapy, surgery) that may damage the nervous system. Although some contend that pain associated with neoplastic disease is unique, in the majority of instances we view it as fitting within our description of acute and chronic pain, as depicted in Figure 2.1. Moreover, pain associated with cancer can have multiple causes, namely, disease progression, treatment, and co-occurring diseases (e.g., arthritis). Regardless of whether the pain associated with cancer stems from disease progression, treatment, or a co-occurring disease, it may be either acute or chronic. Thus, we do not advocate a separate classification of cancer pain as distinct from acute and chronic pain.

Some concerns have also been raised regarding the common usage of malignant and benign pain[4]; often, pain unrelated to cancer is referred to as "benign" to distinguish it from cancer-related pain. Certainly, people who have pain associated with neoplastic disease experience a unique and disease-specific situation, but from a mechanistic perspective there may be little to substantiate continued use of this dichotomy. Moreover, patients who have chronic non–cancer pain who are told that their pain is "benign" may feel denigrated because, from their perspective, the inference is that their pain is not a serious concern.

Recurrent pain: Episodic or intermittent occurrences of pain, with each episode lasting for a relatively short period of time but recurring across an extended period of time (e.g., migraine headaches, tic douloureux, sickle cell crisis). Our distinction between acute and chronic pain using the integration of the dimensions of time and pathology does not specifically include recurrent pain. In the case of recurrent pain, patients may experience episodes of pain interspersed with periods of being completely pain free. Although recurrent pain may seem acute because each pain episode (e.g., sickle cell crisis) is of short duration, the pathophysiology of many recurrent pain disorders (e.g., migraine) is not well understood. Syndromes characterized by recurrent acute pain share features in common with both acute and chronic pain. The fact that these syndromes extend over time, however, suggests that psychosocial and behavioral factors, not only physical pathology, may be major contributors to illness behavior.

Transient pain: Pain elicited by activation of nociceptors in the absence of any significant local tissue damage. This type of pain is ubiquitous in everyday life and is rarely a reason to seek heath care. It is seen in the clinical setting and only in incidental or procedural pain, such as during a venipuncture or injection. This type of pain ceases as soon as the stimulus is removed. There are situations where sources of transient pain may be treated by providers with preventive analgesic or topical medication.

Addiction: A behavioral pattern of substance, including prescribed medication, abuse characterized by overwhelming involvement with the use of a drug (i.e., compulsive use), the securing of its supply, and a high tendency to relapse. The compulsive use of the drug results in physical, psychological, and/or social harm to the user and use continues despite this harm. See also Physical Dependency.

**Alloydnia*: Pain due to a stimulus that does not normally provoke pain.

Analgesia: Absence of the spontaneous report of pain or pain behaviors in response to stimulation that would normally be expected to be painful. The term implies a defined stimulus and a defined response. Analgesic responses can be tested in animals as well as humans.

**Anesthesia dolorosa*: Spontaneous pain in an area or region that is anesthetic.

Breakthrough pain: A transient increase in pain to greater than moderate intensity superimposed on an otherwise stable pattern or level of pain of mild to moderate intensity. Breakthrough pain includes (1) incident pain that may arise from some activity or physical function (e.g., coughing, standing up), (2) pain that routinely increases as the duration of analgesic medication in reaching its limit (end-of-dose failure), and (3) spontaneous exacerbation of a stable level of pain for nonspecific reasons.

Catastrophizing: A cognitive and emotional process that involves magnification of pain-related stimuli, feelings of helplessness, and a negative orientation to pain and life circumstances. Catastrophizing has been shown to be an important predictor of response to both acute and chronic pain.[5]

**Central pain*: Pain initiated or caused by a primary lesion or dysfunction in the central nervous system.

Central sensitization: Increase in the excitability and responsiveness of neurons in the spinal cord.

**Complex regional pain syndrome type 1 (formerly reflex sympathetic dystrophy)*: A syndrome that usually develops after an initiating noxious event, is not limited to the distribution of a single peripheral nerve, and is apparently disproportionate to the inciting event. It is associated at some point with evidence of edema, changes in skin blood flow, abnormal pseudomotor activity in the region of the pain, or allodynia or hyperalgesia.

**Complex regional pain syndrome type 2 (formerly causalgia)*: A syndrome of sustained burning pain, allodynia, and hyperpathia following a traumatic nerve lesion, often combined with vasomotor dysfunction and later trophic changes.

Cost–benefit analysis: Evaluation of the costs and effects of an intervention in a common, usually monetary unit. The standardization of unit has an advantage because it permits comparisons across dissimilar intervention programs. On the other hand, the conversion of treatment effects to monetary units may not always be feasible. Estimation of the cost to outcome ratio is possible, as are comparisons between interventions using the rates of improvement (e.g., return to work) with common denominators.

Cost-effectiveness analysis: Estimation of treatment outcome entails criteria other than monetary terms, such as lives saved or return to work. An intervention is cost-effective when it satisfies one of the following conditions:

1. It is more effective than an alternative modality at the same cost;
2. it is less costly and at least as effective as an alternative modality;
3. it is more effective and more costly than an alternative treatment, but the benefit exceeds the added cost; or
4. it is less effective and less costly, but the added benefit of the alternative is not worth the additional cost.

Diffuse noxious inhibitory control: Inhibition of wide dynamic range neurons in the dorsal horn of the spinal cord by heterosegmental noxious afferent input.

Disability: Any restriction or loss of capacity to perform an activity in the manner or within the range considered normal for a human being, such as climbing stairs, lifting groceries, or talking on a telephone. It is a task-based concept that involves both the person and the environment. Disability is essentially a social and not a medical term or classification. Level of disability should be determined only after a patient has reached maximum medical improvement following appropriate treatment and rehabilitation.

**Dysesthesia*: An unpleasant abnormal sensation, whether spontaneous or evoked.

**Hyperalgesia*: An increased response to a stimulus that is normally painful.

**Hyperesthesia*: Increased sensitivity to stimulation, excluding special senses.

**Hyperpathia*: A painful syndrome characterized by an abnormally painful reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold.

**Hypoalgesia*: Diminished pain in response to a normally painful stimulus.

Hypochondriasis: An excessive preoccupation with bodily sensations and fears that they represent serious disease despite reassurance to the contrary.

Impairment: Any loss of use of, or abnormality of, psychological, physiological, or anatomical structure or function that is quantifiable. It is not equivalent to disability. Impairment is to disability as disease is to illness.

Malingering: A conscious and willful feigning or exaggeration of a disease or effect of an injury in order to obtain a specific external gain. It is usually motivated by external incentives such as financial compensation, avoiding work, or obtaining drugs.

Maximum medical improvement: The state beyond which additional medical treatment is unlikely to produce an improvement in function.

Minimum clinically important difference (*MCID*): The magnitude of reduction in pain or related problems that a patient would consider minimally important. In considering the determination of clinically important differences, two different aspects of the interpretation of clinical trial results must be distinguished. One is establishing the difference in the magnitude of response between the treatment and control groups that will be considered large enough to establish the scientific or therapeutic importance of the results. The other is establishing what change in the outcome measure represents a meaningful difference for patients. This later consideration has come to be referred to as the minimum clinically important difference. The development of criteria for determining what are important changes in an individuals' scores on the outcome measures used in chronic pain trials would provide clinicians and researchers with essential methods for evaluating treatment responses of individuals in clinical trials and clinical practice. Such individual-level criteria make it possible to conduct responder analyses that classify each trial participant as "improved," "stable," or "worse" on the basis of validated criteria of important change. (See description of patient global impression of change.)

Multidisciplinary (interdisciplinary) pain center: An organization of health care professionals and basic and applied scientists that includes research, teaching, and patient care related to acute and chronic pain. It includes a wide array of health care professionals including physicians, psychologists, nurses, physical therapists, occupational therapists, and other specialty health care providers. Multiple therapeutic modalities are available. These centers provide evaluation and treatment and are usually affiliated with major health science institutions.

**Neuralgia*: Pain in the distribution of a nerve or nerves.

**Neuritis*: Inflammation of a nerve or nerves.

**Neurogenic pain*: Pain initiated or caused by a primary lesion, dysfunction, or transitory perturbation in the peripheral or central nervous system.

Neuropathic pain: Pain arising as a direct consequence of a lesion or disease affecting the somatosensory system.[6]

**Neuropathy*: A disturbance of function or pathological change in a nerve: in one nerve, mononeurapathy; in several nerves, mononeuropathy multiplex; if diffuse and bilateral, polyneuropathy.

Nocebo: Negative treatment effects induced by a substance or procedure containing no toxic or detrimental substance.

**Nociceptor*: A receptor preferentially sensitive to tissue trauma or to a stimulus that would damage tissue if prolonged.

Nociception: Activation of sensory transduction in nerves by thermal, mechanical, or chemical energy impinging on specialized nerve endings. The nerve(s) involved conveys information about tissue damage to the central nervous system.

**Noxious stimulus*: A stimulus that is capable of activating receptors for tissue damage.

Pain behavior: Verbal or nonverbal actions understood by observers to indicate that a person may be experiencing pain and suffering. These actions may include audible emissions (e.g., signs, moans), facial expressions, abnormal postures or gait, use of prosthetic devices, avoidance of activities, and verbal indications of pain, distress, and suffering.

Pain clinic: Facilities focusing on diagnosis and management of patients with pain problems. It may specialize in specific diagnoses or pain related to a specific area of the body.

Pain relief: Report of reduced pain after a treatment. It does not require reduced response to a noxious stimulus and is not a synonym for analgesia. The term applies only to humans.

Pain threshold: The least level of stimulus intensity perceived as painful. In psychophysics, this is defined as a level of stimulus intensity that a person recognizes as painful 50% of time.

**Pain tolerance level*: The greatest level of noxious stimulation that an individual is willing to tolerate.

Pain sensitivity range: The difference between the pain threshold and the pain tolerance level.

**Paresthesia*: An abnormal sensation whether spontaneous or evoked.

Patient global impression of change (PGIC): Patients' overall evaluation of improvement or worsening of symptoms over the course of treatment. This measure is often a single-item rating by patients on a 7-point scale that ranges from "very much improved" to "very much worse" with "no change" as the midpoint.

**Peripheral neurogenic pain*: Pain initiated or caused by a primary lesion or dysfunction or transitory perturbation in the peripheral nervous system.

Physical dependence: A pharmacological property of a drug (e.g., opioid) characterized by the occurrence of an abstinence syndrome following abrupt discontinuation of the substance or administration of an antagonist. It does not imply an aberrant psychological state or behavior or addiction.

Placebo: A substance or procedure without therapeutic effect that is provided as a treatment. It is frequently used to control patients' expectations for the efficacy in testing a treatment intervention.

Placebo effects: Refers to the positive benefit(s) from a placebo (i.e., inert) preparation or procedure when such benefit is generally achieved only with an active treatment intervention. Active treatments also are likely to have a placebo component that augments the active component associated with the treatment.

Plasticity, neural: Nociceptive input leading to structural and functional changes that may cause altered perceptual processing and contribute to pain chronicity.

Pseudoaddiction: Refers to drug-seeking behavior or misuse by patients who have severe pain and are under-medicated or who have not received other effective pain treatment interventions. Such patients may appear preoccupied with obtaining opioids, but the preoccupation reflects a need for pain relief and not drug addiction. Pseudoaddictive behavior differs from true addictive behavior because when higher doses of opioid are provided, the patient does not use these in a manner that persistently causes sedation or euphoria, the level of func-

tion is increased rather than decreased, and the medications are used as prescribed without loss of control over use.

Psychogenic pain: Report of pain attributable primarily to psychological factors usually in the absence of any objective physical pathology that could account for pain. This term is commonly used in a pejorative sense. It often suggests a Cartesian dualism and is not usually a helpful method of describing a patient.

Quality of life/health-related quality of life: Quality of life (QOL) refers to an individual's perception of his or her position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns. Concerns with this all-encompassing description have led a number of investigators to use a more circumscribed construct, *health-related quality of life* (HRQOL). Although HRQOL has been used interchangeably with terms such as health status and functional status, HRQOL is a narrower term than QOL because it does not include aspects of work, environmental conditions, housing, and other variables that are often considered relevant to QOL but that do not involve health directly.[7]

Rehabilitation: Restoration of an individual to maximal physical and mental functioning in light of his or her impairment.

Residual functional capacity: The capacity to perform specific social and work-related physical and mental activities following rehabilitation related to impairment or when a condition has reached a point of maximum medical improvement.

Summed pain intensity difference (*SPID*): A strategy for combining relief magnitude and duration in a single score. It is calculated by the sum of the time-weighted pain intensity difference (difference between current pain and pain at baseline) multiplied by the interval between ratings.

Symptom magnification: Conscious or unconscious exaggeration of symptom severity in an attempt to convince an observer that one is truly experiencing some level of pain. It differs from malingering as it is an effort to be believed, not necessarily to achieve a positive outcome (i.e., secondary gain) such as financial compensation.

Suffering: Reaction to the physical or emotional components of pain with a feeling of uncontrollability, helplessness, hopelessness, intolerability, and interminability. Suffering implies a threat to the intactness of an individual's self-concept, self-identify, and integrity.

Tolerance, drug: A physiological state in which a person requires an increased dosage of a psychoactive substance to sustain a desired effect.

Total pain relief (*TOPAR*): Is used in clinical trials to assess pain relief over time. It is a cumulative measure that is comprised of the sum of time-weighted pain relief score multiplied by the interval between ratings. TOPAR is frequently used in clinical trials of medications designed to ameliorate pain.

Wind-up: Slow temporal summation of pain mediated by C-fibers due to repetitive noxious stimulation at a rate faster than 1 stimulus every 3 seconds. May cause the person to experience a gradual increase in the perceived magnitude of pain.

TAXONOMIES

The lack of a classification of chronic pain syndromes that is used on a consistent basis inhibits the advancement of knowledge and treatment of chronic pain and makes it hard for investigators as well as practitioners to compare observations and results of research. Bonica[8] referred to this language ambiguity as "a modern tower of Babel."

In order to identify target groups, conduct research, prescribe treatment, evaluate treatment efficacy, and for policy and decision-making, it is essential that some consensually-validated criteria are used to distinguish groups of individuals who share a common set of relevant attributes. The primary purpose of such a classification is to describe the relationships of constituent members based upon their equivalence along a set of basic dimensions that represent the structure of a particular domain. Infinite classification systems are possible, depending upon the rationale about common factors and the variables believed to discriminate among individuals. The majority of the current taxonomies of pain are "expert-based" classifications.

Expert-Based Classifications of Pain

Classifications of disease are usually based on a preconceived combination of characteristics (e.g., symptoms, signs, results of diagnostic tests), with no single characteristics being both necessary and sufficient for every member of the category, yet the group as a whole possesses a certain unity.[9] Most classification systems used in pain medicine (e.g., International Classification of Diseases [ICD],[10] Classification and Diagnostic Criteria for Headache Disorders, Cranial Neuralgias, and Facial pain,[11] International Association for the Study of Pain Classification of Chronic Pain[2]) and dentistry (i.e., Research Diagnostic Criteria for Temporomandibular Disorders[12]) are based on the consensus arrived at by a group of "experts." In this sense they reflect the inclusion or elimination of certain diagnostic features depending on agreement.

"Expert-based" classification tends to result in preconceived categories and "force" individuals into the most appropriate one even if not all characteristics defining the category are present. Expert-based classification systems do not explicitly state the mathematical rules that should exist among the variables used in order to assign a case to a specific category.

In an ideal classification, the categories comprising the taxonomy should be mutually exclusive and completely exhaustive for the data to be incorporated. Every element in a classification should fit into one, and only one, place and no other element should fit into that place. An example of such an ideal, natural taxonomy is the periodic table in chemistry. We can also develop artificial classifications such as a telephone directory. The criterion for the classification, namely, the sequence of letters in the alphabet, bears no relation to the people, addresses, and telephone numbers being classified; but it is quite satisfactory for the intended purpose.[3] No classification in medicine or dentistry has achieved such aims. For example, the Research Diagnostic Criteria (RDC) for Temporomandibular Disorders[12] includes eight different diagnoses. In one study, over 50% of the sample received three or more RDC diagnoses.[13] Thus, the classifications or diagnoses are not mutually exclusive.

The most commonly used classification system of pain is the International Classification of Diseases published by the World Health Organization. In the most recent edition, the ICD-10,[10] conditions are classified along a number of different dimensions including causal agent, body system involved, pattern and type of symptoms, and whether or not they are related to the artificial intervention of an operation, time of occurrence or grouped as signs, symptoms, and abnormal clinical and laboratory findings. Within major groups there are subdivisions by symptom pattern, the presence of hereditary or degenerative disease, extrapyramidal and movement disorders, location, and etiology. Overlapping occurs repeatedly in such approaches to categorization; thus, they are not ideal even if they serve a useful function.

Further complications arise when clinicians require a separate coding system. In the United States, for example, in addition to the ICD codes a clinician must select current procedural terminology (CPT) coding schemes for the billing purpose. This has created a tendency where the fulfillment of the CPT coding may dictate the ICD selections to justify the procedures. Such practices

often needlessly create diagnoses and additional treatments for billing purposes only.

It is clear that the classification of pain cannot approach the ideal found in chemistry or telephone books, but this is not unique to pain; it characterizes medical classification systems in general. Classification in medicine, dentistry, and psychology is pragmatic. It does not provide absolute truth but rather provides categories with which we can work to identify individuals with similar phenomena, prognoses, or causes.[3] Currently, the majority of pain classifications in pain medicine rely upon various parameters of pain experience such as anatomy, system, severity, duration, and etiology.

Classification Based on Anatomy

Several pain syndromes are classified by body location. For example, low back pain, pelvic pain, and headache each refer to the specific location of symptoms. However, the extent to which the anatomy-based classification of pain is clinically meaningful is limited, at least partially, due to the lack of anatomically defined specificity in the neurophysiology of pain.

Classification Based on Duration

As previously discussed, one common way to classify pain is to consider it along a continuum of duration. Thus, pain associated with tissue damage, inflammation, or a disease process that is of relatively brief duration (i.e., hours, days, or even weeks), regardless of how intense, is frequently referred to as acute pain (e.g., postsurgical pain). Many pain problems can be classified as chronic. For example, pain that persists for extended periods of time (i.e., months or years), accompanies a disease process (e.g., rheumatoid arthritis), or is associated with an injury that has not resolved within an expected period of time (e.g., low back pain, phantom limb pain) are all referred to as chronic. As noted, however, a single dimension of duration is inadequate because pathological factors may be relatively independent of duration.

Classification Based on the Etiology of Pain

Another way to classify pain is based on etiology. The crudest classification of this kind is to simply distinguish somatogenic pain from psychogenic pain (pain of psychological origin). Simply put, when a range of physical examination, diagnostic imaging, and laboratory tests fail to identify the physical basis for the report of pain, pain is attributed to psychic conflict or psychopathology. Variations on the dichotomous somatogenic versus psychogenic classification exist. For example, Portenoy[14] proposed that three primary categories of pain be used: nociceptive, neuropathic, and psychogenic. In this system, somatogenic pain is subdivided into two subtypes that contrast with psychogenic pain.

The processes by which clinicians determine whether pain is somatogenic or psychogenic are distinctive. The classification of somatogenic pain is established by identification of positive organic findings, whereas psychogenic pain is indicated only in the absence of positive signs. We question the utility of such a classification scheme.

Classification Based on Body System

Classification may focus on the body system involved. For example, Fricton[15] proposed the use of five categories; namely, myofascial, rheumatic, causalgic, neurologic, or vascular. In this case patients are assigned to one of five rather than two or three categories as proposed by Portenoy.[14] However, the decision regarding classification is still based on a single dimension system for the experience of pain.

Classification Based on Severity

Frequently, pain is classified unidimensionally on the basis of severity (0- to 10-point scale with 0 = no pain and 10 = the worst pain that can be imagined). That is, regardless of the scale's level of measurement—nominal, ordinal, or interval—the construct involves a single dimension. When pain is classified on the basis of severity, it is dependent on the subjective report of patients. Assuming pain threshold is normally distributed, there will be significant variability among patients' rating severity of what might be objectively the same nociceptive stimulation.

Ratings of pain severity will be anchored to how questions are asked and responses may vary widely depending on the question. For example, if the ratings associated with "pain right now," "over the past week?" "usual severity," "severity at its worst," "severity at its lowest," "during specific movements," or "at rest?" Pain severity may be very useful in evaluating individual patients but less so for comparison among groups.

Classification Based on Functioning

The International Classification of Functioning Disability and Health (ICF)[16] aims to provide a standard framework for the comparison and understanding of health outcomes. For any given health outcome, including chronic pain, the ICF identified three main outcomes: impairment, activity limitations, and participation restrictions. To date, the efforts of the ICF have been largely focused on identification of common domains across measures that can be used to evaluate patients and treatment outcomes. It has less emphasis on classification of patients but it can be used for this purpose. The empirical approach described below can be readily applied to the ICF conceptual model.

Mechanism-Based Classification of Pain

The conventional classifications of pain disorders based upon anatomy, duration, and systems have drawn criticism for their deficiency in sensibility for guiding treatment or research.[17] Woolf et al.[17] support developing a mechanism-based classification of pain, proposing a potential list of pain mechanisms (Table 2.1). They argue that the list needs to include affective, behavioral, and cognitive factors relevant to pain, although they do not specify what these factors may be, or how they would be incorporated within the proposed classification system.

The mechanism-based classifications of pain differ from the conventional classification in that the former frees pain from diseases that may accompany reports of pain. Mechanism-based classification groups patients who are homogeneous in pain mechanisms but heterogeneous in disease conditions or diagnoses. Woolf et al.[17] emphasize that their proposal is not to replace but rather to supplement the current system.

The basic premise underlying the mechanism-based classification of pain is helpful, both in guiding treatment and in bridging research to clinical practice in pain medicine. However, such a system is still at the conceptual stage. Ongoing efforts to synthesize findings from various areas of pain research will help to formulate this new classification system.

This approach contrasts with our description of the use of two dimensions, time and severity, to distinguish acute and chronic pain (Fig. 2.1). An explication of attempts to develop multidimensional classification systems incorporating features of several of the classifications is reviewed in the next section.

TABLE 2.1

CATEGORIES OF PAIN AND POSSIBLE MECHANISMS

TRANSIENT PAIN
Nociceptor specialization

TISSUE INJURY PAIN
Primary Afferent
Sensitization
Recruitment of silent nociceptors
Alteration in phenotype
Hyperinnervation

CNS Mediated
Central sensitization recruitment, summation, amplification

NERVOUS SYSTEM INJURY PAIN
Primary Afferent
Acquisition of spontaneous and stimulus-evoked activity by nociceptor axons and somata at loci other than peripheral terminals
Alteration in phenotype

CNS Mediated
Central sensitization
Deafferentation of 2nd order neurons
Disinhibition
Structural reorganization

Multidimensional Classification of Pain: International Association for the Study of Pain Taxonomy

An alternative to the unidimensional approaches is a multidimensional approach that uses several relevant rather than a single dimension as the basis for developing the classification system and for assigning patients to a particular subgroup or diagnosis. The IASP has published an expert based multiaxial classification of chronic pain[1,2] intended to standardize descriptions of relevant pain syndromes and to provide a point of reference. The published taxonomy classifies chronic pain patients according to five axes based upon the best published information and consensus:

1. **Region** of the body (Axis I),
2. **System** whose abnormal functioning could conceivably produce the pain (Axis II),
3. **Temporal characteristics of pain and pattern of occurrence** (Axis III),
4. **Patient's statement of intensity and time since onset of pain** (Axis IV), and
5. Presumed **Etiology** (Axis V)(see Table 2.2).

This system establishes a five-digit code that assigns to each chronic pain diagnosis, a unique number. For example, the code for carpal tunnel syndrome is 204.X6. Thus,

200 = REGION: upper shoulder and upper limbs
00 = SYSTEM: the abnormal functioning is attributed to the nervous system
4 = TEMPORAL CHARACTERISTICS: symptoms occur irregularly
X = PATIENTS STATEMENT OF INTENSITY AND TIME SINCE ONSET: this will vary by patient
06 = ETIOLOGY: degenerative, mechanical

Table 2.3 contains the IASP scheme developed for the coding of chronic pain diagnoses.

The IASP classification is the most comprehensive approach to classification of chronic pain syndromes. By design the IASP classification is a heuristic, multiaxial guide that emphasizes the consideration of both signs and symptoms. Unfortunately, it excludes assessment of psychosocial or behavioral data. Moreover, to be useful, any classification system must be reliable and valid, but as yet little published research has evaluated the reliability, validity, or utility of the IASP classification. What little evidence is available[18] indicates that, although Axis 1 (body region) demonstrated reliable coding across examiners, Axis 5 (etiology) failed to achieve acceptable inter-rater reliability. The consistency (test–retest reliability) of the IASP taxonomy has yet to be established. Further research is needed in order to evaluate the psychometric properties of the classification system and to facilitate refinements of the system. The classifications we have described are only a few examples and are definitely not exhaustive. Specialists can arrive at classification categories based on clinical experience, published data, and consensus [e.g., 6]. There is no single system for classifying pain patients that is universally accepted by clinicians or researchers. Furthermore, several problems associated with the current classification systems have generated debate and research concerning an alternative classification of pain. We provide several examples to illustrate different attempts to devise alternative taxonomies of pain and chronic pain patients.

Empirically-Based Classifications of Pain

Those who advocate the use of empirically-derived taxonomies maintain that quantitative analysis should define the relationships of contiguity and similarity among individuals. That is, the taxonomic system must reflect clinically relevant characteristics that exist in nature, defined by empirical methods rather than based on expert judgment and consensus.

The American College of Rheumatology provides an empirical diagnosis for the classification of FM. In a multicenter study,[19] a group of FM experts from several medical centers collected FM-related variables and used those variables in an attempt to differentiate FM patients from patients with other types of chronic pain syndromes. The acceptable sensitivity and specificity were achieved by two criteria: presence of widespread pain (i.e., above and below the waist, right and left side of the body, and along the midline) and at least 11 of 18 positive tender points upon palpation. Other symptoms commonly reported by FM patients, such as fatigue and stiffness, did not differentiate between FM and other types of chronic pain. Since publication, most subsequent research seems to conform to this classification system, making it a bit easier to compare results across studies. Nonetheless, debate remains about the extent that this classification contributes to clinical practice and the meaning of tender points and the necessity of the tender point criterion.[20]

Several statistical methods (e.g., cluster analysis) can be used to empirically identify categories that share relationships derived directly from data rather than hypothesized relationships. This is the case with more traditional consensus-based deductive systems. The results of identification analyses can lead to explicit, mathematically-derived categories. This permits physicians and clinical investigators to assign patients to specific categories on an objective basis.

Although quantification, replication, and objectivity are the hallmarks of the inductive approach, it is important to acknowledge that all relevant factors cannot be measured by a single classification system. The use of an inductive approach depends on what the investigator chooses to include within the statistical analysis. Thus, in practice, the inductive approach to classification is not a totally objective process that is completely atheoretical. In light of this notion, some advocate the dual-diagnostic approach, using the two loosely defined domains biophysiologic

TABLE 2.2

INTERNATIONAL ASSOCIATION FOR THE STUDY OF PAIN: SCHEME FOR CODING CHRONIC PAIN SYNDROMES

Axis I: Regions	
Head, face, and mouth	000
Cervical region	100
Upper shoulder and upper limbs	200
Thoracic region	300
Abdominal region	400
Lower back, lumbar spine, sacrum, & coccyx	500
Lower limbs	600
Pelvic region	700
Anal, perineal, & genital region	800
More than three major sites	900
Axis II: Systems	
Nervous system (central, peripheral, and autonomic) and special senses; physical disturbance or dysfunction	00
Nervous system (psychological and social)	10
Respiratory & cardiovascular systems	20
Musculoskeletal system and connective tissue	30
Cutaneous and subcutaneous and associated glands (breast, apocrine, etc)	40
Gastrointestinal system	50
Genito-urinary system	60
Other organs or viscera (e.g., thyroid, lymphatic hemopoietic)	70
More than one system	80
Unknown	90
Axis III: Temporal Characteristics of Pain: Pattern of Occurrence	
Not recorded, not applicable, or not known	0
Single episode, limited duration (e.g., ruptured aneurysm, sprained ankle)	1
Continuous or nearly continuous, nonfluctuating (eg, low back pain)	2
Continuous or nearly continuous, fluctuating (eg, ruptured intervertebral disc)	3
Recurring irregularly (e.g., headache, mixed type)	4
Recurring regularly (e.g., premenstrual pain)	5
Paroxysmal (e.g., tic douloureux)	6
Sustained with superimposed paroxysms	7
Other combinations	8
None of the above	9
Axis IV: Patient's Statement of Intensity: Time Since onset of Pain	
Not recorded, not applicable, or not known	.0
Mild—1 month or less	.1
Mild—1 month to 6 months	.2
Mild—more than 6 months	.3
Medium—1 month or less	.4
Medium—1 month to 6 months	.5
Medium—more than 6 months	.6
Severe—1 month or less	.7
Severe—1 month to 6 months	.8
Severe—more than 6 months	.9
Axis V: Etiology	
Genetic or congenital disorders (e.g., congenital dislocations)	.00
Trauma, operation, burns	.01
Infective, parasitic	.02
Inflammatory (no known infective agent), immune reaction	.03
Neoplasm	.04
Toxic, metabolic (e.g., alcoholic neuropathy) anoxia, vascular, nutritional, endocrine, radiation	.05
Degenerative, mechanical	.06
Dysfunctional (including psychophysiological)	.07
Unknown or other	.08
Psychological origin (e.g., conversion hysteria, depressive hallucination)	.09

IASP Chronic Pain Syndromes

A. Relatively generalized syndromes

B. Relatively localized syndromes of the head and neck
   - I. Neuralgias of the head and face
   - II. Craniofacial pain of musculoskeletal origin
   - III. Lesions of the ear, nose, and oral cavity
   - IV. Primary headache syndromes, vascular disorders, and cerebrospinal fluid syndromes
   - V. Pain of psychological origin in the head, face, and neck
   - VI. Suboccipital and cervical musculoskeletal disorders
   - VII. Visceral pain in the neck

C. Spinal pain—spinal and radicular pain syndromes

D. Spinal pain—spinal and radicular pain syndromes of the cervical and thoracic regions

E. Local syndromes of the upper limbs and relatively generalized syndromes of the upper and lower limbs
   - I. Pain in the shoulder, arm, and hand
   - II. Vascular disease of the limbs
   - III. Collagen disease of the limbs
   - IV. Vasodilating functional disease of the limbs
   - V. Arterial insufficiency in the limbs
   - VI. Pain of psychological origin in the lower limbs

F. Visceral and other syndromes of the trunk apart from spinal and radicular pain
   - I. Visceral and other chest pain
   - II. Chest pain of psychological origin
   - III. Chest pain referred from abdomen or gastrointestinal tract
   - IV. Abdominal pain of neurological origin
   - V. Abdominal pain of visceral origin
   - VI. Abdominal pain syndromes of generalized diseases
   - VII. Abdominal pain of psychological origin
   - VIII. Diseases of the bladder, uterus, ovaries, and adnexa
   - IX. Pain in the rectum, perineum, and external genitalia

G. Spinal pain—spinal and radicular pain syndromes of the lumbar, sacral, and coccygeal regions
   - I. Lumbar spinal or radicular pain syndromes
   - II. Sacral spinal or radicular pain syndromes
   - III. Coccygeal pain syndromes
   - IV. Diffuse or generalized spinal pain
   - V. Low back pain or psychological origin with referral

H. Local syndromes of the lower limbs
   - I. Local syndromes in the leg or foot: pain of neurological origin
   - II. Pain syndromes of the hip and thigh of musculoskeletal origin
   - III. Musculoskeletal syndromes of the leg

TABLE 2.3

LIST OF DESCRIPTIONS IN EACH SYNDROME IN THE IASP CLASSIFICATION

Definition
Site
System(s) involved
Main features of the pain including its prevalence, age of onset, sex ratio if known, duration, severity, and quality
Associated features; aggravating and relieving agents
Signs
Laboratory findings
Natural course
Complications
Social and physical disability
Pathology or other contributing factors
Essential features and diagnostic criteria
Differential diagnosis
Code based on the five axes
References (optional)

and psychosocial.[12,21] In this framework, physiologically homogeneous patients exhibit a range of psychosocial heterogeneity.

Multiaxial Classification of Pain

Ever since the gate control model underscored the importance of cognitive–evaluative and motivational–affective factors in the process of pain experience, the importance of integrating the psychosocial domains in the classification of pain has been proposed by a number of clinical investigators. However, as in other domains of pain medicine, the psychosocial classifications of pain have largely depended upon the traditionally defined diagnosis system, in this case, identification of psychopathology. Although the psychiatrically-defined classification of pain patients may help identify patients with specific psychiatric disorders thereby directing treatments for those disorders, psychological classification systems to identify the specific psychological components (affective, evaluative, motivational) of pain have been introduced.

The Emory Pain Estimate Model

The Emory Pain Estimate Model (EPEM) was the first attempt to integrate the biophysiologic and psychosocial domains in classifying pain patients.[22,23] Brena and colleagues arbitrarily labeled the dimensions "pathology" and "behavior." The pathology dimension included the quantification of physical examination procedures (e.g., ratings of joint mobility, muscle strength) as well as assigning numerical indices to reflect the extent of abnormalities determined from diagnostic procedures such as radiographic studies. The behavioral dimension comprises a composite of activity levels, pain verbalizations, drug use, and measures of psychopathology based on the elevations of scales of the Minnesota Multiphasic Personality Inventory (MMPI).

Using median divisions on the pathology and behavior dimensions, the EPEM defines four classes of chronic pain patients (see Fig. 2.2). Class I patients are characterized by higher scores on the behavior dimension and lower scores on the pathology dimension. The EPEM describes these patients as displaying low activity levels, high verbalizations of pain, prominent social and psychological malfunctions, and frequent misuse of medications. Class II patients are those who display lower scores on both the pathology and behavioral dimensions. These patients are described as displaying dramatized pain complaints with ill-defined anatomical patterns. However they do not display significant behavioral

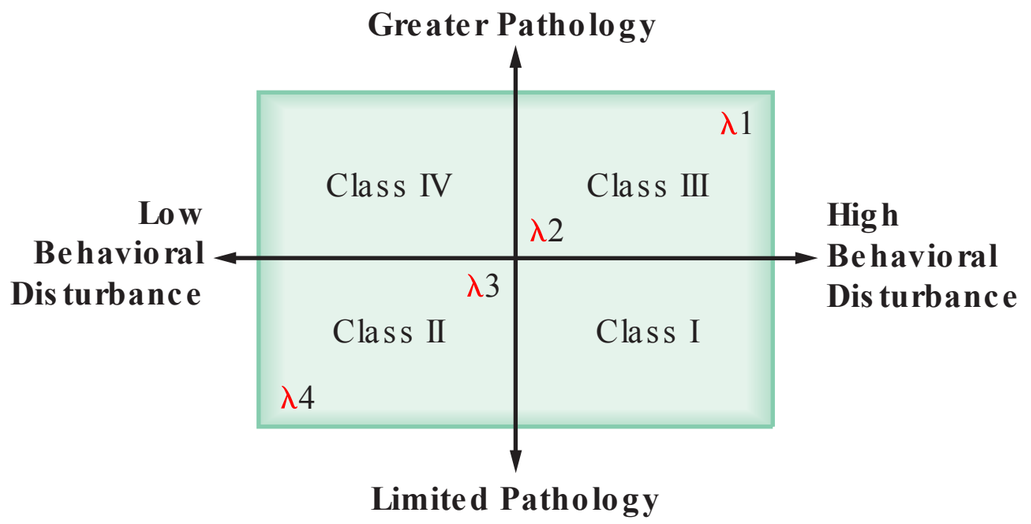

FIGURE 2.2 The Emory pain estimate model. (Redrawn after Turk DC, Rudy TE. Classification logic and strategies in chronic pain. In: Turk DC, Melzack R, eds. *Handbook of Pain Assessment*. New York: Guilford: 1992:409–428.)

dysfunction. Class III represents patients with higher scores on both dimensions, characterized as showing clear evidence of physical pathology and high intensity illness behavior. Finally, Class IV patients are those who have higher scores on the pathology dimension and a lower score on the behavior dimension, thus demonstrating competent coping in the presence of a physical pathological condition.

Although Brena and his colleagues[22,23] appropriately emphasized the importance of integrating physical and psychological data in order to develop a classification system for chronic pain patients, some of the basic theoretical and quantitative characteristics of the EPEM are problematic. We see this framework as a conceptual model rather than an adequately operationalized empirical one. For example, from a theoretical standpoint, the inclusion of activity levels, pain verbalizations, and measures of psychopathology under a single dimension labeled "behavioral" is troubling because research shows that there is little association between pain behaviors and psychopathology. Thus, the behavioral dimension is most likely not unidimensional and, therefore, cannot measure behavior directly.

Examination of the empirical aspects of the scoring and classification system used in the EPEM identifies additional problems. For example, the weights assigned to specific medical–physical findings are *a priori* and were not empirically derived. Moreover, applying median divisions to the two dimensions, although intuitively appealing, artificially creates four classes of patients. That is, there is no statistical demonstration that four nonoverlapping groups of pain patients naturally exist in these data or that, in fact, the pathology and behavioral dimensions are independent. Review of the 2 × 2 grid displayed in Figure 2.2 reveals that within the EPEM extreme, scores are treated the same as scores near the medians. For example, the scores of patients 1 and 2, depicted as points in Figure 2.2, would both be assigned to Class III, whereas those of patients 3 and 4 would be classified in Class II. In reality, however, the scores of patients 2 and 3 are more similar than they are with the scores of patient 1 or patient 4. Thus, this method of establishing classification rules may lead to erroneous or nonindependent patient assignments because it is derived from artificial and external mathematical criteria rather than from divisions or clustering of groups that occur naturally within patients' scores. Von Korff and colleagues[24] developed a similar model, the Chronic Pain Grade, which integrates the conceptual approach of the EPEM but adds greater emphasis of empirical determination of criteria for subgroup classification and empirical validation. The Chronic Pain Grade classifies patients into one of five categories: (1) pain free, (2) low pain intensity and low disability, (3) high pain intensity and low disability, (4) low pain intensity and high disability, and (5) high pain severity and high disability.

Empirically-Based Classification of the Psychological Components of Pain

Many taxonomies of pain recognize that the conceptualization and operationalization of cognitive, affective, and behavioral factors associated with pain merit consideration. Numerous instruments assess pain-related psychosocial constructs but most are unidimensional, inadequate for pain populations, or lack predictive validity for treatment outcomes. We describe one specific multidimensional psychosocial classification system used primarily with patients with chronic pain conditions.

The Multidimensional Pain Inventory[25] consists of a set of empirically-derived scales designed to assess chronic pain patients' (1) reports of pain severity and suffering; (2) perceptions of how pain interferes with their lives, including interference with family and marital functioning, work, and social and recreational activities; (3) their dissatisfaction with present levels of functioning in family, marriage, work, and social life; (4) appraisals of support received from significant others; (5) perceived life control incorporating perceived ability to solve problems and feelings of personal mastery and competence; (6) their affective distress, including depressed mood, irritability, and tension; and (7) activity levels. Using the MPI, Turk and Rudy[26] were able to group patients within three relatively homogeneous sets.

Turk and Rudy[26] performed cluster analyses on a heterogeneous sample of chronic pain patients' responses on the MPI scales. Three distinct profiles were identified: (1) dysfunctional (DYS), patients who perceived the severity of their pain to be high, reported that pain interfered with much of their lives, reported a higher degree of psychological distress due to pain, and reported low levels of activity; (2) interpersonally distressed (ID), patients with a common perception that significant others were not very supportive of their pain problems; and (3) adaptive copers (AC), patients who reported high levels of social support, relatively low levels of pain and perceived interference, and relatively high levels of activity. Reliable, external scales supported the uniqueness of each of the three subgroups of patients. Performing a 12-dimension Bayesian calculation to test goodness of fit can identify the profile that best fits a patient.

In addition to categorical classification that assigns an individual patient to a specific diagnosis, the empirical–statistical approach permits judgments about how well a patient matches the central features of that diagnosis. This is especially useful in complex pain syndromes that involve various clinical characteristics with rather large individual variability, even within a single diagnostic group. Using an empirical method, one can not only establish whether a patient fits the diagnostic classification but also determine how good a fit the diagnosis is to the patient. For example, based on a set of patient characteristics, signs, and symptoms, a prototype for a diagnosis is established. It is possible to statistically determine how close an individual case matches that prototype. Assume that a perfect match to a prototype is 0.99. A particular case may fit within the diagnosis but not be a perfect fit, thus the fit might be 0.80. Some statistical rule can decide the minimum fit to the characteristics of the diagnosis; for example, 0.67. Thus, any two individuals with the same diagnosis must share certain characteristics but not necessarily all; the similarity of two patients with the same diagnosis has a statistical definition.

Subsequent testing of the MPI profiles across various pain disorders suggests that the MPI psychosocial classification is independent of the conventionally defined pain syndromes, such as low back pain, TMD, migraine headaches, FMS, and pain associated with cancer. In other words, two patients whose pain pathologies are likely to differ (cancer and migraine headaches, for example) could have a homogeneous psychological classification of pain. On the other hand, two patients, both having same type of TMD based upon the RDC[12] for comparable duration, may fare differently in the psychological classification of pain. Clinical trials using the MPI-based classification have yielded differential responses to a cognitive–behavioral approach.[27,28] Such results strongly suggest that the psychosocial treatment components need to conform to the psychological classification of pain.

We suggest that disease classification should reflect physical assessment and treatment [e.g., 2] and that a psychosocial–behavioral taxonomy should determine complementary psychological treatment strategies. Both physical and psychosocial diagnoses are important in the person with a chronic pain syndrome. Several groups[12,21,29] have proposed the use of a dual-diagnostic approach, whereby two diagnoses are assigned concurrently: physical and psychosocial–behavioral. Treatment could then target both simultaneously. A chronic pain patient might have diagnoses on two different but complementary taxonomies; for example, IASP and MPI-based classification. Thus, a patient might be classified as having complex regional pain Type 1 of the upper extremity (203.X1, Axis 1 Region = upper shoulder and upper limbs, Axis II System = nervous, Axis III Temporal Characteristics of Pain: Pattern of Occurrence = none of the codes listed, Axis IV Intensity and Time of Onset = based on patient report, Axis V Aetiology = trauma) on the IASP taxonomy and be classified DYS on the MPI-based taxonomy. Note that not all CRPS-1 patients would be classified as DYS and not all DYS patients would have CRPS-1. A second patient might have the same IASP diagnosis, CRPS-1, but be ID on the MPI-based classification. Conversely, patients might have quite different classifications on the IASP system but have an identical MPI-based classification. The most appropriate treatment for these different groups might vary, with different complementary components of treatments addressing the physical diagnosis (IASP) and the psychosocial diagnosis (MPI-based).

Psychometric Considerations

The general utility of any proposed empirical taxonomy links closely to the psychometric properties (i.e., reliability, validity, and utility) of the measures, scales, or instruments used to derive the classification system. Because these are the building blocks used to generate profiles or clusters, the reliability and validity of the classification system depends, in part, on the psychometric quality of the measures used. Because reliability and validity coefficients are generic terms, the specific psychometric techniques used to evaluate a measure's "psychometric properties" require consideration. There are multiple ways to demonstrate the reliability and validity of measures. Therefore, the more psychometric support there is for a measure, the more likely it will perform well when used in taxometric identification and classification procedures. Additionally, replication of classification accuracy on new samples and demonstrating substantial, statistically significant differences across patient profiles for conceptually related measures *external* to the measures used to develop the profiles are some of the best ways to demonstrate the reliability and validity of empirically derived profiles. Evaluation of any classification should demonstrate reliability, validity, and utility prior to widespread adoption.

CONCLUSION

Pain management specialists have witnessed rapid advances in the basic sciences and clinical arenas of pain medicine over the past 3 decades. Many pain-related terms, once a major source of confusion, have received clear definitions, aiding efficient and productive communication among researchers and clinicians. The classification systems that direct our research and clinical practice need to reflect the progress in our understanding of mechanisms,

multifactorial integration, and outcome predictability of classification criteria. In this chapter, we have reviewed several conventional classifications as well as emerging classification systems that can supplement the conventional ones. The review of various classification systems suggests that the comprehensive taxonomy of pain require multifactorial assessments (See Table 2.4).

The multiaxial approach to the assessment of pain and dysfunction described earlier appears to be a reasonable strategy to adopt. Given a comprehensive set of physical, psychosocial, and behavioral measures, the strategy of matching patients to existing classification systems could provide a basis for treatment decisions. The use of the dual-diagnostic approach holds promise because it incorporates biomedical, psychosocial, and behavioral data in the assignment of patients to empirically derived categories. Future research needs to relate patient classification to performance on standardized physical capacity assessment protocols, rehabilitation, and ability to engage in gainful employment and regular homemaking activities.

The utility of any classification system depends upon application. The important question is whether assignment of an individual to a class truly facilitates treatment decisions or predictions of future behavior. Few of the taxometric systems have demonstrated their utility to predict treatment outcome.[21] Preliminary results on the MPI-based classification demonstrate the potential of such an approach. Research efforts to evaluate the predictive value of any classification of pain need to demonstrate the validity of that classification system or taxonomy.

CHAPTER 3 ■ PERIPHERAL PAIN MECHANISMS AND NOCICEPTOR SENSITIZATION

MICHAEL S. GOLD AND GERALD F. GEBHART

INTRODUCTION TO PERIPHERAL PAIN MECHANISMS AND NOCICEPTOR SENSITIZATION

Pain has been categorized by duration (acute vs. chronic), location (superficial or deep; cutaneous, bone/joint, muscle, or viscera) and cause or type (inflammatory, neuropathic, cancer). Generally, activation of and/or ongoing activity in nociceptors underlies the experience of pain regardless of how it is categorized. Accordingly, nociceptors are key players in understanding mechanisms of and managing pain.

Sherrington anticipated by many decades the existence of nociceptors (sensory receptors that respond to noxious stimuli) and provided for us the operational definition of stimuli that are noxious (i.e., stimuli that damage or threaten damage of tissue). Two considerations are important to this discussion. First, Sherrington's definition of the nociceptor is a functional definition, meaning that the response to its activation by a noxious stimulus (e.g., a nociceptive withdrawal reflex, pain) defines the receptor. Second, the definition of an applied stimulus as noxious is based on response to stimuli applied to skin and subcutaneous structures.

Sherrington's definition of a nociceptor continues to the present day, although the term has undergone change and challenge over the past 100 years. It is therefore important to consider, within the context of our current knowledge, how a nociceptor is defined, identified, and studied. The importance of these issues relates to management of pain that is based on understanding mechanisms of pain. Nociceptors underlie important features of those mechanisms. All would agree that a nociceptor is a sensory receptor which, when activated or active, can contribute to the experience of pain. Nociceptors are present in skin, muscle, joints, and viscera, although the density of innervation (i.e., the number and distribution of sensory endings) varies between as well as within tissues. Strictly speaking, a nociceptor is the peripheral sensory terminal (i.e., the site of energy transduction, see following section), although commonly the term is used to also include the cell body (either in a dorsal root, trigeminal, or nodose ganglion) and its central termination in the spinal cord or brainstem. Beyond this, agreement about important features of nociceptors is less uniform. Because stimuli adequate for activation of nociceptors differ between tissues (e.g., tissue damage is not always required), defining a noxious stimulus has become a challenge. For example, some nociceptors in skin and joints and most nociceptors in the viscera have low thresholds for mechanical activation that do not conform to the condition that stimulus intensity must be either damaging or threaten damage. Further, so-called "silent" or "sleeping" nociceptors are unresponsive to intense mechanical stimulation (and are better denoted as mechanically insensitive nociceptors), but develop spontaneous activity and mechanosensitivity after exposure to inflammatory and other endogenous mediators. These types of nociceptors—low threshold and sleeping—are considered further in discussion of sensitization below.

As indicated above, nociceptors are defined classically in a functional context. However, in experimental situations where function cannot be assessed, other criteria to classify a cell as a nociceptor have been advanced. These include the presence or absence of axon myelination, cell size and/or cell content (e.g., peptide or ion channel), or central termination pattern. Sensory neurons commonly identified as nociceptors are those with unmyelinated (C-fiber) axons and small cell body diameters ($<$20 or 25 μm). More recently, the presence or absence of certain markers (e.g., the tetrodotoxin-resistant sodium channel NaV1.8, the transient receptor potential vanilloid receptor TRPV1, etc.) have been used to identify subsets of nociceptors. With respect to cell body size and myelination, it should be appreciated that there exist some large diameter cells with heavily myelinated and rapidly conducting axons that have been documented functionally to be nociceptors. Conversely, many non-nociceptors have unmyelinated axons and thus axon myelination or cell diameter cannot be applied as reliable criteria to define a nociceptor. Similarly, identifying nociceptors by content or what they express has limitations. For example, cells other than nociceptors express TRPV1 and the subset of nociceptors that stain positive for the isolectin B4 does not apply to the visceral innervation. These and other markers have been advanced as characteristics of nociceptive sensory neurons, but the extent to which any one or several reliably reveals a cell's function remains to be established.

The fact that no single criterion can be used to identify all nociceptors highlights another important point: this population of afferents is extremely heterogeneous. In addition to the anatomical, biochemical, and physiological heterogeneity in the afferent population generally referred to as nociceptors, there is functional heterogeneity. As will be discussed below, this functional heterogeneity is manifest both within the context of nociceptive signaling (i.e., subpopulations of nociceptors may underlie distinct "types" of pain such as cold allodynia or thermal hyperalgesia) and in the context of non-nociceptive function (i.e., such as the maintenance of tissue integrity).

That said, there are two functional properties common to all nociceptors: they encode stimulus intensity into the noxious range and they sensitize. Given our current understanding of the complexity of peripheral pain mechanisms, it seems unlikely that the range of intensities within any one modality (thermal, mechanical) that is encoded by a nociceptor and initiates nociceptive transmission involves only a single voltage- or ligand-gated channel. Though the ability to sensitize is one means of functionally defining a peripheral neuron as a nociceptor, the endogenous mediators and factors that contribute to an increase in the excitability of nociceptors (i.e., sensitization) are numerous, synergetic, and differ in different pain conditions (e.g., inflammation, nerve injury, etc.). A sampling of the complexities and contributors to sensitization are discussed in the following section.

Why include in a clinical textbook of pain management a chapter on peripheral pain mechanisms and nociceptors? There are many reasons. First, in most cases blockage of peripheral nociceptor activity removes the "drive" for the experience of pain. Further, if a primary goal is to develop mechanism-based

strategies for pain management, it is critical that characteristics of a key player—the nociceptor—are fully understood. Finally, nociceptor characteristics change as the local environment in which they reside changes (inflammation, nerve injury, etc.). We discuss below how nociceptors are activated, differ in different tissues, contribute to the experience of pain, and how their behavior changes when they become sensitized. Where possible, we have added relevant clinical examples and have inserted text boxes to elaborate on key issues.

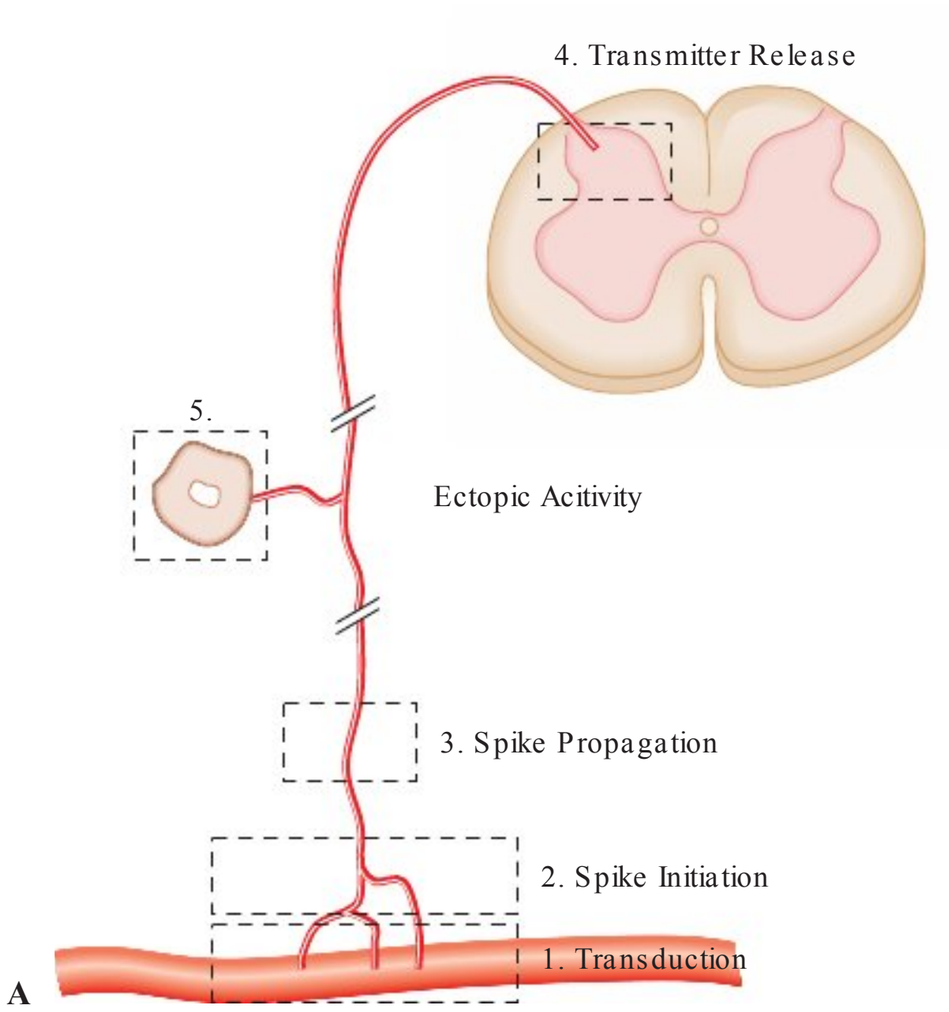
NOCICEPTOR CHARACTERISTICS

Anatomy of the Nociceptor

As stated above, nociceptors are sensory neurons with a cell body located in dorsal root, trigeminal, or nodose ganglia. All sensory neurons arising from these ganglia are pseudounipolar neurons with a central process terminating in the central nervous system (e.g., spinal dorsal horn) and a peripheral process terminating in a peripheral target such as the skin, muscle, or viscera. Both central and peripheral processes terminate in a branching pattern referred to as a terminal arbor. The extent of the peripheral arbor depends on the afferent type and site of innervation with the general rule that the higher the spatial resolution for sensory discrimination, the smaller the terminal arbor. In contrast to low threshold afferents that are responsive to non-noxious stimuli, such as brush or vibration, and which terminate in specialized structures, such as Rufinni endings or Merkel discs,[1,2] nociceptors are said to have ‘‘free’’ (unencapsulated) nerve endings because peripheral terminals of these afferents do not appear to be associated with any specific cell type.[3]

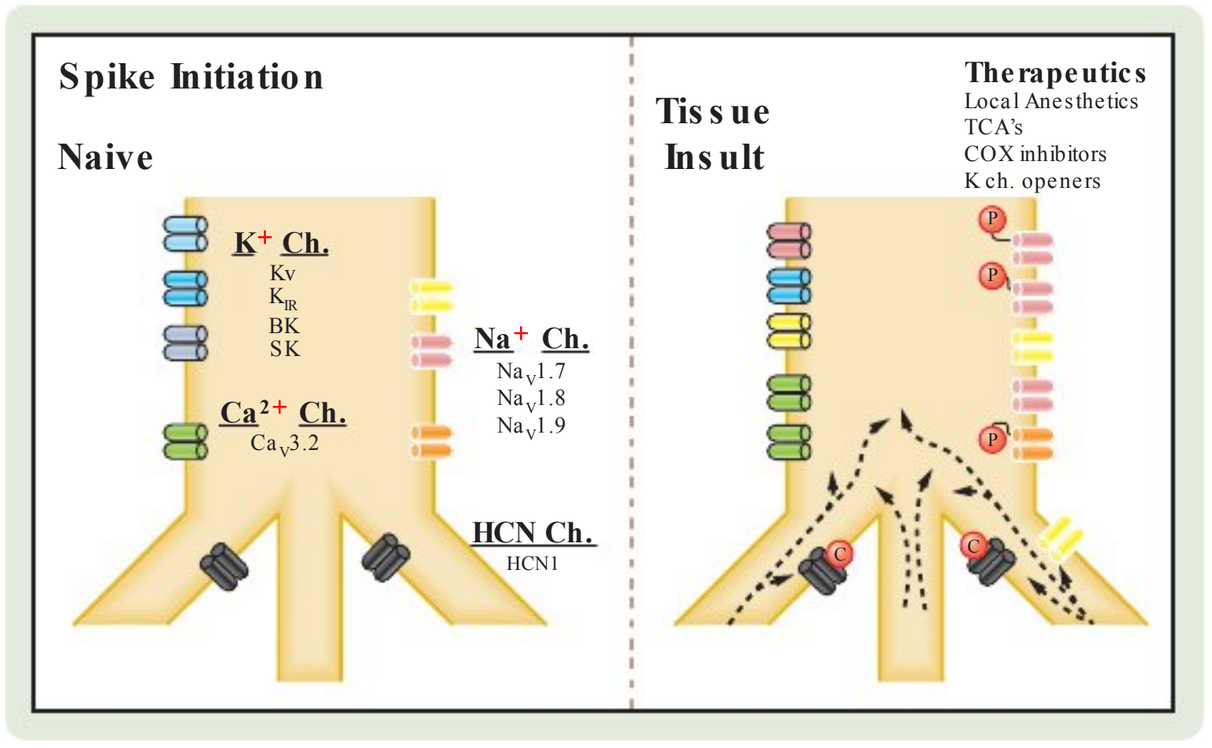
Both light and electron micrographic analyses of peripheral nociceptor terminals reveal complex anatomical structures. As suggested above, the structure of the terminal arbor varies with target of innervation. There is also evidence that subpopulations of nociceptive afferents have distinct terminal arbor patterns within the same structure. For example, the terminal arbor morphology of cutaneous C-fibers varies according to whether the C-fiber is peptidergic (i.e., expresses substance P or calcitonin gene-relative peptide) or expresses the Mas-related gene, MrgD.[4] Recent evidence suggests that these distinct but overlapping subpopulations of nociceptors may signal distinct aspects of the painful experience (i.e., sensory/discriminative versus emotional/motivational),[5] suggesting that it may someday be possible to selectively treat the suffering associated with chronic pain while still enabling patients to appropriately respond to noxious stimuli in their environment.

Four distinct events are necessary for a nociceptor to convey information to the central nervous system about noxious stimuli impinging on peripheral tissues (Fig. 3.1—the events are discussed fully in the following paragraphs). First, ‘‘energy’’ from the stimulus (mechanical, thermal, or chemical) must be converted into an electrical signal. This process, referred to as signal transduction, results in a generator potential or depolarization of the peripheral terminal. Second, the generator potential must initiate an action potential, the rapid ‘‘all or nothing’’ change in membrane potential that constitutes the basic unit of electrical activity in the nervous system. This process is sometimes referred to as transformation. Third, the action potential must be successfully propagated from the peripheral terminal to the central terminal. And fourth, the propagated action potential invading the central terminal must drive a sufficient increase in intracellular calcium ions to enable release of enough transmitters to initiate the whole process once again in the second order neuron. Distinct sets of proteins underlie each of these processes, and are therefore the targets of a wide variety of therapeutic interventions.



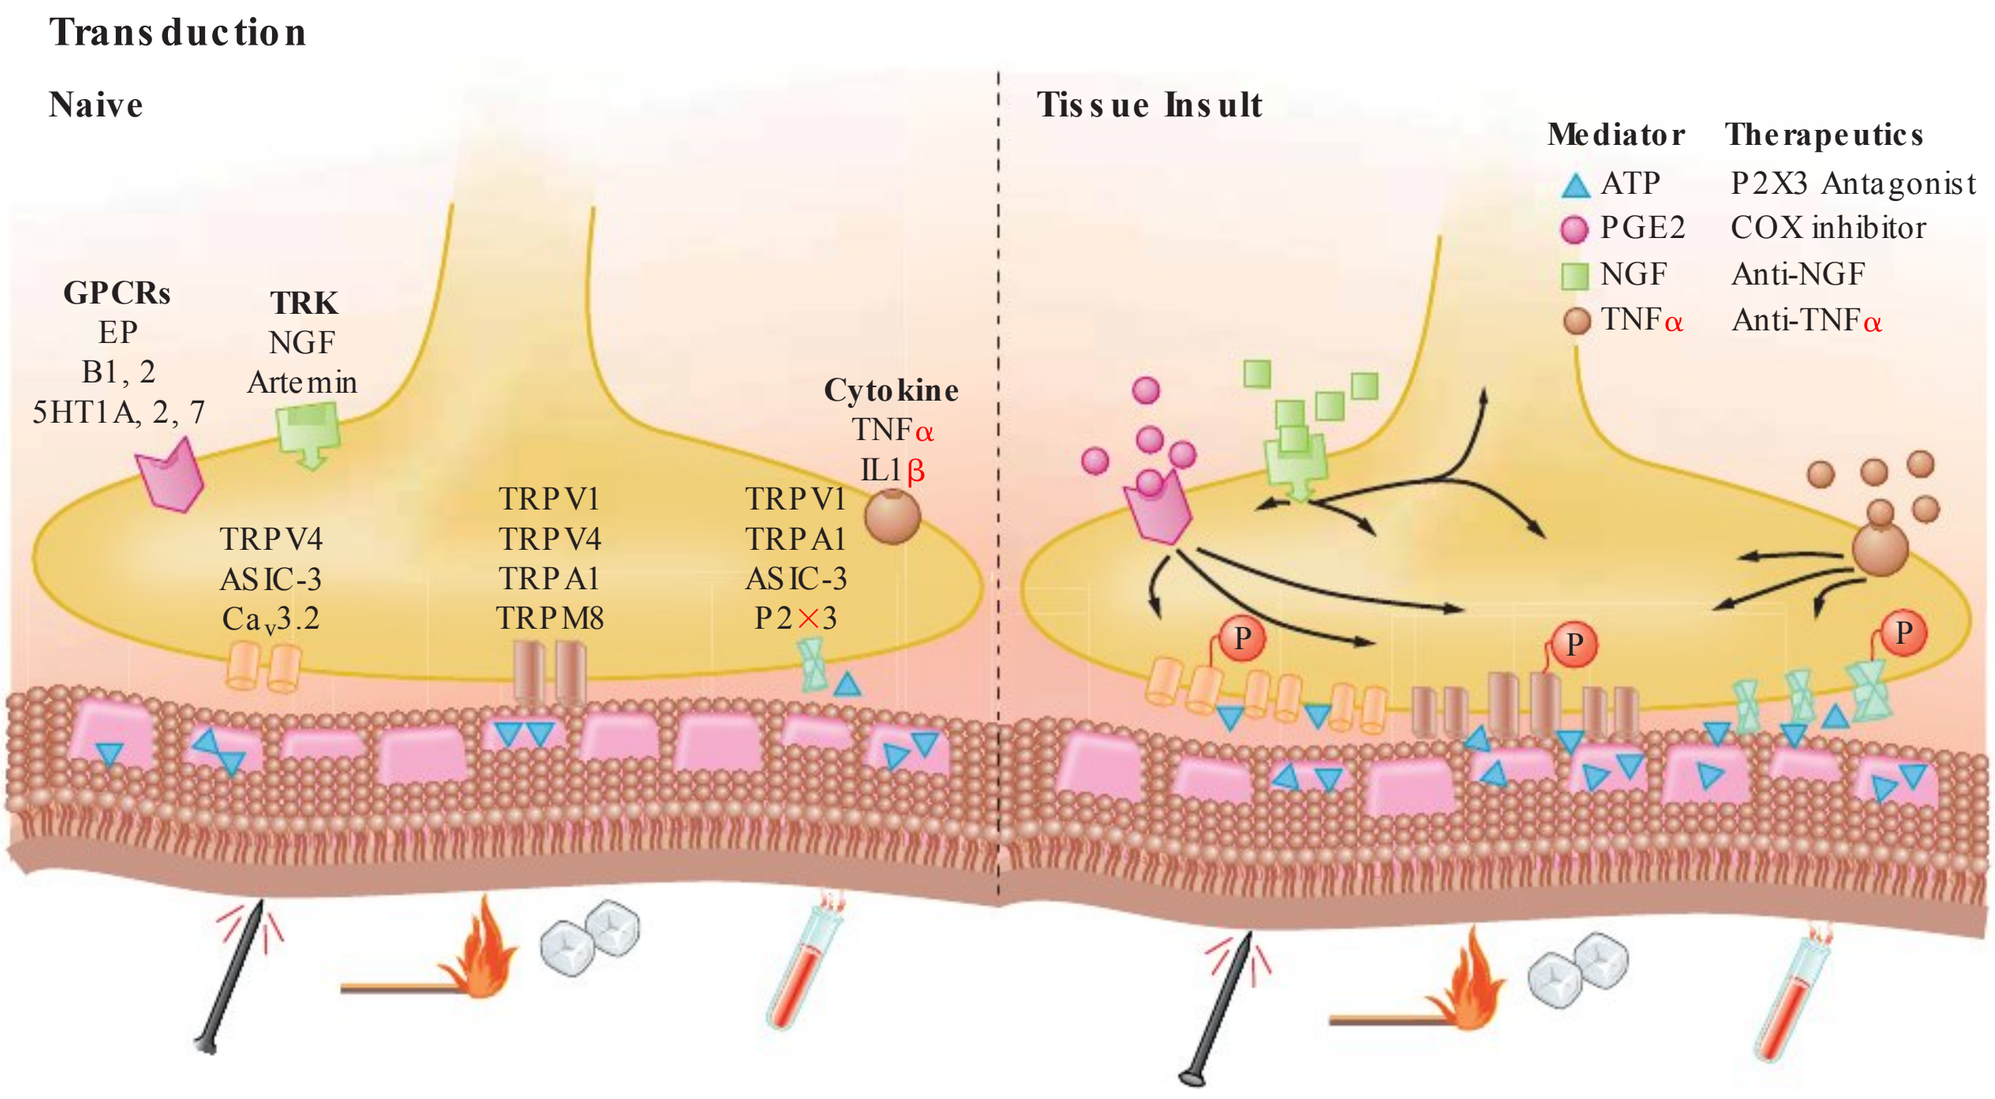
Stimulus Transduction

An important implication of the fact that nociceptive afferents terminate in ‘‘free nerve endings’’ is that they are not dependent on other cell types for the transduction of a noxious stimulus. That is, proteins responsible for transduction should be intrinsic to the nociceptor. Consistent with this suggestion, isolated sensory neurons are responsive to thermal (both heating[6,7] and cooling[8,9]), mechanical,[10] and a wide variety of chemical stimuli, including both endogenous[11,12] and exogenous[13,14] compounds that activate nociceptors in vivo. Proteins involved in the transduction of each stimulus modality have been identified.[15]



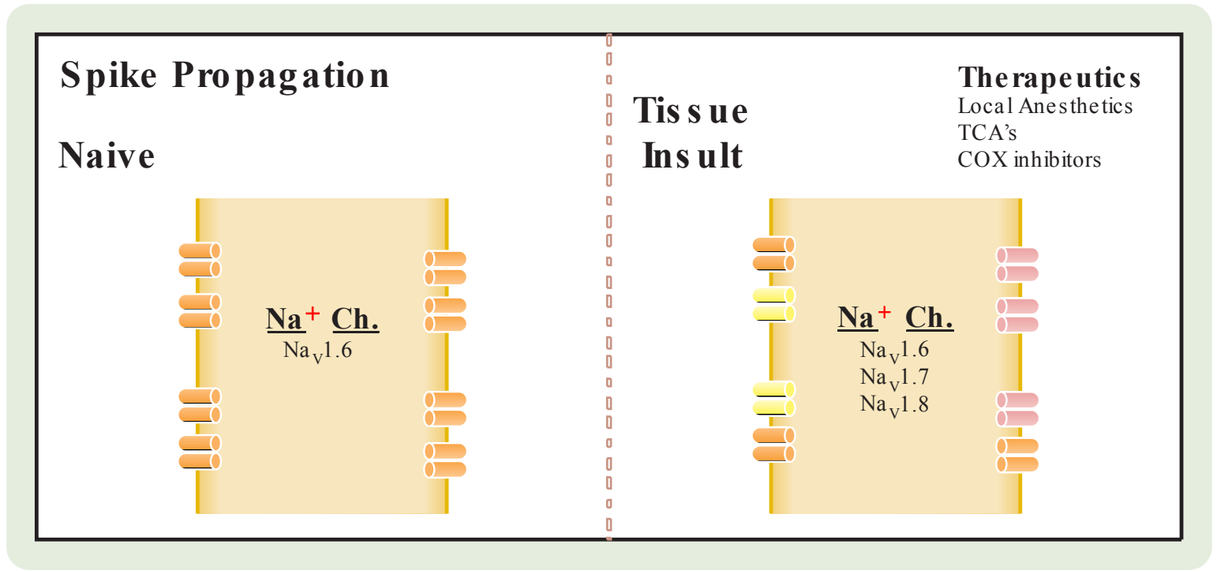
With the exception of transient receptor potential (TRP) channels (see below), and possibly the acid sensing ion channels (ASICs), chemotransducers are, in general, only activated by chemical stimuli (and not also mechanical or thermal stimuli) and encompass various families of proteins that respond to specific molecules such as adenosine triphosphate (ATP)[16] and protons.[17] There is also compelling evidence to support the suggestion that different members of the TRP superfamily underlie thermal transduction of temperatures ranging from the very cold (TRPA1[18]) to the very hot (TRPV2[19]), with receptors for cool,[20] warm,[21,22] and hot,[23] in between. Subsequent research, however, suggests that in contrast to traditional chemoreceptors, TRP family members are not modality specific, as all are activated by specific chemicals,[24] and several contribute to mechanical transduction.[25,26]

Because the only sensation associated with TRPV1 activation is pain, this receptor has received considerable attention from pain researchers. Cloned in 1997, data from an array of studies paint a picture of TRPV1 as an excellent example of a polymodal receptor; it is activated by exogenous compounds such as capsaicin and resiniferatoxin, endogenous compounds ranging from protons to lipids, and noxious heat.[24] Recent evidence suggests that TRPV1 is present on the central terminals of nociceptive afferents where it also facilitates transmission of noxious mechanical stimuli.[27] Furthermore, excessive activation of the receptor with compounds such as capsaicin results in desensitization of the nociceptive terminal to all modes of stimuli, a process that underlies the therapeutic efficacy of topical capsaicin application.[28] More recently, intrathecal application of resiniferatoxin has been used to selectively ablate the central terminals of TRPV1 containing nerve terminals, resulting in a sustained block of nociceptive transmission.[29] There is also evidence that TRPV1 receptor antagonists may have analgesic efficacy, although the therapeutic potential of these compounds may be limited by a small but significant hyperthermia associated with systemic administration of blood-brain barrier permeable analogs.[28]



Of the three modalities of noxious stimuli, molecular mechanisms of mechanotransduction remain the most elusive. Many mechanically sensitive proteins have been identified,[30] but none appear to be both necessary and sufficient for mechanotransduction in nociceptive afferents. Data from null mutant mice, where the deletion of a single putative mechanotransducer results in an increase in mechanosensitivity in one population of afferents and a decrease in others,[31,32] suggests that several different proteins are likely to work together in specific subpopulations of afferents to enable responses to specific forms of mechanical stimuli (e.g., stretch or compression). That even these more specialized forms of mechanosensitivity reflect intrinsic properties of afferents is suggested by the emergence of mechanosensitivity at the severed ends of a subpopulation of axons within hours of transection.[33] Despite the lack of success in this area, identification of a nociceptor specific mechanotransducer blocker remains an active area of investigation because of its therapeutic potential in light of the fact that mechanical hypersensitivity is the primary complaint associated with the vast majority of chronic pain syndromes.[34]

A

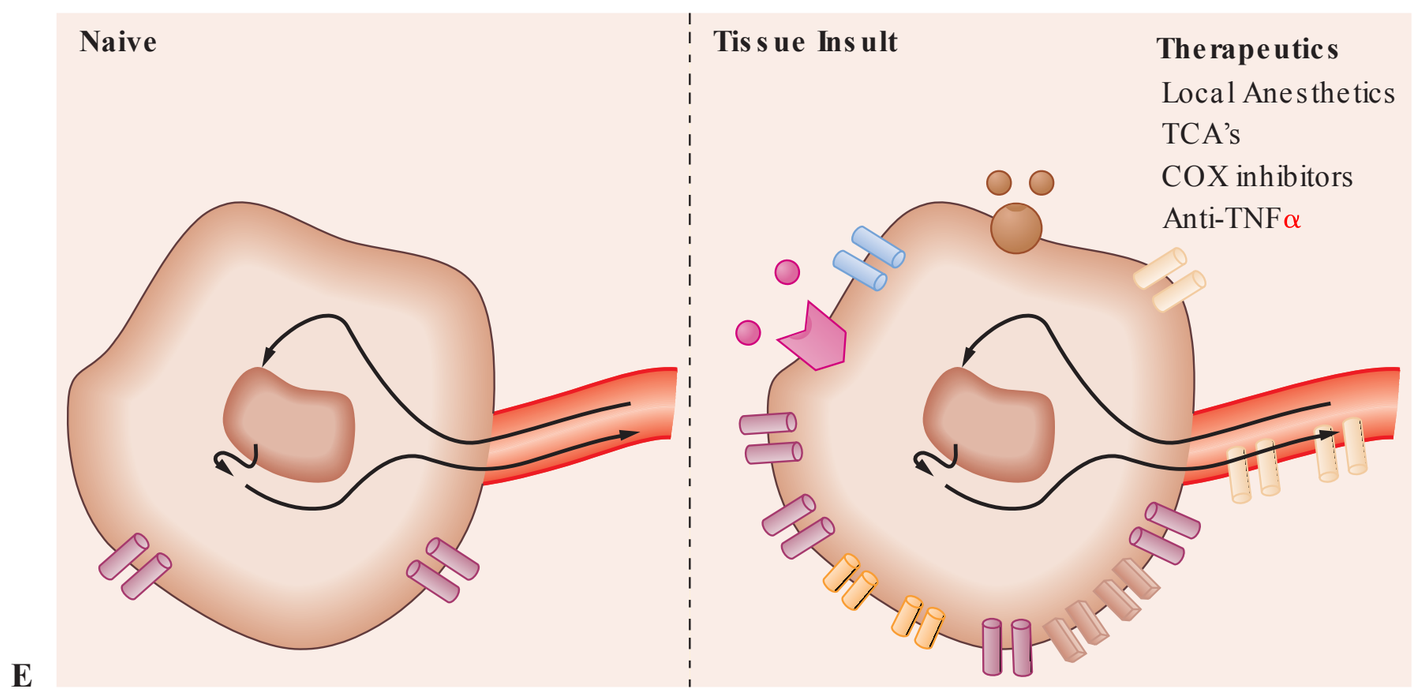


C

B

FIGURE 3.1 Nociceptive afferents terminate as free nerve endings in skin and other tissues. **A.** Their principal sensory functions consist of: (1) transduction of external or internal chemical or physical stimuli into generator potentials, (2) transformation of a generator potential into an action potential, (3) propagation of the action potential toward the central nervous system, and (4) release of neurotransmitters and neuromodulators into the superficial dorsal horn of the spinal cord or brainstem. Nociceptive afferents also release transmitters in the periphery, a process that contributes a neurogenic component to inflammation (not shown). The sensory neuron cell body (soma, 5) appears to be a site critical for the integration of neural activity. Proteins and signaling molecules are delivered to the soma via axonal transport mechanisms (not shown) under normal conditions, which may contribute to aberrant or ectopic activity under pathological conditions. Many of the proteins responsible for each of these processes, both under normal and pathological conditions, have been identified. While not a complete list, several lines of data implicate each of the proteins and mediators illustrated in each subpanel. **B. Transduction**: In naïve tissue, proteins thought to play a role in mechanotransduction include transient receptor potential vanilloid type 4 (TRPV4), acid sensing ion channel type 3 (ASIC-3) and the low threshold voltage-gated calcium channel (VGCC) CaV3.2. Several different classes of TRP channels are involved in transduction of changes in temperature from noxious cold (TRPA1, ankyrin type 1), cool (TRPM8, melastatin type 8), warm (TRPV4), and hot (TRPV1, vanilloid type 1). Many chemoreceptors are present in nociceptive afferents including those involved in the response to tissue acidosis (TRPV1 and ASIC-3), noxious organic compounds (e.g., aldehydes at TRPA1) and endogenous chemicals (e.g., ATP at P2X3, the ionotropic purine receptor type 3). A wide variety of other receptors for both pro- and anti-inflammatory (not shown) mediators are also present on the terminals of nociceptive afferents. These include G-protein

(*continues*)



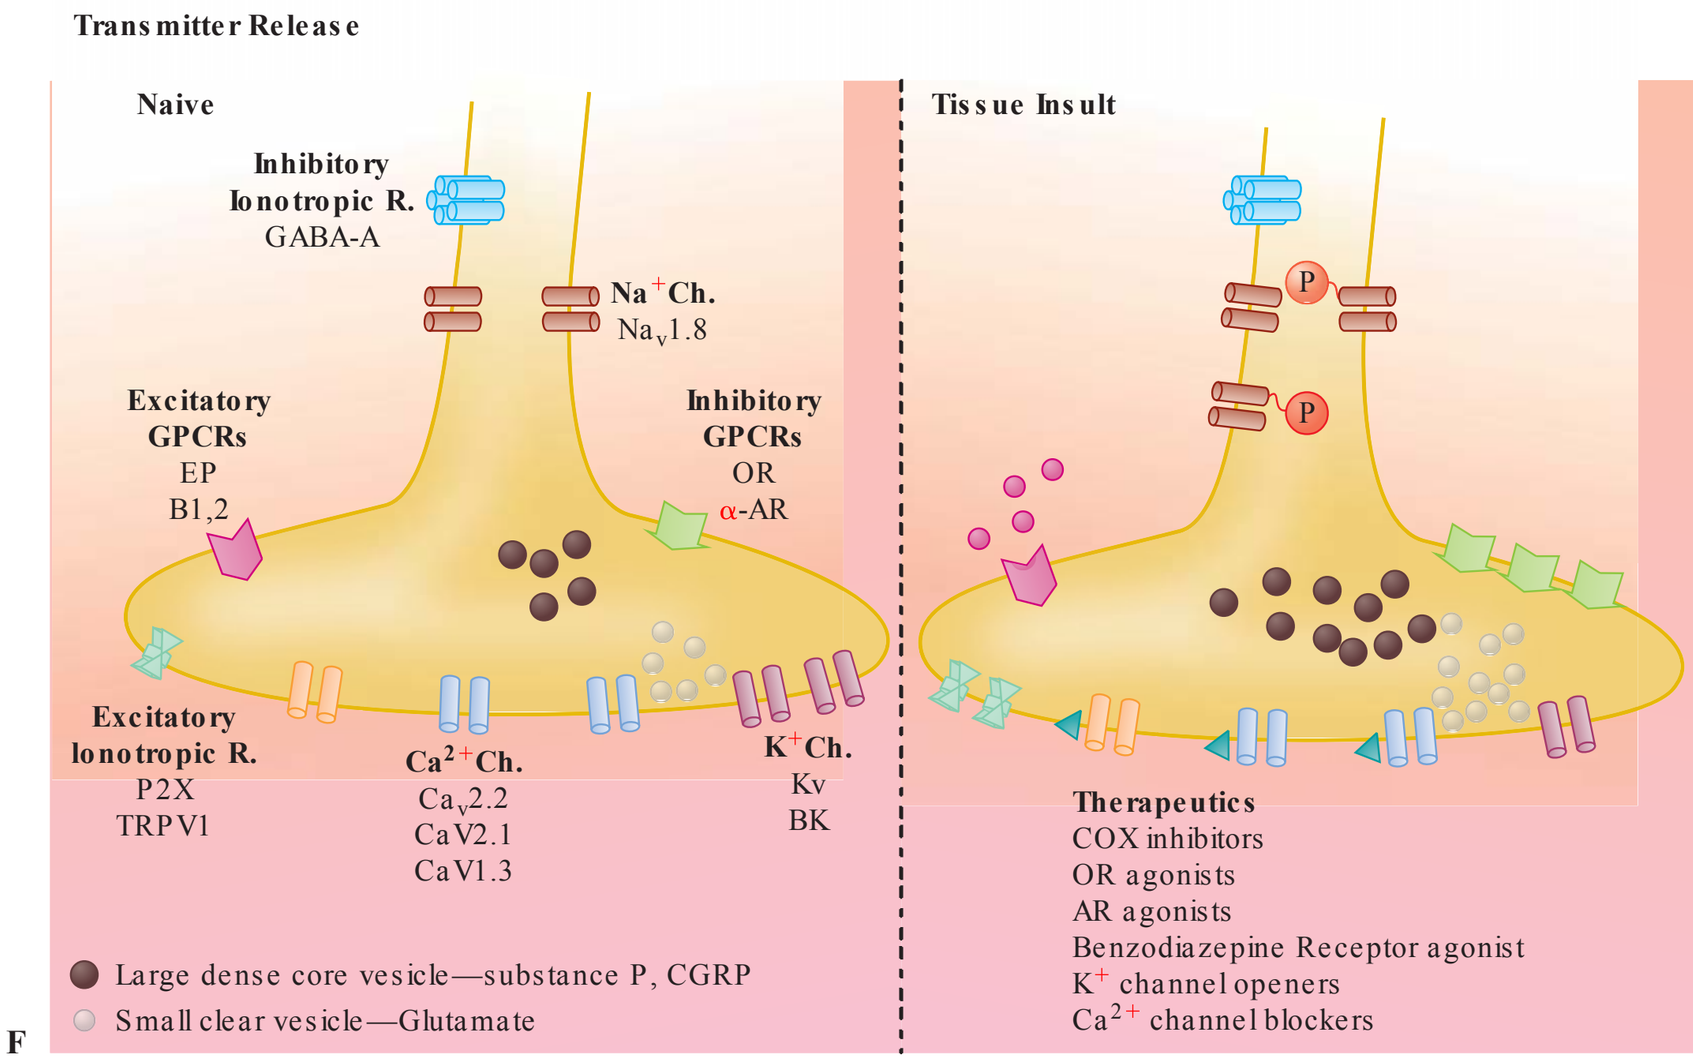


FIGURE 3.1 (*continued*) coupled receptors (GPCRs) responsive to E-type prostaglandins (EP), bradykinin (B) types 1 and 2, and serotonin (5HT) types 1A, 2, and 7. Tyrosine receptor kinases (TRK), responsive to trophic factors such as nerve growth factor (NGF) and artemin, are present as are receptors for cytokines such as TNF-α and interleukin 1-β. Also depicted are transmitters such as ATP stored in epithelial cells. Following tissue insult, there are changes in nociceptive terminals that result in both an increase in sensitivity to noxious stimuli as well as the emergence of membrane depolarization. There are increases in the density of several transducers as well as posttranslational modifications (depicted as phosphorylation, P) that increase channel activity or sensitivity such that the transducers are activated by lower intensity stimuli. These changes are brought about by actions of inflammatory mediators such as ATP, prostaglandin E2, NGF, and TNF-α that can directly depolarize nociceptive terminals, drive posttranslational changes via the activation of second messenger cascades and/or alter the expression of transducers via influencing transcription and/or translation. All of these processes may be facilitated as a result of an increase in the release of mediators from epithelial cells, resident (mast) cells and recruited (macrophages) immune cells. Several therapeutics currently in use or in development act via suppressing the actions of proinflammatory mediators. The specific pattern of changes and mediators depends on many factors, including the type and site of injury, time after injury, previous history of the injured tissue, as well as age and sex, which also influence the relative efficacy of the therapeutic intervention. **C. Spike Intiation**: The appropriate anatomical distribution of ion channels is critical for normal function. A number of ion channels play an important role in determining the threshold for spike initiation and upstroke of the spike. Action potential threshold appears to be critically regulated by K^+ channels, which include voltage-gated K^+ channels (K_V), inward rectifying K^+ channels (K_{IR}), 2-pore K^+ channels (K2P), large-conductance calcium modulated K^+ channels (BK), and small conductance calcium dependent K^+ channels (SK). The nonselective inward rectifying cation channel (HCN) also contributes to action potential threshold. In some cases, the low-threshold calcium channel (CaV3.2) may contribute to action potential threshold, but when present, CaV3.2 appears to play a more prominent role in mediating burst activity. The voltage-gated sodium channel (VGSC) NaV1.9 may also contribute to establishing action potential threshold. Finally, the channels responsible for the upstroke of the action potential include the VGSCs NaV1.7 and NaV1.8. As with transduction, there are a number of changes in ion channels that affect action potential threshold and spike initiation to increase in the excitability of nociceptive afferents in the presence of insult. These changes include a decrease in K^+ channel density and/or current and an increase in CaV3.2, HCN, and NaV channel density and/or activity. These changes are the result of both posttranslational modifications and/or changes in transcription driven by the same inflammatory mediators that influence transduction. Thus, several of the therapeutics listed under transduction may also act by inhibiting changes in channels underlying spike initiation. Other drugs may act via direct inhibition of the ion channels underlying spike initiation (which include local anesthetics, tricyclic antidepressants [TCAs], and several cyclooxygenase inhibitors). K^+ channel openers such as retigabine may also have efficacy in increasing the threshold for spike initiation. **D. Action Potential Propagation**: The ion channels underlying action potential propagation are distinct from those underlying spike initiation. The channel most prominently implicated in action potential propagation is the VGSC NaV1.6. In myelinated axons, NaV1.6 is clustered at nodes of Ranvier, while in unmyelinated axons, the channel is distributed throughout the axon. Following insult, however, the pattern of channel expression can change, including redistribution of VGSCs NaV1.7 and/or NaV1.8 to the cell membrane. The dependence of action potential propagation on VGSCs confers the therapeutic efficacy of sodium channel blocking compounds such as local anesthetics, TCAs, and some COX inhibitors. **E. Ectopic Activity**: As is true for all neurons in the absence of tissue insult, the soma serves as the supply depot for the rest of the neuron, synthesizing and packaging the proteins, transmitters, and lipids that will be used

(*continues*)

F

FIGURE 3.1 (*continued*) throughout the cell. While the soma is capable of generating action potentials and is likely depolarized in response to neural activity in the axons, it is not necessary for action potentials to invade the soma for information to propagate from the periphery to the central nervous system. In nociceptive afferents, the VGSC NaV1.8 can be the primary, if not the only sodium channel in the cell underlying action potential generation. In the presence of nerve injury, however, changes in the soma and/or proximal axon can include an increase in transducer proteins that may make the soma responsive to mechanical, thermal, and chemical stimuli, an increase in sodium channels that may lead to membrane instability (manifesting as oscillatory behavior) and an increase in inflammatory mediators and their receptors. The result of such changes is that the soma and/or proximal axon may become a source of aberrant or ectopic activity. An important implication of this activity is that local administration of therapeutic agents to block activity arising from peripheral terminals may not provide pain relief. Given the source of much of this activity, therapeutic interventions designed to block sodium channels and/or inhibit the actions of inflammatory mediators are predicted to have the greatest efficacy. **F. Transmitter Release**: The release of transmitter at the central terminals of nociceptive afferents is essential for transmission of nociceptive information to the central nervous system. This process is calcium dependent—extracellular calcium enters the central terminal generally via high threshold VGCCs that are activated following invasion of the action potential into the central terminals. N-type channels (CaV2.2) are the most abundant, but P/Q-type (CaV2.1) and L-type (CaV1.3) are also present. CaV2.2 is most readily modulated following activation of inhibitory GPCRs, serving as the primary mechanism for the therapeutic efficacy of intrathecal opioid receptor and alpha adrenergic receptor (α-AR) agonists. Transmitters present in nociceptive afferents are generally packaged in vesicles referred to as small clear vesicles, which generally contain the excitatory amino acid glutamate, and large dense core vesicles, which contain, among other things, neuropeptides such as substance P and calcitonin gene-related peptide (GRP). There are a number of excitatory ionotropic receptors, including P2X3 and TRPV1, that appear to facilitate transmitter release from the central terminals. Inhibition of the central terminal may involve activation of voltage gated (K_V) and calcium modulated (BK) K^+ channels. Under normal conditions, presynaptic ionotropic γ-aminobutyric acid (GABA) receptors (GABA-A) play a major role in mediating presynaptic inhibition of the central terminals of nociceptive afferents. The VGSC that appears to play a major role in enabling spike invasion of the central terminals of nociceptive afferents is NaV1.8. Finally, excitatory GPCRs (e.g., EP and B1,2 receptors) are also present. As with other steps in the process, a number of changes occur in the central terminals of nociceptive afferents after tissue insult that contribute to the transmission of nociceptive information. These include an increase in the alpha2delta1 subunit in VGSCs. This subunit is important for trafficking channels to the membrane and, importantly, is a binding site for gabapentin and pregablin. There is also an increase in neuropeptide expression, the emergence of additional excitatory receptors, modulation of ion channels such as NaV1.8 and a decrease in K^+ currents that facilitate nociceptive signaling. Interestingly, there is a growing body of evidence suggesting that there may be changes in GABA-A receptor signaling as well such that activation of these receptors may become excitatory secondary to changes in the regulation of intracellular chloride. This issue is complicated by the fact that benzodiazepine receptor agonists may have therapeutic efficacy in the presence of tissue insult which appears to involve, at least in part, activation of presynaptic receptors. From the therapeutic perspective, it is important to note that following tissue insult, in particular that associated with inflammation, there may be an increase in the expression of inhibitory receptors, ultimately facilitating the therapeutic efficacy of opioid and adrenergic receptor agonists. Additional therapeutic interventions may also involve inhibitors of VGCCs, K^+ channel openers, and inhibitors to inflammatory mediators.

Whereas mechanotransduction is an intrinsic property of many nociceptors, there is evidence that epithelial cells may also be mechanosensitive.[35] Because these cells may store and release transmitters such as ATP, it has been suggested that afferent activity evoked with mechanical stimulation of peripheral structures such as the bladder,[35] gastrointestinal tract,[36] and skin[37] may be secondary to the transduction event that has occurred in the epithelial cell that subsequently releases a chemical mediator capable of activating nearby nociceptor terminals. The implication of this mechanism from a therapeutic perspective is that it may be possible to attenuate mechanical hypersensitivity in several peripheral tissues with the appropriate antagonist of the responsible chemoreceptors on nociceptive afferents.[38] Consistent with this idea, there is evidence that mechanical hypersensitivity observed in several visceral structures can be attenuated with ATP receptor antagonists.[39]

Aberrant expression of transducers may play a significant role in chronic pain associated with tissue injury. The presence of a functional transducer at a site other than the peripheral terminal may underlie the emergence of ectopic activity and contribute to ongoing or spontaneous pain. Such changes have been most extensively detailed following nerve injury, where, as mentioned above, mechanical sensitivity is detectable in cut axons within hours of injury[33] and may persist in neuromas indefinitely. Similarly, chemosensitivity, particularly to adrenergic agonists, develops at both the cut ends of nociceptive afferents[40] as well as within the ganglia itself,[41] contributing to ectopic activity arising from both the site of injury and from the ganglia. The emergence of ectopic activity arising from sites distant to the site of injury may explain why interventions targeting the site of injury are unsuccessful.

Action Potential Generation

A generator potential at a primary afferent terminal ending is not equivalent to an action potential propagated along that afferent's axon. The generator potential decays over distance from the point of origin as a function of membrane resistance, membrane capacitance, and internal resistance of the nerve terminal and may or may not be propagated beyond the terminal ending. Generally considered stable properties, there is evidence for dynamic remodeling of the terminal arbor of central nervous system neurons[42] which may influence both membrane capacitance and internal resistance; it remains to be determined whether such changes may also impact passive conduction of generator potentials in peripheral terminals. In contrast, a number of ion channels have been identified that may establish resting membrane resistance and therefore the spread of the generator potential within the terminal arbor.[43] This issue is important to nociceptive signaling because action potential initiation does not always occur at the site of stimulus transduction.[44] Consequently, the magnitude of the generator potential at the site of action potential initiation must be greater than or equal to action potential threshold. Thus, at least in some fiber types, it may be possible to block nociceptor signaling, and therefore pain with manipulations such as the local administration of potassium (K^+) channel openers[45,46] that decrease membrane resistance and therefore the spread of the generator potential.

Voltage-gated sodium channels (VGSCs) are responsible for the upstroke of the action potential in virtually all excitable tissue. As their name implies, these channels are gated (opened and closed) by changes in membrane potential. VGSCs are generally composed of an alpha subunit and up to two beta subunits. The alpha subunit is a large molecule (~200 kD) that contains all features necessary for a functional channel including voltage sensor, ion selectivity filter, channel pore, and inactivation gate.[47] Ten alpha subunits have been identified, nine of which form functional channels in heterologous expression systems. The channels encoded by each of these subunits can be distinguished by a combination of pharmacological and biophysical properties. Eight of these nine alpha subunits are present in the nervous system, all eight of which are present in nociceptive afferents.[15] Beta subunits influence channel gating properties as well as trafficking and localization in the plasma membrane.[48] Four beta subunits have been identified, at least three of which are present in nociceptive afferents.[15]

The VGSC alpha subunit primarily responsible for action potential initiation in the majority of nociceptors is NaV1.8. This subunit is unique in several ways. First, it is normally only expressed in primary afferents[49,50] where it is primarily expressed in nociceptors.[51] This unique pattern of distribution, in combination with its primary function in spike initiation, makes it an ideal target for novel therapeutics.[52] Second, NaV1.8 has a relatively high threshold for activation. Whereas many other VGSCs begin to activate at membrane potentials between −50 and −40 mV, a depolarization to −30 mV or greater is necessary to activate NaV1.8.[53] This feature may explain, at least in part, why greater intensity stimuli are generally needed for nociceptor activation. Third, NaV1.8 is relatively resistant to steady-state inactivation, a voltage-dependent process whereby channels residing in a closed or resting state transition to an inactive state before they ever get a chance to open. Recovery from the inactivated state requires membrane hyperpolarization; thus, inactivated channels cannot contribute to the upstroke of the action potential. Even a small sustained depolarization to −50 mV can inactivate virtually all other VGSCs. However, NaV1.8 is still fully available for activation at this membrane potential.[53] Fourth, NaV1.8 recovers from inactivation rapidly.[54] These last two features enable the channel to underlie sustained activity in the face of a persistent depolarization that might be observed in the presence of inflammatory mediators. Fifth, NaV1.8 is resistant to cooling-induced inactivation.[55] Other VGSCs are completely inactivated at temperature at or below 18° C. However, NaV1.8 is still functional at temperatures down to 4° C, enabling the burning pain associated with noxious cold stimuli. Sixth, in contrast to all but one other VGSC alpha subunit (NaV1.9), NaV1.8 is resistant to tetrodotoxin (TTX), and is therefore referred to as a TTX-resistant channel.

Whereas NaV1.8 is critical for action potential initiation in nociceptors, in many of these afferents this alpha subunit appears to work in concert with another VGSC alpha subunit, NaV1.7.[56] The NaV1.7 subunit has unique features enabling it to play a significant role in spike initiation.[57] That this channel plays a critical role in nociceptor activity is highlighted by the recent discovery of individuals possessing both gain-of-function and loss-of-function point mutations in this subunit. Strikingly, two distinct pain syndromes—primary erythermalgia (PE) and paroxysmal extreme pain disorder (PEPD)—reveal the specific impact of gain-of-function mutations.[58] PE is associated with burning pain in the hands and feet, and PEPD is associated with pain in the rectum at early stages, ultimately progressing to trigeminal structures including the eye and jaw. The unique distribution of these pain syndromes, in light of the widespread distribution of NaV1.7 in the peripheral nervous system as well as neuroendocrine tissues, highlights the importance of other channels in sculpting the response properties of sensory neurons. Furthermore, in contrast to the impact of the gain-of-function mutations, loss-of-function mutations that result in nonfunctional channels are associated with a complete insensitivity to pain.[59]

Recent evidence suggests that low voltage activated, or T-type, calcium channels may also contribute to spike initiation in the periphery.[60] Whereas there is compelling evidence that these channels are present in high density in low threshold D-hair affer-

ents,[61] there is also evidence that they may be present in a subpopulation of nociceptors as well.[62] The biophysical properties of these channels enable them to play a particularly important role in mediating bursting activity, as the channels underlie a sustained membrane depolarization after a single action potential that provides the driving force for the initiation of subsequent action potentials.[63] This feature has led some to speculate that selective T-Type channel blockers may be particularly effective for treating paroxysmal pain[62] such as that associated with trigeminal neuralgia.

Whereas the focus on NaV1.8 has been on its role in action potential initiation in the periphery, there is also evidence that the channels are present and functional at central nociceptor terminals.[64,65] At the central terminal, the channel appears to facilitate the spread of the invading action potential throughout the terminal arbor and consequently the release of transmitter from the primary afferent. There is also a growing body of evidence suggesting that action potentials may also be initiated at the central terminals of nociceptors, where they are conducted antidromically to the periphery.[66] This activity, referred to as the dorsal root reflex, appears to play a significant role in the neurogenic inflammation that develops following tissue injury.

Action Potential Propagation

Whereas NaV1.8 and NaV1.7 underlie action potential generation and even propagation over the first 5–10 mm of peripheral axon, a different set of VGSCs underlies action potential propagation into the central nervous system in the absence of tissue injury. NaV1.6 is the subunit primarily responsible for propagation in both myelinated and unmyelinated axons of both nociceptive and non-nociceptive afferents,[67] although other subunits may contribute as well. Unfortunately, the distribution of NaV1.6 in the peripheral nervous system in combination with its widespread expression in the central nervous system precludes selective block of propagation in nociceptors via a NaV1.6 specific mechanism. Nevertheless, block of these channels with local anesthetics and/or TTX remains an effective means of blocking input into the central nervous system.

Transmitter Release

Voltage-gated calcium channels (VGCCs) are primarily responsible for the initial influx of calcium necessary for initiation of machinery underlying the release of neurotransmitters. Like VGSCs, these channels consist of a large alpha subunit that contains all of the features necessary for a functional channel. Ten alpha subunits have been identified, encoding channels that are commonly defined by their threshold for activation or pharmacological properties.[68] T-type channels (CaV3.1–3.3), as mentioned above, have a low threshold for activation while all others have a high threshold for activation. The high threshold channels are further subdivided based on their sensitivity to specific channel blockers: L-type channels (CaV1.1–1.4) are blocked by dihydropyridines such as nimodipine, N-type channels (CaV2.2) are blocked by the snail toxin ω-conotoxin GVIA, P/Q-type channels (CaV2.1) are blocked by the spider toxin ω-agatoxin IVA, and R-type channels (CaV2.3) are blocked by the spider toxin SNX-482. In contrast to VGSCs, VGCCs are not effectively targeted to the plasma membrane in the absence of the alpha2delta-subunit complex.[69] A single beta subunit also appears to be important for efficient gating.[70] All VGCC subtypes are present in nociceptors. And whereas there is evidence that all high-threshold calcium channels may contribute to transmitter release, N-type channels appear to play a dominant role in the release of transmitter from nociceptors.[71]

The dominant role N-type channels play in mediating transmitter release from nociceptive afferent terminals makes them an ideal target for both endogenous and exogenous analgesics. Opioid and adrenergic receptor agonists act through inhibitory G-protein coupled receptors which enable inhibition of VGCCs via two major intracellular pathways. The first is a rapid, membrane delimited pathway involving G-protein βγ-subunit displacement of the VGCC β-subunit, resulting in a "sleepy" or "unwilling" channel that requires a larger membrane depolarization for channel opening.[70] The second pathway involves more traditional second messenger-kinase dependent signaling with a slower onset and offset.[72] Interestingly, neither pathway results in complete VGCC block, yet both result in a dramatic inhibition of transmitter release. This amplification effect reflects the fact that there is considerable cooperativity of calcium in mediating vesicle fusion to the cell membrane that is necessary for transmitter release: 4–5 calcium ions are needed to trigger vesicle fusion.[73] This amplification effect is also likely to facilitate the use of relatively low concentrations of the N-type channel blocker SNX-111 (ziconotide), enabling the block of transmitter release from nociceptive afferent terminals in the superficial dorsal horn while minimizing side effects associated with block of channels at more distant sites. Finally, while it remains to be determined exactly how gabapentin and pregabalin block high VGCC, the fact that it binds to the α2δ-subunit complex critical for membrane targeting of the alpha subunit puts the compound in a good position to interfere with ion flux through the channel.[74]

NOCICEPTOR SENSITIZATION

Sensitization is a characterizing feature of nociceptors; non-nociceptors do not sensitize following tissue insult. Sensitization represents an increase in nociceptor excitability, which is expressed and defined as an increase in response to a noxious stimulus. Sensitization is also typically accompanied by a reduction in the threshold for activation and occasionally by the development of ongoing, spontaneous activity. Nociceptor sensitization is the cause of primary hyperalgesia (i.e., increased pain produced by stimulation at the site of tissue insult) and is important because nociceptor sensitization is the trigger for initiation of an increase in excitability of central neurons in the nociceptive pathway, an event termed "central sensitization."

An increase in nociceptor excitability is a reflection of changes in the behavior of nociceptor voltage- and/or ligand-gated ion channels produced by actions of endogenous substances either released or synthesized at the site of tissue insult or attracted there. Endogenous substances considered classically to contribute to sensitization include products of arachidonic acid metabolism (e.g., prostaglandin E2), histamine, serotonin, protons, and ATP, but the list has grown quite extensively and now also includes cytokines, chemokines, growth factors, peptides, etc., some of which are released from immune competent cells attracted to the site of insult (e.g., macrophages), released from nearby cells (e.g., mast cells), or from nociceptor (and other) nerve terminals (e.g., peptides). Interestingly, despite the variety of mediators capable of producing nociceptor sensitization, several appear to play particularly important roles. This list includes prostanoids, as evidenced by the antihyperalgesic efficacy of nonsteriodal anti-inflammatory drugs (NSAIDs) that act via inhibition of cyclooxygenase and thus prostanoid synthesis. More recently, the importance of tumor necrosis factor alpha (TNF-α) in chronic inflammatory conditions has been highlighted by the antinociceptive efficacy of compounds such as entanercept, which are designed to absorb TNF-α released at sites of inflammation. Finally, nerve growth factor appears to play a major role in orchestrating a variety of signaling cascades necessary for an inflammatory response and therefore has also been targeted with antibody based strategies.[75–78]

The mechanisms that trigger changes in nociceptor excitability are not fully known. A growing body of evidence suggests that despite what appears to be a bewildering assortment of mediators and membrane receptors, there are only a few common intracellular pathways that are ultimately accessed and influenced by what appear to be disparate extracellular or membrane mechanisms that initiate common intracellular pathways. For example, both prostaglandins and bradykinin, which are among the most extensively studied inflammatory mediators, act at G-protein coupled receptors. Two major G-protein dependent pathways have been implicated. One involves a stimulatory G-protein, Gs, which drives activation of adenylate cyclase, resulting in an increase in cyclic adenosine monophosphate and the activation of protein kinase A (PKA).[79,80] The other involves a Gq-dependent pathway, resulting in the activation of phospholipase C, the liberation of diacyl glycerol (DAG) and IP3, and the subsequent activation of protein kinase C (PKC).[81,82] The PKC-epsilon isoform appears to play a particularly important role in nociceptor sensitization. Other mediators that appear to play important roles in nociceptor sensitization, such as TNF-α and interleukin 1β, utilize a mitogen-activated protein kinase (MAPK)-dependent pathway ultimately resulting in the activation of p38.[83] Channels underlying transduction and spike initiation, in particular TRPV1 and NaV1.8, respectively, appear to be final common targets for this diverse array of mediators and second messenger pathways.[84] Phosphorylation of specific residues on the channel or associated proteins results in increases in channel density and/or increases in channel function.

Still other mediators directly activate ion channels. For example, protons (which increase in concentration during inflammation) act at TRPV1 and acid-sensing ion channels (ASICs). ASIC-3 is important to pain associated with ischemia, such as occurs during angina, and deep muscle pain where protons and lactic acid accumulate. In contrast, ATP and its metabolites act at ionotropic P2X and metabotropic P2Y receptors to modulate nociceptor excitability.

Types of Nociceptors

To this point, we have discussed nociceptors only in a general context, but there are in fact many types of nociceptors, our knowledge of which has been advanced by human psychophysical studies while recording from afferent fibers (Box 3-1). In human skin, for example, there exist nociceptors that respond only to mechanical, only to cold thermal, or only to hot thermal stimuli as well as those that are insensitive to both mechanical and heat stimuli (mechanically insensitive or sleeping nociceptors). The most abundant nociceptor is the polymodal nociceptor, which responds to mechanical, thermal, and chemical stimuli. In general, nociceptors that innervate skin have the broadest range of modality-selectivity whereas nociceptors innervating deeper structures tend to be less modality-selective and more polymodal in character. For example, mechanical sensitivity is a prominent feature of visceral and joint nociceptors because stimuli adequate for their activation include hollow organ distension and over-rotation, respectively. Many of these nociceptors also respond to chemical and/or thermal stimuli as well, although the functional significance of thermal sensitivity in deep tissues in uncertain. An important characteristic of polymodal nociceptors, whether the modalities of stimulation to which they respond is two or all three, is that when sensitized, (e.g., by an inflammatory insult) responses to the other modality(ies) of stimuli to which it responds are all increased. That is, it is not only the mechanosensi-

BOX 3.1

MICRONEUROGRAPHY

The development of a method to record from human nerve fibers in situ,[85] termed microneurography, provided a unparalleled opportunity to expand our knowledge about peripheral sensory receptors, including nociceptors. The method involves percutaneous insertion of the tip of a sharp, insulated metal microelectrode into a nerve (e.g., peroneal or radial nerve) and the application of search stimuli to sites distal to the electrode. In earlier work, mechanical search stimuli (e.g., von Frey filaments) were used and, accordingly, only mechanosensitive afferents were studied. An electrical search stimulus (surface electrode), however, has become favored because the electrical stimulus identifies afferent fibers independent of sensitivity to natural stimulation. After an afferent fiber is isolated, the innervation territory can be drawn on the skin and the adequate, natural stimulus/stimuli determined.

Because microneurography can be easily coupled with a psychophysical approach, human subjects are able to describe stimulus-produced experiences (e.g., pain) while recording from single afferent fibers. Microneurography has also been expanded to include intraneural electrical stimulation of the fiber through the recording electrode, providing additional insight into the qualities of sensation produced, for example, by low- and high-frequency stimulation in addition to qualities associated with natural stimulation. Microneurography has confirmed in psychophysical experiments sensations associated with activation of rapidly adapting (flutter, vibration) and slowly adapting (pressure) cutaneous mechanoreceptors, Aδ-mechanonociceptors ($AM_{[mechano]}$; sharp pain), C-polymodal nociceptors ($CM_{[mechano]}H_{[heat]}$; dull, burning [heat] pain), and group IV muscle nociceptors (cramping pain).

Electrical search strategies have revealed a wider range of nociceptors, including[86]: A-mechanoheat (AMH), which have similar heat thresholds as CMH (C-polymodal) fibers and also typically respond to chemical stimuli; C-mechano-nociceptors (CM), C-heat (CH); C-mechano- and heat-insensitive (CM_iH_i, or sleeping nociceptors); and C-mechano-insensitive-histamine responsive (CM_iHis+, or itch fibers[87];). Microneurography has also been extended to psychophysical study of pathological pain states in humans. In a study of patients suffering from erythromelalgia, a condition characterized by painful, red, and hot extremities, a proportion of CM_iH_i fibers were found to be spontaneously active or sensitized to mechanical stimuli. Because CM_iH_i fibers also mediate the axon flare reflex, their hyperexcitability was considered to contribute to the patients' ongoing pain and tenderness as well as the redness and warming in this pain syndrome. In patients with painful peripheral neuropathy, Ochoa et al.[88] reported hyperexcitability in CMH and CM_iH_i fibers. Signs of hyperexcitability included reduced thresholds to mechanical and heat stimuli, spontaneous activity, and increased responses to stimulation. In diabetic neuropathic pain patients, Ørstavik et al.[89] found that the ratio of CMH to CM_iH_i fibers was reduced by about 50%, apparently due to loss of mechanical and heat responsiveness in CMH fibers.

These and future studies will help to understand which nociceptors (and perhaps non-nociceptors) in which conditions contribute to spontaneous, ongoing pain as well as stimulus-evoked pain, and what therapeutic strategies are most effective.

tive modality, for example, that becomes sensitized, but other modalities to which it responds are sensitized as well.

With respect to mechanosensitivity, nociceptors at the opposite extremes of sensitivity are most interesting. Nociceptors with low mechanical thresholds for response and those with very high mechanical thresholds for response (i.e., sleeping nociceptors) are both clinically important. Mechanosensitive sensory neurons with low thresholds for response have long been classed as non-nociceptors because it was considered that nociceptors had to have response thresholds in the noxious range. Some mechanosensitive skin, joint, and many visceral sensory neurons have low thresholds for response (i.e., in the non-noxious range), but possess characteristics that suggest an important role in pain. First, they encode stimulus intensity well into the noxious range and, moreover, typically give greater responses to all intensities of stimulation than do nociceptors with high mechanical thresholds for response. Second, they sensitize after tissue insult. The mechanically-insensitive, sleeping nociceptors, on the other hand, normally provide no information to the central nervous system but after tissue insult become spontaneously active and mechanosensitive.

Clinical Implications of Nociceptor Function

As researchers have begun to explore the basis for chronic pain syndromes generally associated with specific body regions and/or organs (e.g., temporomandibular joint disorder [TMJD], inflammatory bowel disease [IBD], irritable bowel syndrome [IBS] or painful bladder syndrome [formerly interstitial cystitis, IC]), a number of common themes have emerged that are likely to impact future treatment approaches. First, specific mechanisms underlying injury-induced sensitization of nociceptors vary as a function of target of innervation. For example, inflammation-induced sensitization of masseter muscle afferents appears to reflect a decrease in a specific subpopulation of voltage-gated potassium channels.[90] The same channels do not appear to contribute to the sensitization of TMJ afferents.[91] Similarly, inflammation-induced increases in the excitability of bladder sensory neurons appear to reflect one pattern of changes in voltage-gated[92] or ligand-gated[93] ion channels whereas the inflammation-induced increase in sensory neurons innervating the stomach,[94–96] ileum,[97,98] or colon[99] reflect other patterns. While tissue-specific patterns of inflammation may contribute to these differences between subpopulations of afferents, differences persist when the response to inflammatory mediators is studied in vitro.[100] The implication of these observations is that it may be possible, if not necessary, to treat pain arising from a specific structure with a specific intervention. Second, specific mechanisms underlying insult-induced sensitization of nociceptors also varies as a function of the type of insult. For example, acute phosphorylation-dependent modulation of the VGSC NaV1.8[101] results in an increase in current which contributes to an inflammation-induced increase in nociceptor excitability.[102] In contrast, following traumatic nerve injury, redistribution of NaV1.8 to the axons of uninjured afferents appears to be necessary for the expression of mechanical hypersensitivity associated with nerve injury.[103] The dynamic allodynia that often develops after nerve injury, however, likely represents more than only a redistribution of NaV1.8 (Box 3-2). With respect to the viscera, because each organ receives innervation from two nerves, the effect of organ insult can be different in the two groups of sensory neurons that innervate the organ.[93] These observations underscore the importance of developing diagnostic criteria that enable identification of the factors primarily responsible for ongoing pain. Third, the history of the nociceptor influences the response to subsequent challenge. For example, in naïve tissue, peripheral injection of prostaglandin E2 produces a PKA-dependent sensitization of nociceptors that lasts approximately 90 minutes, whereas the same manipulation in previously inflamed tissue results in a PKC-dependent sensitization that lasts for more than 24 hours.[82] This "memory" of a previous insult lasts for at least 21 days in the adult. Furthermore, there is evidence of a developmental window within which injury may produce permanent changes in nociceptors.[104] With the development of more specific therapeutic tools, patient history may become a critical factor in the identification of the most appropriate intervention. Fourth, there is evidence for sex differences in both the excitability of different groups of nociceptors[105] as well as the response to tissue injury.[106] These differences appear to be mediated, at least in part, through the actions of gonadal hormones and may contribute to sex differences in the manifestation of a number of chronic pain syndromes. Finally, there is recent evidence for age-dependent changes in nociceptor function.[107] With the aging of society, this particular issue in is need of further investigation.

As indicated above, the consequences of tissue insult are not limited only to changes in the excitability of nociceptors and the awakening of sleeping nociceptors. Because sensitization leads to an increased response to noxious stimuli and a decrease in response threshold, previously non-noxious intensities of stimulation also are now able to activate nociceptors. In addition, spontaneous activity may develop. In the aggregate, central nervous system input from sensitized nociceptors, awakened sleeping nociceptors, and spontaneously active nociceptors is significantly increased. For example, approximately 15% of human cutaneous C-fibers are sleeping nociceptors,[86] comprising significant new input to the central nervous system if awakened. Consequently,

BOX 3.2

AFFERENT CONTRIBUTIONS TO NEUROPATHIC PAIN AND ALLODYNIA

One of the most striking positive symptoms of neuropathic pain is dynamic mechanical allodynia, a term used to describe pain resulting from light tactile stimuli that would never be considered noxious in the absence of nervous system injury. This phenomenon can be recapitulated with a subcutaneous injection of capsaicin.[108] Data from detailed psychophysical analysis in combination with microneurography[109] and dorsal horn recording in animal models[110] all suggest that dynamic mechanical allodynia reflects activity in low-threshold afferents that signal pain as a result of changes in the central nervous system. The exact nature of these changes, generally referred to as central sensitization, is still debated,[111,112] but it is clear that they depend on activity in nociceptive afferents. Another possibility, however, is that low threshold afferents undergo a phenotypic switch such that they begin to transmit information to the central nervous system as if they were nociceptive afferents. Consistent with this possibility, there is evidence following peripheral nerve injury that a subpopulation of putative non-nociceptive afferents begins to express the neuropeptide, substance P,[113] although this change does not appear to be necessary for the expression of allodynia.[114] Evidence of a third possibility, which would involve sprouting of non-nociceptive afferents into more superficial layers of the dorsal horn to enable low threshold drive of nociceptive dorsal horn neurons,[115] remains largely unsubstantiated.[116–118]

the amount of neurotransmitters (as well as perhaps their relative proportions) released onto central neurons is increased, which in turn alters the excitability of central neurons. The increase in excitability of central neurons is manifest as an increase in the size of the cutaneous receptive field (i.e., secondary hyperalgesia) or area of tenderness referred from deep structures, particularly the viscera. Although the principal focus of study of mechanisms of central sensitization has been the spinal cord, it should be appreciated that nociceptor-driven changes in central excitability extend throughout the central nervous system.

CHAPTER 4 ■ SUBSTRATES OF SPINAL CORD NOCICEPTIVE PROCESSING

TIMOTHY NESS AND ALAN RANDICH

INTRODUCTION

The spinal cord and brainstem nuclei are home to second order neurons, the first step of central nervous system (CNS) processing. The first site of sensory integration and modulation, second order neurons are more than a simple relay and any plan for the treatment of nociception must understand the critical role these neurons play in the formation of painful sensation. The second order neuron converts afferent input from multiple sites and often multiple modalities into an encoded message that is sent to other parts of the CNS. Those other parts of the CNS, in turn, modify the second order neuron through both excitatory and inhibitory mechanisms. These modifying influences are the subject of the next chapter whereas the present chapter will focus on the neuroanatomical and neurochemical characteristics of these spinal substrates.

Although it seems like a simple statement that pain-related second order neurons are the neurons which receive primary afferent input related to tissue damage (nociceptors), it must be accepted that this statement may or may not be wholly true since in certain pathological states pain can be evoked by non–tissue-damaging stimuli (allodynia). It is unfortunate that there has been a tendency in pain-related research to turn common observations into over-generalizations and so an attempt will be made in this chapter to be precise when possible. Sometimes ''assumptions'' related to neuronal substrates of sensation have been necessarily used as ''premises'' on which to build scientific logic. The primary premise on which this chapter is based is that all nociceptive second order neurons receive nociceptive primary afferent input as *one* of their excitatory modalities. If one can accept that premise, then one can identify where the neurons receiving such input are located and can further identify where these neurons send the information.

DEFINING NOCICEPTIVE SYSTEMS

Models of Pain Processing

Pain is both a sensation and responses to that sensation. The sensory component of pain is described in terms of tissue damage (e.g., cutting, burning, rending) even when tissue damage is not occurring and so the sensation of pain is defined as nociception. The sensory systems of our body which encode for nociception can be modeled in two main ways: (1) as a system which is specific for pain (Specificity Theory) or (2) as a system that requires a pattern of neuronal activation to occur for the experience of pain to be generated (Pattern Theory). The simplest and oldest of the pattern theories is that which suggests pain is due to high intensities of input that is independent of modality (Intensity Theory). Each of these theories (or the multiple variants thereof) has prominent proponents who can make persuasive arguments that focus on subsets of data that support their particular view. Each knowledgeable person must derive their own model system which is ideally based on characterized human phenomena and which must clearly go beyond simple models.

As is apparent from the preceding chapter, primary afferent neurons with sensory endings have been characterized using electrophysiological and immunohistochemical methods. A subset of these primary afferents with sensory endings in cutaneous tissues are only activated by (and so *specific* for) pain-producing stimuli. Although these afferents may be polymodal (i.e., encode for multiple different stimuli), the stimuli which excite these primary afferents have in common the potential for producing tissue damage. They have therefore been defined as nociceptors. Primary afferent nociceptors are thinly myelinated or nonmyelinated and so fall into the Aδ- and C-fiber classes. Human psychophysical data support that when Aδ- and/or C-fiber function is disrupted by ischemia or pharmacological agents, then cutaneous sensations associated with immediate (first) or briefly delayed (second) pains are similarly disrupted. Unfortunately (for sake of easy logic), there are also many primary afferents that do not encode for tissue-damaging stimuli (e.g., ''warm'' receptors) but which are also of the Aδ- and C-fiber classes. Hence, it is a flawed logic that interprets all Aδ- and C-fiber–related input to second order neurons as nociceptive. Existent literature constrains further definition of specific nociceptor neurochemical and localization characteristics except on an anecdotal (single unit) basis. With that caveat, there are basic patterns that appear common to most Aδ- and C-fibers and generalizations related to these fiber groups have some validity as being representative of nociceptor localization and neurochemical content.

Methods of Neuronal Characterization

To definitively describe the structure and function of CNS structures is a daunting task. Standard histological, ultrastructural, and immunohistochemical methods used to examine CNS structure have allowed for precise definition of axons, dendrites, and neurotransmitter content but, unfortunately, they do not allow for the precise definition of function. Studies of neuronal function typically utilize electrophysiological techniques to measure the real-time electrochemical activity of single neuronal units (e.g., action potentials) which may be evoked by multiple manipulations. These neurophysiological measures utilize electrodes placed either extracellularly or intracellularly. When the former technique is utilized, correlative anatomic localization is possible but little more. Electrophysiological techniques such as retrograde activation of axonal extensions can define some of the neuronal anatomy, but true morphology is only certain with the intracellular injection of a dye. Immunohistochemical characterization of intracellularly labeled neurons is methodologically feasible and so it is possible to quantitatively define sensory elements. However, such studies are sufficiently tedious and subject to interpretive concerns related to sampling error and preparation effects (i.e., anesthesia) that, to date, have only been performed at a rudimentary level. A compromise microscopic analysis technique is that which uses c-*fos* gene induction in response to neu-

ronal activation to functionally identify neurons excited by a tissue-damaging stimulus. A proto-oncogene, c-*fos*, is activated after potentially tissue-damaging stimuli are applied to most tissues. The expressed product, Fos protein, is immunohistochemically identifiable within hours of stimulation. As a consequence, mapping of gene induction or Fos protein in the nucleus of activated neurons can be used to functionally define these neurons as "nociceptive."[1] Labelled neurons can then be co-labelled with antibodies against neurotransmitters or important cell proteins or specific histological stains to further characterize the neurons. Analgesic pharmacological manipulations such as systemic morphine reduce both the total number of labeled neurons and the total Fos content of the spinal cord following a noxious stimulus. Even newer technologies have been able to identify a changed form of receptors following neuronal activation by noxious stimuli. For example, the internalization of neurokinin (NK) 1 receptors following activation by substance P[2] or the phosphorylation of glutamate receptor subtypes[3] have been used as surrogates for neuronal excitation. Macroscopic examination of CNS activation sites using magnetic resonance imaging technologies have allowed confirmation of microscopic techniques and further demonstrated the functional complexity of spinal and supraspinal connections. At a microscopic level, "tracer" dyes which are taken up by the terminal endings of axons of neurons and transported back to the neurons' cell bodies allow for a histological identification of axonal projections of spinal neurons that is dependent on the site of dye injections (e.g., spinothalamic neurons are back-labelled to the spinal cord by injections in the thalamus). Such labeling techniques, when coupled together with functional techniques, have made it possible to construct a quantitative but nonspecific "global" neuroanatomic view of spinal cord nociceptive processing that appears to agree with anecdotal definitive evidence generated by single-unit studies.

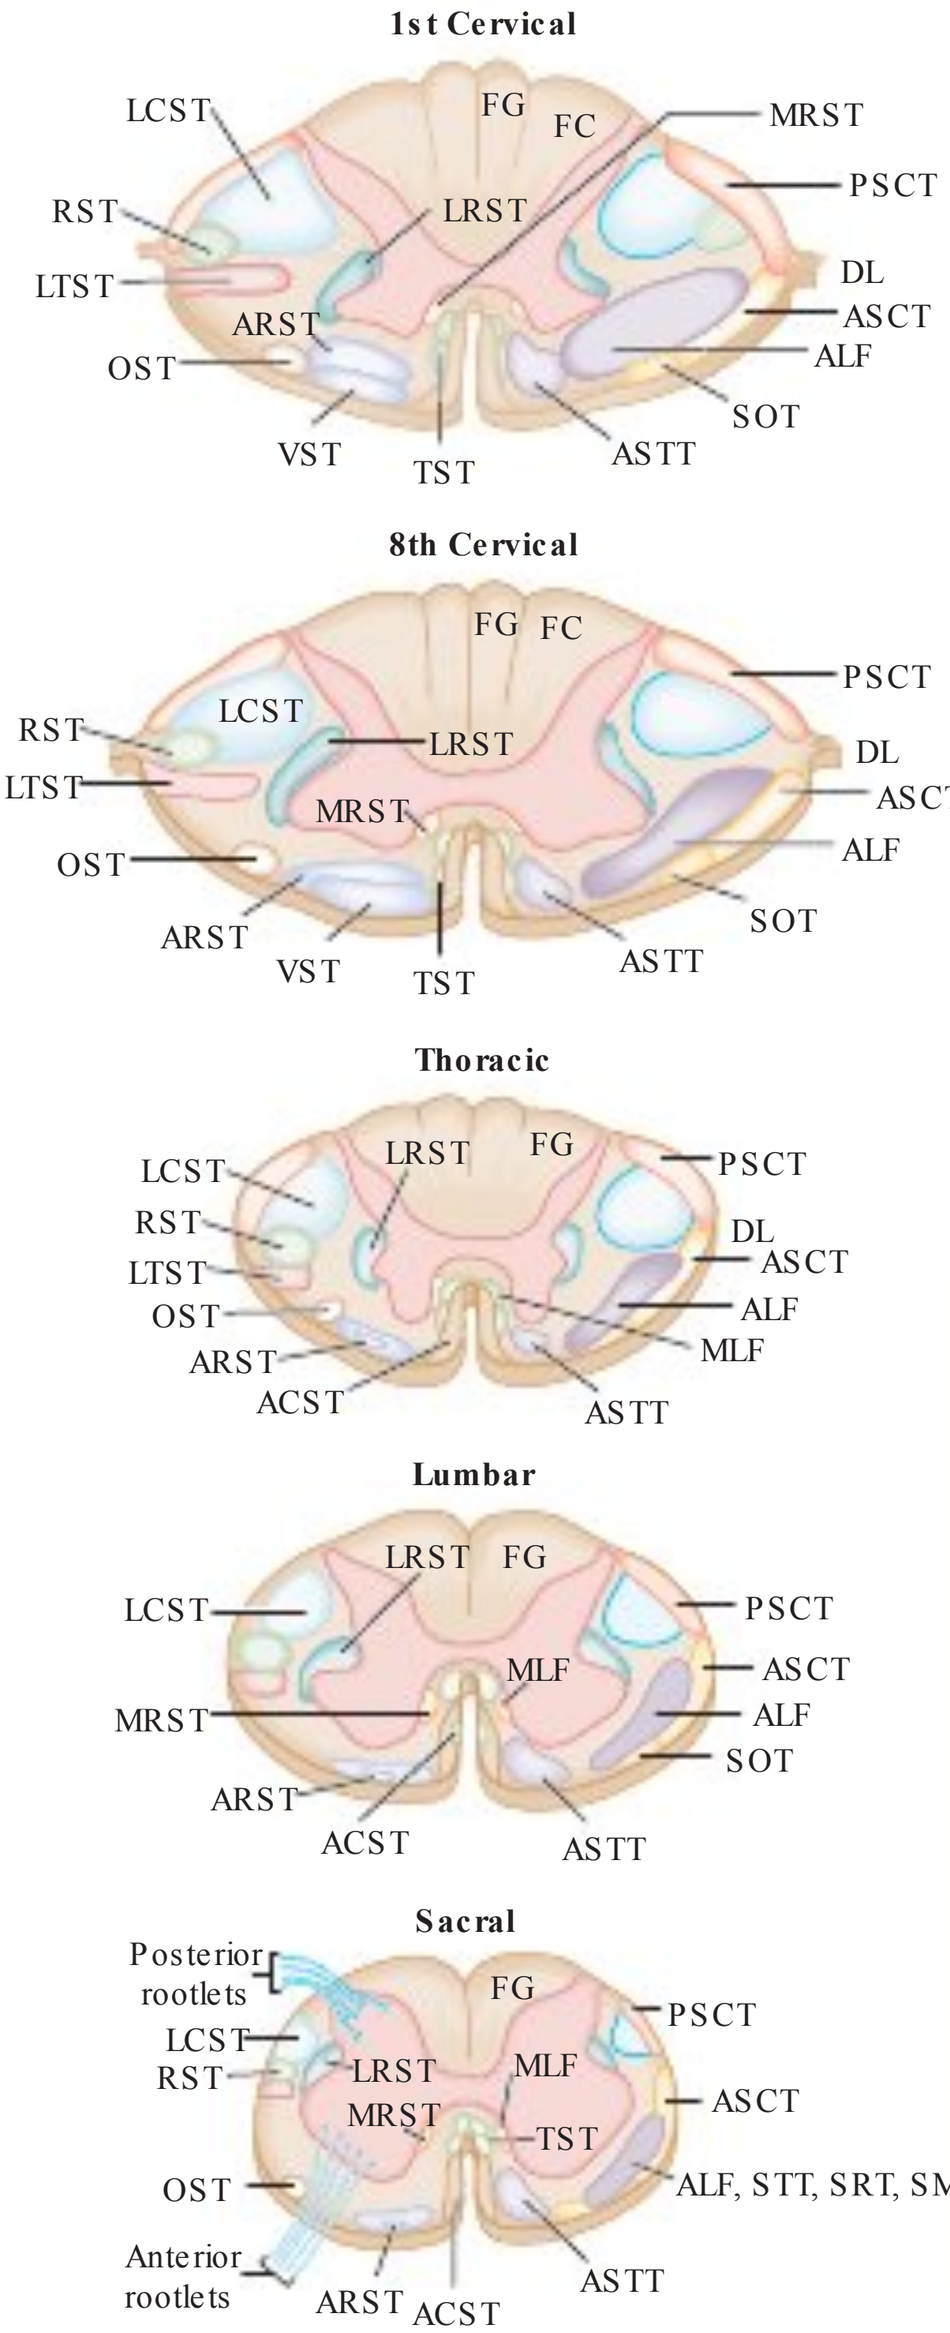
Defining Nociceptive Second Order Neurons

Strict proponents of Specificity Theory state that all discussion related to pain should only involve CNS neurons excited *exclusively* by primary afferent nociceptors. Such specific second order neurons are a small but obviously important minority of the total sample of spinal neurons receiving input from primary afferent nociceptors. One can also argue that the presence of primary afferent neurons with specificity for pain-producing stimuli does not necessitate that the second order neurons responsible for pain sensation have a similar specificity. For purposes of the present discussion, the primary premise of the rest of this chapter is that such excitatory input is a *necessary* requirement of pain-related second order neurons, but it is notable that most second order neurons receiving such input receive other types of sensory input. Excitation of second order neurons may come from primary afferent pathways or from segmental (interneurons), propriospinal (nonsegmental intraspinal), and supraspinal sources. Inhibition arises from the same CNS sources. Inhibition can promote neuronal specificity by selectively reducing responsiveness to nonnociceptive inputs. It is for this reason that proponents of Pattern Theory argue that all second order neurons receiving nociceptive inputs should be considered as candidates for inclusion in pain-processing pathways.

Development of Sensory Systems

The embryological development of the nervous system suggests reasons that differences can exist between peripheral and central phenomena since excitatory systems develop before inhibitory systems. The edges of the neural plate that come together to form the neural tube split off to become the migratory cells of the neural crest. These cells spread to form the sensory components of the peripheral nervous system. At a spinal cord level, substances from the ventrally located notochord induce the formation of motoneurons with axonal extensions extending to the periphery. The dorsal aspect of the spinal cord, lacking effects of the notochord, forms short connections (local connectivity) or develops axonal projections attracted to distant spinal cord and/or brainstem sites. Sensory structures that develop from the neural crest send axonal projections both to the periphery as well as into the dorsal aspect of the spinal cord and contain neurotransmitters that are predominantly excitatory. At birth, sensory systems have very little inhibitory connectivity. This changes during development until inhibitory connections become the predominant form of CNS communication.

In humans, the precise timing of both excitatory and inhibitory system maturation is not fully known, but based on experiments in nonhuman animals these systems appear highly plastic with cell death processes as important as cell growth processes in relation to the final product.[4] Specific transcriptional factor expression has been used to track neuronal subgroup development and has demonstrated a profound role for pathological modification of nociceptive circuitry.[5] The general phenomenon of use-dependent growth (or preservation) appears to hold in multiple sensory systems ranging from taste to vision with the nociceptive systems notwithstanding. Ruda and colleagues[6] have demonstrated that injury during critical periods of development, such as the neonatal period, can have profound effects on the subsequent development of nociceptive systems. In humans, critical periods of neuronal outgrowth and myelination occur in childhood, during puberty, and following events that injure nervous system structures.



TARGETS OF PRIMARY AFFERENT INPUT

Gross Anatomy of the Spinal Cord

The spinal cord is segregated into areas that, on gross examination, appear as white and grey matter, and which consist of predominantly myelinated nerve fiber tracts and cell bodies, respectively. Wrapped in protective pial, arachnoid, and dural meninges, the spinal cord is continually being penetrated by centrally directed axons of primary afferent neurons whose cell bodies reside within the neighboring dorsal root ganglia. These axons enter as the dorsal roots and may traverse several spinal segments rostrally or caudally in the dorsolaterally located Lissauer's tract before entering the grey matter for synaptic contact. The spinal cord white matter is divided into multiple subdivisions with component "tracts" consisting of ascending or descending axonal fibers of various origins and destinations. There is significant overlap of these tracts such that any lesion of white matter is likely to interrupt fibers of passage with multiple origins and multiple sites of termination. The white matter gets larger as one ascends the spinal cord from sacral to cervical levels as additional ascending fibers to the brain add to the white matter and progressive numbers of descending fibers to spinal targets drop out to form synaptic connection. Grey matter is largest at the cervical and lumbar enlargements due to association with sensation and motor control of the limbs. The most notable divisions of the white matter that are important to pain sensation are the dorsal columns, the dorsolateral fasciculus, and the ventrolateral (anterolateral) fasciculus and their associated subdivision into tracts (Fig. 4.1).

Spinal Laminae

The morphology of neurons in the grey matter of the spinal cord differs depending on location. Using Rexed's classification system, there are at least 10 different layers or laminae of neu-

MLF	Medial longitudinal fasciculus
ARST	Anterior reticulospinal tract
MRST	Medial reticulospinal tract
ACST	Anterior corticospinal tract
LRST	Lateral reticulospinal tract
LCST	Lateral corticospinal tract
FG	Fasciculus gracilis
FC	Fasciculus cuneatus
PSCT	Posterior spinocerebellar tract
DL	Dentate ligament
ASCT	Anterior spinocerebellar tract
ALF	Anterolateral fasciculus
SOT	Spino-olivary tract
ASTT	Anterior spinothalamic tract
TST	Tectospinal tract
VST	Vestibulospinal tract
OST	Olivospinal tract
LTST	Lateral tegmentospinal tract
RST	Reciculospinal tract

FIGURE 4.1 Diagram of the white matter of the spinal cord. The ascending tracts are emphasized on the right side and the descending tracts on the left side. The anterolateral (ventrolateral) funiculus, which is composed of the anterolateral fasciculus (ALF), composed of the spinothalamic (STT), spinoreticular (SRT), and spinomesencephalic (SMT) tracts in the spinal cord. As it ascends, the ALF becomes progressively larger, the largest part being in the upper cervical region. This is not only because the STT continues to add axons but also because there are more SRT cell bodies (and hence axons) in the cervical enlargement than in the lumbosacral enlargement. Throughout the course of the ALF in the spinal cord, the three nociceptive pathways are situated medial to the anterior (ventral) spinocerebellar tract, lateral to the ventrolateral and ventral horns, and posterolateral to the spino-olivary tract. The anterior spinothalamic tract (ASTT), which may be an alternate nociceptive pathway, is separate from the three tracts of the ALF. Because a cordotomy lesion in the upper thoracic or cervical segments, usually extends from the dentate ligament medially the ASTT and some of the descending tracts are likely to be interrupted with the operation. In the cervical region, the ALF is shaped as a somewhat flat triangle with the apex medial and the base lateral. At successively higher cervical levels there is a gradual dorsolateral shift of the ALF.

rons—the first six of which (I–VI) are termed the dorsal horn of the spinal cord (Fig. 4.2). These laminae, plus the area around the central canal (lamina X), receive a bulk of primary afferent inputs. Spinal dorsal horn neurons receiving excitatory inputs from nociceptive afferents have been demonstrated to be present throughout the dorsal horn, but with particular localization to laminae I, II, V, VI, and X. One must remember that laminar assignment is based on the central location of the neuronal soma. However, dendritic extensions of these neurons may extend throughout numerous laminae such that the immunohistochemical demonstration of primary afferent neuron terminations in specific laminae does not limit connectivity to just neurons of those laminae. Mapping of individual C-fiber primary afferents encoding for cutaneous nociception have demonstrated sites of connectivity that are highly localized into tight ‘‘baskets’’ typically located in superficial laminae of a single spinal segment. In contrast, single primary C-fiber afferents from deep, visceral structures have been demonstrated to travel via Lissauer’s tract to reach multiple spinal segments and multiple laminae (I, V, X, and even contralateral sites)[7] (Fig. 4.3). Fine muscle afferents and

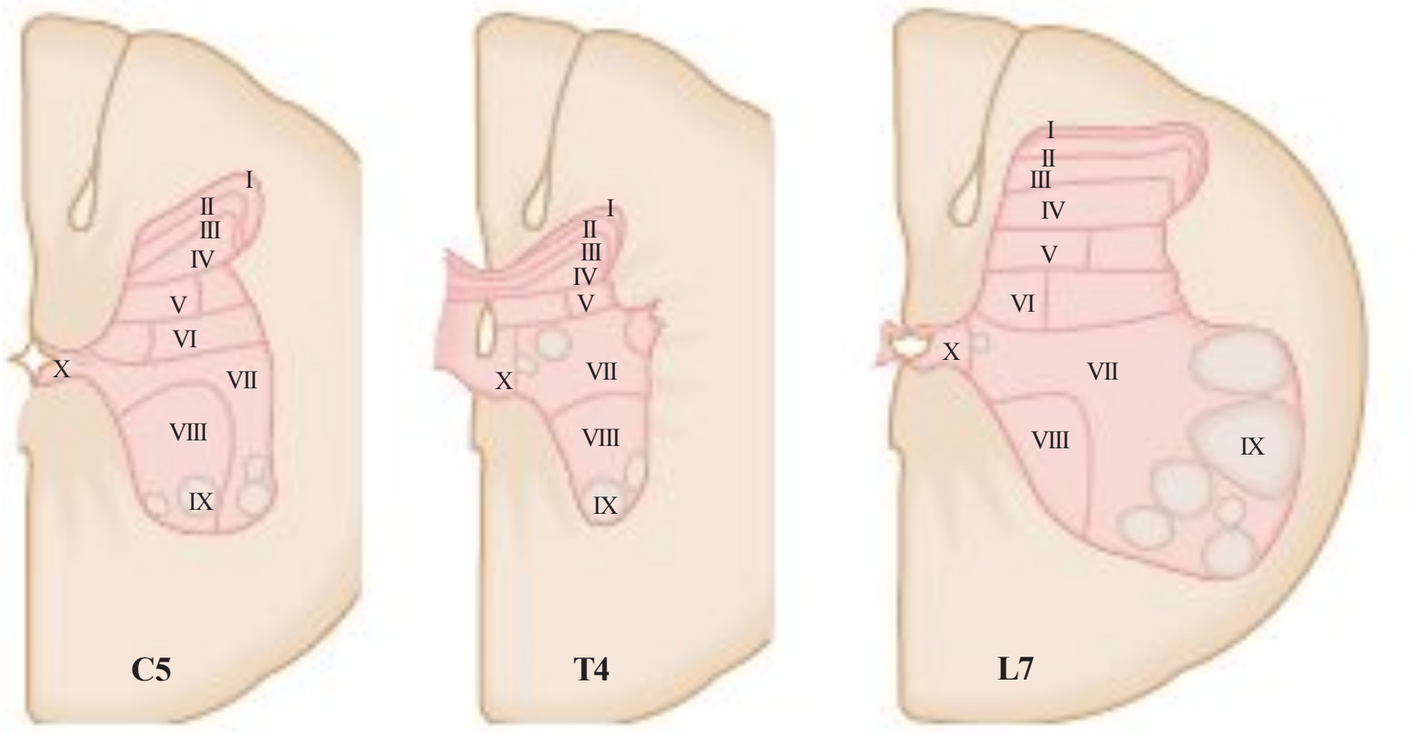


FIGURE 4.2 Diagrams showing Rexed's laminar histologic organization of the cat spinal cord grey matter at three levels. The dorsal horn corresponds to laminae I through VI inclusive. (Redrawn after Rexed B. The cytoarchitectonic organization of the spinal cord in the cat. *J Comp Neurol* 1952;96: 415–495, with permission.)

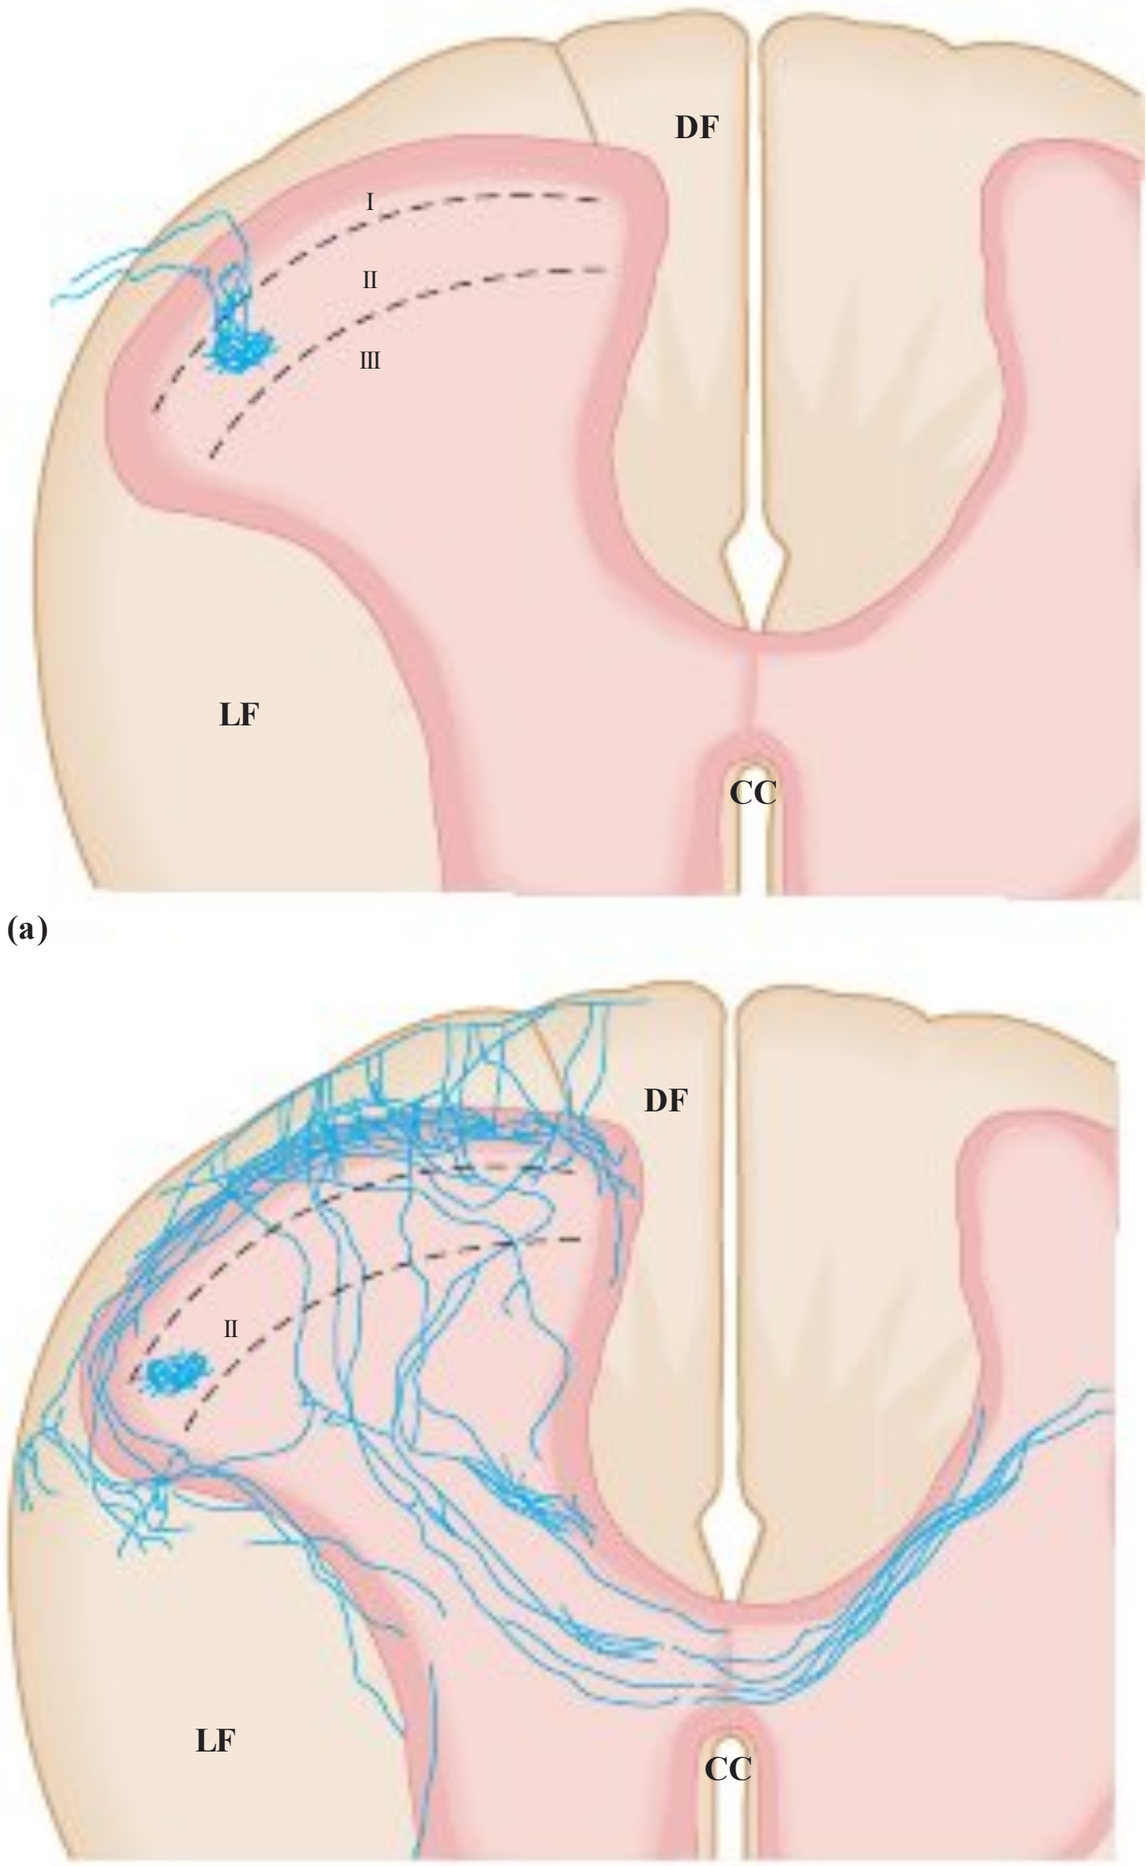

FIGURE 4.3 The different extents of central terminal fields are shown here for an individual somatic C-fiber primary afferent **(A)** and a visceral C-fiber primary afferent **(B)** from guinea pigs that were injected with phaseolus vulgaris leucoagglutinin after functional identification. The visceral C-fiber afferent had many more central branches and numerous arbors that include contralateral projections, whereas the somatic C-fiber afferent had a more limited terminal field (*CC*, central canal; *Df*; dorsal funiculus; *LF*, lateral funiculus.) (Redrawn after Sugiura Y, Terui N, Hosoya Y. Difference in distribution of central terminals between visceral and somatic unmyelinated (C) primary afferent fibers. *J Neurophysiol* 1989;62:834–840, with permission.)

articular afferents have sites of termination similar to those of visceral afferents. By using intracellular recording and labeling techniques it has been possible to determine that nociceptive afferents connect with second order neurons that have many different morphologies—some of which correlate with electrophysiological characteristics (see Morris et al.[8]). The morphology and neurotransmitter content of each lamina will be briefly discussed.

Lamina I is termed the marginal zone as it forms the outermost layer of the dorsal horn. This single lamina contains a heterogenous population of neurons with morphological studies identifying neurons with pyramidal, fusiform, and multipolar shapes, some with smooth dendrites, some with spiny dendrites. Lamina I and the adjoining Lamina II are the predominant location of excitatory neuropeptide input from primary afferent neurons with heavy immunohistochemical labeling for substance P and calcitonin gene-related peptide (CGRP). Axonal projections of a subset of lamina I neurons extend to supraspinal structures such as the medulla, midbrain, and/or thalamus. Fos induction in response to noxious stimuli has consistently been reported to occur in lamina I with double-labeling noted in association with antibodies to preproenkephalin, dynorphin, glutamate, N-methyl-D-aspartate (NMDA) receptors, gamma amino butyric acid (GABA), glycine, GABA-B receptors, NK1 receptors, calbindin, glucocorticoid receptors, and estrogen receptor-α[1].

Lamina II is called the substantia gelatinosa due to its gross appearance in fresh cut tissue. The neurons of this lamina are generally small with four or more distinct morphologies, two of which are viewed as important to the local processing of nociceptive information: stalked and islet cells (using the terminology of Gobel[9]). Stalked cells have soma at the outer edge of lamina II with centrally arborizing dendrites and axons that synapse with lamina I projection neurons. Islet cells have fusiform cell bodies with extensive dendritic and axonal arborizations containing inhibitory neurotransmitters such as GABA or enkephalin.[10,11] Axodendritic, dendrodendritic, and axoaxonic synapses are manifest throughout lamina II on ultrastructural analysis demonstrating a profound potential for neuronal interaction and signal processing. Primary afferent input from both nociceptive and nonnociceptive neurons has been noted and descending axonal connections are also present with evidence of serotonergic and noradrenergic inputs to these neurons. A distinction is frequently made between lamina II-outer (II_o) and lamina II-inner (II_i) with II_o commonly combined with lamina I in discussions of the superficial dorsal horn.

Lamina III and **Lamina IV** are known as the nucleus proprius as both receive highly myelinated low-threshold primary afferent neuronal inputs that include proprioceptors. Whereas lamina III consists mainly of small neurons with morphologies similar to lamina II, lamina IV has a subpopulation of large cells with extensive dendritic extensions that reach superficially. Lamina IV also has neurons with axonal projections extending up the dorsal columns.

Lamina V neurons receive input from Aδ- and C-fiber nociceptors as well as myelinated afferents carrying low threshold information. Cell bodies are frequently moderately sized pyramidal cells and may have dendritic extensions through the entire dorsal horn reaching to lamina I and II sites of synaptic contact as well as laterally. Neurons of this lamina have been demonstrated to receive input from all somatic, muscle, and visceral afferent types. Axonal projections of lamina V neurons to supraspinal sites are common.

Lamina VI neurons are small neurons present in the cervical and lumbar enlargements, but largely missing in the rest of the spinal cord. Low-threshold muscle afferents and both low- and high-threshold cutaneous afferents reach to this lamina.

Laminae VII–IX represent neurons of the ventral horn.

Lamina X neurons are arranged around the central canal of the spinal cord. They receive bilateral inputs of unmyelinated, poorly myelinated, and highly myelinated afferents. Cell bodies are of moderate size with local dendritic arborizations. Some neurons in the dorsal aspects of lamina X have axonal projections extending up the dorsal columns to reach medullary targets. Peptidergic inputs are extensive and immunohistochemical localization of noradrenergic and serotonergic inputs have been identified. Inhibitory neurons with immunohistochemical identification of glycinergic and GABAergic enzymes are locally present.

Functional Characterization of Nociceptive Neurons

In addition to morphological heterogeneity, the multiple laminae of the spinal cord also have functional heterogeneity.

Second order neurons have been characterized electrophysiologically according to their responsiveness to cutaneous and deep tissue stimuli. Most commonly, a distinction is made between excitatory responses that are produced by noxious (potentially tissue-damaging) stimuli such as high intensity mechanical or thermal stimuli and those produced by innocuous stimuli such as hair movement or vibration. Using these two criteria, the simplest nomenclature defines neurons as Class 1 if excited only by innocuous stimuli, Class 2 if excited by both innocuous and noxious stimuli, and Class 3 if excited only by noxious stimuli. Similar nomenclatures, but with additional subtle meanings implied by their original descriptions, include the use of terms such as *low threshold* for Class 1 neurons, *wide-dynamic-range*[12] or "convergent" neurons[13] for Class 2 neurons, and *high threshold* or *nociceptive-specific* neurons for Class 3 neurons. A fourth *nonresponder* group also must be factored in for neurons that fail to be excited by any of the employed stimuli. Despite the "clean" nature of this categorization, there unfortunately appears to be a spectrum of responses to all afferent input modalities with varying overlap that is somewhat dependent on the precise stimuli and definitions employed. The definition of neurons according to excitatory stimuli also appears to be preparation dependent as extracellular dorsal horn recordings of spinal neurons in cats have demonstrated that the classification of an individual neuron may change with the administration of anesthesia.[14]

The number of neuronal subgroups in any classification system is a function of the number of criteria employed for that classification. Despite this, it has been suggested that the use of inhibitory inputs as part of a classification criterion might actually simplify overall schema. One such inhibitory influence used in classification is known as *diffuse noxious inhibitory controls* (DNIC) which is proposed to be an endogenous inhibitory system activated by a nonsegmental noxious stimulus. DNIC produces inhibition of ongoing or evoked dorsal horn neuronal activity and according to its original description,[15,16] DNIC is specific for Class 2 (WDR, convergent) neurons and has no effect on Class 3 (nociceptive specific) neurons. Subsequent studies of DNIC would support the general statement that DNIC effects are highly *selective* for Class 2 neurons with lesser effect on Class 3 neurons. Nomenclatures using a combination of responses to excitatory and inhibitory inputs have not been universally accepted.

Classification According to Site of Projection

Second order nociceptive spinal dorsal horn neurons frequently have axonal extensions projecting to rostral (and caudal) sites of termination. These sites include other segments of the spinal cord and supraspinal structures such as the thalamus, the hypothalamus, the midbrain, the pons, and the medulla. These axons travel predominantly within the white matter of the spinal cord in two main sites: the ventrolateral quadrants and the dorsal midline. Ascending fiber tracts in the dorsolateral funiculus have also been

described. Decussation of fibers to the contralateral ventrolateral white matter occurs for axons projecting to the thalamus and most other brainstem sites although many axons with sites of termination in "reticular" structures remain in the ipsilateral ventrolateral white matter. Dorsal column pathways have sites of termination in the gracile or cuneatus nucleus of the medulla. Intraspinal pathways that may stay within the grey matter have also been demonstrated as well as extensive collateralization of axons with multiple sites of termination at supraspinal and intraspinal sites.

TARGETS OF AXONAL PROJECTIONS

Intraspinal Pathways

Multiple interconnections occur between spinal neurons. On a segmental level this is referred to as interneuron connectivity. When connections are more distant, the pathways of connection are termed "propriospinal" based on the initial demonstration of a coordinating connectivity between the cervical and lumbar enlargements of quadrupeds that allowed for coordinated motion. Intraspinal connectivity has also been demonstrated in the case of neurons receiving afferent input from pelvic structures with a dual innervation through thoracolumbar sympathetic and sacral pelvic nerves. These intraspinal connections appear to coordinate autonomic functions related to the pelvic organs.[17,18] A precise white matter localization of the axonal extensions of propriospinal nociceptive neurons has not been performed but they are presumed to follow the paths of other propriospinal neurons which include dorsally located white matter paths and some within grey matter extensions. Collateral intraspinal extensions of ascending axons located within the ventrolateral white matter have also been demonstrated.

A separate system of intraspinal connections, the multisynaptic ascending system, may have particular relevance to chronic pain. In concepts championed by Noordenbos but first proposed by Goldschneider,[19] long chains or "webs" of neuronal connections extend through the length of the spinal cord and carry nociceptive information in a slow but progressive fashion to the brain by short "hops." Support for this concept is given by animal experiments in which opposing hemisections performed at differing spinal levels fail to block nociceptive behaviors, but total transections at a single level are effective.[20] Traditionally described as an ascending pathway, bidirectionality of signaling is possible with a potential for the generation of "reverberatory" circuits.

Spinothalamic Tract

Ventrolateral (Anterolateral) Axonal Pathways

The most studied spinal projection pathway is the spinothalamic tract which is located within the ventrolateral white matter of the spinal cord. Both ipsilateral and contralateral localization of axon pathways have been demonstrated en route to supraspinal sites, but the predominant path for axonal projections traveling to the ventrobasal thalamus resides on the contralateral side. Experiments utilizing lesions of the ventrolateral spinal white matter have demonstrated reduction or abolition of ventrobasal thalamic neuronal responses to most somatic noxious stimuli. Consistent with this observation, surgical or traumatic interruption of ventrolateral fiber pathways results in the lack of sensation to noxious cutaneous stimuli (i.e., pinprick) applied to the contralateral side of the body at spinal segments below the level of the lesion. The second order neurons which project to the thalamus have been identified in rodent, feline, and primate models using neuroanatomical (retrograde dye labeling or chromatolytic responses to axonal section) and electrophysiological (antidromic activation) methods. Neurophysiological experiments have not always proven that the neurons of study had axonal projections that actually reach the thalamus, but have always demonstrated that neurons of interest have axons present within the ventrolateral spinal white matter and so the term "spinothalamic tract" neurons (STT) is generally employed to describe the neurons rather than the more specific term "spinothalamic."

Neospinothalamic versus Paleospinothalamic

There exist two different components of the spinothalamic tract—the neospinothalamic tract (nSTT) and the paleospinothalamic tract (pSTT), the former of which forms a direct, dedicated relay to the ventrobasal group of the thalamus and the latter of which has many neurons with one or more axonal bifurcations that form dichotomizing fibers ending in synaptic contact with medullary, pontine, midbrain, and medial thalamic structures. Ascending information transmitted through the pSTT produces activation of numerous limbic structures and has therefore been viewed as important to affective and motivational aspects of pain, whereas the nSTT, through relays in the ventrobasal and posterior thalamus, activates the somatosensory cortex and so has been viewed as important to localization and intensity coding of pain-related sensations. Axonal collateral branchings of pSTT neurons have been identified that correspond to multiple areas of limbic and autonomic activation which include medullary, pontine, mesencephalic, hypothalamic, and medial thalamic targets.

Laminar Distribution of Spinothalamic Tract Neurons

The cells of origin of the STT reside within all laminae of the spinal cord except motoneuronal layers and therefore can have multiple different morphologies. At lumbar levels in primates, the greatest number of nSTT neurons reside in laminae I and V, but also are highly represented in laminae IV, VI, IX, and X with additional representation in III, VII, and VIII. In contrast, the neurons of the pSTT have soma in deeper laminae (VI–VIII) with a lesser representation in I, IV, and V. The axons of STT neurons typically decussate to the contralateral side via the dorsal commissure within one to two spinal segments of the neuronal soma but at sacral and upper cervical levels, a significant number (up to 26%) of axons of STT neurons may remain ipsilateral.[21] A general somatotopic organization of the ascending fibers within the STT has been noted with an inner-to-outer progression of layers of fibers to the white matter from cervical to sacral levels (Fig. 4.4). A similar somatotopy is noted at medullary levels. The STT splits into two parts through the rostral medulla and pons to merge again at mesencephalic regions where an anterior-to-posterior somatotopic distribution is noted. Differences in conduction velocity of subsets of STT neurons has been identified (lamina I STT neurons have slower conduction velocities than lamina V STT neurons) suggesting differences in axonal diameter and myelination processes. That, in turn, suggests a potential for temporally different delivery of sensory information to brain structures and differential susceptibility to pathological processes.

Functional Characterization of Spinothalamic Tract Neurons

Quantitative electrophysiological characterization of STT neurons has demonstrated a predominance for neurons processing nociceptive information. However, approximately 20% of STT neurons encode exclusively for nonnoxious light touch sensa-

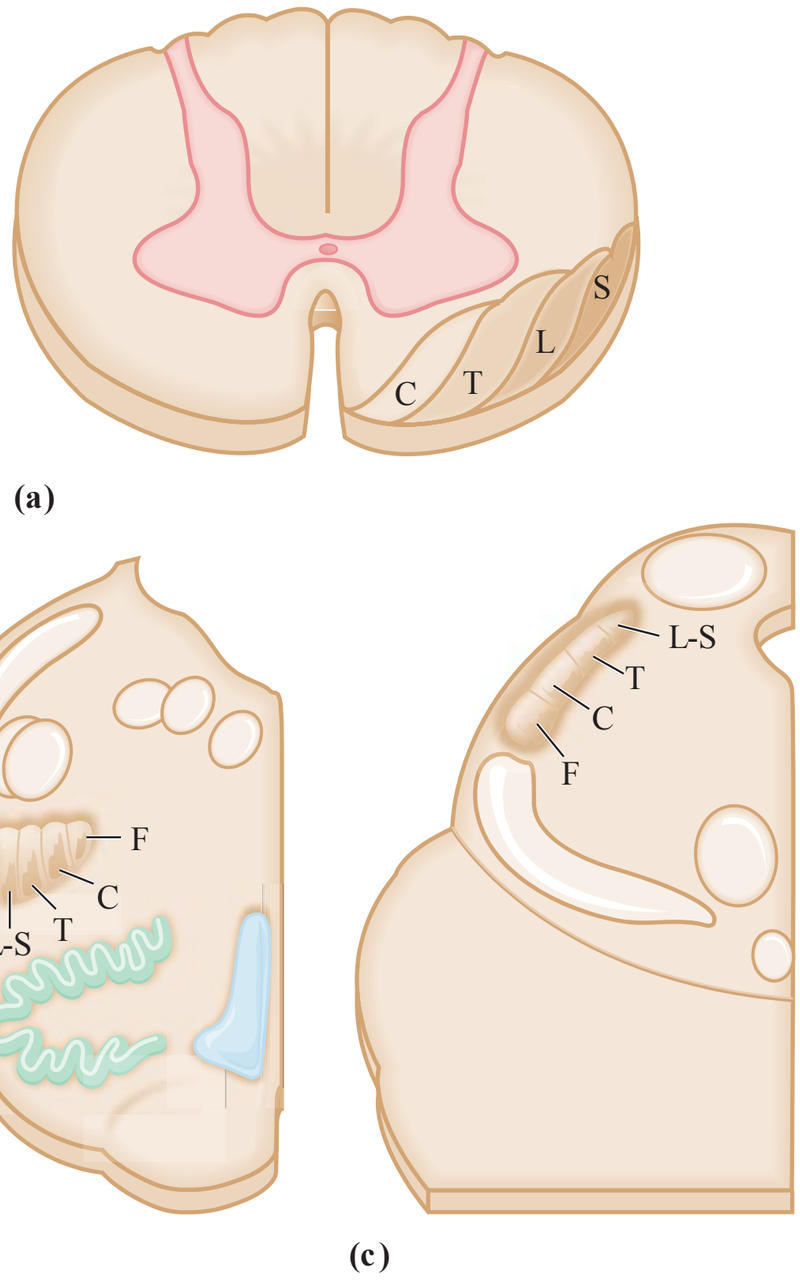

FIGURE 4.4 Schematic diagrams showing cross-section of the spinal cord, medulla, and midbrain, depicting the laminar arrangement of the ascending tracts in the ventrolateral funiculus in the upper part of the cervical spinal cord **(A)** and with the addition of the trigeminothalamic tract in the medulla **(B)** and midbrain **(C)**. (*S*, sacral, *L*, lumbar, *T*, thoracic, *C*, cervical, *F*, face.)

tions[11] and a small subset encode for proprioceptive information. Multiple subsets of nociceptive neurons have been identified that have selective laminar localization. Nociceptive specific (NS) STT neurons, with slow adapting responses to noxious pinch, heat, or chemical stimulation are commonly located in lamina I but are also present in deeper laminae. Noxious cold has been used as an additional characterizing stimulus[22] and allowed for the identification of additional subsets of lamina I NS STT neurons. Wide dynamic range (WDR) STT neurons, which demonstrate excitatory responses to multimodal sensory inputs (including both noxious and nonnoxious stimuli), are found extensively in lamina V but can also be found in all other laminae. Convergence of visceral, myofascial, articular, and cutaneous inputs is the rule rather than the exception when examining WDR STT neurons,[23] but similar convergence has been noted in NS STT neurons. Overall, with the possible exception of noxious cold inputs, the presence or absence of a particular group of sensory inputs has been of limited value in identifying lamina specific, morphological, functional, or projection-related neuronal subsets. However, there are important generalities that are apparent in quantitative analyses of neuronal subsets[24]: lamina I STT neurons tend to be NS neurons; lamina V (and other deep laminae) STT neurons tend to be WDR neurons; STT neurons with projections to the medial thalamus (pSTT) are more likely to be NS rather than WDR neurons and frequently have large receptive fields; STT neurons with projections to the lateral thalamus (nSTT) are more likely to be WDR rather than NS neurons and often have smaller receptive fields; and STT neurons with projections to both medial and lateral thalamus appear similar to neurons with projections only to the lateral thalamus.

Dorsolateral and Ventromedial Axonal Pathways

Spinothalamic neurons with soma primarily located within lamina I have been demonstrated to send axonal projections to the contralateral posterior nuclei of the thalamus via a contralateral dorsolateral pathway.[25,26] Estimated to form up to a quarter of all spinothalamic neurons,[27] these neurons have been identified electrophysiologically to be primarily NS neurons with small cutaneous receptive fields. Deeper laminae neurons and WDR neurons are also represented in this pathway. Many axons of spinothalamic neurons also travel within the ventromedial white matter of the spinal cord with soma located within laminae I, IV, V, VI, and VII.[28] Functional characterization of spinothalamic neurons with axons in the ventromedial white matter suggest a mixture of nonnociceptive and nociceptive neurons with supraspinal targets in the mesencephalon and intralaminar nuclei of the thalamus.

Spinoreticular and Spinomesencephalic Tracts

Ventrolateral (Anterolateral) Axonal Pathways

As noted previously, ascending axonal fibers of nociceptive second order neurons traveling to the thalamus may frequently branch and send collaterals into brainstem structures including the medulla, pons, and mesencephalon. However, numerous ascending fibers travel to these brainstem structures without having collaterals to the thalamus and collectively are described as spinoreticular if they reach medullary and pontine sites or spinomesencephalic if they reach midbrain targets. Subsets of spinoreticular neurons, defined by known targets for the axons, include spinomedullary, spinopontine, spinoolivary, spinosolitary, spinoraphe, and spinoparabrachial neuronal groups. Identification of these subgroups has been possible using focal injections of retrogradely transported neuronal dyes at supraspinal sites or antidromic electrical activation of axonal extensions. Although the former technique has reasonable localization potential, the latter does not always discriminate axons of passage from final sites of termination. The presence of collateralization of axons to multiple targets has been identified but not quantitatively defined and so the overlap between the sampling of groups is not known. The spinal localization of spinoreticular and spinomesencephalic ascending axons overlap with those of the ventrolateral STT except for a greater propensity for remaining ipsilateral within the spinal cord and a slightly more medial line of passage upon entering the medulla. Spinomesencephalic neurons also utilize the dorsolateral funiculus for a subset of lamina I neurons in a fashion similar to that of similar spinothalamic neurons.

Features of Spinoreticular Neurons

The locations and functional characteristics of spinoreticular neurons in primates are virtually identical with the same features of STT neurons with projections to the medial thalamus. They demonstrate a predominant localization to deeper laminae of the spinal cord and tend to have large, sometimes whole body, receptive fields of the NS and WDR types. Synaptic targets include many areas of the medulla and brainstem highly involved in autonomic regulation as well as the regulation of nociceptive systems. The potential for feedback control of nociceptive processing is therefore anatomically present. An important relay site is the parabrachial nucleus in the pons[29] which has extensive projections to limbic subcortical structures such as the amygdala.

Features of Spinomesencephalic Neurons

In contrast to spinoreticular neurons, the locations and functional characteristics of spinomesencephalic neurons in primates are similar to STT neurons with projections to the lateral thalamus although significant differences are present. They demonstrate a predominant localization of soma to laminae I and V of the spinal cord with a small scattering to other deep laminae. Electrophysiological characterization of spinomesencephalic neurons suggests a predominance of NS neurons. Synaptic targets include the periaqueductal gray, a site with known importance to the regulation of nociception, as well as the collicular and cuneiformis nuclei.

Postsynaptic Dorsal Column Neurons

Recently, there has been increasing evidence for the existence of a spinal pathway in the midline of the dorsal spinal cord that carries the rostral transmission of deep tissue nociception. Traditionally the dorsal columns have been viewed as transmitting information related to nonnociceptive information such as vibration or other light touch sensations. However, discrete neurosurgical lesions of this portion of the spinal cord have been demonstrated to relieve cancer-related pain in patients with pelvic visceral and deep muscle pathology.[30,31] Parallel studies in nonhuman animals have demonstrated that in this area of spinal white matter there exist axons of postsynaptic dorsal column (PSDC) neurons receiving noxious excitatory input from the colon, bladder, and/or uterus. Excitatory responses of neurons located in the ventrobasal thalamus to noxious deep tissue stimuli are attenuated/abolished with lesions of the dorsal midline region of the spinal cord[30] but are only minimally affected by lesions of the traditional spinothalamic pathways (ventrolateral quadrant).

The soma of PSDC neurons are located predominantly in lamina III, IV, and X and, in a limited number of studies, the neurons have been demonstrated to be responsive to both somatic and visceral nociceptive inputs. Both NS and WDR neuronal types have been reported and their role in nociception is linked more to the secondary effects of dorsal column lesions than inherent neuronal characteristics. Targets for synaptic contact include the gracile and cuneatus nuclei of the medulla (dorsal column nuclei) but it is notable that the presence or absence of collaterals to other ascending tracts or other supraspinal targets has not been performed.

Other Ascending Pathways

There exist other pathways to the brain apart from those noted. The spinocervicothalamic tract is important in other species but appears minimal or absent in humans. Direct projection pathways to the hypothalamus, amygdala,[29] and cerebellum have also been identified with presumed roles in autonomic function, affective-emotional modulation, and motor coordination, respectively. Extraspinal pathways for peripheral primary afferents exist and can sometime lend confusion to studies of central pathways. Vagal afferents can reach the brainstem carrying extensive information from visceral and other deep tissue structures leaving brainstem-mediated responses intact despite the interruption of spinal pathways. Similarly, primary afferents from deep structures including the viscera and peripheral vasculature can travel via the sympathetic chain to enter the spinal cord at levels much higher than expected and so can "bypass" selective spinal lesions of ascending pathways forming synaptic contact at levels above the lesions. Clinically, these other pathways sometimes prove important to consider, particularly in conditions of spinal cord injury.

NEUROCHEMISTRY OF SECOND ORDER NEURONS

Neurotransmitters from Primary Afferents

Excitatory neurotransmission of second order spinal neurons is produced predominantly by the release of excitatory amino acids (EEAs), such as glutamate and aspartate, from primary afferent neurons. Various other neurotransmitters lead to neuroexcitatory effects by channel activation or sometimes via second messenger systems but, in most cases, these other neurotransmitters appear to have the augmentation of EAA-induced excitatory responses as their primary function. Most notable of these neurotransmitters are calcitonin-gene-related polypeptide (CGRP), substance P, and NK-A, but roles for serotonin, adenosine triphosphate (ATP), and cholecystokinin (CCK) have been identified. The inhibitory neuropeptides galanin and somatostatin are also released from primary afferents, but they are small in number and with limited effects on second order neurons. A summary of spinal cord dorsal horn neurotransmitter location and associated receptors is given in Table 4.1.

Excitatory Amino Acids: Ionotropic Receptor/Channels

EAAs act on ligand-activated ion channels to produce immediate excitatory postsynaptic potentials (EPSPs) but also act at metabotropic receptors to alter intracellular second messenger systems (discussed later). Three different EEA-activated ion channels have been characterized: α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA) receptors; *N*-methyl-D-aspartate (NMDA) receptors; and kainate (KA) receptors. These receptors have differential functions despite frequent co-localization on the same neurons due to differences in their regulation by baseline membrane potentials. As different receptors/channels, they are also differentially affected by the presence of other agonists and ions such as magnesium.

Activation of AMPA receptors immediately allows selective sodium ion flow through the extracellular membrane and is responsible for a majority of the "fast" transmission in nociceptive systems. AMPA receptors are unaffected by the baseline depolarization state of the second order neuron. In contrast, NMDA receptors are both voltage and ligand gated and allow permeability to both sodium and calcium ions. Magnesium ions act to block the channels of NMDA receptors which only become unblocked following a sustained depolarization of the extracellular membrane. Such a sustained alteration in membrane potential enables the magnesium ion to disengage intracellularly which then allows the opening and activation of the NMDA receptor-channel complex which, in turn, results in a *very* sustained depolarization. Since the NMDA receptor-channel is permeable to calcium, its sustained activation can produce alterations in intracellular second messenger functions of calcium.

Two phenomena have been clearly linked to NMDA receptor activation: "wind-up" (increasing responses to repeated stimuli of equal intensity) and "central sensitization" (decreased thresholds for response and/or increased vigor of responses due to a sensitizing event). NMDA antagonists will block/blunt both phenomena, but these phenomena can also be stopped prior to their development by pharmacological antagonists that block the initial event that led to the sustained depolarization that allowed the NMDA receptor activation. As a consequence, the antagonism of other excitatory systems (i.e., AMPA receptors) or the activation of endogenous inhibitory systems may also blunt or block these "hyperalgesic" phenomena. Clinical use of NMDA receptor antagonists such as ketamine or dextromethorphan has been demonstrated to produce prolonged analgesic effects when coadministered with opioids or as part of a perioperative regimen.

Pharmacological systems thought to contribute to the transmission and modulation of second order nociceptive neurons in the dorsal horn of the spinal cord. The various neurochemicals and receptors depicted each has its own pharmacological profile and may represent independent populations of neurons and fibers, but more commonly coexist and interact with each other at individual synapses. Interactions may take place at presynaptic terminals, dendrites, and somata.

x, origin of neurotransmitter; +, pronociceptive effect; −, antinociceptive effect; α1, α2, alpha adrenoceptors; A1, adenosine receptor 1; Ach, acetylcholine; mAChR and nAChR, muscarinic and nicotinic acetylcholine receptors; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate; ATP, adenosine triphosphate; CB1, cannabinoid receptor 1; CCK, cholecystokinin; CGRP, calcitonin gene-related peptide; CRF, corticotrophin releasing factor; 5HT, serotonin; GABA, gamma amino butyric acid; Gal1 and Gal2, galinin receptors types 1 and 2; KA, kainate receptors; mGlu, metabotropic glutamate receptor; MOR, DOR, and KOR, mu, delta, and kappa opioid receptors; NFF, neuropeptide FF; NK1 and NK2, neurokinin 1and 2 receptors; NM, neuromedin receptor; NPY, neuropeptide Y; ORL1, nociceptin/orphanin FQ peptide receptor; SSN-R2 and -R4, somatostatin receptor 2 and 4; TRH, thyrotropin-releasing hormone; TRPV1, transient receptor potential vanilloid-1; VIP, vasoactive intestinal polypeptide. (Supportive references: 2, 33, 35, 44–49, 51, 58–63.)

The third ligand-activated ion channel, the KA channel, is not well understood but is likely to affect nociceptive systems in a yet-to-be-defined fashion. Metabotropic effects (second messenger-mediated) of the KA receptor that are in addition to its primary ionotropic effects have been observed in CNS sites such as the hippocampus. Evidence of participation in intracellular signaling cascades and G protein activation that lead to the modulation of GABA release suggest that KA receptors could have a role in nociceptive processing.[32]

Metabotropic Glutamate Receptors

Acting via second messenger systems rather than channel activation, the eight different metabotropic glutamate receptors (mGluRs) can be classified into three groups on the basis of sequence similarity and whether they positively couple to the phospholipase C cascade or negatively couple to the adenyl cyclases.[33] Group I (mGluR1 and mGluR5) has been linked to nociceptive processing as these receptors produce alterations in NMDA receptor-channel opening. As such they have been implicated in processes of central sensitization and persistent pain. Group II (mGluR2 and mGluR3) has also been used to modify nociceptive behavioral responses in models of neuropathic and inflammatory pain. Group III (mGluR6, mGluR7, and mGluR8) has not yet had a clearly defined role in nociception.

Substance P

This neuropeptide has long been attributed a special role in pain processing as it is located in small diameter primary afferents and is released following cutaneous noxious stimuli.[34,35] Substance P acts by binding to NK1 receptors on second order neurons thereby affecting intracellular G-protein–related phosphorylation processes. It is often co-localized with, and so co-released with, glutamate from primary afferents and promotes membrane depolarization produced by glutamate. In this way it modifies the gain of nociceptive transmission. It is important in conditions of inflammation, particularly neurogenic inflammation, where it is released from peripheral axons and produces a local tissue effect. However, substance P may not be necessary for acute nociceptive transmission since the pharmacological or genetic "knock-out" of the NK1 receptor has minimal effect on acute responses to most nociceptive stimuli. Substance P is present in highest concentration is laminae I and II_o as well as in laminae V and VI. Other neurokinin receptors also exist which bind other neuropeptides such as NK-A which has physiological effects similar to substance P. Neuropeptide antagonists such as the NK1 antagonists have proved to have disappointing results in clinical trials when pain was the clinical endpoint,[36] although efficacy has been noted in association with nausea therapy.

Calcitonin Gene-Related Peptide

The most commonly located neuropeptide in afferent systems, CGRP, has a poorly defined role in nociceptive processing with mixed results from depletion, augmentation, and antagonism studies.[37] At present, its most important effects appear to be related to peripheral vasodilation that is associated with the generation of headaches.[38] Electrophysiological studies of spinal WDR second order neurons have demonstrated an augmentation of nociceptive responses due to direct application of CGRP in a neuromodulatory fashion similar to substance P and NK1 receptor activation.[39] Like substance P, the knockout of CGRP synthesis has little effect on acute experimental models. CGRP localizes in primary afferent terminals in laminae I, II, and V. Human and nonhuman animal studies suggest that CGRP may be most important in relation to neurogenic inflammatory processes—particularly those associated with migraine headache.

There is a clear association between headache symptomatology and the peripheral release of CGRP and antagonists to the GCRP receptor have been reported as efficacious for the relief of acute migraine attacks.[40] For these reasons, CGRP may not be as important as a substrate for spinal cord processing as it is for the peripheral effects of nociceptor activation.

Cholecystokinin

A peptide present in primary afferent neurons, CCK has little effect in animals without pathology but the neuropeptide increases in content and its receptors in number following nerve injury.[41,42] Opioid receptor function and CCK receptor activation are also related in a complex fashion as CCK receptor antagonists may promote opioid analgesia and slow morphine tolerance development at spinal levels. Consistent with this, CCK receptor antagonists may be analgesic in neuropathic pain models and this analgesia is antagonized by naloxone. CCK is localized predominantly to lamina I, II, IV, and X and is a neurotransmitter present in both primary afferents and interneurons.

Other Neuropeptides

Multiple other neuropeptides that are in primary afferent neurons or which have receptors on the central terminals of primary afferent receptors have been implicated in nociceptive spinal processing. These include vasoactive intestinal polypeptide (VIP), bombesin, gastrin-releasing peptide, neuromedin B, neuromedin C, neuropeptide YY, and thyrotropin-releasing hormone. Action of most of these neurotransmitters on nociceptive systems appears to be predominantly a facilitatory presynaptic action on primary afferent neurotransmitter release. VIP has a presence in the ventral horn of the spinal cord, but the predominant source of VIP to the dorsal horn is primary afferents with strong localization in lamina I and a sparse representation in lamina V. Two neuropeptides located in primary afferent terminals, galanin and somatostatin, have inhibitory influences on second order neurons.[42,43] Trophic factors such as nerve growth factor and brain-derived neurotrophic factor also act as influences to the second order neurons particularly in conditions of nerve injury or death.

Adenosine Triphosphate

Present in many primary afferents, ATP, as a neurotransmitter, is known to activate the ligand-gated ion channels of the P2X family as well as the metabotropic P2Y family of receptors. P2X receptor activation both potentiates glutamatergic transmission and produces fast transmission related to nociceptor activation.[44,45] Ubiquitous as the compound used to drive most energy-requiring processes of metabolism, ATP also has breakdown products that may serve as agonists to other purinergic receptors (A1, A2) located both extracellularly and intracellularly on second order neurons.

Co-localization of Neurotransmitters

A combination of neurotransmitters released from primary afferent neurons is the typical rule rather than exception in relation to small diameter fibers. EAAs coexist with ATP, substance P, NK-A, CGRP, and other neuropeptides. These neuropeptides coexist in nerve terminals in varying combinations with each other with all possible mixtures described in overlap. CGRP is the most ubiquitous of the neurotransmitters located within C-fibers and so commonly co-localized with other neurotransmitters.

Neurotransmitters from Interneurons

Whereas the predominant effect of primary afferent neurotransmitter release upon second order spinal neurons is excitation, the predominant effect of interneuron neurotransmitter release is inhibition. Second order neurons may act as interneurons and at the same time may also be third, fourth, or higher order neurons responsible for excitatory and/or inhibitory effects on other second order neurons. This is apparent in intermediate laminae neurons which have complex cutaneous receptive fields that represent the total body when both excitatory and inhibitory influences are considered.[13] Interneurons utilize many of the same excitatory neurotransmitters as primary afferents but, in addition, utilize many other neurotransmitters to produce inhibitory influences. These fall mainly into the amino acid, neuropeptide, and small molecule groups. A listing of these neurotransmitters is also given in Table 4.1.

Inhibitory Amino Acids

GABA and glycine are the two main inhibitory amino acids of the CNS. GABAergic systems appear to be more predominant at supraspinal sites and glycine at spinal sites, but both are present throughout the CNS. GABA acts through a "fast" ligand-activated ion channel that allows chloride ion flow which in turn produces hyperpolarization of the neuronal membrane. Termed the $GABA_A$ receptor, it has associated structures that allow benzodiazepine or barbiturate binding to alter the GABA-affinity and channel activation characteristics of the receptor-channel complex. The "slow" metabotropic receptor for GABA, the $GABA_B$ receptor is the binding site for baclofen and works via G-protein–linked systems to alter potassium (promotes) and calcium (inhibits) ion channel flow. Via actions on motoneurons, $GABA_B$ receptor activation leads to decreased spasticity and muscle tone. At brainstem levels, in association with cranial nerve function, $GABA_B$ activation may be analgesic and so is indicated in the treatment of various cranial neuralgias. A putative $GABA_C$ receptor which is ionotropic has been described but with an uncertain role in sensory systems.

Glycine acts through both strychnine-sensitive and strychnine-insensitive receptors. The former, a ligand-gated anion channel very similar to the $GABA_A$ complex, is diffusely located but with particular effect in the ventral horn of the spinal cord such that the administration of strychnine can lead to spontaneous muscle contractions. Also present in spinal sensory systems, the antagonism of glycine effects with strychnine in animal models leads to motor and autonomic hyperreflexia. Paradoxically, glycine can also have excitatory effects via binding as a coagonist to a separate site of the NMDA receptor. Because of their multiple nonspecific effects, anti- or pro-glycinergic drugs have not been employed clinically although theoretical uses are present.

Opioids

Endogenous opioids form the most prominent family of inhibitory neuropeptides in the dorsal horn. Arising from intrinsic spinal interneurons, enkephalins, dynorphin, and β-endorphin bind to G-protein–related receptor complexes that fall into three major classes: the mu opioid receptors (MOR), the kappa opioid receptors (KOR), and the delta opioid receptors (DOR). Exogenously administered MOR agonists are the mainstay of analgesic therapy for severe pain today with actions at both spinal and supraspinal sites. Spinal effects arising from supraspinal actions of MOR agonists are via descending serotonergic and noradrenergic mechanisms. MOR agonists administered to spinal sites act both presynaptically on primary afferents to inhibit release of excitatory neurotransmitters and postsynaptically to directly inhibit second order neurons. KOR agonists, such as the endogenous dynorphins, have been demonstrated to be neurotoxic when administered in high concentrations. Peripherally, these same agents appear to produce analgesia particularly in the realm of deep tissue afferents. DOR agonists hold great promise with many of the favorable characteristics of MOR agonists. However, to date, study of selective DOR agonists have been hampered by the lack of highly selective, nontoxic drugs for use.

An opioid-receptor related neurotransmitter is the substance nociceptin and its receptor, the N/OFQ peptide receptor. Due to the technology of functional genomics this receptor, formerly known as the opioid receptor like orphan receptor-1, was the first of hundreds of G-protein coupled receptors identified which had no known endogenous ligand or function. Subsequently, nociceptin (orphanin FQ) was identified and functional pharmacology performed with agonists to the N/OFQ peptide receptor showing some promise in relation to the treatment of anxiety, stress-induced anorexia, cough, neurogenic bladder, edema, drug dependence, cerebral ischemia, and epilepsy.[46] The precise role of nociceptin in pain processing is still being determined with both antiopioid and opioid-potentiating modulatory properties demonstrated.[47]

Acetylcholine

A developing, novel pharmacology only increasing recognition for its importance to nociceptive processing is that involving the cholinergic systems. Numerous dorsal horn interneurons label positive for enzymes associated with acetylcholine synthesis and/or degradation and pharmacological effects have been noted in relation to both nicotinic and muscarinic subtypes. Use of neuraxially delivered cholinesterase inhibitors, which lead to the increased activation of both nicotinic and muscarinic receptors, clearly produces analgesia in nonhuman animal models, but also produces intractable nausea in clinical studies (which reduces enthusiasm for their use). Cholinergic interneurons may act as intermediary steps for other analgesic treatments such as descending norepinephrine-related inhibitory systems.

Other Neurotransmitters Within Interneurons

Numerous other neuropeptides and small molecules have been localized to interneurons which include thyroid-stimulating hormone (TSH), neurotensin, neuropeptide FF, and neuropeptide Y. All of these have been demonstrated to have dorsal horn localization and all produce neuromodulatory effects, many with mixed excitatory/inhibitory interactions with opioid systems.

Neurotransmitters from Supraspinal Sources

Spinal transection leads to a depletion of the content of several neurotransmitters within the dorsal horn of the spinal cord. Most notable of these are the monoamines serotonin and norepinephrine. Spinal transection still leaves residual serotonin content within the ventral horn indicating some local production of neurotransmitter that may be in addition to that circulating in blood components. Any residual noradrenergic content appears to be of sympathetic origin. As will be discussed in the next chapter, descending noradrenergic and serotonergic fibers originating in the brainstem produce robust inhibitory effects on second order spinal neurons. It has also been recently appreciated that these same neurotransmitters may also produce excitatory effects and may therefore serve as the mechanisms of descending facilitation, another topic of the next chapter.

Serotonin (5-Hydroxytryptamine; 5-HT)

The pharmacological characterization of responses to the endogenous substance, serotonin, has identified a highly complex interaction of this substance with multiple receptors, some with multiple subtypes. At last count, four major groups of 5-HT receptors had been identified, some with inhibitory and some with excitatory effects. The receptor of relevance to pain production or excitatory phenomena is the 5-HT3 receptor, the only one of the receptors which is a ligand-gated ion channel.[48] Excitatory responses to serotonin administered peripherally suggest that it can directly activate nociceptive primary afferent neurons. Actions on the dorsal roots have been postulated to be pronociceptive, antinociceptive, and pro-pruritic. Boutons with serotonin content have been noted throughout the dorsal horn and cell bodies with serotonin have been identified in the ventral horn. A co-localization within synaptic boutons with the neuropeptide substance P has been commonly noted.

Noradrenaline

Adrenoceptors important to the spinal processing of pain appear to be of the α_1 or α_2 subtypes based on the use of agonists (i.e., clonidine) and antagonists administered spinally. Descending from brainstem noradrenergic neuronal nuclei (primarily A5, A6, and A7), known pharmacological sites of action for norepinephrine include presynaptic terminals of nociceptive primary afferent neurons (α2 inhibitory), second order neurons (α2 inhibitory), and interneurons (α1 excitatory) and, as such, has been implicated in both descending inhibition and descending facilitation of nociceptive transmission.[49] Immunohistochemical localization of noradrenergic nerve fibers have found them widely dispersed throughout the dorsal horn and much of the release of neurotransmitter appears nonsynaptic in nature,[50] such that the neurotransmitter has to diffuse from its site of release to its site of action which may be neuronal or glial.[51] Extensive synaptic contact of noradrenergic nerve endings does occur within the ventral horn and intermediolateral grey.

Other Neurotransmitters in Descending Systems

Often co-localized with other neurotransmitters, certain neuropeptides and other monoamines are also in descending fibers that make contact with the spinal dorsal horn. These include substance P, CCK, corticotrophin releasing factor, urocortin 1, and thyrotropin-releasing hormone (TRH) which have excitatory neuromodulatory effects and dopamine, oxytocin, and endogenous opioids which have inhibitory neuromodulatory effects. These descending fibers modulate more than just nociceptive sensory information but when exogenously administered to the spinal cord can produce profound autonomic and motor effects. TSH has been noted to have effects that are like CCK in that it appears to inhibit opioid analgesia.

Neurotransmitters from Glia or Unknown Sources

Numerous substances alter the excitability of second order neurons to nociceptive input that are not from neural structures. For example, bradykinin, which is normally known for its peripheral nervous system effects, activates B2 receptors in the dorsal horn with the subsequent induction of hyperalgesia phenomena. Destruction of primary afferents results in the loss of two thirds of these receptors, but the source of the activating bradykinin is unknown. Likewise, other substances associated with inflammation, such as prostanoids and cytokines, have similar neuromodulatory effects and the spinal administration of prostaglandin receptor agonists such those associated with PGE2, PGD2, or PGI2 leads to hypersensitivity. Prostaglandin receptor activation may require other receptors for full expression of sensory phenomena as appears to be the case for PGE2 which needs an intact NMDA receptor and PGD2 which requires intact NK1 receptors. Cytokines such as IL-1B, IL-6, and tumor necrosis factor-α, which are released by activated microglia and other neuroimmunological cellular components of the CNS following nerve injury, have also been appreciated as having neurotoxicity effects on nociceptive neurons that involve purinergic mechanisms.[52,53] Growth factors such as nerve growth factor (NGF), glial-derived neurotrophic factor (GDNF), and brain-derived neurotrophic factor (BDNF) may come from multiple sources, including neural structures, and

have obvious effects on central nervous system systems producing trophic and potentially phenotypic changes with resulting actions on pain-related structures.[54–56]

Other Important Receptors/Channels

Consideration needs to be given to the presence of receptors or channels that are either "universal" in that their pharmacological modulation seemingly affects all spinal cord neurons in a relatively nondiscriminative fashion or "selective" in that they are present in a subset and/or sub-site of neurons such as the end terminals of primary afferent neurons. A particular group of ion channels that are in the *selective* group are the N-type calcium channels found on primary afferent neurons.[57] Calcium influx into the intercellular space due to receptor activation (ligand-gated) or due to membrane depolarization (voltage-gated) results in both membrane depolarization effects and second messenger cascade activation. In primary afferents, this calcium influx is associated with the release of neurotransmitter at synapses. There exist at least 5 families of voltage-gated channels (L, N, P/Q, R, and T) with differing pharmacologies and localization within the spinal cord. Some of the families share auxiliary subunits such as the L- and N-type channels which both have an $\alpha 2\delta$ subunit. This subunit is the site to which the drugs gabapentin and pregabalin bind with a subsequent reduction, but not abolition of membrane excitability. The N-type calcium channels are located throughout the CNS, but at a spinal cord level have particular localization to the nerve terminals of small diameter primary afferents. The ω-conotoxin ziconitide binds to and blocks ion flow through this channel and has found clinical utility in the control of pain when administered intrathecally.

WHAT IS IMPORTANT TO THE CLINICIAN

The substrates of nociception that exist at a spinal level are as complex as the phenomenon of pain itself. More than 30 different neurotransmitters acting at more than 50 different receptors have been identified as present in the spinal cord and associated with some pain-related phenomenon. Sensory pathways connecting the spinal cord to the brain have been identified that result in rapid transmission of information that is highly organized and site-specific but similar pathways have also been identified which have slow transmission that is poorly organized and therefore resistant to attempts at ablation. The clinician must synthesize these diverse pieces of information into a general model of nociceptive processing and must accept that, at this point in time, the model is incomplete. The effectiveness of therapeutic interventions intended to treat pain is dependent on the modulation of these substrates of nociception which forms the topic of the next chapter.

CHAPTER 5 ■ MODULATION OF SPINAL NOCICEPTIVE PROCESSING

ALAN RANDICH AND TIMOTHY NESS

INTRODUCTION

The preceding chapter addressed the neuroanatomy and neurochemistry of neurons located within the spinal cord that process information related to pain-related sensation. These neurons are highly regulated components of the central nervous system (CNS) with inhibitory and excitatory feedback mechanisms. Pain may be a result of a failure of feedback regulation as much as it can be due to increased primary afferent input. Too much "gain" or inadequate "braking" can result in an excess of sensory transmission. In the normally functioning state, the responses of second order neurons can be suppressed or facilitated dependent on other events important to the organism. Some modulatory effects are relatively "hardwired" occurring in a reliable and predictable fashion. Other modulators are less predictable and may be dependent on psychic/cognitive processes that vary from organism to organism and may involve learning, motivation, or emotional factors. In most cases, modulatory systems are adaptive in that they help an organism to function optimally. Unfortunately, with disease, some of these same modulatory systems have become maladaptive and serve to impede both physiological and social processes of healing. The complex nature of these modulatory influences will be discussed in three parts beginning with a discussion of mechanisms based at spinal levels, followed by a discussion of mechanisms related to descending influences, and finally by a discussion of three particular "triggers" that may occur pathologically and/or iatrogenically: inflammation, nerve injury, and chronic opioid treatment. These triggers will be used as examples of the interactive nature of these modulatory forces. There is value in understanding endogenous modulatory systems because they are the systems which the clinician activates or suppresses by using exogenous modulators, such as electrical stimulation or pharmacological agents. Modulation occurs at each step of processing within the CNS, but the focus of the present discussion will be the modulation of the spinal second order nociceptive neuron.

SPINAL CORD-BASED MODULATORY MECHANISMS

Acute Segmental Modulatory Effects

Sensory inputs to the spinal cord and trigeminal nucleus begin to interact at the very first steps of transmission. Activation of

large diameter afferents (Aβ) produces an inhibitory effect on the processing of signals from small diameter (Aδ & C-fiber) afferents. This effect has been documented since ancient times and is relearned by every child who rubs or massages injured parts of their bodies in order to achieve pain relief. The mechanism of this manipulation has been more difficult to explain than the time-honored efficacy of the effect.[1] What is clear is that second order neurons of the spinal cord have both excitatory and inhibitory "receptive fields." Namely, stimulation of different parts of the body using one or more types of stimuli (e.g., noxious heat, low threshold mechanical, high threshold mechanical) results in the depolarization or hyperpolarization of individual second order neurons. Inhibition of second order neurons which is produced by noxious stimuli can be evoked from heterosegmental sites and so is discussed separately later. Inhibition of second order neurons which is produced by nonnoxious stimulation appears to be predominantly segmentally organized. Theoretically formulated as the initial Gate Control Theory of Melzack and Wall,[2] this effect was hypothesized to occur because of a combination of presynaptic inhibition and the actions of inhibitory interneurons located in lamina II (substantia gelatinosa) of the spinal cord which are activated by large diameter afferents (Fig. 5.1). Although the specifics of this theory have evolved further to include nonsegmental effects, its general description has served as the theoretical underpinnings for the clinical effects of neuromodulatory (electrostimulatory analgesic) techniques ranging from transcutaneous electrical nerve stimulation to spinal cord stimulation and aspects of acupuncture.

Numerous electrophysiological studies of second order neurons have observed that low intensity, high frequency electrical stimulation of nerves or somatic tissues located at the same segmental level as the neuron produces an inhibitory effect which is not reduced by naloxone (nonopioidergic) but which may involve GABAergic or glycinergic mechanisms. This phenomenon is present in both spinally transected and intact animals and so does not necessarily involve a brainstem mechanism. Dorsal column stimulation which produces retrograde activation of Aβ-fiber inputs to the spinal cord (but may also activate descending modulatory pathways) produces similar nonopioid, GABAergic, and/or glycinergic inhibition of spinal nociceptive processing.

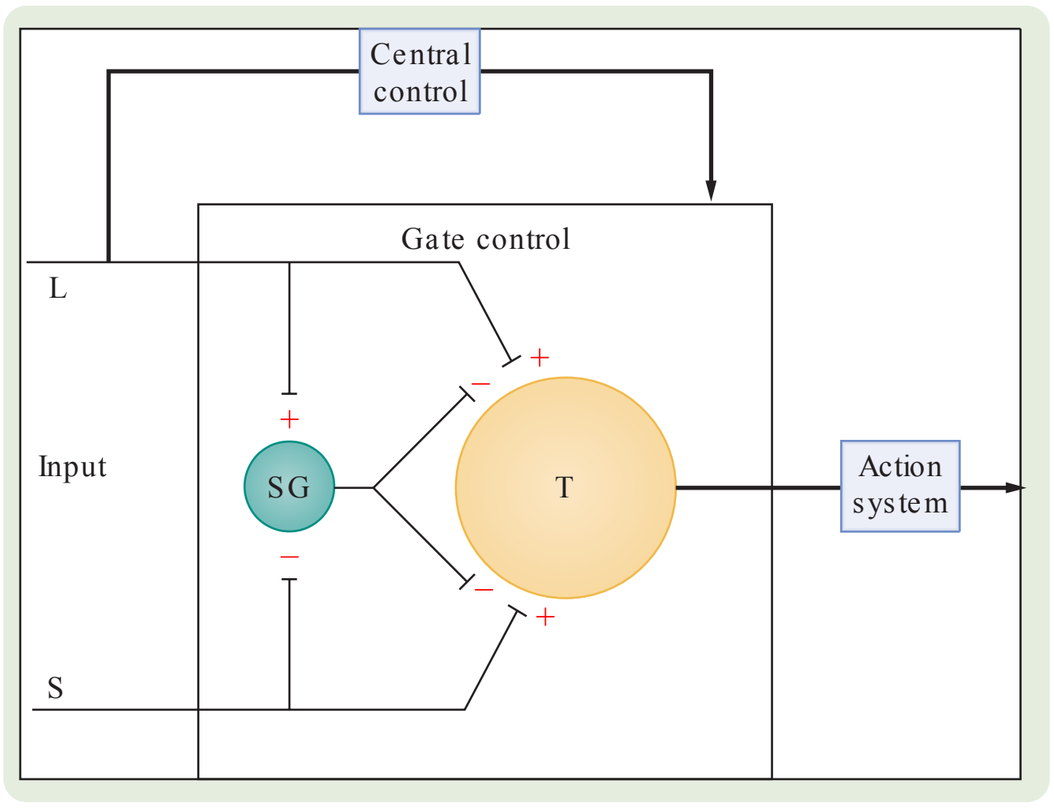

FIGURE 5.1 Gate control theory as originally schematically described by Melzack and Wall[2] where large-diameter (L) and small-diameter (S) primary afferent fibers project to substantia gelatinosa (SG) and second order transmission (T) neurons in the spinal dorsal horn. The inhibitory effect of SG neuronal activity is increased by L and decreased by S fiber activity. T neurons transmit information to the brain and other action sites. Activation of peripheral or central projections of L fibers using transcutaneous nerve stimulation, peripheral nerve stimulators, or dorsal column stimulators would all be expected to produce inhibition of S fiber input to the T cells.

Heterosegmental Modulatory Systems

Both excitatory and inhibitory effects can occur at one spinal level when stimuli are presented to distant portions of the body. Excitatory effects have generally been described in imprecise terms as "extended connectivity" or as "propriospinal" pathways. Some of these intraspinal networks serve to integrate both sensory and motor functions involving the upper and lower extremities with an example being crossed flexion-extension reflex responses to noxious stimuli. A coordination of pelvic organ function also relies on intraspinal excitatory and inhibitory connections that link processing of sensory information from afferents traveling in the pelvic nerve to the lumbosacral cord with that of afferents traveling in sympathetic nerves to the thoracolumbar spinal cord.[3,4] Intraspinal networks of neurons which form a reticular webwork in the deeper parts of the spinal dorsal horn have been described in the context of the multisynaptic ascending system of Noordenboos.[5] This same network could just as easily serve as the substrates for multisynaptic descending modulatory influences.

The most formally studied heterosegmental interaction related to nociception is the phenomenon known as diffuse noxious inhibitory controls (DNIC). This endogenous inhibitory system is activated by heterosegmental noxious stimuli which produce an inhibition of ongoing or evoked dorsal horn neuronal activity. The mechanisms of DNIC are postulated to involve the activation of brainstem nuclei that subsequently produce inhibition of spinal dorsal horn neurons through a descending modulatory mechanism, but it is notable that the neurophysiological phenomena associated with DNIC have been demonstrated in spinally transected preparations. These "propriospinal" phenomena represent a general inhibitory system activated by heterosegmental noxious conditioning stimuli which is either synonymous with or highly augmented by the presence of a brainstem and mechanisms of DNIC. According to its original description by Lebars et al.,[6,7] DNIC results in the inhibition of Class 2 (wide dynamic range; convergent) neurons and has no effect on Class 3 (nociceptive specific) neurons. A consistency of many studies related to DNIC (and propriospinal heterosegmental inhibition) is that they have identified that most spinal neurons responsive to noxious stimuli effectively have "total body" receptive fields in that noxious stimuli will produce excitation or inhibition that is dependent on precise body site.[8]

C-fiber Windup and Central Sensitization

Changes in excitability occur in second order neurons when repetitive or prolonged high intensity input is received from primary afferent C-fibers. One of these changes in excitability is termed C-fiber "wind-up." Noted by Mendell[9] when recording from ascending axons of spinal dorsal horn neurons, wind-up is the phenomenon whereby repeated electrical C-fiber activation at certain rates (i.e., ≥1 Hz) leads to a sequential increase in the number of action potentials evoked by each stimulus (Fig. 5.2). Slower stimulus rates do not produce progressive increases in activation. Mechanical and thermal stimuli at intensities sufficient to activate C-fibers also produce similar wind-up. This sequential increase in response can be blunted through use of N-methyl-D-aspartate (NMDA) receptor antagonists and the effect disappears after a few seconds of nonstimulation.

Another general category of increased neuronal excitability is termed "central sensitization." This term has been used in a focused manner to describe acute changes in the responsiveness of

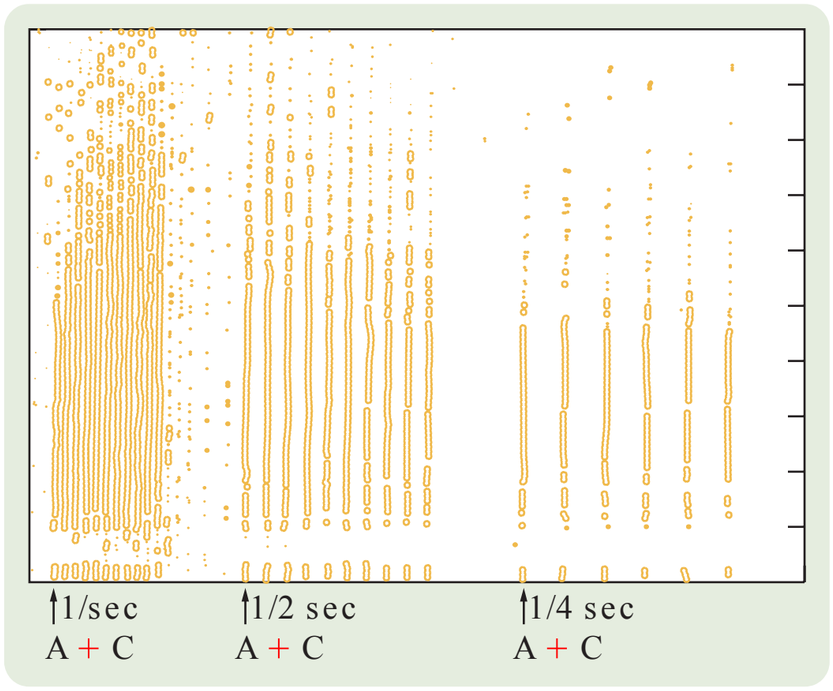

FIGURE 5.2 Wind-up responses of single dorsolateral column axon to repeated stimulation of the sural nerve at sufficient intensity to activate A and C fibers (no wind-up seen with A-fiber stimulation by itself). The vertical time markers on the far right represent 100 msec. Each mark at the bottom of the time line represents the stimulation artifact and the burst of activity immediately above each of these stimulations is the response to A-fiber stimulation (each dot represents an action potential). The more delayed responses are to the more slowly conducting C-fiber inputs. Response to stimulation shows increasing C-fiber wind-up responses on to 1 per second stimulation (not to 1 every 2 or 1 every 4 second stimulation rates at right). Wind-up lasts for only several seconds following the stimulation as seen by transient increase in spontaneous activity. (Redrawn from Mendell LM. Physiological properties of unmyelinated fiber projections to the spinal cord. *Exp Neurol* 1966;16:316–332.)

second order neurons following high intensity or prolonged stimuli such as occur with nonneuronal tissue injury and subsequent inflammation. The term has also been used to describe phenomena such as delayed-onset nerve injury-related hypersensitivity and, in that case, is more subacute or chronic in nature with a potential for morphological as well as biochemical alteration. For purposes of the present discussion, injury-induced central sensitization as described by Woolf[10] will be used as the archetype model of central sensitization (Fig. 5.3). Multiple studies have demonstrated that tissue injury produces an augmentation of nociceptive reflexes that is NMDA receptor dependent. In preclinical models, pharmacological treatment has the greatest effect if given prior to injury and a blocking of afferent input serves to delay the onset of development of hypersensitivity. Extrapolating from this data and coupling it with evidence of long-term potentiation (LTP) of synaptic efficacy in the spinal cord after even brief bouts of NMDA receptor activation,[11] some have further extrapolated these laboratory data to the clinical concept of "preemptive analgesia." Treating pain before (and after) it begins has a clear potential for clinical benefit although the true clinical significance of early intervention has proven difficult to define. On a neurophysiological basis, an expansion of cutaneous excitatory receptive fields has been noted following tissue injury which follows a similar pharmacology, but specific results have been model and species dependent.

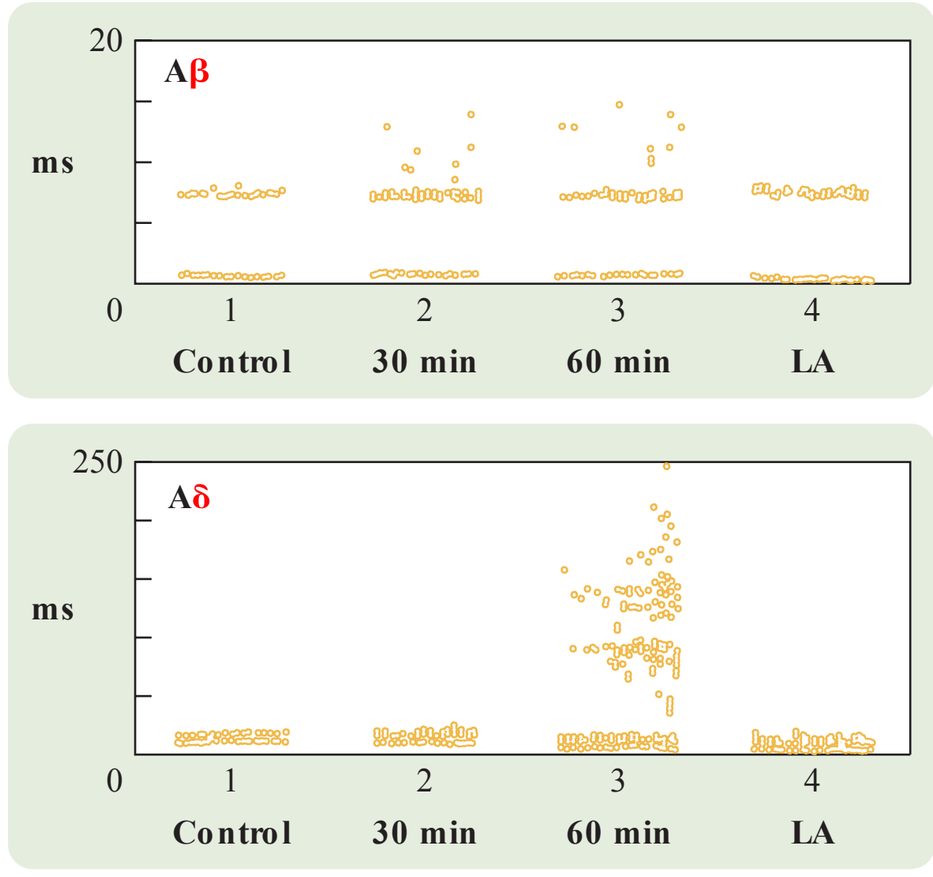

FIGURE 5.3 Raster dot displays of a single biceps femoris unit activated by stimulation of the sural nerve once every 2 seconds before an ipsilateral thermal injury (Control), 30 and 60 minutes postinjury, and 10 minutes after the injured foot has been completely anesthetized with local anesthetic (LA). Each dot represents a unit discharge. The vertical scale is the latency of the responses after sural nerve stimulation, and the stimulus artifact can be seen at time 0. Stimulation strengths were sufficient to activate Aβ, Aδ, and C-fibers. Note the different time scales used in the three panels to record the activity evoked by the three different fiber populations. In the preinjury state, only Aβ input was evoked. Thirty minutes after injury, a C-fiber response begins to occur; whereas, at 60 minutes both Aδ and C-fiber evoked responses are present (the C-fiber responses with wind-up). Ten minutes after LA, the C-fiber evoked responses remain higher than before the injury suggesting a central component of the sensitization. (Redrawn from Woolf CJ. Evidence for a central component of post-injury pain hypersensitivity. *Nature* 1983;306:686–688.)

SUPRASPINAL MODULATORY SYSTEMS

Tonic Descending Inhibition

A characteristic of spinal nociceptive systems is that they are under tonic descending inhibition such that a common effect of injury to spinal pathways is a release from this inhibition. Hyperreflexive states with secondary spasticity and autonomic lability can occur. The precise neurophysiological circuits associated with this descending inhibition is of significant debate, but known inhibitory neurotransmitters such as norepinephrine (NE) and serotonin (SHT) are synthesized in the brainstem and transported to the spinal cord from multiple supraspinal sites. This role for supraspinal structures in providing descending influences on spinal reflexes has long been recognized. In 1915 Sherrington and Sowton[12] demonstrated enhanced flexion reflexes following spinal transaction. Later in 1926, Fulton[13] suggested that this effect reflected removal of tonic descending inhibitory modulation of spinal interneurons mediating those reflexes. Descending

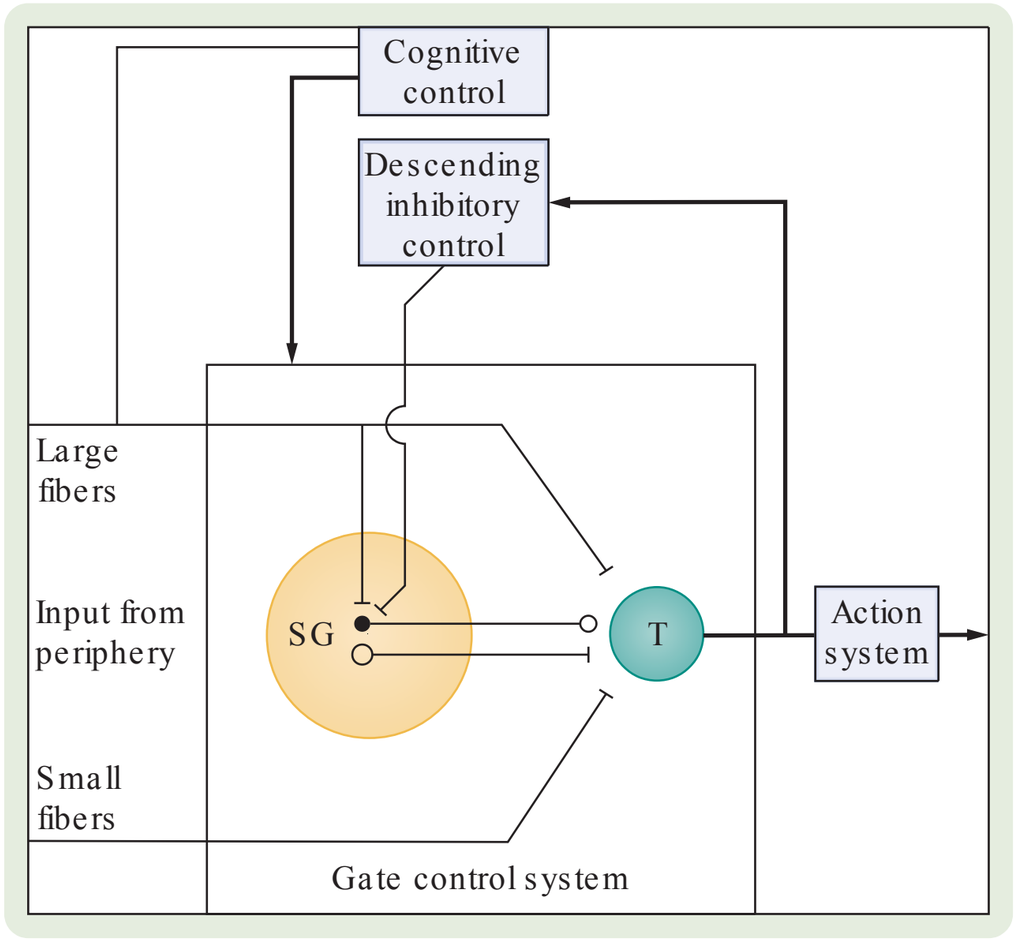

FIGURE 5.4 A modification of the gate control theory schematic models includes excitatory (*white circle*) and inhibitory (*black circle*) links form the substantia gelatinosa (SG) to the transmission (T) cells, as well as descending inhibitory control from brainstem systems. The round knob at the end of the inhibitory link indicates that its actions may be presynaptic, postsynaptic, or both. All connections are excitatory except the inhibitory link from SG to T cells. (Redrawn after Melzack R, Wall PD. *The Challenge of Pain*. New York: Basic Books; 1983.)

control of flexion reflexes was extensively studied in ensuing years,[14] but these studies did not target the issue of how the brain might specifically modulate incoming nociceptive signals from peripheral tissue.

A series of seminal events in the late 1960s and early 1970s led to a full-fledged appreciation and analysis of descending modulation of spinal nociceptive processing. These included a modification of the original Gate Control theory to include supraspinal systems (Fig. 5.4). This change was prompted by studies which showed that spinal dorsal horn neurons were subject to tonic descending inhibitory influences[15] and Reynolds' demonstration that electrical stimulation of the midbrain periaqueductal grey (PAG) produced analgesia sufficient to perform abdominal surgery in a rat.[16] This last phenomenon was referred to as "stimulation-produced analgesia" (SPA).[17,18] SPA can also be produced in humans[19] and it suggests the existence of endogenous systems that can selectively modulate pain. This served as the impetus for the extensive, formal analyses of supraspinal structures involved in descending modulation of spinal nociceptive processing that ensued during the next 35 years. Later, a number of investigators found that electrical or chemical stimulation of other brain regions could also promote *facilitation* of nociceptive processing,[20,21] suggesting the existence of similar descending facilitatory systems.

Brainstem Substrates Mediating the Descending Modulation of Pain

The midbrain PAG and the medullary nucleus raphe magnus (NRM) figured prominently in the original analyses of descending modulation of pain. Indeed, they are often viewed as the "backbone" of the pain modulatory system[22] and have been more extensively studied than any other brain regions. Yet, other brainstem nuclei/cell groups also serve in this role and include the nucleus gigantocellularis (NGC), nucleus reticularis gigantocellularis pars alpha (NGCα), midbrain reticular formation, locus coeruleus/A6 cell group (LC/A6), lateral reticular nucleus (LRN), parabrachial/A7 and A5 cell groups, and the nucleus tractus solitarius (NTS). A limited amount of information has also become available on cortical and diencephalic systems that contribute to descending modulation. It is the investigation of these structures that has led to our current understanding of how descending pain modulatory systems affect pain perception. Each is described separately below and a summary of the most important components is described in Figure 5.5.

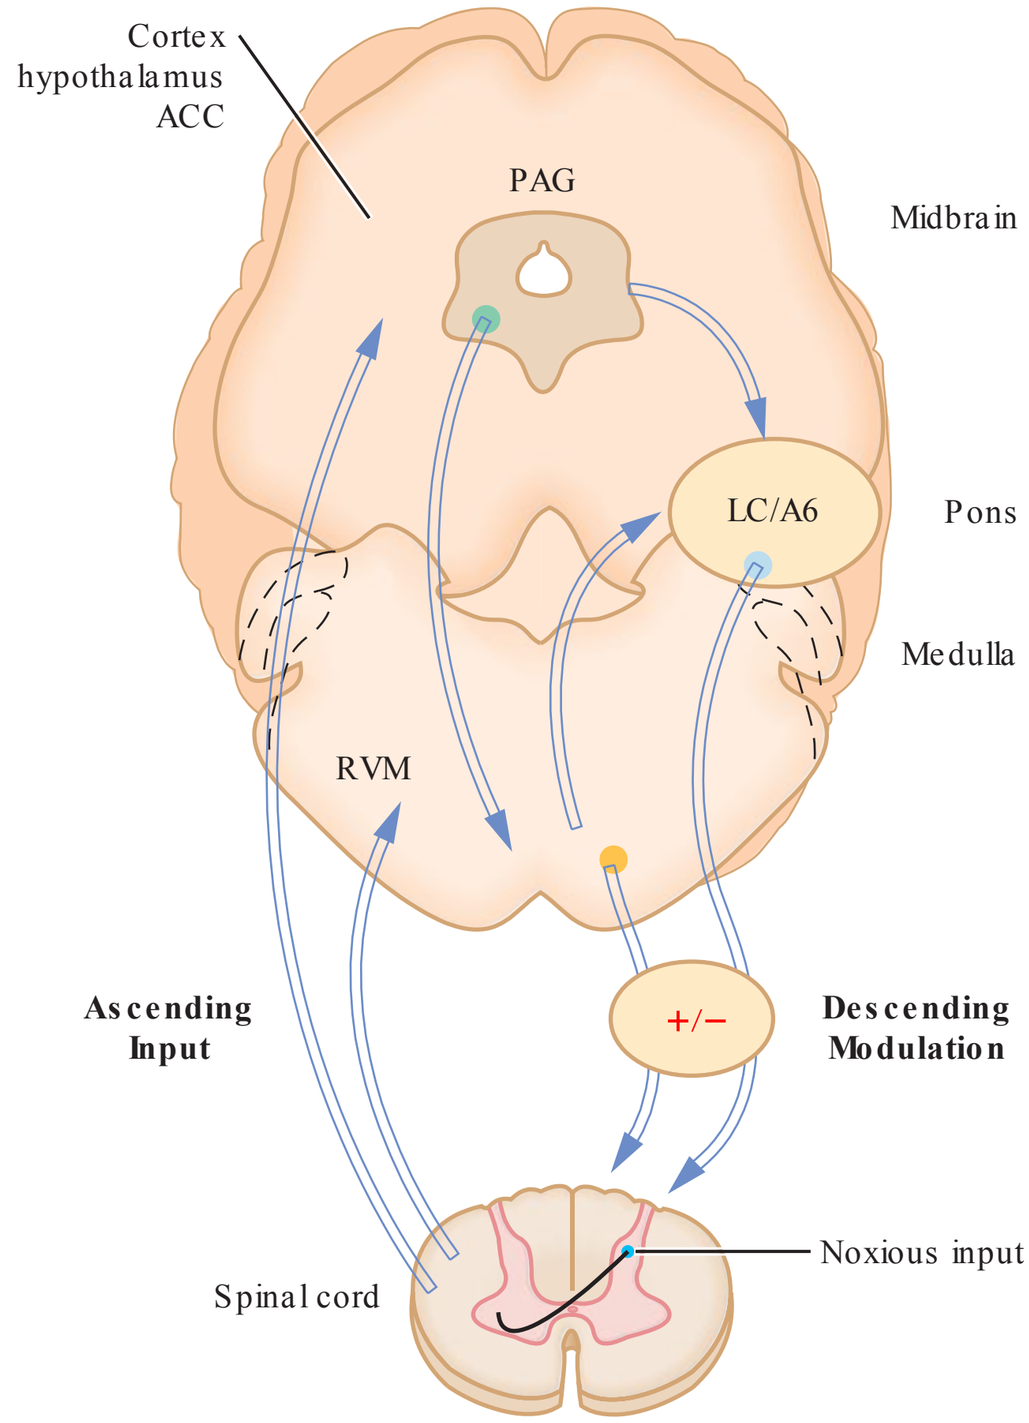

FIGURE 5.5 Schematic diagram of descending modulatory influences of spinal nociceptive processing. Multiple sites within the brain have been demonstrated to be of importance including the midbrain periaqueductal grey (PAG), locus coeruleus/A6 cell group (LC/A6), and the rostral ventromedial medulla (RVM). These sites are reciprocally interconnected, are activated by ascending nociceptive information, and serve as relays for other brain sites known to modulate spinal processing including the anterior cingulate cortex (ACC), other cortical sites (somatosensory, motor, insular, ventrolateral orbital), and the hypothalamus. Resultant modulatory effects on spinal dorsal horn processing can be inhibitory (−) or facilitatory (+) to nociceptive primary afferent input.

Periaqueductal Grey of the Mesencephalon

The PAG was the initial site of investigation for endogenous pain control systems and is still viewed as an integral component of these systems. Early studies of the PAG provided some evidence that the effects of SPA from this region were limited to nociceptive processing and could not be explained by more gross stimulation-produced deficits in sensory or motor function. Fardin et al.[23,24] performed an exhaustive analysis of the PAG of the rat and showed that a "pure" antinociceptive effect (i.e., with no side

effects) could only be derived from sites of stimulation located in the ventrolateral and ventromedial regions of the PAG. Stimulation in other more dorsal sites could produce antinociception, but often occurred in conjunction with aversive reactions (vocalizations, flight, jumping), gnawing, rotation, and/or tremor. Other investigations suggested that while the primary effects of PAG stimulation indeed were on spinal and trigeminal nociceptive processing, it could also inhibit responses of nonnociceptive neurons in dorsal column nuclei (DCN) and low threshold neurons in the trigeminal nucleus caudalis.[25]

Antinociception produced by SPA from the PAG is profound and comparable to that produced by a high dose of morphine. It eliminates behavioral and spinal dorsal horn neuronal responses to noxious stimuli including electric shock applied to the tooth pulp or limbs, noxious heating of the tail and hind paws, noxious pinching of the limbs, and injection of irritants into the viscera. The effects of SPA are produced almost immediately after the onset of stimulation and may last from a few seconds to hours after termination of stimulation. Microinjection of opiates into the PAG also produces behavioral antinociception and inhibition of spinal nociceptive transmission[26,27] via disinhibition of inhibitory interneurons in the PAG. The subsequent discovery of endogenous opioid receptors[28] and peptides[29–31] and demonstration of the presence of opioid receptors in the PAG[32] further established a role for the PAG in pain modulation. Similarities were also observed between phenomena associated with PAG-derived inhibitory effects and opiate-induced analgesia, including tolerance and cross tolerance[33] and reversibility by the opiate receptor antagonist naloxone,[34,35] although the latter finding was not confirmed by all laboratories.[36] SPA and morphine induced antinociception from the PAG also involve a spinal release of 5-HT and NE, and mediation by both spinal 5-HT receptors and α_2 adrenoreceptors.[37–39] The resultant summary of these studies is that the PAG represents a brain site that provides descending influences on spinal and trigeminal nociceptive processing, utilizes several neurotransmitters in the production of their effects, can mediate the analgesic actions of exogenous opiates, and leads to multiple spinal neurochemical alterations.

Nucleus Raphe Magnus/Rostral Ventromedial Medulla

Anatomical studies reveal relatively few fibers that descend from the PAG directly to the spinal cord.[40] However the PAG does have strong projections to the NRM and adjacent areas of the rostral ventromedial medulla (RVM). Attention has therefore been focused on the NRM as the primary relay in mediating the antinociceptive effects of activation of PAG neurons. Studies of the NRM were performed in a manner analogous to those performed in the PAG, and often with comparable results.[40,41] Electrical stimulation of sites within the PAG or NRM produces inhibitory postsynaptic potentials (IPSPs) in dorsal horn neurons including those with ascending projections.[42] Acetylcholine (Ach), 5-HT, and NE all are implicated in mediating these effects in both trigeminal and spinal regions.[43] Electrical stimulation of the NRM produces strong antinociception that can be reversed by either naloxone[44] or intrathecal 5-HT receptor antagonists or α_2 adrenoreceptor antagonists.[45] Glutamate microinjection in either the NRM or adjacent NGCα produces antinociception[46,47] supporting the view that cell bodies located in these regions are responsible for producing the antinociception. The antinociception derived from the NRM, but not the NGCα, could be blocked by intrathecal administration of a δ2 opioid receptor antagonist[48] confirming possible involvement of spinal opioid systems.

Electrical and chemical stimulation of the NRM inhibits responses of spinothalamic tract cells to noxious inputs in monkeys. Lesions of the dorsolateral funiculi (DLFs) of the spinal cord eliminate this inhibition and so this white matter pathway has been viewed as the primary spinal locus for descending fibers from the NRM.[49] Ventrolateral funiculi (VLFs) have also been implicated as the spinal pathways by which descending systems access the spinal dorsal horn but there is greater evidence for these descending paths to promote facilitatory influences as opposed to inhibitory influences.

NRM neurons responsible for producing spinal mechanisms of antinociception may be part of a direct raphespinal system, but NRM neurons also relay to secondary sites in the brain prior to joining other descending systems to the spinal cord. Inhibitory effects from the NRM/RVM can be antagonized by systemic or intrathecal administration of not only 5-HT antagonists, but also NE antagonists and GABA antagonists. For example, SPA from the NRM and the nucleus reticularis paragigantocellularis (NRPG) can be attenuated by either intrathecal administration of the nonspecific 5-HT receptor antagonist methysergide or the NE antagonist phentolamine.[50,51] Antinociception produced by microinjection of morphine in the NRM is blocked by either systemic naloxone or a 5-HT receptor antagonist.[52] While some investigators viewed the NRM and NRPG as functioning separately in pain suppression, Hammond and Yaksh[51] argued against a selective involvement of 5-HT and NE bulbospinal systems in SPA derived from the NRM and NRPG, respectively. NRM innervation of the A7 cell group could explain the NE component of inhibitory influences produced by activation of NRM cells, and although sparser connections exist to A5 and A6 regions, both support antinociception.[53]

Detailed electrical stimulation mapping and intensity studies of the RVM, and the NGC and NGCα in particular, reveal that these regions not only support inhibition of nociceptive reflexes, but also facilitation or enhancement of those reflexes under certain conditions.[21] Inhibition of the tail flick reflex has been observed in the majority of sites tested, particularly in the NRM, and ventral and lateral regions of the NGC and NGCα, but a substantial number of other sites, located primarily in the NGCα or more dorsally, supported facilitation of the tail flick reflex at lesser intensities of electrical stimulation. In most cases, facilitatory effects were supplanted by inhibitory effects at a given site of stimulation when greater intensities of electrical stimulation were examined. The results of behavioral studies were paralleled by in-depth analyses of the effects of either electrical stimulation or glutamate microinjection into the NGC and NGCα on spontaneous activity and noxious heat-evoked activity of spinal dorsal horn neurons. The results are generally comparable in nature. Electrical stimulation or glutamate microinjection produce only spinal inhibitory effects at most sites or biphasic effects (i.e., facilitatory effects at low intensities of stimulation and inhibitory effects at greater intensities of stimulation) at most of the remaining sites. Facilitatory effects are observed as a parallel leftward shift in the stimulus-response functions (SRFs) to graded heat, whereas inhibition is manifested as a rightward shift or a decrease in the slope of the SRF to heat. Inhibitory effects were also bilateral, such that unilateral and bilateral transactions of the DLFs both had an influence on descending inhibitory effects in the rat, as was shown previously for the NRM in behavioral studies. However, DLF transections did not affect facilitatory effects in the rat, presumably because the descending systems responsible for facilitation traveled in the ventrolateral funiculi (VLFs). Cumulative sum analyses, which are used to determine how rapidly an effect occurs, revealed that the latency for inhibitory effects was much shorter (approximately 80 msec) than facilitatory effects (approximately 231 msec) derived from the RVM.

These outcomes, in conjunction with the behavioral studies, reinforced the notion that that activation of cell bodies in the NGC/NGCα can produce direct descending inhibitory effects via pathways traveling in the DLFs, but that the facilitatory effects required at least another relay prior to passage in the VLFs of the spinal cord.[54] Electrophysiological studies performed in monkeys

have been generally consistent with studies in rodents with a few exceptions.[20] Specifically, electrical stimulation of the NGC has been shown to either inhibit or facilitate spinothalamic projection neurons in the lumbosacral or cervical regions of primates. These effects are somewhat preferential for nociceptive input, but responses to all types of stimuli, including nonnoxious stimuli, were affected. There was no obvious topographic organization of sites in the NGC that supported inhibition or facilitation. Unlike studies in rat, both inhibitory and facilitatory influences in primates are apparently unaffected by lesions of the DLFs.

In the rat, facilitation involving descending projections in the VLFs was mediated by spinal 5-HT_1 receptors[55] and cholecystokinin $(CCK)_B$ receptors, whereas inhibition involved descending projections in the DLFs and spinal cholinergic and monoaminergic receptors.[54,56–58] In a series of studies, Urban and colleagues[57,58] reported that low dose neurotensin microinjected in the RVM facilitated nociceptive reflexes and responses of spinal dorsal horn neurons to noxious thermal stimuli, but high doses of neurotensin inhibited spinal nociceptive processing. Urban and Gebhart[57] found that a neurotensin receptor antagonist SR48692 was able to block the high-dose inhibitory, but not the low-dose facilitatory effects of neurotensin administration in the NRM. Neubert et al.[59] then showed that microinjection of low doses of neurotensin in the RVM selectively activated subpopulations of medullary neurons and facilitated the paw withdrawal response to noxious heat. Recent evidence[60] indicates that the activation of the NT receptor subtype 1 (NTR1) is responsible for producing facilitatory effects and is mediated by spinal release of both NE and 5-HT, whereas activation of the NT receptor subtype 2 (NTR2) produces antinociception and is mediated by spinal release of NE. The source of endogenous neurotensin to the RVM is not known, but may include the PAG, nucleus cuneiformis, PB, and/or the NCPG.

Brain-derived neurotrophic factor (BDNF) also may be part of the PAG-RVM facilitatory network. Guo et al.[61] reported that microinjection of BDNF in the RVM facilitated the paw withdrawal response to noxious heat and this effect was blocked by administration of AP5, suggesting mediation by NMDA receptors (NMDARs). They also showed that a BDNF efferent projection exists from the ventrolateral PAG to the RVM, PAG stimulation releases BDNF in the RVM, and PAG stimulation activates TrkB and its signaling cascade and produces facilitatory effects. However, this pathway does not appear to be tonically active and may be a system reactive to tissue injury. Specifically, peripheral inflammation increased levels of both BDNF in the PAG and TrkB in RVM neurons, and sequestration of BDNF and RNAi of TrkB in the RVM suppressed the inflammatory hyperalgesia. Finally, CCK release in the RVM may also play a significant role in producing pronociceptive influences and may play a unique role in mediating "antiopioid" effects and opioid tolerance.

Locus Coeruleus

Using the nomenclature of Dahlstrom and Fuxe[62] the noradrenergic nuclei of the central nervous system are designated as "A" nuclei numbered in ascending order from the caudal medulla near the lateral reticular nucleus (A1) to the lateral pons near the parabrachial nucleus (A7). One of the most important of these nuclei is the A6 nucleus which colocalizes with and is also ventral to the morphologic structure, the locus coeruleus (LC). This area has extensive direct axonal projections to the spinal cord. Electrical stimulation or glutamate microinjection in the LC/A6 region produces antinociceptive effects in animals. These treatments generally inhibit reflex responses to noxious somatic stimuli, noxious colorectal distention, and responses of both trigeminal caudalis and spinal dorsal horn neurons to noxious stimuli in the rat.[63–68] The LC in rats and primates is composed primarily of NE-containing neurons[69] which provide most of the noradrenergic innervation of the spinal cord[70] and stimulation of the LC results in spinal release of NE.[71] The descending fibers mediating the antinociception travel in the ventrolateral funiculi. The spinal inhibitory effects related to LC stimulation are primarily mediated by spinal α_2 adrenoreceptors[63] and the α_{2A} subtype may be critical. α_{2A} adrenoreceptor labeling is heavy throughout the spinal dorsal horn[72] and immunohistochemical studies show localization on terminals of capsaicin-sensitive, substance P containing primary afferents.[73] Spinal administration of α_2 adrenoreceptor agonists, and particularly those with an affinity for the α_{2A} subtype, produce antinociception in a wide variety behavioral assays of both somatic and visceral nociception.[74] There is some evidence that the α_{2C} receptor also may play a role in mediating the antinociceptive effects of adrenoreceptor agonists under conditions of neuropathic pain,[75] but this may be specific to that state and not normal pain modulation.[76] The effects of LC/A6 descending inhibition are independent of midbrain or medullary mediation, although the reverse is not necessarily true.

Parabrachial Nucleus/A7/Kölliker-Fuse Area

The parabrachial nucleus (PB) and adjacent A7/Kölliker-Fuse area has also been examined in relation to descending pain modulation. The Kölliker-Fuse nucleus, which is lateral and ventral to the LC, is the principal source of descending NE-containing fibers in the cat and may play a comparable role to that of the LC noted above for rat and primate.[77] The parabrachial nucleus (PB) has long been known for its role in respiratory and cardiovascular function, taste and aversions, locomotion, and sleep. However, the PB, the Kölliker-Fuse nucleus, and nucleus cuneiformis may all have particular relevance to descending modulation of nociception.

Unilateral electrical stimulation of or glutamate microinjection into the A7 cell group produces antinociception; for example, as indexed by bilateral increases in paw withdrawal responses to noxious heat, although it is generally more effective on the side ipsilateral to the stimulation site.[78] A7-mediated antinociception can be significantly reduced or abolished by intrathecal administration of nonselective α adrenergic receptor antagonists or selective α_2 adrenergic receptor antagonists. NE containing neurons in the A7 cell group project via the DLFs to terminate primarily in the ipsilateral spinal dorsal horn[79] and it is likely that these descending pathways mediate the effects of A7 stimulation, rather than relaying to other NE-containing cell groups in the brainstem. It is also likely that some antinociceptive effects derived from activation of RVM neurons are relayed to the A7 NE-containing neurons to produce their effects in conjunction with direct descending influences from the RVM. Similarly, the antinociceptive effects of SPA derived from the ventrolateral PAG may be mediated, in part, by direct projections to the A7 cell group[80] which then send their projections to the spinal cord.

Electrical stimulation in or glutamate activation of the PB inhibits nociceptive responses of trigeminal neurons,[81] although these effects have also been observed in neurons responsive to low threshold mechanical input. Occasional facilitation of nonnociceptive and nociceptive response of trigeminal nociceptive neurons when stimulating in the PB has also been observed. These facilitatory effects may bear on those described previously in the RVM, but have not been systematically studied. The PB has few direct projections to spinal cord but has connections with PAG, NRM, nucleus paragigantocellularis, and the ventrolateral medulla.

A5 Cell Group

Electrical stimulation of the region of the A5 cell group in the ventrolateral pons produces antinociception that can be antago-

nists.[82,83] The A5 cells project to the spinal cord, although their overall contribution to the total NE innervation of the spinal cord is relatively small, and A5 neurons may exert their effects primarily on lamina X neurons.[84] Afferents to the A5 cell group arise from the RVM, NTS, LC, dorsal raphe and lateral hypothalamus, and these regions are innervated by ascending fibers from the spinal cord. SPA derived from the ventrolateral PAG may be mediated by direct projections to the A5 cell group.[80]

Lateral Reticular Nucleus

The LRN is a bilateral structure located in the ventrolateral medulla (VLM) and lies in close proximity to the A1 (norepinephrine-containing) and C1 (epinephrine-containing) cell groups. Electrical and glutamate stimulation of the LRN inhibits spinal nociceptive reflexes and responses of spinal dorsal horn neurons to noxious stimuli.[85–87] These effects can be antagonized by spinal administration of α_2 receptor antagonists.[87] The involvement of spinal adrenoreceptors in these antinociceptive effects suggests that the LRN relays to a NE containing cell group to produce these outcomes because little or no NE-containing fibers descend from the LRN. The A5 or A7 regions may be involved in this mediation since local anesthetic blockade of the LC does not affect antinociceptive effects of LRN activation.[86] The descending inhibitory effects of LRN activation are mediated by fibers traveling in the DLFs, not the VLFs, again suggesting potential involvement of A5 or A7 cell groups rather than the A6 cell group. The LRN is also innervated by the PAG, parabrachial nucleus, LC, and NRM regions suggesting complex reciprocal interactions exist between all these regions. The LRN has also played a role in the issue of tonic descending inhibitory influences on spinal nociceptive function. It was suggested that the LRN was the primary source of tonic descending inhibitory influence based on lesions studies of the cat but these outcomes were not reproduced in studies of the rat.[85,86]

Nucleus Tractus Solitarius

Several studies have demonstrated that the NTS is a region that is both capable of modulating pain and may serve as a relay site for peripheral cardiopulmonary afferent influences on nociception. Electrical stimulation of the NTS inhibits the nociceptive tail flick reflex evoked by noxious heat[88–90] and inhibits noxious heat-evoked, pinch-evoked, and C-fiber evoked responses of spinal dorsal horn neurons in rat and cat.[91,92] Systematic mapping studies indicated that lateral sites within the NTS supported antinociception, while medial sites evoke motor responses.[90,91] Glutamate microinjection in caudal, but not rostral, NTS produces antinociception[93] and inhibits responses of spinal dorsal horn neurons to noxious heat and stimulation of spinal afferents.[92,94] The NTS has few direct spinal projections suggesting that changes in nociception derived from the NTS involved secondary relays including the NRM, LC/A6, PAG, A5 cell groups, and other forebrain loops.[93,94] This view is consistent with the finding that antinociception produced by glutamate microinjection in the NTS can be antagonized in a dose-dependent manner by intrathecal administration of the combination of an α-adrenergic and 5-HT receptor antagonists, but is unaffected by intrathecal administration of either agent alone, or by the opioid receptor antagonist naloxone.

Diencephalon

Electrical stimulation of a variety of hypothalamic structures results in antinociception, although not necessarily with similar characteristics. The hypothalamus has connections with a variety of structures implicated in descending inhibitory influences including the PAG, NTS, and RVM and these sites may be necessary for the effects of the hypothalamus on nociception.[95–99] Electrical stimulation of the paraventricular nucleus of the hypothalamus inhibits both the tail flick reflex in lightly anesthetized rats and the paw lick response in the hot plate test in conscious rats[100] which is unaffected by naloxone administration. In contrast, electrical stimulation of the arcuate nucleus of the hypothalamus also inhibits the tail flick reflex and intrathecal administration of naloxone reverses this inhibitory effect.[101] Electrical stimulation of either the anterior hypothalamus or lateral hypothalamus (LH), or morphine microinjection into either the LH or posterior regions of the hypothalamus, inhibits a variety of responses to noxious input including the tail flick reflex to noxious heat, behavioral responses in the formalin test, and responses of wide dynamic range neurons to noxious heating of the skin.

Cerebral Cortex

Stimulation of both somatosensory cortex (SSC) and motor cortex (MC) have been used in the clinical treatment of neuropathic pain, central post stroke pain, and phantom limb pain. These have been achieved using either electrical stimulation or transcranial magnetic stimulation and, while spinal influences of such treatments have been reported, there is reason to believe most of their effects are mediated at the supraspinal level.[102] These factors notwithstanding, there is evidence for SSC and other cortical influences in producing descending inhibition of spinal nociceptive transmission via various brainstem sites. Senapati et al.[103] provided one of the stronger demonstrations of cortical influences on spinal nociceptive transmission. They showed that electrical stimulation of either the ipsilateral or contralateral primary SSC of rats inhibited responses of L5–L6 WDR neurons to noxious pressure and pinch, but not brush. In contrast, electrical stimulation of the secondary SSC has been reported to produce only a weak behavioral antinociception in the second phase of the formalin test, and was without effect on responses to noxious thermal or mechanical stimuli.[104] There are reports that electrical stimulation of or glutamate microinjections into the ventrolateral orbital cortex (VLO) can inhibit the tail flick reflex via the PAG,[105,106] but others have found pronociceptive effects of similar treatments.[107] Morphine administration in the VLO also has been reported to inhibit both the hot plate and paw withdrawal responses to noxious heat in intact rats, and the tactile allodynia, hot plate, and paw withdrawal responses in rats with peripheral mononeuropathy. The antinociceptive effects observed in neuropathic rats were reversed by naloxone while those observed in intact rats were not affected by naloxone. However, it cannot be ascertained from these studies whether descending inhibitory systems were activated by morphine since all of the response measures were are organized at the supraspinal level.[108] Morphine microinjection in the rostral agranular insular cortex (RAIS), a structure immediately caudal to the VLO, also has been reported to inhibit nociceptive responses in the formalin test, reduce c-Fos expression in the spinal cord ipsilateral to a formalin stimulus, and produce a naloxone-reversible inhibition of spinal dorsal horn neuronal responses to a noxious thermal stimulus.[109] The influence on the RAIS on descending inhibitory influences may critically depend on dopamine acting on neurons in this region.[110]

There is also evidence that some cortical regions can provide descending facilitatory influences. Electrical stimulation or chemical activation of metabotropic glutamate receptors (mGluRs) in the anterior cingulate cortex (ACC) produced significant facilitation of the tail flick reflex evoked by noxious heat in rats and could be blocked by local anesthesia of the RVM, whereas microinjection of either the mu-opioid receptor, DAMGO, or the delta-opioid receptor agonist, DPDPE, into the ACC inhibited paw lick responses in mice.[111] Similar evidence of hyperalgesia derived

from activation of the ACC were obtained by Zhang et al.[112] They showed that high frequency electrical stimulation of the ACC produced long lasting increases in C-fiber field potentials evoked from the sciatic nerve, decreases in paw withdrawal latencies to noxious heating of the rat hind paw, and similar effects were obtained using microinjections of either NMDA or homocysteic acid into the ACC. These effects could be blocked by bilateral lesions of the dorsal reticular nucleus, a site often cited as a possible final common pathway for descending facilitatory influences. Interestingly, these effects were particularly long-lasting, with some lasting over an hour, and merit further research on possible stimulation-induced changes in the ACC itself.

Summary of Supraspinal Influences

There is overwhelming support for the structures discussed in the previous sections in mediating descending inhibitory and facilitatory influences on spinal nociceptive transmission. There is also overwhelming support that activation of most of these structures involves spinal release of *both* SHT and NE in producing inhibitory phenomena, but many other neurotransmitters including acetylcholine, GABA, glycine, substance P, corticotrophin releasing factor, urocortins, thyroid stimulating hormone, and oxytocin which have been described as part of both excitatory and inhibitory mechanisms.[113] Thus, ''coactivation'' or ''recruitment'' of more than a single system appears to be the rule rather than the exception.[114] Only the inhibitory effects derived from activation of the A5 and A6 cell groups appears to involve a single transmitter, NE, and a single spinal receptor system, α_2 adrenoreceptors. It is quite surprising, therefore, that while the discovery of endogenous opioids prompted the intense study of descending modulatory systems, endogenous opioids per se have not figured prominently in the ''system'' side of the analyses. Rather they appear far more critical in the local circuitries of specific brainstem or spinal regions that allow these systems to function. Furthermore, while the structures supplying these transmitters affecting spinal nociceptive transmission have been identified, for the most part, our general knowledge about how those structures interact in producing inhibitory and facilitatory effects is still not well understood.

On-, Off-, and Neutral Cells

With the identification of CNS sites that could be stimulated to produce inhibitory and/or facilitatory effects at the spinal cord level came theories related to the neuronal constituents of those sites. Studies performed by Fields and colleagues[115,116] demonstrated the existence of three types of neurons in the RVM that can be classified based on the neuron's response to noxious heat applied to the tail of a lightly anesthetized rat that elicited the tail flick reflex. ON cells were shown to increase their firing rate just before the occurrence of the tail flick, OFF cells decreased their firing rate just before the occurrence of the tail flick, and NEUTRAL cells showed no change in activity throughout the application of noxious heat. Importantly, the activity of ON and OFF cells, but not NEUTRAL cells, was shown to be affected by systemic administration of morphine. At doses of systemic morphine that inhibit the tail flick reflex, OFF cells became continuously active and failed to pause before reflex movements whereas ON cell activity decreased.[116,117] These and other findings led to the proposition that OFF cells exert descending inhibitory effects on spinal nociceptive transmission. ON cells were hypothesized to exert a pronociceptive or facilitatory influence. NEUTRAL cells were purported to have no role in nociception.

Extensive studies have examined the role of ON and OFF cells in relation to other descending modulation-related phenomena with a mixture of results, but the role of a subpopulation of these neurons in pain modulation is firmly established. Neurons with the same characteristics as RVM ON and OFF cells have been identified in other CNS sites such as the PAG such that an exclusive role of the ON and OFF cells located in the RVM is unlikely. An exclusive association of ON and OFF cells with nociception is similarly unlikely. Mason[22] has argued that there is substantial evidence that these cells are involved in a variety of homeostatic control functions including micturition, arterial blood pressure control, and that they should be viewed as modulating a much broader spectrum of somatosensory inputs than nociception. Indeed, correlative data supporting a role of ON and OFF cells in control of arterial blood pressure is equally as compelling as for pain modulation. Whether different subsets of ON and OFF cells serve different functions, or whether individual ON and OFF cells can subserve or coordinate many different functions, remains to be determined.

TRIGGERS OF CLINICAL HYPERSENSITIVITY

Allodynia and Hyperalgesia

The terms allodynia and hyperalgesia are clinical terms that represent different forms of hypersensitivity. Defined using clinical terms, allodynia has been defined as ''pain produced by a stimulus that does not normally cause pain.'' Similarly defined, hyperalgesia is ''an increased response to a stimulus that is normally painful'' which may mean either a lower threshold for evoking pain or a higher intensity of pain perception produced by a given intensity of a suprathreshold painful stimulus. Based on psychophysical experiments, hyperalgesia may be either ''primary'' when it is located at a site of injury such as a burn or ''secondary'' when altered sensations are evoked from uninjured tissue that typically surrounds the site of injury, but in some cases could be physically distant. Primary hyperalgesia has generally been relegated to mechanisms involving the primary afferents and secondary hyperalgesia to spinal second order neuron effects.

Both allodynia and hyperalgesia are normal physiological responses to injury but also occur in other conditions including neuropathic pain. Notably, when studying hypersensitivity in nonhuman animal models interpretive issues can be problematic, particularly when studying phenomena that have clinical definitions. For purposes of the present discussion hyperalgesia will be defined as augmented responses and/or lowered stimulus thresholds for response to a nociceptive stimulus. Allodynia will be defined as the evocation of responses that would have been called nociceptive (e.g., flexion-withdrawal responses) to clearly non-nociceptive stimuli (e.g., light brushing).

Inflammation-Induced Hypersensitivity

As noted previously, tissue damaging events can result in the peripheral sensitization of primary afferent nociceptors and the central sensitization of spinal dorsal horn neurons. Historically, these two phenomena have played a fundamental role in accounting for primary and secondary hyperalgesia, respectively. These phenomena were viewed as either increased input to or increased responsiveness of second order neurons with an emphasis on local spinal mechanisms. However, a role for brainstem descending control systems in both primary and secondary hyperalgesia phenomena are now receiving increasing attention and have led to a much better understanding of persistent pain states. There is now evidence that the RVM and the LC are responsible for exerting primarily descending inhibitory influences under conditions of primary hyperalgesia associated with either somatic or visceral tissue damage, and primarily descending facilitatory influences

under conditions of secondary hyperalgesia. These processes are not well understood but spinobulbospinal loops are now being proposed to recognize that enhanced afferent input from the spinal dorsal horn ascends either directly or indirectly to the RVM, which in turn, changes this balance and ultimately, the perception of pain.

A wide variety of evidence supports a role for the RVM in both the development and maintenance of secondary hyperalgesia resulting from inflammation.[118,119] Similar results have been obtained in behavioral studies with various inflammatory agents including mustard oil, carrageen, and formalin. For example, topical application of mustard oil to the ankle of a rat produces tactile allodynia of the foot which can be prevented by either spinal transaction or local anesthetic blockade of the RVM.[120] Lidocaine microinjection reversed or prior bilateral ibotenic acid lesions of the rostral medial medulla prevented secondary thermal hyperalgesia induced by either intraarticular administration of carrageenan or topical application of mustard oil to the hind leg, but did not affect primary hyperalgesia produced by intraplantar administration of carrageenan.[121] Interestingly, the ibotenic acid lesions in this study were highly restricted, localized only to the NGC and dorsal paragigantocellular nuclei, and none impinged on either the NGCα or the NRM. Yet, secondary thermal hyperalgesia was also eliminated using the same preparation and topical application of mustard oil to the hind leg with either spinal transaction or extensive electrolytic lesions of the RVM that appeared more ventral to the ibotenic acid lesions, and included the NRM.[122] Thus, the NGC, dorsal paragigantocellular nuclei, NGCα, and NRM may all contribute to this phenomenon.

There is also substantial evidence that RVM ON cells, originally hypothesized to exert a pronociceptive effect, may be responsible for contributing to the descending facilitatory influences that result in secondary hyperalgesia in persistent pain states. Acute inflammation produced by ipsilateral topical application of mustard oil above the knee of a rat increases ongoing ON cell discharge and decreases ongoing discharge of OFF cells. These changes correlate with a decrease in the withdrawal latency of the ipsilateral, but not contralateral paw. Thus, mustard oil-induced inflammation caused a shift in the balance between ON and OFF cell firing, such that ON cells were more likely to be in an active phase and OFF cells in a quiescent phase.[123] This hyperalgesic effect could be blocked by either lidocaine infusion[123] or a local infusion of the NMDA-receptor antagonist APV[124] into the RVM suggesting the NMDA-receptor activation induced by inflammation contributes to the secondary hyperalgesia.

The spinobulbospinal loop engaged by peripheral cutaneous inflammation and mediating secondary hyperalgesia may involve spinal release of CCK because intrathecal administration of CCK antagonists block these effects.[122] These data suggest that at least one descending facilitatory system uses either intrinsic spinal CCK neurons, or descending medullospinal CCK projecting neurons in producing these effects. However, administration of these CCK receptor antagonists, and blockade of these facilitatory effects, also reveals an underlying descending inhibition that was engaged by the inflammatory treatment; supporting the view that concomitant activation of both facilitatory and inhibitory descending systems occurs under conditions of inflammation and the relative balance between the two dictates the type of pain state.

Inflammation-Induced Inhibitory Systems

Whereas secondary hyperalgesia may be augmented by descending facilitatory systems, primary hyperalgesia (increased primary afferent activity) associated with either acute or persistent inflammation may actively engage descending *inhibitory* influences. Schaible et al.[125] showed that a mixture of kaolin and carrageenan injected into the knee joint of the cat resulted in a progressive increase in both spontaneous activity and evoked activity of spinal dorsal horn neurons to innocuous and noxious stimuli. Reversible interruption of descending modulatory influences using spinal cold block further increased activity in a progressive fashion demonstrating that spinal descending inhibitory influences were being progressively engaged by inflammation. Ren and Dubner[126] showed that primary thermal hyperalgesia produced by carrageenan administration into the hind paw of the rat was increased by prior transactions of the DLFs, and that lidocaine microinjection in the RVM increased the spontaneous activity of nociceptive dorsal horn neurons, and their responses to mechanical and thermal stimulation of the inflamed hind paw.

In the RVM, this enhancement of descending inhibitory influences may reflect inflammation-induced increases in the synthesis of enkephalins and/or enhanced efficacy of endogenous opioids acting at mu- and delta-opioid receptors such that the effectiveness of opioids is increased.[127,128] Mechanistically, these changes would be consistent with opioid inhibition of pronociceptive ON cells and disinhibition of pro-inhibitory OFF cells; the net outcome of which should be enhanced descending inhibition. They also depend on RVM glutaminergic influences which apparently vary as a function of time after inflammation. At shorter times after inflammation, for example, 3 hours, an increase in glutaminergic descending facilitation tends to counteract the descending inhibitory influences, but then dissipates as a function of time over the next 24 hours.[129,130] There are corresponding spinal changes that accompany these changes in the RVM including increased sensitivity to both NE and opioidergic spinal inhibitory mechanisms.

Complete Freund's Adjuvant (CFA) injected into the hind paw of the rat has been reported to increase the NR1, NR2A, and NR2BNMDA receptor subunit expression in the RVM beginning at 5 hours after inflammation and persisting for up to 7 days.[131] These data suggest that inflammation can produce a prolonged upregulation of NMDA receptor subunit gene expression that could contribute to RVM excitability and be viewed as "brainstem central sensitization" following inflammation. CFA injected into the hind paw of the rat also induces increases in mRNA for spinal lumbar dynorphin and enkephalin, and therefore may be molecular markers of hyperalgesia associated with inflammation. These changes in mRNA expression are increased further in rats with thoracic spinal transection indicating that descending afferents inhibit responses of opioid-containing neurons to noxious stimulation.[132]

The LC/A6 region may play a comparable role to the RVM in attenuating the development of primary hyperalgesia induced by acute inflammatory pain, but not necessarily persistent inflammatory pain. For example, behavioral thermal hyperalgesia produced by subcutaneous injection of carrageenan resulted in a small, but significant enhancement by prior bilateral lesions of the LC.[133] However, this effect was only observed 4 hours after carrageenan injection, and not observed 7 days after carrageenan, even though edema and hyperalgesia were still present at 7 days.[134] Interestingly, recruitment of the descending LC inhibitory influence derived from unilateral hind paw inflammation was expressed only unilaterally, but both in the lumbar region innervating the inflamed paw and in the cervical region markedly distant from the area of primary inflammation.[135] Systemic naloxone administration produced a further decrease of the paw withdrawal latencies to noxious thermal stimulation at 4 hours after carrageenan administration in LC-lesioned, but not in sham-operated rats. Similar effects of bilateral LC lesions in enhancing thermally evoked noxious responses of spinal dorsal horn neurons in rats have been reported.[136] These data suggest that the development of hyperalgesia in the acute phase of inflammation might depend on the interaction between the descending modulation system from the LC and an opioid inhibitory system, and that an intact LC system suppresses the opioid influence. Upregulation of spinal α_2 adrenoreceptors under conditions of inflamma-

tion may therefore enhance the potency of this descending inhibitory influence.

That descending inhibitory influences are recruited from both the RVM and LC under conditions of inflammation are supported by studies of spinal cord lesions. Wei et al.[137] observed that the c-fos expression observed in the L4–L5 spinal segments observed 24 hours after hind paw injection of CFA was significantly increased on the side ipsilateral, but not contralateral to the injection by either bilateral DLF or VLF lesions. The increases occurred in both superficial and deep laminae, as well as lamina III-IV, region of termination of mechanoreceptor afferents. Presumably, descending facilitatory influences accompanying the CFA-induced inflammatory state, and which should have been eliminated by these lesions, were masked by the descending inhibitory influences.

However, outcomes obtained with formalin are not as quite as clear with respect to descending inhibition and primary hyperalgesia. Vanegas and Schaible[119] argued that if the early phase (1–5 minutes) and late (15–60 minutes) phase responses to subcutaneous injection of formalin are viewed as a primary hyperalgesia, then the predominant formalin-activated descending influence is facilitation rather than inhibition. However, these views were based on a limited number of studies involving a spinal 5-HT3 antagonist (ondansetron) and RVM recordings of ON and OFF cells[138] that were not consistent with those obtained by Robinson et al.[139] Hence, additional work may be required before the role of descending influences can be stated for formalin-induced pain.

Neuropathic Pain

The injury of peripheral nerves has many consequences, one of which is an alteration in spinal dorsal horn neuron excitability. One of the recently identified mechanisms important to this is the activation of spinal microglia by substances such as fractaline released by the central processes of the injured nerves. Subsequent release of cytokines, purines, and growth factors result in the sensitization of second order nociceptive neurons[140] and subsequent increased excitability reflected as hyperalgesia and allodynia. These spinal mechanisms are not the whole phenomenon as there is clear evidence that supraspinal modulatory systems are also important to the development of hypersensitivity following nerve injury. In particular, the RVM is now believed to significantly contribute to neuropathic pain produced by such experimental treatments such as loose ligation of L5–L6 spinal and chronic sciatic nerve transection. For example, inactivation of the RVM with lidocaine injections both enhanced the withdrawal response and the thermal and tactile hypersensitivity produced by peripheral nerve injury.[141,142] Various lines of evidence suggest that RVM ON cells may be critical for sustaining neuropathic pain. Selective lesions of ON cells, produced by microinjection of demorphin conjugated to the cytotoxin saporin, blocks the thermal hyperalgesia and tactile hyperesthesias produced by peripheral nerve injury.[142] Other evidence suggests that the effect of ON cells in contributing to neuropathic pain may reside in spinal release of 5-HT and a presynaptic action on 5-HT_3 receptors located on SP-containing terminals.[143] Similar effects may be responsible for selective effects on the mechanical allodynia that occurs in spinal cord injury (SCI). For example, administration of the 5-HT_3 receptor antagonist ondansetron significantly attenuates mechanical allodynia in an SCI model and administration of m-chloropheynlbiguanide (m-CPBG), a 5-HT_3 agonist, exaggerated pain behaviors.[144] Interestingly, however, similar studies conducted of inflammatory pain using carrageenan revealed little influence of a descending system using 5-HT_3 receptors.[145] Yet, the precise details relating ON cell activation to spinal 5-HT release remain to be worked out since some studies have reported that neither ON nor OFF cells contain 5-HT.[146,147] In neuropathic pain, the influence of the LC/A6 may be reduced. Following rhizotomy, the antinociceptive effect produced by LC stimulation is reduced.[148]

Opioid-Induced Hyperalgesia

Opiates remain the primary treatment for a wide variety of pain disorders in both acute and chronic clinical pain disorders. Prolonged administration of opiates can be associated with significant reactive processes including the development of tolerance to the analgesic effects of the drugs such that greater doses of drug are required to achieve adequate pain relief. Recently it has been recognized that exposure to opioids can also result in paradoxical pain including regions not described in the initial pain complaint,[149] a phenomenon commonly referred to as ‘‘opioid-induced hyperalgesia’’[150] although the terms ‘‘opioid-abstinence hyperalgesia’’ and ‘‘opioid-withdrawal hyperalgesia’’ have also been used to describe similar, if not identical, phenomena. Many substances delivered spinally can reverse or block antinociceptive tolerance as well as opioid-induced hyperalgesia which include NMDA receptor antagonists, phosphokinase C inhibitors, cyclooxygenase inhibitors, and use of differing opioid receptor subtype agonists/antagonists.[150] It is also clear that there is an effect of chronic opioids on descending pain modulatory systems that is critical to the development of the spinal cord changes mediating paradoxical pain and antinociceptive tolerance with known neuroexcitatory effects arising within the RVM and PAG[151–154] when the effects of opioids are rapidly reversed by naloxone or other substances interacting with opioid systems. Additional evidence that supraspinal modulatory systems are involved in the mechanisms of opioid-induced hyperalgesia includes the demonstration that animals with lesions of the dorsolateral funiculi of the spinal cord do not appear to develop abnormal pain or antinociceptive tolerance that are normally a consequence of prolonged opiate administration.[155,156] Further, the effects of both acute and prolonged exposure to morphine (tactile hyperesthesia, thermal hyperalgesia, and antinociceptive tolerance) are abolished by local anesthesia blockade of the RVM.[155–157] Thus, opioid-induced pain and tolerance in these circumstances may be mediated in part by activation of descending facilitatory mechanisms arising in the RVM. This, in turn, has been suggested to act as a trigger for the upregulation of spinal dynorphin that serves to promote enhanced input from nociceptors.[158] An underlying assumption related to these studies has been that opioid-induced hyperalgesia requires the activation of opioid receptors. However, it is possible that opioid drugs may also be acting by nonopioid mechanisms to produce their physiological effects. The demonstration that opioid-induced hyperalgesia can be elicited in mice without functional mu-, kappa-, or delta-opioid receptors supports this possibility.[159] At this point in time, it is clear that the use of opioids for the treatment of pain leads to a series of complicated interactions in spinal pain processing systems such that the resultant physiological effects may be at times beneficial (analgesic) and at other times detrimental to the function of the organism.

CONCLUSION

The original proposition of Gate Control theory of Melzack and Wall[2] that nociceptive input to spinal dorsal horn neurons could be modulated by a number of systems prompted investigations of the systems that modulate our perception of pain. One could hardly have envisioned both the diversity and complexity of the systems that have been identified. The original notions of systems descending from supraspinal sites to the spinal cord to inhibit pain have been expanded to include descending systems that also enhance our perception of pain. At the present time, our analyses

indicate these two systems are functionally and anatomically intertwined and appear to operate as a unit rather than as separate entities. The ultimate perception we develop following exposure to noxious events represents some balance between these two systems. It is possible that these systems attenuate or amplify responses to noxious stimuli in order to enhance our ability to localize and attend to peripheral stimuli that threaten us. Studies of stress, inflammation, neuropathic pain, drug-induced hypersensitivity, or other mechanisms leading to chronic pain states have begun to demonstrate that deficits in descending inhibition and/or activation of descending facilitation-related systems may also serve as mechanisms of pain generation or amplification.

Studies related to the neurotransmitters of modulation have consistently identified NE, SHT, and endogenous opioids to be key substances involved in the balance of inhibitory and excitatory influences. It should come as no small wonder then, that the drugs clinicians find useful in the treatment of hypersensitivity and pain are associated with noradrenergic, serotonergic, and opioidergic function within the CNS. It is the subtleties of the pharmacology that will define future refinements in therapeutics and many of these subtleties are only now being defined.

CHAPTER 6 ■ SUPRASPINAL MECHANISMS OF PAIN AND NOCICEPTION

JÜRGEN LORENZ AND MICHAEL HAUCK

INTRODUCTION

The two preceding chapters addressed the peripheral and spinal mechanisms of nociceptive processing. Neither normal nor pathological pain can be understood without knowledge of supraspinal mechanisms. Supraspinal structures include the hindbrain (lower and upper brainstem and cerebellum) and the forebrain. The forebrain has two major divisions, the lower diencephalon involving hypothalamus and thalamus and the cerebrum involving the cortex, basal ganglia, and the limbic system (cingulate cortex, amygdala, hippocampus). The cerebrum has two hemispheres, each divided into frontal, parietal, temporal, and occipital lobes (Fig. 6.1). In humans, the forebrain anatomically dominates and physiologically controls much more than in other species' nociceptive processing. Because the human forebrain forms a large proportion of the entire central nervous system (CNS) volume (85%) when compared to the spinal cord (2%), descending modulatory influences from that site assume much greater importance than in the rat in which the forebrain comprises 44% and the spinal cord 35% of CNS volume.[1] Thus, the great variety of psychological phenomena characterizing normal and abnormal pain in humans are best studied in humans, although anatomical tracing and electrophysiological techniques and behavioral studies in rodents and primates have contributed significantly to our current knowledge about the pathways connecting the dorsal horn with supraspinal structures.

FUNCTIONAL IMAGING OF PAIN IN HUMANS

Since release of the last edition of this textbook, functional brain imaging in human volunteers and patients has addressed many questions pertaining to brain structures involved in pain processing. Before going into the details of supraspinal regions engaged in pain processing and perception, we will briefly describe the methodological basis of these technologies.

Methodologies of Noninvasive Functional Brain Imaging

Functional imaging techniques applied for the study of pain are positron emission tomography (PET), functional magnetic resonance imaging (fMRI), multi-channel electroencephalography (EEG), and magnetoencephalography (MEG).

PET measures cerebral blood flow, glucose metabolism, or neurotransmitter kinetics. A very small amount of a labeled compound (called the radiotracer) is intravenously injected into the patient or volunteer. During its uptake and decay in the brain, the radionuclide emits a positron, which, after traveling a short distance, "annihilates" with an electron from the surrounding environment. This event results in the emission of two gamma rays of 511 keV in opposite directions, the coincidence of which is detected by a ring of photo-multipliers inside the scanner. In

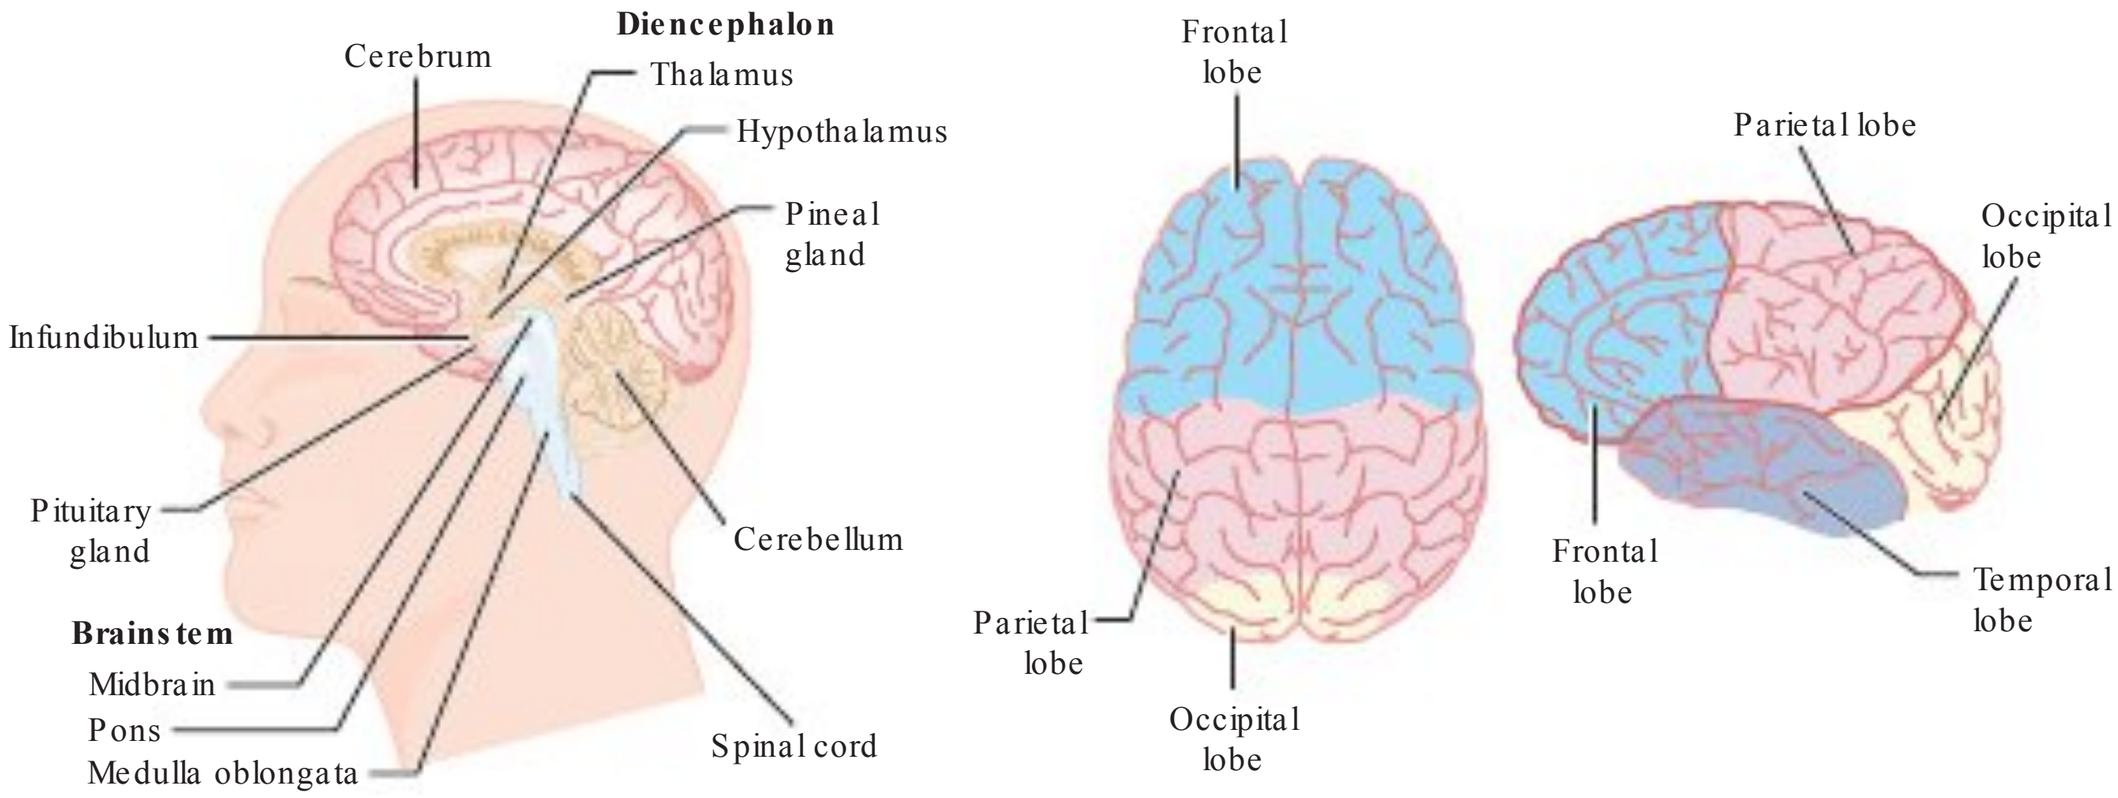

FIGURE 6.1 Structure of the brain.

case of the most common use of O^{15}-water injection, counting and spatial reconstruction of these occurrences within the brain anatomy allow visualization of the regional cerebral blood flow response (rCBF) as an indicator of neuronal activity. Usually scans during painful stimulation are statistically compared with scans during the resting state or nonpainful stimulation (blocked design) and plotted as 3-dimensional color-coded t- or Z-score statistical maps. Radio-labeled fluordeoxy-glucose (FDG) is applied to measure regional energy consumption as a function of metabolic rate. An interesting refinement of PET technology represents the use of neurotransmitters as tracers to investigate binding mechanisms and kinetics, for example in the opioidergic system.

FMRI images blood oxygenation, a technique called BOLD (blood oxygen level-dependent), which exploits the phenomenon that oxygenated and deoxygenated hemoglobin possess different magnetic properties resulting in different relaxation behavior following radio-frequency pulses inside the magnet. Both the rCBF using O^{15}-water PET and the BOLD technique rely on neurovascular coupling mechanisms that are not yet fully understood, but which overcompensate local oxygen consumption, thus causing a flow of oxygenated blood into neuronally active brain areas in excess of that utilized.[2]

EEG and MEG are noninvasive neurophysiological techniques that measure the respective electrical potentials and magnetic fields generated by neuronal activity of the brain and propagated to the surface of the skull where they are picked up with EEG-electrodes or, in the case of its magnetic counterpart, received by SQUID (supra conducting quantum interference device) sensors located outside the skull. Compared with PET and fMRI, EEG and MEG are direct indicators of neuronal activity and yield a higher temporal resolution of investigated brain function. The spatial distributions of EEG potentials and MEG fields at characteristic time points following noxious stimulation are analyzed using an inverse mathematical modeling approach called equivalent current dipole (ECD) reconstruction. An ECD evoked by painful stimuli hence represents a source model of pain-relevant activity within the brain. Similar approaches such as beamforming use spatial filtering techniques, firstly applied in antenna and ultrasound technologies. The spatial acuity of MEG is higher than that of EEG because the latter measures the extracellular volume currents that are distorted by the differentially conducting tissues such as grey and white matter, cerebrospinal fluid, dura mater, and bone. In contrast, MEG measures the magnetic field perpendicular to the intracellular currents undistorted by the surrounding tissue. Given the different geometry of electrical potentials and magnetic fields, MEG is predominantly sensitive to dipoles oriented tangentially to the head convexity, whereas EEG depends primarily on radial, but also on tangential dipoles.[3]

BRAINSTEM

The brainstem represents the connection of the diencephalon (hypothalamus and thalamus) with the spinal cord (Fig. 6.1). It comprises the mesencephalon (midbrain) and rhombencephalon (pons and medulla).

Reticular Formation

A major rhombencephalic structure is the reticular formation (RF) which encompasses a distributed network of small and large nerve fibers and extends from the medulla up to the level of the thalamus. It has a multitude of local interneuronal connections within the brainstem and contains both ascending and descending projecting systems. It is divided into three vertical zones. The medial magnocellular zone contains the ascending reticular activating system (ARAS), a major pathway to the thalamus, hypothalamus, and basal forebrain (a group of structures at the base of the frontal lobe, including the nucleus basalis, diagonal band, medial septum, and substantia innominata). The median and paramedian zones contain the raphe nuclei of serotonergic projection neurons. The lateral parvocellular zone receives afferents from the amygdala and hypothalamus. The RF and basal forebrain have reciprocal connection with virtually all cortical and subcortical structures through cholinergic (from the basal forebrain), noradrenergic (from the locus ceruleus), dopaminergic (from the substantia nigra and ventral tegmentum), and serotoninergic (from the raphe) pathways. Reciprocal connections with the spinal cord mediate motor, respiratory, and cardiovascular functions and pain modulation.

The RF is an important mediator of consciousness. The stream of information about the outer world that reaches specific nuclei of the thalamus and cortex through the sensory pathways of vision, audition, gustation, and somatosensation is blocked when the activity of the mesencephalic RF that drives nonspecific thalamic sites drops below a critical level, such as during slow wave sleep or certain types of absence epilepsies.[4] Wakefulness and arousal are thus closely coupled to the RF, which acts as the "energetic supplier" of conscious perception and behavior. Widespread areas of the RF are responsive to noxious stimuli.[5] The gigantocellular and magnocellular fields of the medullar reticular formation, that is, the bulboreticular region, mediate escape behavior following acute painful stimuli[6,7] and respond neurochemically during persistent pain.[8] The close relationship of nociception and pain with arousal and consciousness guarantees optimal alertness and readiness to avoid bodily harm. Sleep is therefore disrupted by the awakening nature of pain through its influence upon the RF. Similarly, opioid-induced sedation is antagonized by residual pain. These aspects will be discussed in more detail later.

The view of a more or less unspecific role of RF in pain through enhancing arousal and escape behavior has been challenged by more recent research. The subnucleus reticularis dorsalis (SRD) represents a homogenous population of neurons in the caudal-dorsal medulla whose axons form both ascending and descending collaterals to the thalamus and spinal cord, respectively. SRD neurons are strongly activated by noxious cutaneous and visceral stimuli from any part of the body.[9] It is regarded as a medullary substrate of the link between nociceptive and motor activities. SRD has also been suggested as major supraspinal site mediating the "pain-inhibits-pain," or counterirritation, phenomenon as formulated in the concept of diffuse noxious inhibitory controls (DNIC).[10] As part of a spinal-bulbospinal feedback loop, SRD is proposed to facilitate the extraction of nociceptive information by increasing the signal-to-noise ratio between a pool of deep dorsal horn neurons activated by a tonic painful focus and the remaining population of such neurons, which are inhibited for simultaneous phasic noxious input.

Periaquaductal Grey Matter: A Key Structure of Endogenous Analgesia

The periaqueductal gray is a midbrain territory that surrounds the cerebral aqueduct and plays a critical role in the expression of a variety of emotion-related behaviors, including pain.[11] It represents a key structure in relaying descending pain modulation via nuclei of the rostroventral medulla (RVM; nucleus raphe magnus and nucleus gigantocellularis pars alpha) and of the dorsolateral pontine tegmentum (DLPT; locus ceruleus and A7 catecholamine cells) to the spinal and trigeminal dorsal horn. It receives input from both ascending spinomesencephalic and descending pathways, the latter originating in the limbic forebrain, namely medial prefrontal cortex, rostral anterior cingulate cortex, amygdala, and hypothalamus. Early systematic studies identified PAG and RVM as brainstem sites that elicit powerful surgical levels of

analgesia through focal brain stimulation,[12] subsequently more elaborated and referred to as "stimulus-induced analgesia."[13–15] A milestone contribution to the understanding of the interaction between PAG and RVM and its role in opioid analgesia was delivered by Field's working group who identified two classes of pain modulatory cells in the RVM exerting inhibitory and facilitatory actions through respective off- and on-cells.[16] Off-cells are activated by local infusion of μ-opioid agonists and their activity inhibits nociceptive transmission. In contrast, on-cells facilitate nociceptive transmission, are inhibited by local μ-opioids, and are activated by naloxone and morphine abstinence. Approximately 15% of RVM neurons are serotonergic and are neither on- nor off-cells and do not respond to opioids.[17] Some respond to baroreceptor input integrating cardiovascular and nociceptive function.[18] Descending fibers from the RVM project to dorsal horn neurons via the dorsolateral funiculus.

The biological significance of endogenous pain control is generally seen in the context of behavioral conflicts in which the subject needs to disengage from pain in order to fight or escape at the presence of body injury. Analogous human life situations are sporting competition or combat, during which a subject may fail to be aware of even severe tissue damage, which becomes painful when the victim releases engagement in these activities. Thus, forebrain input to the PAG mediates contextual information from the prefrontal cortex, the amygdala, the anterior cingulate cortex, and the hypothalamus about momentary behavioral goals, past experience, and bodily needs. Evidence furthermore indicates that injury and inflammation causing increased sensitivity to painful stimuli (primary hyperalgesia) triggers the RVM pain modulating circuitry.[19]

Recently, using the expression of the immediate early gene, c-*fos,* as a marker of neuronal activation, an interesting regional distinction for deep versus cutaneous pain had been demonstrated within the midbrain PAG. Noxious stimulation of a range of deep somatic and visceral structures evoked a selective increase in Fos expression in the ventrolateral PAG column (vlPAG), whereas noxious cutaneous stimulation evoked Fos expression predominantly in the lateral PAG column (lPAG).[20] Ventrolateral and lateral PAG areas are suggested to represent different modes of behavioral adaptation characterizing inescapable and escapable types of pain, respectively. Earlier studies showed that both deep pain as well as microinjection of excitatory amino acids (EAA) into the vlPAG of freely moving animals evoked a response of quiescence, decreased vigilance, decreased reactivity, hypotension, and bradycardia. In contrast, cutaneous pain as well as activation of the lPAG evoked fight and flight behavior, increased vigilance, hyperreactivity, hypertension, and tachycardia. Lamb et al.[21,22] presented evidence that differential representation of escapable and inescapable pain in the PAG extends to distinct representations of "first" and "second" pain, as indicated by the columnar distribution of neurons activated by inputs from respective Aδ- and C-nociceptors. Furthermore, the functional organization of projections from circumscribed regions of the hypothalamus to the different columns of the PAG indicates that the behavioral significance of the pain signal is represented in brain regions other than the PAG. A PET study comparing brain activity of heat pain inflicted on normal skin of healthy volunteers with that of a normally warm stimulus, but perceived as equally painful on the same skin area when it was sensitized by topical capsaicin (heat allodynia), lends further support for the view that the brain represents different types (exteroceptive vs. interoceptive) or behavioral significances (escapable vs. inescapable) of pain in a region-specific manner.[23] This PET study demonstrates that in parallel with a unique recruitment of medial thalamus and frontal lobe structures, the midbrain encompassing the PAG exhibited significantly greater activation following heat allodynia after capsaicin-induced C-fiber sensitization than during normal heat pain that involves both C- and Aδ-nociceptor activation (Fig. 6.2). It is therefore conceivable that different pathways inform the brain about the nature and significance of pain as coming from outside (normal heat pain) or inside the body (inflammatory heat hyperalgesia and allodynia) to engage highly elaborated forebrain structures that interact with region-specific output systems of the PAG. Such specificity may coordinate antinociception with adequate behavioral and autonomic responses to prevent damage, in case of an imminent threat, or promote healing when an injury is already manifest.

HYPOTHALAMUS

The hypothalamus occupies the ventral half of the diencephalon below the thalamus on either side of the third ventricle. It lies just above the pituitary gland with which it is intimately coupled for various neuroendocrine secretions subserving autonomic functions. Neurosecretory neurons are mainly located in periventricular and supraoptic nuclei. Fiber tracts to the pituitary gland are subdivided into two parts: (1) magnocellular secretory cells expressing vasopressin and oxytocin innervate the posterior pituitary gland and (2) parvocellular secretory cells which secrete factors related to the release and/or inhibition of other hormones from the anterior pituitary gland. The hypothalamus receives nociceptive inputs from the midbrain parabrachial nucleus, the ventrolateral medulla, and the spinal and trigeminal dorsal horn.[24,25] The nucleus of the solitary tract (NTS), a major relay of cardiorespiratory, visceral, and gustatory information, is also connected with the hypothalamus. Its role in nociception is not quite clear, but the convergence of autonomic, visceral, and nociceptive information in the hypothalamus underpins the importance of it for the control of homeostasis as part of the brain's defense system.

THALAMUS

The thalamus is the major structure of the diencephalon, which additionally contains, in relation to thalamus, basally the hypothalamus, laterally the globus pallidus and nucleus subthalamicus, and medially the third ventricle. With the exception of the olfactory system, all sensory systems send afferent input to the thalamus from where it is projected into the specific cortical representation areas. This is why the thalamus is often referred to as "the gate to consciousness." The intralaminar and ventral motor nuclei are the main sources of thalamic inputs to the striatum (putamen and caudate nucleus). Thalamostriatal and corticostriatal connections form the motor loop of the basal ganglia which is under control of dopaminergic input from the midbrain substantia nigra. The thalamic extension of the ascending reticular activating system contributes to arousal and wakefulness driven by the midbrain reticular formation (see previous text). The multidimensional nature of pain as composed of sensory-discriminative and affective-motivational determinants, first introduced by Melzack and Casey[26] four decades ago, formed a conceptual framework that guided many research groups studying supraspinal pain mechanisms. One of their postulates was that sensory and affective pain dimensions are anatomically represented by spinal pathways that differentially target respective lateral and medial nuclei of the dorsal thalamus.

The Lateral Pain System: The Sensory-Discriminative Pathway

The cell bodies of spinothalamic tract (STT) fibers are located in the most superficial layers, lamina I, the outer region of lamina II, and deeper laminae V–VI according to the Rexed scheme. STT axons cross via the anterior commissure to the anterolateral

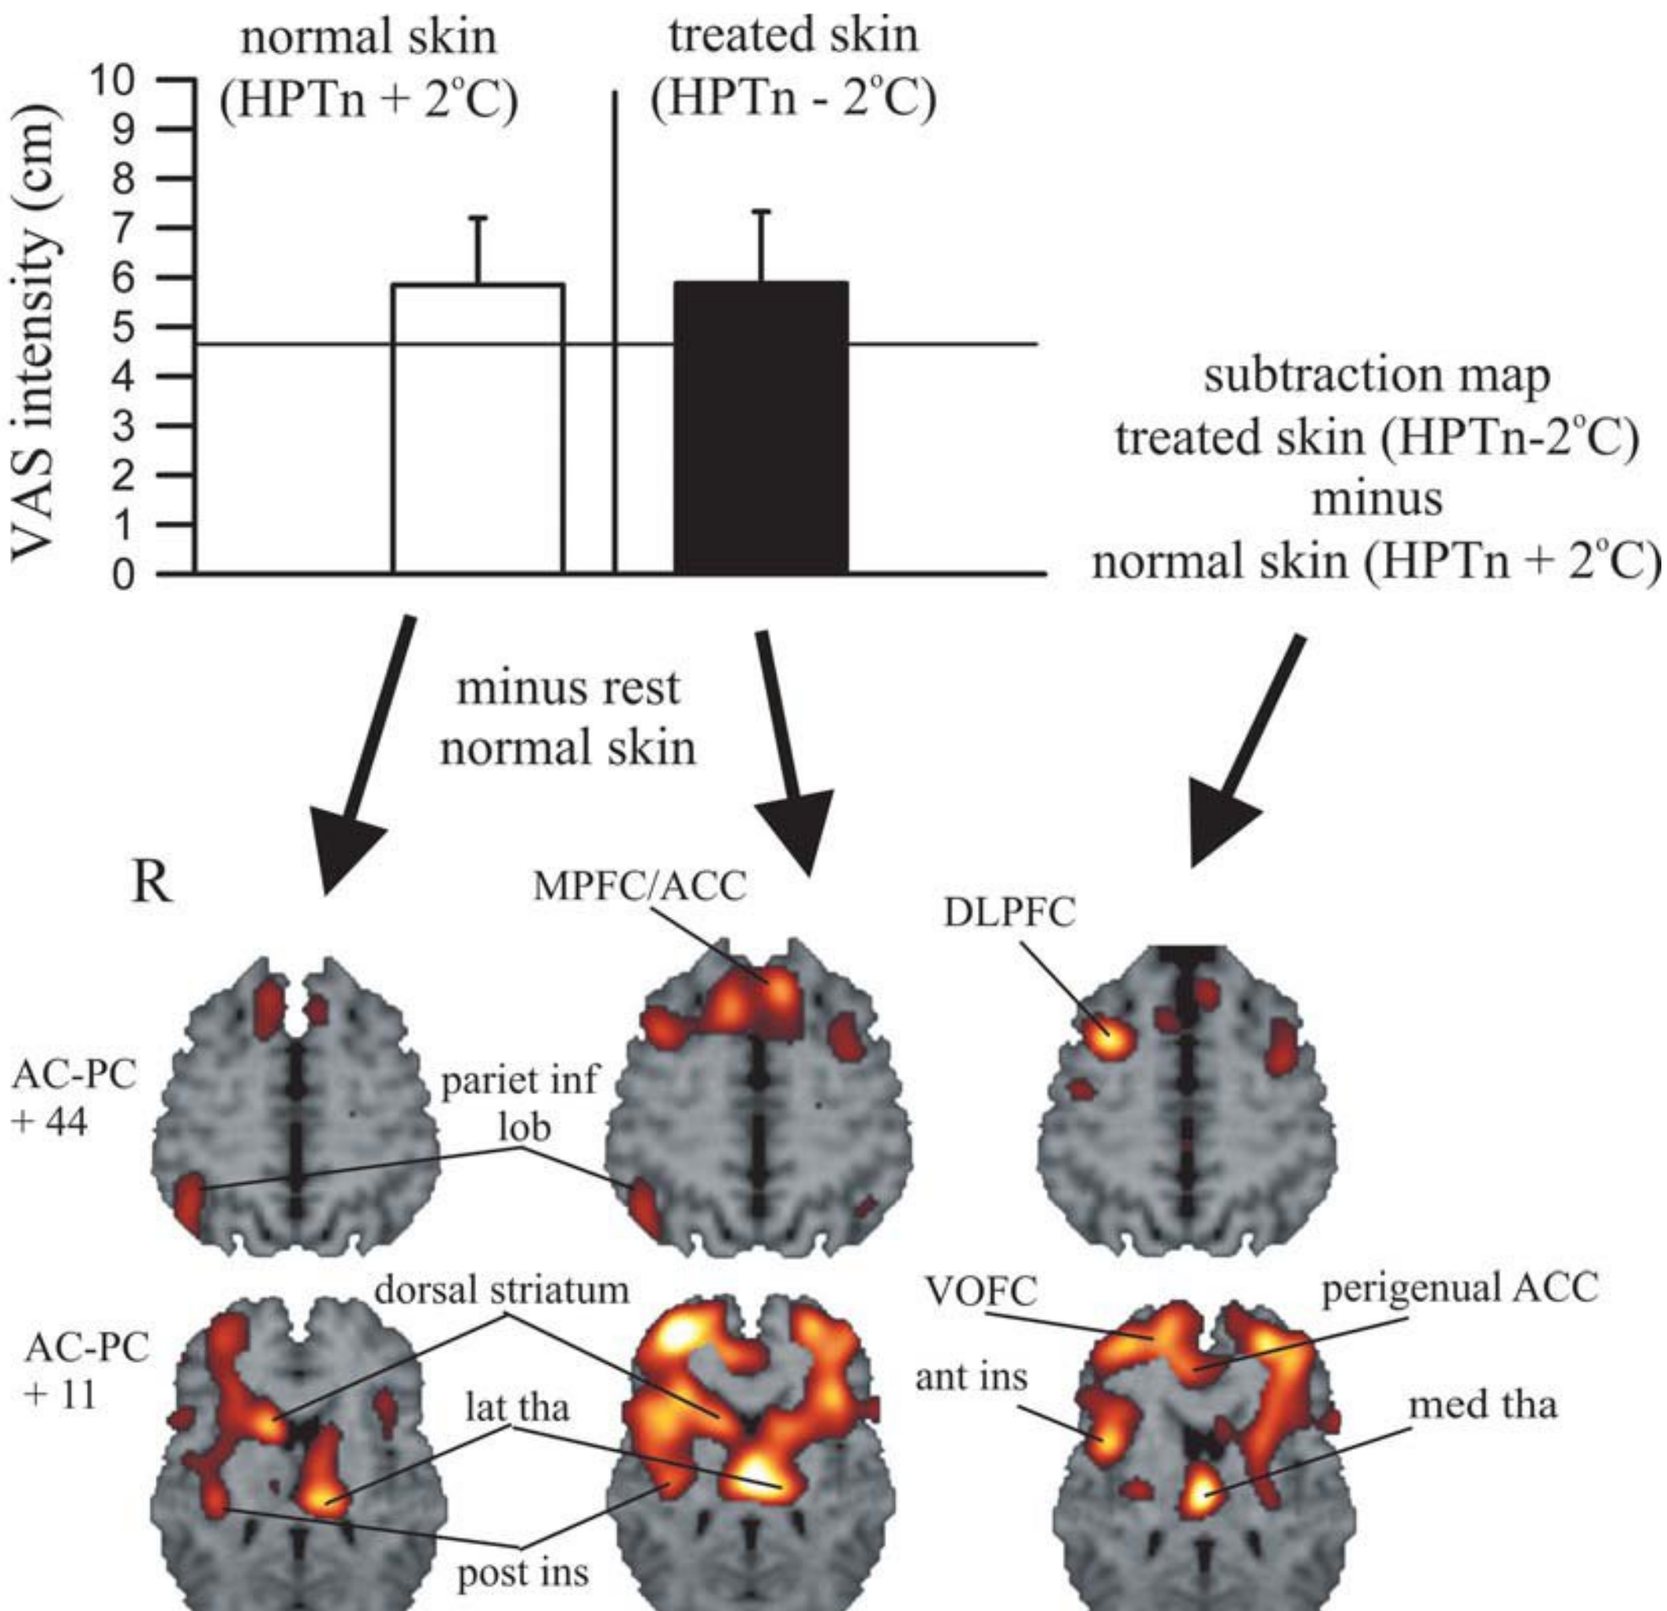

FIGURE 6.2 Regional brain activity during equally intense pains across normal and capsaicin-treated skin conditions. *Top*: Stimulation of the normal skin with the high intensity stimulus yields the same pain intensity as stimulation with the low intensity stimulus on capsaicin-treated skin. However, the O^{15}-water PET images during heat pain (*left*) and equally intense heat allodynia (*middle*) are different when compared against normal rest condition. Similar magnitudes of activity in the dorsal striatum, lateral thalamus (*lat tha*), and posterior insula (*post ins*) are removed in the image subtraction of heat allodynia minus heat pain (*right*) contrasting activity in the ventral striatum, medial thalamus (*med tha*), anterior insula (*ant ins*), midbrain, dorsolateral prefrontal cortex (DLPFC), medial prefrontal (MPFC) and ventral/orbitofrontal (VOFC), and perigenual anterior cingulate cortex (ACC) during heat allodynia. portion of the contralateral hemisphere and have their main thalamic targets in lateral nuclei, namely ventral posterolateral (VPL; from the body) and posteromedial (VPM; from the face) nuclei, and the ventral posterior inferior (VPI) nucleus. These fibers contribute to thermal and pain sensation. The lateral thalamic nuclei have small receptive fields and mostly gradual stimulus response functions over nonnoxious and noxious intensities, representing the ''wide-dynamic-range,'' or to a lesser extent, over noxious range only, representing the ''nociceptive-specific'' type of cells. These features render lateral thalamic targets of spinal nociceptive afferents ideally suited for the encoding of spatial localization and intensity of painful stimuli, similar to the properties of touch. The sensory-discriminative determinant of pain is thus governed by a spinal afferent pathway that mainly reaches lateral thalamic nuclei, from where neuronal activity is projected into the contralateral primary (SI) and bilateral secondary (SII) somatosensory cortices and mid and posterior sections of the insula (see later).

Spinal Connections to Brainstem and Medial Thalamus: The Affective Pathway

Although direct connections of lamina I STT cells exist with medial thalamic nuclei, namely the central lateral nucleus and intralaminar complex,[27–29] the major source of nociceptive input to the medial thalamus is likely indirect through the brainstem that relays spinoreticular, spinomesencephalic, and spino-parabrachial input from both superficial and deeper dorsal horn. Medial thalamic nuclei project densely into key structures of the limbic system, such as the anterior cingulate cortex, the amygdala, the hippocampus, the anterior insula, and prefrontal cortex which represent the perceived intrusion and threat by pain, referred to as affective-motivational and cognitive-evaluative determinants of pain.[26]

The concept of a nociceptive pathway that closely parallels or is partly convergent with that of touch at distinct sites of spinal cord, thalamus, and parietal lobe as a key element for the sensory-discriminative or exteroceptive function of pain has recently been challenged by Craig.[30] An important component of his hypothesis is the assumption that pain is a purely interoceptive perception like hunger, thirst, or itch. It originates in specific lamina I neurons which impinge upon specific thalamic nuclei, such as the posterior part of the ventral medial nucleus (VMpo) and the ventral caudal part of the mediodorsal nucleus (MDvc). These distinct thalamic nuclei relay afferent input to the dorsal posterior insula and caudal ACC respectively, and form separate pathways regarded as important elements of a hierarchical system subserving homeostasis, linking thermal sensation and pain contributing to the sense of the physiological condition of the body (interoception) with subjective feelings and emotion.

CORTEX

The human cortex is divided according to functional and anatomical criteria. The German neuroanatomist and psychiatrist Brodmann[31] introduced a systematic classification of the human cortex based on cytoarchitectonic properties, which, in refined modification, is still often referred to in the neuroimaging literature. Functional classifications consider the specific relevance of different cortical structures for motor, sensory, cognitive, emotional, or autonomic information processing. These functional areas can be divided into hierarchically organized subregions, for example, primary and secondary projection areas, or network systems consisting of distributed areas. The current view is that higher order projection areas and distributed networks rather than a unique ''pain center'' represent the cortical substrate of pain perception. This view is consistent with the multidimensional definition of pain[26,32] which postulates differential projection of lateral and medial thalamic pathways to respective sensory and limbic cortical structures in addition to cortico-cortical as well as cortico-subcortical interactions for the composition of sensory-discriminative, affective-motivational, and cognitive-evaluative determinants (see previous text). According to this concept the primary (SI) and secondary somatosensory (SII) cortices receiving input from lateral thalamic nuclei are responsible for sensory-discriminative processing. Emotional content and aversive quality to noxious stimuli motivating escape and avoidance behavior are linked to limbic areas. The limbic system involves cortical and subcortical areas from the frontal, parietal, and temporal lobe that from a ring (limbus) around the upper brainstem and diencephalons, first regarded by Papez[33] as important for emotion. It includes the cingulate cortex, the insula, the prefrontal cortex, and, as subcortical structures, amygdala, hippocampus, medial thalamus, and hypothalamus.

Sensory Areas

Primary Somatosensory Cortex

The primary somatosensory cortex (SI) is located in the parietal lobe within the postcentral gyrus (Fig. 6.3). It includes the Brodmann areas 1, 2, 3a, and 3b, the latter two occupying the depth and the posterior wall of the central sulcus and generally considered to be the major recipient of cutaneous somatosensory input. Early studies of patients with cortical lesions reported controversial results. Whereas Head and Holmes[34] did not find deficits in pain sensitivity following cortical lesions, studies on World War I and II injury victims with lesions of SI (area 3a) reported loss of cutaneous pain sensibility.[35–37] Experimental data using single cell recordings in awake monkeys revealed a strong correlation between SI firing rate and stimulus intensity and duration of painful stimuli.[38] Patients with subdural electrodes implanted for surgical treatment of intractable epilepsy showed encoding of intensity of painful stimuli within SI.[39] Direct intracerebral electrical stimulation of SI in awake patients, however, failed to elicit painful sensations.[40,41] Thus, it appears that SI processes nociceptive input, but it is not sufficient to cause a pain sensation. Due to its spatial and intensity encoding properties, SI is regarded to contribute to discriminative analysis of painful stimuli but does obviously not cause the aversive nature of pain perception.

Consistent evidence for SI involvement in pain processing is derived from more recent functional neuroimaging studies in humans. SI is organized somatotopically; that is, neighboring peripheral skin areas are also represented by neighboring cortical sites. Human imaging studies established a somatotopic organization of SI for painful laser stimuli[42] (Fig. 6.4). Accordingly, laser stimuli at the foot and hand activated SI regions medially, near the interhemispheric gap, or more laterally, respectively. Ploner et al.[43] and Tran et al.[44] showed that laser-evoked MEG responses to Aδ- and C-fiber activation, respectively, appeared simultaneously in SI and SII, a finding which contrasts the sequential activation of SI and SII following tactile stimuli. Kanda et al.[45] confirmed these results by using implanted subdural electrodes. Yet, not all functional imaging studies revealed SI activation related to pain. PET and fMRI studies exhibited robust SI activity following painful stimuli when using contact heat,[46–48] laser radiant heat,[42,49] or electrical pain,[50,51] but less consistently during spontaneous or provoked clinical pain states.[52,53] Casey et al.[54] noted a clear temporal dynamic of SI activity following painful contact heat using PET. Notably, hypnotic suggestion of sensory pain quality enhanced SI activity following thermal stimulation,[55] whereas that of the affective pain quality did not.[56] This latter result with experimental pain stimuli fits with clinical observation that SI lesions alter sensory qualities but leave affective or cognitive aspects of pain, especially chronic pain, largely

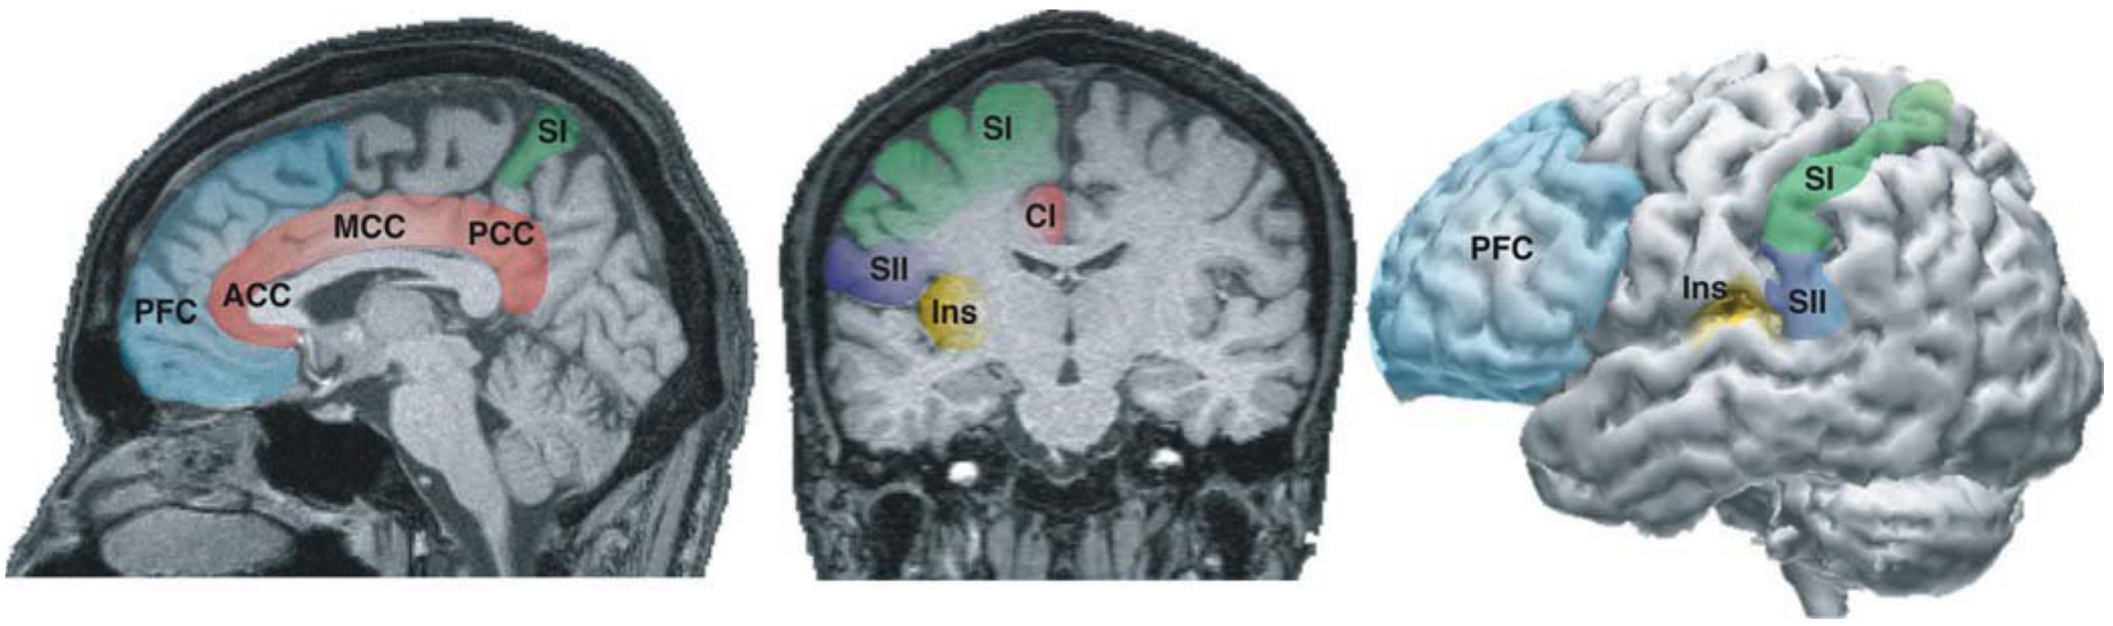

FIGURE 6.3 Schematic anatomical localization of cortical areas, which are regarded as important for pain processing. Somatosensory areas, which are responsible for sensory-discriminative pain processing such as intensity and stimulus decoding, are the primary (SI) and secondary somatosensory cortex (SII). Adjacent to SII is the insula (*Ins*), which belongs to the limbic system and is involved in emotional-affective pain processing. Other limbic structures include the cingulate gyrus with its subdivisions anterior cingulate cortex (ACC), midcingulate cortex (MCC), and posterior cingulate gyrus (PCC). Finally the prefrontal cortex (PFC) plays an important role in cognitive-evaluative pain processing especially for the organization of context-dependent pain behavior.

unchanged.[57] Collective evidence thus indicates that noninvasive imaging methods strongly support the participation of SI in sensory-discriminative aspects of pain perception although temporal aspects of the applied stimulus method and imaging technique and attentional and cognitive factors can significantly modify SI activity.[54,58,59]

Secondary Somatosensory Cortex

The existence of a secondary somatosensory cortex (SII) was introduced for the first time by Adrian[60] in the cat. SII is situated lateral and posterior to SI and occupies the posterior parietal operculum at the upper bank of the Sylvian fissure (Fig. 6.3), encompassing Brodmann areas 40 and 43.[61] Because SII receives input from the thalamus via the spinothalamic projection into lateral nuclei (VPI, VPL, VPM) and sends output to the adjacent insula, SII is in a position to link nociceptive information to limbic cortical regions, such as the anterior cingulate cortex and medial prefrontal cortex. Because of the robust generation of dipolar electric activity following noxious laser stimuli in SII that is oriented tangentially to the skull convexity, multichannel MEG recordings became an important functional brain imaging method to study pain-related SII activity in humans at high temporal resolution. The activity starts between 90 and 150 ms after the painful laser stimulus, depending on the body site and activated nerve fiber spectrum[62–64] and coincides with parallel SI activation.[43] Selective C-fiber activation also activates SII.[65] PET and fMRI revealed SII as one of the most consistent structures activated by pain.[57,58,66,67] Although less precise than SI, SII is also organized somatotopically[41,42,59,68] (see also Fig. 6.4). Patients with lesions within the SII-cortex have been reported to exhibit elevated pain thresholds at contralateral sites,[69] sometimes associated with a central (neuropathic) pain syndrome.[70,71] Several authors point to the problem of differentiating SII from the adjacent posterior insula.[66] Recent evidence from intracerebral recording and stimulations in patients, however, indicates separate representations of nociceptive processing in SII and insula.[41,72] The functional role of SII is not clear. Given its coarse somatotopy, it is unlikely to represent a critical site for spatial discrimination, but rather supplements SI in the organization of spatially guided defensive

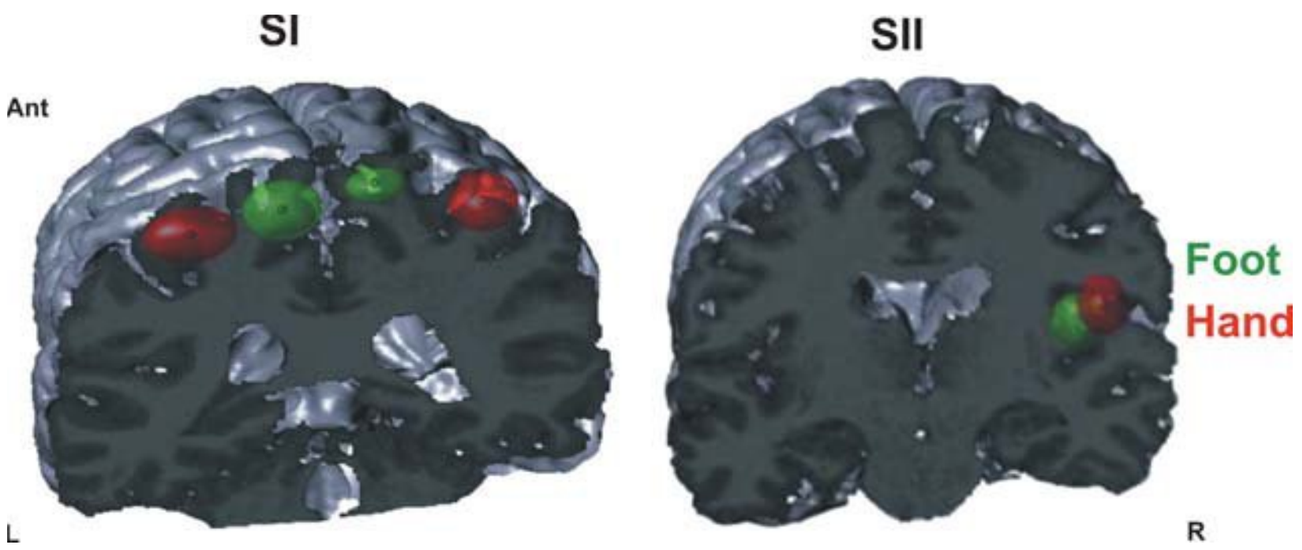

FIGURE 6.4 Somatotopic organization of somatosensory areas. Experimental pain was induced using an infrared laser, which elicits a short burning and pinprick-like pain sensation. Laser stimuli were given at both hands and feet, before pain-induced activation of the primary (SI) and secondary somatosensory (SII) areas were localized using functional magnetic resonance imaging (fMRI) technique. Pain induced activation after hand stimulation (*red*) was found in SI near the interhemispheric gap, whereas foot stimulation (*green*) elicits more lateral activation of SI. Pain induced localization in SII is less spatially separated between hand and foot stimulation. The center of the colored circles is the mean coordinate of the subjects, whereas the radius of the circle is the standard deviation. (Reproduced from Bingel U, Lorenz J, Glauche V, et al. Somatotopic organization of human somatosensory cortices for pain: a single trial fMRI study. *Neuroimage* 2004;23(1):224–232, with permission.)

and protective behavior against bodily threat. Accordingly, SII seems to be involved in recognition, memory, and learning of painful events[73] in that it links a primordial sensory representation of pain with further cognitive evaluation and affective appraisal.

Limbic Areas

Insular Cortex

As stated above, the insula belongs to the limbic system and is located adjacent to SII and can be divided cytoarchitectonically into Brodmann areas 13 (anterior insula) and 41 (posterior insula). Functionally, the anterior insula which lies rostral to the most lateral point of the central sulcus, mainly processes visceral autonomic (i.e., interoceptive) functions, and is closely linked to taste and smell, thus, proximal senses. In contrast, the posterior part is related to distal senses such as hearing, vision and somatosensation (i.e., exteroceptive functions). Craig[30] attributes a key role to the insular cortex in the integration of thermosensation and pain for homeostatic feelings and behavior. Despite the already cited evidence of distinct representations of pain in SII and posterior insula (see previous text), there are not enough data to clearly delineate SII and posterior insula functionally. However, the anterior part appears to represent separate functions from posterior insula and SII, from where it receives input. Further input comes from the amygdala and brainstem nuclei. Projections from the anterior insula go to various limbic structures such as the anterior cingulate cortex and the entorhinal cortex of the temporal lobe (amygdala and hippocampus).

Few lesion studies from patients have been conducted. Isolated anterior insula lesions without damage of the posterior insula and SII yield normal heat pain thresholds.[69] Others reported that damage of the anterior insula reduces pain affect and the ability to assign pain an appropriate meaning referred to as pain asymbolia.[74] Functional imaging studies strongly confirmed the engagement of the anterior insula in pain and the ability to manipulate anterior and posterior insula differentially.[75] Using PET, Casey et al.[54] demonstrated that anterior insula responds early, while posterior insula is activated late following painful contact heat stimuli. This result is consistent with the dissociation of anterior and posterior insula according to respective anticipatory and real pain sensations.[76] Lorenz et al.[23] found stronger anterior insula activation with PET following heat stimuli applied on sensitized skin (heat allodynia) in comparison with equally intense heat stimuli applied on normal skin, whereas posterior insula and SII exhibited same activation across skin conditions (Fig. 6.2). This result may be partly related to the fact that heat allodynia is more unpleasant than normal heat pain. Consistent with this assumption, Schreckenberger et al.[77] found a significant positive correlation of unpleasantness ratings with regional glucose metabolization rate in bilateral insula following painful injections of an acidic solution into skin and muscle as measured with FDG-PET (Fig. 6.5). Thus, although both portions of the insula vary with pain intensity, anterior insula additionally represents subjective relevance and meaning of the pain in terms of its relation to an exteroceptive or interoceptive threat. This is also consistent with the role of the anterior insula in processing stimulus novelty.[78]

Cingulate Cortex

The cingulate cortex represents a key structure of the limbic system. Anatomically, it is located in the medial portion of both hemispheres above the corpus callosum. Cytoarchitectonically it is divided into distinct areas: the anterior cingulate cortex (ACC, area 24 and 25) and the posterior cingulate cortex (PCC, area 23). A more recent view additionally separates the midcingulate cortex (MCC, area 24) and the retrosplenial cortex (RSC). A major input to ACC comes from medial and intralaminar thalamic nuclei[79] which places the ACC into the center of the medial pain system subserving affective-motivational and cognitive-evaluative pain determinants.[26] Anatomically distinct regions are thought to relate to different functions, some more specifically related to pain, others to motor, autonomic, and cognitive functions[79,80] (Fig. 6.6). Whereas cingulotomy for intractable pain yielded only a modest relief from pain, it appeared that the degree to which pain interfered with other cognitive activities, behaviors, and social functions was significantly reduced.[81] Also, cingulate lesions in animals revealed minimal deficits in discriminative pain function but robust changes in pain-related behavior and learning.[82,83] A multimodal integrative rather than a specific nociceptive role of the ACC is also underlined by its large receptive fields and the absence of somatotopy.[79] MEG activity following laser radiant heat pain demonstrates a preferential response of the

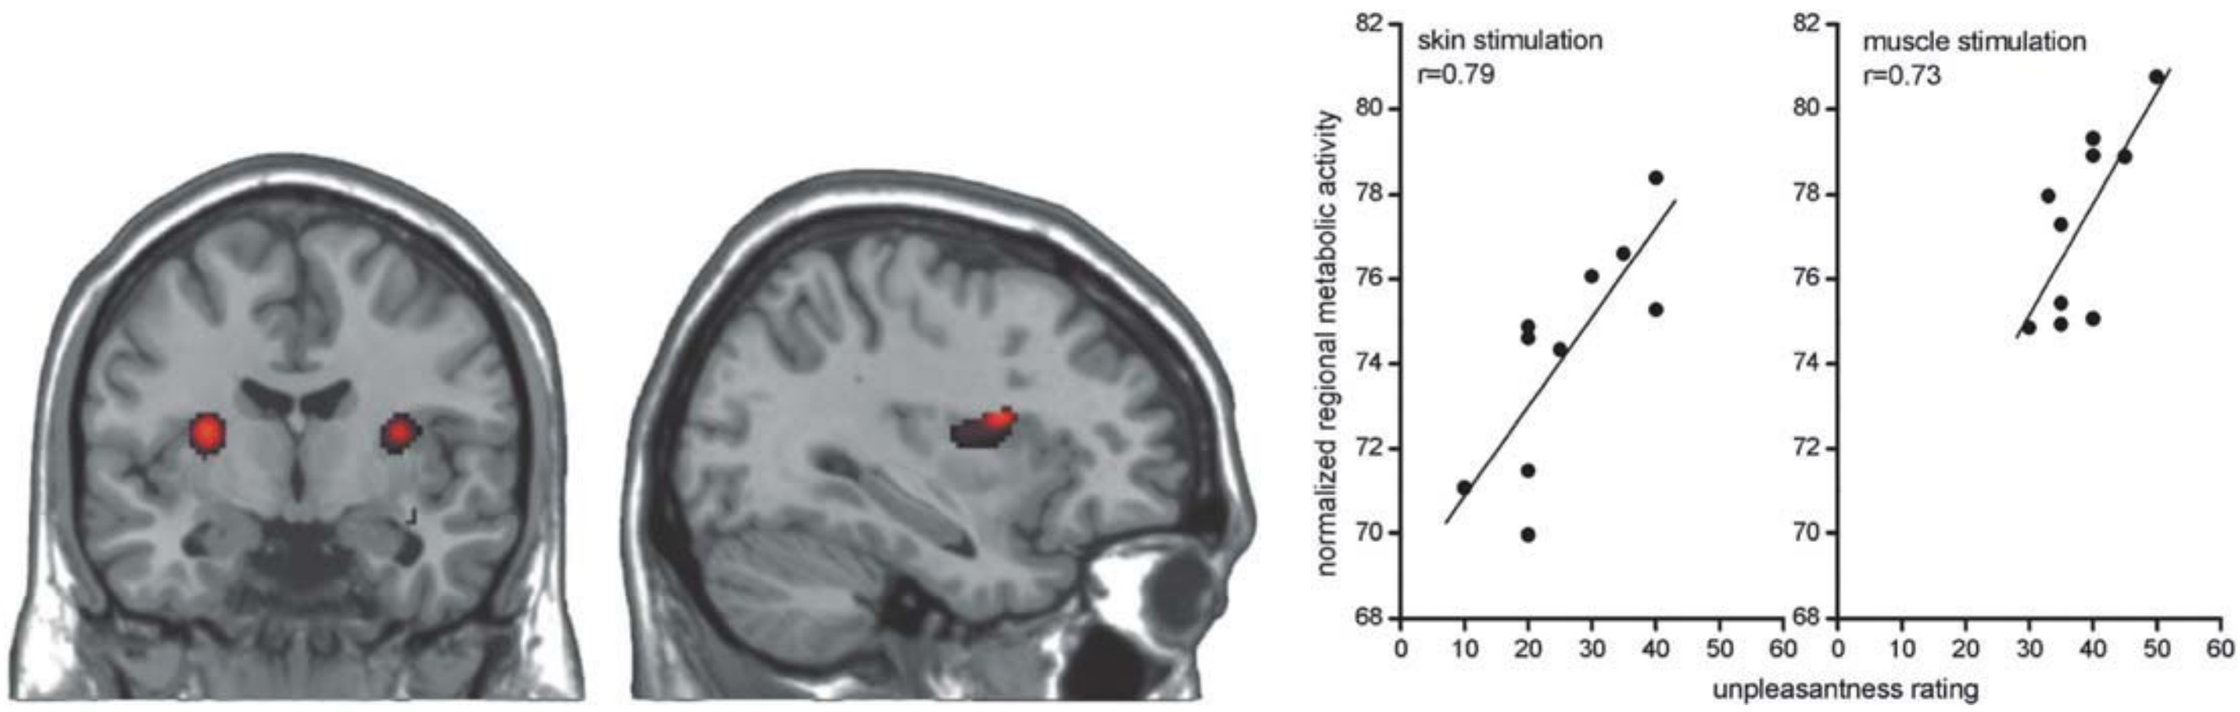

FIGURE 6.5 Correlation between unpleasantness rating and insula activation. Experimental pain was induced by infusion of low pH (5.2) solution in either the skin or the hand muscle. Subjects had to rate the unpleasantness of the painful stimulation, which was then correlated with regional metabolized activity within the insula using positron emission tomography (PET). Results show a strong significant ($p < 0.05$) correlation between unpleasantness ratings and insula activity for both skin and muscle pain. (Reproduced from Schreckenberger M, Siessmeier T, Viertmann A, et al. The unpleasantness of tonic pain is encoded by the insular cortex. *Neurology* 2005;64(7):1175–1183, with permission.)

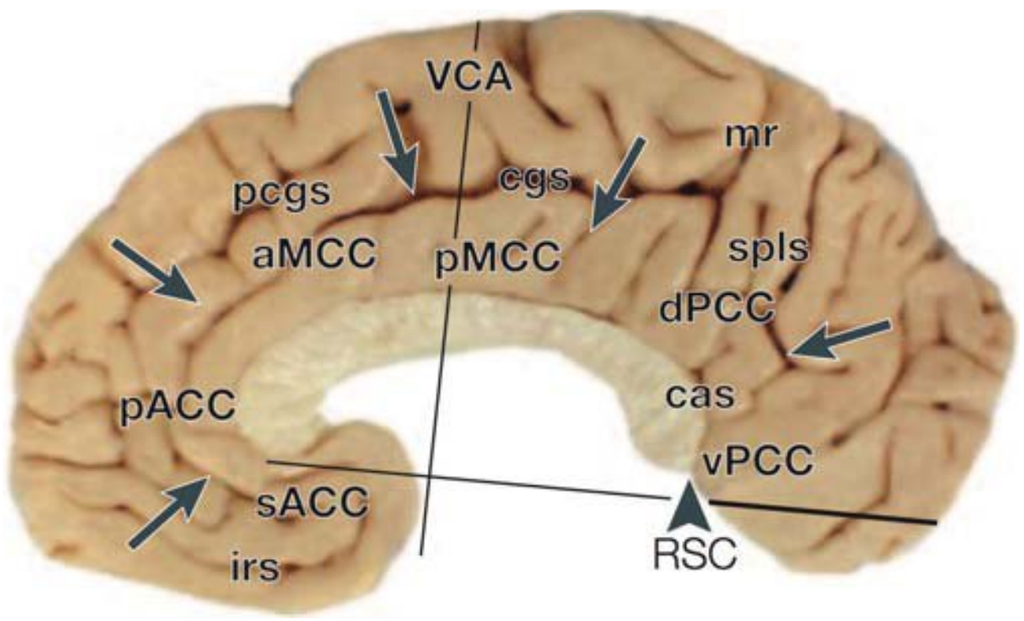

FIGURE 6.6 Region borders of the cingulate cortex according to Vogt. Subregions are marked with arrows and were determined based on postmortem cases that were coregistered to a stereotaxic atlas with the vertical plane at the anterior commissure (VCA) and the anteroposterior commissural line. A functional overview, derived from the analysis of a large volume of literature, is provided. This illustrates general regional function and, where known, subregional specializations. aMCC, anterior midcingulate cortex; cas, callosal sulcus; cgs, cingulate sulcus; dPCC, dorsal posterior cingulate cortex; irs, inferior rostral sulcus; mr, marginal ramus of cgs; pACC, pregenual anterior cingulate cortex; pcgs, paracingulate sulcus; pMCC, posterior midcingulate cortex; RSC, retrosplenial cortex; sACC, subgenual anterior cingulate cortex; spls, splenial sulci; vPCC, ventral posterior cingulate cortex. (Modified from Vogt BA. Pain and emotion interactions in subregions of the cingulate gyrus. *Nat Rev Neurosci* 2005;6(7):533–544, with permission.)

ACC to C-fiber input, regarded as important for the sustained "suffering" component of pain associated with C- rather than Aδ-fiber activity.[84] Together with SII and insula, ACC is the most consistent region activated by pain.[63,67,75] However, imaging of subjects engaged in a variety of cognitive, affective, and motor tasks also revealed ACC as the most consistent brain area.[85] The MCC is involved in response selection, fear avoidance, and motor function. Despite the diversity of perceptual, emotional, cognitive, motor, and autonomic processes harbored within distinct or overlapping cingulate cortex structures as revealed from numerous functional imaging studies, a common function to which all these processes converge may be seen in the awareness and monitoring of bodily threat or behavioral conflict demanding executive control. Such a view would explain why both detrimental effects of pain upon cognition as well as beneficial effects of cognitive distraction upon pain are represented in the anterior cingulate cortex.[86,87] Thus, the reciprocity of pain and cognitive processes at the level of the ACC might significantly determine the degree by which pain interrupts cognitive performance and is intrinsically difficult to ignore.[88]

Prefrontal Cortex

The prefrontal cortex (PFC) is the anterior part of the frontal lobe and contains numerous neurons and a large volume (30% of brain mass) and is furthest developed in humans compared to nonhuman species.[89] It can be divided into different subdivisions[85]: the mid-dorsal (area 9), dorsolateral (BA 46), ventrolateral, orbitofrontal, and medial frontal parts (BA 10, 11, 13, 14). All these frontal areas receive convergent input from different sensory modalities and again project to different associative sensory areas, motor areas, and limbic structures. The PFC is considered to be important for higher cortical functions that characterize the flexibility of human behavior, the ability to control attention, and the richness of intellectual and emotional competence. With respect to pain, PFC plays a major role in cognitive, attentional, and emotional processing of painful stimuli and recruitment of endogenous pain control. A particular part of the PFC, the dorsolateral prefrontal cortex (DLPFC), is important for continuous monitoring of the external world, maintenance of information in short-term memory, and governing efficient performance control in the presence of distracting or conflicting stimuli.[90,91] In turn, orbital and medial portions of the prefrontal cortex are known to be important for mood and emotional behavior; for example, when guided by cues of reward or punishment, as well as for visceral and autonomic homeostasis related to eating and drinking behavior.[92] The famous case of Phineas Gage demonstrated that lesions of the PFC can strongly interfere with the maintenance of an individual's personality, socially appropriate behavior, and learning capabilities.[93,94] There is evidence of elevated pain thresholds in patients with frontal lobe lesions.[95]

The PFC is activated in several, not all, functional imaging studies using experimental painful stimuli or clinical pain states. It typically fails to show a clear pain-related stimulus-response function,[49,96] which led to the assumption that PFC activity mainly relates to the engagement of attention during pain processing.[66] Evidence indicates that the PFC, irrespective of pain intensity, integrates information about the psychological and bodily context of pain in order to allow disengagement from pain through activating endogenous pain control. Lorenz et al.[23,97] confirmed strong responses of dorsolateral PFC and orbitofrontal and medial PFC (OMPFC) during inflammatory pain as induced by topical capsaicin (see Fig. 6.2). Whereas DLPFC exhibited a negative relationship, OMPFC yielded a positive relationship to the unpleasantness of perceived pain. Furthermore, the interregional correlation of activity between midbrain and medial thalamus was significantly reduced during high compared to low left DLPFC activity, which could indicate a top-down mode of inhibition of effective synaptic connectivity between brainstem and medial thalamus as a cause for the inverse relationship of DLPFC activity to pain unpleasantness. A role of the DLPFC in the initiation of endogenous pain control is further supported by its participation in placebo analgesia. Wager et al.[98] demonstrated that DLPFC responds to cues that inform test participants about an expected analgesic effect in a placebo experiment. The analgesic effect itself, however, goes along with stronger rostral ACC activation[98,99] being stronger when coupled with the brainstem PAG.[100]

Recent clinical studies lend further support for the association of the DLPFC with pain suppression. Apkarian et al.[101] observed a reduction of the grey matter density determined by morphometry of magnetic resonance scans in bilateral DLPFC and right thalamus in chronic back pain patients that was strongly related to pain characteristics. In agreement with the suggested role of DLPFC in pain control, high-frequency transcranial magnetic stimulation (rTMS) over left DLPFC was able to ameliorate chronic migraine.[102] This is consistent with earlier studies in animals where electrical stimulation of fiber connections of the prefrontal cortex to the midbrain mediates antinociceptive effects in rodents.[103] In summary, collective evidence suggests that the PFC represents an important brain substrate for the human ability to actively disengage from pain.

Amygdala

The amygdala is an almond-shaped structure deep in the midtemporal lobe and belongs to the limbic system. The amygdala complex comprises about 13 nuclei, which are further divided into subregions.[104] These nuclei can also be grouped by functional properties in frontotemporal, autonomic, main, and accessory olfactory systems.[105] Tracer studies reveal that the amygdala gets multiple inputs from different cortical and subcortical structures and all sensory modalities. Cortical somatosensory and pain input arises directly from SI, SII and the insula,[102] whereas subcortical pain signals arise among others from the thalamus and the brainstem parabrachial nucleus. In addition, numerous projections from the amygdala go back to the brainstem, the hippo-

campus, and cortical areas such as the prefrontal cortex, whereas output connections to sensory areas are rare.[106] Numerous, but not all, imaging studies reveal amygdala activation during pain perception. There is no steady increase of activity in the amygdala with stimulus intensity, but rather a step-wise increase once stimulus intensity transits into pain.[49] This finding may point to learning following painful stimuli or to processing the emotional valence of pain stimuli.[107] Amygdala activation during pain might also reflect activation of a "defensive behavioral system," which controls transmission of nociceptive experience to the brain through descending modulatory circuits.[108] There are projections of the amygdala to the periaqueductal grey matter (PAG) that might initiate antinociceptive function during emotional stress or pain expectation.[109–111] Lesions in the amygdala, also known as Klüver-Bucy syndrome, lead to flattened emotional reactivity and loss of fear conditioning, but, as with ACC lesions, do not impair pain discrimination but change the behavioral response to pain. It is conceivable that the amygdala is important for the memory storage of past pain experiences and their context, in terms of the processes underlying fear conditioning to facilitate defensive autonomic reactions and behavior.

Hippocampus

The hippocampus forms, relative to the amygdala, the caudal extension of the deep medial temporal lobe (Fig. 6.5). It can be subdivided into the dentate gyrus and the cornu ammonis (CA1 and CA2). Its major input comes from the entorhinal cortex, a network including the DLPFC and parietal association cortex. Reports of Patient H. M.[112,113] highlight the role of the hippocampus in learning and explicit memory. Moreover, the importance for the involvement in pain processing and learning pain-related behavior is evident, because associations between pain and predictive cues have fundamental adaptive value.[114] Furthermore, learning adverse effects can play an important role in chronic pain and chronic pain-related avoidance behavior. Functional imaging revealed hippocampus activity during mild and moderate heat pain,[108,115] in a pain-learning paradigm when pain was not expected, and when pain stimuli were manipulated as to induce anxiety.[114] Together with the assumed role of the amygdala in pain, these findings show that medial temporal lobe structures participate in elaborating the experience of pain based on emotional state, expectation, and past experience.[57]

VIGILANCE, AROUSAL, AND ATTENTION

Attention is not a single neurophysiological entity. Many authors, including Parasuraman et al.,[116] describe different major components of attention that rely on a finite set of brain processes being hierarchically organized and interacting with each other. A basic component serves the maintenance of behavioral goals over time and is largely synonymous with arousal, vigilance, alertness, or sustained attention. It also involves the regulation of the sleep–wake cycle. Cholinergic and noradrenergic ascending systems originating in the reticular formation (see previous text) and the locus ceruleus and dopaminergic projections into the striatum are regarded as important for this function referred to as "the vigilance network" by Posner and Petersen.[117] Another component concerns the bias or filtering of task-relevant against irrelevant information. It serves to cope with capacity limits of central information processing which cannot deal with the huge amount of input from a large variety of sensors in different modalities at the same time. This component is often referred to as selective or focused attention and, according to Posner and Pertersen,[117] depends on the posterior attention network that includes brain structures such as the superior colliculus, thalamic pulvinar, and the posterior parietal cortex. Selective attention is often metaphorically described by a "spotlight" or "cocktail party" effect, which emphasizes the phenomenon that the focus of awareness can momentarily fluctuate between sensory objects, features, or locations sometimes without overt orientation in the form of eye or head movements. It is believed that the gating of the afferent flow of information within attentional channels (i.e., the set of stimuli benefiting from selective attention) optimizes functional efficiency even at very early stages of modality-specific cortical processes. Closely linked to this function is a supervisory component of attention that temporarily intervenes into ongoing performance when called for by new relevant, unfamiliar, or potentially dangerous information; the detection of performance errors; or when internal representations need to be continuously updated, that is, during working memory operations. This component is often referred to as executive attention, largely governed by the anterior attention network *sensu*[117] that comprises the anterior cingulate, medial and lateral prefrontal cortex areas, and the supplementary motor area.

Long duration mental tasks yield a characteristic vigilance decrement that can be measured subjectively or by behavioral indicators such as reaction time.[116] Similarly, amplitudes of pain-relevant evoked potentials after electrical stimuli, painful chemical stimulation of the nasal mucosa, and laser stimulation are strongly attenuated by habituation and decreases of vigilance over time.[118] Although pain generally enhances arousal, the test situation for the recording of pain-relevant laser evoked potential (LEP) is characterized by short durations of single laser stimuli, presented at long inter-stimulus intervals in quite monotonous long-stimulus blocks, which contribute to reduced LEP amplitudes by vigilance decrements. Experimental pain studies therefore use study designs to avoid or control for habituation. Pain habituation can be observed during short-term pain experience but also during longer lasting pain after several days. FMRI experiments on the mechanisms of habituation revealed decreases of activation in major pain areas including the thalamus, insula, SII, and the putamen. Notably, an increase in activation was observed in the ACC.[119] One possible mechanism could be the involvement of the endogenous opioidergic pain control system (see previous text). In an animal model of habituation, naloxone sufficiently prevents habituation to repeated electrical pain stimuli.[120] There are important inter-individual differences regarding the strength of habituation that are not well understood. However, it is described that especially chronic pain patients show an impairment of habituation.[121–124]

Beydoun et al.[125] examined subjects who they allowed to fall asleep after one day of sleep deprivation to look for LEP during different sleep stages compared to normal wakefulness. They demonstrated the abolition of the major LEP component at the vertex position during sleep stage II, defined by the appearance of sleep spindles, and its strong amplitude attenuation during sleep stage I, defined by drop-out of alpha activity and appearance of lateral eye movements. It appears that there is a reciprocal relationship between sleep and pain, allowing sleep to reduce pain but also pain to reduce or disturb sleep.[126] Furthermore, decreases of pain sensitivity also accompany sedation and drowsiness when induced pharmacologically using benzodiazepines,[127] clonidine,[128] or subanesthetic isoflurane.[129] It is therefore often difficult to differentiate drowsiness or sedation from analgesia.

Given the profound role of attention for conscious perception, it significantly impacts behavior and pain experience.[88] Pain is a salient stimulus and draws attention for extended periods.[78] The manipulation of attention by distraction or focused attention has been used as a therapeutic intervention for several years[130,131] and reflects everyday life experience such as when a mother tries to distract her children when they are hurt. Clinical evidence suggests that attentional mechanisms may be also involved in the amplification of some chronic clinical pain stages.[132] Patients

with chronic pain problems seem to selectively attend to pain and the degree by which pain distracts attention from concurrent tasks appears to depend on the evaluation of pain stimuli as threatening or worrying.[88] In tasks where attentional shifts are required, anxious patients exhibit difficulties disengaging from painful stimuli.[133]

The neural mechanisms underlying attentional modulation of pain are not fully understood, but various areas of the pain matrix appear to be involved.[134] More recent studies using EEG and MEG focused on cortical synchronization processes as indicators of attentional modulation of sensory input. Mainly derived from experiments with nonpainful stimuli, it is proposed that selective attention may act by modulating sub-threshold oscillations in sensory assemblies and by enhancing the gain of oscillatory responses to stimuli that match stored contextual information.[135,136] A recent study indicates that during selective attention to pain, bilateral somatosensory cortical sites yield enhanced oscillatory activity in the gamma bandwidth of MEG (120 Hz rhythms), and a stronger inter-regional degree of synchronization as sign of increased communication[137] (Fig. 6.7). One possible neuronal correlate of abnormal attentional amplification may therefore be suspected as an "over-synchronization" in pain-related cortical areas, leading to an uncontrolled spread of signals even in the case of weak or absent nociceptive input. Thus, the dynamic control of neuronal signal flow might be disturbed, preventing an appropriate context-dependent modulation of the gain of neural signals, and reducing the capacity for descending control of nociceptive afferent inputs. As assumed for states of chronic pain, such an "over-synchronization" might be viewed as the result of central neuroplastic changes underlying a learning process.[138]

PAIN PLASTICITY

The brain is an adaptive system, which has a high plasticity to change the excitability of its networks according to a variety of external and internal processes. The uniqueness of pain compared with other human senses is characterized by its enormous plasticity to adapt according to both the bodily and the psychological context in which pain occurs. Studies on acute pain models in animals and humans had long made clear that clinically important pains exhibit distinct neurophysiological and pharmacological properties due to alteration of impulse generation at the site of an injury and propagation into and through the central nervous system. Once tissue damage and inflammation occur, the production and release of chemical mediators excite and sensitize nociceptors, rendering their axons much more responsive and giving rise to tenderness and hyperalgesia as well as spontaneous pain.

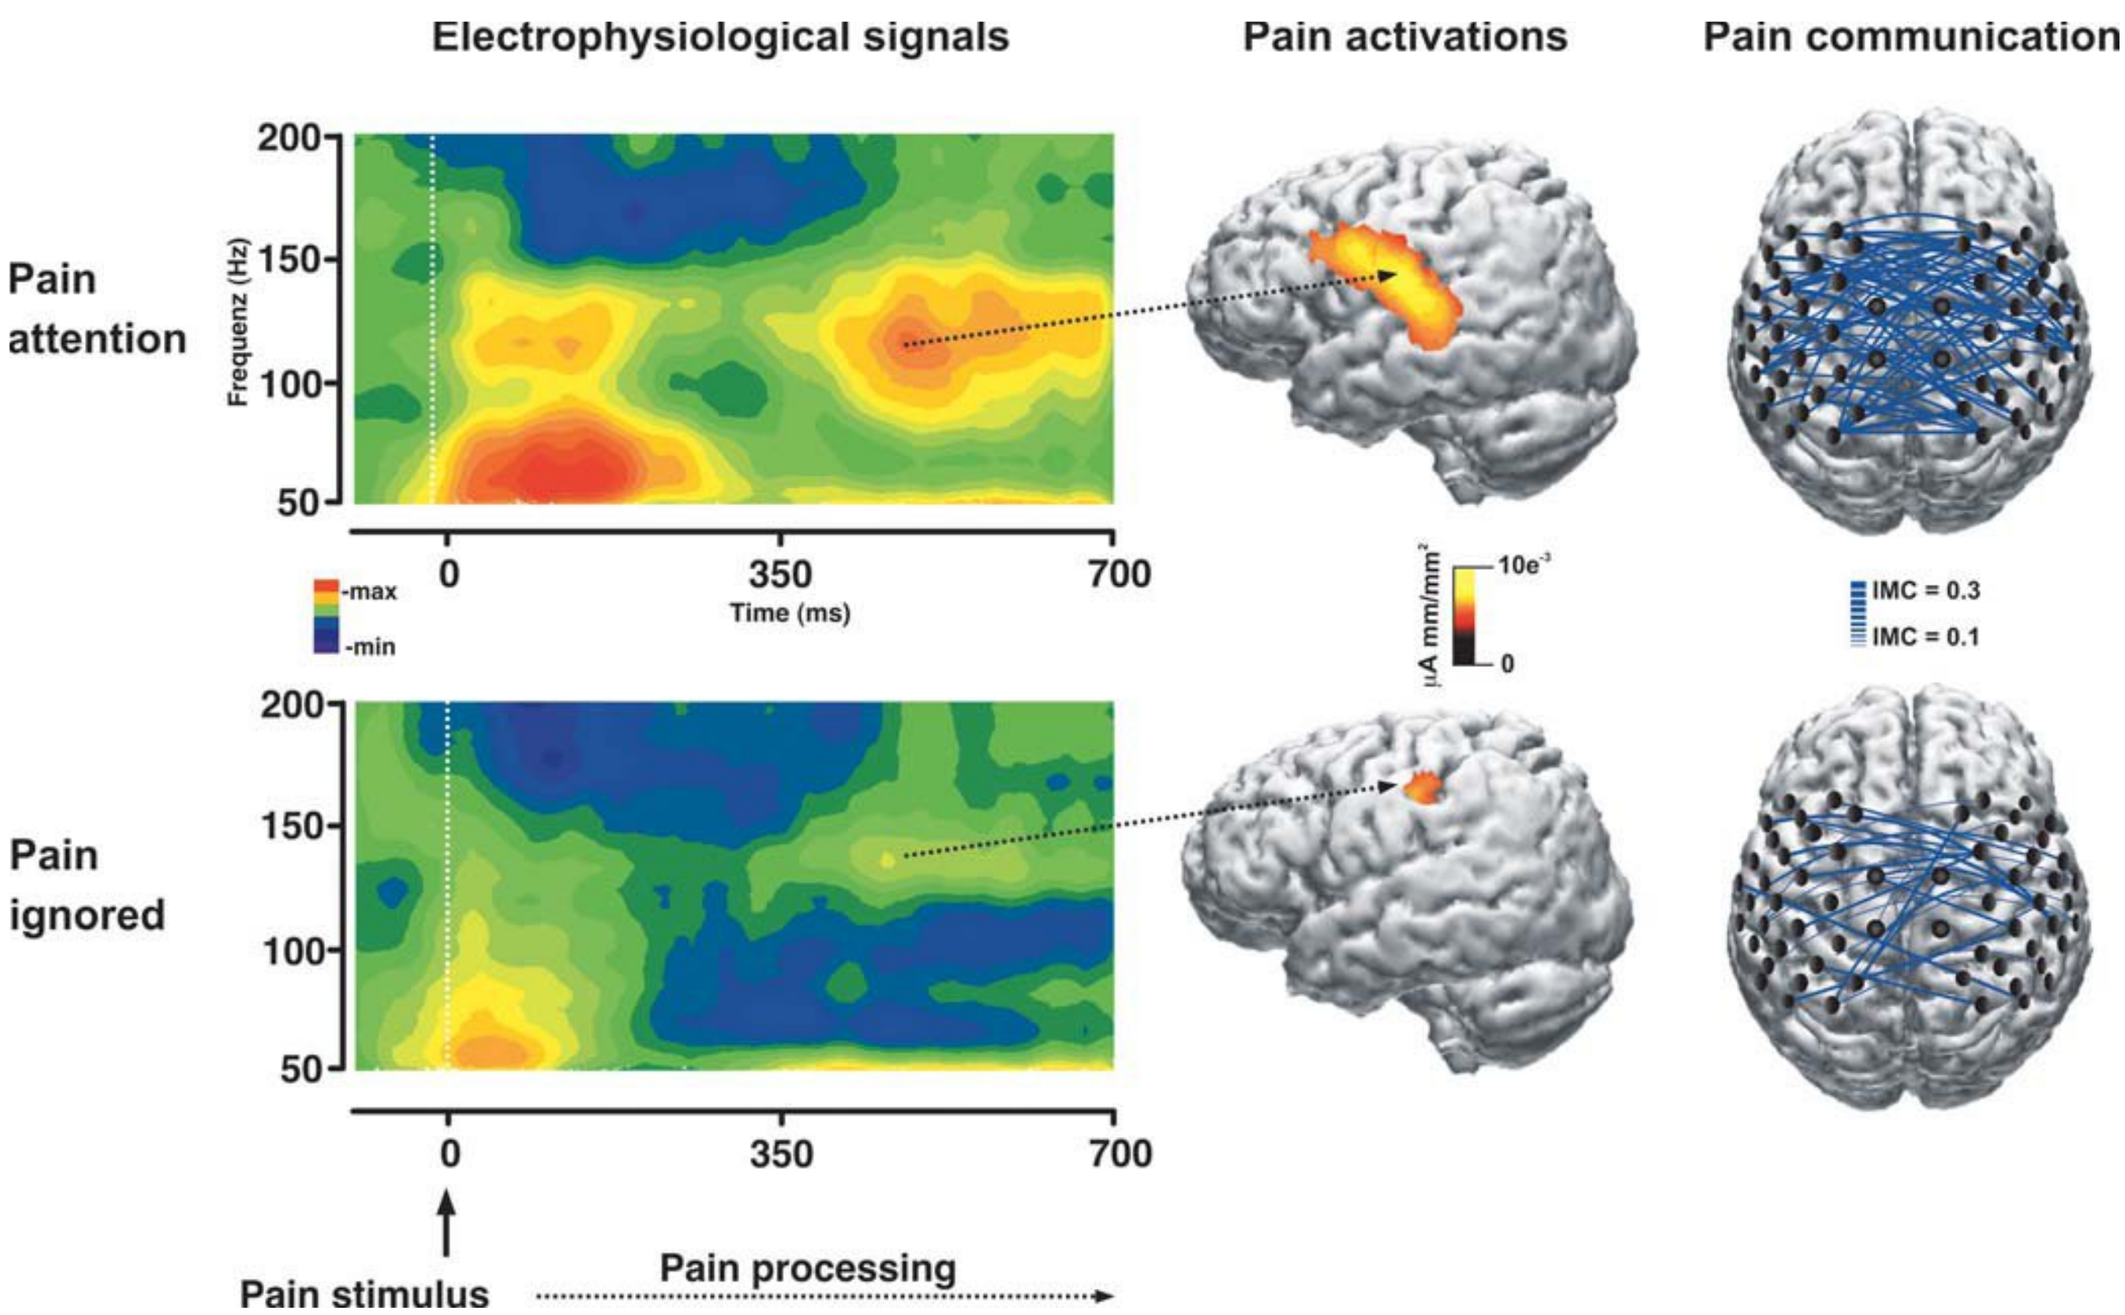

FIGURE 6.7 Pain modulation by attention. Attention to pain (pain attention) was induced by counting rare electrical pain stimuli at one finger, while ignoring frequent pain stimuli at the other finger (pain ignored) within a random series (oddball paradigm). Electrophysiological signals were recorded using magnetoencephalography (MEG). After time-frequency transformation, neuronal oscillations around 120 Hz (gamma band) and with latencies around 500 ms indicated a difference for attention. This effect was localized in sensory-motor areas. Furthermore, an increased communication (imaginary coherence, IMC) between both sensory-motor sites was observed during attention. (Modified from Hauck M, Lorenz J, Engel AK. Attention to painful stimulation enhances gamma-band activity and synchronization in human sensorimotor cortex. *J Neurosci* 2007;27(35): 9270–9277, with permission.)

Hyperexcitability also occurs at the level of the dorsal horn in the spinal cord following tissue damage and inflammation, further aggravating sensitization and even rendering innocuous tactile stimuli outside the lesion capable of producing pain through increase of synaptic efficacy of local interneurons, a phenomenon called allodynia. Thus, the bodily context of normal versus damaged tissue dramatically determines the perception of pain.

Several pain states, such as chronic pain or phantom pain, can induce central cortical changes in the pain matrix. Patients suffering from cancer with intractable unilateral pain developed a decrease in metabolism within the contralateral thalamus, which was abolished after blocking nociceptive input by surgical hemicordotomy.[139] A smaller representation of the affected hand was found in somatosensory areas (SI and SII) for nonpainful stimulation that correlated with symptom severity in patients suffering from complex regional pain syndrome (CRPS),[140] whereas representation for nociceptive input is extended in somatosensory areas in these patients.[141] Similarly, other chronic pain states yielded exaggerated activation and occupied larger areas in somatosensory cortex as demonstrated for low back pain,[142] fibromyalgia,[143] and neuropathic pain.[144] Anatomical changes in grey matter density can also be observed for chronic pain patients. Using MRI scans with voxel based morphometry analysis, changes in white and grey matter can be compared between groups and within subjects during different time points. Changes in different cortical areas were found for different pain syndromes. In chronic back pain patients,[101] atrophy in the thalamus and the prefrontal cortex were observed (Fig. 6.8). Interestingly, these grey matter density changes occur in pain-related regions such as the prefrontal cortex, thalamus, the insula, and the cingulate cortex. Others describe atrophy in the hippocampus, the midcingulate cortex, the frontal cortex, and the insula in fibromyalgia.[145] Similar findings were made in chronic headache.[146] Whether this is a result of the brain atrophy, or a consequence of ongoing pain, is still debated. Another possible explanation for the decreased grey matter density in these disorders might be atrophy secondary to excitotoxicity and/or exposure to inflammation-related agents, such as cytokines.[101]

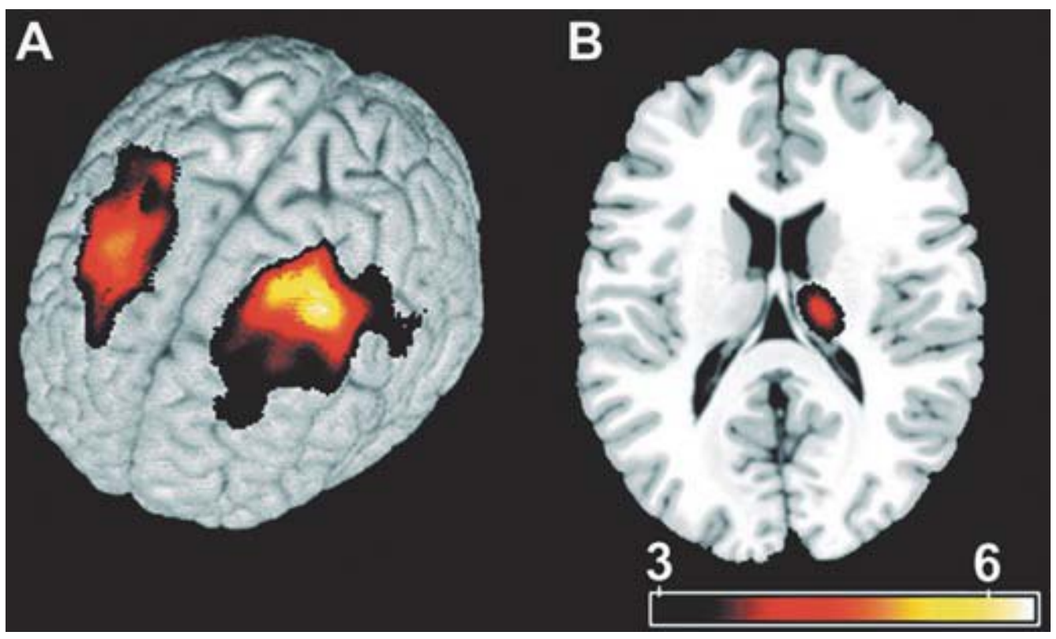

FIGURE 6.8 Regional grey matter density decreases in patients suffering from chronic back pain (CBP). A nonparametric comparison of voxel-based morphometry (VBM) between CBP and control subjects is shown. **(A)** Grey matter density is bilaterally reduced in the dorsolateral prefrontal cortex (DLPFC). The result is from a VBM permutation-based pseudo-*t* test and voxel-level contrasts when all brain grey matter voxels were compared between controls and CBP subjects. Pseudocolor highly positive values indicate regions where grey matter density was reduced in CBP subjects (controls, CBP). **(B)** A nonparametric comparison spatially limited to the thalami revealed a significant decrease in grey matter density in the right anterior thalamus. A slice at the peak of decreased thalamic grey matter is shown. Pseudo-*t* values are color coded; range is 3–6. (Reproduced from Apkarian AV, Sosa Y, Sonty S, et al. Chronic back pain is associated with decreased prefrontal and thalamic gray matter density. *J Neurosci* 2004;24(46):10410–10415, with permission.)

CONCLUSION

Noninvasive functional neuroimaging of pain in human volunteers and patients has attracted enormous interest and activity in pain research and significantly enriched our knowledge about the contribution of the brain in processing and modifying peripheral and spinal nociceptive signals. Supraspinal mechanisms of nociception and pain rely on a multilevel organization of brain structures involving the brainstem (medulla, pons, midbrain), diencephalon (thalamus, hypothalamus), primary (SI) and secondary (SII) somatosensory cortices, and fronto-limbic circuits (prefrontal cortex, anterior cingulate cortex, insula, amygdala, hippocampus). Spinal nociceptive afferents that reach predominantly lateral thalamic nuclei convey nociceptive signals into the sensory cortex (SI, SII) and provide the individual with the capability to recognize intensity, location, and duration of noxious stimuli. This lateral pain system is therefore commonly referred to as the major brain anatomical substrate of the sensory-discriminative determinant of pain. Direct and multi-synaptic projections from the dorsal horn and brainstem into medial thalamic nuclei transmit nociceptive signals into the limbic system (insula, ACC, prefrontal cortex). This medial pain system predominantly comprises the affective-motivational determinant of pain. A pivotal role of the dorsolateral prefrontal cortex (DLPFC) in pain is its ability to coordinate nociceptive signals with momentary bodily needs and behavioral goals to account for the significance and threat value of pain. The numerous supra-modal connectivity of the DLPFC with sensory and motor systems allow the individual to maintain attention upon pain, but also to release it in favor of superior behavioral goals or in expectation of positive outcome through recruitment of endogenous pain control systems. A predominant feature of pain in comparison with other human senses is its enormous ability to adapt its response properties according to both the bodily and psychological context. This plasticity implies fundamental changes in the course of pathological processes underlying tissue damage and inflammation, or in the course of memory processes and learning from past pain experiences. Supraspinal mechanisms thus contribute to such plasticity by integrating information about the nature and behavioral significance of pain by recruiting unique pathways during normal or sensitized conditions and by facilitating learned pain behaviors. While in most instances such plasticity is adaptive to avoid actual bodily damage or promote the healing process, it also forms the basis for maladaptive consequences underlying chronic pain and neuropathic pain.

CHAPTER 7 ■ PSYCHOLOGICAL ASPECTS OF PAIN

DENNIS C. TURK, KIMBERLY S. SWANSON, AND HILARY D. WILSON

INTRODUCTION

Advances in the knowledge of the neurophysiology of pain have resulted in the development of new pharmacological agents, sophisticated surgical interventions, and the use of advanced technologies (e.g., spinal cord stimulation, implantable drug delivery systems) for the treatment of pain. Despite these advances, the cure of pain remains elusive. Regardless of the treatment, the amount of pain reduction averages only about 35%, and fewer than 50% of persons treated with these interventions obtain this result. The extent of improvement in emotional, physical, and social functioning is often below these dissatisfying levels.[1]

Despite the poor track record of chronic pain treatments, chronic pain patients are often given an expectation for a cure. Although individuals with acute pain can often receive relief from primary health care providers, people with persistent pain become enmeshed in the medical system as they shuttle from doctor to doctor, diagnostic test to diagnostic, in a frustrating search to have their pain successfully treated. This experience of "medical limbo"—the presence of a painful condition that, in the absence of acceptable pathology, is either attributed to psychiatric causation or malingering on the one hand, or an undiagnosed but potentially progressive disease on the other—is itself a source of significant and chronic stress that can initiate emotional distress or aggravate a premorbid psychiatric condition.

The person who has a chronic pain condition resides in a complex and costly world that is populated not only by them but also by their significant others, health care providers, employers, and third–party payers. Family members feel increasingly hopeless and distressed as medical costs, disability, and emotional suffering increase while income and available treatment options decline. Health care providers grow increasingly frustrated and feel defeated and ineffective as available treatment options are exhausted, while the pain condition remains a mystery and may worsen. Employers, who are already resentful of growing worker's compensation benefits, pay higher costs while productivity suffers because the employee frequently calls out sick or is unable to perform at his or her usual level ("presenteeism"). Third-party payers watch as health care expenditures soar with repeated diagnostic testing, often with inconclusive results. In time, the legitimacy of the individual's report of pain may be questioned, since oftentimes a medical etiology fails to substantiate the cause of the symptoms.

People with chronic pain may begin to feel that their health care providers, employers, and even family members are blaming them when their condition does not respond to treatment. Some may suggest that the individual is complaining excessively in an attempt to receive attention, avoid undesirable activities, or be relieved from onerous obligations (e.g., gainful employment, household chores). Others may suggest that the pain is not real, they are feigning or exaggerating their symptoms, and is all in their head—"psychogenic." Third-party payers may even suggest that the individual is intentionally exaggerating his or her pain in order to obtain financial gain while others may attribute reported symptoms to the desire to obtain mood-altering medications. In this way they may come to be viewed as "whimps," "crocks," or "fakes." Patients may in turn come to view health care providers as "quacks," "hacks," or "thieves." Often, the result is an unfortunate and inappropriate adversarial relationship.

As a result of the attitudes, and in the absence of cure or even substantial relief described, individuals with chronic pain may withdraw from society, lose their jobs, alienate family and friends, and become more and more isolated, despondent, depressed, and, in general, demoralized. Their bodies, the health care system, and their significant other have all let them down; they may feel they have even let themselves down as they relinquish their usual activities and responsibilities due to symptoms that are intractable, yet often inscrutable when not validated by objective pathological findings. This emotional distress, however, can be exacerbated by a variety of other factors, including fear, inadequate or maladaptive support systems, inadequate personal and material coping resources, treatment-induced (iatrogenic) complications, overuse of potent drugs, inability to work, financial difficulties, prolonged litigation, disruption of usual activities, and sleep disturbance. Living with persistent pain conditions requires considerable emotional resilience and tends to deplete people's emotional reserves, taxing not only the individual sufferer but also the capacity of family, friends, coworkers, employers, and society to provide support.

Based on the evidence presented, two conclusions are obvious: (1) psychosocial and behavioral factors play a significant role in the experience, maintenance, and exacerbation of pain; and (2) since some level of pain persists in the majority of people with chronic pain regardless of treatment, self-management is an important complement to biomedical approaches. In this chapter we will emphasize a set of important psychological constructs including dispositional, cognitive, affective, and behavioral factors. We discuss them separately for ease of explication. It is important to note, however, that although we will describe these separately, there is considerable overlap and integration among them. We will conclude with a discussion of integrative models and treatments of chronic pain.

COGNITIVE FACTORS: PREDISPOSITIONS, APPRAISALS, BELIEFS, PERCEIVED CONTROL, AND SELF-EFFICACY

Predispositions

Temperament is putatively, at least partly, heritable and may show continuity throughout life. Personality in adulthood reflects the molding of underlying temperament by life experiences. Temperament and personality may predispose individuals toward misinterpretation of pain sensations and maladaptive pain beliefs, or they can have a protective role.

Potential vulnerability factors that have been proposed are negative affectivity, anxiety sensitivity (AS), and illness/injury sensitivity. Negative affectivity may be considered as heritable, stable, and promoting a tendency to experience a broad range

of negative emotions and to view the world as threatening and distressing.[2] Negative affectivity has been associated with heightened vigilance to bodily sensations and interpretational biases toward ambiguous internal signals.[3,4] Studies in nonclinical populations found negative affectivity to predict lower pain tolerance.[5] However, studies in chronic pain populations have so far not provided consistent evidence for a role of trait negative affectivity. Thus, although negative affectivity has often been implicated as a vulnerability factor in chronic pain, convincing evidence is lacking.

More convincing has been the research on another potential vulnerability factor: AS. AS is defined as the fear of anxiety-related sensations, and is conceived as a partly heritable personality trait.[6] Individuals with high AS interpret unpleasant physical sensations (like rapid heart beating, feeling faint) more often as a sign of danger than individuals with low anxiety sensitivity. There is growing evidence that AS may also be a risk factor for the maintenance and exacerbation of chronic pain and disability.[7] AS has been shown to correlate with measures of fear-avoidance and is associated with distress, analgesic use, and physical and social functioning in patients across a wide range of different pain-related conditions.[8] Moreover, path analyses and mediation models suggest that anxiety sensitivity exacerbates fear-avoidance beliefs and the negative interpretation of bodily sensations, which in turn leads to enhanced pain experience and pain avoidance.[9,10] Studies examining the predictive value of AS in relation to cognitive and behavioral reactions to experimentally induced pain support a causal, negative biasing role of AS in maladaptive cognitive and behavioral pain response.

In contrast to the extensive search after negative predisposing factors described, there has been relatively little research on protective factors for chronic pain and disability. Three potential resilience factors will be discussed here: optimism, hope, and benefit finding. Review of the literature suggests that optimism may be one of the most important personality traits in relation to adjustment to chronic pain. Dispositional optimism is defined as "the tendency to believe that one will generally experience good outcomes in life"[11] and is distinguishable from neuroticism and trait anxiety.[12] In cross-sectional and prospective studies, optimism was found to be associated with better general health, adaptation to chronic disease, and recovery after various surgical procedures.[12–14]

Only a few studies have explored the role of dispositional optimism or hope in adaptation to chronic pain. Novy[15] found that optimism was related to less catastrophizing and more use of active coping strategies in chronic pain patients. Affleck and Tennen[16] reported that dispositional optimism predicts pleasant daily mood in fibromyalgia but that it is not related to daily pain. Finally, in studying rheumatoid arthritis patients, Treharne and colleagues[17] found that optimism was associated with less depression and pain, and higher life satisfaction for patients in the early and intermediate stages of disease.

The primary mechanism of the beneficial effect of optimism may be differences in coping behavior between optimistic and pessimistic people.[18] In general, pessimists turn to avoidant coping strategies and denial more often, while optimists employ more problem-focused coping strategies. When problem-focused coping is not possible, they turn to coping strategies such as acceptance, use of humor, and positive reframing of the situation.[12,13] Thus, it may not be the use of specific coping strategies, but flexibility of coping that protects against disability and distress.[14] Snyder has described a similar pathway for hope, with people with low hope showing a tendency to catastrophize, whereas people with high hope seek means to encounter future challenges and show flexibility in finding alternative life goals when their original goals are blocked.[19]

Appraisal and Beliefs

Specific appraisal and beliefs are largely shaped by an individual's learning history through direct experience, observational learning, or information from others. These experiences may interact with an individual's traits and their general outlook on the world. That is, personality factors may predispose some people to make certain kinds of appraisals and to be more susceptible to some beliefs than to others.

Pain appraisal refers to the meaning ascribed to pain by an individual.[20] In accordance with the transactional stress model,[21] a distinction can be made between primary appraisal (evaluation of the significance of pain in terms of threatening, benign, or irrelevant) and secondary appraisal (evaluation of the controllability of pain and one's coping resources). Beliefs refer to assumptions about reality that shape how one interprets events, and can thus be considered as determinants of appraisal. Pain beliefs develop during the lifetime as a result of an individual's learning history and cover all aspects of the pain experience (e.g., the causes of pain, its prognosis, suitable treatments).

Appraisal and beliefs about pain can have a strong impact on an individual's response to pain. If a pain signal is interpreted as harmful (threat), it may be perceived as more intense, more unpleasant, and evoke more escape or avoidance behavior. For instance, Smith and colleagues[22] demonstrated that cancer patients who attributed pain sensations after physiotherapy directly to cancer reported more intense pain than patients who attributed this pain to other causes. Perception of danger of an experimental pain stimulus may also lead to avoidance of this stimulus. Arntz and Claassens[23] experimentally manipulated the appraisal of a mildly painful stimulus (a very cold metal bar placed against the neck) by suggesting that it was either very hot or very cold. As expected, participants rated the stimulus as more painful in the condition where they were informed that it was hot. The effect appeared to be mediated by the belief that the stimulus would be harmful. These studies demonstrate the important role of people's interpretations regarding the meaning of the pain.

Pain appraisal and pain beliefs are also prominent determinants of adjustment to chronic pain.[24,25] Pain that is viewed as a signal of damage, leads to disability, is uncontrollable, and is a permanent condition has been shown to affect individuals' responses[25,26] and these beliefs are widespread.[27,28]

Catastrophizing and Fear-Avoidance Beliefs

Pain catastrophizing can be defined as an exaggerated negative orientation toward actual or anticipated pain experiences. Current conceptualizations most often describe it in terms of appraisal or as a set of maladaptive beliefs.[29–31] Cross-sectional studies have demonstrated that catastrophizing is associated with increased pain, increased illness behavior, and physical and psychological dysfunction across numerous clinical and nonclinical populations. Prospective studies indicated that catastrophizing might be predictive of the inception of chronic musculoskeletal pain in the general population,[32,33] and of more intense pain and slower recovery after surgical intervention.[34,35]

People with chronic pain often anticipate that certain activities will increase their pain or induce further injury. These fears may contribute to avoidance of activity and subsequently greater physical deconditioning, emotional distress, and, ultimately, greater disability. Their failure to engage in activities prevents them from obtaining any corrective feedback about the associations among activity, pain, and injury.

In addition to fear of movement, people with persistent pain may be anxious about the meaning of their symptoms for the future—will their pain increase, will their physical capacity diminish, will they have progressive disability where they ultimately

end up in a wheelchair or bedridden? In addition to these sources of fear, pain sufferers may fear that on the one hand people will not believe that they are suffering and on the other they may be told that they are beyond help and will "just have to learn to live with it." Such fears can contribute to additional emotional distress and to increased muscle tension and physiological arousal that may directly exacerbate and maintain pain.

The role of catastrophizing and the belief that pain means harm and activity should be avoided has been most articulated in fear-avoidance models (FAMs) of chronic pain.[36,37] Although FAMs are multifaceted and include affective (fear) and behavioral (avoidance) components, cognitions are identified as the core determinants of entering into a negative pain cycle. The tenets of contemporary FAMs can be summarized as follows: When pain is perceived following injury, an individual's idiosyncratic beliefs will determine the extent to which pain is catastrophically interpreted. A catastrophic interpretation of pain gives rise to physiological (arousal), behavioral (avoidance), and cognitive fear responses. The cognitive shift that takes place during fear enhances threat perception (e.g., by narrowing of attention) and further feeds the catastrophic appraisal of pain.[36]

There is substantial evidence that fear-avoidance beliefs are associated with disability and impaired physical performance in chronic pain.[37–39] A systematic review of the literature on psychological risk factors in back and neck pain indicated that the evidence for the association between fear-avoidance beliefs and increased pain and disability was of the highest level.[37] In addition, prospective studies have shown that fear-avoidance beliefs in patients seeking care for acute pain may be predictive of pain persistence, disability, and long-term sick leave.[40–42]

Fear-avoidance beliefs of health care providers have also been found to be related to their treatment behavior and their recommendation for engaging in physical activities.[43–45] The beliefs of patients and health care providers may further interact with each other in a mutually reinforcing way because a patient's beliefs may guide the choice of which health care provider is visited.[46]

Perceived Control and Self-Efficacy

Perceived control over pain refers to the belief that one can exert influence on the duration, frequency, intensity, or unpleasantness of pain. Perceived controllability of a pain stimulus may modify the meaning of this stimulus and directly affect threat appraisal.[47] As a consequence, pain may be rated as less intense or less unpleasant, and pain tolerance may increase.

The belief that one has control over pain has a strong influence on disability in patients with chronic pain complaints,[25,48] and an increase in this belief after multidisciplinary pain treatment may predict pain reduction and decreases in disability[49–51] demonstrated that perceived control over the effects of pain was more strongly related to better adjustment and less disability than perceived control over pain itself.

Related to perceived control is the construct of self-efficacy. Self-efficacy is the conviction that one can successfully perform a certain task or produce a desirable outcome.[52] A major determinant of self-efficacy is prior mastery experience. In laboratory experiments, self-efficacy beliefs predict pain tolerance.[53,54] In chronic pain patients, self-efficacy positively affects physical and psychological functioning,[55,56] and improvements in self-efficacy after self-management and cognitive-behavioral interventions are associated with improvements in pain, functional status, and psychological adjustment.[57,58] Recent reviews of psychological factors in chronic pain have concluded that the evidence for the role of self-efficacy across a broad range of pain populations is impressive.[29,57] Moreover, self-efficacy also influences the prognosis after acute physical interventions like surgery. Prospective studies in patients who underwent surgery demonstrated that high self-efficacy before the start of rehabilitation and larger increases over the course of rehabilitation speed recovery and predict better long-term outcome.[59,60] A preoperative intervention (an instruction video demonstrating movement and breathing skills) in hysterectomy patients was able to enhance preoperative self-efficacy and decrease pain associated with postoperative activities and promote earlier mobilization.[61] Perceived self-efficacy has been shown to have a direct effect on the body's opioid and immune systems[62] confirming the important association between psychological constructs and physiology.

STRESS AND AUTONOMIC RESPONSES: HYPOTHALAMIC-PITUITARY-ADRENAL AXIS DYSREGULATION

It is becoming clear that the pain experience is determined by a multitude of factors. Although the focus has historically been directed at sensory mechanisms, more attention is being placed on factors related to cognitive and homeostatic factors. The primary basis for including discussions of homeostatic factors is that chronic pain threatens the organism and produces a cascade of events that eventually contributes to the maintenance of such conditions. If one views pain as a primary threat to the organism, then mechanisms should be present to engage and motivate the organism to restore basic homeostatic function.[63] The major consequence of homeostatic imbalance is stress. Regardless of the source, stressors activate numerous systems such as the autonomic nervous system and the hypothalamic-pituitary-adrenal (HPA) axis. Prolonged activation of the stress system has disastrous effects on the body[64] and sets up a condition of a feedback loop between pain and stress reactivity.

During periods of short-term stress and homeostatic imbalance, the hypothalamus activates the pituitary gland to secrete adrenocorticotropic hormone, which acts on the adrenal cortex to secrete cortisol. Secretion of cortisol elevates blood sugar levels and enhances metabolism, an adaptive response that allows the organism to mobilize energy resources to deal with the threat and restore homeostatic balance (i.e., fight or flight response). The situation is much more serious during prolonged periods of stress and homeostatic imbalance that is associated with long-term psychological stress, chronic pain, and other pathological conditions. Prolonged, elevated levels of cortisol are related to the exhaustion phase of Selye's General Adaptation Syndrome.[64] The negative effects of this stage of the adaptation syndrome include atrophy of muscle tissue, impairment of growth and tissue repair, and immune system suppression which together might set up conditions for the development and maintenance of a variety of chronic pain conditions.[65,66] According to Melzack,[67] psychological stress, as well as sensory and cognitive events, modulates the neurosignature of the body-self neuromatrix which, as a consequence of altered neuromatrix output, is associated with chronic pain conditions. The concept of the neuromatrix has potentially important explanatory implications for brain function in general, and also provides a theoretical framework for the biopsychosocial perspective of chronic pain. As will be discussed later, there is a growing literature demonstrating the importance of psychosocial factors (emotion and cognition) in this neuromatrix conceptualization.

EMOTION

Pain is ultimately a subjective, private experience, but it is invariably described in terms of sensory and affective properties. As defined by the International Association for the Study of Pain: "[Pain] is unquestionably a sensation in a part or parts of the body but it is also always unpleasant and therefore also an *emotional*

experience"[68] (emphasis added). The central and interactive roles of sensory information and affective state are supported by an overwhelming amount of evidence.[69] The affective component of pain incorporates many different emotions. Depression and anxiety have received the greatest amount of attention in chronic pain patients; however, anger has recently received considerable interest as a significant emotion in chronic pain patients. Additionally, the ability to maintain positive affect during times of stress has been investigated in relationship to pain.[70]

In addition to affect being one of the three interconnected components of pain, pain and emotions interact in a number of ways. Emotional distress may predispose people to experience pain, be a precipitant of symptoms, be a modulating factor amplifying or inhibiting the severity of pain, be a consequence of persistent pain, or a perpetuating factor. Moreover, these potential roles are not mutually exclusive and any number of them may be involved in a particular circumstance interacting with cognitive appraisals. For example, the literature is replete with studies demonstrating that current mood state modulates reports of pain as well as tolerance for acute pain.[71] Levels of anxiety have been shown to influence not only pain severity but complications following surgery and number of days of hospitalization.[72,73] Individual difference variables, such as anxiety sensitivity, have also been shown to play an important predisposing and augmenting role in the experience of pain.[74] Level of depression has been observed to play a significant role in premature termination from pain rehabilitation programs.[75]

Emotional distress is commonly observed in people with chronic pain. People with chronic and recurrent (episodic) acute pain often feel rejected by the medical system, believing that they are blamed or labeled as symptom magnifiers and complainers by their physicians, family members, friends, and employers when their pain condition does not respond to treatment. They may see multiple physicians and undergo numerous laboratory tests and imaging procedures in an effort to have their pain diagnosed and successfully treated. As treatments expected to alleviate pain are proven ineffective, pain sufferers may lose faith and become frustrated and irritated with the medical system. As their pain persists, they may be unable to work, have financial difficulties, difficulty performing everyday activities, sleep disturbance, or treatment-related complications. They may be fearful and have inadequate or maladaptive support systems and other coping resources available to them. They may feel hostility toward the health care system in its inability to eliminate their pain. They may also feel resentment toward their significant others who they may perceive as providing inadequate support. And, they are even angry with themselves for allowing their pain to take over their lives. These consequences of chronic pain can result in depression, anger, anxiety, self-preoccupation, and isolation—an overall sense of demoralization. Because chronic pain persists over long periods of time, affective state will continue to play a role as the impact of pain comes to influence all aspects of the pain sufferers' lives.

Although most of the literature has focused on the relationship between negative affect and pain, research has indicated the ability to maintain positive affect during stress is an important factor contributing to ongoing adaptation to chronic illness. Positive affect serves to decrease distress in chronic pain patients by broadening the individual's range of affective and cognitive responses permitting a wider range of experiences.[70,76,77] Positive affect can serve as psychological immunity in that chronic pain patients may experience more optimal functioning and improved quality of life while living with ongoing pain. There is some evidence suggesting that, specifically, patients with fibromyalgia report less positive affect, appear to have deficits in daily experiences with positive emotions, and are less able compared to others with chronic pain to maintain positive affect during stress.[70,76,77] This lack of positive emotional regulation heightens the vulnerability of fibromyalgia patients.

Although we will provide an overview of research on the predominant emotions—anxiety, depression, and anger—associated with pain individually, it is important to acknowledge that these emotions are not as distinct when it comes to the experience of pain. They interact and augment each other over time.

Anxiety

It is common for patients with symptoms of pain to be anxious and worried. This is especially true when the symptoms are unexplained, as is often the case for chronic pain syndromes. For example, in a large scale, multicentered study of fibromyalgia syndrome patients, between 44% and 51% of patients acknowledged that they were anxious.[78] People with persistent pain may be anxious about the meaning of their symptoms and for their futures—will their pain increase, will their physical capacity diminish, will their symptoms result in progressive disability where they ultimately end in a wheelchair or bedridden? In addition to these sources of fear, pain sufferers may be worried that, on the one hand, people will not believe that they are suffering and, on the other, they may be told that they are beyond help and will "just have to learn to live with it." Fear and anxiety will also relate to activities that people with pain anticipate will increase their pain or exacerbate whatever physical factors might be contributing to the pain. These fears may contribute to avoidance, motivate inactivity, and, ultimately, greater disability. Continual vigilance and monitoring of noxious stimulation and the belief that it signifies disease progression may render even low intensity aversive sensations less bearable. In addition, such fears will contribute to increased muscle tension and physiological arousal that may exacerbate and maintain pain.

Threat of intense pain captures attention from which it is difficult to disengage. The experience of pain may initiate a set of extremely negative thoughts, as noted previously, and arouse fears—fears of inciting more pain and injury, fear of their future impact.[37] Fear and anticipation of pain are cognitive-perceptual processes that are not driven exclusively by the actual sensory experience of pain, and can exert a significant impact on the level of function and pain tolerance.[79,80] People are motivated to avoid and escape from unpleasant consequences; they learn that avoidance of situations and activities in which they have experienced acute episodes of pain will reduce the likelihood of re-experiencing pain or causing further physical damage. They may become hypervigilant to their environment as a way of preventing the occurrence of pain.

Investigators[81,82] have suggested that fear of pain, driven by the anticipation of pain and not by the sensory experience of pain itself, produces strong negative reinforcement for the persistence of avoidance behavior, and the putative functional disability in pain patients. Avoidance behavior is reinforced in the short-term, through the reduction of suffering associated with noxious stimulation.[83] Avoidance, however, can be a maladaptive response if it persists and leads to increased fear, limited activity, and other physical and psychological consequences that contribute to disability and persistence of pain.

Studies have demonstrated that fear of movement and fear of (re)injury are better predictors of functional limitations than biomedical parameters or even pain severity and duration.[84,85] For example, Crombez, Vlaeyen, and Heuts[84] showed that pain-related fear was the best predictor of behavioral performance in trunk-extension, flexion, and weight lifting tasks, even after partitioning out the effects of pain intensity. Moreover, Vlaeyen and colleagues[86] found that fear of movement/(re)injury was the best predictor of self-reported disability among chronic back pain patients, and that physiological sensory perception of pain and biomedical findings did not add any predictive value. The importance of fear of activity appears to generalize to daily activities, as well as in the clinical experimental context. Approximately

two-thirds of chronic nonspecific low back pain sufferers avoid back straining activities because of fear of (re)injury.[84] For example, fear-avoidance beliefs about physical demands of a job are strongly related to disability and work lost during the previous year, even more so than pain severity or other pain variables.[87,88] Interestingly, reduction in pain-related anxiety predicts improvement in functioning, affective distress, pain, and pain-related interference with activity.[83] Clearly, fear, pain-related anxiety, and concerns about harm-avoidance all play important roles in chronic pain and need to be assessed and addressed in treatment.

Pain-related fear and concerns about harm avoidance all appear to exacerbate symptoms.[82] Anxiety is an affective state that is greatly influenced by appraisal processes; to cite the stoic philosopher Epictetus, "There is nothing either bad or good but thinking makes it so." Thus, there is a reciprocal relationship between affective state and cognitive-interpretive processes. Thinking affects mood and mood influences appraisals and, ultimately, the experience of pain.

Depression

Research suggests that 40% to 50% of chronic pain patients suffer from depression.[89,90] Epidemiologic studies provide solid evidence for a strong association between chronic pain and depression, but do not address whether chronic pain causes depression or depression causes chronic pain. Prospective studies of patients with chronic musculoskeletal pain have suggested that chronic pain can cause depression,[91] that depression can cause chronic pain,[92] and that they exist in a mutually reinforcing relationship.[93]

One fact often raised to support the idea that pain causes depression is that the current depressive episode often began after the onset of the pain problem. The majority of studies appear to support this contention.[94] However, several studies have documented that many patients with chronic pain (especially those disabled patients seen in pain clinics) have often had prior episodes of depression that predated their pain problem by years.[95] A small longitudinal study[96] followed patients with herpes zoster for 1 year. They observed that those who developed more severe pain (i.e., postherpetic neuralgia) 3 months after the initial diagnosis scored higher on baseline levels of depressed mood. However, these results were not confirmed in a recent larger study conducted by this group.[97] One important prospective study[98] demonstrated that levels of depression predicted the development of low back pain 3 years following the initial assessment. Patients with depression were 2.3 times more likely to report back pain compared to those who did not report depression. Depression was a much stronger predictor of incident back pain then any clinical or anatomic risk factors. This has led some investigators to propose that there may exist a common trait of susceptibility to dysphoric physical symptoms (including pain) and negative psychological symptoms (including anxiety as well as depression). They conclude that "pain and psychological illness should be viewed as having reciprocal psychological and behavioral effects involving both processes of illness expression and adaptation."[99]

Given the scenario of chronic pain just described, it is hardly surprising that chronic pain patients are depressed. It is interesting, however, to ponder the flip side of the coin—why are not *all* chronic pain patients depressed? Turk and colleagues[93,100] examined this question and determined that two factors appear to mediate the pain-depression relationship: patients' appraisals of the effects of the pain on their lives, and appraisals of their ability to exert any control over their pain and lives. That is, those patients who believed that they could continue to function and that they could maintain some control despite their pain were less likely to become depressed. Here we see the interdependence of cognition and affect.

As noted previously, in the majority of cases depression appears to be reactive, although some have suggested that chronic pain is a form of "masked depression," whereby patients use pain to express their depressed mood because they feel it is more acceptable to complain of pain than to acknowledge that one is depressed. Once a person has a chronic pain diagnosis, it no longer matters which is the cause and which is the consequence—pain or depression. Both need to be treated.

Anger

Anger has been widely observed in people with chronic pain.[101] Even though chronic pain patients might present an image of themselves as even-tempered, Corbishley and colleagues[102] found that 88% acknowledged their feelings of anger when these were explicitly sought. Approximately 98% of the patients referred to a multidisciplinary pain rehabilitation center reported that they were feeling some degree of anger at the time of the assessment.[103] We must be cautious in interpreting data from patients recruited at pain centers, however, as there may be a referral bias such that the most distressed patients are sent to these facilities, and they do not represent the large number of people with persistent pain who are never evaluated in treatment facilities that specialize in pain management.

Since anger is frequently considered as socially undesirable, some patients in the studies cited previously may have found it difficult to admit that they were angry to the health care professionals. Thus, it is possible that the anger rates may actually be an underestimate. The high prevalence of anger observed is perhaps not surprising, given the frustrations related to persistence of symptoms, limited information on etiology, and repeated treatment failures along with anger toward others (employers, insurance companies, the health care system, family members), and anger toward themselves, perhaps, for their inability to alleviate their symptoms and to move on with their lives.[103] Several empirical studies provide preliminary support for the association between anger and pain intensity,[104,105] unpleasantness of pain,[106] affective component of pain,[107] and emotional distress in chronic pain patients,[108,109] as well as families of chronic pain patients.[101]

Anger in chronic pain has been considered by some to be attributable to enduring personality dispositions associated with unconscious conflicts,[110] whereas others have suggested that anger may be a reaction to the presence of recalcitrant symptoms that have been unsubstantiated by objective medical findings and unrelieved by medical treatments.[111] There is some evidence supporting the latter hypothesis. For example, a laboratory study[112] demonstrated that the mere anticipation of pain was sufficient to provoke angry behavioral responses in healthy individuals. Using the cross-lagged design with a clinical sample, Arena, Blanchard, and Andrasik[113] found that an increase in pain tends to precede anger, directly contradicting the anger-somatization association.

The relatively fruitless debate over the cause–effect relationship between anger and pain is reminiscent of the arguments on the associations between pain and depression.[114] In order to refine our understanding of the association between anger and pain beyond this debate, several investigators have begun to examine individual differences in how anger is expressed. In an early study, Pilowsky and Spence[115] found that chronic pain patients are less willing to express anger compared to outpatient medical patients. Similarly, individuals with chronic pain problems appear to inhibit their anger compared to pain-free, healthy persons.[116,117] Furthermore, inhibition of anger seems to contribute to aversion of the chronic pain experience. Inhibition of anger has been found to be related to pain severity and overt pain behaviors,[118] as well as to increased emotional distress.[108,119]

Denial of anger also appears to be common among chronic pain patients. However, awareness of anger should not be con-

fused with anger expression. For example, Corbishely et al.[102] observed that chronic pain patients tend to show strong reservations about expressing socially undesirable emotions that could create interpersonal conflict. For these individuals, it seems that expression of the emotion is under conscious control. They are aware of their anger but choose not to express it. On the other hand, some chronic pain patients may lack awareness of their angry feelings and have increased difficulties in recognizing and reporting these feelings.[120]

Fernandez and Turk[111] proposed that the specificity of targets toward which patients experience angry feelings may be important in understanding of the relationship between pain and anger. When a pain sufferer is angry, there are a range of possible targets (e.g., employer, insurance company, health care providers). The presence or intensity of anger toward different targets may be differentially related to chronic pain experience. That is, there may be some targets of anger that are more relevant to the chronic pain experience than others. As will be discussed later, Okifuji et al.[103] found that anger directed toward oneself was particularly common among chronic pain patients evaluated at a pain rehabilitation facility.

Another important issue regarding anger concerns gender differences. There is a growing literature suggesting the presence of important differences in the ways that males and females respond to pain.[121] Moreover, in the Western cultures, there appear to be social conventions regarding the expression of anger. In general, it seems acceptable for men to display angry feelings, whereas women are socialized to avoid overt expression of anger. However, research investigating gender differences in anger expression has revealed unequivocal results. Some studies report that females report significantly higher levels of generalized anger than males,[122] some report the opposite results,[109,123,124] and still others report no gender differences in anger expression.[125,126] In the chronic pain population, some studies note that male patients seem to acknowledge angry feelings more readily than do female patients.[109,123] In contrast, other investigators[103,127,128] suggest that there may be substantial variability within groups of men and women. There seems to be a subgroup of females who do outwardly express anger, whereas some male patients may suppress their anger.

Although the effects of anger and frustration on exacerbation of pain and treatment acceptance has not received as much attention as anxiety and depression, Kerns et al.[118] found that the suppressed feelings of anger accounted for a significant portion of the variance in pain intensity, perceived interference, and frequency of pain behaviors. Furthermore, Summers et al.[105] found that anger and hostility were powerful predictors of pain severity in people with spinal cord injuries.

It is thus reasonable to expect that the presence of anger may serve as a complicating factor, increasing autonomic arousal and blocking motivation and acceptance of treatments oriented toward rehabilitation and disability management rather than cure, which are often the only treatments available for chronic pain.[71] It would be reasonable to expect that the presence of anger may serve as a complicating factor, increasing autonomic arousal and blocking motivation and acceptance of treatments oriented toward rehabilitation and disability management rather than cure.

Frustrations related to persistence of symptoms, unknown etiology, and repeated treatment failures, along with anger toward employers, insurers, the health care system, family, and themselves, all contribute to the general dysphoric mood of patients.[103] Okifuji et al.[103] reported that 60% of patients expressed anger toward health care providers, 39% toward significant others, 30% toward insurance companies, 26% toward employers, and 20% toward attorneys. The target of anger most commonly acknowledged, however, was anger toward themselves (endorsed by approximately 70% of the sample). Internalization of angry feelings is strongly related to measures of pain intensity, perceived interference, and frequency of pain behaviors.[118] Overall, correlations between anger and pain severity have been shown to be statistically significant, ranging from 0.17 to 0.35.[118,127] Okifuji et al.[103] reported that anger was significantly correlated with pain intensity (correlations = 0.30–0.35). Okifuji et al.[103] also reported that anger was significantly correlated with disability ($r = 0.26$) and was highly associated with depression ($r = 0.52$).

The precise mechanisms by which anger and frustration exacerbate pain are not known. One reasonable possibility is that anger exacerbates pain by increasing autonomic arousal.[129,130] Anger may also interact with depression to modulate perceived severity of pain. In addition, anger may block motivation for, and acceptance of, treatments oriented toward rehabilitation and disability management rather than cure. Yet, rehabilitation and disability management are often the only treatments available for these patients.

In summary, it is important to be aware of the significant role of negative mood in chronic pain patients because it is likely to influence treatment motivation and compliance with treatment recommendations. For example, patients who are anxious may fear engaging in what they perceive as demanding activities; patients who are depressed and who feel helpless may have little initiative to comply; and patients who are angry with the health care system are not likely to be motivated to respond to recommendations from yet another health care professional. Thus, clinicians who are treating people with persistent pain must focus on their mood states, as well as physical pathology and somatic factors. Pain cannot be treated successfully without attending to the patient's emotional state. This is true for acute pain, such as pain associated with surgery, and persistent pain states.

PSYCHOGENIC CONCEPTUALIZATIONS OF CHRONIC PAIN

As a result of the multiple psychosocial factors involved in the onset and maintenance of chronic pain, a number of different psychological perspectives on chronic pain have evolved. Many of the psychological treatments for chronic pain are based on different psychological principles which at times compete and differ from one another. Thus, it is important to consider the varying perspectives.

Psychogenic View

Frequently in medicine, when physical explanations seem inadequate or when the results of treatment are inconsistent, reports of pain are attributed to a psychological etiology (and thus are "psychogenic"). Although psychogenic views of pain have been discussed since the formulation of psychodynamic theory, a psychodynamic perspective on chronic pain was first described systematically in the 1960s. During this time people with pain were viewed as having compulsive and masochistic tendencies, inhibited aggressive needs, and feelings of guilt—"pain-prone personalities."[131] It was commonly held that people with pain had childhood histories fraught with emotional abuse, family dysfunction (e.g., parental quarrels, separation, divorce), illness or death of a parent, early responsibilities, and high orientation toward achievement.[132] Some current research has reported associations between chronic pain and childhood trauma, although the research is not consistent.[133] Based on the psychogenic perspective, assessment of persons with chronic pain is directed toward identifying the psychopathological tendencies that instigate and maintain pain. Although the evidence to support this model is scarce, the American Psychiatric Association[134] has created a psychiatric diagnosis, Somatoform Pain Disorder. Diagnosis of a pain disorder requires that the person's report of pain must be either incon-

sistent with the anatomical distribution of the nervous system or, if it mimics a known disease entity, cannot, after extensive diagnostic evaluation, be adequately accounted for by organic pathology.[134] Even in the presence of a medical condition that may cause pain, psychological factors may be implicated and, thus, the person may receive a psychiatric diagnosis of "pain disorder associated with both psychological factors and a general medical condition."

It is assumed that reports of pain will cease once the psychogenic mechanisms are resolved. Treatment is geared toward helping patients gain "insight" into the underlying maladaptive psychological contributors.[133,135]

Empirical evidence supporting the psychogenic view is scarce. A number of chronic pain sufferers do not exhibit significant psychopathology. Furthermore, insight-oriented psychotherapy has not been shown to be effective in reducing symptoms for the majority of patients with chronic pain. Studies suggest that the emotional distress observed in patients with chronic pain more typically occurs in *response to* the persistence of pain and not as a causal agent[93,136] and may resolve once pain is adequately treated.[137] The psychogenic model has thus come under scrutiny, and may be flawed in its view of chronic pain.

BEHAVIORAL FORMULATIONS

Classical Conditioning

According to the classical or respondent conditioning model, if a painful stimulus is repeatedly paired with a neutral stimulus, the neutral stimulus will elicit a pain response. For example, a person who experienced pain after performing a treadmill exercise may become conditioned to experience a negative emotional response to the presence of the treadmill and to any stimulus associated with it (e.g., physical therapist, gym). The negative emotional reaction may instigate muscle tensing, thereby exacerbating pain, and further reinforcing the association between the stimulus and pain. Based on this, people with chronic pain may avoid activities previously associated with pain onset or exacerbation.

Operant Conditioning

In 1976, Fordyce[138] introduced an extension of operant conditioning to chronic pain. This view proposes that acute pain behaviors (such as avoidance of activity to protect a painful area from additional pain) may come under the control of external contingencies of reinforcement (responses increase or decrease as a function of their reinforcing consequences) and thus develop into a chronic pain problem. Fordyce underscored the fact that since there is no objective way to measure pain—no pain thermometer—the only way we can know of anyone's pain is by their behavior, whether verbal or nonverbal expressions. Overt pain behaviors include verbal reports, paralinguistic vocalizations (sighs, moans), motor activity, facial expressions, body postures and gesturing (limping, rubbing a painful body part, grimacing), functional limitations (reclining for extensive periods of time, inactivity), and behaviors designed to reduce pain (taking medication, use of the health care system).

The central features of pain behaviors are that they are (1) sources of communication and (2) observable. Observable behaviors are capable of eliciting a response and the consequences of behavior will influence subsequent behavior. Through a process of learning, responses that receive positive consequences, especially repeated desirable consequences, will more likely be maintained; behaviors that fail to activate positive consequences, or that receive negative consequences, will be less likely to occur (i.e., extinguished). Pain behaviors may be positively reinforced directly (e.g., attention from a spouse or health care provider, monetary compensation, avoidance of undesirable activity).[139] Pain behaviors may also be maintained by the escape from noxious stimulation through the use of drugs or rest, or the avoidance of undesirable activities such as work. In addition, "well behaviors" (e.g., activity, working) may not be positively reinforcing and the more rewarding pain behaviors may, therefore, be maintained.

The operant conditioning model considers pain an internal subjective experience that can be directly assessed and may be maintained even after an initial physical basis of pain has resolved rather than the initial causes. The pain behavior originally elicited by organic factors caused by injury or disease may later occur, totally or in part, in response to reinforcing environmental events.

It is important, however, not to make the mistake of viewing pain behaviors as being synonymous with malingering. Malingering involves consciously and purposely faking a symptom such as pain for some gain, usually financial or to gain attention. Contrary to the beliefs of many third-party payers, there is little support for the contention that outright faking of pain for financial gain is prevalent.

Social Learning

The *social learning model* emphasizes the point that behavior can be learned not only by actual reinforcement of the individual's behavior, but also by observation. This is a powerful way of learning especially when the others being observed are judged to be similar to the observer. For example, a middle-aged man might learn what to expect by observing how other middle-aged men with similar medical problems are treated. People can acquire responses that were not previously in their behavioral repertoire by the observation of others performing these activities. Expectancies and actual behavioral responses to nociceptive stimulation are based, at least partially, on prior social learning history.

Another example of social learning occurs in children. Children develop attitudes about health and health care and the perception and interpretation of symptoms and physiological processes from their parents and others they confront in their social environment. They learn how others respond to injury and disease and thus may be more or less likely to ignore or over-respond to symptoms they experience based on behaviors modeled in childhood. For example, children of chronic pain patients may make more pain-related responses during stressful times or exhibit greater illness behaviors (e.g., complaining, days absent, visit to school nurse) than children of healthy parents based on what they observed and learned at home.[140] Models can influence the expression, localization, and methods of coping with pain. Even physiological responses may be conditioned during observation of others in pain.[141]

A central construct of the social learning perspective is that of self-efficacy.[52] Self-efficacy is a personal expectation that is important in patients with chronic pain. A self-efficacy belief is defined as a personal conviction that one can successfully execute a course of action (perform required behaviors) to produce a desired outcome in a given situation.[52] Given sufficient motivation to engage in a behavior, it is a person's self-efficacy beliefs that determine the choice of activities that the he or she will initiate, the amount of effort that will be expended, and how long the individual will persist in the face of obstacles and aversive experiences. In this way, self-efficacy plays an important role in therapeutic change and compliance to psychological and medical regimes.[142]

Efficacy judgments are based on four sources of information regarding one's capabilities, listed in descending order of importance[52]: one's own past performance at the task or similar tasks, the performance accomplishments of others who are perceived

to be similar to oneself, verbal persuasion by others that one is capable, and perception of one's own state of physiological arousal, which is, in turn, partly determined by prior efficacy estimation. Performance mastery can then be created by encouraging people to undertake sub-tasks that are initially attainable but become increasingly difficult, and subsequently approaching the desired level of performance. It is important to remember that coping behaviors are influenced by the person's beliefs that the demands of a situation do not exceed their coping resources.

How people interpret, respond to, and cope with illness is determined by cultural norms and perceptions of self-efficacy. These two sets of factors contribute to the marked variability in response to objectively similar degrees of physical pathology noted by health care providers.

Gate Control Model

Although not a psychological formulation itself, the *gate control model*[143] was the first to popularize the importance of central, psychological factors in pain perception. Perhaps the most important contribution of the gate control theory is the way it changed thinking about pain perception. Melzack and Casey[144] differentiate three systems related to the processing of nociceptive stimulation—sensory-discriminative, motivational-affective, and cognitive-evaluative—all thought to contribute to the subjective experience of pain. Thus the gate control theory specifically includes psychological factors as an integral aspect of the pain experience. It emphasizes the central nervous system (CNS) mechanisms and provides a physiological basis for the role of psychological factors in chronic pain.

The gate control model contradicts the notion that pain is *either* somatic *or* psychogenic. Instead, it postulates that both factors have potentiating and moderating effects. According to this model, both the central and peripheral nervous systems interact to contribute to the experience of pain. It is not only these physical factors that guide the brain's interpretation of painful stimuli that is at the center of this model; psychological factors (e.g., thoughts, beliefs, emotions) are also painful stimuli.

Prior to the Melzack and Wall[143] formulation of the gate control theory, psychological processes were largely dismissed as reactions to pain. Although the physiological details of the gate control model have been challenged,[145] it has had a substantial impact on basic research and can be credited as a source of inspiration for diverse clinical applications to control or manage pain, including neurophysiologically based procedures (e.g., neural stimulation techniques from peripheral nerves and collateral processes in the dorsal columns of the spinal cord, pharmacological advances, behavioral treatments, and those interventions that target modification of attentional and perceptual processes involved in the pain experience).

COGNITIVE-BEHAVIORAL PERSPECTIVE

The *cognitive-behavioral model*, perhaps the most commonly accepted model for the psychological treatment of individuals with chronic pain,[146,147] incorporates many of the psychological variables previously described—namely, anticipation, avoidance, and contingencies of reinforcement—but suggests that cognitive factors rather than conditioning factors are of central importance. The model suggests that conditioned reactions are largely self-activated on the basis of learned expectations rather than automatically evoked. The model suggests that behaviors and emotions are influenced by interpretations of events, and emphasis is placed on how peoples' beliefs and attitudes interact with physical, affective, and behavioral factors. It proposes that conditioned reactions are largely activated by learned *expectations* rather than automatically evoked. In other words, it is the person's information processing that result in anticipatory anxiety and avoidance. The critical factor, therefore, is that people learn to anticipate and predict events and to express appropriate reactions.[148]

From the cognitive-behavioral model, people with pain are viewed as having negative expectations about their own ability to control certain motor skills without pain. Moreover, people with chronic pain tend to believe they have limited ability to exert any control over their pain. Such negative, maladaptive appraisals about the situation and personal efficacy may reinforce the experience of demoralization, inactivity, and overreaction to nociceptive stimulation. These cognitive appraisals and expectations are postulated as having an effect on behavior leading to reduced efforts and activity, which may contribute to increased psychological distress (helplessness) and subsequent physical limitations. If one accepts that pain is a complex, subjective phenomenon that is uniquely experienced by each person, then knowledge about idiosyncratic beliefs, appraisals, and coping repertoires becomes critical for optimal treatment planning and for accurately evaluating treatment outcome.

People with chronic pain's beliefs, appraisals, and expectations about pain, their ability to cope, social supports, their disorder, the medicolegal system, the health care system, and their employers are all important because they may facilitate or disrupt the sufferer's sense of control. These factors also influence patients' investment in treatment, acceptance of responsibility, perceptions of disability, adherence to treatment recommendations, support from significant others, expectancies for treatment, and acceptance of treatment rationale.

Cognitive interpretations also affect how patients present symptoms to others, including health care providers. Overt communication of pain, suffering, and distress will enlist responses that may reinforce pain behaviors and impressions about the seriousness, severity, and uncontrollability of pain. That is, complaints of pain may induce physicians to prescribe more potent medications, order additional diagnostic tests, and, in some cases, perform surgery. Significant others may express sympathy, excuse the person with chronic pain from responsibilities, and encourage passivity, thereby fostering further physical deconditioning. It should be obvious that the cognitive-behavioral perspective integrates the operant conditioning emphasis on external reinforcement and respondent view of conditioned avoidance within the framework of information processing.

People with persistent pain often have negative expectations about their own ability and responsibility to exert any control over their pain. Moreover, they often view themselves as helpless. Such negative, maladaptive appraisals about their condition, situation, and their personal efficacy in controlling their pain and problems associated with pain reinforce their experience of demoralization, inactivity, and overreaction to nociceptive stimulation. These cognitive appraisals are posited as having an effect on behavior, leading to reduced effort, reduced perseverance in the face of difficulty, reduced activity, and increased psychological distress.

The cognitive-behavioral perspective on pain management focuses on providing the patient with techniques to gain a sense of control over the effects of pain on his or her life as well as actually modifying the affective, behavioral, cognitive, and sensory facets of the experience. Behavioral experiences help to show pain sufferers that they are capable of more than they assumed, increasing their sense of personal competence. Cognitive techniques (e.g., self-monitoring to identify relationships among thoughts, mood, and behavior, distraction using imagery, and problem solving) help to place affective, behavioral, cognitive, and sensory responses under the person's control.

The assumption is that long-term maintenance of behavioral changes will occur only if the person with pain has learned to attribute success to his or her own efforts. There are suggestions

that these treatments can result in changes of beliefs about pain, coping style, and reported pain severity, as well as direct behavior changes. Treatment that results in increases in perceived control over pain and decreased catastrophizing also results in decreases in pain severity and functional disability. When successful rehabilitation occurs there is a major shift from beliefs about helplessness and passivity to resourcefulness and ability to function regardless of pain, and from an illness conviction to a rehabilitation conviction.

A number of studies have attempted to identify cognitive factors that contribute to pain and disability.[142,149] These studies have consistently demonstrated that a person's attitudes, beliefs, and expectancies about their plight, themselves, their coping resources, and the health care system affect reports of pain, activity, disability, and response to treatment. For example, people respond to medical conditions in part based on their subjective ideas about illness and their symptoms. When pain is interpreted as signifying ongoing tissue damage or a progressive disease, it is likely to produce considerably more suffering and behavioral dysfunction than if it is viewed as being the result of a stable problem that is expected to improve.

Once beliefs and expectancies are formed, they become stable and rigid and relatively impervious to modification. Pain sufferers tend to avoid experiences that could invalidate their beliefs (disconfirmations) and guide their behavior in accordance with these beliefs, even in situations where these beliefs are no longer valid. It is thus essential for people with chronic pain to develop adaptive beliefs about the relationships among impairment, pain, suffering, and disability, and to deemphasize the role of experienced pain in their regulation of functioning.

Distorted thinking can also contribute to the maintenance and exacerbation of pain. A particularly potent and pernicious thinking style that has been observed among people with chronic pain is catastrophizing (holding negative thoughts about one's situation and interpreting even minor problems as major catastrophes).[150] Research has indicated that people who spontaneously use more catastrophizing thoughts report more pain than those who do not catastrophize.[150]

Coping strategies, or a person's specific ways of adjusting to or minimizing pain and distress, act to alter both the perception of pain intensity and one's ability to manage or tolerate pain and continue everyday activities. Overt behavioral coping strategies include rest, medication, and use of relaxation, among others. Covert coping strategies include various means of distracting oneself from pain, reassuring oneself that the pain will diminish, seeking information, and problem solving, to list some of the most prominent.

Studies have found active coping strategies (efforts to function in spite of pain or to distract oneself from pain) to be associated with adaptive functioning, and passive coping strategies (depending on others for help with pain control, avoiding activities because of fear of pain/injury, self-medication, alcohol) to be related to greater pain and depression.[151] Regardless of the type of coping strategy, if people with chronic pain are instructed in the use of adaptive coping strategies, their rating of intensity of pain decreases and tolerance of pain increases.[151] Thus, the perspective on how people function and the emphasis on facilitating self-management are more important than any specific cognitive or behavioral techniques that are used to bring about change in thinking and changes in behavior.

BIOPSYCHOSOCIAL MODEL

Although the gate control model described previously introduced the role of psychological factors in the maintenance of pain symptoms, it focused primarily on the basic anatomy and neurophysiology of pain. The biopsychosocial model, which expands the cognitive-behavioral model of pain, views illness as a dynamic and reciprocal interaction between biological, psychological, and sociocultural variables that shape the person's response to pain.[85,151] What is unique about the model is that it takes into consideration the influence of higher order cognitions, including perception and appraisal. It accepts that people are active processors of information and that behavior, emotions, and even physiology are influenced by interpretations of events, rather than solely by physiological factors.[85,151] People with chronic pain may therefore have negative expectations about their own ability and responsibility to exert any control over their pain. Moreover, behaviors of people with pain elicit responses from significant others that can reinforce both adaptive and maladaptive modes of thinking, feeling, and behaving.

Loeser[152] originally formulated a general model that delineated four dimensions associated with the concept of pain: nociception, the stimulation of nerves that convey information about possible tissue damage to the brain; pain, the subjective perception that is the result of transduction, transmission, and modulation of sensory information; suffering, the emotional responses that are triggered by nociception or some other aversive event associated with it, such as fear or depression; and pain behavior, those things that people do when they are suffering or in pain, such as avoiding activities or exercise for fear of (re)injury. Subsequently, Waddell[153] emphasized that pain cannot be comprehensively evaluated without an understanding of the individual who is exposed to the nociception. Waddell also made a comparison between Loeser's[154] model of pain and the earlier discussed call by Engel[155] of the need for a new, more biopsychosocial model in medicine. Engel proposed the important dimensions of the physical problem, distress, illness behavior, and the sick role, which corresponded to Loeser's dimensions of nociception, pain, suffering, and pain behavior, respectively. Thus, with this general perspective, a diversity of pain or illness can be expected (including its severity, duration, and psychosocial consequences). In order to fully understand a person's perception and response to pain and illness, the interrelationships among biological changes, psychological status, and the sociocultural context all need to be considered. Any model that focuses on only one of these dimensions will be incomplete.

FAMILY SYSTEMS PERSPECTIVE

In *family systems* (and this could be expanded to significant others and not only traditional conceptualizations of nuclear families) the family is viewed as an interactional unit, and family members profoundly impact each other's emotions, thoughts, and behaviors. Thus, the functioning of family members is interdependent and family relationships are an important factor not only in psychological but also physical health.[156]

Increasingly, evidence supports family members contribute to behavioral risk factors such as smoking, lack of exercise, poor diet, to the development of numerous chronic illnesses, as well as compliance to treatment regimes.[157] Additionally, families influence the development of chronic pain via operant theory. For example, expressions of acute pain (reporting pain, grimacing, avoidance of activity, and use of pain medication), because they are overt and observable, may be reinforced through expressions of concern from family members. Furthermore, in support of this idea, a number of investigators[90,139] found that spousal attentiveness to expressions of pain was positively correlated with higher levels of reported pain, pain behavior frequency, and disability.

The experience of chronic stress within the family has also been hypothesized to contribute to the development of chronic illness.[158] Specifically, chronic stress within the family may play an important role in sympathetic nervous system and endocrine dysregulation often found in chronic pain patients.

As noted previously, pain does not take place in isolation but in a social context. Pain does not occur solely in people's bodies,

nor does it occur solely in their brains, but, rather, it occurs in their lives. The emphasis on the role of significant others is important, as it reminds us that to successfully treat chronic pain patients requires that we not only assess and treat the patient, but must also target significant others that can either impede or facilitate rehabilitation.[159]

CONCLUSION

For the person experiencing chronic pain, there is a continuing quest for relief that often remains elusive, leading to feelings of helplessness, hopelessness, demoralization, and outright depression. Emotional distress may be attributed to a variety of factors, including inadequate or maladaptive coping resources, iatrogenic complications, overuse of medication, disability, financial difficulties, litigation, disruption of usual activities, lack of social support, and sleep disturbance. Thus, chronic pain is a demoralizing situation that confronts the person not only with the stress created by pain but with a cascade of ongoing stressors that compromise all aspects of the life of the sufferer. Living with chronic pain requires considerable emotional resilience and tends to deplete emotional reserve, and taxes not only the pain sufferer but also the capacity of significant others to provide support.

There is a large body of evidence to demonstrate that psychological factors can interfere with or hinder a person's ability to cope with the pain experience. As a result, psychological intervention in the assessment and treatment of chronic pain is becoming standard practice. Psychological treatments can focus on the emotional distress that accompanies chronic pain and provide education and training in the use of cognitive and behavioral techniques that may reduce perceptions of pain and related disability. Psychologists and psychological principles have played a major role in the understanding and treatment of people with pain, and psychologists have an important function in interdisciplinary pain rehabilitation program (IPRPs) as clinicians and researchers.

None of the treatments described are successful in eliminating pain completely, in fact, the same statement can be made in reference to the most commonly used pharmacological, medical, and surgical interventions[1]; consequently, the majority of people have to adapt to the presence of chronic pain and learn self-management in the face of persistent pain and accompanying symptoms. The various psychological interventions described in this chapter provide a general overview of different treatment strategies. By far, however, treatment with cognitive-behavioral therapy alone or within the context of an IPRP holds the greatest empirical evidence for success. There is a substantial and overwhelming body of research supporting the effectiveness of various psychological approaches. At point, it seems prudent to consider the use of psychological treatments in combination with traditional medical interventions.

CHAPTER 8 ■ INDIVIDUAL DIFFERENCES IN PAIN: THE ROLES OF GENDER, ETHNICITY, AND GENETICS

ROGER B. FILLINGIM

INTRODUCTION

Abundant evidence clearly demonstrates that pain responses are characterized by substantial interindividual variability. In other words, an identical noxious stimulus produces vastly different experiences of pain in different people. Such individual differences in pain responses are inarguable; however, the contributing factors and clinical importance of individual differences in pain remain important topics of study. The purpose of this chapter is to discuss the nature of individual differences in responses to pain and its treatment. After a brief discussion of individual differences in clinical and experimental pain responses as well as interindividual variability in treatment outcomes, an overview of the role of demographic factors such as sex/gender and ethnicity will be provided as examples of variables influencing individual differences in pain. Also, the contribution of genetics to individual differences in pain will be reviewed. The chapter will conclude with consideration of the clinical relevance of individual differences, including implications for treatment tailoring.

In the clinical setting, individual differences across patients in the severity and impact of clinical pain are the rule. This variability is often attributed to differences in disease severity, based on the misguided assumption that the noxious stimulus itself is the primary determinant of the pain experience, despite considerable evidence suggesting otherwise. For example, the majority of individuals who show radiographic evidence of osteoarthritis are asymptomatic,[1] and, even in symptomatic patients, radiographic measures of disease severity in osteoarthritis account for a minimal proportion of the interindividual variability in pain and disability.[2–5] Likewise, physical and diagnostic findings have limited value in predicting the occurrence or severity of low back pain.[6,7] Moreover, in the acute pain setting, patients undergoing similar surgical procedures report vastly different amounts of pain.[8–12] Thus, for many forms of clinical pain, estimates of the intensity of the noxious clinical stimulus appear to be poor predictors of the degree of pain experienced.

Of course, a disadvantage in the clinical setting is that the noxious stimulus is not precisely quantified or controlled. Moreover, clinical pain reports are often influenced by previous or current therapies, which can contribute to interindividual variability. However, these issues can be overcome with the application of painful stimuli in the laboratory setting. Evidence from studies of experimentally induced pain also clearly demonstrates individual differences in pain perception.[13] For example, a recent study of 188 healthy adults reported pain intensity ratings ranging from 0 to 100 for an identical cold water stimulus, and ratings of the maximum heat stimulus delivered ranged from 0 to 95.2.[14] These authors estimated that stimulus intensity accounted for only 40% of the variance in pain ratings, while true individual differences accounted for the other 60%. Similarly, Diatchenko and colleagues[15] created a summary index of experimental pain sensitivity by summing standardized (z-scores) scores across 16 individual pain measures, such that the group mean was set to 0 and negative values reflected lower pain sensitivity. Their findings revealed a normal distribution of summed z-scores, which ranged from –20 to greater than 30 across the sample of 202 healthy young females. Thus, even when the research setting and the noxious stimulus are highly controlled, dramatic individual differences in pain responses emerge (Fig. 8.1).

In addition to interindividual variability in clinical and experimental pain sensitivity, substantial individual differences in responses to pain treatments exist. For example, in a study of postoperative pain, the median number of morphine boluses required to achieve pain relief (Visual Analog Scale rating <30) was 4, but the number of boluses ranged from 1 to 20 across patients.[8] In a clinical trial of opioids for chronic neuropathic pain, treatment-related changes in pain ranged from a 100% decrease to a nearly 70% increase in pain.[16] Even in the context of experimentally induced pain, responses to opioids vary greatly across individuals.[17–19] Moreover, responses to nonpharmacologic pain treatments also show considerable variability across individuals. For example, a long-term (8–10 year) follow-up study of outcomes from surgical and nonsurgical management of spinal stenosis showed that approximately half of the patients in both treatment groups reported improvement in their symptoms over the follow-up period, while 20% to 25% reported no change and 20% to 25% reported that their symptoms had worsened.[20] Significant variability in analgesic responses to acupuncture have also been reported,[21] and responses to cognitive-behavioral interventions for pain vary robustly both within and between studies.[22] Indeed, the well-recognized variability in pain treatment responses has prompted some to recommend individual responder analyses of clinical trial outcomes as an alternative to analysis of group means to take advantage of these individual differences in treatment response.[23]

This brief discussion and the examples cited make it clear that responses to pain and its treatment are characterized by robust and consistent interindividual differences. While variability in pain responses has been studied for decades,[24,25] interest in individual differences in pain and responses to treatment has increased substantially in recent years, reinvigorated largely by the genomics revolution. However, variability in pain perception and responses to treatment is driven by complex interactions among multiple biopsychosocial factors, including, but certainly not limited to, genetic influences. Before embarking on a discussion of specific individual difference factors associated with variability in pain responses, a general framework for conceptualizing sources of individual differences in pain will be presented.

Individual differences in pain (and treatment) responses are typically manifested as between subject variability in a particular measure of interest, such as pain ratings or pain relief. Interestingly, considerable statistical and methodological effort is often

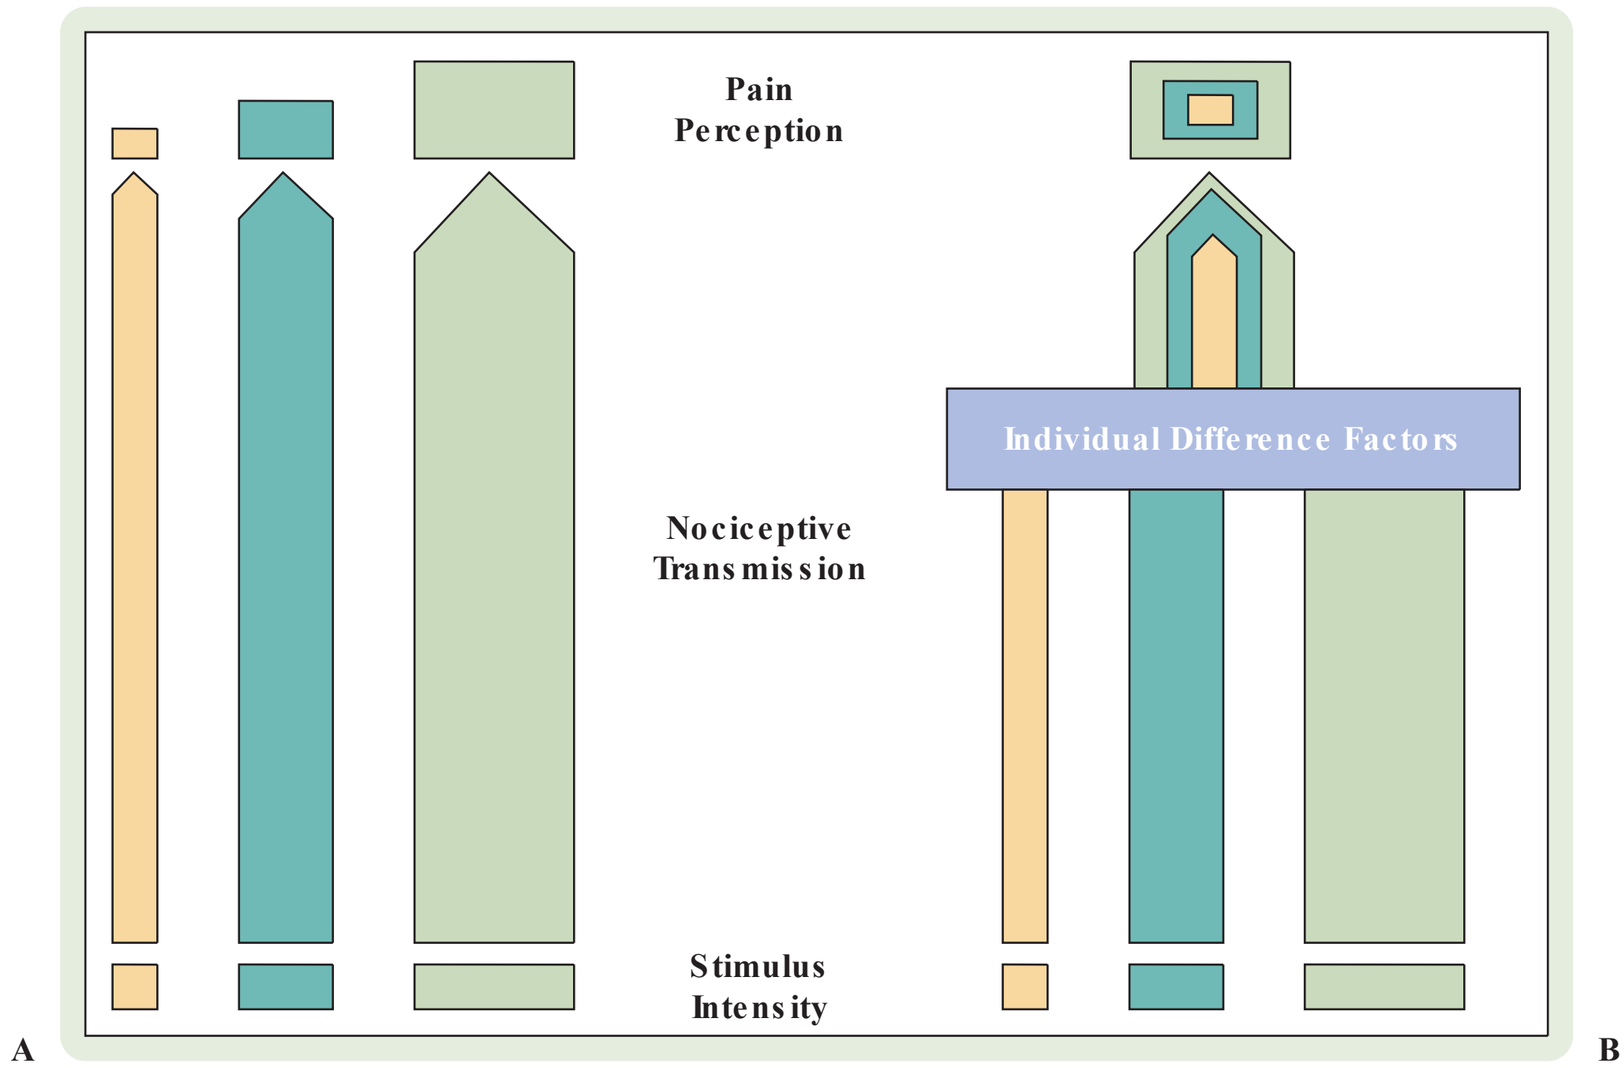

FIGURE 8.1 Schematic representation of the relatively poor association between stimulus intensity and perceived pain. **(A)** Traditional, and inaccurate, view that stimulus activity is strongly associated with pain sensitivity, which ignores the voluminous literature on individual differences in pain perception. **(B)** More valid view that while stimulus intensity may predict activation of nociceptive pathways, once filtered by individual difference factors, it becomes very difficult to predict the magnitude of perceived pain.

expended to minimize this variability, based on the assumption that it represents error variance. However, it is important to recognize that error variance is a general term, which refers not only to actual measurement error but also to sources of variance outside those of most interest to the investigator. For example, in a clinical trial investigating the pain relieving effects of a new medication, the proportion of change in clinical pain that is not attributable to the medication is defined as "error variance." While some percentage of this variance is actually associated with measurement error, multiple additional sources of variability are present (e.g., age, sex, ethnicity, genetics, environmental factors, etc.). In the context of most clinical trials, the investigator will try to reduce this "error variance" by statistically controlling for these factors, in hopes of increasing the probability of achieving statistical significance. However, in contrast to controlling away the influence of these factors to reduce error variance, investigators studying individual differences in pain would argue that there is scientific and clinical merit to elucidating the mechanisms whereby these various factors influence pain treatment responses. A graphical depiction of these sources of variability is presented in Figure 8.2.

An important goal of research on individual differences in responses to pain and its treatment is to develop the ability to generate accurate a priori predictions of a person's response to pain or pain treatment based on assessment of specific characteristics of that individual. For example, if sufficient knowledge were available, we might predict response to a pain medication based on a combination of body size, genetics, sex, ethnicity, and other factors. Of course, before this type of individualized pain medicine can be realized, a substantially better understanding of individual differences in responses to pain and pain treatment will be needed. The remainder of this chapter will discuss current knowledge of three important individual difference factors related to pain: sex/gender, race/ethnicity, and genetics.

SEX AND GENDER DIFFERENCES IN PAIN

Clinical Pain

Research regarding sex, gender, and pain has exploded over the past 15 years.[26,27] This interest in sex differences in pain is driven primarily by epidemiologic and clinical findings indicating that the burden of pain is substantially greater among women than

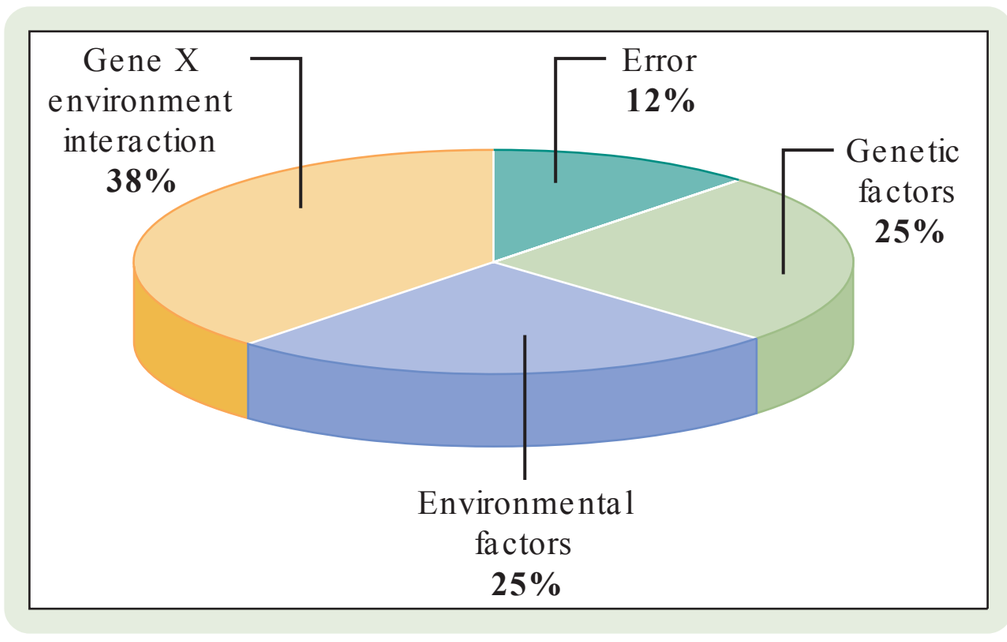

FIGURE 8.2 Graphical example of the sources of variability in pain perception or treatment response. The specific percentages are for illustrative purposes only and do not reflect actual proportions of variance accounted for. Indeed, the proportions of variance would be expected to vary depending on multiple factors, including the nature of the pain, the characteristics of the sample, the influence of longstanding and transient environmental influences, etc. . . .

men. Several population-based surveys have demonstrated higher frequencies of pain among women than men. The NUPRIN Pain Report was a telephone survey of 1254 adults in the United States, which queried respondents about seven types of pain: headache, backache, muscle pain, joint pain, stomach pain, dental pain, and perimenstrual pain.[28] Women reported more frequent headaches, stomach pain, joint pain, and back pain than men. In a Canadian household survey, women reported higher rates of both temporary and persistent pain,[29] and a mail survey of more than 3600 adults in Scotland found that women were significantly more likely than men to report chronic pain.[30] A postal survey in rural Sweden revealed that women reported pain in multiple body sites more often than men,[31] and in a Norwegian population-based survey women reported pain in a significantly higher number of body sites compared to men.[32] Similarly, in a survey of health maintenance organization enrollees in Seattle, Von Korff and colleagues[33] found that women were significantly more likely than men to report at least three of the following five pain conditions: headache, back pain, chest pain, abdominal pain, and facial pain. Numerous other population-based studies echo these findings,[34,35] and even among healthy young adults, women have been found to report pain with greater frequency than men.[36,37]

In addition to these data on general pain symptoms, considerable evidence suggests that specific pain conditions show sex differences in their prevalence.[34,38–42] Berkley[43] provided a thorough list of pain disorders separated by those showing higher prevalence among females, those with higher prevalence among males, and those showing no sex difference in prevalence. Substantially more disorders showed higher prevalence among females than males; however, many of the pain disorders listed are relatively uncommon. When restricting the list of pain disorders to those associated with the greatest frequency and most significant societal costs, the differences become even more dramatic[35] (see Table 8.1). Furthermore, these represent population prevalence rates, and because women are more likely to seek health care for pain,[44–47] females typically make up an even greater proportion of individuals in the clinical setting. Thus, the prevalence rates of the most common and costly pain conditions are generally higher among women than men, suggesting that the public health burden of pain is disproportionately distributed among women.

Additional clinical evidence of sex differences in pain comes from studies examining whether the severity of clinical pain and related symptoms differs among women and men. Several investigators have explored sex differences in postoperative pain. In mixed surgical populations, inconsistent findings have emerged, with some reporting greater pain among women[48,49] and others reporting greater pain among men.[50] Studies have also examined sex differences in postoperative pain among patients undergoing specific surgical procedures. For example, women have reported more severe pain after oral surgery in several studies,[51–55] though others have reported no sex differences.[56] Greater pain among women has also been observed after orthopedic surgery,[57–61] cardiothoracic surgery,[62,63] and laparoscopic cholecystectomy.[11,64] Moreover, women report more pain than men following endoscopic colorectal cancer screening procedures.[65,66] On balance, studies of clinical pain associated with surgery or other invasive procedures suggest greater pain severity among women.

Sex differences in clinical pain have also been investigated among patients presenting for evaluation and treatment of ongoing chronic pain. One survey study reported that among individuals with pain that limited their activity, women reported more frequent pain, greater pain-related negative affect, and higher levels of disability compared to men.[67] Among patients with arthritis, evidence indicates that women report greater pain and disability than men,[68,69] including individuals undergoing imminent total hip arthroplasty.[70] In addition, pain among women with multiple sclerosis report more frequent and severe pain than men with this disease.[71] Also, in a heterogeneous chronic pain population recruited from a multidisciplinary pain clinic, women had higher pain severity than men.[72] George and colleagues found that pain ratings were similar across sex in a sample of patients with chronic musculoskeletal pain, but women indicated a greater area of pain based on their pain drawings. However, other investigators have reported minimal sex differences in pain severity in heterogeneous chronic pain populations.[73–75] Also, no sex differences in measures of clinical pain, experimental pain sensitivity, psychological/personality factors or illness behaviors were reported among patients with pain due to temporomandibular disorders.[76] A recent study found that men had higher levels of pain and poorer pain-related adjustment in a sample of patients seeking treatment primarily for myofascial pain in a multidisciplinary clinic.[77] Thus, the evidence regarding sex differences in the severity of chronic clinical pain is mixed.

TABLE 8.1

SEX DIFFERENCES IN THE PREVALENCE OF COMMON CHRONIC PAIN CONDITIONS

Condition	Overall Point Prevalence*	Female: Male Ratio*
Migraine headache	12%–20%	2–3:1
Chronic tension-type headache	2%–5%	2:1
Low back pain	4%–33%	1.2:1
Irritable bowel syndrome	15%–20%	1.5:1
Temporomandibular disorder	4%–12%	2:1
Fibromyalgia	2%–4%	6:1
Chronic widespread pain	10.6%–13%	1.5–2:1
Arthritis	21.6%	1.4–1.6:1

* Prevalence data and female:male ratios were estimated from several sources.[26,38,41] These estimates reflect the overall population rates, and it is important to recognize that both the prevalence and female:male ratio can vary greatly across the lifespan.[35]

Experimental Pain

The literature reviewed above suggests that women experience more frequent and more severe clinical pain than men, which has led some investigators to suggest that sex differences in nociceptive processing may contribute to the greater burden of clinical pain among women.[78,79] This possibility seems particularly plausible in light of findings that several female predominant pain disorders are characterized by enhanced sensitivity to experimentally induced pain.[80–85] One potential hypothesis is that enhanced pain sensitivity represents a preexisting risk factor for the development of certain pain conditions.[86] One corollary of this hypothesis states that if women show greater pain sensitivity than men, this that places women at greater risk for certain pain conditions.

As previously reviewed,[79,87–89] a large number of studies have examined sex differences in perceptual responses to experimentally evoked somatic pain. Taken together, the findings demonstrate lower pain thresholds and tolerances among women relative to men, across multiple stimulus modalities. While the direction of the findings is quite consistent, the magnitude of the sex difference varies across studies, with a previous meta-analysis showing that the average effect size was moderate.[87] Since the publication of this quantitative review, additional evidence has emerged addressing sex differences in the perception of laboratory-induced pain. For example, several studies have demonstrated greater temporal summation of pain among women compared to men.[90–92] Cairns and colleagues[93,94] reported that

injection of glutamate into the masseter muscle produced higher peak pain, longer lasting pain, and a greater area of pain among women compared to men. Similarly, muscle injections of hypertonic saline produced greater intensity of pain and greater areas of referred pain among females.[83] In contrast to these findings, another experimental model of muscle pain, delayed onset muscle soreness, has consistently failed to show sex differences.[95–97] Similarly, studies of visceral pain perception (e.g., rectal distention, esophageal stimulation) have revealed minimal sex differences.[98,99]

In addition to perceptual responses to laboratory pain stimuli, several investigators have examined sex differences in autonomic, electrophysiological, and cerebral responses to noxious stimuli. Maixner and Humphrey[100] reported that men exhibited more robust blood pressure responses to ischemic pain compared to women, despite higher ratings of pain among women. In contrast, women showed greater pupil dilation, a marker of autonomic reactivity, in response to pressure pain relative to men.[101] Further, the nociceptive flexion reflex, a pain-related muscle reflex, has been shown to occur at lower stimulus intensities among women than men.[102,103] Functional brain imaging has been used to explore sex differences in cerebral responses to evoked pain. In response to a painful (50° C) thermal stimulus, women provided higher pain ratings and showed greater activation in the contralateral prefrontal cortex, insula, and thalamus compared to men.[104] Using individually tailored laser stimuli to produce warmth, mild pain and moderate pain, Derbyshire and colleagues[105] found that males showed greater pain-related activation in bilateral parietal cortex and contralateral secondary somatosensory and prefrontal cortices. More recently, it was shown that in response to mild and moderate intensity visceral pressure, men showed greater activation in the anterior insular compared to women, whereas women showed greater deactivation in the midcingulate and thalamus.[106] Also, in a functional magnetic resonance imaging (fMRI) study using heat pain stimuli, Moulton and colleagues reported greater pain-related activation in men in several brain regions, including primary somatosensory, mid-anterior cingulate, and dorsolateral prefrontal cortices.[107] However, these authors then determined that these sex differences were primarily driven by greater negative blood oxygen level dependent (BOLD) signal changes in women, which may indicate greater pain-related deactivation in these brain regions among females. In a study of both cutaneous and muscle pain, fMRI revealed that females showed greater increases in BOLD activity in the mid-cingulate cortex and greater decreases in activity in the cerebellum and hippocampus, while men showed greater BOLD activity decreases in the dorsolateral prefrontal cortex.[108]

Responses to Pain Treatment

An expanding body of literature addresses whether women and men respond differently to a variety of pharmacologic and non-pharmacologic pain treatments. Several studies have compared females' and males' responses to mu-opioids. For example, some findings of patient controlled analgesia following surgery suggest that women generally consume significantly lower amounts of opioid medication for postoperative pain compared to men.[50,109] In contrast, the absence of sex differences in morphine analgesia has been reported following oral surgery[50,109,110] and among patients with chronic cancer pain.[111] Others have shown enhanced opioid analgesia among males. Cepeda and Carr[49] reported that for comparable analgesic efficacy, women required 30% more morphine than men, and in a mixed postsurgical sample women required significantly higher doses of morphine to achieve pain relief.[48] Other investigators assessing responses to kappa-agonist-antagonists using an oral surgery model have found that women showed more robust and/or longer lasting analgesic responses to pentazocine, nalbuphine, and butorphanol compared to men.[56,112–114] Also, a study of trauma-related pain in the emergency room showed that butorphanol was more effective than morphine for women, and men showed marginally greater morphine analgesia women.[115] Using experimental pain models, one study has showed more robust morphine analgesia in women.[19] However, this study was not placebo controlled. This may be important, because Pud and colleagues[116] also found that while women showed greater morphine analgesia than men, when women's greater placebo response was controlled, the sex difference in morphine analgesia was not significant. Others report no sex differences in responses to morphine and other mu agonists,[18,117] and the only experimental studies examining kappa-agonist-antagonists revealed no sex differences in analgesic responses.[118,119] Overall, the conflicting nature of the evidence regarding sex differences in opioid analgesia can be attributed to a variety of factors, including the specific opioid and dose administered, the type of pain being treated, and characteristics of the study sample.

Sex differences in responses to nonpharmacologic pain treatments have also been investigated. Among patients with back pain, a conventional physical therapy intervention produced better outcomes for men, but women showed greater pain reduction in response to intensive dynamic back exercises.[120] Similarly, another investigation of back pain showed that women undergoing cognitive-behavioral treatment with or without physical therapy showed increased health-related quality of life and lower rates of disability, while men showed no such treatment responses.[121] In contrast, other investigators show no sex differences in the effectiveness of rehabilitation treatments for chronic low back pain.[122,123] Multidisciplinary treatment for pain due to temporomandibular disorder was associated with significant decreases in pain over a 2-year period in women, but not men.[124] More recently, Keogh and colleagues[125] found that women and men showed comparable initial responses to multidisciplinary pain treatment; however, men maintained their treatment gains over the 3-month follow-up period, while women regressed to their pretreatment levels. Thus, the literature on sex differences in responses to nonpharmacologic treatment yields conflicting results.

As reviewed elsewhere,[27,43,79,89,126,127] multiple biopsychosocial factors contribute to these sex differences in clinical and experimental pain responses. For example, several lines of evidence indicate that gonadal hormones can influence responses to pain and pain medications.[126,128,129] Several clinical pain syndromes show alterations in their severity across the female menstrual cycle.[129] Evidence from human studies indicates that females exhibit greater pain sensitivity during the late luteal (i.e., premenstrual) phase versus the follicular (i.e., postmenstrual) phase of their menstrual cycle; although, the effects are inconsistent across studies and are often small in magnitude.[130,131] Exogenous hormone use, especially hormone replacement among postmenopausal women, has been associated with increased risk for clinical pain[132–134] and experimental pain sensitivity,[135] though others have failed to show such an association.[136] While these findings support a pronociceptive role for estrogen, other results suggest that estrogen may be antinociceptive. For example, brain responses to heat pain, especially in regions associated with the affective component of pain, were lower during high versus low estrogen menstrual phases.[137] Moreover, exogenous administration of estrogen was associated with both reduced muscle pain sensitivity and enhanced pain-related brain mu-opioid receptor binding in healthy women,[138] suggesting that estrogen promotes pain endogenous opioid-mediated inhibition. Thus, while gonadal hormones can alter pain responses, a complete understanding of the pattern and direction of these effects remains elusive.

Psychosocial factors also contribute to sex differences in pain responses. For example, women and men differ in pain coping, which may partially account for sex differences in clinical and experimental pain.[139,140] In addition, sex differences in mood are commonly observed, and the association of affective variables to

pain responses often differs for women versus men.[73,141–143] Further, stereotypic gender roles have been associated with responses to experimental pain, based on the assumption that traditional feminine roles may encourage reporting pain, while masculine roles promote stoicism. Indeed, both women and men describe women as more willing to report pain compared to men, and this willingness to report pain has accounted for sex differences in experimental pain responses.[91,144] Also, using traditional measures of gender roles, masculinity and femininity have been associated with lower and higher pain sensitivity, respectively,[145–149] and men who identified strongly with masculine gender norms had higher pain tolerance than men with low masculine identification.[150] The extent to which such gender roles contribute to sex differences in clinical pain has received little empirical attention.

ETHNIC GROUP DIFFERENCES IN PAIN

Ethnicity represents another demographic factor associated with individual differences in pain responses. Disparities in health status across ethnic and racial groups in the United States have been well documented, such that minority groups, especially African Americans and Hispanics, generally have poorer health status compared to non-Hispanic whites.[151] It has become increasingly clear that these ethnic/racial group differences extend to pain conditions.[152,153] In order to better frame the discussion of ethnic differences in pain, a brief consideration of some important methodologic and conceptual issues is warranted. Amidst the debate regarding terminology used to characterize population groups, one rare point of agreement is that the terms race and ethnicity have different definitions and their interchangeable and imprecise use has produced confusion and slowed the progress of research on differences in health and disease across population groups.[154] Historically, the term race was used to connote biological differences among groups of people who had distinguishing physical characteristics, while ethnicity referred to groups defined by a combination of cultural factors (e.g., language, religion, diet) typically associated with race.[155] The validity of race as a biological or genetic construct has been challenged by many experts,[156,157] while others point to well-documented differences in frequency of genetic variants across self-reported racial and ethnic groups, some of which may be relevant to health and disease.[158,159] The only firm conclusion is that race and ethnicity are poorly defined terms applied to complex and dynamic social constructs whose connection to biology is far from perfect. Given the lack of consensus, the author will generally use the combined term ethnic/racial.

Clinical Pain

An increasing clinical literature suggests that the experience of clinical pain varies across ethnic/racial groups in the United States. For example, greater pain among African Americans compared to non-Hispanic whites has been documented for several painful conditions, including cancer,[160] arthritis,[161–164] back pain,[165] and among children with temporomandibular disorders.[166] Also, one study demonstrated more widespread pain among African American women, while Caucasian women reported greater pain severity and increased tenderness to palpation.[167] Also, in studies of heterogeneous chronic pain populations, African Americans have shown higher levels of pain and poorer pain-related adjustment than non-Hispanic whites.[168–171] Evidence of racial/ethnic group differences also emerges from studies of Hispanics in the U.S. For example, among chronic pain patients, Hispanics reported the highest pain levels.[172] Also, one study showed that Hispanic workers were more likely to report musculoskeletal pain than non-Hispanic whites,[173] and another study reported a greater proportion of persistent symptoms among Hispanics versus non-Hispanic whites following an occupational injury.[174] In addition to these findings related to chronic painful conditions, ethnic differences have been reported for acute clinical pain and for reports of pain in nonclinical samples. "Latino" and "black American" patients reported greater pain after oral surgery compared to patients of European descent,[175] and African Americans reported greater pain than whites following spinal fusion.[176] Community-based surveys have also indicated a greater prevalence of severe pain among Hispanics and African Americans compared to whites,[177] and that whites report a longer duration of pain, while African Americans and Hispanics reported more severe pain.[178] Importantly, while these findings indicate ethnic/racial group differences in clinical pain, additional studies of ethnic/racial influences on pain prevalence or severity have reported no such group differences.[179–183]

Experimental Pain

These ethnic/racial group differences in clinical pain are inevitably driven by complex interactions among multiple system, provider, and patient level variables. For example, socioeconomic variables, such as education and income, are associated with increased risk for pain and poor health status and are likely to contribute to ethnic/racial disparities in pain.[164,178,184–186] Also, considerable evidence indicates that African American and Hispanic patients are at increased risk for undertreatment of pain,[153,187–190] which could obviously contribute to increased severity of pain in these groups. In addition to these system and provider level factors, ethnic/racial group differences in the actual experience of pain could contribute to the group differences in clinical pain characteristics. That is, if certain ethnic/racial groups expressed greater sensitivity to pain, this could translate into enhanced clinical pain. Evidence of ethnic/racial group differences in pain perception derives from studies using controlled laboratory pain stimuli.

The most frequent comparisons in experimental studies have been between African Americans and non-Hispanic whites. More than 60 years ago, Chapman and Jones[24] found that African Americans displayed significantly lower heat pain thresholds and tolerances compared to non-Hispanic Whites. In a large study involving more than 40,000 participants, African Americans showed lower pressure pain tolerance than whites.[191] Also, higher cold pain tolerance was observed in non-Hispanic whites compared to a combined group of Hispanics and African Americans.[192] Edwards and Fillingim[193] reported that while neither heat pain thresholds nor ratings of heat pain intensity differed across ethnic/racial groups, African Americans had lower heat pain tolerances and higher ratings of heat pain unpleasantness compared to whites, and similar findings were subsequently reported by others.[194] Several recent reports have demonstrated lower pain tolerances, but not pain thresholds, among African Americans compared to whites.[195–198] Weisse and colleagues found that African Americans provided higher ratings of cold pain intensity and unpleasantness; however, an interaction of participant ethnic/racial group and experimenter gender revealed that these higher ratings were only observed when the experimenter was female.[199] One study among patients with chronic pain revealed lower ischemic pain tolerance among African American compared to white patients,[200] while another study failed to show ethnic/racial group differences in ischemic pain responses among patients with chronic pain.[201]

Some additional studies have examined differences in laboratory pain responses among other ethnic/racial groups. Regarding Asian populations, "oriental" subjects provided higher ratings of cold pain than "occidental" subjects.[202] Another study compared

Japanese subjects tested in Japan to "American" subjects tested in America; however, the American group was comprised of half "Caucasians" and half second- or third-generation Japanese living in America (referred to as Nisei). Overall, the American group had higher pain threshold and required a higher stimulus intensity to achieve moderate pain, but this group difference was driven primarily by the Nisei participants who showed the lowest pain sensitivity of all three groups.[203] More recently, South Asian groups have been found more sensitive to heat pain[204] and capsaicin-induced pain[205] compared to Europeans. In contrast, others have reported no differences in pressure pain perception between "Afro-Asian" and white participants.[206] One study found that Asian Indians reported higher cold pain tolerance than Americans, and interestingly individuals in this study were tested in separate labs in their home countries.[207]

Responses to Pain Treatment

While ethnic/racial group differences in clinical and experimental pain responses have received considerable empirical attention, little research has addressed ethnic/racial group differences in responses to pain treatment. Multiple studies have demonstrated that African American and Hispanic patients are likely to receive analgesic interventions at lower doses or with lower frequency than their non-Hispanic white counterparts,[153,187–190,208,209] though some studies have shown no such disparity.[210–212] However, few studies have examined whether responses to of analgesics vary across ethnic/racial groups. Kaiko and colleagues[111] found that African Americans with chronic cancer pain showed greater analgesic responses to morphine than whites. Also, ethnic differences in respiratory responses to morphine have been reported, with native Indians (from Columbia) showing greater respiratory depression than whites,[213] while whites showed greater respiratory depression than Chinese patients.[214] Also, after administration of meperidine or morphine, white patients showed more nausea and vomiting than black patients.[214,215] Thus, the influence of ethnic/racial group on responses to pain medications warrants additional investigation.

As with sex differences, ethnic/racial group differences in pain are mediated by multiple biopsychosocial factors. Little research has directly investigated biological contributions to ethnic/racial group differences in pain. However, a recent study examined the association of stress-induced increases in blood pressure, norepinephrine, and cortisol on experimental pain responses in African Americans and whites.[197] Stress-induced physiological reactivity was more strongly associated with reduction of pain responses among white compared to African American participants. This research group also found that lower resting levels of allopregnanolone, higher cortisol, and higher beta-endorphin were associated with reduced pain sensitivity among non-Hispanic whites but not African Americans.[216] Thus, neuroendocrine factors may contribute to ethnic/racial group differences in pain perception. Regarding psychosocial factors, ethnic/racial group differences in pain coping have been observed. Among patients with rheumatoid arthritis, African Americans reported greater use of distraction and praying/hoping, while whites reported higher use of ignoring pain and coping statements and a greater perceived ability to control pain,[217] and others have also reported group differences in pain coping.[180,218] In a study of experimental pain perception, African Americans showed higher levels of passive coping and hypervigilance; however, these psychological variables did not account for group differences in pain perception.[195] Sociocultural factors also contribute to both variation in pain responses both within and between ethnic/racial groups.[219] Zborowski[220] proposed that expression of pain is culturally prescribed, based on attitudes toward pain behavior and expression that are inherent within cultural groups. In general, these hypotheses have not been empirically tested; however, a recent study reported that higher levels of ethnic identification were associated with greater pain sensitivity among African American and Hispanic groups, but not among non-Hispanic whites.[198] Additional investigation of sociocultural contributions to clinical and experimental pain responses is needed.

GENETIC CONTRIBUTIONS TO PAIN

In recent years, research on individual differences in pain responses has increasingly involved consideration of genetic contributions. A comprehensive review of this literature is beyond the scope of this chapter[221–224]; rather, the author would like to highlight some relevant findings in the broader context of individual differences in pain, including interactions between genetics and other individual differences factors, such as sex and ethnic/racial group.

Clinical Pain

Increasing evidence from human research documents the importance of genetic influences in numerous clinical pain conditions. Significant familial aggregation has been demonstrated for several syndromes, including arthritis, fibromyalgia, irritable bowel syndrome, and migraine and tension-type headache.[225–229] This is consistent with a genetic contribution, but could also be explained by shared environmental influences. However, heritability estimates derived from large scale twin studies, comparing monozygotic to dizygotic twins, suggest that genetic factors account for a substantial proportion of the variance in multiple pain conditions, including chronic widespread pain, back pain, neck pain, arthritis, headache, and functional bowel disorders.[230–236] While one possibility is that genes associated with the pathophysiological processes of specific diseases may produce high heritability for a given condition, this is difficult to determine, because several of the pain conditions that show high heritability are not characterized by any known specific etiopathogenesis. An alternative possibility is that genetic influences on pain perception or endogenous pain modulation could potentially contribute to the heritability of chronic pain conditions. This possibility is bolstered by findings that many of these heritable pain syndromes are characterized by enhanced pain sensitivity and/or altered endogenous pain modulation.[237–239]

Experimental Pain

Considerable evidence from preclinical models suggests that both basal nociceptive sensitivity and antinociceptive responses to drugs show significant heritability,[240] and increasing research has addressed genetic contributions to experimental pain sensitivity in humans. Pressure pain threshold was assessed in monozygotic and dizygotic twins and showed a heritability of only 10%[241]; however, twin studies are typically underpowered for detecting genetic associations for multifactorial traits like pain sensitivity. Also, these investigators tested twin pairs together, which may have inflated any environmental contribution. Two more recent twin studies have examined additional laboratory pain phenotypes. Nielsen and colleagues[14] found a significant genetic contribution to both heat pain and cold pain ratings, with heritability estimates of 26% for the former and 60% for the latter. Also, another recent twin study reported significant heritability estimates ranging from 22% to 55% for several experimental pain phenotypes, including responses to heat pain and chemically induced pain.[242] Another approach to investigating genetic influences has been to examine genetic associations between single

TABLE 8.2

SUMMARY OF ASSOCIATIONS STUDIES LINKING SPECIFIC CANDIDATE GENES WITH EXPERIMENTAL PAIN PERCEPTION

Authors	Candidate Gene(s)	Pain Measures	Sample Size	Findings
Zubieta et al. 2003[248]	*COMT* (val158met)	Hypertonic saline in masseter muscle; brain mu-opioid receptor binding	18 healthy adults	val/val Ss showed greater mu-opioid activation and lower pain responses than met/met Ss
Diatchenko et al. 2005[15]	*COMT* (haplotypes)	Summed z-score across multiple pain measures	202 healthy females	LPS haplotype associated with lower summed z-score (reduced pain sensitivity) compared to HPS haplotype
Diatchenko et al. 2006[282]	*COMT* (haplotypes and val158met)	Heat, pressure, ischemic pain	202 healthy females	LPS haplotype showed lower sensitivity to heat pain compared to HPS; met/met showed lower temporal summation of heat pain compared to val/val; Associations with pressure and ischemic pain not significant
Kim et al. 2004[269]	*COMT, TRPV1, OPRD1*	Heat pain, cold pain	384 healthy adults	Among white females only, *TRPV1 val585val* higher cold pain tolerance compared to heterozygotes or *ile585* homozygotes; Among males *OPRD1 Phe27Cys* heterozygotes report lower heat pain ratings than homozygotes; No association with *COMT val158met*
Kim et al. 2006[283]	*COMT, TRPV1, TRPA1, TRPM8, FAAH*	Heat pain, cold pain	368 healthy European American adults	In females, a *TRPA1* SNP (rs11988795) was associated with cold pain tolerance, and a *COMT* SNP (rs6269) was associated with cold pain ratings. In males, 2 *FAAH* SNPs (rs932816 and rs4141964) were associated with cold pain responses
Fillingim et al. 2005[256]	*OPRM1* (A118G)	Heat pain, pressure pain, ischemic pain	167 healthy adults	Ss with 1 or 2 rare alleles had higher pressure threshold than A118A Ss; Sex X genotype interaction emerged for heat pain ratings, as G allele was associated with lower ratings in men, but higher ratings in women
Lotsch et al. 2006[257]	*OPRM1* (A118G)	ERP response to intranasal CO_2	45 healthy adults	N1 ERP response to CO_2 was lower in carriers of the rare (G) allele
Tegeder et al. 2006[246]	*GCH* (haplotype)	Thermal, pressure, ischemic pain	547 healthy adults	Significant association of haplotype with pressure pain thresholds
Kim and Dionne, 2007[247]	*GCH* (haplotype)	Cold pain, heat pain	735 healthy adults	No significant associations
Mogil et al. 2005[284]	*MC1R* (multiple SNPs)	Electrical pain	47 healthy adults	Ss with two or more variant alleles across 3 SNPs had significantly higher electrical pain tolerance than those with 0 or 1 variant alleles

ERP, event-related potential; HPS; high pain sensitive; LPS, low pain sensitive; SNPs, single nucleotide polymorphisms.

nucleotide polymorphisms (SNPs) of specific genes and responses to experimentally induced pain. Specific SNPs of several genes have been associated with various experimental pain phenotypes, as shown in Table 8.2. As is common in genetic association studies,[243–245] few of these associations have been replicated in more than one sample. Therefore genetic associations that have been examined across multiple cohorts will be discussed in more detail here, and readers are referred to other recent reviews for a more thorough presentation of the literature.[222–224]

One group of investigators implemented a translational approach to identifying a potential genetic marker of pain sensitivity.[246] First, they found that an enzyme (GT cyclohydrolase, or GCH) and its end product BH4 were upregulated in an animal model of neuropathic pain, and the importance of BH4 in neuropathic pain was demonstrated by blocking GCH, which reversed mechanical and cold hypersensitivity. A similar pattern of results was shown for inflammatory pain, and BH4 injected intrathecally produced increased basal pain sensitivity in rats and heightened hypersensitivity in rats following nerve injury and inflammation. Next, the findings were translated into humans by identifying a haplotype of the *GCH1* gene that was associated with lower levels of persistent pain following lumbar surgery for disc herniation. The authors also showed that this pain protective haplotype conferred reduced sensitivity to experimentally induced pain in a separate cohort of healthy adults. Another group of investigators has failed to replicate these results in a separate study, perhaps due to a different haplotypic structure in their population as well as differences in the pain models examined.[247]

Another gene that has been examined across multiple samples is the gene that encodes catechol-*O*-methyltransferase (*COMT*), an enzyme that metabolizes catecholamines. One functional *COMT* polymorphism that has received substantial attention in-

volves the substitution of valine by methionine at codon 158 (*val158met*), which produces a thermally unstable enzyme and reduced enzymatic activity. Zubieta and colleagues[248] reported that the val158met SNP of *COMT* was associated with brain mu-opioid receptor binding in response to chemically-induced muscle pain, such that the *val/val* genotype group showed significantly greater pain-related mu-opioid activation. Moreover, *val/val* individuals required a greater amount of hypertonic saline to evoke moderate pain over the last 10 minutes of the pain induction period, suggesting lower pain sensitivity in this group. Subsequently, this same *COMT* SNP failed to show an association with ratings of cold pain.[249] Diatchenko and colleagues[15] constructed *COMT* haplotypes based on 4 SNPs and then examined associations with a pain phenotype created by computing a summary score of pain sensitivity across multiple stimulus modalities. *COMT* haplotype was associated with overall pain sensitivity as well as risk for subsequent development of temporomandibular pain. Associations of *COMT* with other clinical pain conditions have been reported by some investigators,[250,251] and a recent report suggests that *COMT* haplotype may interact with psychological factors to predict clinical pain severity in patients with shoulder pain.[252]

An additional candidate gene that has been examined for associations with pain responses is the mu-opioid receptor gene (*OPRM1*). The A118G SNP of *OPRM1* is a common polymorphism with potential functional effects, as the variant receptor showed higher binding affinity for beta-endorphin in one study[253] but not another,[254] and the G allele resulted in lower mRNA expression and protein yield compared to the A allele.[255] Carriers of at least one rare allele showed lower mechanical pain sensitivity compared to homozygotes for the consensus allele,[256] suggesting that the G allele may confer reduced pain sensitivity. Consistent with this finding, pain-related evoked potential responses were found to be reduced in carriers of the G allele compared to those carrying two consensus alleles.[257] Interestingly, the G allele showed lower frequency in a sample of chronic pain patients compared to a group of postsurgical patients.[258] In addition to these data regarding basal pain responses, several studies have investigated whether *OPRM1* is associated with responses to mu-opioid agonists. In a laboratory study, carriers of the G allele showed significantly reduced analgesic responses to alfentanil relative to individuals with two consensus alleles, and G homozygotes also showed significantly reduced respiratory depression, such that their therapeutic window was actually improved.[259] These investigators subsequently showed that alfentanil attenuated pain intensity-related cortical responses more strongly in A versus G homozygotes.[260] Another group showed that the rare allele was associated with reduced analgesic responses to another mu-opioid agonist, M6G, but A118G genotype was not related to respiratory depression.[261] Clinical evidence supports these laboratory findings, as homozygous carriers of the rare allele have shown increased morphine requirements for postoperative[262,263] and cancer pain.[264] Interestingly, the G allele showed lower frequency in a sample of chronic pain patients compared to a group of postsurgical patients, and among the chronic pain patients that consensus allele homozygotes were consuming higher opioid doses than those with one or two minor alleles.[258] While this runs counter to the above findings in postoperative pain, higher opioid doses may have been required in the major allele group due to enhanced clinical pain rather than poorer analgesic response.

INTERACTIONS AMONG INDIVIDUAL DIFFERENCE FACTORS

The previous discussion treats each individual difference factor separately, as though sex, race/ethnicity, and genetic factors each exist in isolation. Obviously, these and many other individual difference variables coexist and have the potential to interactively influence pain responses. For example, little is known regarding whether sex differences vary as a function of racial/ethnic group, but it is conceivable that such sex by ethnicity interactions may occur. In contrast, some evidence has examined interactions between sex and genetic factors. For example, family history of pain has been more strongly associated with pain complaints and with experimental pain responses among women than men[265–267]; although, these findings could be explained by genetic or environmental factors. More direct evidence comes from a large twin study, in which the heritability of neck pain was significantly higher in females (51%) than males (33%).[230] Several laboratory studies also suggest sex by genotype interactions. Using a translational approach, Mogil and colleagues[268] identified a novel sex-dependent genetic association, such that the melanocortin-1-receptor gene (*MC1R*) was associated with analgesic responses to a kappa-opioid agonist in female but not male mice. They then examined pentazocine analgesia among humans as a function of *MC1R* status and found a sex by genotype interaction, with a significant genetic association among women but not men. In another study, while the sex X genotype interaction was not statistically significant, the association of *OPRM1* with pressure pain thresholds was only significant among men, and a frankly significant sex X genotype interaction emerged for ratings of heat pain.[256] Kim and colleagues[269] reported that the delta-opioid receptor gene (*OPRD1*) was associated with heat pain ratings only among men, which is consistent with previous murine evidence.[270] Thus, genetic contributions to pain and analgesic responses may differ across sexes, which indicates the importance of including both females and males in genetic studies.

Genetic contributions to pain and analgesia may also differ as a function of racial/ethnic group. Indeed, despite considerable genetic similarity across groups, it is well recognized that allele frequencies for many SNPs differ considerably across ethnic/racial population groups, which may contribute to group differences in health relevant phenotypes.[159,271–273] While little evidence has addressed this issue in pain research, it has been documented that allele frequencies for the A118G SNP of *OPRM1* differ across ethnic groups, with the rare allele occurring with significantly lower frequency among African Americans.[274,275] Given that the rare allele predicts reduced pain sensitivity[256,257] and higher morphine requirements,[262,263] it is tempting to speculate that this SNP may contribute to the previously reported increased pain sensitivity[195,198] and reduced morphine requirements[111] among African Americans. However, empirical confirmation of this speculation is required. Even when allele frequencies are similar across ethnic groups, genetic associations may differ. For example, preliminary data from our laboratory suggests that while Hispanic and non-Hispanic whites show similar allele frequencies of the A118G SNP of *OPRM1*, the rare allele is associated with reduced pain sensitivity among non-Hispanic whites, while Hispanics with the G allele show a tendency toward increased pain sensitivity. Another candidate pain gene, *COMT*, is also characterized by ethnic differences in allele frequency,[276] and COMT enzyme activity is significantly higher in African Americans compared to whites.[277] Thus, it is plausible to suggest that racial/ethnic group differences in allelic frequencies of pain-related SNPs, or differences in the association of SNPs with pain-related phenotypes could contribute to group differences in pain sensitivity and analgesic responses, but additional research is needed to directly support or refute this possibility.

CONCLUSION

Multiple factors contribute to the robust interindividual differences that characterize pain and analgesic responses, and the above discussion highlights the influences of sex, ethnic/racial

group, and genetics. Relative to men, women are at greater risk for many forms of clinical pain, and they display significantly greater sensitivity to experimentally induced pain. Sex differences in analgesic responses have been investigated, but the results are complex and sometimes contradictory. Regarding ethnic differences, minority patients, specifically African Americans and Hispanics, have shown higher levels of pain and disability than non-Hispanic whites in several clinical populations. These minority groups also exhibit greater perceptual responses to experimental pain. Thus, both sex and racial/ethnic group are associated with variability in pain responses. Multiple biopsychosocial mechanisms contribute to these sex and racial/ethnic group differences. Despite these sometimes large and consistent group differences, it is important to remember that differences are always greater within than between groups. Moreover, the factors contributing to pain responses can differ substantially across groups. For example, several studies have demonstrated that anxiety is more strongly associated with both clinical and experimental pain responses among men than women.[73,278–281] Also, examples above show that genetic associations with pain or analgesia can be sex-specific. Thus, demographic group variables such as sex and ethnic/racial group not only represent individual differences factors themselves, but they may also moderate the effects of other pain-related individual difference factors.

One undeniable implication of this information regarding individual differences in pain is that measures of tissue damage will continue to be poor predictors of pain and disability. Hence, treatments based solely on biomedical findings or markers of disease or injury will continue to achieve suboptimal outcomes. Given the current state of the evidence, tailoring pain treatment based on sex, ethnic/racial group, or genetics may not be practical at this time; however, with enhanced understanding of the influences of these and other individual difference variables on pain, individualized treatment could become a reality in the future. Of particular importance will be large-scale studies that provide opportunity for modeling interactions among multiple individual difference factors. More widespread recognition of the importance of individual differences in pain along with additional research to illuminate the nature of mechanisms of these individual differences will ultimately lead to more effective pain diagnosis and treatment.

CHAPTER 9 ■ FUNCTIONAL NEUROANATOMY OF THE NOCICEPTIVE SYSTEM

ROBERT GRIFFIN, EZEKIEL FINK, AND GARY J. BRENNER

INTRODUCTION TO FUNCTIONAL NEUROANATOMY OF THE NOCICEPTIVE SYSTEM

From the standpoint of the physician, there are two perspectives from which to view pain. One is as a symptom of a disease process that will inform about the underlying pathophysiology. The other is as the primary cause for suffering that requires treatment in its own right. These two views of pain often coexist when the pain reveals pathology whose treatment will not resolve the pain rapidly enough for the patient to tolerate. For example, in acute myocardial ischemia, the pain is the cardinal symptom of the underlying illness but in itself can provide an ongoing stimulus for a catecholaminergic state that will increase myocardial demand and potentially worsen the ischemic state. Both of these

perspectives, either using the pain as a clue or addressing it as the primary aim of treatment,[1] are enhanced by considering the patient's report of their pain in light of the specific anatomic structures that collect information about noxious stimuli and communicate this information to the central nervous system (CNS) where pain is perceived and a behavioral response is generated.

Pain may be described according to three major parameters: acute vs. chronic, physiologic (nociceptive) vs. pathologic (neuropathic), and somatic vs. visceral. Full understanding of the nature of any pain complaint requires knowledge of the anatomic structures involved and the functional status of these structures. Chronicity of pain is determined by the duration of the irritating stimulus and by the plastic response of the peripheral and CNS to injury or ongoing stimulus. Pain may be either nociceptive, induced by high-threshold sensory stimuli required for activation of peripheral nociceptors, or pathologic, induced by low-threshold stimuli due to a heightened state of nervous system excitability brought on by either inflammatory cell–cell signaling (i.e., inflammatory pain) and signal transduction or by the extensive anatomic and physiologic alterations brought on by nerve injury (i.e., neuropathic pain).[2] Finally, pain may be somatic, transmitted by the somatosensory nervous system, or visceral, transmitted by splanchnic sympathetic and pelvic nerve afferent fibers (or by specific cranial nerves in the case of the head and neck).[3,4] This chapter will touch on the specific anatomic structures that are involved in the transduction of physical stimuli into sensory responses, the conduction of sensory information to the CNS, the processing and relay of this sensory information within the spinal cord and brain, and will discuss some of the major perturbations in these structures as related to clinical pain phenomena.

ORGANIZATION OF THE PERIPHERAL NOCICEPTIVE SYSTEM

There are several major anatomic units involved in pain sensation. First, primary sensory neurons whose peripheral terminals respond to physical energy conduct action potentials along long axons bundled into peripheral nerves from the site of sensory stimulus to the CNS.[5] Next, nociceptive synaptic relay occurs at the dorsal horn of the spinal cord, where substantial sensory processing occurs.[6–8] Ascending fiber tracts carry this information to the brainstem and, from there, diverse brain regions. Descending fiber tracts project from the brainstem and brain to the dorsal horn of the spinal cord and regulate the processing of incoming sensory information.[9]

The peripheral nerves that carry sensory information from visceral organs, bone, muscle, joint, or skin to the CNS may be either cranial nerves or spinal nerves. Cranial nerves carry sensory information to the brainstem,[10] while spinal nerves carry sensory information to the spinal cord and may bear axons for neurons that synapse within the spinal cord or brainstem.[11,12] Spinal nerves are mixed nerves that carry general somatic afferent fibers, general visceral afferent fibers, general somatic efferent fibers, and general visceral efferent fibers. Somatic afferents primarily carry information from skin, muscle, tendon, and joint, whereas visceral afferents carry information from the other tissues. The cell bodies of both the somatic and the visceral afferent fibers carried by spinal nerves reside in the dorsal root ganglia (DRG) of the spinal cord, whereas those carried by cranial nerves reside in the brainstem cranial nerve nuclei.[12]

The ability to localize painful stimuli depends on the topographic organization of the nervous system. The somatic afferent system and the visceral afferent system are strikingly different in this regard, with precise stimulus position detected and encoded by the somatic nervous system but only relatively diffuse information coming to conscious awareness from the visceral afferent system.[4] In the clinical setting, precise localization of pain is often considered as evidence that the pain is detected by somatic afferents rather than visceral afferents. For example, knife-like well-localized pain associated with inspiration is likely detected by somatic fibers innervating the parietal pleura.[13] In the abdomen, well-localized lower right quadrant pain occurring late in the course of acute appendicitis is likely due to spread of the periappendiceal inflammation that irritates the somatic nerves innervating the abdominal wall overlying the appendix.[14]

In the somatic system, the spinal cord is segmentally organized, such that each spinal segment receives afferent information about a specific cutaneous band or dermatome (Fig. 9.1).[15] This organization arises during embryonic development when the embryonic neural tube and adjacent mesodermal tissues segment into a series of rostro-caudally adjacent somites.[16] Each spinal nerve innervates tissue developing from a single somite.[17] Spinal nerves from several different spinal segments, such as axons from neurons with cell bodies located in several different DRG, join to give rise to peripheral nerves with cutaneous fields of innervation that span multiple dermatomes (Fig. 9.2).[18] The innervation of specific peripheral cutaneous nerves, as compared to the organization of the cutaneous dermatomes, is illustrated (Fig. 9.3).

In contrast to cutaneous sensation, visceral pain is perceived as deep and is typically not well spatially localized. The clinical features of visceral as compared to somatic pain are summarized in Table 9.1. Visceral pain has a different quality than somatic pain. It is referred to structures or areas other than the organ being affected, such as the experience of arm pain with myocardial infarction.[19] The diffuse nature of the visceral pain is felt to be secondary to the large receptive field of the sensory fibers in the viscera which corresponds to the low density of sensory innervation.[20,21]

Although there are many anatomical similarities between the somatic and autonomic afferent fibers, there are significant differences in the clinical presentation of visceral pain and somatic pain. Pain symptoms resulting from visceral afferents are felt in a location different than the organ itself. This is felt to be as a result of convergence from somatic structures and viscera at multiple sites of the CNS. Convergence occurs in the dorsal horn neurons in lamina I, IV, and V as well as in the intermediate gray matter in lamina X (Fig. 9.4)[22] as well as other areas of the CNS including the brainstem, basal forebrain, thalamus, and cerebral cortex.[23] Functional neuroimaging studies have shown that regions of the cortex that are activated by noxious stimuli can also be activated by visceral stimuli.[24] A possible explanation for the clinical symptoms of referred pain is that peripheral nociceptors from somatic and visceral origin converge on a single projection neuron in the dorsal horn. As a result, higher levels of the CNS cannot distinguish the source of the signal input and attribute the sensation to somatic structures by default because somatic sensory representation predominates in the CNS. In the thorax, substernal chest pain may be due to any of the visceral sensory afferents from the T1 to T6 spinal segments and may arise from the heart and great vessels, esophagus, lungs, or chest wall. Visceral pain in the abdomen tends to follow the structure of endodermal embryonic development with pain due to foregut structures (stomach, proximal duodenum, liver, biliary system, and pancreas) perceived in the epigastrium or upper abdomen, pain due to midgut structures (distal duodenum, small bowel, cecum, appendix, ascending colon, and proximal transverse colon) perceived in the periumbilical region, and pain due to hindgut structures (distal transverse colon, descending colon, sigmoid, rectum, and urinary bladder) perceived in the lower abdomen.[14]

The central processes of the visceral fibers synapse extensively above and below the segment where they entered, thus activating spinothalamic cells at multiple levels. Clinically, noxious stimulation of the viscera elicits an autonomic spinal reflex reaction, with sympathetic activation that causes symptoms such as excessive sweating and pronounced changes in circulatory system resulting

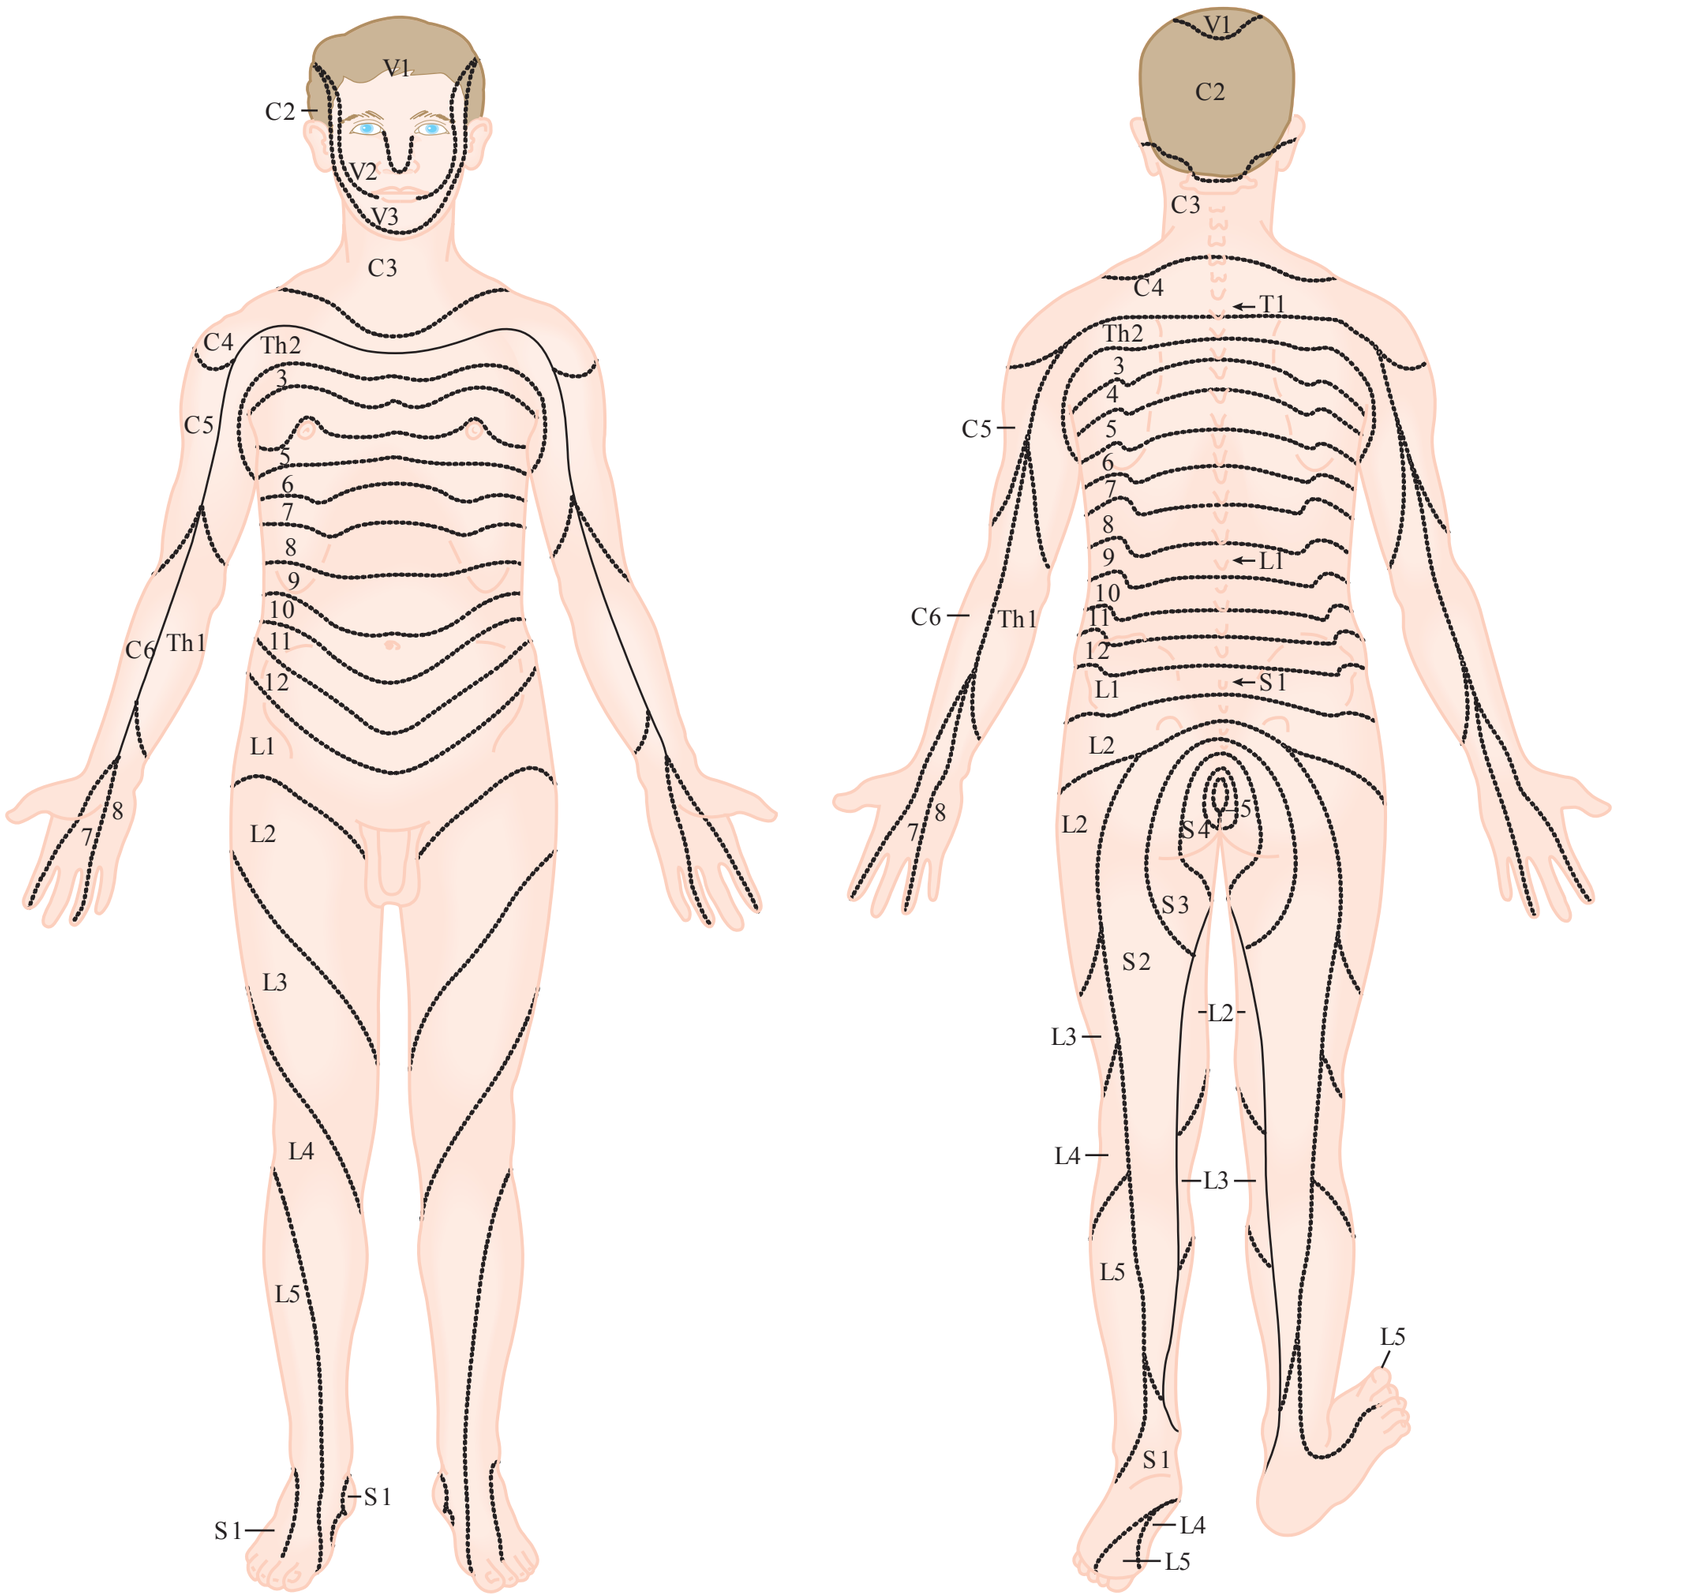

FIGURE 9.1 The dermatomes developed by Bonica on basis of personal observation and data published by others. See text for description.

in increased blood pressure. This reflex reaction tends to be more pronounced than what is seen with noxious stimulation of the skin. Noxious visceral stimulation can also result in hypotension and bradycardia by either reflex inhibition of sympathetic outflow or activation of the parasympathetic nervous system.[25] These reactions may be mediated by the periaqueductal gray matter (PAG) and the nucleus of the solitary tract. There are also protective reflexes that are directed toward reducing pain, such as the inhibition of visceral motility. Deregulation of this reflex as well as aberrant response by vagal afferents in the enteric system is thought to contribute to the pathophysiology of irritable bowel syndrome.[26] Coordination centers at higher levels of the CNS, such as the PAG, also mediate nausea and vomiting as well as complex somatic responses in the context of visceral pain.

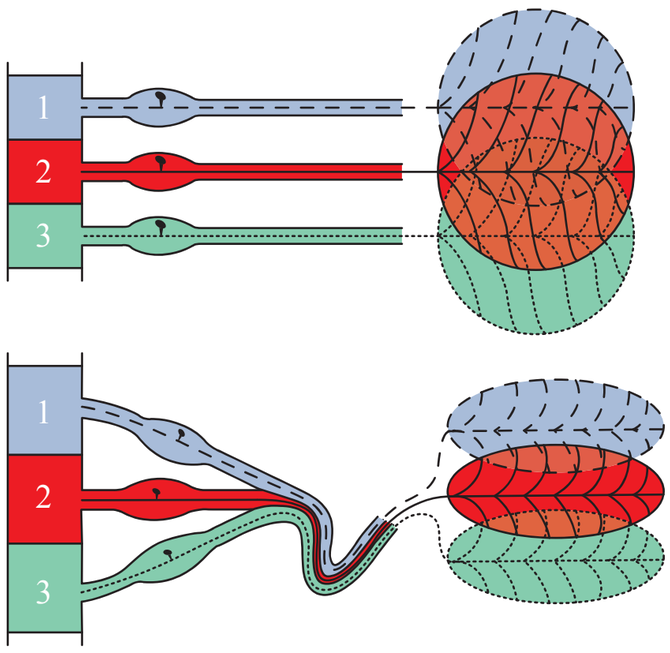

FIGURE 9.2 Simple diagrams to illustrate the overlap of cutaneous fields of segmental and peripheral nerves. In the upper figure, three intercostal (segmental) nerves extending from the periphery to the spinal cord are represented. The lower figure illustrates a somewhat analogous but less extensive overlap in the peripheral nerves.

PERIPHERAL NERVOUS SYSTEM STRUCTURES OF PAIN SENSATION

Within the DRG, there are several neuronal populations classified primarily according to caliber and myelination and secondarily according to the expression of chemical markers.[27] Large myelinated fibers comprise the A-beta (Aβ) population, which respond predominantly to low-energy, nonpainful mechanical stimuli and conduct action potentials rapidly. Small, thinly myelinated fibers make up the A-delta (Aδ) population, which respond to high-energy mechanical stimuli and have intermediate conduction velocity. Small, unmyelinated fibers are classified as the C-fiber population, and have slow conduction velocity.[28] In general, C-fibers can respond to chemical, thermal, and high-threshold mechanical stimuli, with several subclasses of C-fibers exhibiting responses to various combinations of these stimulus categories.[29] Typical of electrically excitable cells, the conduction of action potentials along the axons of primary afferent sensory neurons depends on voltage gated ion channels. The inward current of the action potential is carried by voltage-gated sodium ion channels. There are six types of these in the DRG neurons of which two,

TABLE 9.1

COMPARISON OF SOMATIC AND VISCERAL NOCICEPTIVE PAIN

	Somatic nociceptive pain	Visceral nociceptive pain
Localization	More focused	More diffuse and poorly localized; pain felt in distribution innervated by the same spinal segment as organ; referred to other locations
Quality	Sharp, aching, burning, stabbing	Vague discomfort Hyperesthesia, hyperalgesia, allodynia
Associated symptoms	Accompanied by motor reflexes	Accompanied by motor and autonomic reflexes: associated muscle contraction/spasm, nausea/vomiting, faint sensation, circulatory changes in the region, decreased pulse/blood pressure, cold sweat
Triggers	Tissue injury	Distention, contraction, ischemia, inflammation; pain not evoked from all viscera (organs such as liver and kidneys are not sensitive to pain)

Nav 1.8 and Nav 1.9, have expression pattern limited to sensory neurons, with Nav 1.8 limited to nociceptors.[30–32]

C-fiber neurons are further subdivided into two groups. One group expresses the nerve growth factor (NGF) receptor TrkA, as well as the neuropeptides substance P and calcitonin gene-related peptide (CGRP), while the other group of C-fibers expresses the glial derived neurotrophic factor receptor c-ret and binds to the isolectin B4 (IB4).[33,34] Interestingly, recent data has demonstrated that the free nerve endings in the epidermis are anatomically structured such that the peptidergic fibers terminate in the stratum spinosum, while the nonpeptidergic fibers terminate in the more superficial stratum granulosum.[35] This topographic separation is maintained at the level of the dorsal horn of the spinal cord, where the peptidergic and nonpeptidergic afferents terminate in distinct Rexed laminae.

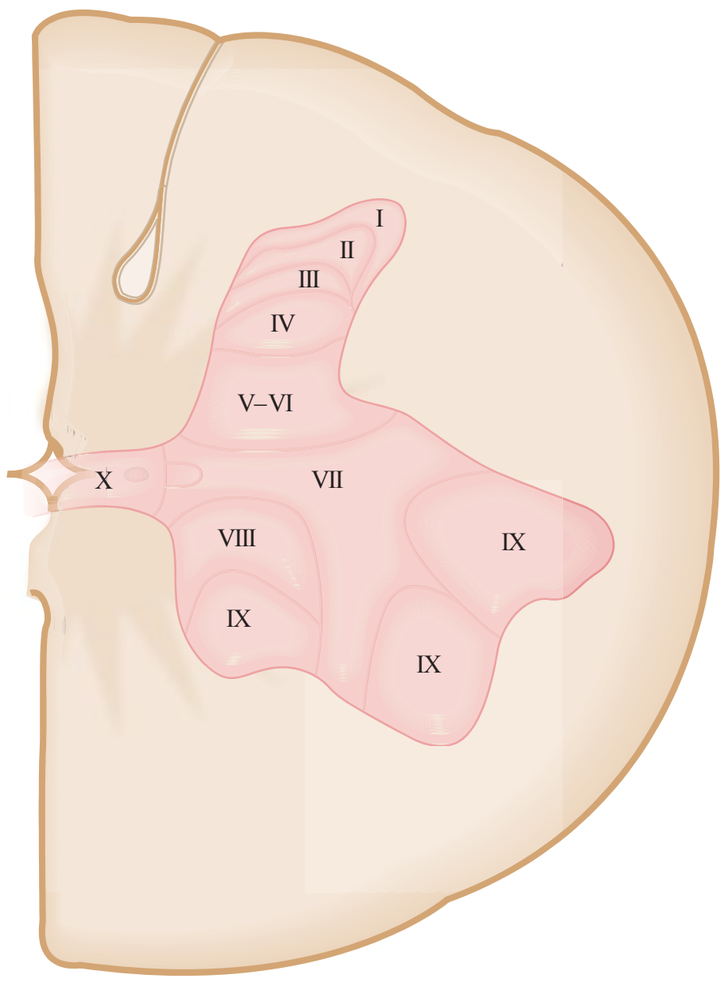

FIGURE 9.4 Schematic drawing of a cross-section of the cervical spinal cord highlighting the lamina. (Modified from Kiernan JA. *Barr's: The Human Nervous System: an Anatomical Viewpoint*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 1998.)

The peripheral terminals of DRG neurons are specialized to respond to thermal, mechanical, or chemical energy. Briefly, thermosensation depends on thermosensitive ion channels in the transient receptor potential (TRP) family, with TRPV1 and TRPV2 responsive to heat that is usually perceived as painful.[36,37] Recently, a specific inhibitor of TRPV1 has been identified that may eventually prove to have a role as a pain-specific local anesthetic agent.[38] Mechanosensation likely also depends on a set of mechanosensitive ion channels; however, the receptors responsible for transducing this information have yet to be unequivocally identified.[39–41] A wide range of chemical mediators can also act on the peripheral terminals of DRG neurons, acting either directly to activate nociceptors or indirectly by sensitizing the peripheral terminals to be activated at a lower stimulus threshold. Chemical mediators may be either exogenous (e.g., capsaicin, mustard oil, chemical acids, bee venom) or endogenous (e.g., many of the myriad inflammatory mediators). Endogenously released chemical mediators that cause pain directly are typically associated with tissue destruction that alters the chemical microenvironment, for example H^+ ions and adenosine triphosphate, or causes an inflammatory response, such as bradykinin.[42,43]

FUNCTIONAL ANATOMY OF THE CENTRAL NERVOUS SYSTEM

Among the sensations that are transmitted from the periphery to the CNS for processing, pain is the most distinctive of all the sensory modalities. Unlike other senses, pain is defined by not only the physiologic perception of nociception but also the affective and emotional response to that perception. Pain is a highly individual and subjective experience to the extent that the same stimulus can produce different responses in different individuals under the same conditions. The CNS is both the processing center for the perception of noxious stimulation and the primary regulator of adaptive and modulatory mechanisms to produce a pain behavior. Pain is primarily categorized by duration of symptoms (acute vs. chronic) and the origin of the pain signal (visceral vs. somatic and nociceptive vs. neuropathic). Understanding the anatomy and function of the pain structures and pathways in the CNS is essential to understanding and managing the different categories of pain.

Dorsal Horn

The dorsal horn represents the termination point of the dorsal root in the CNS. There is a correspondence between the functional and anatomical organization of the dorsal horn. It is arranged into 10 laminae, and distinct sensory modalities from the periphery terminate in distinct laminae (see Fig. 9.4).[44] Signals conducting nociceptive signals (Aδ and C-fibers) terminate in the superficially located laminae I (also called the marginal layer) and II (also called the substantia gelatinosa). Many neurons from lamina I respond exclusively to noxious stimulation and project to higher levels of the CNS. Some neurons called wide dynamic range neurons respond in a stepwise fashion to peripheral stimulation. The neurons of lamina II are mostly interneurons and modulate nociceptive responses at the level of the dorsal horn. The Aδ fibers also terminate in lamina V which contains wide dynamic range neurons that project to higher levels of the CNS including the thalamus.[45] There is some convergence of somatic and visceral nociceptive input into lamina V, which may explain referred pain from visceral structures.[46] Single axons of all receptors give off ascending and descending branches after entering the spinal cord. In addition to synapsing at the level they enter, these branches give off multiple collaterals that end in the gray matter of the dorsal horns at one to two levels above and below where the axon entered the spinal cord.[47] Integration of signals from the periphery and higher levels of the CNS occur at the level of the dorsal horn through the dense network of dendrites and interneurons.

Synaptic transmission by nociceptive afferent neurons at the level of the dorsal horn is mediated primarily by the excitatory neurotransmitter glutamate. Both ionotropic and metabotropic glutamate receptors are located in high concentration in the substantia gelatinosa.[48] Many neuropeptides (e.g., substance P, vasoactive intestinal polypeptide, cholecystokinin, and CGRP) which are theorized to modulate synaptic action are present in the neurons in the dorsal horn. The receptors for most of these neuropeptides are concentrated in the substantia gelatinosa which suggests that they are involved in the transmission of pain. Among the neuropeptides, substance P and its receptor, neurokinin-1, are likely to be involved in the processing and modulating of pain signals in the dorsal horn. Substance P may increase the excitation from incoming sensory fibers by enhancing and prolonging the actions of glutamate. This has been demonstrated experimentally: substance P and CGRP have been found to increase the release of glutamate; substance P induces the *N*-methyl-D-aspartate (NMDA) receptors to become more sensitive to glutamate. This unmasks normally silent interneurons and sensitizes second order spinal neurons.[49] Blocking the neurokinin-1 receptors can prevent many of these effects. Substance P can also extend long distances within the spinal cord and sensitize dorsal horn neurons several segments away from the initial nociceptive signal. This results in an expansion of receptive fields and the activation of wide dynamic neurons by non-nociceptive afferent impulses.[50]

Sustained noxious stimulation or high-intensity nociceptive signals to the dorsal horn neurons may lead to increased neuronal responsiveness or central sensitization.[51] Hyperalgesia, which is an exaggerated perception of painful stimuli, is at least partially mediated through low-threshold mechanoreceptors (Aβ afferents) in the dorsal horn. Allodynia, which is a perception of innocuous stimuli as painful, is mediated through high threshold nociceptors (Aδ or C-fibers) in the dorsal horn. The factors that contribute to these hyperexcitable states include altered function of neurochemical and electrophysiological systems as well as changes in the anatomy in the dorsal horn.[52]

"Wind up" refers to a central spinal mechanism in which repetitive noxious stimulation results in a slow summation of these signals that is experienced as increased pain.[53] The amplification of the pain signal occurs in the spinal cord when nociceptive C-fibers synapse on the dorsal horn nociceptive neurons activating the NMDA receptors.[54] A cascade of events ensues with the activation of nitric oxide synthase.[55] This ultimately leads to enhance the release of sensory neuropeptides, including substance P, from presynaptic neurons, contributing to the development of hyperalgesia and maintenance of central sensitization.[56] Wind-up can be elicited if identical nociceptive stimuli are applied at a frequency of 3 seconds or less.[57]

Spinothalamic Tract

Prior to synapsing in the dorsal horn of the spinal cord, C- and Aδ fibers may ascend or descend one to two spinal levels, forming a tract dorsal to the dorsal horn called the tract of Lissauer (Fig. 9.5); Lissauer's tract also contains axons of interneurons that may travel for several spinal segments. Following synapsing of the central projections of C- and Aδ afferents, the axons of many of the second-order neurons cross the midline, forming the lateral spinothalamic tract which ascends without interruption from the dorsal horn through the brainstem to the thalamus. This somatotopically organized tract carries information from neurons about the location, intensity, and duration of nociceptive stimuli. This tract is also responsible for relaying the sensation of temperature and, to a lesser extent, it transmits touch and pressure sensation. A large proportion of the neurons that contribute fibers to the lateral spinothalamic tract originate in lamina I. There is also a dorsally located spinothalamic tract arising ipsilaterally from lamina I neurons, though this projection of second-order nociceptive neurons is less well described.

Lamina V also contributes a large group of neurons to the spinothalamic tract mostly comprised of Aδ fibers. The anterior spinothalamic tract, which conveys information about the location of nociception, is largely composed of fibers from lamina VII and VIII. Conversely, lamina II sends very few fibers to the spinothalamic tracts despite being the destination for many C-fibers. The fibers from lamina II modulate the spinothalamic cells in lamina I, V, VII, and VIII at the level of the nociceptive input as well as at spinal segments above and below via spinal interneurons that travel in the tract of Lissauer. This complex mesh of interneurons plays a significant role in determining whether signals from nociceptors will be propagated to higher levels of the nervous system or be inhibited. Spinal interneurons modulate the intensity of a stimulus and also establish connections with other spinal neurons to form somatic and autonomic reflex arcs at the level of the spinal cord. While interruption of the spinothalamic tract results in immediate loss of pain and temperature perception in the contralateral side of the body, injuries of the spinothalamic tract can develop into central pain syndromes.

Nociceptive afferents from visceral organs and somatic structures terminate in the same population of spinothalamic cells in the spinal cord, which in turn synapse in the thalamus. The convergence of nociceptive signals in the spinal cord is segmentally arranged and may account for pain from visceral organs being referred to somatic structures. This topic is discussed in more detail later in the chapter.

There are several other ascending tracts that supply nociceptive signals to higher levels of the CNS. The spinoreticular tract transmits nociceptive signals on the ipsilateral side of the spinal cord. This tract is clinically important as it may explain the persistence of pain after an anterior cordotomy.

Thalamus

The majority of the second order lateral spinothalamic tract fibers terminate in the lateral nuclear group of the thalamus which contains both the ventroposterior lateral (VPL) nucleus and the ventroposterior medial (VPM) nucleus. The VPL nucleus of the thala-

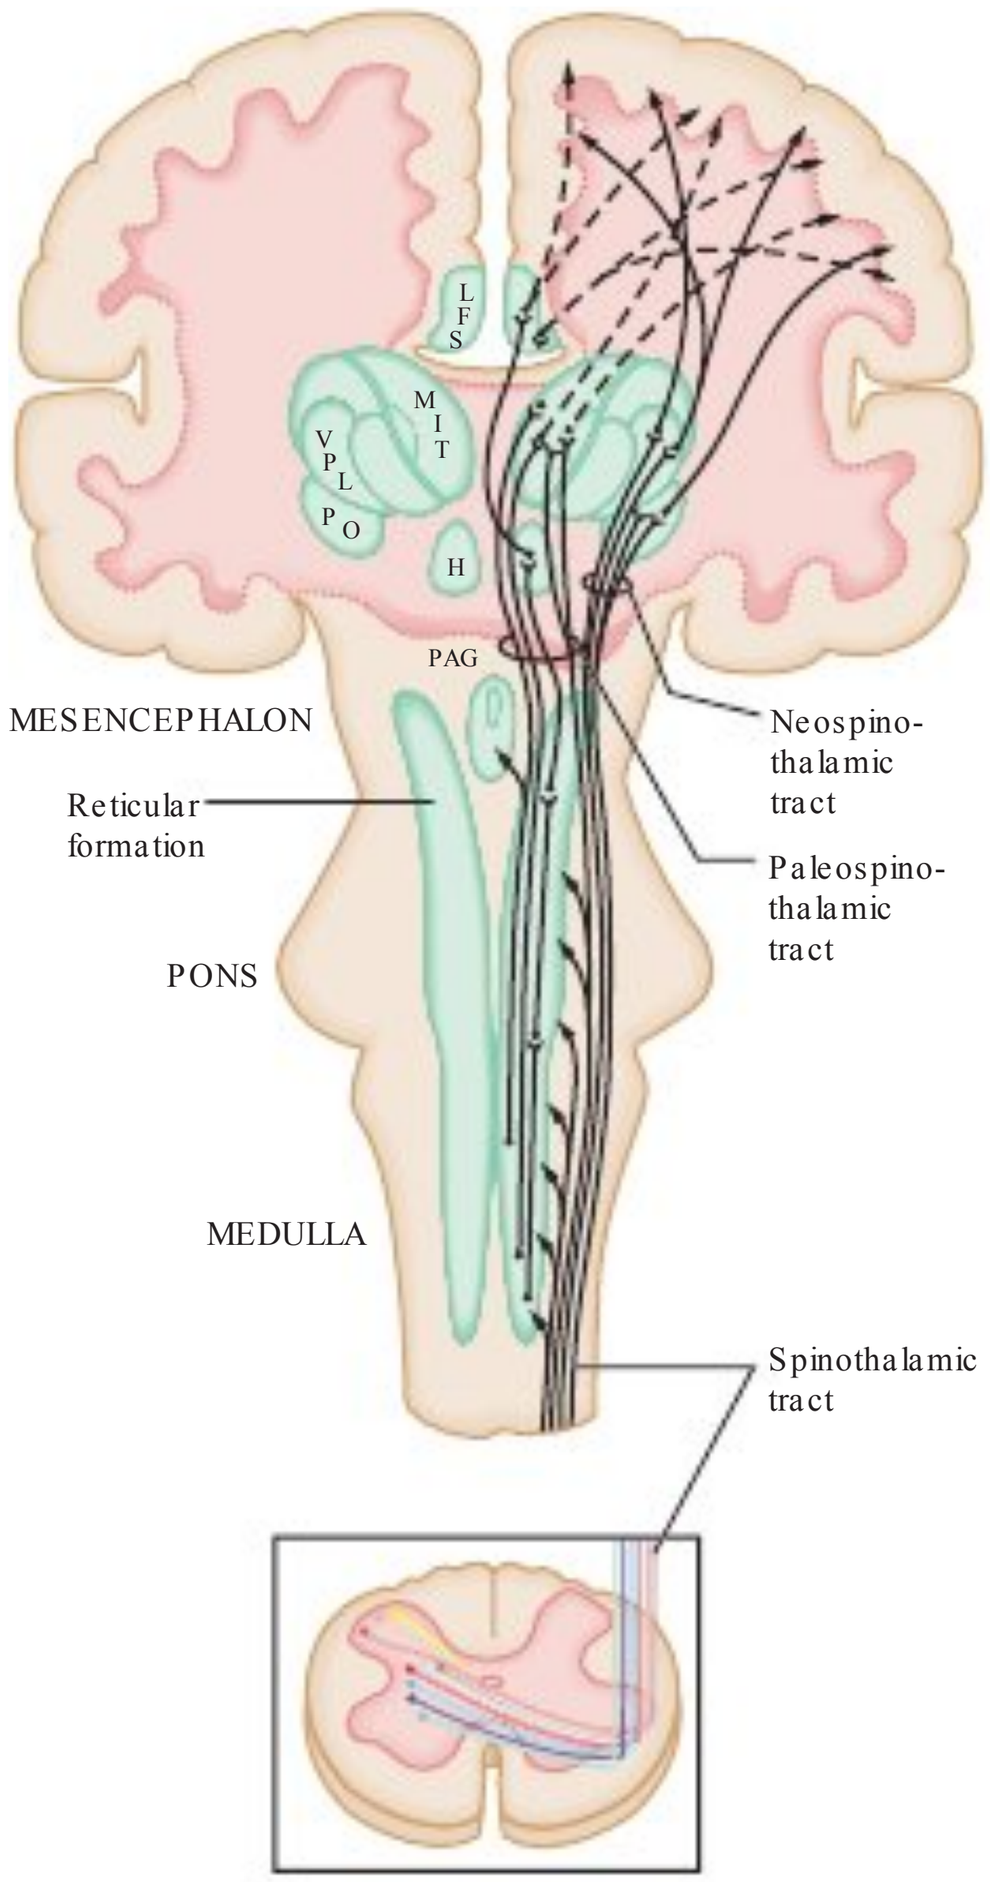

FIGURE 9.5 Simple diagram of the course and termination of the spinothalamic tract. Most of the fibers cross to the opposite side and ascend to the brainstem and brain, although some ascend ipsilaterally. The neospinothalamic part of the tract has cell bodies located primarily in laminae I and V of the dorsal horn, whereas the paleospinothalamic tract has its cell bodies in deeper laminae. The neospinothalamic fibers ascend in a more superficial part of the tract and project without interruption to the caudal part of the ventroposterolateral thalamic nucleus (VPLc), the oral part of this nucleus (VPLo), and the medial part of the posterior thalamus (POm). In these structures, they synapse with a third relay of neurons, which project to the somatosensory cortex (SI, SII, and retroinsular cortex) (*solid lines*). Some of the fibers of the paleospinothalamic tract pass directly to the medial/intralaminar thalamic nuclei, and others project to the nuclei and the reticular formation of the brainstem and thence to the PAG, hypothalamus (H), nucleus submedius, and medial/intralaminar thalamic nuclei. Once there, these axons synapse with neurons that connect with the limbic forebrain structure (LFS) via complex circuits and also send diffuse projections to various parts of the brain.

mus receives information from the lateral spinothalamic tract while the VPM nucleus receives sensory information from the spinal trigeminal nucleus, which transmits sensory information from the face (Fig. 9.6). Spinothalamic fibers also terminate in areas of the intralaminar nuclei and in the mediodorsal nucleus. These fibers transmit signals to the limbic system which integrates autonomic and arousal responses and attention to the perception of pain. Many of the fibers originating in lamina I terminate in the ventromedial (VM) nucleus. Most of the neurons in VM are activated by nociceptors. Lesions of the thalamus, such as stroke, can result in severe central pain syndromes on the contralateral side of the body.

With the exception of olfaction, all sensory pathways traveling from the periphery to the cerebral cortex synapse in the thalamus. The spinothalamic fibers terminate in multiple areas of the thalamus and subsequently are relayed to different areas of the cortex. VPL/VPM supplies the primary and secondary somatosensory cortex (S1, S2) with nociceptive signals. Spinothalamic fibers terminating in other areas of the thalamus influence other cortical areas, such as the insular cortex.

Sensory Cortex

Nociceptive signals from the thalamus terminate in multiple areas of the cerebral cortex and subcortical regions. The somatosensory cortex is somatotopically organized and has a laminated columnar structure. The thalamic fibers project primarily to layer IV of the primary somatosensory cortex (S1) to transmit information about limb position, sense of touch, and discriminative aspects of sensation. This area of the cortex makes a limited contribution to the perception of nociception. The cortical association areas and secondary somatic sensory cortex are connected with S1 and help further process tactile information necessary for object recognition and spatial relationships.

Functional imaging has demonstrated that the insula and anterior cingulate gyrus are the areas most consistently linked with nociceptive stimulation.[58] The insular cortex receives direct projections from the medial thalamic nuclei as well as from the lateral nuclear group. This area of the cortex processes nociceptive information on the internal state of the body and regulates the autonomic component of the pain response. Patients with lesions of the insular cortex do not display appropriate emotional responses to pain as part of a syndrome termed pain asymbolia.[59] The anterior cingulated gyrus integrates the affective component of pain. The anterior cingulate gyrus in particular is a target for ablation in some patients with chronic pain. This lesion separates the nociceptive perception from the affective/ motivational component of the pain behavior.

To a lesser extent, S1, the premotor cortex, the prefrontal cortex, and posterior parietal cortex are activated with nociception. In the subcortical region, the amygdala, hypothalamus, PAG, basal ganglia, and cerebellum are all activated with nociception. While there are multiple cortical regions that play significant roles in the perception of nociception, there is enough variability in the patterns of activation that, as of yet, there is not a defined area considered to be specific for nociceptive perception.

Descending Pathways of the Central Nervous System

There are descending pathways from the cortex that modulate sensory impulses. For example, somatotopically organized fibers from the S1 terminate in the thalamus, brainstem, and spinal cord which selectively modulate, both facilitating and inhibiting, sensory signals from specific receptors and/or areas of the body. The inhibitory effects are most common and are usually transmit-

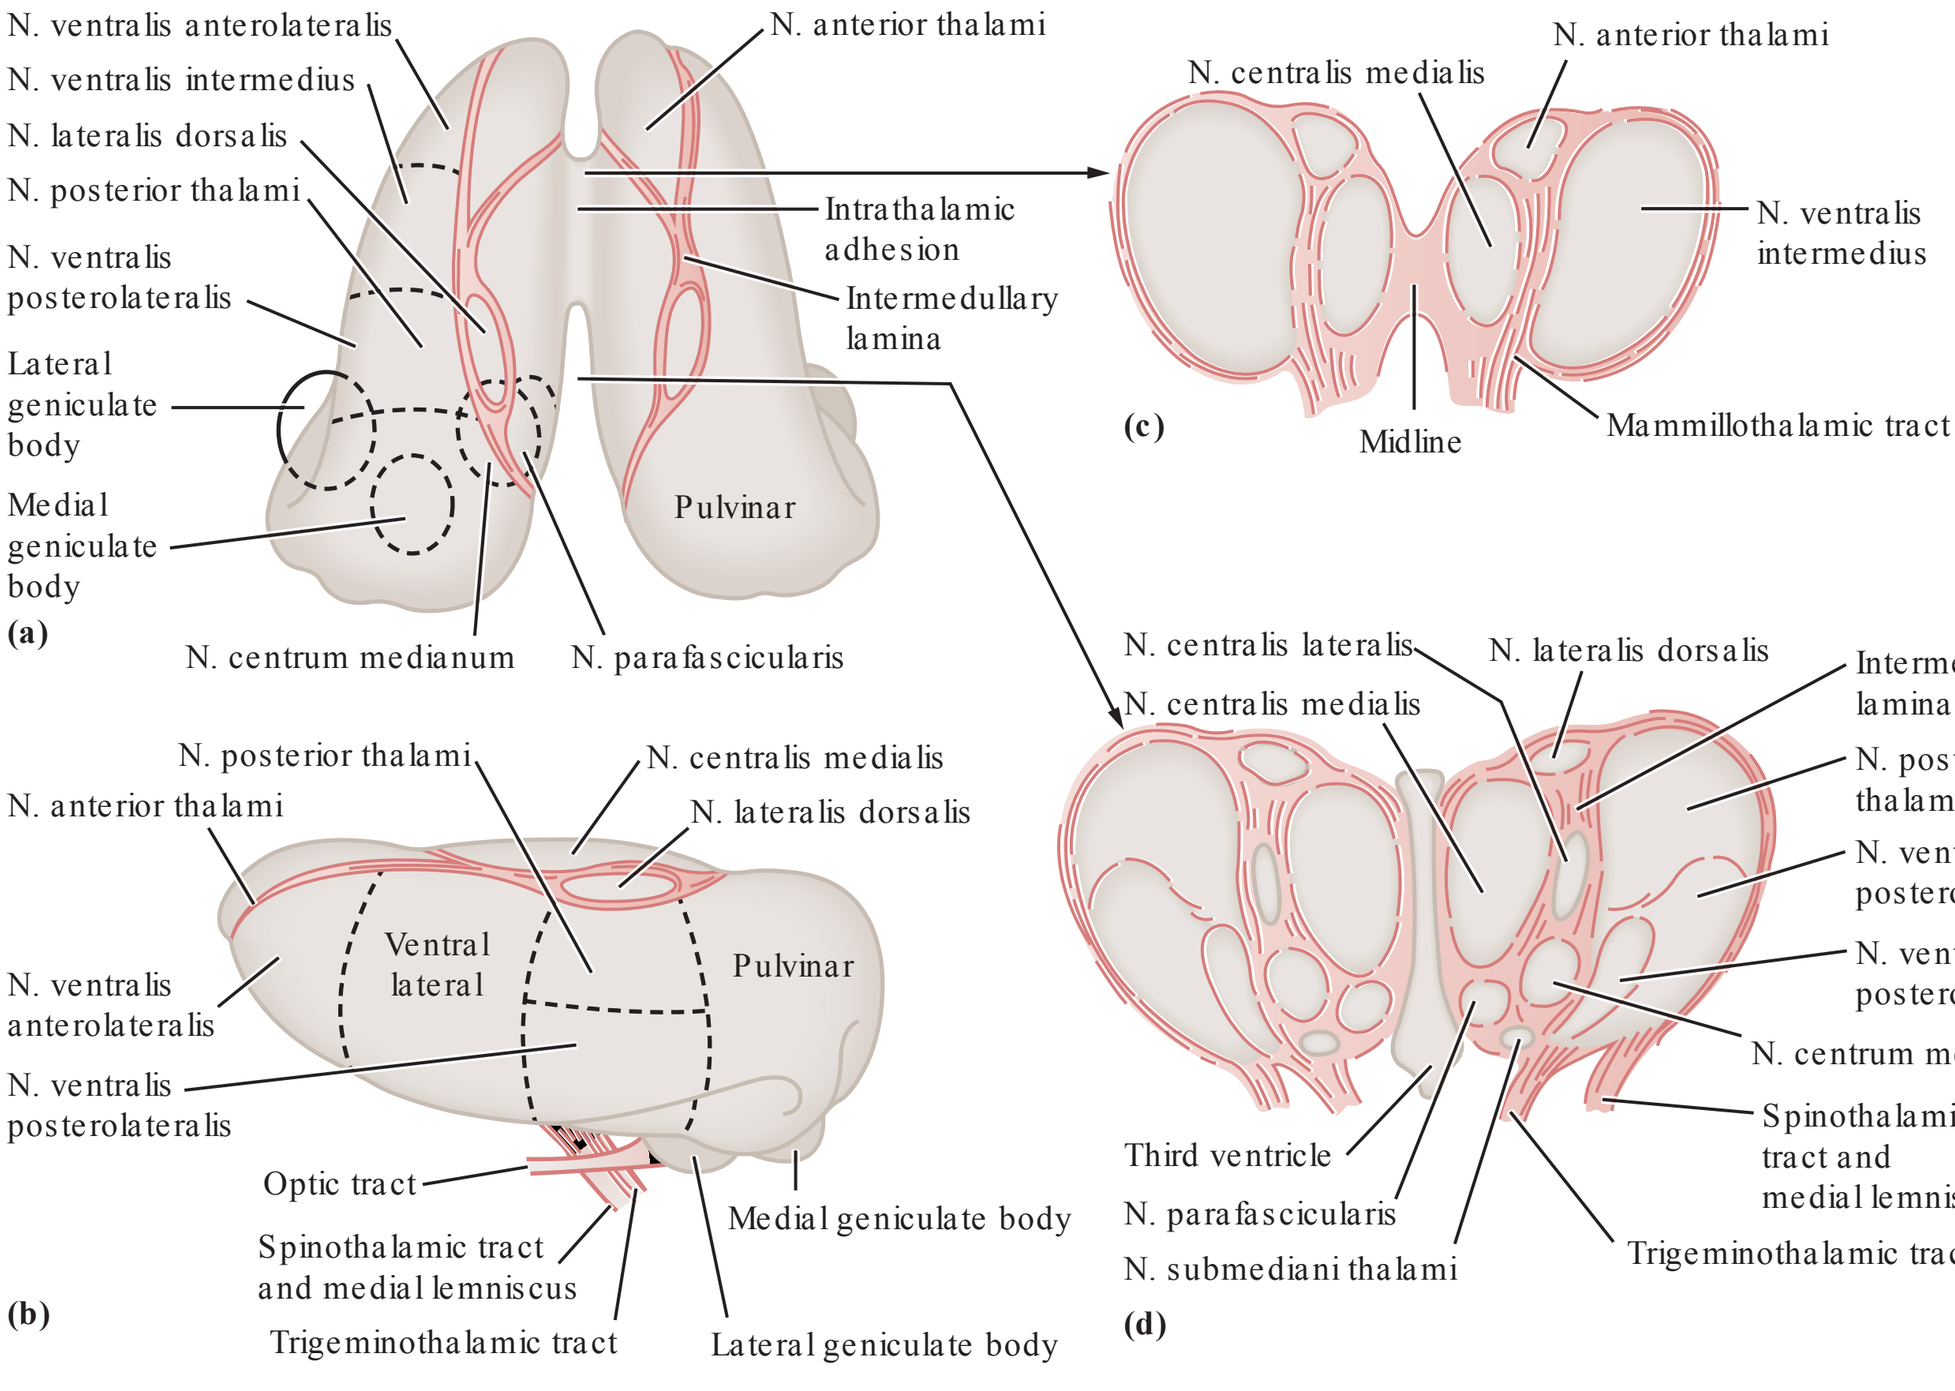

FIGURE 9.6 Schematic diagram of the human thalamus. **A.** Superior view. **B.** Lateral view shows the locations of the most important nuclei. **C.** Frontal section of the anterior part of the thalamus depicts the relationships of various nuclei. **D.** Frontal section of the middle part of the thalamus. ted through inhibitor interneurons. The sensory system is designed to react to the dynamic nature of the environment. As a result, sensory signals are highly monitored at multiple levels of the nervous system.[60]

Collateral fibers from the PAG modulate both descending and ascending pain pathways. The PAG has been experimentally demonstrated to produce analgesia when stimulated and is felt to play a major role in modulating nociception at the level of the dorsal horn as well as at higher levels of the CNS.[61] The PAG receives signals from limbic and cortical centers involved in the affective component of pain. The descending signal from the PAG travels through the nucleus raphe magnus (NRM) in the medulla as well as the medullary reticular formation. The serotonergic NRM fibers descend to inhibit peripheral nociceptors in the dorsal horn in lamina I and II. Clinically, this descending system blocks the spinal withdrawal reflex at the level of the dorsal horn. The PAG has ascending connections which may modulate sensory signals at the level of the thalamus. The PAG also supplies the reticular activating system responsible for arousal to painful stimuli. Of note, there are a number of other pathways in the CNS which modulate the sensation of pain and the response to nociceptive input.

Central Pain

Central pain (CP) is a term that includes dysesthesias, paresthesias, and even pruritus[62] initiated by a lesion that interferes with the pathway of nociceptive signals within the CNS from the spinothalamic tract to the parietal somatosensory areas. CP remains an underdiagnosed condition that occurs with damage to the CNS. Studies suggest that up to 10% of all strokes,[63] up to two-thirds of SCIs,[64] 18% of patients with multiple sclerosis, and an undefined number of patients with other neurologic conditions suffer CP.[65]

CP is a complex complaint with several subtypes of pain that can be moderate to severe in intensity. Patients may complain of a constant pain often described as aching, burning, pricking, dysesthesias, paresthesias, or pruritus in isolation or in combination. The majority of patients with CP also complain of evoked pain with stimulus. Patients may complain of spontaneous episodic pain superimposed on their chronic symptoms that is most commonly characterized as lancinating.[61] These uncomfortable sensations are difficult to treat and are often poorly tolerated, which leads to a decrease in quality of life.

The neurologic examination usually reveals areas of hypoanesthesia to thermal and nociceptive stimulation. In the evaluation of the single patient, pain scales can be employed but these are most useful in the research setting. Pain with peripheral nerve injuries, such as a diabetic peripheral neuropathy, often has similar qualities to CP. Pain associated with muscle cramping or dystonia as a result of abnormal tone, posture, or muscle excitability is often seen after CNS damage and must be differentiated from CP.[66]

Central poststroke pain was first described by Dejerine and Roussy[67] in 1906 who found that thalamic stroke on one side of

the brain can cause a pain syndrome affecting the contralateral half of the body. This syndrome may occur after a stroke in any location in the CNS. There are several theories as to the mechanism of central poststroke pain. Interruption of the descending inhibitory pathway, hyperexcitability of the affected afferent sensory pathways, denervation hypersensitivity, as well as loss of balance between excitatory (glutamergic) and inhibitory (GABAergic) neurotransmitters are all possible contributors.

Central Pain After Spinal Cord Injury

Chronic pain is a major complication of spinal cord injury (SCI), with approximately two-thirds of all SCI patients experiencing some type of chronic pain and up to one-third complaining of that their pain is severe.[68] The prevalence of pain after SCI often increases with time after injury.[68] There are an estimated 40 cases per million population in the United States, or approximately 11,000 new cases each year.[69] Research suggests that chronic pain in SCI patients significantly interferes with their rehabilitation and activities of daily living and therefore reduces quality of life. Attempts to manage these pain symptoms are costly and success is often limited.[70]

In addition to central pain, there are multiple types of pain that develop after SCI including musculoskeletal, visceral, and peripheral neuropathic pain. The etiology of pain in SCI is multifaceted and the various types of SCI pain differ with regard to clinical findings, pathophysiology, and therapy. The mechanisms involved in the development of CP after SCI are not fully elucidated but continuing research has identified possible mechanisms for pain generation. CP has been reported with injury to all levels of the spinal cord.[71]

CP is a common sequelae of SCI. It has many descriptors; it is often characterized by patients as a continuous burning, shooting, aching, and tingling. The distribution of pain is usually bilateral and can involve multiple adjacent dermatomes or be regional in nature. In addition, many patients with SCI report feeling the phantom phenomenon of their body below the lesion and it is described in a distorted fashion. This occurs despite most patients having no conscious appreciation of sensory input below the spinal cord lesion.[72] Central neuropathic pain after SCI has been categorized based on the location of the complaint as either at the level of the injury or below the level of the injury. Although it may be difficult to distinguish the two clinically (and both may be present in the same patient), CP that occurs at the level of injury is due to segmental spinal cord damage, not nerve root damage. CP that occurs at the level of injury can be within two dermatomal levels either above or below the level of injury.[73] CP associated with SCI may be caused by syringomyelia.[72]

Physiologic changes occur to the nociceptive neurons in the dorsal horn following SCI, including an increase in abnormal spontaneous and evoked discharges from dorsal horn cells.[74,75] Noxious stimulation causes primary afferent C-fibers to release excitatory amino acid neurotransmitters in the dorsal horn. Prolonged high-intensity noxious stimulation activates the NMDA receptors, which induces a cascade that may result in central sensitization.[76] The cascade includes upregulation of neurokinin receptors and activation of the intracellular cyclo-oxygenase-2, nitric oxide synthase, and protein kinase C enzymes.[77] Other neuroanatomic and neurochemical changes thought to impact CP in SCI include alteration in the activity of the neurotransmitter glutamate,[78] interruption of descending serotonin inhibitor pathways,[79] and dysfunction of the inhibitory GABAergic interneurons,[80] all at the level of the dorsal horn. On a molecular level, abnormal sodium channel expression within the dorsal horn (laminae I–VI) bilaterally has been implicated as a major contributor to hyperexcitability.

Thalamic neurons appear to undergo changes after SCI in both human and animal models. In the animal model, enhanced neuronal excitability in the VPL has been demonstrated directly[81] as well as indirectly; enhanced regional blood flow has been found in the rat VPL after SCI, suggesting increased neuronal activity.[82] There appears to be somatotopic maps as well as an increase in the peripheral receptive fields of VPL neurons.[83] Magnetic resonance spectroscopy studies have demonstrated changes in metabolism of the neurons in human thalamus associated with pain in SCI.[84] Much like the neurons in the dorsal horn, the thalamic neurons after SCI show increased activity with noxious and non-noxious stimuli. VPL neurons are spontaneously hyperexcitable following SCI without receiving input from the spinal cord neurons suggesting that the thalamus may act as a pain signal generator in CP accompanying SCI.[72]

There is emerging evidence that cortical reorganization may play a role in the development of phantom symptoms after loss of limbs, but little evidence of the cortical mechanisms at work with the development of phantom phenomena after SCI.[85] The full spectrum of anatomical, chemical, and physiologic changes contributing to central neuropathic pain after SCI is still being elucidated.

AUTONOMIC NERVOUS SYSTEM

At the turn of the 20th century, the Cambridge physiologist John Newport Langley coined the term "autonomic nervous system" (ANS) to describe the portion of the nervous system that mediated the unconscious function of the internal organs.[86] Soon afterward, the concept of two distinct components of the ANS, the sympathetic and parasympathetic systems, which antagonize each other to maintain homeostasis, was developed. The enteric system is also recognized as being a distinct part of the ANS. In addition to regulating the activity of visceral organs, vessels, and glands, the ANS has been found to play an active role in many pain states. Understanding the complexity of the pain–ANS interaction is essential to physicians managing all types of pain. The anatomy of the ANS with the current understanding of the interrelationship between these structures is shown in Figure 9.7. The ANS is composed of peripheral and central portions.

Peripheral Autonomic Nervous System

The peripheral efferent pathways of both the sympathetic and parasympathetic nervous system have two components: a pri-

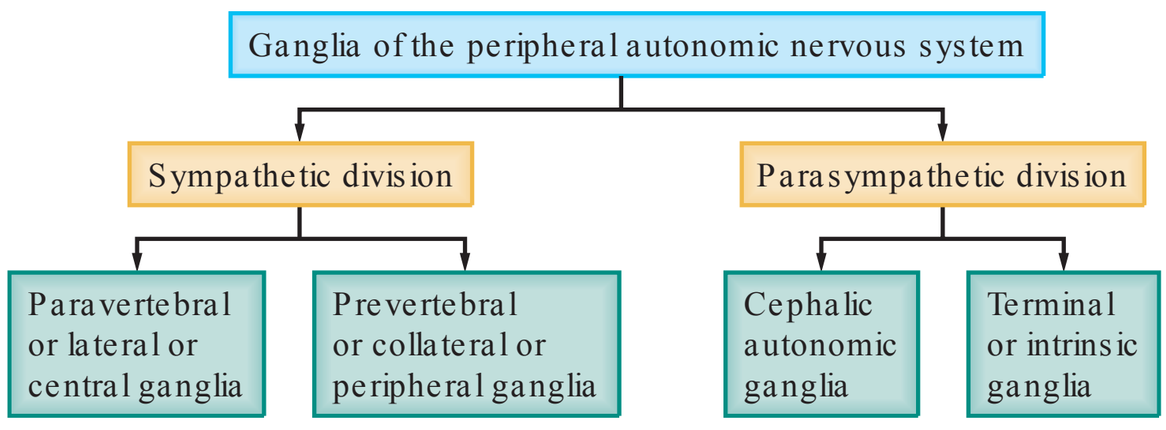

FIGURE 9.7 Ganglia of the peripheral autonomic nervous system.

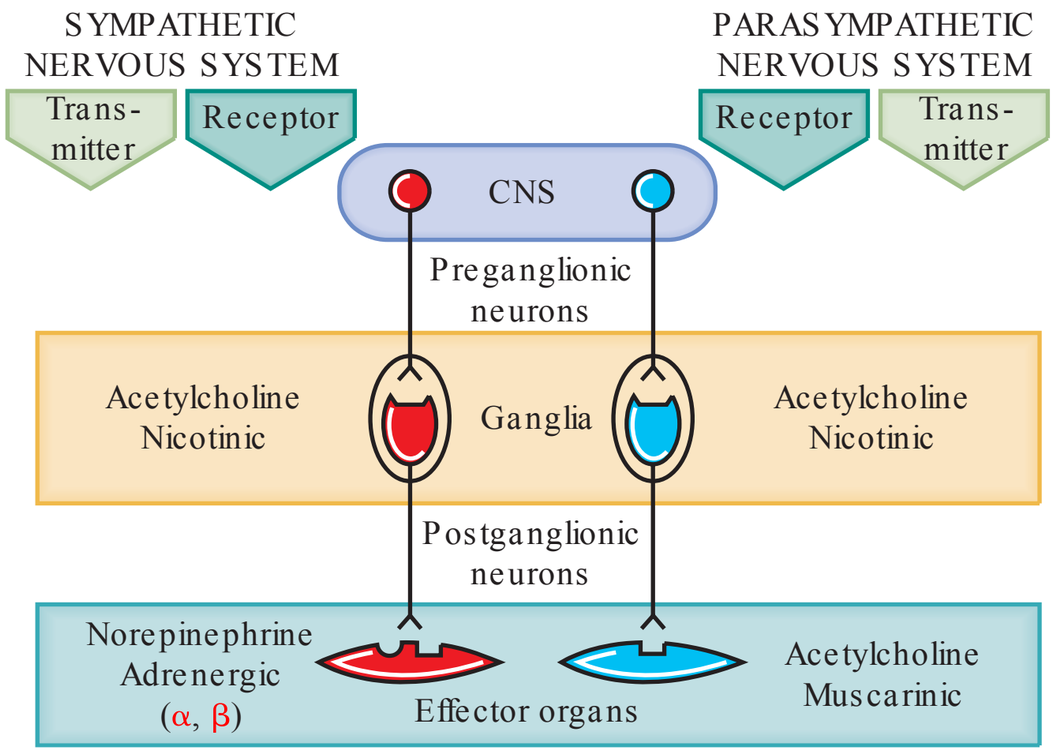

FIGURE 9.8 Transmitter substances in the peripheral autonomic nervous system. (Modified from Jänig W. The autonomic nervous system. In: Schmidt RF, Thews G, eds. *Human physiology*. Berlin: Springer-Verlag; 1983:111.)

mary presynaptic or preganglionic neuron and a secondary postsynaptic or postganglionic neuron. Unlike the somatic motor system which has its motor neurons in the CNS, the motor neurons of the ANS are located in the periphery. As such, the transmission of autonomic signals from the CNS synapses at ganglia in the periphery prior to reaching the target organ (Fig. 9.8). The different locations of the cell bodies of the primary preganglionic neurons of the different divisions of the ANS will be discussed later.

The cell bodies of the postganglionic neurons are arranged in aggregates known as ganglia, wherein the synapses between pre- and postganglionic neurons take place. The ganglia of the ANS are complex collections of nerve fibers regulating a host of vital functions. In addition to this, some ganglia receive sensory fibers from visceral organs and have interneurons suggesting that there is regulation of autonomic signaling at this level. As shown in Figure 9.7, there are four general groups of these ganglia, two with the sympathetic division and two with the parasympathetic division.

A typical feature of the ANS is that postganglionic fibers form nerve plexuses around their target organs composed of both sympathetic and parasympathetic fibers. Unlike their somatic efferent counterparts, the postganglionic fibers branch extensively, forming a network of varicosities in the vicinity of their effector cells allowing one fiber to act on several effector cells.

Parasympathetic Division

The parasympathetic preganglionic fibers travel from the CNS to synapse in ganglia located close to their target organs. In most areas, parasympathetic innervation tends to be more precise than sympathetic innervation. Parasympathetic fibers generally innervate visceral organs. Table 9.2 summarizes parasympathetic nerve supply to essential body structures.

Cranial Parasympathetics

The preganglionic parasympathetic neurons have their cell bodies in the gray matter of the brainstem, and their fibers travel with the oculomotor, facial, glossopharyngeal, and vagus nerves (Fig. 9.9). The preganglionic fibers from the oculomotor, facial, and glossopharyngeal nerves synapse in the ciliary, sphenopalatine, otic, and submaxillary ganglia, all of which are located in the head. From these ganglia, the postganglionic fibers travel to the target organs (e.g., the lacrimal and salivary glands).

The preganglionic parasympathetic fibers in the vagus nerve travel out of the head to terminate in visceral organs. In the abdomen, many of these fibers synapse in a diffuse network of postganglionic neurons to form a plexus within the wall of the gastrointestinal tract. The postganglionic neurons within this plexus send short processes to innervate the smooth muscles and glands in the gastrointestinal tract. In the thorax, the vagus nerve supplies parasympathetic innervation to the heart (via the cardiac plexus) and airways. In the heart, the sinus node and atrioventricular node have significant parasympathetic innervation. This is in contrast to the ventricles, which are supplied with dense sympathetic innervation.[87]

Sacral Parasympathetics

The sacral portion of the parasympathetic system consists of preganglionic neurons which have their cell bodies in the intermediolateral column of the gray matter of the S2–S4 spinal segments (see Figs. 9.9 and 9.10). The preganglionic fibers travel via the ventral roots to the corresponding spinal nerves for a short distance and then form the pelvic splanchnic nerves. These nerves form the pelvic plexuses which are in close proximity to the target organs (rectum, bladder, prostate gland in the male, cervix in the female). Many of these preganglionic fibers synapse in the plexus while other fibers pass through the plexus without interruption and terminate in intramural ganglia of their target organs (e.g., urinary bladder, descending colon, sigmoid colon and rectum, and genital organs). All of the pelvic organs are innervated by postganglionic parasympathetic fibers. These fibers play an essential role in eliminating waste products from the bladder and rectum.[88]

Sympathetic (Thoracolumbar) Division

The peripheral sympathetic nervous system is composed of efferent and afferent fibers. The efferent portion of the sympathetic division of the ANS consists of preganglionic neurons, the two paravertebral (lateral) sympathetic chains, prevertebral and terminal ganglia, and postganglionic neurons (see Figs. 9.9 and 9.10).[89,90]

Sympathetic Preganglionic Neurons

The cell bodies of the efferent preganglionic neurons are located in the intermediolateral column in the spinal cord from T1–L2. The efferent fibers of these preganglionic neurons travel from the spinal cord into the periphery through the ventral roots accompanying the somatic fibers at these levels at the thoracolumbar spine. From this point, the preganglionic neurons diverge to provide inputs to ganglia in multiple locations. Each preganglionic fiber synapses on multiple postganglionic cells, thus serving to amplify the sympathetic outflow from the CNS.[91] Some of the sympathetic fibers leave the spinal nerve immediately after the ventral and dorsal roots fuse to form the white communicating ramus which synapses with postganglionic neurons in the sympathetic ganglia outside the neuraxis (see Fig. 9.10). The white rami are usually present only in the thoracic and upper two or three lumbar segments corresponding to the location of the intermediolateral column in the spinal cord (see Fig. 9.10). The white color of the rami is a result of the sympathetic fibers being myelinated.

The peripheral ganglia of the sympathetic nervous system are located close to the CNS. These paravertebral ganglia are segmentally arranged in two sympathetic trunks, each of which is a vertical row along the anterior margin of the vertebral column. Each trunk is comprised of a longitudinal network of ganglia connected

TABLE 9.2

SUMMARY OF PARASYMPATHETIC NERVE SUPPLY TO ESSENTIAL BODY STRUCTURES

	Parasympathetic nerve supply		Action
Region/structure/organ	Location of cell body/ preganglionic neurons in the CNS	Site of synapse of the preganglionic with postganglionic neurons	
Head and neck			
Eye	Parasympathetic oculomotor nucleus/ Edinger Westphal Nucleus	Ciliary ganglion	Pupillary constriction, accommodation for near vision
Lacrimal gland	Superior salvatory nucleus	Pterygopalatine nucleus	Secretion
Parotid gland	Inferior salvatory nucleus	Otic ganglion	Secretion
Submandibular and sublingual glands	Superior salvatory nucleus	Submandibular ganglion	Secretion
Thoracic viscera			
Heart	Dorsal motor vagus nucleus	Cardiac plexus	Decreased heart rate and cardiac output
Trachea, bronchi, and lungs	Dorsal motor vagus nucleus	Pulmonary plexus	Constriction of bronchial muscles and increased glandular secretion
Abdominal viscera			
Stomach	Dorsal motor vagus nucleus	Gastric plexus	Increased motility and secretion, relaxed sphincter
Pancreas	Dorsal MVN	Periarterial plexus	Dilation of blood vessels and increased secretion
Pelvic viscera			
Ureter	Sacral cord S3–S4	Pelvic plexus	Increased tone and motility
Bladder	Sacral cord S3–S4	Pelvic plexus	Contracted detrusor muscle

to each other by ascending and descending nerve fibers that extend the entire length of the spinal column. As each spinal segment develops in the embryo, one sympathetic ganglion is formed for every level on each side. Some of these ganglia fuse, so the final number of ganglia is usually less than the number of spinal segments.[92] This is most prominent in the cervical region where only the superior, middle, intermediate, and inferior cervical ganglia are present for seven cervical vertebrae. The middle cervical ganglion is often not present, and the inferior cervical ganglion commonly fuses with the upper thoracic ganglion forming the stellate ganglion. The cephalic end of the paravertebral ganglia continues beyond the cervical spine, traveling along the carotid nerve to eventually distribute sympathetic fibers within the head. The caudal end of the two trunks converges and terminates in front of the coccyx as the ganglion impar.[89]

The paravertebral sympathetic ganglia are connected by interganglionic fibers forming the lateral sympathetic chain which extends from the skull to the coccyx. On entering the sympathetic chain, some preganglionic axons synapse in the ganglia at the spinal level they exited the neuraxis. Other preganglionic fibers pass uninterrupted cephalad or caudad within the sympathetic trunk before they synapse to ensure that preganglionic fibers synapse at all levels of the sympathetic trunk.

Some preganglionic sympathetic fibers pass uninterrupted through the sympathetic chain to form splanchnic nerves that synapse within one of the prevertebral ganglia that are found at the junction of the celiac and mesenteric arteries and the abdominal aorta. The postganglionic fibers that travel from the prevertebral ganglion tend to follow arteries within the abdomen to their target organs. The greater and lesser splanchnic nerves are formed from preganglionic fibers from the T6–T10 levels, pass through the sympathetic chain without synapsing, and terminate in ganglia that innervate the abdominal viscera in the upper and middle part of the abdomen. Splanchnic nerves also contribute preganglionic fibers to the adrenal medulla. These fibers synapse within chromaffin cells, which are homologous to postganglionic neurons but release epinephrine into the bloodstream with sympathetic stimulation.[93]

The DRG contains sympathetic efferent fibers. After an injury in the periphery, more sympathetic fibers grow into the DRG and predominantly surround the cell bodies of mechanoreceptors. This is of unclear clinical significance, but it may contribute to the augmentation of peripheral stimuli (allodynia, hyperalgesia, the wind-up phenomenon, and central sensitization) in painful conditions.[94]

Sympathetic Postganglionic Neurons

The axons of the postganglionic neurons travel via multiple pathways into the periphery. Some of the postganglionic neurons which have their cell bodies in the paravertebral chain re-enter the spinal nerves via the gray communicating ramus, which, in distinction to the white rami, has a gray color because most of these postganglionic fibers are unmyelinated. Postganglionic sympathetic neurons from gray rami communicans travel in all spinal nerves. These postganglionic sympathetic fibers follow the

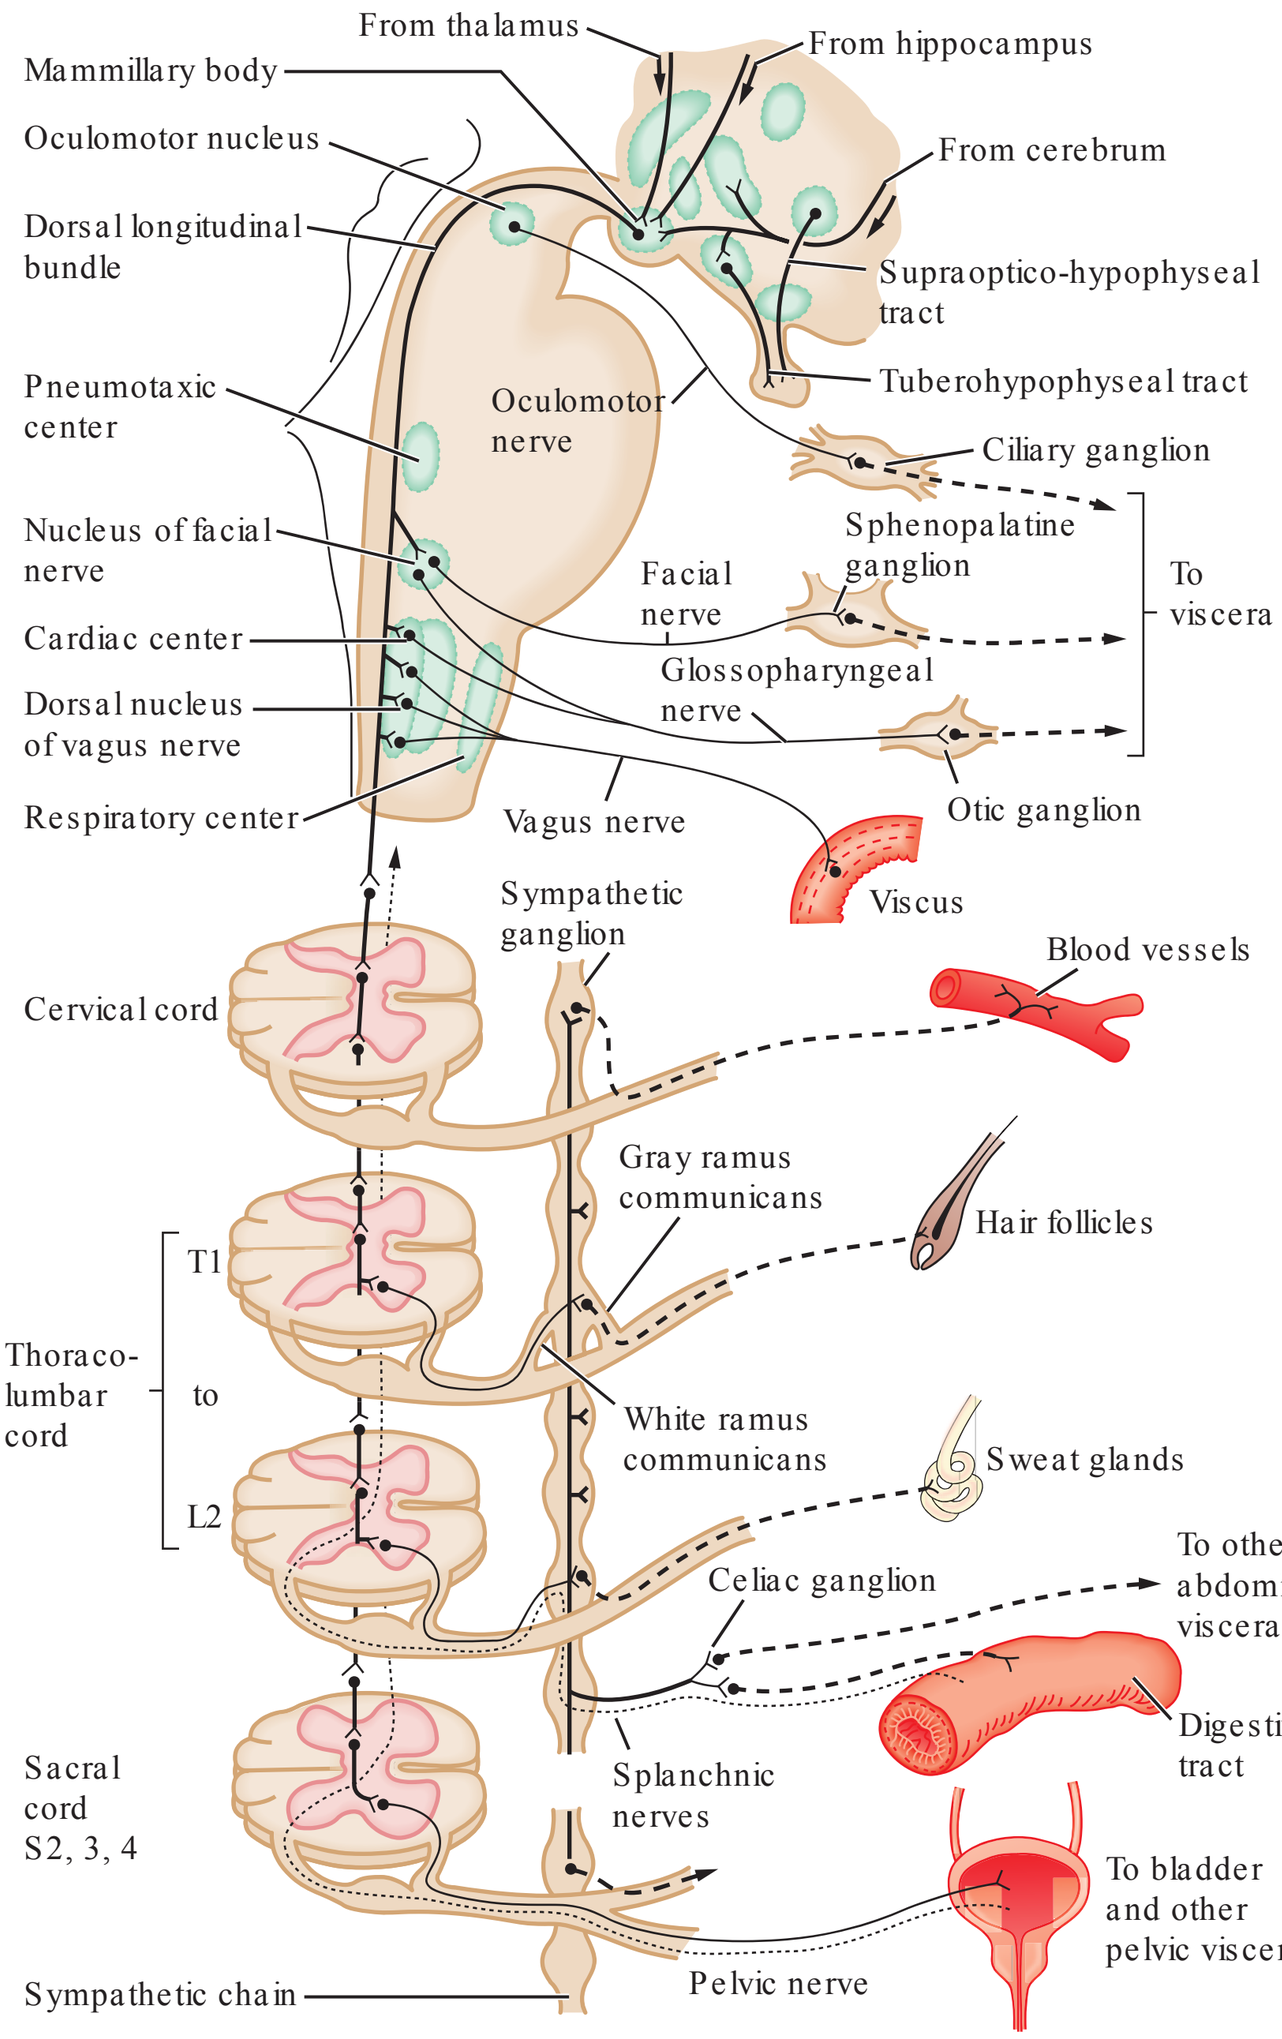

FIGURE 9.9 Schematic representation of autonomic pathways in the neuraxis and the efferent peripheral pathways. Note the connection among the various hypothalamic nuclei and between these structures and the nuclei and important autonomic centers in the brainstem and spinal cord. The dorsal longitudinal fasciculus (DLF) passes from the hypothalamus caudad through the central and tegmental portion of the mesencephalon and the tegmental portion of the pons to terminate in the reticular formation, the autonomic centers and cranial nerve nuclei in the brainstem, and in the intermediolateral cell column of the spinal cord. The DLF is composed of both crossed and uncrossed fibers, including some long ones and an extensive system of short fibers, which are arranged in the gray matter in frequent relays. Note also that the cell bodies of preganglionic sympathetic neurons are located only in spinal cord segments T1 through L2, whereas the parasympathetic neurons are located in cranial nerves and in S2, S3, and S4. The solid lines represent preganglionic fibers, the dashed lines represent postganglionic fibers, and the dotted lines are afferent (sensory) fibers. Not shown are the sensory fibers contained in the facial, glossopharyngeal, and vagus nerves, which transmit nociceptive and other somatosensory information from the head.

spinal nerves into somatic areas innervating various somatic, sudomotor, and pilomotor structures, such as the sweat glands and smooth muscle fibers in hair follicles in the skin. The axons of other postganglionic neurons, which have their cell bodies in the paravertebral chain, travel largely along arteries to pass to the thoracic and pelvic viscera. This is in contrast to the preganglionic neurons that pass uninterrupted to the prevertebral ganglia via the greater and lesser splanchnic nerves and are distributed to the viscera in the upper and middle part of the abdomen. The visceral organs in the lower abdomen receive their sympathetic innervation from the lumbar splanchnic nerve which also synapses in prevertebral ganglia. The celiac ganglia is usually the largest of the prevertebral ganglia and it surrounds the celiac artery at its juncture with the aorta. The sympathetic innervation of the heart originates in the cervical and thoracic ganglia and travels via the cardiac nerves to the heart. Table 9.3 summarizes the autonomic and nociceptive pathways to various body structures.

In addition to the gray rami, the sympathetic trunks give off postganglionic rami that supply the viscera of the head, chest, and abdomen. These rami include the carotid nerve, the superior, middle, and inferior cardiac nerves, the superior, middle, and inferior thoracic splanchnic nerves, and the lumbar and sacral splanchnic nerves.

Some preganglionic fibers synapse in the intermediary ganglia in the white communicating rami, ventral nerve roots, or the spinal nerves outside of the sympathetic chain.[89,90] These anomalous sympathetic pathways are most commonly found in the sympathetic trunk at the cervicothoracic juncture and the thoracolumbar juncture.[95–97] These pathways explain why surgical interruption of the sympathetic chain may not completely block sympathetic outflow. Conversely, these anatomic variations often respond to sympathetic blockade with a local anesthetic solution because it diffuses locally to affect these pathways.[95] A sympathetic block can therefore be a poor predictor of the efficacy of surgical sympathectomy. In cases of incomplete sympathectomy,

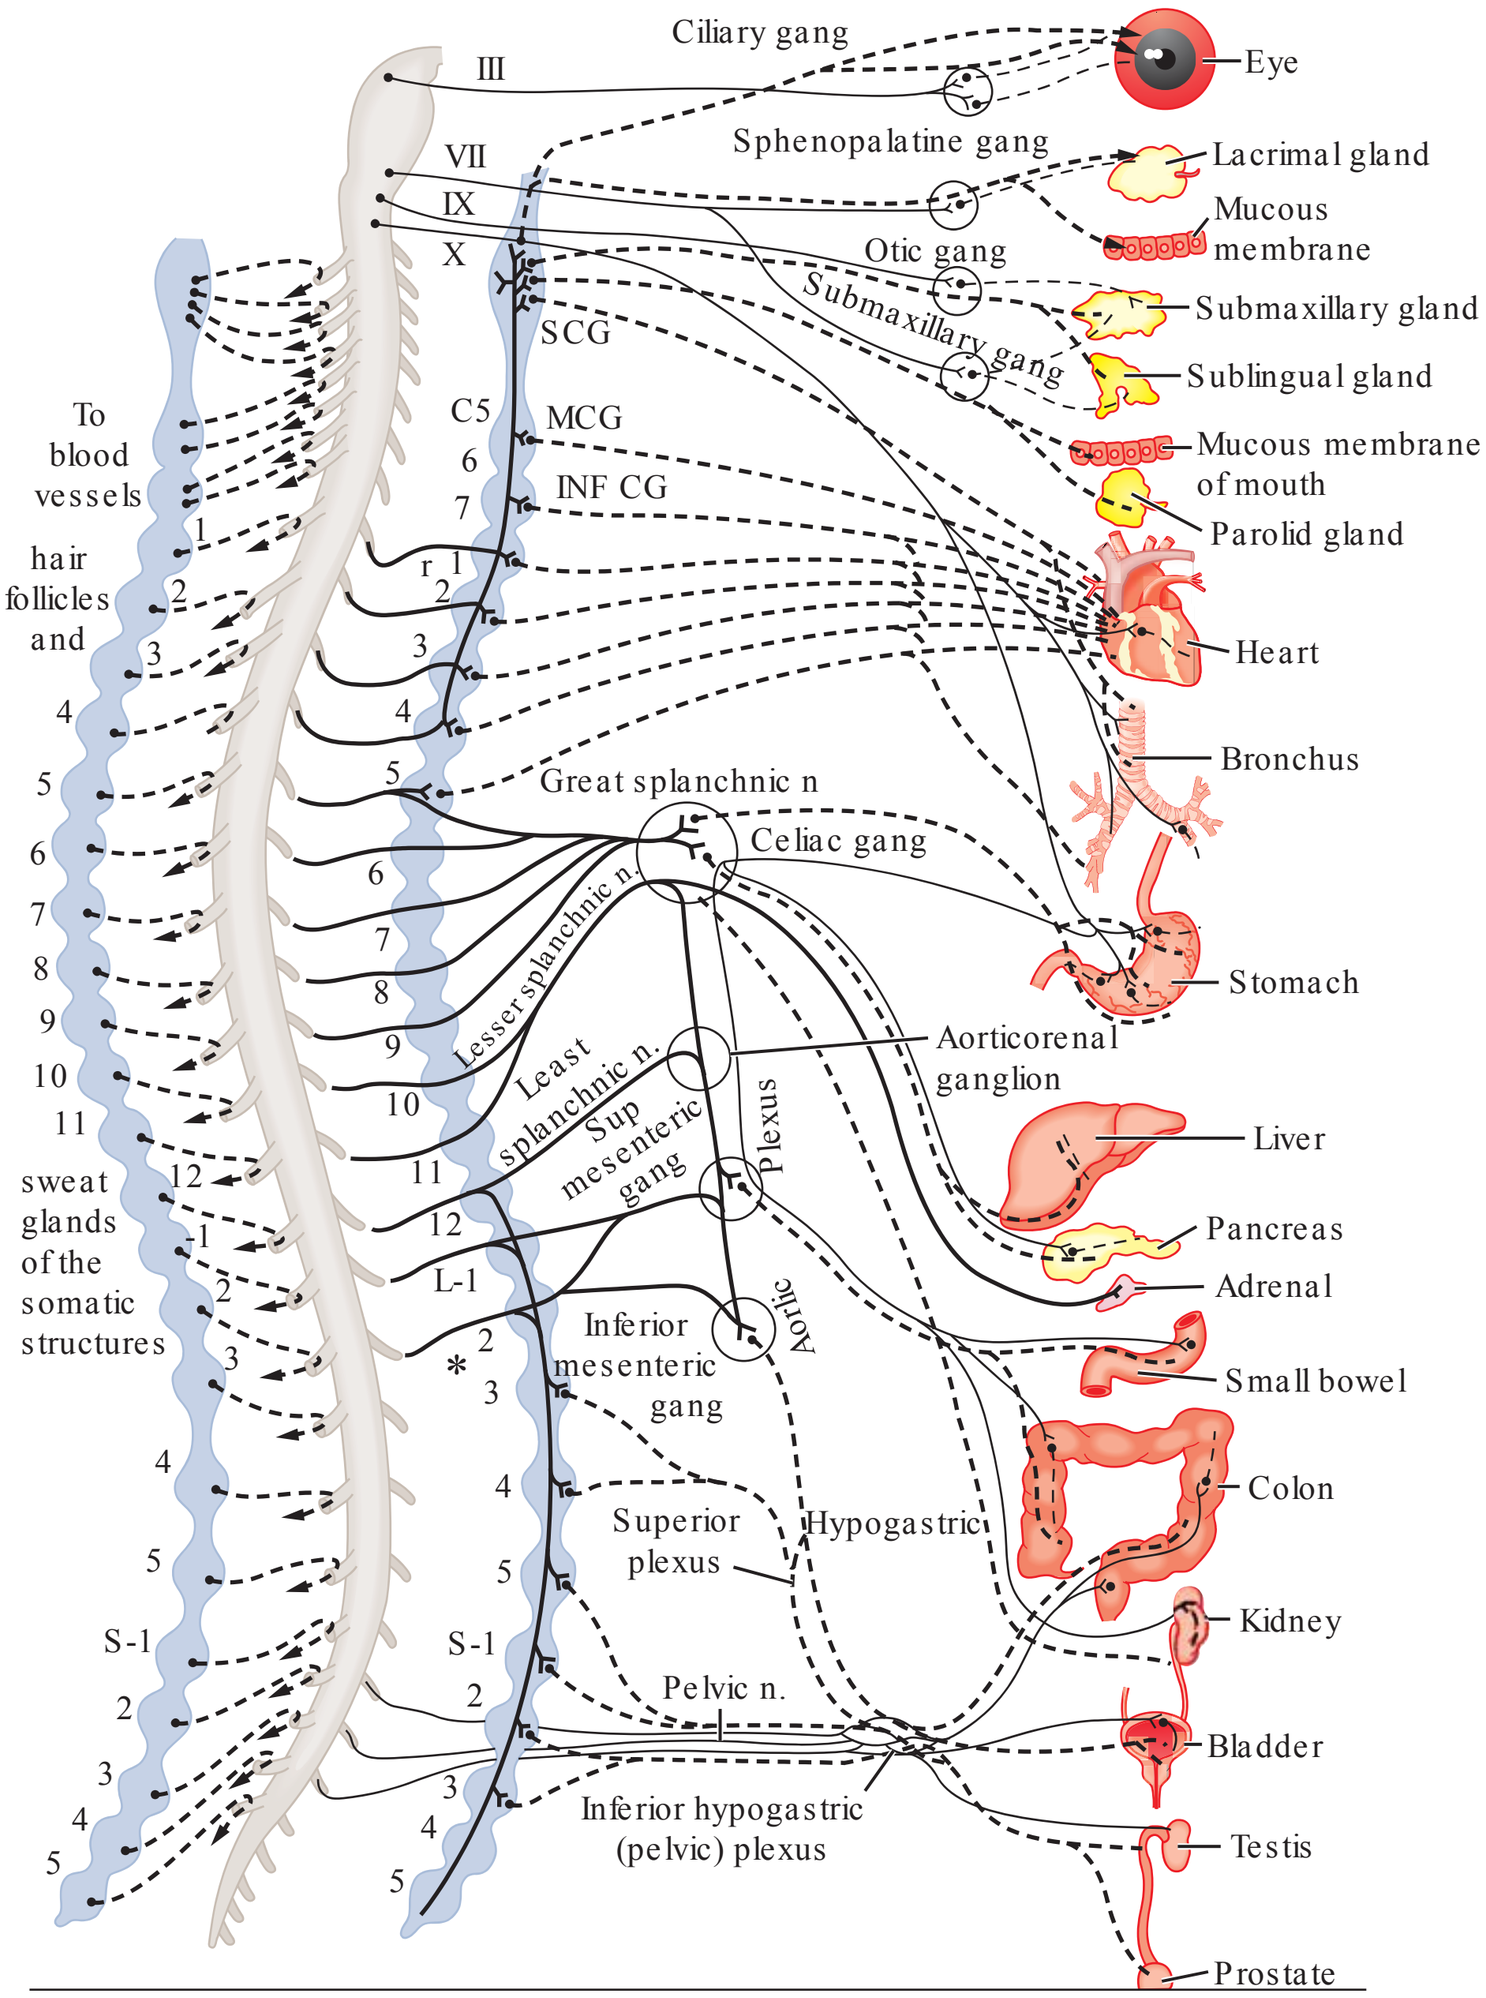

FIGURE 9.10 Distribution of peripheral autonomic nervous system to various structures of the body. On the reader's right are shown (from above downward) the four cranial nerves which contain preganglionic parasympathetic fibers, the axons of preganglionic sympathetic fibers (which pass from the anterior root to the paravertebral sympathetic chain), and the parasympathetic preganglionic axons in S2, S3, and S4. Note that the axons of all of the preganglionic sympathetic neurons pass via the white rami communicantes into the paravertebral chain, in which some synapse with postganglionic neurons, whereas others pass to the prevertebral sympathetic ganglia, in which they synapse with postganglionic fibers. On the reader's left are depicted the gray rami communicantes, containing postganglionic sympathetic fibers, which originate in the paravertebral chain and then pass to each of the spinal nerves to innervate blood vessels, hair follicles, and sweat glands in various parts of the body.

a postsurgical sympathetic block that produces complete interruption of sympathetic outflow and pain relief in sympathetically dependent pain syndromes may suggest the presence of anomalous sympathetic ganglia.[95,96]

Sympathetic postganglionic neurons may be involved in the generation of pain, hyperalgesia, and inflammation in disease. Depending on the extent of the peripheral nerve lesion, plastic changes can occur at multiple levels of the ANS. Release of mediators (e.g., epinephrine, norepinephrine) from efferent sympathetic nerves both locally and systemically and upregulation of adrenoreceptors in nociceptive afferents contribute to the increased excitability of nociceptors and changes in local vasomotor and sudomotor activity.[98] This reorganization of the peripheral neurons may lead to chemical coupling between sympathetic and afferent neurons. This may be responsible for sensitization and/or activation of primary afferent neurons by the sympathetic neurons.[99]

Sensation in Visceral Organs

Visceral afferent fibers convey sensory information from the internal organs to the CNS. Although these fibers do not establish direct connections with the peripheral autonomic neurons, sensory fibers from viscera follow autonomic nerves as they travel centrally; the majority of the fibers conducting nociceptive information travel along sympathetic nerves. The neurons of visceral afferent fibers are structurally similar to somatic afferent fibers and, like their somatic counterparts, have cell bodies in the DRG

TABLE 9.3

SUMMARY OF SYMPATHETIC AND NOCICEPTIVE NERVE SUPPLY TO MORE IMPORTANT BODY STRUCTURES

	Sympathetic nerve supply			Nociceptive pathways	
Region, structure	Location of cell body in spinal cord and course of preganglionic neurons	Site of synapse of preganglionic with postganglionic neurons	Course of postganglionic axons	Location of primary afferent pathway	Entrance into central nervous system
Head and neck					
Meninges and arteries of brain	T1, 2 (3)† To and through cervical sympathetic chain	All cervical sympathetic ganglia	Plexuses around internal carotid and vertebral arteries	Cranial nerves (CN) V, IX, X C-1–3	Trigeminal subnucleus caudalis C-1–3 spinal segments
Eye*	T1, 2, 3 (4) To and through cervical sympathetic chain	Superior cervical ganglion and ganglia in internal carotid plexus	Internal carotid and cavernosus plexuses→ciliary ganglion or nasociliary nerve→ciliary nerves or along ophthalmic artery	Ophthalmic branch of CN V	Trigeminal subnucleus caudalis
Lacrimal gland*	T1, 2 To and through cervical sympathetic ganglia	Superior cervical sympathetic ganglion	Internal carotid plexus→vidian nerve→sphenopalatine ganglion→maxillary nerve→zygomatic/lacrimal nerves	Lacrimal nerve→ ophthalmic branch of CN V	As above
Parotid gland*	As above	All cervical sympathetic ganglia	External carotid plexus→internal maxillary and middle meningeal plexus→to auriculotemporal nerve and plexus and to the parotid arterial plexuses	Parotid nerve→ auriculotemporal nerve of mandibular division of CN V	As above
Submandibular and sublingual glands*	As above	As above	External carotid plexus→facial plexus→submandibular ganglion→direct glandular filaments or via lingual nerves or directly to glands along vessels	Submandibular branch of lingual nerve→ mandibular division of CN V	As above
Thyroid gland	As above	Middle and inferior cervical sympathetic ganglia	Perivascular sympathetic plexuses accompanying superior and inferior thyroid arteries	Afferents accompanying sympathetic pathways	T1 and 2 spinal cord segments
Blood vessels of skin and somatic structures Sweat glands Hair follicles	T1–4 To and through cervical sympathetic chain	All cervical sympathetic ganglia	In perivascular plexuses accompanying various branches of external and internal carotid arteries	Afferents accompanying sympathetic nerves CN V, IX, X C2–4	Tl–4 spinal cord Subnucleus caudalis C2–4 spinal cord segments
Thoracic viscera					
Heart	T1–4 (5) To upper thoracic and cervical sympathetic chain	All cervical and upper four (5) thoracic ganglia	Superior, middle, and inferior cervical cardiac nerves and the four (5) thoracic cardiac nerves→cardiac plexuses	Afferents in middle and inferior cervical cardiac and the thoracic cardiac nerves	T1–4 (5)

†Segments in parentheses are inconstant.

of spinal nerves. Their central processes pass to the spinal dorsal horn, primarily in lamina I and V, and from there visceral information travel centrally via dorsal column pathways as well as by the spinothalamic and spinoreticular tracts. At the level of the dorsal horn, some primary afferents make synaptic connections with somatic motor neurons while others synapse with preganglionic neurons in the intermediolateral cell column, thus mediating complex visceral reflexes. These reflexes usually involve alteration of the function of the viscera, increase in skeletal muscle tension, and increased sympathetic activity.

Visceral afferent fibers mediate reflexes such as coughing, cardiopulmonary reflexes, and emptying of the bladder. Most of the visceral receptors are free nerve endings with large receptive fields that are able to respond to varied stimuli. The receptors responsible for transmitting nociceptive signals are largely chemoreceptors that are sensitive to changes that disrupt the internal milieu such as ischemia, inflammation, or the presence of an irritant (e.g., bile, blood). Indeed, in inflammatory diseases of the viscera, such as Crohn's disease or ulcerative colitis, the peripheral nerve endings may become essentially engulfed in the inflammatory infiltrate that invades the mucosa. The visceral afferent fibers are sensitive to distension and contraction, not cutting or tearing of tissue like the somatic afferents. Although visceral sensations are for the most part not consciously perceived, nociceptive information is transmitted. These fibers also transmit information about the immune system and contribute to the development of fever in the presence of infection.[91,100]

Cervical spinothalamic cells receive input from cardiothoracic afferent fibers and transmit the information to autonomic and nociceptive centers higher in the CNS; these afferent fibers also activate propriospinal pathways in the cervical spine that modulate visceral input from lower levels of the spine.[101]

Autonomic Centers in the Central Nervous System

Unlike the peripheral ANS, distinctions between the somatic and autonomic structures and pathways are often difficult in the CNS. The cortex is the central integration center for both somatic and vegetative functions. Multiple cortical structures have been identified as playing a role in the pain–ANS interaction. The insula, in addition to being associated with the limbic system, is the primary cortex for the viscerosensory system and is involved in the discriminative aspect of pain sensation. It plays a role in the subjective experience of pain and has connections with multiple centers (amygdala, lateral hypothalamus, etc.) involved with autonomic outflow.[102,103] The anterior cingulate cortex receives nociceptive inputs and maintains broad connections with multiple areas of the central autonomic network. In addition to being included as part of the limbic system and being involved in goal related behavior, it plays an essential role in affective and motivational components of pain.[104] Surgical stimulation of this region elicits a range of autonomic responses.[105] The amygdala is comprised of several nuclei with distinct functional properties. It plays an essential role in modulating the ANS and is closely linked to the hypothalamus. The amygdala plays a role in the subjective perception of pain as well as expression of emotional response to pain.[106] The PAG is a complex region of the CNS that has distinct anatomical and functional regions. Different areas of the PAG receive sensory information and help integrate and regulate autonomic responses to these signals and modulate the sympathetic nervous system in analgesia.[107] The PAG receives sensory signals from lamina I and V of the dorsal horn and helps regulate responses to cardiovascular and nociceptive input.

There are several autonomic centers in the brainstem that have been physiologically delineated. In addition to regulating vital functions such as breathing and circulation, aggregates of neurons in the medullary and pontine reticular formation regulate the ANS through ascending and descending tracts. In the medulla, the nucleus of the solitary tract is a control center of vegetative functions and also appears to contribute antinociceptive input to the dorsal horn.[24] The parabrachial nucleus integrates nociceptive and visceral information through its extensive connections with the medulla, hypothalamus, and amygdala to maintain homeostasis. The autonomic centers in the brainstem give rise to the parasympathetic visceral efferent fibers of the cranial nerves.[108]

TABLE 9.4

AUTONOMIC CENTERS (AC) IN SPINAL CORD

Structure	Location of AC in spinal cord
Head and neck	T1–4

Abdominal (sympathetic)	T5–L2
Pelvic (parasympathetic)	S2–4

The spinal cord is a central area of integrating the somatic and autonomic functions. Through spinal reflexes, somatic nociception can exert a major impact on the autonomic system. Noxious stimulation to the skin induces a cascade of sympathetic responses, including increased sweat production and skin vasomotor responses.[109]

The location of the preganglionic neurons for the sympathetic and parasympathetic nervous systems in the CNS differ. The sympathetic preganglionic neurons are located in the T1 through L2 spinal segments of the spinal cord. The parasympathetic preganglionic neurons are located in the brainstem and the S2–S4 spinal segments (see Figs. 9.9 and 9.10). The locations of the cell bodies of preganglionic sympathetic and parasympathetic neurons, which mediate their function in various parts of the body, are listed in Table 9.4. There are essential differences between the ganglia these neurons form. The sympathetic ganglia are distributed widely throughout the body, are located close to the CNS, and use epinephrine as the primary neurotransmitter. In contrast, the parasympathetic ganglia largely innervate visceral organs, which they are in close proximity to, and use acetylcholine as a neurotransmitter. Figure 9.9 depicts the autonomic pathways that connect the preganglionic neurons in the intermediolateral horn of the spinal cord with the hypothalamus and other brainstem structures.

Transmission in the Peripheral Autonomic Nervous System

The majority of preganglionic neurons in the autonomic nervous system are cholinergic, as are some sympathetic postganglionic neurons, such as sweat glands. Acetylcholine binds nicotinic receptors in the membrane of postganglionic neurons. Postganglionic parasympathetic neurons also release acetylcholine, which binds to muscarinic receptors in effector organs (e.g., cardiac and smooth muscle, glandular cells). There are drugs that selectively block each of these receptors (see Fig. 9.8).

Norepinephrine is the transmitter substance in the majority of sympathetic postganglionic nerve endings. The response of the

*By circulating epinephrine only.

effector cells is mediated by two types of receptors: the alpha and beta adrenergic receptors. These receptors have different effects at different organs. For example, in the heart norepinephrine binding to a beta receptor causes an increase in heart rate, while in the bladder and airways this same process causes a relaxation of smooth muscle cells. A variety of pharmacologic agents can either enhance or block the action of these receptor subtypes.

The cells in the adrenal medulla, which are homologues of the postganglionic neurons, mainly release epinephrine into the bloodstream with sympathetic stimulation. Though it has many of the same effects as norepinephrine, epinephrine stimulates the beta receptors in the fat and liver cells accelerating metabolism of fat and glucose.

There are other neurotransmitters in the ANS. Most preganglionic neurons contain neuropeptides (enkephalin, somatostatin) of unclear functional purpose in addition to acetylcholine. Some autonomic neurons do not contain either acetylcholine or norepinephrine. These are primarily located in the gastrointestinal tract.

Physiology of the Autonomic Nervous System

The ANS regulates activities that are required for maintenance of the internal environment of an organism but which are not normally under voluntary or conscious control. This includes modulating functions such as metabolism, circulation, respiration, body temperature, digestion, sweating, circadian rhythm, and endocrine secretion. The ANS coordinates these physiologic processes to maintain homeostasis,[110] such as the constancy of the internal environment.

The effects of stimulating either portion of the ANS and its impact on various organs, visceral structures, and effector cells are summarized in Table 9.5. The sympathetic nervous system is focused on catabolic function and mobilizing the body's resources. In contrast to the sympathetic nervous system, the parasympathetic function is anabolic and dedicated to regulating functions that maintain an organism over the long term. Through regulation of the enteric system, it conserves and stores energy, it plays a central role in coordinating the muscular contraction of the bladder and rectum to eliminate waste products, and it maintains the basal heart rate and respiration under normal conditions.[92]

The functional balance that is normally maintained by the two divisions of the ANS can be disturbed in disease. Linkages exist between the autonomic and immune systems that may be important in the production of disease states and the response to neoplasia and other chronic disease that may lead to pain.[111] Pain itself may alter the immune response and thereby alter the progression of a disease.[112] Animal and human physiologic and pharmacologic studies of visceral as well as somatic pain have demonstrated both plasticity and functional characteristics that are far more complex than the basic anatomy described in this chapter; entire books have been written, for example, on visceral pain.[113]

Enteric Nervous System

The enteric nervous system (ENS) is a highly dynamic division of the ANS often referred to as the "Little Brain" of the gut and contains as many neurons as the spinal cord. It controls gastrointestinal motility and secretion and is involved in visceral sensation. The digestive tract consists of two plexuses, the myenteric and submucous plexuses, formed from sympathetic and parasympathetic postganglionic neurons and a significant number of enteric neurons (Fig. 9.11).[114] Though these plexi interact with the ANS ganglia in the periphery as well as the spinal cord, brainstem,

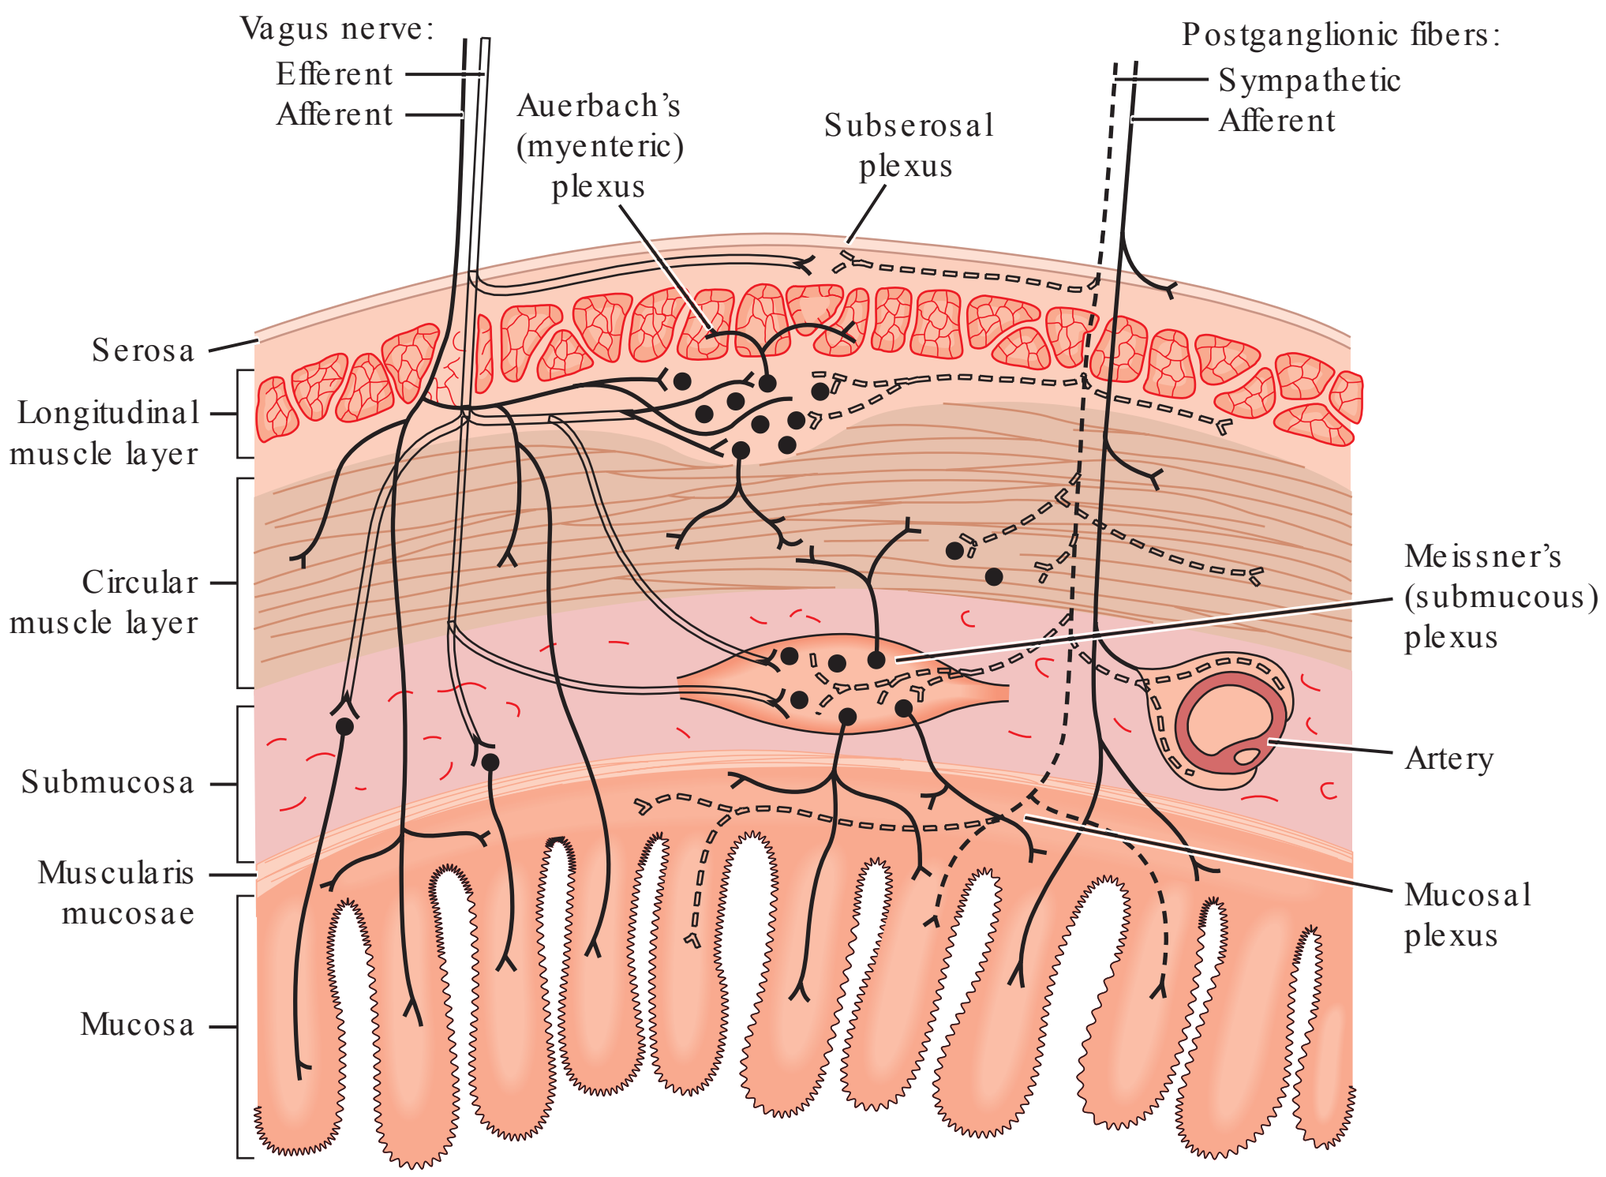

FIGURE 9.11 Arrangement of nerve cells and nerve fibers in the intramural plexuses in the intestine. The axonal endings of the parasympathetic preganglionic neurons synapse in the wall of the intestine, whereas the axonal endings of postganglionic sympathetic neurons are largely distributed to the intramural ganglia and the blood vessels. (Modified from Kuntz A. *Autonomic nervous system*. 4th ed. Philadelphia: Lea & Febiger; 1953:215.)

and cortex, the ENS can function autonomously without input from the sympathetic and parasympathetic systems or the CNS.[115] Enteric neurons were once felt to be postganglionic parasympathetic fibers but are now felt to comprise an independent system in the ANS. The ENS regulates the gastrointestinal system to maintain homeostasis through control of peristalsis, blood vessels, and glandular activity. The ENS also has extensive interaction with the immune system. Disruption of this delicate relationship may be the cause of functional bowel disorders such as irritable bowel syndrome.[26] Enteric neurons appear able to change their function and phenotype, a phenomenon called neuronal plasticity, which contributes to the pathogenesis of visceral hypersensitivity.[114]

CONCLUSION

Complete evaluation of individuals with persistent pain includes anatomic localization of the lesion or lesions responsible for both the initiation and maintenance of pain. It is necessary to distinguish between pain that is of peripheral, central, and mixed origin; it is necessary to determine whether pain is somatic or visceral. Thus, optimal evaluation and care of patients with persistent pain is dependent upon a thorough knowledge of the anatomy of nociceptive systems. Future advances in our understanding of the anatomy and physiology of pain in conjunction with improvements in evaluative and diagnostic technologies (e.g., imaging, genetic, etc.) will no doubt enhance the care of individual patients.

CHAPTER 10 ■ CLINICAL TRIALS

ROGER CHOU AND RICHARD A. DEYO

Controversies abound in the clinical management of pain, and there are enormous geographic variations in care. Lumbar spine surgery rates vary fivefold among developed countries, with rates in the United States being highest and rates in the United Kingdom being among the lowest[1]—yet patient outcomes appear to be broadly similar across countries. In smaller geographic areas, variations are also striking. Within the United States, rates of lumbar fusion surgery among Medicare enrollees vary more than 20-fold between regions, from 4.6 per 1000 enrollees in Idaho Falls, Idaho, to 0.2 per 1000 in Bangor, Maine.[2] Within Washington state, county back surgery rates vary more than sevenfold, even after excluding the smallest counties.[3]

Another problem in pain management is the successive uptake of a series of fads in treatment. Research has eventually discredited many of these, but they enjoyed widespread use, with substantial costs and side effects, before they were found to be ineffective. Examples include sacroiliac joint fusion for the treatment of low back pain, coccygectomy for coccydynia, bed rest and traction for back pain, and many others.[4] This phenomenon is prominent in the field of pain medicine, but not unique to it. Examples of abandoned therapies from other areas of medicine include internal mammary artery ligation for treating angina pectoris, gastric freezing for duodenal ulcers, and vitamin E and hormone therapy for prevention of cardiovascular events.[5–7] Promoting such ineffective treatments drains resources from more useful interventions, produces side effects, and eventually damages professional credibility.

Despite welcome breakthroughs in basic science research on pain, increases in knowledge regarding optimal ergonomics of work tasks, and the development and use of more technologically advanced medical therapies, studies show an increasing prevalence of chronic back pain and disability. In the state of North Carolina, the prevalence of chronic, impairing back pain more than doubled from 3.9% in 1992 to 10.2% in 2006.[8] A large and steady rise in use of surgery and interventional therapies for low back pain has not been associated with improved health status, but appears to be an important factor contributing to increases in health care expenditures associated with back pain.[9,10] Thus, despite impressive gains in our understanding of the molecular and cellular origins of pain, there is an important gap in translating this knowledge into effective clinical management. One reason may be the widespread reliance on inadequate research designs that lead to conflicting, confusing, or misinterpreted results. Biostatistical and epidemiologic methods make it possible to substantially improve this situation, but many key principles are not widely appreciated.

UNCONTROLLED STUDIES PARADIGM

Historically, much of pain treatment research consisted simply of uncontrolled studies in which clinicians treated a group of patients, then reported mean pain scores or the proportion who improved. Such studies are often referred to as *case series*, though the alternative term *before-after study* may help distinguish them from studies that identify cases based on an outcome (such as an adverse event) rather than an exposure (such as a medical intervention), and only assesses patients at one point in time.[11] The before-after study design remains popular in part because it usually does not require extensive resources, but is vulnerable to many pitfalls.[12]

First, many uncontrolled studies are retrospectively reported. After treating a certain number of patients, the clinician looks back at his or her experience and tries to summarize the characteristics, treatments, and outcomes of the patients studied. Unfortunately, in this retrospective approach, there is often incomplete baseline information on patient characteristics. For example, factors such as age, sex, previous surgery, disability compensation, neurological deficits, psychological comorbidities, and pain duration often have a major influence on the outcomes of back surgery. Yet, in a systematic review of outcome studies on surgery for spinal stenosis, 74 relevant articles were found, but less than 10% mentioned all of these patient characteristics.[7]

Another problem with the retrospective approach is that it can be difficult to identify an inception cohort of all patients (or a random sample) who met specified criteria and received the intervention. A systematic review of 72 uncontrolled studies of spinal cord stimulation for chronic low back pain or failed back surgery syndrome found that less than one-quarter clearly described evaluation of a consecutive or representative sample of patients.[13] In such studies, it is impossible to know if patients with poorer results were excluded for arbitrary reasons, or how many patients received the treatment but were lost to follow-up. If patients lost to follow-up were more likely to experience poor outcomes than those who were followed, this could result in serious overestimates of benefits.

A third problem with uncontrolled studies is that, even if the researcher collects data prospectively, there is typically no blinding of patient, therapist, or outcome assessor to the nature of the treatment provided. This allows important unconscious biases to creep into the assessments. This is particularly important with outcomes related to pain, which by nature are subjective. Most of us would not trust outcomes rated by a surgeon evaluating his or her own patients, and yet this is the norm in much of the literature.

By definition, uncontrolled studies do not include control groups for comparison. The assumption seems to be that patients with painful conditions, and especially chronic pain, will not improve unless effective treatment is given. However, there are many reasons why patients improve in the face of ineffective therapy, some of which are listed in Table 10.1. First, the natural

TABLE 10.1

WHY PATIENTS MAY IMPROVE WITH INEFFECTIVE THERAPY

Natural history of a condition to improve
Placebo effects
Regression to the mean
Nonspecific effects: concern, conviction, enthusiasm, attention

history of many painful conditions is to improve spontaneously. This may be true even for patients with long standing pain, who sometimes improve for unclear reasons. For conditions such as acute low back pain, rapid early improvement is the norm.[14] Second are placebo effects, which are not well understood but are consistently underestimated, and may be particularly important when assessing pain.[7] Several factors may mediate placebo effects, including patient expectations, learning and conditioning from previous treatments, reduction of anxiety, and endorphin effects.

Another poorly appreciated factor is *regression to the mean*.[15] This term was coined by statisticians who observed that in a group of patients who are assembled because of the extreme nature of some clinical condition, there is a tendency for the condition to return to some average level that is less severe over time. Figure 10.1 shows what we often assume to be the course of chronic pain problems, with a steady level of severity that falls after successful intervention. However, the second panel is more likely to represent the true natural history, with good days and bad days, and fluctuations being the norm.[16] Patients seek us out when their symptoms are most extreme. We might easily be misled into believing that improved outcomes are due to the intervention when, in fact, random fluctuations are why their symptoms have returned toward a more average level. As Sartwell et al. pointed out, "the term chronic has a tendency to conjure up ideas of stability and unchangeability . . . it is changeability and variation, not stability, that is in fact the dominant characteristic of most long-lived conditions."[17]

A host of other nonspecific effects also can affect assessments of patient improvement. Increased concern, conviction, enthusiasm, and attention of a therapist, a researcher, and a clinical staff may all have positive but nonspecific effects on patient outcomes. Table 10.2 shows a potential consequence of all these factors, using data from a clinical trial of patients with chronic low back pain.[16] The 31 patients in Table 10.2 had had back pain an average of 4 years. They received a clinical intervention that resulted in 20% to 44% improvements in pain frequency, severity, and function, all of which were highly statistically significant. However, this seemingly effective treatment for chronic pain was a sham transcutaneous electrical nerve stimulation (TENS) unit, along with hot packs twice a week. This was the control arm of a randomized trial, and illustrates the substantial improvements that may occur among those with long standing pain who receive ineffective treatments.

Finally, an issue that has begun to receive more attention is that uncontrolled studies are highly susceptible to publication bias.[18] There is little incentive for clinicians to publicize poor or even average results. Estimates of efficacy from uncontrolled studies that get published will therefore often over-represent the most positive results.

There is considerable room for improvement in the design and conduct of uncontrolled studies of pain interventions.[13,19] However, even when conducted well, the ability of uncontrolled studies to provide reliable information about treatment efficacy will always be limited. Exceptions can occur when the relationship between an intervention and outcomes is obvious, the effects are immediate, and the effects are so dramatic that that they cannot be explained by other factors.[20] Examples include surgery for appendicitis, eyeglasses for correction of refractive error, and cataract surgery. For nearly all pain conditions, however, there are many plausible explanations for the observed changes in outcomes, and reliable conclusions about treatment efficacy require the use of more rigorous study designs. There is simply too much noise to sort out whether outcomes are due to the treatment or to other factors.[21]

Control Groups: An Improvement Over the Case Series

Given the variety of factors that may produce improvement with ineffective therapy, it is incumbent on investigators to have a

comparison group of subjects with the same likelihood for improvement as a treatment group, but who do not receive the active therapy. The goal should be to minimize the potential differences across groups in the effects of the various nonspecific causes for improvement that are listed in Table 10.1. With this goal in mind, the appropriate comparison group is unlikely to be one that receives no care at all. Patients in such a group would not experience placebo effects or the nonspecific effects of clinical concern and enthusiasm. The importance of having an adequate placebo is illustrated by a trial that found acupuncture more effective than no treatment for chronic low back pain, but no more effective than sham acupuncture.[22] Similarly, using a *waiting list* control group is usually not adequate because these patients experience none of the placebo or nonspecific effects of the intervention group. A preferable control group would be one that receives other credible, appropriate care that does not include the specific treatment under study. This might consist of usual care supplemented by a placebo of some sort. The placebo should be difficult to distinguish from the intervention under study so that it is perceived as being as likely to help as the active therapy. This is the reason for providing inactive pills in the control groups of drug trials; but, even for nondrug treatments, credible placebos should be provided when possible. Examples include the use of sham TENS units in trials of TENS, the use of sham injections in trials of interventional therapies, the use of subtherapeutic weight in trials of traction, or misplaced needling as a control for acupuncture.

In some cases, it may be unethical or impossible to provide a true placebo. Examples include many surgical interventions, psychological therapies, and rehabilitation interventions. In such situations, a reasonable alternative is to provide a placebo that creates some sense that patients are receiving an additional intervention and attention, but is not likely to have a strong effect on outcomes. One example might be a brief educational brochure.[23]

In addition to choosing an appropriate control intervention, it is also important to make the treatment and control groups as similar to each other as possible in other ways. Confounding is a critical concept that refers to variables associated with both the intervention being evaluated and the observed outcomes. A classic example of confounding is the association between alcohol consumption and lung cancer. This association is confounded by smoking, which is associated with alcohol consumption and is also an independent risk factor for lung cancer. Examples of common confounders in pain research include severity of baseline pain or functional deficits, psychological and medical comorbidities, age, and use of other therapies. The consequence of confounding is that the observed treatment effect is a poor estimate of the true effect. The modifying effect of the confounding variables result in either an overestimate or underestimate of treatment benefits, and can sometimes even result in a positive effect when the true effect is negative (or vice versa).

Selection of controls to minimize the potential for confounding is often a challenge. Control groups that are convenient to assemble are also, unfortunately, frequently associated with important pitfalls. For example, it would be unwise to choose patients who did not have adequate insurance coverage for the treatment being provided as a control group, because insurance coverage is related to important sociodemographic characteristics. Patients with the best insurance are typically those with the highest salaries and the most satisfying jobs, are happier with their insurance, and are more likely to practice healthy behaviors. Failure to adjust for socioeconomic status in observational studies could have resulted in the subsequently disproven belief in the positive cardiovascular benefits of hormone replacement therapy.[24] Similarly, selecting patients noncompliant with intended therapy as a control group is a flawed strategy. In a large-scale study of cholesterol-lowering therapy, control patients were divided among those who took more than 80% of their placebo tablets and those who took less than 80%.[25] Even after adjusting for 40 coronary risk factors, there were enormous differences in mortality between the compliant and noncompliant groups. Patients who were compliant with their placebos had a 5-year mortality of only 16%, whereas those who were not compliant had a 5-year mortality rate of 26% ($p < 0.0001$). These findings were probably related to important differences between the groups that were not reflected in their coronary risk factors. These may have included other health habits, behaviors, attitudes toward risk, and occupations. Thus, noncompliant patients are often strikingly different from compliant patients, and we cannot assume that any differences in outcome are related only to treatment effects.

Sometimes the issues of proper selection of control patients and treatments are intertwined. A study that assigned patients with presumed discogenic low back pain to intradiscal electrothermal therapy (IDET) or rehabilitation therapy, based on their insurance coverage for IDET, reported an average 4.5 point improvement in pain scores.[26] Subsequent randomized trials found either no advantage of IDET, or only a 1 point difference between IDET and sham treatment.[27,28] In addition to potential socioeconomic differences related to differential insurance coverage, patients who were denied intradiscal electrothermal therapy probably had lower expectations about the likely benefits of rehabilitation therapy, particularly since some had previously received this treatment but had not responded.

Confounding by indication is particularly important in studies that assess treatment efficacy. It refers to the strong, natural (and appropriate) tendency for clinicians to selectively use therapies in patients most likely to benefit. A striking example of confounding by indication is a study of new users of nonsteroidal anti-inflammatory drugs (NSAIDs) that found use of ulcer-healing drugs associated with a tenfold *increase* in risk of gastrointestinal bleeding or perforations.[29] Obviously, ulcer-healing drugs don't cause ulcers. Rather, the increased risk of gastrointestinal complications in patients deemed appropriate for ulcer-healing drugs dwarfed any protective effect of the drugs.

There are ways to minimize or adjust for the effects of confounding. These include matching patient selection on the variables thought to be the most important potential confounders, restricting enrollment to patients defined by a narrow set of inclusion criteria, and statistical adjustment or analysis on known confounders.[30] Nonetheless, the effects of confounding can be dramatic even when one or more of these strategies are employed. For example, confounding by indication was strong in the study on ulcer-healing drugs, even though it attempted to restrict enrollment to lower-risk patients without a previous ulcer, or who had even been previously prescribed an ulcer-healing drug.[29]

Matching also may not be enough to overcome effects of confounding. Table 10.3 shows how one might assemble two groups of objects that are well matched on five different characteristics

and yet literally be comparing apples and oranges.[16] Table 10.4 shows real data from a comparison of outcomes of two groups of Medicare patients who underwent low back surgery. They were matched on diagnosis (all had spinal stenosis), gender, age, insurance (all Medicare), and surgical procedure (all had a laminectomy without fusion). Despite being well matched on these five characteristics, the likelihood of reoperations differed almost fourfold between the two groups. Differences of this magnitude might easily be attributed to some dramatic advantage of the treatment used in group A. However, these groups were intentionally assembled in such a way that group A was composed of African American patients who had not had prior surgery, and group B was composed of white patients with prior surgery.[16] These two characteristics, which might have easily been overlooked, accounted entirely for the difference in reoperation rates. Unfortunately, it usually isn't as simple as matching on a few critical and easily measured variables. The cholesterol-lowering placebo study described previously shows how even matching (or adjusting) for 40 different risk factors may not capture important differences between two groups of patients.[25]

If waiting lists, patients with insufficient insurance coverage, noncompliant patients, or even carefully matched patients receiving appropriate placebo treatments make poor control groups, is there a better solution? Fortunately, the concept of random allocation provides an ideal method of establishing a comparison group that is likely to be similar in nearly all respects to an intervention group.

RANDOMIZED ALLOCATION OF TREATMENT AND CONTROL GROUPS

The term *randomized trial* has become familiar among clinicians and, yet, is often misunderstood. Some assume that a randomized trial is one in which patients are randomly selected from a population of interest. However, just the opposite may be true. Patients may be highly selected from a group of potential candidates based on specific characteristics that make the study treatment safe and likely to succeed. Randomization does not refer to the selection of patients to be studied, but rather to the patients' allocation to the treatment or the control group.

Why is randomization such a desirable way of creating a control group? It is attractive because the problem of confounding is largely eliminated.[31] Because it is never possible to completely understand or measure all confounders, residual confounding is always a potential issue in studies that are not randomized.[32] With random allocation, we may not even know the important prognostic factors, but they will be equally distributed (given a fair randomization and enough patients) between the treatment and control groups. Effective randomization requires the generation of a truly unpredictable (random) allocation sequence, as well as its successful implementation via allocation concealment.[33]

There is sometimes confusion about what constitutes randomization. Randomization requires using a list of random numbers that may be published or determined by a computer program. Each successive subject has an equal likelihood of being assigned to each treatment arm, though the order in which they are assigned is unpredictable. Alternating assignment is not the same as randomization because it is predictable. Similarly, assigning patients without conscious bias, or haphazardly, is not the same as random allocation. Using hospital numbers, date of birth, or day of the week is also not randomization. If day of the week is used, a patient could simply come in (or be told to come in) on the day that the desired intervention will be offered. Allocation concealment means that the allocation sequence remains unknown until at least after patients have been assigned to therapy, thus preserving the actual randomization. A traditional method to help preserve allocation concealment is use of opaque sealed envelopes containing the treatment assignment. An increasingly common alternative is to have an off-site facility that keeps the random sequence, so research personnel cannot know the next assignment as a subject is enrolled.[34]

A dramatic example of the effects of randomization in pain research is a systematic review of TENS therapy for postoperative pain that found that 15 of 17 randomized trials of efficacy showed no benefit.[35] By contrast, 17 of 19 nonrandomized studies showed a substantial positive treatment effect. Some investigators have also quantified the magnitude of bias that occurs when allocation concealment is inadequate. One such study, shown in Table 10.5, compared randomization with adequate allocation concealment with randomization with inadequate allocation concealment and with nonrandom allocation of controls.[36] The investigators examined a series of treatments for acute myocardial infarction and, as Table 10.5 shows, demonstrated that maldistribution of prognostic factors was least with randomization with adequate allocation concealment and greatest with nonrandom allocation. Similarly, the likelihood of finding a substantial improvement in case fatality rate rose dramatically, from just 9% of trials with randomization and adequate allocation concealment to up to almost 60% of trials with nonrandom allocation. Other studies suggest that, on average, inadequate allocation concealment inflates results by about 40% compared to studies with adequate allocation concealment.[34,37]

Why is allocation concealment so important? There are probably several reasons. Failure to conceal allocation makes it easy

TABLE 10.5

BIAS IN STUDIES OF MYOCARDIAL INFARCTION

Allocation method	Prognostic maldistribution (%)	Difference found in case-fatality (%)
Blinded randomization	14	9
Unblinded randomization	27	24
Nonrandomized	58	58

Data from Chalmers T, Celano P, Sacks HS, Smith J. Bias in treatment assignment in controlled clinical trials. *N Engl J Med* 1983;309: 1358–1361; reprinted from Deyo RA. Practice variations, treatment fads, rising disability. Do we need a new clinical research paradigm? *Spine* 1993; 18:2153–2162, with permission.

to subvert the randomization process. If this occurs, confounding by indication can be as much of a problem as in nonrandomized studies.[34] Some overt methods that have been used to bypass randomization include adjusting treatment assignments based on posted allocation sequences, or ignoring allocation to treatments perceived as less desirable.[38] Inadequate allocation concealment can also have more subtle effects. If the investigator has a bias as to which treatment group is more effective—even a subconscious bias—he or she may approach the next subject differently if he or she can determine what the next treatment assignment will be. This may affect the way in which a clinical trial is presented to a patient, the enthusiasm with which consent is sought, or the rigor with which eligibility criteria are applied.

For certain interventions, it may be undesirable or unfeasible to randomly allocate individual patients to a treatment or a control group. For example, if one were testing a guideline that involved changes in clinic organization and changes in management by nurses or other ancillary staff, it might be extremely difficult to ensure that all involved gave one particular approach to some patients and not to others. Furthermore, individual physicians would have difficulty treating certain patients according to a guideline and others not according to the guideline. In such a circumstance, one might wish to allocate clusters of patients, such as entire clinics, to intervention or control arms. Such studies are referred to as cluster randomized trials.[39] When these designs are used, specific statistical methods are needed to account for the similarities among patients of a single physician or facility, which can inflate estimates of treatment effects. Analytic techniques, such as the cluster correlation correction for such studies, have been well described[40] and appropriate computer software is available to perform these analyses.

OTHER METHODS FOR REDUCING BIAS IN CLINICAL TRIALS

Randomization is a powerful method for minimizing the possibility of confounding, but does not protect against other types of bias, or systematic errors in measurement. The quality of a trial refers to how rigorously it employs measures to protect against bias. Table 10.6 lists criteria that have been proposed for critical readers to evaluate the quality of studies on treatment efficacy.[41,42] A lengthier and more detailed set of criteria for evaluating clinical trials has been developed by the back subgroup of the Cochrane Collaboration.[43] Additional guidance for clinical investigators includes recommendations on how to report the methods and results of randomized trials.[44] The list of criteria in Table 10.6 begins with random allocation, which was discussed in detail previously.

Baseline Similarity of Study Groups

Randomization usually provides the best way to produce groups with equivalent prognoses. However, randomization may not always work and investigators should present a comparison of baseline characteristics of patients in the treatment and control groups. In a properly randomized trial, any observed differences are chance occurrences, but may still be sufficiently large to compromise the validity of the study. When this occurs, investigators sometimes adjust for baseline differences using statistical techniques. However, such statistical adjustments should be based on how strongly the prognostic factor is thought to be associated with the outcomes and the clinical importance of baseline imbalances, not on the results of statistical tests for significant differences.[45] Statistical tests can be misleading, as small differences may be clinically trivial but statistically significant in large trials, and large differences may be clinically important but statistically nonsignificant in small trials.

TABLE 10.6

READERS' GUIDES FOR AN ARTICLE ABOUT THERAPY

Are the results of the study valid?
- Primary guides
  - Was the assignment of patients to treatments randomized?
  - Were all patients who entered the trial properly accounted for and attributed at its conclusion?
  - Was follow-up complete?
    - Were patients analyzed in the groups to which they were randomized?
- Secondary guides
  - Were patients, health workers, and study personnel "blind" to treatment?
  - Were the groups similar at the start of the trial?
  - Aside from the experimental intervention, were the groups treated equally?

What were the results?
- How large was the treatment effect?
- How precise was the estimate of the treatment effect?

Will the results help me in caring for my patients?
- Can the results be applied to my patient care?
- Were all clinically important outcomes considered?
- Are the likely treatment benefits worth the potential harms and costs?

Reprinted from Guyatt GH, Sackett DL, Cook DJ. Users' guides to the medical literature II. How to use an article about therapy or prevention. A. Are the results of the study valid? *JAMA* 1993;270:2598–2601, with permission.

Even if adjustment is appropriate, it cannot control for differences in unmeasured confounders. It is also important to consider whether baseline imbalances could be due to intentional subversion of randomization.[46]

Blinding

The importance of blinding is that it helps to create similar expectations on the part of patients and similar enthusiasm by the therapists. Furthermore, it ensures that the same level of attention and concern is provided to both a treatment and a control group. Blinding is particularly important in studies that assess subjective outcomes such as pain. In one study, lack of blinding inflated estimates of treatment effects by 30% in trials with subjective outcomes, but had no effect on estimates in trials with objective outcomes.[47]

It is common to talk about *double-blind* trials, but the term is often used ambiguously.[48] Typically, it is meant to imply that the patient is unaware whether he or she is receiving active treatment or a placebo, and the person administering or prescribing the treatment is also unaware. In some cases, it may be impossible to blind patients or therapists, as in trials of surgical treatments or some rehabilitation interventions. There is also a third party that may be blinded—an independent assessor of outcomes. Maintaining such a blinded assessor should generally be feasible, even when it is impossible to blind patients and therapists. Trials should explicitly describe who was blinded, rather than use nonspecific jargon such as single-, double-, or even triple-blinded.[48]

As noted in the discussion of control groups, creativity can sometimes produce credible placebo or alternative treatments that at least help to maintain blinding. In many situations, it would be informative to test the success of blinding at the end of a study. This is not done frequently, but is important for certain drugs and other interventions that have side effects or other characteristics that can give the treatment away.[49] In a trial of TENS

therapy for low back pain, for example, sham treatment does not produce the same sensation as active therapy, so patients could know they are receiving sham rather than active therapy. This would essentially result in an unblinded trial. In fact, one trial of TENS found that patients and physicians were able to guess better than random chance whether individual patients were in the treatment or control group, but the magnitude of blinding failure was sufficiently modest that the results could be presented with some confidence.[50]

In trials of drug therapy, crossover designs have commonly been used because they help to reduce the effects of interpatient variability in baseline and outcome measures. For many pain treatments, however, such designs may be undesirable because patients would experience both treatments and could determine with a high level of certainty whether they were receiving active treatment or placebo. For example, maintenance of blinding would be very difficult in a crossover study from sham TENS to true TENS, or from subtherapeutic weight to therapeutic weight with traction, or from mild exercise to strenuous exercise. Because of the potential for loss of blinding and other issues such as carryover effects and loss to follow-up during the first intervention period,[51] crossover trials may be undesirable for many types of pain therapy.

Were Groups Treated Equally Except for the Experimental Treatment?

Sometimes patients in a treatment group are given multiple interventions and, yet, the authors or readers are tempted to ascribe the results to a single feature of the treatment. For example, a patient who receives a sclerosant injection into the spinal ligaments, along with corticosteroids and spinal manipulation, might be said to have improved because of the sclerosant therapy, and yet much of the observed improvement might be due to the cotreatments.[52] Thus, it is important that any cotreatments also be given to the control group and that the intensity of the treatments is equal.[53]

Furthermore, use of multiple treatments for chronic painful conditions is common. Many patients obtain over-the-counter pain medications, visit multiple physicians, or seek alternative forms of therapy such as chiropractic care, acupuncture, or massage. In outpatient trials, it may be difficult to prevent patients from obtaining such cotreatments, and it may simply be necessary to inquire about these cointerventions and determine if they are roughly equivalent between two groups. Alternatively, investigators may make strenuous efforts to ensure that patients do not receive certain types of cointerventions. Even the nature of follow-up should be consistent between study groups. If one group has closer or more frequent follow-up, for example, more adverse events might be reported, or treatment might be given more intensively. Increased contact with a caring clinician can also have important nonspecific effects, as noted previously.

Low Loss to Follow-Up and Intention-to-Treat Analysis

The second item in the list in Table 10.6 concerns completeness of follow-up for patients who entered the trial. As discussed in the section on uncontrolled studies, investigators should attempt to follow-up on every patient who enters the study because those who drop out may be systematically different from patients who remain in the study, resulting in attrition bias. For example, disgruntled patients who have failed to improve may drop out of a trial, leaving an obvious bias in favor of the new treatment. On the other hand, patients with dramatic improvements may drop out because they are so much better they see no need for continued medical contact. Dropouts from clinical studies often differ systematically from those who remain with regard to their baseline characteristics.

In highly mobile societies, such as the United States, obtaining complete follow-up can be difficult. Strategies for maximizing follow-up include gathering multiple telephone numbers at the time of enrollment for the patient, relatives, and friends; excluding patients who are planning to move in the near future; excluding patients who have no telephone; multiple mailings of questionnaires; financial incentives to return data; maintaining contact with greeting cards or newsletters; using the briefest possible follow-up questionnaires; and even use of the Internet to track patients through public records.

A useful rule of thumb is that at least 85% of patients who enter a trial should be included at the end of the study. One way to ensure that the results are robust in the face of dropouts is to do a worst-case analysis, in which one assumes that all dropouts from the treatment group failed to improve, whereas all dropouts from the comparison group improved substantially. If this worst-case analysis does not change the conclusion, one can be confident in the findings.[41]

It is also important that patients be analyzed in the groups to which they were randomized (intention-to-treat analysis), regardless of whether they received the intended treatment, how well they adhered to the assigned therapy, and whether they completed the trial.[54] We have seen the hazards of assuming that patients who are noncompliant are otherwise the same as compliant patients. Indeed, patients who do not receive the intended therapy may be systematically different from those who do. The only way to maintain the benefits of randomization and to avoid a biased comparison is to keep patients, for analytic purposes, in the group to which they were assigned. Intention-to-treat analyses take into account the fact that patients in clinical practice are autonomous and do not always follow the trial protocol to the letter—or at all. In some cases, intention-to-treat analyses can be difficult to interpret. In the Spine Outcomes Research Trials of surgery, nearly 40% of patients crossed over from surgery to nonsurgical therapy, and vice versa.[55] The intention-to-treat analysis still provides information about patient outcomes when they are advised to undergo surgery or nonsurgical therapy, even though many patients decided not to proceed with the recommended therapy. An as-treated analysis provides additional information based on which therapy the patients actually received. This can also be informative, so long as potential confounders are adjusted for, and the high probability of some residual confounding is recognized.[56]

OTHER ISSUES IN CLINICAL TRIALS

Measurement of Outcomes

What outcomes should be measured in a clinical trial? In traditional clinical trials, investigators often seek the most objective possible outcomes for evaluation, such as joint range of motion, spinal fluid endorphins, or dynamometer measures of muscle strength. Although the search for objective outcome measures is appropriate for many medical conditions, pain is inherently a subjective phenomenon and one that often correlates only modestly with these physiologic measures. Table 10.7 illustrates several examples of dissociations between physiologic measures and pain or functioning.[57] Some researchers have argued that the essence of hard data is their reproducibility under the same circumstances.[58] Happily, many subjective phenomena can be measured in reproducible fashion. A good example is the use of visual analog pain scales and other ordinal rating scales for quantifying pain.

TABLE 10.7

EXAMPLES OF DISSOCIATIONS BETWEEN VARIOUS OUTCOME MEASURES

- Biofeedback reduces paraspinal electromyography activity but not pain.
- Tricyclic antidepressants relieve pain and depression but do not alter cerebrospinal fluid beta-endorphin levels or paraspinous electromyography activity.
- Statements of pain severity correlate poorly with medication use, health care use, and activity level.
- Reduced spinal mobility may be associated with improvement in pain and disability or lower risk of pain.
- Muscle function does not predict 10-year incidence of back symptoms.
- Correlations between lumbar spine mobility and modified Oswestry questionnaire are only .04–.17 (absolute value).
- In a clinical trial of rigid corset, improvements in symptoms with activity were observed but not in spine mobility or straight-leg raising.

Reprinted from Deyo RA. Measuring the functional status of patients with low back pain. *Arch Phys Med Rehabil* 1988;69:1044–1053, with permission.

For evaluation of therapies for chronic pain, trials should go beyond the self-report of pain to routinely examine patients' behavior and function in their daily lives.[59] Function should be considered a separate domain from pain and be measured separately because improvements in pain and function often correlate only loosely with one another.[60] For example, trials of opioids for chronic noncancer pain and exercise therapy for low back pain both found considerably smaller benefits according to measures of function compared to measures of pain.[61,62] So how should function be assessed? Performance measures such as a series of timed tasks or an obstacle course may have the attraction of seeming objectivity, but performance can be highly influenced by motivation, mood, setting, financial incentives, and other nonphysical attributes of the patient and his or her environment. Such measures often do not correlate well with how a patient actually functions on a day-to-day basis. By contrast, a number of self-report measures of health status or functional status have been validated and are quite reproducible. Examples include the Sickness Impact Profile[63,64] and the Medical Outcomes Study Short-Form-36,[65] as well as condition-specific scales such as the Roland Morris Disability Questionnaire and Oswestry Disability Index for patients with back pain,[66] the Arthritis Impact Measurement Scale,[67] the Western Ontario and McMaster Universities Osteoarthritis Index physical function subscale,[68] and many others.

To provide a full picture of the effects of pain interventions, the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) recommends that clinical trials routinely measure outcomes in multiple core domains. In addition to pain, physical functioning, and emotional functioning, IMMPACT recommends assessment of participant ratings of global improvement and satisfaction with treatment, symptoms and adverse events, and participant disposition.[59]

Work status is often used as an outcome measure for chronic pain treatment because of its clear relevance to both patients and to society. However, it has a number of drawbacks as an outcome measure, most important of which is that it is influenced by many nonmedical factors. For example, studies have demonstrated that the likelihood of return to work in the face of a painful medical condition varies depending on job satisfaction, relationships with fellow employees and supervisors, regional unemployment rates, the presence of another breadwinner in the family, proximity to retirement age, and physical job demands. Similarly, the duration of pain-related disability is strongly associated with the patient's educational status, income,[69] and the generosity of disability benefits. For many members of our society, including students, homemakers, and retired persons, return to employment is simply not available as an indicator of outcome. Thus, although this measure of outcome is important in many settings, it should be interpreted in light of these potentially confounding factors.

Reporting the Results

Many clinical trials report mean outcome scores, or mean differences in scores compared to baseline values. This can be difficult to interpret clinically, as a 10-point mean improvement on a 100-point scale could indicate that nearly all patients experienced only very mild improvement, or that some proportion of patients experienced a clinically significant improvement while others did not. Reporting the proportion of patients that met a certain threshold for improvement can be very helpful for interpreting the clinical significance of results. The minimal important change, or the smallest change in outcome scores perceived by patients to be meaningful, is a key concept.[70] It refers to the smallest amount of improvement perceived by patients as being important. For low back pain, a consensus group recently proposed a 30% improvement from baseline in pain or function as the minimum important change.[71]

In some studies, actual outcome measurements are not reported. Rather, only the *p* values for the significance of results are provided. A *p* value tells us the probability of obtaining a result that is at least as extreme as the one actually observed, assuming that the null hypothesis of no difference between treatments is true. However, this gives a reader no idea what the magnitude of treatment effects may have been.[72] In a very large trial, a difference between groups may achieve statistical significance even though the difference is too trivial to be clinically relevant. On the other hand, in a very small trial, a large treatment effect might fail to achieve statistical significance. Thus, the magnitude of treatment effect is somewhat independent of statistical significance, and should be reported. An ideal way to present the results is to give the actual estimate of success rates or mean scores along with 95% confidence limits, which allow the reader to see the range of results that would be consistent with the study findings. The 95% confidence limits are closely related to *p* values, but give readers a better understanding of the potential range of effects compatible with the data.

Statistical Power

When a trial shows no statistically significant difference, it is often interpreted as meaning that it has proven that there is no difference between the intervention and control groups. However, this interpretation is often incorrect. In fact, most trials are too small to prove that there is no difference between groups—rather, they only show an absence of evidence of a difference.[73] This is a critical distinction. The likelihood that a true difference may not have been detected is referred to as Type II (or β) error, in contrast to Type I (or α) error (which is reflected in the *p* value).[74] Statistical power (calculated as $1-\beta$) refers to the likelihood that a clinically relevant difference between groups will be identified. Larger sample sizes increase statistical power. On the other hand, statistical power decreases as the size of the clinical effect to be detected (typically the minimal important change) goes down. Nonstatistically significant results should always be interpreted in the context of the statistical power of the study.

Generalizability of Results and Efficacy Versus Effectiveness

Even if a clinical trial is internally valid, its results may not be applicable (generalizable) to other patients and settings. Patients who enroll in low back pain clinical trials, for example, tend to be better educated, more frequently employed, and different in other prognostically important ways from patients in everyday practice[75] Clinical trials often exclude patients with medical or psychological comorbidities, or use run-in periods to identify and exclude patients who experience adverse events before randomizing them. For example, older patients have often been excluded from trials of arthritis drugs, even though they are the most likely to receive such drugs in actual practice. Patients enrolled in clinical trials are usually recruited from tertiary care settings, and the resources available in clinical trials to help maximize patient compliance and follow-up are rarely available to most clinicians. A number of other threats to generalizability have been described.[76] It is important for patients, treatments, and study conditions to be adequately reported so readers can determine whether they would be likely to apply to their own situations.

Related to generalizability is the concept of efficacy versus effectiveness. Most clinical trials are designed to evaluate efficacy, or the benefits of an intervention in optimal populations and under ideal conditions. Such studies generally focus on narrow, short-term outcomes. Effectiveness studies, on the other hand, are designed to evaluate whether an intervention will actually work under conditions encountered in usual practice.[77] Of course, there is a continuum between efficacy and effectiveness, though most randomized trials fall squarely on the efficacy side of the spectrum. Factors that can enhance the ability of clinical trials to evaluate effectiveness are the use of less stringent eligibility criteria, enrollment of patients from primary care populations, evaluation of multiple clinically relevant outcomes, and longer duration of follow-up.[78] Observational studies can also be helpful for evaluating effectiveness, once efficacy has been established in randomized trials.

Subgroup Analyses

Sometimes, analyses are performed to examine whether the effects of an intervention differ in clinically relevant groups of patients defined by some factor (such as baseline pain score, sex, or age).[79] For example, a trial of glucosamine for osteoarthritis found no overall treatment benefit, but a subgroup analysis found that it was effective in patients with high baseline pain scores.[80] There is a great risk that subgroup analyses may be overinterpreted, as results could simply represent chance effects, particularly when data are mined to look for significant results. Confidence in subgroup analyses is enhanced if the treatment effects are large, are unlikely to have occurred by chance, occur in an analysis based on a prespecified and plausible hypothesis, come from a small number of subgroup analyses, and are replicated in other studies.

Effects of Funding Source

Commercially funded clinical trials are consistently more likely to report results that favor the funder than trials that are not commercially funded.[81,82] This appears to be true for devices, such as surgical implants, as well as drugs.[83,84] Why might this be? One reason is publication bias. This refers to the differential tendency for studies to be published depending on the strength and direction of results.[85] Generally, studies that report statistically significant and more strongly positive results are more likely to be published compared to those that report statistically insignificant or less striking results. The result is inflated estimates of treatment effects. Publication bias can occur no matter what the source of funding is, but commercially funded clinical trials appear to be particularly susceptible, either due to overt or more subtle pressures.[82,86,87] A related situation is the selective reporting of outcomes.[88–90] This leads to bias because more favorable results tend to be reported and publicized, and there is often no indication to readers that other (less favorable) outcomes were even assessed. Results can also be spun to appear more favorable than they really are. One study found that of 36 industry-sponsored new drug approval trials of antidepressants viewed by the U.S. Food and Drug Administration (FDA) as having negative or questionable results, 22 had not been published, and another 11 were reported in a way that conveyed positive outcomes.[91] Another questionable strategy that has begun to receive increased scrutiny is the practice of *seeding* trials following new drug approvals.[92] Such trials are framed as scientific research but, in reality, are marketing tools designed to increase familiarity and use of the medication by experienced clinicians.

This is not to say that commercially funded trials cannot be conducted and reported rigorously. However, replication of results in noncommercially funded trials may be required to increase confidence in the findings of commercially funded trials, even when methodological shortcomings are not readily apparent. Statistical and graphical methods are available to formally assess for the likelihood of publication bias, though all have some limitations.[93] The FDA website can be a useful resource for identifying unpublished trials and unreported outcomes, but data are often incomplete or redacted. Ideally, publication and selective outcome reporting bias would not only be detected, but would not occur in the first place. The development of clinical trial registries and mandatory requirements for researchers to submit trial protocols and full results in order to be considered for journal publication, or for new drug approvals, may help reduce the effects of these biases.[94,95] However, the usefulness of clinical trial registries will depend on how assiduously and quickly researchers comply with reporting requirements.

Assessment of Harms

In order to generate balanced conclusions about an intervention, it is important to understand both its benefits and harms.[96] However, benefits have been accorded far greater prominence than harms when conducting and reporting clinical trials. In fact, most randomized trials lack prespecified hypotheses for harms. Rather, hypotheses are usually designed to evaluate beneficial effects, with assessment of harms a secondary consideration. As a result, the quality and quantity of harm reporting in clinical trials is often inadequate.[97]

There are other problems with relying solely on clinical trials to assess harms.[98] Few clinical trials have large enough sample sizes or are long enough in duration to adequately assess uncommon or long-term harms. For example, one systematic review found that trials of opioids for chronic noncancer pain averaged only 5 weeks in duration, even though patients frequently remain on these medications indefinitely.[61] In addition, patients who are more susceptible to adverse events are often excluded from clinical trials, though they may commonly receive the therapy in clinical practice. For example, all trials of opioids for chronic noncancer pain that reported information on history of drug addiction excluded such patients.[61] Harms may also be downplayed or misrepresented if there is a vested interest in doing so.[99] Aggressive promotion of unsubstantiated claims of lower abuse, diversion, and withdrawal risks of OxyContin (Purdue Pharma, Stamford, CT), a sustained-release formulation of oxycodone, eventually resulted in a criminal conviction and $634 million fine against the Purdue Frederick Company, Inc., along with three company executives.[100]

Assessment and reporting of harms in clinical trials can certainly be improved. This is also an area where observational studies can be a very useful source of information. Unlike assessments of treatment benefits, confounding by indication is usually not an issue with unexpected or unpredictable adverse events because such outcomes are not related to the decision to use the therapy.[31,101] An example would be the observational studies on risk of myocardial infarction associated with cyclo-oxygenase-2 selective NSAIDs. Those conducted prior to knowledge regarding the cardiovascular risks of rofecoxib were unlikely to be affected by confounding by indication related to the baseline risk of heart disease. Observational studies can also provide important information on rare or long-term adverse events and in populations under-represented in clinical trials (such as pregnant women, children, older adults, or those with important comorbidities). Even uncontrolled studies such as case reports have been invaluable for evaluating harms, and may be the first or primary signal of a rare adverse event.

Trial-based Cost-effectiveness Analysis

Even if the balance of benefits to harms of a treatment is acceptable, widespread implementation may not make sense if costs are very high. Clinical trials can also be designed to assess the question "Is it worth it?" by collecting cost data alongside clinical outcomes.[77] Unlike decision analytic studies that model costs and clinical outcomes, such trial-based cost-effectiveness analyses directly measure the cost per some increment of clinical utility (often a quality-adjusted life-year). One challenge with cost-effectiveness analyses of clinical trials is that cost data are often associated with large variability, so estimates can be imprecise unless sample sizes are large.[102] In addition, distributions of cost estimates are often quite skewed, which can pose a statistical challenge.

NEW DIRECTIONS IN CLINICAL TRIALS

Pragmatic Trials

With increased attention to effectiveness has come an increased demand for pragmatic trials that attempt to inform routine clinical practice better than traditional efficacy trials. Key features of pragmatic trials are that they are set in normal practice settings rather than highly specialized or controlled settings, apply few exclusion criteria, allow flexibility in use of treatment interventions, and assess key, patient-centered outcomes.[103] For example, a pragmatic trial of acupuncture for chronic low back pain was conducted in general practice and private acupuncture clinics in the UK, enrolled anyone aged 18 to 65 with nonspecific low back pain of 4 to 52 weeks' duration (with few exclusion criteria), allowed acupuncturists to determine the content and number of treatments, and evaluated bodily pain as well as outcomes related to use of analgesics and patient satisfaction.[104]

Expertise-based Trials

For nonpharmacological interventions, such as surgery, that are highly dependent on the skill and training of the clinician, expertise-based randomized controlled trials have been proposed.[105] In the traditional randomized controlled trial, participants are randomized to one of two interventions and individual clinicians provide intervention A to some patients and intervention B to others. In the expertise-based randomized trial, participants are randomized to individual clinicians with expertise in intervention A or to clinicians with expertise in intervention B. Proposed advantages of expertise-based randomized trials are that they can reduce the effects of differential expertise bias. In the case of surgery this can be important because many procedures require considerable experience to gain proficiency. In addition, the expertise-based design reduces potential effects of differential enthusiasm or skepticism for the different procedures, as each surgeon provides only the procedure that he or she believes is the best. As yet, however, there is relatively little evidence on the validity of expertise-based randomized trials.

Comparative Effectiveness

Another direction in clinical trials is toward increased evaluations of not just effectiveness of interventions versus placebo, but comparative effectiveness of two or more interventions.[106] Head-to-head trials that compare two interventions are the most direct method for evaluating comparative effectiveness. However, head-to-head trials are not always available. An alternative method for evaluating comparative effectiveness is through indirect comparisons. This refers to assessments of the relative benefits and harms of competing interventions based on how well each performs against a common comparator (usually placebo). Methods are available for conducting indirect comparisons that preserve some of the benefits of randomization, as well as for more complex network analyses and mixed treatment comparisons that incorporate both indirect and direct evidence.[107] In all cases, the validity of indirect comparisons is based on the critical assumption that treatment effects are consistent across all trials. This assumption can be violated due to a number of factors, including differences in study quality, patient populations, settings, outcomes, and other factors. In fact, large discrepancies between indirect and direct studies have been reported. For example, in patients with neuropathic pain, an indirect comparison found tricyclic antidepressants associated with a much higher likelihood of achieving pain relief compared to gabapentin, but head-to-head trials found no significant difference.[108] Indirect comparisons should only be used when the critical assumption of similarity of treatment effects is met, and verified against results from head-to-head trials as they become available.

Equivalence and Noninferiority Trials

Traditional clinical trials are designed to determine whether an active treatment is superior to another treatment (often placebo). The null hypothesis is that there is no difference between the treatments being compared. In equivalence trials, on the other hand, the purpose is to determine whether one (typically new) intervention is therapeutically similar (equivalent) to another, usually established, treatment.[109] This requires testing of a different null hypothesis—specifically the null hypothesis that there *is* a difference being treatments. Noninferiority trials are similar to equivalence trials, but they are designed to focus on whether a new treatment is no worse than (rather than therapeutically similar to) an established treatment. For either type of trial, boundaries for what will be considered equivalent or noninferior must be defined in order to perform appropriate hypothesis testing. Unfortunately, many trials that report equivalence do not define these boundaries, or are based on misapplied or misinterpreted statistical analyses, often based on standard superiority hypotheses or inadequate sample sizes.[110] Guidance is available to help improve the conduct, reporting, and interpretation of equivalence and noninferiority trials.[109]

Factorial Design

In a factorial design, patients are simultaneously randomized to receive or not receive two different treatments.[111] In the UK Back

Pain Exercise and Manipulation (BEAM) trial, for example, patients were allocated to receive exercise therapy versus no exercise therapy and to receive spinal manipulation or no spinal manipulation.[112] Such factorial designs have important efficiencies if the dropout rate is low. If there is no statistical interaction between the two treatments (in this example, exercise therapy and spinal manipulation) then one has an unbiased assessment of the effect of each treatment. Such designs might be useful in studying combinations of therapy such as an analgesic plus a muscle relaxant, drug therapy plus physical therapy, and other clinically relevant combinations. Indeed, factorial designs may be the best way to evaluate the multicomponent therapy that is widely advocated for the treatment of chronic pain. If there is no synergy between treatments, the investigator essentially has two trials for the price of one. If there is synergy or additive effects between treatments, there is no other way to identify this effect. Factorial designs introduce analytical complexities that are avoided in simple parallel designs, but in some circumstances, the benefits may outweigh the disadvantages.[113]

Bayesian Statistical Inference and Adaptive Designs

Another direction in clinical trials is the use of Bayesian frameworks of statistical inference instead of the standard classical (frequentist) framework.[114] Although a full discussion of Bayesian statistical inference is beyond the scope of this chapter, in essence the Bayesian framework incorporates new evidence or observations to update probabilities that a hypothesis might be true. Bayesian adaptive trials use Bayesian methods to incorporate data collected during the course of a trial in order to inform decisions regarding the need to update, modify, or stop the trial.

SYSTEMATIC REVIEWS

The relatively rapid advances in other fields of medicine, such as oncology and cardiology, occur because a succession of large randomized trials, typically implemented in multiple centers, result in cumulative knowledge. Such large, multicenter trials are still the exception rather than the rule in pain treatment, perhaps in part because of lower research funding for nonfatal conditions. Nonetheless, more pain research trials are being conducted, resulting in an ever-growing body of literature. This growth has been exponential. Between 1950 and 1990, more than 8000 randomized controlled trials of pain research were published, with over 85% appearing during the last 15 years of that period.[115]

Given the amount of evidence, it is difficult for clinicians to keep up with the literature on even a circumscribed area of medicine. Review articles can be a useful way to summarize the evidence on a given topic. A systematic review is a particular type of review article that applies explicit methods to reduce bias and error when summarizing evidence.[116] This is in contrast with traditional or narrative reviews, which do not use explicit methods to identify, select, and assess evidence. Such review articles are relatively subjective and are apt to be based on incomplete, outdated, or flawed evidence. This increases the likelihood of incorrect or unsubstantiated conclusions.

A systematic review attempts to bring the same level of scientific rigor to the review article as should be used when conducting original research. Systematic reviews can be qualitative or quantitative. The latter are also referred to as meta-analyses even though, strictly speaking, a meta-analysis is not necessarily based on systematic methods. Potential advantages of systematic review over traditional review articles are shown in Table 10.8. A high-quality systematic review minimizes bias and random error by using transparent, reproducible, and objective methods. In addition to summarizing existing data, systematic reviews can also increase statistical power for evaluating low frequency events, provide more precise estimates of treatment effects, permit formal comparisons between studies, permit formal assessments of publication bias, and help delineate areas of uncertainty.

TABLE 10.8

POTENTIAL ADVANTAGES OF SYSTEMATIC REVIEWS OVER NARRATIVE REVIEWS

Designed to address a focused clinical question
Describes explicit methods used to identify as many of the relevant trials as possible
Reports literature search dates
Describes and applies predefined study inclusion criteria
Formally assesses characteristics of studies associated with biases
Follows explicit methods for weighing and synthesizing studies
Can pool studies quantitatively, leading to more precise estimates and increased statistical power
Can test for statistical heterogeneity and explore reasons for heterogeneity through subgroup, sensitivity, and other analyses
Research gaps and areas of uncertainty more clearly delineated
Can test for and estimate effects of publication bias on results
Conclusions more directly linked to data and analyses

Before trusting the results of systematic reviews, it is important to critically evaluate whether rigorous methods were used. In fact, results of lower quality reviews can be misleading, as they are more likely than higher quality reviews to produce positive conclusions about the effectiveness of interventions.[115,117] Table 10.9 lists some factors that can influence whether a systematic review is likely to be reliable. A number of other methods for assessing the quality of systematic reviews are available, including the more detailed list of criteria in the Assessment of Multiple Systematic Reviews (AMSTAR) tool.[118] All quality rating methods are based on the idea that systematic reviews that are comprehensive, up-to-date, and use appropriate methods to identify, select, assess, and synthesize the literature are more likely to provide a complete and unbiased picture than those that use suboptimal methods.

The Cochrane Collaboration is an international effort to systematically review the results of multiple randomized clinical

TABLE 10.9

FACTORS TO CONSIDER WHEN ASSESSING QUALITY OF SYSTEMATIC REVIEWS

Was the search comprehensive?
Was selection of studies unbiased?
Is the systematic review current?
Was quality of included studies appropriately assessed?
Was evidence combined and summarized appropriately?
Was publication bias assessed?
Are the conclusions justified?

From Chou R. Using evidence in pain practice. Part I. Assessing quality of systematic reviews and clinical practice guidelines. *Pain Medicine* 2008;9:518–530, with permission.

trials and make the results widely available via the Internet. The number of Cochrane reviews on pain topics is rapidly expanding, and many have been published in conventional journals as well as in the Cochrane Library.

CONCLUSION

Despite the rapid growth of research literature on the treatment of pain, there remain wide variations in care and the successive use of fads that are later demonstrated to be ineffective when well-designed studies are performed. Both the prevalence of painful conditions and their associated disability are increasing, and there is only a limited professional consensus on optimal approaches to many painful conditions. The disappointing pace of progress may be partly the result of few comprehensive theories that would guide treatment innovations. However, an equally important factor may be the methodological inadequacy of the research used to justify the introduction of new or innovative therapies to clinical care. Flaws in research design jeopardize not only the internal validity of research results, but also their generalizability to routine clinical practice. Greater attention to scientific principles in the design of clinical research should accelerate progress in this area, lead to more consistent clinical practices, and improve patient care.

CHAPTER 11 ■ SOCIOCULTURAL DIMENSIONS OF PAIN MANAGEMENT

DAVID B. MORRIS

"Chronic pain is a transdermal phenomenon and the environment is always a player in the chronic pain patient's predicament."
—J. D. Loeser[1]

INTRODUCTION

"A threshold has been crossed," writes sociologist Nikolas Rose.[2] Rose is Director of the BIOS Centre for the Study of Bioscience, Biomedicine, Biotechnology and Society at the London School of Economics and Political Science. He wants to avoid what he calls "breathless epochalization"—a sense that history is undergoing an abrupt massive transformation—and he understands the present as the unfolding of "multiple histories" that emerge from the intersection of numerous "contingent pathways." Nonetheless, he also provides in *The Politics of Life Itself* (2007) an indispensable framework for considering how much has changed since the first edition of John Bonica's ground-breaking text *The Management of Pain* (1953). Pain too has changed, especially chronic pain, as pain has moved from the status of symptom to diagnosis, from the category of what humans passively endure (a mark of our changeless humanity) to what patients and health professionals together, as partnered agents of somatic change, now actively manage.

The single change that Rose sees as the embodiment of our unfolding multiple histories of the present and future is what he calls "a molecular vision of life." Contemporary medicine and the biotechnologies on which it relies increasingly understand life at a sub-cellular level and with consequences that extend far beyond the old categories of illness and health, of pathology and normality, of treatment and enhancement. The new techno-medicine, he argues, does not just cure disease or correct organic damage but, in its promise to refigure human vital processes at the molecular level, even changes "what it is to be a biological organism."

What it is to be a biological organism has always included vulnerability to pain. Not only has pain changed since 1953—including the volume of research devoted to eliminating it—but also pain patients. Today traditional patients have often been transformed into well-briefed self-educated medical consumers, relentlessly informed (or misinformed) by Internet sites and by ad campaigns. Often too (in addition to their newly self-aware status as proto-plaintiffs) patients accept a role implicit in the molecular gaze as they embrace a unique "genetic citizenship."[3] Test the fetus for Down syndrome. Regulate your cholesterol. Find the gene for pain and knock it out. Never mind that most researchers do not seek a single specific "gene for" but rather variations in multiple loci within multiple gene systems, with resulting wide distribution of phenotypes and of susceptibilities. Chronic pain, once a burden, is now a scandal. No longer a predictable companion of old age or a fact about the human condition, chronic pain represents an unaccountable failure of the molecular gaze to identify a local culprit neuron, a shameful lockout from the promise of somatic optimization. The damage that chronic pain inflicts on body, mind, and spirit leaves many patients not at the threshold of a shining future but in a futureless limbo.

What follows, then, is an effort to place the new understanding of pain within a conflict-rich field where sociocultural explanations often run counter to the expectations of a molecular gaze that extends far beyond medicine. Today the push for cellular microtherapies and extreme bioengineering may come less from doctors than from patients. ("Hey, doc, can't we inject some stem cells into it?") The dilemma that has developed over the past 50 years, clearer to physicians than to patients, is that chronic pain, in its numerous types from migraine to cancer, is often as amenable to sociocultural analysis and to psychosocial therapies as to biomedical cure. Clearly it is an advance to understand gout as a type of congenital arthritis—not, as in this 19th-century etching (Fig. 11.1), a moral punishment for aristocratic luxuriousness.

The pain of gout, however, clearly correlates not only with molecular processes affecting serum uric acid levels, but also with psychosocial forces underlying diet.[4] What most patients don't know about chronic pain—its links with beliefs, cultures, and social practices—is exactly what an evidence-based, best-practices pain treatment in the era of the molecular gaze cannot ignore.

WHAT IS TRANSDERMAL PAIN?

Pain, especially chronic pain, is a transdermal phenomenon in that it occurs not only within an individual nervous system, including the brain, but also within a social and cultural environment. "Our concepts of pain, impairment, and disability," writes Wilbert E. Fordyce, "must consider environmental factors as well as the person."[5] Clinical practice frequently reduces environmental factors to three main stressors—employment, family, and alcohol or drugs—but this trio can serve as placeholder for a more extensive mix of sociocultural variables. The fundamental question is whether the sociocultural environment merely *influences* pain that already exists as a purely biological phenomenon, simply modulating it, or does the sociocultural environment (beyond mere influence and modulation) help to *construct* and to *constitute* pain.

The difference between influence and construction is significant, with a possibly direct impact on treatment. A theory of influence understands pain as independent of environmental factors, which provide mere triggers or nuances. For influence theory, the individual nervous system alone generates pain, and pain is solely a somatic event, to which the social or cultural environment adds mere modifications. Modifications add local color—such as an honor-driven suppression of a mother's cries in childbirth—but the social environment does not help construct the pain. A theory of construction, by contrast, sees human pain as coming into existence *only* as an individual nervous system

FIGURE 11.1 George Cruikshank. *Introduction of the gout*. 1819 (This impression 1835). Colored etching. (Courtesy of the Wellcome Library, London.)

encounters a specific sociocultural environment. The environment does more than trigger, modify, or color pain—it helps to *constitute* pain. Minus a sociocultural context intrinsic to mental life, the transmission of nociceptive impulses may generate autonomic responses, the human equivalent of a tail flick, but nociception alone does not constitute human pain, which, according to the prestigious International Association for the Study of Pain (IASP) in its classification of pain terms, is "always a psychological state."[6]

Influence theory and construction theory both marshal strong arguments and persuasive evidence, and quick resolution seems unlikely, even unnecessary. The important point here is that most pain specialists today attribute a significant role to the sociocultural environment—a truly historic change in thinking about pain and pain management. This recent transformation in thinking about pain has important implications for pain management. "Prior to 1960," writes John Loeser, "there were no pain specialists. Only one pain textbook had been written—the first edition of *Bonica's Management of Pain*, published in 1953. It was mainly the work of one man. There were no journals devoted to pain, no dedicated research laboratories, and no funding programs aimed at pain research or training for clinicians. . . . Pain was always described as a byproduct of a disease state; the implication was that proper treatment of disease would relieve pain. The sensory nervous system was envisioned as a passive set of wires that conducted incoming impulses to the brain."[7] The molecular gaze, as it intensified its focus, provided not only a greatly revised picture of the human nervous system but also a new understanding of pain.

The Management of Pain, in its first edition, contained no discussion of sociocultural environment. Herbert S. Ripley contributed a brief chapter entitled "The Psychologic Basis of Pain," which came after far more substantial chapters on the anatomical, neurophysiological, and physiopathological basis of pain, but there was little follow-up beyond another chapter by Ripley, "Psychotherapeutic Methods in the Management of Pain." Pain, nonetheless, had decisively entered a new domain of medical management. It is largely due to Bonica and to his colleagues in the emerging field of pain medicine that patients today no longer regard pain as a mostly inescapable aspect of the human condition but rather—in the tradition of the molecular gaze—a treatable, manageable disorder. The transformations that followed *The Management of Pain*, however, consistently expanded an awareness of how far the molecular gaze alone is insufficient.

The new managers of pain, if a sociologist might highlight what doctors regard as self-evident, are now doctors and health care professionals. What matters in this truism is that medicine and health care now account for 16% of the U.S. gross domestic product and, in any nation, cannot be cordoned off from the surrounding culture and subcultures. The surrounding culture interpenetrates medicine and health care, just as cultures and subcultures today are inescapably medicalized. Pain too has been medicalized in the (once not obvious) sense of calling for scientific-technical knowledge—rather than, say, for trepanation, prayer, or home remedies. The medicalization of pain, which patients and doctors may both regard as necessary, is not without consequences, especially when medical care fails. A sociocultural perspective thus needs to emphasize that pain medicine is not a neutral byproduct of scientific knowledge. Pain medicine too belongs to a new sociocultural environment that influences and helps to construct pain. That is, many patients experience pain only within a context that includes pain specialists, both official and unofficial, from orthopedists, oncologists, and neurologists to acupuncturists and homeopaths. Pain specialists cannot excuse themselves from discussion as if they were mere impartial technicians, objective researchers, or altruistic caregivers—who analyze and treat pain but do not affect how patients understand or experience it. Pain specialists are among the players in the new sociocultural environment that helps constitute the chronic pain patient's predicament.

The new active role for pain specialists is certainly driven by patient demand, but not *solely* by patient demand, and it also cannot be ignored as inconsequential. When clinicians employ evidence-based practices, chart pain as a vital sign, or "game" insurance systems on behalf of patients, their actions contribute to the creation and maintenance of a significant new sociocultural environment within which patients experience pain. Although pain medicine did not invent insurance payers and disability systems, it operates today within a field of economic compensation that sets patients in an altered relationship to their pain. In a controversial recommendation, an IASP task force argues that chronic nonspecific low back pain in the workplace, in the absence of an organic lesion and under specified circumstances, should be reconceptualized not as a medical problem but as "activity intolerance."[8] *Activity intolerance* is less a diagnosis than a counter-narrative meant to contest the sociocultural script that redeems chronic low back pain for disability payments and for freedom from job obligations. From the patient's perspective,

the not-inevitable passage from citizenship to patienthood—from person-in-pain to pain patient—involves an invisible phenomenology of forms to fill out, waiting rooms, secretaries, insurance companies, drugs, side effects, disability systems, referrals, more waiting rooms, indignities, task forces, protocols, and waiting rooms.[9] In short, it involves a web of sociocultural interrelations that reframe pain.

FROM INFLUENCE TO CONSTRUCTION: ETHNICITY, RACE, SEX, AND GENDER

The irony is that, while patients increasingly embody the expectations of a molecular gaze, pain medicine finds increasing evidence to support a nonmolecular and sociocultural understanding of pain. Culture and biology both contribute to pain, as a biopsychosocial model implies, interweaving distributed neural networks with rites of passage or disability payments. Although a sociocultural perspective cannot provide a full account of pain, even an openly lopsided account here helps illustrate how human pain is always intersubjective. It depends on social systems from family, church, and nation to jobs and prisons, just as it meshes with variable cultural practices from stoic dispassion to pharmaceutical trials. Of course, some people defy social systems and oppose cultural norms. Even exiles, immigrants, strangers, and renegades, however, cannot wholly live outside the social environments that help shape their resistances. Sociocultural environments are not places, not material locales that you might conceivably be outside of, but internalized subsets of a surrounding *lifeworld* experienced as a state of body, mind, and emotion. Such states remain accessible in memory even when people change locale. Chronic pain, as a mind/body state, is inextricable from the sociocultural lifeworlds that shape it.

There is no question that sociocultural environments shape pain. The relation, however, seldom reduces to a direct connection in which culture *causes* pain, in the sense that stress, say, triggers the biological cascade that produces a tension headache. (Cultures, however, certainly can cause stress.) Data are often conflicting or inconsistent, as in laboratory studies about racial tolerance for thermal pain,[10] especially where underlying categories such as race are poorly defined. Some links between pain and its sociocultural environments, however, are clear and correctible. In New York City, nonwhite patients (often blacks and Hispanics) who lived in disadvantaged neighborhoods had substantially less access to pharmacies than did white patients in affluent neighborhoods. Moreover, the pharmacies in disadvantaged areas did not maintain adequate stocks of pain medication.[11] A sociocultural environment that reduces access to medication indirectly but clearly has an impact on pain. Although reduced access did not directly cause pain, it surely *maintained* pain (pain *eliminated* in other communities) through unequal and unfair social practices.

The 1996 SUPPORT study demonstrated that 50% of hospitalized seriously ill or dying patients failed to receive adequate pain medication.[12] Hospitals, like doctors, belong to the larger sociocultural environment, an environment defined by drug abuse and opioid-phobia, and here too the environment indirectly but clearly influences pain. Researchers can disentangle pain from indirect environmental influences, at least theoretically or in the lab. Anesthesia erases pain, temporarily, by targeting the nervous system alone, not the environment. The paradox, however, is that anesthesia belongs to the sociocultural environment of the hospital, just as illegal street drugs belong to the sociocultural environment of the street. Pure pain—pain free from all direct or indirect sociocultural influence—is a pain that exists nowhere except in theory.

Race and ethnicity are frequently discussed in recent studies on pain, but discussion is often impeded by failures to clarify underlying concepts. Numerous researchers report ethnic differences in the prevalence and severity of pain, and they find interethnic differences in tolerance levels for clinical and experimentally induced pains.[13] Attitudes toward pain, for example, show sharp differences along ethnic lines among surgical patients in Australia.[14] Yet, just what *are* ethnicity and race? Ethnicity is traditionally defined as perceived cultural distinctiveness, while race refers to perceived physical and biogenetic characteristics. The medical literature on ethnicity and pain is extensive enough to have drawn several review articles.[15,16] One review concluded that racial and ethnic disparities in pain perception, assessment, and treatment are found in various medical settings and across all types of pain.[17] The crucial point, however, despite mixed data and questionable assumptions, is that both ethnicity and race affect pain mainly through sociocultural influences, not (with a few exceptions such as sickle cell pain) through specific common genetic traits.

Pain specialists need to engage with recent thinking about race and ethnicity. While a few single-gene defects are responsible for the handful of diseases typical of specific groups, such as Tay-Sachs disease among east European Jews, there is no genetic signature for race. Skin color is a surface similarity that links population groups as different as their languages: say, Italians and Swedes, Scots and Russians, Belgians and Croats. Blackness, as a racial category, includes both West Africans and the historically very different East Africans, as well as Haitians, African Americans, some Hispanics, and various hyphenated groups linked mainly by skin color. The census term "Asian" has a different meaning in Europe than in America, and census data in Western democracies make race and ethnicity a matter of self-identification. In general, there is more genetic variation within (so-called) races than across races, and biological anthropologists regard both race and ethnicity as social rather than genetic categories.[18] The recent turn in health care discussion tends to emphasize *population groups*, where biology and genetics are relevant but not determinative. Rose summarizes this recent movement away from reductive ideas of racial science: "Key, here, is not so much race, but the belief that a particular community has specific health needs that may have a genomic basis, and that research on the genomic basis is essential if these needs are to be met."[19] Population groups, once relatively stable, are now increasingly open to intermarriage and to health-related cultural differences between immigrants and their acculturated offspring.

Race and ethnicity, then, may correlate with the specific health needs of a population group based on genomic difference, but as social categories they are malleable, contentious, and open to historical forces, especially forces associated with discrimination and intolerance. Their influence on pain management is both indirect and direct. Over half of Hispanics who presented at emergency rooms with long bone fractures did not receive pain medication and were twice as likely as similar white patients to go without pain medicine.[20,21] Clearly, medical degrees do not confer immunity from conscious or unwitting acts of discrimination. Although many blacks carry a gene that puts people of African descent at risk for sickle cell disease, their need for pain relief too often runs up against medical suspicions of drug-seeking behavior.[22,23] The history of sickle cell pain warns, like the Tuskegee syphilis experiments on black airmen, about the danger of open or covert racist attitudes within medicine that can influence pain treatment and its absences.[24,25]

Race and ethnicity may one day indicate special needs for pain medication based on genomic discoveries, but today pain management needs to focus on failures of delivery. African American cancer patients in nursing homes were 63% more likely than whites to receive no pain treatment.[26] Other minorities with cancer pain also experience inadequate pain relief[27]—in dispropor-

tion to the generally inadequate relief for all cancer patients. The unequal worldwide distribution and consumption of morphine means that adequate medication for pain is far more available to white patients than to nonwhites.[28,29] This difference is not mainly a function of income. The U.S. campaign against illegal drug trafficking makes inadequate pain relief for Mexican patients largely political in origin, wired into the sociocultural environment.[30] Pain management, in confronting questions about clinical policy and research design, must recognize that race and ethnicity are ill-defined and socially explosive categories dangerously associated with patient stereotypes. The categories apply (and mis-apply) not only to patients but also to the attitudes, beliefs, and sociocultural environments of providers and of institutions.

Sex and gender raise additional complications in assessing sociocultural influences on pain. Animal studies indicate differences between male and female rodents in pain processing, including a greater efficacy of mu-opioids in males. In humans, kappa-opioids produce significantly greater analgesia in women than in men.[31] Red-haired women (in a study that did not test men) show increased sensitivity to thermal pain and reduced responsiveness to subcutaneous lidocaine, because of specific mutations of the melanocortin-1 receptor.[32,33] Biologically based sexual differences play a role in women's pain across a range of chronic pain conditions from migraine to irritable bowel syndrome, although the precise mechanisms are often unclear. Sex steroid hormones in men and women appear to modulate different nociceptive behaviors. Pregnancy, for example, whatever its sociocultural influences associated with pain, creates an antinociception that involves delta-opioid and kappa-opioid but not mu-opioid systems.[34]

Gender differences further complicate the analysis of pain, splintering the neat sexual male/female binary into a rainbow of orientations from gay and lesbian to transgender. While a number of pain researchers examine male and female differences, there are few reliable studies exploring gender as distinct from sexual difference. One persuasive argument holds that gender is largely performative: that is, gender—no matter how individual, eccentric, or dependent on hormone therapies—constitutes a quasi-public social role.[35] The women whom Charcot photographed in his famous hysteria wards in the 19th century clearly "performed" their illness for the camera, even if unknowingly, and today women tend to perform gender roles (as overextended caregivers, for example) that are sociocultural and not entirely unrelated to pain. The same observation applies to men. Pain differences in males and females are biological, but differences in men and women are *both* biological and sociocultural. A treatment program that recognizes the complicating roles of sex, gender, ethnicity, and race—including the openness of these categories to redefinition—is well equipped to understand the multiple lines of causation and of influence that so often converge in chronic pain.

The complex interrelations between biology and culture raise a crucial question for pain management programs. Is it necessary to distinguish biological processes from sociocultural influences? Yes, where possible and with caution, for two reasons. First, drugs and surgery can sometimes erase pain associated with clear organic sources. Back pain, however, especially chronic nonspecific low back pain, exposes the limits of drugs and surgery where sociocultural forces—such as family, job, and disability—are prominently involved. Furthermore, organic lesions do not map exactly onto pain. Most adults who complain of back pain have lumbar disk disease, but so do many adults without pain complaints.[36] In America, long-term functioning of patients treated for back pain is similar whether doctors prescribe medication and bed rest or self-care and education.[37] Pain simply does not provide an accurate report of tissue damage. "The truth is that pain is a very poor reporting system," writes Patrick Wall. He adds: "The doctrine that pain is a useful signal needs heavy qualification."[38] The erroneous belief that pain is a reliable alarm system not only justifies countless unnecessary surgeries but also cannot begin to explain why the two strongest signs predicting that an American worker will develop chronic back pain are job dissatisfaction and unsatisfactory social relations in the workplace.[39,40] It is as if the American low back is wired directly into the sociocultural work environment.

Second, one benefit of separating out sociocultural influences lies in the possibility of system-wide change in pain management. In 1999, a memorandum directed to over 1200 sites required the entire U.S. Veterans Health Administration to make policy and procedural changes implicit in the new principle that pain is the *fifth vital sign*.[41] At one VA outpatient clinic this change produced no improvement in pain-management quality,[42] but the possibilities for system-wide change are impressive. A similar directive altered policies in pain management and in palliative medicine throughout all the hospitals in the vast southwest region of the U.S. Indian Health Service.[43] Such changes acknowledge that pain medicine belongs to a surrounding sociocultural environment that includes the changing subculture of medicine. Systemic changes in pain management thus can influence not only the experience of individual patients but also the wider sociocultural environments within which patients and also nonpatients experience pain.

Can systemic changes in the sociocultural environment of medicine alter individual experience and relieve pain? The IASP defines pain as "always subjective."[44] Pain, by implication, will change when a person's subjective state sufficiently changes. Suppose that a woman from a low-income neighborhood repeatedly fails to receive adequate pain medication from her local pharmacy. Repeated frustration, humiliation, and rage constitute a significant change in her subjective state. Such damaging psychological and emotional changes, along with changes in any presumed neurobiological substrates, arguably will alter her pain for the worse. Fear, as researchers consistently show, elevates pain intensity.[45] Pain specialist Mark Sullivan argues that pain *is* an emotion.[46] Quantitative and qualitative studies are needed to show if and how systemic changes might alter individual subjective experience and thereby alter pain. Patient education and improved access to care offer two promising areas for systemic change. Effective systemic changes in pain management generate additional evidence for the importance of sociocultural environments in shaping and reshaping the individual experience of pain.

ACROSS CULTURES: PAIN BELIEFS AND PAIN BEHAVIORS

Pain varies across individuals, cultures, and times. This strong claim contradicts the universalist view that pain is a changeless sensory signal, identical in everyone, everywhere. It has been demonstrated, at least in women, that sensitivity to a variety of experimental thermal, mechanical, and chemical pain-producing stimuli has a genetic contribution.[47] Universalists, however, cannot explain why individual variations in reported pain intensity produced by exposure to an identical noxious stimulus correlate directly, as functional magnetic resonance imaging (fMRI) studies indicate, with altered brain patterns.[48] Most researchers agree that pain includes both sensory and *affective* components. These affective components of pain show wide variation across individuals and cultures. Paid volunteers in an experiment were told that exposure to an electrical stimulator might possibly produce pain, but researchers deliberately did not explain that the stimulator was set to produce nothing beyond a harmless hum. Fully one half of the volunteers, on hearing the hum, reported pain.[49] Such significant variation in pain reports no doubt involves the biopsychology of expectation,[50,51] as well as at least a passing cultural

familiarity with electronics. The fact that pain and its related brain states vary significantly among individuals exposed to a similar or identical sensory stimulus is nonetheless well established by various forms of quantitative data. True, it is reported that 1950s-era surgically lobotomized patients could still feel pain but said that the pain no longer *bothered* them. It may require a philosopher to decide whether pain that fails to bother us counts as pain. (It won't often show up at pain management centers.) Pain that is wholly affect-free, however, constitutes a self-contradiction.

Real world pain, then, is characterized by an affective quality of aversiveness open to wide modulation. This aversiveness depends on cortico-limbic networks, much as anxiety correlates with activity in the septo-hippocampal system, but emotions are also in part socially constructed and socially modified.[52] Stoic philosophers exalted the use of reason to modify normal pain behavior. "If you desire to master pain/ Unroll this book and read with care," wrote an unknown Byzantine poet in verses regularly copied with the *Meditations* of Roman emperor Marcus Aurelius.[53] Athletes, dancers, yogis, and religious celebrants continue to demonstrate how minds, emotions, and sociocultural environments help modify pain. Environments are not neutral containers for bodies in pain—like mere stage sets. Environmental toxins affect human biology, and sociocultural forces shape human pain. Pain is not *contained* by the environment but influenced and very possibly *constituted* by the social and cultural world. Even the clinic and research lab are sociocultural spaces. They help shape inchoate sensation into pain as surely as ancient religions shaped pain through doctrines of demonic possession. Aversiveness and affect are, in part, learned, and whatever we learn (including what we know and fear about pain) is open to wide variation, to personal modulation, and to targeted sociocultural re-education.

Cross-cultural studies of pain further demonstrate this inherent variation. Chronic low back pain patients in Japan were compared with a similar group in the United States and found significantly less impaired in psychological, social, vocational, and avocational function.[54] Pain evoked in a laboratory setting may differ from everyday pain experienced outside the lab,[55] and outside environments include not only tangible institutions such as families, schools, and workplaces but also intangible feelings and beliefs. Beliefs and feelings often intertwine, and the resulting synergy can affect pain. The general proposition that all men are mortal, for example, is less potent than if intertwined with the particular belief that my own pain signals a brain tumor. Pain beliefs thus are less general propositions than culturally specific, affect-rich, cognitive nodes of hope, fear, and expectation. Catastrophizing—a compound of extreme fear, belief, and expectation—proved the single most important predictor for quality of life in chronic pain patients.[56] Intertwined feelings and beliefs associated with pain are never wholly private, subjective, and inaccessible, as some claim, but, crucially, both personal and *intersubjective*.

Intersubjectivity, as a phenomenon in health care, is understudied, but recent findings about obesity, based on data from the Framingham Heart Study, offer a powerful indication of its importance to illness. Obesity, according to surprising research data, appears to spread through social ties—a finding, as researchers say, that has implication for clinical and public health interventions.[57] Chronic pain too is shaped by social ties. Specific cultures encourage distinctive beliefs about pain, which come to constitute social norms that underlie distinctive practices and behaviors. These normative practices and behaviors, like the beliefs that support them, prove amenable to observation. In fact, observation of pain beliefs (via questionnaire) is a robust sub-discipline within pain medicine.[58–60] Current studies of pain beliefs focus on the big three—catastrophizing, control, and disability—but researchers are beginning to study more diverse cognitive/emotional states associated with religious faith and spiritual practices[61] as well as attitudes about personal identity and self-efficacy.[62] Future studies might well expand their methods and focus to include narrative data. Cultural and personal narratives, as a vehicle for the communication of complex beliefs and feelings, help shape the pain that we live out.[63]

Transdermal pain, then, is not a subclass of pain, but rather an encompassing tautology: all pain, especially chronic pain, is transdermal. It is shaped, invisibly, by sociocultural and intersubjective forces. This counterintuitive claim seems berserk to a weekend handyman who has just hammered his thumb. The common sense sequence is hammer, tissue damage, pain. Like vision, however, common sense is the product of a developmental process that takes place only within a cultural context. (Long-blind adults who recover their eyesight often cannot adjust to the flood of unedited visual information.[64]) Pain too depends on developmental learning and cultural editing. Ice packs on a throbbing thumb invoke an elementary cultural education, as does the limited belief that pain correlates directly with tissue damage. Chronic pain requires a personal and cultural re-education in which talk of neural pathways, genetic susceptibilities, and neurotransmitters is compatible with research into modulating sociocultural variables.[65] Even neuropathic pain in laboratory rats appears to show the impact of rodent-specific social variables.[66] While the literature on sociocultural variables is too vast to review here, future research needs to contemplate two large issues so far merely touched upon: globalization and narrative.

PAIN AND GLOBALIZATION: POWER, MONEY, SYSTEMS

In *Power & Illness* (1977), sociologist Elliott A. Krause shows how health and health care are "intimately involved with the political, economic, and social struggles of the present day."[67] Krause studied power as oppressive and coercive—a perspective that is relevant to current legal, military, and medical discussions of pain in torture, say, or in capital punishment.[68,69] Michel Foucault, however, moves beyond a focus on power as oppressive, top-down, and hegemonic, expressed in prohibitions and restraints. In his later work, Foucault views power as horizontal, distributed, even demotic, expressed as usable energies flowing within a social system, like electricity coursing through the walls.[70] This later perspective illuminates the recent ongoing transformation of patients from passive subjects of a colonizing biomedical gaze to active agents, whose limited but real powers range from noncompliance and litigation to undisclosed alternative, holistic self-care. Such changes, reflected in hospitals that openly post a patient's bill of rights to adequate pain relief, suggest the need to resituate the discussion of pain management within the vast social power shift known as globalization.

Globalization holds potent implications for pain that ripple through cultures directly and indirectly. An economic analysis might focus on corporate mergers and takeovers. For example, the publicly owned, family-run, Midwest-based U.S. pharmaceutical company Upjohn, which marketed ibuprofen and its over-the-counter spin-off, Motrin, merged in 1995 with European conglomerate Pharmacia, headquartered in Sweden; the merged company Pharmacia & Upjohn in 2000 merged with Monsanto and took the name Pharmacia Corporation; and in 2002 Pharmacia Corporation was bought by the international colossus Pfizer in pursuit of full rights to the (now disgraced) blockbuster pain drug Celebrex, previously acquired by Pharmacia. Marketplace dominance consolidated in a few transnational monoliths that underwrite activities and organizations in support of pain specialists justifies Foucault's concept of *biopower*, which describes a modern, medical, state-sponsored authority over health-related activities from sexuality to population control.[71] Nikolas Rose

proposes the term *biopolitics* to describe a postmodern extension of biopower to far broader supra-state manipulations of human vitality, morbidity, and mortality.[72] Pain management, inseparable from a transnational pharmaceutical industry, cannot today be fairly represented as encounters between an individual patient and a caring doctor. A full sociocultural analysis of pain management would need to situate the doctor/patient encounter within a shaping globalized biopolitics as dominant (if dimly perceived) as the force of gravity.

Money and pain? Pain patients are, of course, cared for only within systems assuring that health care professionals are paid. Even indigenous medicine involves compensation, so the key issue is not payment but the particular systems of compensation that characterize the era of global pain management. Local compensation issues are often influenced by national or international forces, such as the traffic in illegal drugs and its effect on domestic licensing and disciplinary boards charged with regulating opioids.[73] Less dramatic questions are equally important. Who is eligible for treatment in a pain center or clinic? The answer may not involve the intensity of pain but matters of citizenship and insurance coverage. Is likelihood of improvement a criterion for enrolling patients? If insurance coverage is held to enhance the likelihood of improvement, then uninsured patients are excluded. Some 16% of the U.S. population has no health insurance, with percentages far higher among black and Latino minorities. These bland statistics expose how pain is silently enfolded within systems of biopower and of biopolitics.

Biopower and *biopolitics* are not mere concepts but realities that influence the profound inequalities (in access to care and in treatment of pain) that face individual patients as the consequences of race, socioeconomic status, and the fast-changing configuration of national and international health care systems.[74] In Haiti, for example, anthropologist-physician Paul Farmer struggles against global pharmaceutical companies and cost-driven policies of the World Health Organization to provide medication for HIV/AIDS patients with multiple drug-resistant tuberculosis.[75] Even national systems of universal health care cannot ignore cost in decisions about whom to treat and how. Among postoperative patients, patient-controlled analgesia (PCA) lessens pain, shortens hospital stays, and reduces pain medication, but it is also expensive, raising unresolved questions about cost-effectiveness, social justice, and access to care.[76] Who gets it? In a balancing act that weighs cost against temporary discomfort, many patients and systems cannot afford adequate pain control.[77] There is no mechanism for creating balance—indeed, no agreement about what constitutes balance. For HIV/AIDS patients in sub-Saharan Africa who may barely find enough to eat, pain medications and nondrug therapies alike are an unaffordable luxury.[78]

The impact of changing worldwide health systems shows up in pain management as patient concern for alternative and complementary medicine. Patients today pick the latest secularized healing art from a menu of eclectic, health-related therapies marketed like vitamin pills to late-capitalist consumers in what has been described as a new global "ethnomedicine."[79] In 1990 Americans made 425 million visits to providers of complementary and alternative medicine or, as it was first called, "unconventional therapy."[80] This figure startled many analysts because it exceeded the population of the United States. It did not express an outright rejection of biomedicine, as 83% of these patients also sought treatment for the same condition from a medical doctor: significantly, they also paid 75% of all costs out-of-pocket. A sense of the illicit nonetheless surrounded these excursions outside the biomedical model. The vast majority (72%) of patients who used unconventional therapies did not tell their physicians.

Official discourse and unofficial practice—including the practice and discourse of pain medicine—has begun to change in response to this new populist, eclectic self-care that draws its principles and therapies from around the globe. From 1990 to 1997 there was an almost 50% increase in visits to "alternative medicine practitioners,"[81] a number that soon exceeded visits to primary care physicians. This change, no mere lifestyle fad, extends even to cancer patients, who show a high prevalence of complementary and alternative medicine (CAM) use, especially among patients who are well-educated, well-off, young, and female. Three quarters of U.S. medical schools now require coursework in CAM, and CAM therapies crossover to pain medicine with surprising ease. Among people reporting back or neck pain within the last 12 months, a national telephone survey in the U.S. found that 54% used complementary therapies (especially chiropractic, massage, and relaxation techniques), compared with 37% who saw a conventional provider.[82] CAM research increasingly supports the use of nontraditional treatments for symptom control among seriously ill and elderly patients.[83] It demonstrates, for example, that mind-body therapies can both cut the number of physician visits and reduce arthritis pain.[84]

Today the U.S. National Center for Complementary and Alternative Medicine (NCCAM), with an annual budget over $100 million, represents a major institutional change in the history of mind-body relations, and pain is the focus of significant research into CAM therapies. The reports are mixed reports. In one study, CAM therapies for low back pain did not result in clinically significant improvements, while greater patient satisfaction for CAM therapies was offset by higher costs.[85] In less extensive samples, back pain was the most common reason for visits to acupuncturists, chiropractors, and massage therapists,[86] and most patients with chronic back pain expressed interest in CAM therapies.[87] CAM *mind-body* therapies, however, are not a popular treatment for pain. Mind/body therapies, one study found, were used infrequently for headaches and for back or neck pain[88] and not commonly used (at least in the U.S.) for prolonged musculoskeletal pain.[89] The inconclusive and scattered data boil down to a strong initial preference among back pain patients for acupuncture, chiropractic, and massage. Beyond individual therapies, a clearer conclusion is visible. Pain management now takes place in a globalized medical marketplace where drugs and surgery face competition from homeopaths, multicultural Internet remedies, mind/body meditation techniques, and CAM therapies. Consumer activism and global options are changing the culture of medicine, at least from a patient's perspective, and additional related changes are predictable for pain management.

The cultural system that has received most attention in its impact on chronic pain is disability insurance. Like most developed nations, for example, Scandinavian countries face rapidly mounting claims for pain associated with automobile accidents. Lithuania, however, which has no auto insurance, also shows no significant difference between accident victims and a control group in reports of headache and neck pain.[90] Chronic whiplash syndrome appears to be partly an artifact of social systems of accident and disability insurance. It is the systems, as much as neurons, that produce a call for pain treatment. This new post-1950s postmodern cash-driven disability narrative, however well intended, entails emotional costs for patients and big social costs for health care systems, and it often makes successful treatment more difficult.[91–94] Pain today, in short, exists inside cultures where national health care systems and third-party insurers establish potential careers for patients as damaging as hysteria in the 19th century. Even the decision to become a patient is a cultural artifact: in a small aboriginal community in Australia, back pain is not regarded as a health issue, people do not show recognizable public pain behaviors, and sorcery is a standard resource.[95] The development of health maintenance and managed care organizations in the U.S. has created new issues for pain management, especially as regards accreditation, regulatory initiatives, and drug costs.[96] Regulation of controlled substances may recast patients as adversaries suspected of drug-seeking behavior. Some

organizations require pain patients to sign contracts that transform prescription drug abuse into legal grounds for denial of treatment. Employers too play a role in reframing pain, as monotonous jobs and lack of workplace autonomy are predictors of chronic pain disability.[97] The category of repetitive stress injury shows how sociocultural changes create new patterns of pain. Older employees with lower education and lower occupational status appear at increased risk for disabling chronic pain,[98] while women of "deprived" socioeconomic status both run higher risk of pain and experience pain as more severe and disabling.[99]

Families as a sociocultural system, like jobs, add significant complications to pain.[100] Large-scale changes in family structure create new challenges for clinicians, as postmodern families emerge reconfigured as nuclear units fractured by divorce, blended across multiple marriages, mixed in race, and marked by local or national demographic shifts. The family dynamics of chronic pain has so far yielded inconclusive data,[101] but researchers agree that pain and families exist in an intricate loop of reciprocal relations, such that the patient's pain affects the family and the family affects the patient's pain.[102] Among people with rheumatoid arthritis, spousal interaction has a complex influence on pain-related catastrophizing.[103] The precise family dynamics across specific disease conditions is less important here than identifiable links between family life and chronic pain patterns. As various predictable, almost scripted social roles and responses grow clearer, pain specialists have expressed new interest in narrative.

PAIN AND NARRATIVE: CULTURE, MEANING, PRESENCE, ETHICS

"When somebody comes in with 25 years of chronic pain, I might sit with them for 90 minutes to get the beginning of the story, to really understand what's happening," explains Scott Fishman, chief of pain medicine at the University of California at Davis. "The insurers would rather pay me $1,000 to do a 20-minute injection than pay me a fraction of that to spend an hour or two talking with a patient."[104] Rita Charon has described in the *Journal of the American Medical Association* a new clinical approach called "narrative medicine."[105] Narrative—from Latin *narro, to tell*—has been described as "*someone telling something to someone about something,*"[106] and narrative medicine sets out to reframe the everyday act of talking with patients. Charon also reframes narrative as a form of knowledge (not chitchat or entertainment). Philosopher Alasdair MacIntyre identifies the widest importance of narrative knowledge when he writes that "we all live out narratives in our lives" and "we understand our own lives in terms of the narratives that we live out."[107] Life, as the new discipline of narrative psychology puts it, is inherently "storied."[108,109] A sociocultural perspective, then, needs to include *narrative knowledge*—a complement to the molecular gaze and to what Charon calls biomedical *logicoscientific knowledge*—as it affects the understanding and experience of pain.[110]

Narrative offers distinctive insights into human pain. As a vehicle for the communication of cultural beliefs and social practices, narrative clearly plays a role in communicating beliefs and practices related to pain. Research concerning adult twins and pressure pain thresholds, for example, makes it clear that cultural patterns help determine perceived sensitivity to pain,[111] and cultural patterning begins early. By 2 months of age, Chinese and non-Chinese Canadian infants show significant differences in acute pain response.[112] Chronic pain requires a longer, more complex personal and cultural education, which for some individuals may amount to noneducation or the acquisition of erroneous beliefs. Pain narratives often encode mistaken beliefs, such as the dominant biomedical myth that regards pain as the invariable consequence and bona fide symptom of tissue damage. (The IASP corrects this myth in asserting that many people report pain "in the absence of tissue damage or any likely pathophysiological cause."[113]) An attention to narrative thus helps to identify erroneous beliefs and harmful practices that may impede treatment. It can help uncover relevant cultural difference, such as the divergence among cancer patients in India and in America, for example, over the meaning of pain and over relations between pain and quality of life.[114] The personal narrative of a pain patient, as it conveys fine nuances of meaning and unaware self-contradiction, offers a significant tool for understanding treatment-related attitudes that may elude the coarse, broad grid of generic questionnaires.[115]

Meaning is intrinsic to human pain.[116] Even children and infants are enfolded in a web of cultural assumptions not of their making. In adults, chronic pain implies a continuous and coextensive process of interpretation—conscious, nonconscious, personal, cultural—that both builds up and deconstructs meaning. Why me? Is it serious? Most important: will I get better? Such questions and the changing responses that they elicit, often subliminally, illustrate how meaning is not merely an add-on. Meaning is intrinsic to pain even at the zero degree where patients (consumers of the dominant biomedical myth) assert that pain is meaningless. We cannot name or discuss pain except in a natural language—English, Spanish, Farsi—that inevitably colors our understanding and shapes our experience.[117] Pain thus comes always already interpreted, and meanings silently infiltrate behavior through underlying implicit narratives, much as athletes often play out a script in which tolerance for pain affirms male courage, team loyalty, and physical strength. Pain in its social functions and in the tacit cultural narratives we act out regularly reverts to its Latin root meaning of punishment. Childhood discipline, spouse abuse, and even the self-punishments of guilt belong to a punitive narrative semantics of pain. While drugs temporarily stop pain and bypass meaning, meaning does not therefore die out. The brief pharmaceutical erasure perpetuates another cultural narrative—a myth backed by heavy narrative-based advertising—that drug therapies can buy you relief from pain. This promotional myth directly affects pain management when patients abuse chemical remedies to an extent that drug detoxification is often a necessary first step in effective treatment.

Meaning and belief in their power to reshape pain find an influential demonstration in the biblical narrative of Adam and Eve. Christian faithful over many generations associated their pain with Adam's original sin, much as today medicine has replaced theology as the main source of pain narratives. Pain beliefs now tend to focus on organic cause, control, duration, outcome, and blame.[118,119] A postmodern semantics of pain, however, is often less explicitly medical, evoking biocultural conditions from childbirth to disability[120,121] in media from feature films to podcasts, and such narratives give currency to a wide variety of pain beliefs—beliefs that extend from chronic pain to acute and even postoperative pain.[122] Moreover, narratized beliefs about pain often carry strong emotion: anger toward a negligent employer, fear of a catastrophic outcome, hope for financial compensation, any of which may complicate treatment. The good news about pain semantics: function is better in patients who believe that they have some control over their pain, who believe in the value of medical services, who believe that family members care for them, and who believe that they are not severely disabled.[123] Pain believed to mean catastrophe ahead or lifelong disability makes it much harder for patients to recover. Narrative meaning is important precisely because patients, often unknowingly, repeat or enact harmful emotional scripts that exacerbate pain as much as a raw nerve or errant neurotransmitter.

A narrative medicine for pain, as Rita Charon calls it, promises significant therapeutic benefits where other approaches fail or fall short.[124] As chronic pain often confronts patients with what anthropologists call damaged or spoiled identity, narrative offers

an insight into a patient's experience of self and a means for patients to reconstruct selfhood as a step toward exiting the role of chronic pain sufferer.[125] The findings in a study of fibromyalgia patients, for example, suggest that narrative approaches both helped participants find their own coping strategies and helped them find identities other than as patients.[126] Narrative in written form also demonstrates, if not analgesic properties, at least an astonishing power to moderate pain. Rheumatoid arthritis patients who wrote in narrative form about stressful experiences showed significant symptom-reduction.[127] Indeed, writing about trauma is associated with various measurable health benefits[128,129]—but the beneficial writing takes a specific form. "Using our computer analyses as a guide," psychologist James Pennebaker explains, "we realized that the people who benefited from writing were constructing stories."[130]

Narrative, like any instrument, has limits to its uses as a therapy.[131] Pain can push both narrative and meaning to an extreme point of collapse, where nothing can be written or spoken, a black hole from which meaning cannot emerge. Victims of torture may undergo an experience so horrific and chaotic that it blocks any possible narration,[132] finding its only available idiom in somatization. Medical narrative offers the formula that a patient "presents" with symptoms. What does it mean to present? The act of "presenting" might be said to create what some theorists call "presence": a bodily, spatial, tangible, immediate, sensual material appearance that is utterly withdrawn from the grids of meaning—including medical meanings—that humans before or after superimpose on it.[133] There would seem to be an ethical obligation to respect the limits of narration, an extreme withdrawal of meaning, in a space where tools and therapies and language may seem as inadequate as squirt guns confronting a forest fire.

Stories hold an underground commerce with ethics. Narrative had no relevance to bioethics construed, at its modern beginnings in the 1970s, as a branch of analytic philosophy, wedded to a rationalist, universalist discourse of principles. From a sociocultural perspective, however, ethics is not a discourse of universal truths and timeless principles but, like medicine, an intersubjective project shot through with narrative.[134] Pain medicine has developed professional guidelines concerning an ethics of research, on animals and on humans, and guidelines are useful in promoting desired behavior, as well as in protecting the interests of professions that depend on public trust. There is room and need, however, for an ethics of pain that moves beyond professional guidelines and beyond principlism to engage contemporary philosophers outside the analytic tradition.[135] Pain, like love, calls into question the basis of our relations with others, including people or creatures who are *radically* other, nothing like us, enemies perhaps or aliens. Does their pain "call" us to act? What, if any, are the limits of empathy? The challenge of a narrative ethics is to understand pain as always embedded in the story of an individual life, where ethical choices are difficult because they fail to map precisely onto a universal logic of principles. A narrative ethics can also illuminate choices and contexts less with moral rules or right action than with human values.

Values, intricately layered with beliefs, have proven correlations with pain. Among adult patients in a pain management unit, success at living in accordance with one's values correlated with measures of disability, depression, and pain-related anxiety.[136] Differences in values often underlie conflict or misunderstanding, and narrative analysis helped researchers discover that patient autonomy (the gold standard in bioethics) meant something very different to Korean-Americans and Mexican-Americans than to their African American and Caucasian neighbors.[137] Religion and spirituality also engage value-based beliefs that narrative helps illuminate. Among predominantly white, Christian, Midwestern patients with chronic musculoskeletal pain, the religious and spiritual beliefs of patients turned out to differ from the beliefs of a healthy population. Surprisingly, private religious practices such as prayer and meditation were inversely related to physical health outcomes; long-time pain patients received less support than other patients from their church community; they tended to lose hope, become bitter, grow angry at themselves, at society, and at God.[138] Pain narratives turn especially complex when values clash or change. Should pain management now be understood as a basic human right?[139] The question is less likely to be resolved by invoking timeless principles or universal truths than by extended narrative discourse that ultimately hammers out an agreement on values. Even if declared a universal human right, pain management depends on values that situate human affliction within the modifying medico-socio-cultural environments of specific times and places.

BEYOND THE GATE: SOCIAL IMPLICATIONS OF THE MOLECULAR GAZE

The threshold leading into an era of the molecular gaze marks difficult new challenges for pain management. While insurers and peer reviewers want hard evidence, chronic pain is characterized by multiple influences not easily reducible to quantitative data or amenable to cellular repair. Research on chronic low back pain is mostly restricted to high-income countries, for example, where rates of low back pain run 2 to 4 times higher than in low-income countries. Within low-income countries, rates of low back pain are higher in urban populations than in rural populations.[140] These variations suggest that low back pain—perhaps the signature representative of much chronic pain—is not a likely candidate for molecular cure. Multidisciplinary treatment programs now recognize the importance of psychosocial factors, but the question is whether the concept of "psychosocial factors" (typically contracted and enfolded within a still dominant biomedical model) is adequate to describe the ways in which chronic pain seems deeply rooted in the sociocultural environment.

The gate control theory, despite its advances, works better for acute pain than for chronic pain because it focuses on neural impulses blocked or transmitted at specific cerebral and spinal locales.[141] Some 21st century specialists find the gate control theory entirely adequate,[142] while others remain quiet or uneasy. Ronald Melzack has radically revised or possibly simply abandoned the theory he co-created in 1965, with its prominent dorsal horn gating mechanism, and he now emphasizes a cortical "neuromatrix."[143] Neuromatrix theory proposes numerous networked brain connections that, beyond nociception, call into play a range of human mental-emotional activity, often rooted in the sociocultural environment. A molecular gaze that focuses on a few "gates" may prove adequate for specific chronic conditions such as neuropathic pain, although (despite gate control theory) treatment for neuropathic pain remains extremely difficult.[144] A molecular gaze that reduces all chronic pain to neural impulses blocked or passing through a gate, however, risks ignoring the complex interrelations of a transdermal perspective.

An additional danger in an unrevised gate control theory is that it may excuse specialists from an opportunity—ethical or medical—to address pain-related conditions outside the nervous system. Pain specialists are not required to be social activists, although *Douleur Sans Frontièrs* (based on the Nobel-Prize winning organization Doctors Without Borders) offers one model of socially engaged care. Reflective practice, however, might encourage specialists to observe how far pain management programs belong to a larger process that sociologist Peter Conrad calls the "medicalization" of society: a transformation of human conditions into treatable disorders.[145] It is laudable work, of course, to assist patients who seek help. Nonetheless, pain management programs contribute inescapably to a medicalization of society that defines selected people in pain as pain patients and then

enfolds them within a professional-economic structure that is never *simply* about compassionate care and rigorous science. It is a structure that redefines pain (as a treatable disorder) in addition to treating it, a structure that reframes people in pain (as patients) in addition to helping them, a structure that rarely encourages follow-up on patients whom it fails to help. Most important, it is a structure that bases much of its knowledge about chronic pain on the study of a subset of people who choose to enroll in research sponsored by pain management programs. Any community, however, includes—like Australian aboriginal communities—people who do not seek medical care for chronic pain but who lead, by their account, happy, productive, successful lives. How do they do it?

The study of chronic pain patients will not necessarily explain how some people not only "cope" (a medicalized concept) but also live successfully with chronic pain. The new field of positive psychology argues for shifting focus away from the study of dysfunction, in an effort to discover what specific practices, beliefs, and attitudes appear to promote effective function and personal happiness.[146] Positive psychology suggests that there is value in identifying "success stories" (another narrative genre relevant to medicine) drawn from people in pain who do not enter pain treatment programs or research protocols.[147] Even the *biopsychosocial* model, in practice, usually throws emphasis on its first syllable, reducing complex psychological states and tangled sociocultural environments to "factors" that affect human neurobiology. The concept of transdermal pain views sociocultural environments as something beyond a "factor" in otherwise mainly biological processes. It views chronic pain as always biological and as always cultural.

A STEP BACK: MOLAR IMAGES OF PAIN

The limitations of a molecular gaze for understanding chronic pain would seem clear in proposals that seek to reduce all pain to one organic cause; for example, to inflammation.[148] Neither inflammation nor any other single molecular process can wholly explain the peculiar difficulties of treating chronic pain in children, for example, where cognitive development, linguistic abilities, and family relations are central.[149] It cannot illuminate the challenges that face elderly chronic pain patients.[150] Or people with HIV/AIDS.[151,152] Or dying patients.[153] Pain, from a transdermal perspective, is never simply a matter of molecules, just as medicine is never merely the application of science. A final step back, into the 19th century, helps make this sociocultural perspective clearer as it applies to the present and future.

British satirist George Cruikshank depicted colic within a visual narrative where pain is the natural consequence of an irrational, fashion-crazed, upper-class, female lifestyle (Fig. 11.2).

Although today colic is a mysterious and usually passing affliction of infants, medical writers from the Middle Ages through the 19th century described colic as an adult affliction: "severe paroxysmal griping pains in the belly."[154] The Greek root of *colic* refers to the colon, especially to the lower part of the intestinal canal (or bowels), and colic may be a 19th century antecedent of irritable bowel syndrome (IBS). IBS, a disorder of the intestines that is associated with belly pain and other symptoms, affects 10% to 15% of people in North America[155] and is twice as common in women.[156] While inflammation, brain-to-muscle signals, and possibly genetics are involved in its painful episodes, IBS is characteristic of chronic pain syndromes in raising questions about the role of sociocultural environment. Biology and genes simply cannot explain all relations among chronic pain, sex, and gender.[157] Childhood sexual abuse, for example, is a sociocultural fact for some boys and girls, as well as a subject of fantasy. Women diagnosed with somatization disorder are more likely to report childhood sexual abuse than are women with mood disorders.[158,159] Chronic pelvic pain in women certainly correlates with sexual dysfunction.[160] Cruikshank's visual narrative, wholly lacking in medical knowledge, places colic within a sociocultural frame where pain is a punishment for sexualized female folly.

Cruikshank's narrative of colic repeats for women the same satiric moral (excess breeds pain) that his image of gout offers men. The framed picture above the sofa (hard to see in this reproduction) depicts an obese woman, at her bedside in a nightcap, drinking from a decanter. *Nightcap*, defined figuratively as an alcoholic drink taken before bed, dates exactly from this period. The obese tippler may not be the tortured woman on the sofa, but their caps and figures connect them. Cruikshank links colic with fashionable excess not only in private alcohol consumption but also in public styles that squeeze a full-bodied woman into

FIGURE 11.2 George Cruikshank. *The Cholic*. 1835. Colored etching. (Courtesy of the Claude Moore Health Sciences Library, University of Virginia, Charlottesville, VA.)

an hourglass shape. The *sofa*—furniture associated with the decline of virtuous simplicity and the rise of luxury and vice[161]—is co-occupied by a devil engaged in sewing or lacing up the corsetlike garment, invoking religious traditions that understand pain as a hellish punishment for sin. Sin seems less evident than self-punitive folly, until we account for additional information within the image that links pain and sexuality.

A sexual subtext is hard to ignore because male admirers ultimately stand behind the woman's painful fashion choice. (She does not dress this way in private.) The constricting rope is pulled tight, at either end, by related parallel figures: an emaciated, hyperactive dog and a leering naked male. The naked figures on the tightrope, female and male, reinforce an aura of sexual tension, but here the sexual subtext connects with larger sociocultural contexts. The two figures also evoke British imperialism and its power over exotic local populations (represented here as free from the absurd repressions of Western fashion). Social historians have shown how medicine served as an instrument of empire.[162] Although individual doctors doubtless acted from altruistic motives, the extension of Western medical knowledge to the ends of empire was not pure philanthropy, a narrative about the white man's burden in carrying light into darkness. The *réal-biopolitick* of empire involved uprooting indigenous medical traditions and imposing institutional controls favorable to colonial power. A future transdermal perspective needs to ask whether a globalized pain management might, however laudable its intentions to extend care, included unintended consequences in uprooting local knowledge, securing commercial interests, and imposing favorable institutions of control.[163]

The central figure in Cruikshank's exploration of links between pain and its sociocultural environment raises the question of whether cultures might shape a distinctively female pain. Pain associated with somatization disorder, for example, runs at a 10 to 1 ratio of female-to-male.[164] Women are frequently overextended caregivers in chaotic families, just as women are no doubt overrepresented among battered spouses. A molecular gaze, while valuable in exploding harmful social myths of illness, creates its own limiting counter-myth if it represents pain as a purely internal state, unrelated to political and social contexts. Cruikshank (it goes without saying only if one is white) represents the fashionable woman suffering from colic as white, while the various punitive devils and sexualized figurines reflect a nonwhite realm. According to U.S. government figures, the amount of five major painkillers sold at retail stores rose 90% between 1997 and 2005.[165] Who bought them? Misuse of painkillers represents three-fourths of the overall problem of prescription drug abuse.[166] Who misused them? Between 2 million and 3 million doses of codeine, hydrocodone, and oxycodone are stolen annually.[167] Who stole them? Such questions, with their inevitable narrative response in individual cases, are not irrelevant to pain management programs and to the valuable work that they perform. Pain and pain-killing drugs belong not only to genetics, to neurobiology, and to a molecular gaze but also, for better or worse, to the transdermal texts and textures of human lives in particular places and in distinctive, even unparalleled, sociocultural histories.

CONCLUSION

There is no magic bullet for chronic pain. Maybe researchers will someday find one. S. Weir Mitchell, founder of modern neurology, on its 50th anniversary in 1896 celebrated the first surgical use of ether as heralding the "death of pain." Chronic pain, on the contrary, appears on the rise in industrial and postindustrial nations, and it does not respond well to ether-like strategies effective in controlling acute pain. The search for a magic bullet may be as misguided as unicorn hunts, which of course does not rule out fruitful byproducts of a fundamentally erroneous pursuit.

The absence of a magic bullet, even if temporary, invites other approaches to understanding and treating chronic pain. *Overdetermination*, in psychoanalytic theory, refers to the concept that multiple causes combine to produce a single behavior, emotion, symptom, or dream. The cumulative data cited in this chapter suggest that chronic pain is over-determined. It does not depend on a single, clear, independent cause that a magic bullet (or gene therapy) might knock out, but rather it appears to develop through multiple, intersecting, proliferating routes of transmission, like a rhizome.

Chronic pain, over-determined in spades, is often described today not as a symptom but as a disease, although it is less a classic disease state than a complex, changing, multivariate event staged within human consciousness. Consciousness—defined, arguably, as an emergent property of human brains—modifies and interprets nociceptive sensory input in ways that depend on cultural and social forces within an individual's environment. Thus, chronic pain is open to significant modification—for better or worse—from, for example, workplace, gender, ethnicity, belief, emotion, money, and narrative. Children, in part because of their distinctive cultural, social, and linguistic backgrounds, may experience pain differently than their parents do. First-generation immigrants may experience pain differently than their assimilated second-generation children do. Persons with HIV/AIDS may face a pain that is distinctive depending on how, in individual cases, a specific infectious disease engages the highly variable forces of geography, nation, social class, race, stigma, and access to care.

Chronic pain, in short, cannot be reduced to a diagram of cellular processes. Cellular processes are open to modification by cultural and social forces. This extracellular and nonmolecular dimension, as it manifests in patients with different personal, social, and cultural backgrounds, remains among the most difficult challenges that pain medicine in the 21st century needs to address effectively.

Acknowledgments

For his assistance, I am grateful to John Loeser, who attributes the phrase "transdermal pain" to his colleague Wilbert Fordyce. Many thanks as well to Daniel B. Carr.

CHAPTER 12 ■ ETHICAL ISSUES IN PAIN MANAGEMENT

BEN A. RICH

INTRODUCTION

The ethics of pain management is intricately intertwined with, and yet in certain essential aspects distinct from, traditional concepts and principles of patient care. The primary focus of this chapter will be those distinctive ways in which ethics has been interpreted and applied in pain management. It is important to note that in previous editions of this text there was no chapter devoted to ethics or any of the other topics covered in this section of the 4th edition. We can only speculate as to why that was so, but it is ironic because since early in the 1970s studies began to indicate that the phenomenon of undertreated pain was pervasive and inconsistent with available therapeutic options.

One can argue that the traditional view of the ethics of pain management, to the extent that it was articulated at all in the professional literature, provided a basis for undertreating pain, particularly if what was required to adequately relieve pain involved the administration of opioid analgesics. In that sense, during the last 15 to 20 years there has been a gradual but highly significant paradigm shift in the ethics of pain management. Until quite recently, as David Morris insightfully notes in his book *The Culture of Pain*: "The everyday medical dealings with pain conceal unacknowledged ethical questions." Even in the care of cancer patients, Morris continues, the clinical ethos has been tainted by "an unacknowledged moral code expressing half-baked notions about the evil of drugs and the duty to bear affliction." He concludes with the grim observation that "The ethics of pain management, unfortunately, may not receive proper attention until the first doctor is successfully sued for failing to provide adequate relief."[1] There was a remarkable prescience to Morris' suggestion, for in the very year in which his book was published, a jury awarded millions of dollars in both compensatory and punitive damages to the family of a patient whose terminal cancer pain was undertreated. That case is discussed in detail in Chapter 16 of this text. Similarly, the ethical issues pertaining to the care of the dying patient are discussed in depth in Chapter 14, and the laws and policies relating to opioid analgesia are surveyed in Chapter 17.

In the decade and a half since the publication of *The Culture of Pain*, the ethics of pain management has finally begun to receive the attention, discussion, and debate that had been so starkly absent before. Herein we will consider that process and the current state of affairs.

PAIN, SUFFERING, AND THE CORE VALUES OF HEALTH CARE

For centuries the core values of medicine and the other health professions never seemed to be in doubt. They were often, however, encapsulated in vague maxims of uncertain origin and authenticity such as "*primum non nocere*" (first do no harm) or "to cure when possible, to relieve often, and to comfort always." The core values on which these maxims were grounded—beneficence and nomaleficence—were unquestionably formulated by physicians during the long reign of paternalism as the overarching paradigm for the professional–patient relationship. What constituted benefit and harm, and when the zealous pursuit of cure should yield to the provision of comfort, or more radically still, occur simultaneously, was for the physician, not the patient to determine. In the latter half of the 20th century, particularly but certainly not exclusively in the United States, the evolution of medical jurisprudence and the revolution in bioethics challenged the legitimacy of the paternalistic paradigm. This challenge was grounded upon an emerging principle of bioethics—respect for individual patient autonomy. Indeed, by the end of that century, paternalism had been almost completely discredited, replaced by a new paradigm grounded on the legal duty to obtain informed consent (and to accept an informed refusal) supported by and in turn operating in affirmation of the most recent bioethical principle.[2] The new paradigm for the professional–patient relationship became that of shared decision making.[3]

While beneficence and nonmaleficence were retained among the core principles of modern bioethics along with a fourth justice, the clinician was no longer considered the final arbiter of what constituted benefit and harm in the care of any particular patient. It is, after all, the patient who must endure the rigors of medical interventions and/or the burdens of disease. Thus, in the case of intractable disputes between clinician and patient, the

patient has come to be recognized as the final arbiter. The dissenting clinician's option is to disengage from the relationship (but not precipitously so as to constitute abandonment) when and if respecting the patient's wishes compromises professional ethics or personal conscience.[4] The relief of pain and suffering, however, was not an integral part of this transformative process. Only quite recently have the legal, ethical, and public policy dimensions of pain management and palliative care begun to receive the attention they deserve, thereby properly placing them within the new bioethical, jurisprudential, and sociocultural framework. Providing the details of this process will be the task of this chapter, and the others in this section of the text.

The Duty to Relieve Pain and Suffering

When, over 2 decades ago, Eric Cassell began his seminal article on suffering and medicine in the *New England Journal of Medicine*, he did not think it necessary to build an extensive case for the proposition that physicians have a duty to relieve pain and suffering that dates back into antiquity. Nevertheless, his initial inquiries into the subject matter revealed a curious phenomenon: Contemporary patients and laypersons attached appreciably more significance to that duty than did his physician colleagues.[5] It is this disparity between lay persons and health care professionals in the prioritization of the need for and duty to provide pain relief that caused, or at least significantly contributed to, the jury verdicts in legal cases alleging undertreatment of pain, which we consider in Chapter 16. If, in the ethos of ancient medicine, the relief of pain and suffering was the essence of beneficence (doing good) and nonmaleficence (avoiding harm), then something transformative took place en route to modern medicine. Otherwise, the opening passage of the preface to Eric Cassell's book would be incomprehensible. That passage, a remarkably stinging indictment of his own profession, reads: "The test of a system of medicine should be its adequacy in the face of suffering . . . modern medicine fails that test."[6] Cassell analyzes in great depth important distinctions between pain and suffering, including notable instances in which a person can experience pain but not suffer, as well as suffer in the absence of pain. However, most pertinently to this chapter and text, he observes that pain is the most common cause of suffering and people in pain experience suffering when it is severe, uncontrolled, and seemingly without end.

Curative v. Palliative Paradigms of Patient Care

According to Cassell, the willful blindness that afflicts modern medicine with regard to pain and suffering relates to the complex nature of persons and the reductionistic tendencies of modern medical science. He cogently expresses the nub of the problem when he declares: "Bodies do not suffer; persons suffer." The implications of this proposition are clear but nonetheless potentially controversial: If a clinician cannot relate to the patient as a person, rather than as a body that is merely the locus of some disease process, then he or she cannot even recognize suffering, and certainly cannot begin to competently and compassionately respond to it. Unsurprisingly, many clinicians view this as a gross exaggeration, verging upon caricature. However, other credible sources bolster Cassel's point. Consider, for example, the assertions of Yale surgeon Sherwin Nuland in his book *How We Die*:

> . . . the challenge that motivates most persuasively; the challenge that makes each of us physicians continue ever trying to improve our skills; the challenge that results in the dogged pursuit of a diagnosis and a cure; the challenge that has resulted in the astounding progress of late-twentieth century clinical medicine—that foremost of challenges is not primarily the welfare of the individual human being, but rather, the solution of the The Riddle of his disease.[7]

Nuland is describing, with only a bit of grandiosity, one of the essential elements of the curative model cogently presented several years later by Ellen Fox.[8] For ease of analysis, her delineation of the essential features of the curative and palliative models of patient care is illustrated below.

Curative Model	Palliative Model
• analytic and rational	humanistic and personal
• clinical puzzle-solving	patient as person
• mind–body dualism	mind–body unity
• disvalues subjectivity	privileges subjectivity
• biomedical model	biocultural model
• discounts idiosyncrasy	respects idiosyncrasy
• death = failure	unnecessary suffering = failure

As illustrated above, point by point the essential features of the reigning curative model are the diametric opposite of the palliative model, the latter being the one that presumably must be followed in order to respond appropriately to the pain and suffering associated with both acute and chronic illness. The clinical puzzle-solving element is precisely what Nuland waxes so euphorically about in his discussion of the zealous pursuit of "the riddle," which he maintains is the primary motivator and the ultimate goal of the best clinicians.

As previously indicated, ethical issues in end-of-life care will be the special focus of Chapter 13 of this volume. Nevertheless, it is worth noting the stark contrast in the perspective on death and dying between the two models. The view of many clinicians in the full grip of the curative model that a patient's death is the ultimate medical failure has led, as Nuland himself admits, to situations in which medical specialists have "convinced patients to undergo diagnostic or therapeutic measures at a point in illness so far beyond reason that The Riddle might better have remained unsolved."[7] The type of clinical situations to which Nuland refers, particularly when patients are intentionally deceived or kept in the dark about the grimness of their prognosis or the dismal prospect that disease-directed interventions will produce any benefit, constitute a form of what might reasonably be characterized not only as "medical futility" but also as "therapeutic belligerence."[9]

THE PHENOMENON OF UNDERTREATED PAIN

The zealous, single-minded pursuit of a diagnosis and the relentless delivery of disease-directed interventions means, as a practical matter, that precious little professional time, energy, or attention is available for assessing and managing pain or suffering, even for patients in the intensive care unit who may be unlikely to leave the hospital alive. That is the bleak conclusion reached by the investigators in the formidable Study to Understand Prognoses, Preferences for Outcomes, and Risks of Treatment (SUPPORT) project in the mid-1990s.[10] The SUPPORT principal investigators sought to evaluate the quality of care in the intensive care unit of five premier academic medical centers across the country. The ICU, of course, is the locus of patient care in which the curative (disease-directed) paradigm of high technology patient care reigns supreme. The findings of the SUPPORT investigators are quite concerning with regard to such considerations as the relief of pain and suffering, the extent to which a patient's plan of care had been discussed with the patient or her proxy, or the likelihood that code status was consistent with what was known about the patient's wishes or values. For purposes of this discussion, at least three fundamental principles of bioethics were frequently violated in ICU care: respect for patient autonomy, beneficence, and nonmaleficence. More particularly, SUPPORT revealed that there was at best a 50–50 chance that the care

provided to patients was consistent with their wishes, values, or written directives, and half of the patients studied were believed to be experiencing significant pain or distress in the last days of their lives.

Similar disappointing findings about pain and symptom management have been reported in the care of pediatric intensive care unit patients,[11] nursing home patients,[12] and in outpatient care of cancer patients.[13] The pervasiveness of deficiencies in pain and symptom management across the life span of patients, types of disease, and settings of care strongly suggests a problem that emanates from core issues in medicine and society to which we now must turn. Otherwise, we would be compelled to consider a highly implausible proposition; that is, that health care professionals are truly indifferent to the pain and suffering of their patients.

Identifying the Barriers to Pain Relief

In the last decade or two, an unprecedented amount of attention has been paid to the root causes of undertreated pain. A consistently cited set of barriers has been identified. At a basic level, these barriers exist with regard to all types of pain: acute, chronic noncancer, and pain associated with terminal illness. Certain barriers, as we shall duly note, are exacerbated in patients with chronic pain. The general categories into which these barriers are divided are professional, patient, and societal in nature and origin.

Professional Barriers

In one sense, as I will endeavor to make clear, the professional barriers to pain relief are the most ethically significant, given the fiduciary nature of the clinician–patient relationship. The key elements utilized in assessing professional competence are knowledge, skills, and attitudes. Deficiencies in any one of these elements can result in inadequate and hence substandard patient care. Deficiencies in more than one for any type of patient care will markedly increase the likelihood that substandard care will result. Marked deficiencies in each of these dimensions have been documented in physicians (of all specialties), nurses, and pharmacists.[14–16] Behavior, or more particularly, professional conduct, is the ultimate consideration. For it is when deficiencies in knowledge, skills, and attitudes concerning the assessment and management of pain coalesce to produce substandard care that their ethical implications become most significant. Given the pervasiveness of pain across the clinical spectrum, only rarely may any clinician legitimately claim that such deficiencies pose no threat of harm to patients. As we shall further consider shortly, however, even clinicians who possess the requisite knowledge, skills, and attitudes may be reluctant to translate them consistently into effective pain management, particularly when what is clinically indicated may be opioid analgesia, because of fears of regulatory scrutiny or other forms of potential legal liability.

None other than John Bonica himself pointed out many years ago that no medical school has been so bold and innovative as to establish and maintain a formal, required curriculum in assessing and treating the most common problem of patients who seek medical care—pain.[17] The glaring deficiency that he described nearly 20 years ago persists. In data ascribed to the Association of American Medical Colleges in 2003, only 3% of medical schools have a separate required course in pain management, and only 4% require students to take a course in end-of-life care.[18]

The absence of any solid evidence of a formal curriculum in the assessment and management of pain in most institutions warrants the conclusion that none actually exists. Some defenders of the status quo have argued that the requisite knowledge, skills, and attitudes are imparted in other, less formal but perfectly acceptable ways, such as in the care of actual patients in the clinical years of medical education. What undermines these assertions is the strong evidence that health care professionals continue to graduate and obtain licensure with major deficits in knowledge, skills, and attitudes concerning pain management and its relevance to quality in patient care.

The ethical significance of this phenomenon is the aforementioned "culpability of cultivated ignorance." The absence of a pain curriculum in medical and other educational programs in the health professions may be an important reason why pain is often undertreated, but is not an excuse for it. Medical schools have been, and continue to be, major culprits in the epidemic of pain. It is not merely an absence of required course work on up-to-date pain assessment and management techniques, but also myths and misconceptions about the risks and purportedly unmanageable side effects of opioids that are deeply entrenched in the minds of clinical faculty and which are passed on from one generation of physicians to the next.[19] That is perhaps why, when the American Medical Association developed the Education for Physicians on End-of-Life Care Project (EPEC), it adopted a train-the-trainer approach in the hope of maximizing the dissemination of current thinking on palliative care to experienced practitioners rather than medical students or residents.[20] When one enters a profession, one assumes a moral responsibility to ensure that one possesses and consistently applies the knowledge and skills essential to minimal competence. That one may in some instances enter the profession with certain deficiencies does not provide a legitimate basis for cultivating the ignorance that may be originally attributable to curricular deficiencies. The medical school curriculum should reflect the current standard of care and anticipate future improvements to it, but it does not set that standard in any definitive sense.

In California, the continuing absence of a pain curriculum in medical schools, combined with increasing public awareness of and outrage over a national, indeed international, epidemic of undertreated pain, moved one crusading member of the California Assembly to introduce and successfully pursue a statute mandating two things: (1) that pain management and end-of-life care be part of the medical school curriculum for applicants seeking a license as a California physician after June 1, 2000; and (2) that inpatient health facilities include pain as a fifth vital sign assessed along with other vital signs and noted in the patient's medical record.[21] In yet another example of lawmakers interceding to address professional deficiencies, the California Assembly in 2001 enacted a statute requiring that all licensed physicians in the state (with the exception of radiologists and pathologists) receive a minimum of 12 hours of continuing medical education prior to January 1, 2007.[22]

These and the other legislative measures described hereinafter actually run counter to a well-established tradition in American government to leave the professions, particularly the health professions, virtually unfettered latitude and discretion to manage their affairs. Only when substantial evidence accumulates—and results in a high level of public concern—are lawmakers prompted to intercede. When morally troubling circumstances are allowed to persist by those who ostensibly have the power and authority to address them through nonlegal measures, the law has been invoked to address the problem. A graphic example was the Nuremberg Code that emerged from the Nuremberg Tribunal's prosecution of the Nazi doctors. The first principle of the Nuremberg Code was the right of human research subjects to informed consent. Twenty-five years later, when the public became aware that a number of clinical trials conducted by prominent medical researchers in the United States were openly and notoriously violating the Code, which was an ethical–professional, not necessarily a legal mandate, the federal government stepped in with the first of what became many regulations of federally funded research involving human subjects.[23]

Similarly, in the early 1980s a phenomenon known as "patient dumping" became the subject of significant public awareness and

concern. When indigent or uninsured patients presented to emergency rooms, they were with increasing frequency shunted off to other (usually government operated) hospitals for care, often with deleterious consequences from the delay in properly addressing an unstable medical condition. When neither the health professions nor national hospital organizations demonstrated any inclination to address the problem, the Congress of the United States passed the Emergency Medical Treatment and Active Labor Act (EMTALA), which imposed a mandate on all emergency departments to provide a medical screening examination to patients upon arrival, and prohibiting transfer of any patient found to be in an unstable medical condition prior to stabilization except under certain carefully described situations.[24] Notably, EMTALA recognized pain as an indication of an unstable medical condition requiring prompt attention and effective remediation. These instances indicate that it is often the failure or refusal of health care institutions and/or professionals to put their own houses in order that prompts major governmental intervention in order to address an otherwise seemingly intractable problem.

One must ask whether there is a causal connection between the failure of health professional schools to recognize the need for a pain curriculum, and the failure of the health professions and the institutions in which health care is delivered to make the prompt, effective, and consistent assessment and management of pain a priority in patient care. We noted early in this chapter how Eric Cassell was perplexed by the seeming indifference to the phenomenon of suffering on the part of physicians given the traditional core values of medicine. The same is true for pain, since another professional barrier has been characterized as the failure of health care institutions and professionals to make pain relief a priority in patient care. One of the primary objectives of many of the policies discussed in Chapter 14 of this text, particularly the Federation of State Medical Boards (FSMB) Model Policy and the Joint Commission Accreditation Manual standards on pain management, was to disabuse their target audience of the persistent notion that effective pain management was not an essential feature of sound patient care.

The final professional barrier to effective pain management is fear of regulatory scrutiny and potential legal liability (civil or criminal). There is little question that the nidus of this concern is opioid analgesia. There is quite simply no discussion about such concerns arising out of nonpharmacological pain management strategies. When one looks at the record of disciplinary actions by state medical boards, those relating in any manner to pain management practices were invariably characterized as excessive prescribing of opioids. Such cases will be addressed in detail in Chapter 15 of this text. It is for this reason that the previously mentioned FSMB policy is of such potential significance, for it seeks to shift the focus of medical boards from ''overprescribing'' or ''underprescribing'' of opioids to inappropriate prescribing, since both extremes pose risks to patients.

From an ethical perspective, it is a troubling state of affairs when clinicians fear that they are at risk of disciplinary action by their professional licensing board if they follow current national clinical practice guidelines on the use of opioid analgesics. Their concerns have not been without foundation, for an initial survey of the knowledge and attitudes of state medical licensing board members regarding opioids and pain management revealed significant knowledge deficits and attitudes that were at best unsupportive and at worst hostile toward the use of opioids, especially for patients with chronic noncancer pain.[25] One analysis of the prevailing attitude among medical board members concerning opioid analagesia characterized it as an ''ethic of underprescribing.''[26] A follow-up study conducted after the promulgation of FSMB guidelines on prescribing opioids and a series of workshops across the country on pain management for medical board members revealed some improvement in areas that might be reassuring to those whom boards are charged with regulating, but also noted the need for further education and wider acceptance of the FSMB model guidelines/policy.[27]

When medical and other health professions' boards issue new and presumably more enlightened policies on pain management, one cannot presume that most affected clinicians will become aware of them. There is still less of a basis to expect that these policies will, in the short term, have a direct and immediate impact on clinical practice even among clinicians who become aware of them. In the event that these new or updated policies were to become part of a mandatory continuing professional education program, there is nevertheless reason for concern that they would in fact be likely to significantly improve the usual custom and practice of minimizing the clinical significance of pain that has been mentored, modeled, and followed by generations of professionals.[28] Concerted efforts must be made to reform practice patterns and the underlying clinical culture that sustains them by infusing more enlightened attitudes about the importance of pain relief to patient health and well-being.

The regulatory barriers also include the federal Controlled Substances Act, the policies and procedures of the Drug Enforcement Administration, and criminal prosecutions of physicians for drug diversion or trafficking when their prescribing practices are deemed far outside the ambit of mainstream medicine. These issues are dealt in depth in Chapters 14 and 15 of this volume. The ethics of public policy formulation and law enforcement strategies and tactics are somewhat beyond the scope of this chapter. Nevertheless, such practices are fraught with moral implications because they affect the lives of many people. Much of the impetus for the new emphasis on balance intended to moderate between seemingly competing considerations of preventing drug abuse and diversion, on the one hand, and ensuring that patients in pain receive the analgesics they require for effective relief, has been based on legitimate concerns that state and federal regulatory and law enforcement measures have been obsessively focused on the former and virtually indifferent to the latter. We will consider the moral dimensions of pain policy and law further from the perspective of the health care professional in a subsequent section of this chapter as well, when we take up the demands of professionalism to make the patient's needs and interests primary in a fiduciary relationship.

Patient Barriers

In one sense at least, it should not be surprising that if clinicians commonly labor under myths and misinformation about the clinical significance of pain and the risk and side effects of opioids, so too will patients. Traditionally clinicians were the primary source of patient information on medicine and health. If they did not themselves possess accurate and up-to-date information about the risks and benefits of pharmacological and nonpharmacological modalities of pain relief, they would not be able to educate their patients. Indeed, that is why pain management has historically been an area of clinical practice in which truly informed patient consent was virtually nonexistent. Now, however, in the Internet age, patients and family members may actually access up-to-date information on pain and its management as or more often than their physicians.

Without adequate information concerning the available range of pain management interventions and their risks and benefits, patients had no basis upon which to formulate reasonable expectations with regard to pain relief. A major public survey on pain in the United States conducted in 1997 revealed that not only is pain pervasive, but the most common reason why people avoid seeking medication to relieve their pain is fear of addiction or physical dependence.[29] Patients may also avoid seeking medical care when they experience pain because they fear it may be caused by some serious, perhaps even life-threatening, condition. Finally, patients experiencing pain that is associated with conditions for which they are currently receiving treatment may not complain

about their pain and seek more effective pain relief because of a mistaken assumption that pain is an unavoidable concomitant of therapy or that their physician would certainly be providing as much pain relief as possible. It is these latter perspectives that help explain how, until the legal cases discussed in Chapter 15 arose, no malpractice claims based upon negligent pain management had been brought despite an epidemic of undertreated pain.[30]

Societal Barriers

Pain and suffering are not just immensely complex and highly individualized human experiences. They occur within familial and other interpersonal contexts, as well as social, organizational, and governmental configurations. Pain in particular may be a symptom of an underlying condition, but it may also, in the case of chronic noncancer pain, become a condition itself, hence the appropriateness of the term "chronic pain syndrome." These are by definition, as Arthur Kleinman has observed, "conditions in which the degree of pathology does not seem to explain the severity of perceived pain or the limitations in bodily functioning the pain produces."[31] This marked disparity between the patient's pathophysiology and reports (often interpreted as complaints) of pain and disability produces a strong element of skepticism, not only on the part of clinicians from whom the patient seeks care, but also from family and friends. These doubts about the veracity of the patient's experience of chronic pain can exacerbate the feelings of isolation and abandonment that characterize the chronic pain patient. At the end of this chapter we further consider the special challenges for the clinician posed by the chronic pain patient.

American culture in particular has precious little patience with or sympathy for the chronically ill. Indeed, much of the recent momentum within the disability rights movement has been an understandably strong reaction to the widespread perception among the healthy and able-bodied that certain profoundly disabling conditions are categorically incompatible with any quality of life whatsoever. In response to such pervasive attitudes, perhaps the most high-profile disability rights organization took the name "Not Dead Yet." Their message is clear to society in general and health professionals in particular: We do not seek your assistance in ending what *you* consider our miserable existence, but rather in enhancing what *we* consider to be our quality of life and our ability to be active and engaged members of our community.

ETHICAL IMPLICATIONS OF THE BARRIERS

There is a new emphasis in both undergraduate and graduate medical education on professionalism and communication.[32] In some small measure, such curricular reforms may begin to address the larger and more fundamental problem identified by previously cited commentators such as Cassel, Fox, Kleinman, and Morris that is posed by medicine's predilection for biological reductionism and obsession with diagnostic and disease-directed interventions. The none-too-subtle point is that one does not enter into a professional relationship with or provide care to a disease process. While a certain cadre of clinicians may romanticize the pursuit of "the riddle" of disease, the professional relationship (fiduciary in nature) and communication are necessarily with the personhood, not the disease of the patient. The assessment of pain, for example, is all about effective communication between patient and physician concerning the subjective experience of pain. If effective pain assessment is absolutely essential to providing effective pain relief, then the clinician must be able to understand and appreciate the patient's experience of illness in a manner and to an extent that may not be true for other aspects of patient care.

The concept of holding oneself out as a professional and the ethical demands of entering into a fiduciary relationship with another person entail the acquisition, utilization, and maintenance of the knowledge, skills, and attitudes necessary to ensure minimally sufficient competence. When a significant percentage of the practitioners of a profession such as medicine or nursing have been found to have major deficiencies in something as pervasive as pain and as integral to good patient care as are its assessment and management, invariably major ethical issues arise. It is in the recognition of these ethical issues that one demonstrates a grasp of the close relationship between ethics and professionalism. Yet there was a period in the early years of the movement to address the widespread phenomenon of undertreated pain when, as noted in the beginning of this chapter, there was little acknowledgment of, and hence attention to, the ethical dimensions of these professional deficiencies.

Turning from barriers associated with knowledge deficits and problematic attitudes toward the significance of pain and its relief to those associated with legal and regulatory concerns, we encounter a challenging ethical quandary. As described in detail in Chapter 14, the regulation of opioid analgesics has created a hostile environment toward their widespread use in pain management. Regulatory barriers, including a pattern of medical board disciplinary actions against physicians for so-called "overprescribing" of opioids, have, as previously noted, caused physicians to feel at risk even if they are scrupulously following state-of-the art clinical practice guidelines.

A fundamental ethical question posed by this situation is: To what extent is it reasonable to expect, indeed to demand, that physicians routinely engage in acts of moral courage in order to ensure that their patients with pain receive the medications that they require for relief? The essence of the duty imposed upon a professional when entering into a fiduciary relationship is that the other person's interests become primary, and any potential conflict of interest shall be resolved in favor of the person to whom the professional duty is owed. Therefore, prescribing inadequate doses of analgesics or opioids from a lower schedule of the Controlled Substances Act (e.g., Schedule III–V) when those from a higher schedule (e.g., Schedule II) are medically indicated in order to avoid regulatory scrutiny would constitute a breach of fiduciary duty. It is also the case, however, that a public policy posture and regulatory regime that routinely demands acts of moral courage on the part of professionals is a fundamentally flawed system that is vulnerable to strong moral critique. Such a critique is at least implied in the Report Card on state and federal pain policies that has been issued by the Pain & Policy Studies Group and which is discussed in some detail in Chapter 14.

EMBRACING A NEW ETHIC OF PAIN RELIEF

While it is important to understand the historical context in which formerly prevailing attitudes toward pain and its relief with opioids developed and ultimately became so pervasive and persistent, we must continue the momentum that has followed from more enlightened attitudes in order to address emerging ethical concerns. The clinical specialty of pain medicine has played a major role in the progress that has been achieved in the last 2 decades. Ultimately, however, each of the health professions has a responsibility to cultivate within its practitioners the knowledge, skills, and attitudes that are essential to the provision of effective pain management. The need for highly trained physicians and nurses in pain and palliative care will continue to grow, but so too will the need for all physicians and nurses to possess certain minimal core competencies in the assessment and management of pain.

A chapter on the ethics of pain management would be woefully inadequate if it did not address some of the special issues and problems of chronic pain patients. It is in this patient population, for reasons we will consider, that the efforts to identify an appropriate balance between the long-standing War on Drugs and the newly-minted War on Pain are primarily focused. Having already noted Arthur Kleinman's seminal work on the plight of the patient with chronic pain, we now must turn to emerging policies, protocols, and guidelines on care of the chronic pain patient, and their sometimes overlooked ethical dimensions. One of the new shibboleths in pain medicine is "pharmacovigilence."[33] The implicit premise of this concept is that clinicians are not truly confronted with a genuine moral dilemma of providing effective pain relief for patients or preventing drug abuse and diversion. The basic presupposition appears to be that the parameters delineated by pharmacovigilance, as conceived by some of the thought leaders in pain medicine, enable a responsible prescribing professional to provide appropriate and effective pain relief to patients while at the same time significantly minimizing the known risk of addiction posed by opioids or their diversion to persons who have no legitimate need for them. In other words, pharmacovigilant pain management recognizes the need in clinical practice for a kind of balance that is similar to the balance sought in laws, regulations, and public policies affecting opioid analgesics as discussed in Chapter 14 of this text.

While in theory all opioid prescribing, indeed, all prescribing of medications of any type should reflect pharmacovigiliance, the term has most often been invoked in the context of chronic pain management. While the available data support the conclusion that all types of pain have been undertreated, the plight of chronic noncancer pain patients has been particularly bleak because it is not uncommon for their reports of pain to exceed the tangible clinical evidence that would appear to support their legitimacy. Furthermore, patients who have just undergone major surgical procedures, been the victims of traumatic injury, or who are facing terminal conditions, do not encounter the same credibility problems when they report high levels of pain and seek relief. The phenomenon of pseudoaddiction, in which patients with genuine pain that has been undertreated engage in behaviors that cause them to appear to be drug seeking (in some illegitimate sense), is most prevalent in the population of chronic noncancer pain patients.[34] While it was once thought that undertreatment of pain at the end of life was the driving force behind the movement to legalize the prescribing of lethal doses of medication at the request of patients with terminal illness, the data accumulated as a result of the Oregon Death With Dignity Act reveal that undertreated pain is actually not even among the five most frequently cited reasons why dying patients seek a lethal prescription.[35]

Some of the practices that have come to be advocated with increasing frequency under the rubric of "pharmacovigilance" or responsible opioid prescribing are opioid contracts and random urine drug screens. Both approaches raise critical questions of an ethical nature about the role of trust in the clinician–patient relationship, as well as questions about why patients with chronic pain are special cases that require such measures when other patients whose conditions necessitate treatment with potentially dangerous medications and strict adherence to clinician recommendations do not. We will focus here particularly on the contracts/agreements that are being so widely promoted, the form that they take, the benefits that are claimed by their proponents, and the risks they pose to the establishment and maintenance of trust in the clinician–patient relationship.

There is an ethically more and less benign way in which to view and characterize the nature and role of these documents. The more benign approach is to simply consider the contract or agreement under the traditional rubric of a written informed consent document. Informed consent is a foundational concept in both medical ethics and medical jurisprudence, and the primary mechanism by which respect for individual patient autonomy is demonstrated.[36] The execution by patients of consent forms is a routine practice for any invasive medical procedure or other therapeutic measure. Thus, to the extent that an opioid contract were nothing more than a patient's written informed consent to undergo opioid therapy, acknowledging thereby both the risks and benefits associated with it, there would be nothing remarkable about it and certainly nothing that would raise serious ethical concerns.

The authors of one important article on the subject state: "The contract is ideally intended to enhance the therapeutic relationship by initiating and supporting an alliance between the patient and the physician. It may enable a patient to have an active role in treatment. . . ."[37] The key word in this passage may be "ideal," for there is growing concern among some that the primary reasons why opioid contracts are becoming routine among those physicians who are willing to consider opioid therapy for chronic noncancer pain patients relate to risk management and regulatory/law enforcement considerations rather than patient well being. For example, one review of opioid contracts that are currently in use revealed that over 90% had specific conditions warranting disciplinary termination of the agreement by the physician (e.g., for violating terms of the contract or missing appointments) and nearly 70% required submission to random drug screens, whereas only 5% stated the potential benefits of opioid therapy and just 3% provided general information regarding treatment.[37] Since the latter two elements are most typically found on consent forms, their absence seriously undermines the argument that these contracts are merely more elaborate or formal consent documents.

Such contract provisions emphasize the physician's power to impose conditions of treatment upon patients rather than the autonomy of the patient to participate meaningfully in the consideration of therapeutic options according to the paradigm of shared decision-making.[38] Interestingly, the American Academy of Pain Medicine (AAPM) features a "Sample Agreement" for "Long-term Controlled Substances Therapy for Chronic Pain" on its Web site, but the document also declares itself to be "a consent form." This agreement/consent form contains 19 provisions, including the more common ones, such as obtaining all opioid prescriptions from a single physician and filling them at a single pharmacy. The form advises that unannounced urine or serum toxicology screens may be "requested," to which the patient is "required" to submit. While, as previously noted, a typical consent form consists in large measure of a description of the proposed intervention, its anticipated benefits and risks, as well as the alternatives, the AAPM agreement/form states: "the risks and benefits of these therapies are explained elsewhere (and you acknowledge that you have received such explanation)."[39]

The absence of such detailed therapeutic agreements in most other clinical settings in which the modalities of treatment and the need for patient adherence to the therapeutic regimen are of equal importance to patient well-being (e.g., cancer chemotherapy) suggests that chronic noncancer pain patients who require opioid analgesia for effective relief warrant a heightened level of suspicion. Furthermore, the widespread and routine use of opioid contracts by many physicians for all of their chronic noncancer pain patients receiving opioid therapy, but not for acute pain or pain associated with terminal illness, implies that there is something intrinsically untrustworthy or suspicious about this category of patient.[40] Clearly, however, merely being a victim of chronic noncancer pain that happens to be refractory to nonopioid analgesics is not inherently suspicious. Such patients and syndromes exist, and a consensus of thought leaders in pain medicine has emerged in support of the position that opioid analgesia should generally be offered to these patients unless there are specific and significant contraindications.[41]

Recent acknowledgment that earlier estimations of the risk of addiction associated with opioid analgesia were much too low does not undercut this consensus view. The best current evidence

is that the incidence of addictive disorders (of all types) in the general population ranges from 3% to 26%, while the rate for hospitalized patients is 19% to 25%, and for major trauma patients as high as 40% to 60%.[42] It is important to note that recently formulated model pain policies do not recommend the routine use of either opioid agreements or urine drug screens in all patients—even all chronic noncancer pain patients—but rather those patients who in the exercise of sound clinical judgment are deemed to pose a "high risk for medication abuse or have a history of substance abuse."[43] Approaches to screening for addiction prior to the initiation of chronic opioid therapy as well as assessing for addiction during therapy (exclusive of urine toxicology screening) have been identified and utilized.[44]

The imposition of random urine drug screening as one condition precedent to offering opioid therapy to a patient appears to have become a common practice among clinicians whose practice includes patients with persistent pain problems. As with opioid agreements themselves, random drug screens may be required of all patients who receive opioid analgesia for an extended period, not simply those whose histories raise questions or concerns about the likelihood that they will take the medications as directed. In this way it might be argued that all patients for whom opioid analgesia is indicated are treated the same, rather than certain patients being stigmatized by differential treatment that calls their capacity to adhere to the treatment protocol in question. Nonadherence to chronic opioid therapy may take a variety of forms, including consuming more (or less) than the amount of the prescribed drug directed by the prescribing clinician, using opioids obtained from other sources, and failing to take the drug prescribed, whether or not the drug is then sold or otherwise diverted from legitimate medical use.

Failure to comply with instructions concerning the taking of medication is not unique to chronic pain patients, and the risks of such behaviors by patients can have serious consequences in many different clinical settings, including diabetes, hypertension, epilepsy, and cancer therapy, to name only a few.[44] Nevertheless, it has not yet become routine to insist on prescription medication agreements and laboratory screening for those patients, even when studies suggest that in some patient populations nonadherence to therapeutic regimens may exceed 50%.[45,46]

One important distinction between nonadherence to opioid therapy and nonadherence to other pharmacological regimens that do not involved prescription medications that are subject to diversion and abuse is the risk posed to society. A patient who must take a prescription medication for a serious medical condition but who fails to do so as directed in most instances places only him or herself at risk of adverse consequences. However, when nonadherence to opioid therapy takes the form of selling or otherwise diverting these medications, there are significant adverse societal implications. There is no question that clinicians have responsibilities to their communities and the society at large and not only to their individual patients. Sometimes, as in the case of public health emergencies, there may be genuine conflicts between these two responsibilities. However, minimizing the risk of opioid addiction and diversion through the responsible use of treatment agreements and adherence monitoring enables the clinician to meet his or her obligations to both individual patient and society. As with the informed consent and information disclosure process itself, the manner in which such approaches are taken is every bit as important as the details of the approach itself. Moreover, it may well be the case that the wider use of measures to warn patients about the risks of nonadherence to prescription medication regimens and to monitor such adherence may be a necessary and appropriate response by the health professions to the data documenting the extent to which patients fail to take their medications as prescribed.

What is needed but presently does not exist are rigorous empirical studies evaluating the effects of patient agreements and drug screening on adherence to or the outcomes of treatment regimens.[38]

It would not be surprising to find that some of the high profile federal prosecutions of physicians with very liberal prescribing practices described in detail in Chapter 15 of this text have fueled the widespread adoption of rigorous opioid contract provisions. Those physicians were alleged to have, among other things, engaged in a form of willful blindness to a host of red flags that some of their patients either had no legitimate medical need for opioids or were flagrantly abusing or selling their medications. The recordkeeping and monitoring by the physicians was poor to nonexistent.

CONCLUSION

The ethics of pain management are in a profound state of flux. Neither the terms evolution nor revolution seem to be an apt characterization, for such terms suggest a gradual and organic development process on the one hand or a transformational paradigm shift on the other, neither of which can be supported by the existing evidence. Rather, the current state of affairs might well be characterized, without risk of serious exaggeration, as a battle for the soul of medicine. For as we noted at the very beginning of this chapter, seminal works on the place of pain and suffering in the context of the patient's experience of illness consistently remind us that their relief is a core value of medicine with roots running back to the very origins of the profession. In the modern era, when organized medicine has confronted phenomena such as physician-assisted suicide (aid in dying) or physician participation in lethal injection, prominent voices in opposition to the legitimacy of the physician's role in such practices have consistently invoked statements of principle such as the following: "Healing the sick and alleviating suffering is the primary role of physicians in U.S. society."[48] Yet those same voices have, for the most part, been silent in the midst of an epidemic of undertreated pain that afflicts chronic noncancer pain patients disproportionately. It has fallen to organizations such as the World Health Organization (WHO) and the International Association for the Study of Pain (IASP) to call for the recognition of pain relief as a human right.[49]

In no other aspect of patient care has the fundamental role of trust in the clinician–patient relationship become more of a pivotal issue than in the care of patients with chronic noncancer pain. With the proliferation of detailed opioid contracts including provisions for routine urine drug screens and rigidly specified grounds for terminating the relationship for nonaderence, we may be at risk of distrust becoming the reigning paradigm.[50] A shibboleth of the cold war era was "trust but verify." This approach may well have a place in patient care and the standard of care with which clinicians must comply. The challenge to the health professions posed by the current ambivalence toward patients requiring opioid analgesia for moderate to severe noncancer pain is formidable. On one hand are prominent voices such as the WHO and the IASP calling for recognition of a human right to pain relief for all patients. On the other hand are dire warnings to clinicians about deceptive, drug-seeking patients who must be engaged with extreme caution, a robust skepticism, rigorous scrutiny, as well as all of the other essential elements of pharmacovigilance. The establishment of a solid consensus among clinical and regulatory stakeholders as to where we ought to situate a healthy and reasonable balance between extreme, unrealistic naiveté and a rigid, pervasive cynicism about the role of trust in the care of patients with persistent pain should become a high priority for all conscientious and caring professionals.

CHAPTER 13 ■ ETHICAL ISSUES IN THE CARE OF DYING PATIENTS

DAVID BARNARD

INTRODUCTION

The Quest for Moral Order Amid Existential Disorder

> To the dying person his doctor, however much he is trusted and regarded as a source of treatment, is no longer one with the power to cure; to the doctor, the patient has become one whose death, despite every possible effort, he is impotent to prevent. This gives rise to problems in the special professional relationship which often develops between a patient and his doctor, and besides that they have the difficulties that face any two people trying to adjust to the fact that one of them is shortly going to die.[1]

This comment by John Hinton is a pointed reminder that the patient's nearness to death places the patient and the doctor in a challenging and disturbing place, both in their relationship with each other and in their sense of personal identity. The direct encounter with death—in the guise of the death of the patient—has the power to disrupt the doctor's relationship and communication with the dying person, throw ordinarily rational decision making into confusion, and capsize carefully wrought treatment plans.

Robert Burt has commented on the "inherent unruliness of death and the persistence of individual and social ambivalence about death" as features that limit our ability to fashion social policies and practice guidelines that are free of moral ambiguity or the possibility for evil and abuse. At the conclusion of his study of the conflict-ridden policies governing abortion, the death penalty, and physician-assisted death in the United States during the last half-century, Burt writes,

> Here is the paradox that we must learn to live with in regulating death: that we must teach ourselves, through our rational intellectual capacities, that our rational intellect cannot adequately comprehend, much less adequately control, death. We are no more compassionate, honorable, or intelligent than our predecessors who embraced the pursuit of rational mastery over death and were led, without acknowledgment, into unreasoned evil. We would do better to admit, as W.H. Auden acknowledged, that "Death is not understood by Death; nor You, nor I."[2]

The Contributions and Limitations of Ethical Analysis in End-of-Life Care

Hinton and Burt suggest that the psychological and existential dimensions of the encounter with death destabilize the doctor–patient relationship and rational decision making. They also require acknowledgment of the limitations as well as the contributions of ethical analysis in end-of-life care. At the most general level, the discipline of ethics itself embodies the cacophony of voices, worldviews, cultural frameworks, and value systems characteristic of postmodernity. As philosophers such as Alasdair McIntyre[3] and H. Tristram Englehardt[4] argue, no single, overarching standpoint or scale of values commands universal allegiance in a secular, pluralist society that is committed to the peaceable resolution of differences. Yet without such a universally compelling standpoint, there is no means short of force to eliminate the contradictions between philosophical systems or the competing claims of multiple moral communities.

Two aspects of uncertainty more specifically related to clinical ethics near the end of life are worth particular note at the outset. Consider the commonly accepted public consensus on the ethics of end-of-life care. Its main points include the following:

1. Competent adults may refuse medical treatment.
2. Treatment refusals may include all forms of life-sustaining medical treatment, including artificially provided nutrition and hydration.
3. Complying with a competent adult's informed wishes to refuse or discontinue life-sustaining treatment should be considered neither homicide nor assisted suicide.
4. From a moral and legal point of view, there is no difference between withholding a treatment (not starting it) and withdrawing a treatment (stopping it after it has been started), if the treatment in question is inconsistent with a competent patient's informed preferences.
5. For a patient who is terminally ill and who values comfort over prolongation of life, symptom control that has as a side effect the shortening of life is morally permissible and is not the moral equivalent of active euthanasia.
6. Incompetent or otherwise nonautonomous people have the same rights as competent people in these matters, with their wishes expressed either in the form of an advance directive or by a person authorized to make health care decisions for them.

To call these points the "public consensus" means that they capture a broad agreement in the bioethics literature, policy statements of professional organizations, judicial decisions, and the actions of state legislatures on the matters in question.[5] It is probably safe to say that these points organize the notes of nearly every medical school and nursing school lecturer on the topic of "the ethics of end-of-life care," and that they are the guiding principles brought to bear on individual cases by the vast majority of clinical ethics consultants at large in the corridors of U.S. hospitals. And yet it must be admitted that the consensus, though undoubtedly broad-based intellectually and influential clinically, masks substantial differences and disagreements within the health professions and the larger society. These differences encompass matters such as the relative weight to be accorded to individual autonomy and the general welfare; the validity of the distinction between, say, "killing" and "allowing to die"; or the proper characterization of artificially provided nutrition and hydration as either "medical treatment" or "basic, humane care."

A second aspect of uncertainty stems from the potential disconnect between an individual health professional's espoused values and ethical commitments, and his or her ability to act according to those commitments in specific clinical situations. To take one of many examples, since the 1960s there has been an enor-

mous shift in physicians' stated attitudes toward disclosing bad news to their patients. Whereas physicians have historically been reluctant to discuss bad diagnoses such as cancer directly with patients for fear of depressing them or eliminating hope,[6] by the late 1970s physicians who responded to surveys overwhelmingly favored full disclosure of a cancer diagnosis to the patient.[7] Patients themselves usually want to know the truth of their cancer diagnosis, and most also want a realistic estimate of how long they are likely to live. Yet when Baile and his colleagues surveyed more than 500 oncologists attending a meeting of the American Society of Clinical Oncology (ASCO), nearly one half rated their ability to break bad news as only fair or poor, and two thirds rated themselves as not very comfortable or uncomfortable dealing with their patients' resulting emotions. Only half had received any training in the subject.[8] These findings are consistent with the fact that, while many studies report general satisfaction on the part of patients and families with the information disclosure process,[9] other studies report significant dissatisfaction with the level of information or emotional support that patients receive from their doctors.[10,11]

With these considerations and qualifications in mind, this discussion of ethical issues in end-of-life care will attempt to bring to bear the public consensus mentioned above on four major themes:

1. The transition from curative to palliative and end-of-life care,
2. surrogate decision making,
3. responding to demands for nonbeneficial treatment, and
4. physician-assisted death.

Though, for the reasons noted, ethical analysis cannot pretend to eliminate moral doubt and disagreement—particularly on some of the most contested issues in these domains—some goals are quite realistic. These include: (1) providing a blueprint or template for careful and systematic ethical scrutiny of a clinical situation, thereby minimizing the risk that important, morally relevant considerations will be left out of account; (2) organizing the dialogue among the various parties to an ethical dispute, thereby assuring that the concerns and perceptions of everyone with a stake in the outcome of a clinical decision are taken seriously; (3) providing a method for isolating particular sources of ethical disagreement, thereby making possible either the marshalling of additional facts or arguments to produce agreement, or allowing people unable to agree to recognize their mutual good faith; (4) pointing to areas of agreement as the basis for creative problem solving that leads to decisions and actions consistent with people's most important values; and (5) encouraging educational efforts for health professionals—especially in the realm of patient-provider communication—to bring professionals' behavior more fully in line with their avowed values and beliefs.

THE TRANSITION FROM CURATIVE TO PALLIATIVE AND END-OF-LIFE CARE

Patients with serious disease and their physicians usually share three goals for the patient's care: cure or long-lasting remission, prolongation of survival, and comfort and quality of life. As prospects for the first and second goals dim with the progression of disease or the exhaustion of available curative therapies, physicians have the opportunity, and the challenge, of recommending that the third goal—now usually referred to generically as "palliative care"—become the main focus of the patient's continuing care. The World Health Organization defines palliative care as "the active total care of patients whose disease is not amenable to curative treatment. Control of pain, of other symptoms, and of psychological, social, and spiritual problems is paramount. The goal of palliative care is the achievement of the best possible quality of life for patients and their families."[12] J. Andrew Billings has suggested a more patient- and family-friendly definition:

> Palliative care is a special service, a team approach to providing comfort and support for persons living with a life-threatening illness and for their families. We are a nurse, social worker, chaplain, and physicians who work with your current health-care team to assure that you and your family receive excellent pain control and other comfort measures, get the information you want to participate in decisions about your care, receive emotional and spiritual support and practical assistance, obtain expert help in planning for care outside the hospital, continue getting good services in the community, and overall enjoy life as best you can, given your condition. We try to coordinate and tailor a package of services that best suits your values, beliefs, wishes, and needs in whatever setting you are receiving care.[13]

For the doctor, arriving at the decision to focus primarily on palliative care rather than continuing active, disease-modifying therapy can be complicated. It usually combines scientific and technical skills related to prognosis and clinical judgment; communication skills, often involving bad news and the need to respond sensitively to the patient's emotions; and negotiation of treatment preferences. Billings' description of the doctor's role at this juncture is:

> The patient and the family need a doctor who respects their expertise and can help them clarify and choose what they want, yet who is authoritative, helping to bring clarity and control by saying, "Let's keep trying" or "Let's face the music, it's time to stop."[14]

Billings' formulation strikes a balance between the two poles that have characterized ethical debates about the doctor–patient relationship for the past several decades: the doctor as neutral respecter of patient autonomy, and the doctor as authority figure under whose guidance patients suspend their own preferences in favor of the doctor's superior insight into their best interests. Despite the strong emphasis on patient autonomy and self-determination in the bioethics literature, when patients are faced with very serious disease and complicated choices, few want to be left completely on their own to make treatment decisions. Billings' formulation captures this reality by emphasizing both respect for the patient's ultimate decision making authority (consistent with the foundational value of informed consent) and the commitment not to abandon the patient by withholding the physician's best professional judgment.

Negotiating Treatment Preferences: The Ideal Decision-Making Process

From the standpoint of ethics, treatment decisions near the end of life, as at any other juncture in health care, ought to be structured by the notion of informed consent.[15] To be valid, the patient's consent should be informed and free of duress or coercion, and should reflect the patient's genuine values and preferences. An ideal decision-making process for medical care would include the following elements:

- *Joint participation* of doctor and patient, with additional participation of significant others of the patient's choice;
- *Clear and truthful communication* by the physician;
- *Clear and thoughtful deliberation* by the patient;
- *Consideration*, by both doctor and patient, of medical and nonmedical factors, including:
  - The patient's medical condition and options for treatment (including no treatment);
  - The reasonable probabilities that particular goals can be achieved;
  - The reasonably expected proportion of benefits of treatment to harmful or painful side effects;
  - The patient's values and life goals;
  - The patient's assessment of his or her quality of life, and the essential elements for a positive quality of life;
  - The patient's tolerance for risks and uncertainty;

- *So that*, the resulting decision:
  - Reflects a reasonable accommodation to the medical facts;
  - Is consistent with the patient's values and the physician's conscience.

Departures From the Ideal

In the end-of-life context, several factors are likely to complicate the ideal framework outlined above. They can be divided into two large groups: factors related to the uncertainty of prognosis and clinical judgment, and factors related to attitudes and values of both patients and physicians. After some discussion of each of these, this section will conclude with some suggestions for approaching conversations with patients that attempt to accommodate both prognostic uncertainties and emotional reactions.

Prognosis and Clinical Judgment

There are now a number of resources available for physicians to consult for prognostic information across a wide range of diseases and conditions, for example, in advanced cancer,[16] heart failure,[17] end-stage chronic obstructive pulmonary disease,[18] dementia,[19] cirrhosis,[20] and coma following cardiopulmonary resuscitation.[21] While the general outcomes and trajectories of diseases that are the major causes of death in the United States are known, and a typical patient's survival (assuming accurate diagnosis) can usually be estimated within a known range of probabilities, when any particular individual will die remains an inexact prediction. *Most people appreciate this, however, and the inability to give very precise predictions of a patient's remaining life expectancy should not be a barrier to physicians' participating in discussions with patients who want to have some realistic idea of their situation.* As will be described further below, the most important question for the physician is the level of information a patient desires to receive. The question, "Doctor, how long am I going to live?" cannot be answered helpfully without some initial exploration of the meaning the question has to the patient, what has motivated the question, and the patient's preferred level of detail.

A physician's prognostic accuracy seems to vary inversely with the length of time the physician has known the patient. The longer the relationship, the more likely it is that the physician will overestimate the patient's remaining time.[22] While the mechanism of this effect is not clearly established, the possibility of the physician's emotional attachment to the patient and investment in his or her survival cannot be ruled out. Lamont and Christakis comment in relation to this data that a palliative medicine specialist, or some other physician with relevant expertise but with no prior relationship to the patient, is likely to be a helpful resource to the treating physician in formulating prognostic information for individual patients.[23]

Another tendency of physicians that can diminish the usefulness of prognostic information is to provide it solely in terms of the quantity of remaining life (weeks, months, or years), without attempting to describe the quality of life the patient is likely to enjoy. Especially for people with chronic, degenerative conditions or conditions for which available disease-modifying therapies have significant side effects, their remaining quality of life is likely to be as important as a bare estimate of survival. Some issues that are likely to be of particular interest to the patient include the pace and timing of decreases in functional and/or cognitive status, pain and discomfort and the availability of the means to relieve them, loss of independence, and the expected burden on caregivers. It bears repeating that the physician's offer to go into detail on any of these matters should be contingent on a signal from the patient that he or she does in fact want to discuss them. Some people would prefer *not* to have such a clear image of impending decline to look forward to, though they may wish someone in the family to have this information so as to be better prepared.

Patients' Attitudes and Values

The physician's first responsibility in preparing for a conversation about treatment preferences in the setting of end-life care is to assess the patient's emotional and cognitive capacity to participate in the conversation. Among the emotional and attitudinal factors that may cause patients to depart from the ideal decision-making process outlined above are the patient's denial of the seriousness of the disease, or the presence of depression or other psychiatric disorders, as well as other forms of cognitive impairment that may be related either to the disease or its treatment. Appropriate treatment of the underlying causes of the cognitive impairment should be the first order of business. If this is not possible, the physician should consider the availability of a surrogate decision maker, as discussed in the next section.

Other emotional factors short of psychiatric impairment can diminish the patient's capacity to participate meaningfully in these discussions. For example, some patients may appear determined to *continue* pursuing active treatment for their disease because they believe other people want them to do this, not because it is their own preference. Some patients may worry about family members' ability to cope with the patient's worsening illness, or about their future security and well-being once the patient has died. Some patients may find it hard to reject treatments because they do not want to disappoint the doctor.

On the other hand, patients may *reject* further treatments not because they genuinely believe this is in their best interest but because treatment refusal is a language for expressing other concerns, such as fear (of being a burden to others, of the treatment, of the process of dying), anger, exhaustion, helplessness, mistrust, or unrelieved physical symptoms. A similar phenomenon can underlie patients' requests for physician-assisted death. In either context, sensitive exploration of the background and motivations underlying the patient's stated preferences is essential before the physician concludes that he or she has a clear understanding of the patient's perspective.

Physicians' Attitudes and Values

Several factors on the physician's side can also cause a dialogue about treatment preferences to deviate from the ideal. The physician's counterpart to the patient's denial is the tendency alluded to above for physicians to overestimate expected survival, especially for patients with whom they have had long-term relationships. It is often easier to perceive the deterioration in the patients of one's colleagues than in one's own patients.

A number of conceptual and philosophical commitments may also lead physicians to minimize or avoid open discussion with the patient about the transition from curative to palliative care. For example, medical training is primarily focused on providing the tools and skills necessary for the active investigation, diagnosis, and treatment of pathology. This instills an ideology of intervention, according to which any pathological state or process that is potentially reversible *should* be reversed. To stand back and look at the "big picture"—to accompany a patient into death without investigating or treating conditions for which (at least short term) remedies are available—requires a shift in perspective that many physicians find very difficult and contrary to their professional identity.

A closely related issue, especially in academic medical centers, is the imperative of research and therapeutic innovation. From this perspective, it is precisely the point in the patient's illness when all known effective remedies have been exhausted that presents the greatest opportunity for scientific progress. The research imperative demands that these opportunities be seized for trials of new and unproven treatments, to push back the boundaries of medical power. Many patients (especially if they are of a socioeconomic status that has entitled them to regular access to health care) are themselves caught up in the ideology of medical progress, having absorbed a lifetime of exhortations from doctors

and hospitals to avail themselves of regular checkups and the very latest in medical technology to ensure a longer, happier life.

The power of medical technology to forestall the time of death, especially in the intensive care unit, gives rise, in Daniel Callahan's phrase, to an ideology of "technological brinkmanship."[24] This is the idea that we can and should employ our technology for its maximum life-extending benefit, and then back off just at the point—but no later—when its marginal benefits begin to be outweighed by its burdens and costs. The reality is that the point of diminishing return is almost always only discernible in retrospect, after the patient has been subjected to a period of intensive and invasive treatments to no positive end, and the family is left to wonder why the patient couldn't have enjoyed a more peaceful death.

The availability of technology to forestall death creates an additional psychological pressure. This derives from the apparently observable fact that the death of any individual patient (especially in the ICU) almost always results from a decision to withhold or withdraw medical treatment. In other words, while in principle we ought to be able to take comfort from the fact that death is natural and universal—as in the ancient syllogism, "Socrates is a man; all men are mortal, therefore Socrates is mortal"—death for *this* patient *now* seems to us always to be optional, and its psychological reality for the doctor is that the death occurred only because he or she brought it about when he or she recommended, or acquiesced when the patient or family requested, termination of treatment.

Finally, a very common concern for physicians faced with recommending the transition from curative to palliative care (identified by nearly 60% of the respondents to Baile and colleagues' ASCO survey as the most difficult part of breaking bad news) is "being honest without taking away hope." This is particularly the case when "hope" is uniquely identified with the prospects for cure or significantly extended life. In fact, there are many other objects of patients' and families' hope that physicians almost always can help them realize; for example, comfort and freedom from pain, companionship, completion of important tasks, security for those who will be left behind.[25] Indeed, as suggested by Billings' previously quoted definition, these concerns are precisely the focus of palliative care. Nevertheless, the strong association between the shift to palliation from active treatment and "giving up all hope" can lead physicians to dread serious discussion of a patient's end-of-life treatment preferences.

Communication With Patients About Treatment Preferences Near the End of Life

The physician has four primary goals in the dialogue with a patient in the context of end-of-life decision making:

1. To learn about the patient's preferences for receiving information, and to assess the patient's coping style when confronting threatening situations;
2. To provide the patient with sufficient information about his or her current and projected medical situation and corresponding therapeutic and supportive options to enable the patient to make choices that reflect his or her values and preferences;
3. To establish rapport and trust in order to enhance the physician's credibility as a source of reliable information and interpersonal support;
4. To so balance genuine appreciation of the clinical situation with realistic optimism as to empower the patient—by mobilizing his or her adaptive capacities and social supports—to maximize his or her quality of life for as long as possible.

The goal of effective information transfer, while obviously of cardinal importance, is only one of several goals. If the others are not also satisfied, information transfer itself may not successfully occur. For this reason, most expert opinion on communication with patients about bad news—which for the purposes of this chapter will embrace not only prognostic disclosures but also discussions of referral to palliative care or hospice, responding to requests for nonbeneficial treatment, and requests for physician-assisted death—recommends that the physician address the interpersonal and emotional dimensions of communication as well as the clear presentation of scientific facts.

In an extensive literature review Penelope Schofield and her colleagues[26] identified 10 major considerations for communication about the transition from curative cancer treatment to palliative care:

1. Preparation prior to the discussion.
2. Eliciting the person's understanding of the illness and preferences for information transfer.
3. Providing information.
4. Responding to emotional reactions.
5. Negotiating new goals of care.
6. Arranging for continuity of care.
7. Addressing family concerns.
8. Acknowledging cultural and linguistic diversity.
9. Concluding the discussion.
10. Documenting the discussion and appropriately informing other members of the treatment team.

Baile and colleagues[8] consolidate these dimensions in a six-step protocol with the mnemonic **SPIKES**. In their formulation the physician's communication with the patient proceeds as follows:

Step 1: SETTING UP the Interview

Mental rehearsal, arranging for a private setting, involvement of significant others, sitting down, making eye contact, and taking steps to avoid interruption.

Step 2: Assessing the Patient's PERCEPTION

Ask before telling: Ascertain what the patient knows, how they want to receive information; for example, "What have you been told about your medical condition so far?" or "What is your understanding of the reasons we did the MRI?"

Step 3: Obtaining the Patient's INVITATION

Ask before telling: Ascertain the patient's preference for receiving information, recognizing that shunning information is a valid psychological response for some people. Asking this at the time of test ordering can help set the stage; for example, "How would you like me to give you the test results? Would you like all of the information, or just the big picture, with more time for us to talk about a treatment plan? Is there anyone else with whom you would prefer us to discuss this information?" Lamont and Christakis[23] suggest: "Some people want to know everything possible about their illness and others prefer to know very little. How much about your illness do you want to know from me today?"

Step 4: Giving KNOWLEDGE and Information to the Patient

Give a "warning shot"; for example, "Unfortunately I've got some bad news to tell you. . ." Start at the patient's comprehension level, avoiding technical words (say "spread" rather than "metastasize"); give information in small chunks with pauses to check understanding; avoid phrases such as "there is nothing more we can do."

Step 5: Addressing the Patient's EMOTIONS with Empathic Responses

Another mnemonic, **NURSE**, is helpful here.

Name the emotion: You look (sound) as if this is a real shock to you.

Understand: I cannot imagine what it is like to be so sick.

Respect: I really appreciate how you have been coping with this.

Support: I want you to know that regardless of what happens I will be there for you.

Explore: Tell me more.

Step 6: STRATEGY and SUMMARY

Ask before telling: Determine whether the patient wants to discuss future treatment plans at the present time; check the patient's overall understanding of what has been said; present treatment options if appropriate in the moment; offer time for the patient to reflect; offer to be available for questions that may arise after the interview; schedule a follow-up appointment.

In summary, the physician–patient dialogue about the transition from active treatment to palliative care can help the physician fulfill several aspects of the ideal decision-making process. By acknowledging emotional aspects of the situation that are likely to be present on both sides, by offering patients the opportunity to receive information—or not—at their own pace, by examining one's professional biases and assumptions that may hinder an open discussion of the patient's circumstances and the realistic benefits of a palliative approach, and by attention to the interpersonal as well as factual aspects of information transfer, the physician is most likely to support treatment decisions by patients that reflect their genuine values, and also to strengthen the foundations for the physician's role as a supportive companion to the patient throughout the course of the illness.

SURROGATE DECISION MAKING

At the time end-of-life treatment decisions have to be made, patients may not be able to speak clearly for themselves. They may be too sick to speak, too confused to listen to medical information or to deliberate about preferences, or even completely unconscious and beyond any communication at all. Typical contexts when patients lack decisional capacity near the end of life include patients suffering from dementia or other long-term cognitive impairment; patients suffering from delirium as a consequence of their disease or side effects of its treatment (e.g., metabolic derangements, drug-induced delirium, "ICU psychosis,"), severely depressed patients, patients with waxing and waning mental capacity, or who give inconsistent, contradictory answers to treatment-related questions within a short period of time; postoperative patients under the influence of anesthetics or medications to promote ventilator compliance; patients suffering loss of consciousness due to stroke, cardiac arrest, or other traumatic event; and patients in coma or persistent vegetative state.

Surrogate decision-making is the process by which these patients may be brought as close as possible to the ideal decision-making process described above. It involves the following basic elements: (1) assessment of the patient's decisional capacity; (2) for patients deemed lacking in capacity, attempts to rule out or eliminate reversible causes; (3) identification of an appropriate surrogate; (4) clarifying the surrogate's roles and responsibilities; and (5) anticipating, where possible, future needs for surrogate decision making through a process of advance care planning.

Assessing Decisional Capacity

Decisional capacity is task specific. Someone may be properly judged capable of making some decisions—jello or custard for dessert, baseball or NASCAR on TV—and incapable of making other decisions—financial investments, whether or not to enter a nursing home, or, most relevant here, the choice of medical treatments in the setting of advanced disease. For the latter, the patient's capacity should be assessed in terms of:

- **Understanding:** Does the patient understand the meaning of the diagnostic or prognostic information provided to him or her? Can the patient restate the information in his or her own words in a way that demonstrates this understanding?
- **Appreciation:** Does the patient appreciate the implications of the information for himself or herself? Does he or she appreciate that decisions have to be made from among alternative treatment plans, and that his or her input is necessary for these decisions?
- **Deliberation:** Can the patient weigh the alternative treatments according to his or her personal goals and values?
- **Communication:** Can the patient communicate his or her treatment preferences in an understandable manner? Do the patient's stated preferences appear logically related to the patient's goals?

There is no rigid, quantifiable measure of the patient's abilities in these domains. In general, the more significant the decision that needs to be made—in terms of risks, benefits, and side effects—the more stringent our standards should be in satisfying ourselves that the patient has the requisite capacity.[27]

Contrary to common practice, especially in hospitals where psychiatric consultation is readily available, a formal psychiatric consultation is not required to assess a patient's decisional capacity. Nonpsychiatrist physicians ordinarily are capable of forming a reasonable judgment of the patient's abilities in these four domains. Moreover, even if a psychiatric consultant judges the patient to have capacity, it remains the attending physician's responsibility to satisfy himself or herself that the patient is in fact capable of giving informed consent before proceeding with treatment. Where psychiatric opinion is most relevant is when the physician suspects mental illness or delirium as the (possibly reversible) cause of the patient's lack of capacity, or where appointment of a legal guardian is anticipated, in which case the court will be interested in authoritative medical opinion.

Ruling Out or Eliminating Reversible Causes of Incapacity

Reversible causes of incapacity can be biological or situational. Biological causes include transient delirium, treatable depression, or the side effects of anesthetic or analgesic medications. Situational causes include anxiety or fear as an immediate consequence of receiving bad news, confusion or anxiety due to the effects of hospitalization, the sensory overload of the ICU, and/or separation from familiar people. Before deciding that a patient's lack of capacity warrants turning to a surrogate, realistically assess the importance of making particular decisions right away. If urgent decisions are not required, attempt to diagnose and eliminate the patient's incapacity. This could entail adjustments of medication, psychosocial intervention, or simply the passage of time.

Identifying a Surrogate

If the gold standard for ethical health care decision making is the thoughtful participation of an informed patient, the gold standard for surrogate decision making involves a surrogate who is:

- **authorized** by the patient, because the patient considers the surrogate to be trustworthy and in the best position to advocate for the patient's best interests;
- **willing** to accept the patient's trust and to fulfill the role of surrogate in good faith;
- **informed**, through prior acquaintance or explicit conversation with the patient, about the patient's values and preferences regarding medical care near the end of life;
- **capable** of understanding the physician's explanations of the patient's condition and weighing treatment options in light of the patient's preferences;

- **available** to represent the patient's interests at the time decisions have to be made.

Since Congress passed the Patient Self-Determination Act in 1990 in the wake of the *Nancy Cruzan* decision of the U.S. Supreme Court, there have been many local and national efforts to encourage people to identify a surrogate in case of their own future incapacity. All 50 states have adopted legislation authorizing health care decision making by surrogates under various criteria and qualifications, for example, the state of the patient's health (usually the patient must be "terminally ill" as variously defined, permanently unconscious, or in an advanced stage of a serious, incurable condition), the process by which the surrogate has been designated, and the scope of the surrogate's authority. Despite these efforts, most people for whom end-of-life medical decisions must be made have not designated a surrogate in advance.[28]

A number of states have addressed this gap legislatively by prescribing, in lexical order, the persons who are empowered to act as the patient's surrogate. A typical ordering begins with the patient's spouse, and then moves in descending order through adult children, parents, adult siblings, adult grandchildren, and (only then) other adults who may be in a position to know the patient's beliefs about medical treatment. In states where this regime applies, physicians as well as patients may be faced with the situation where the prescribed surrogate does not fulfill the criteria noted above as well as someone lower on the list—or not on the list at all. Gay partners, for example, have legitimate reason to fear exclusion and disenfranchisement in decision making for each other under strict interpretations of these surrogacy laws.

From the point of view of ethics, the physician's primary responsibility as the patient's advocate is to identify the surrogate who meets those criteria to the greatest extent. In cases where that person is available and willing to serve in the role, but another, less qualified, person with lexical priority is expressing conflicting preferences for care, it is advisable for the physician to seek consultation from an ethics committee or from a hospital's legal counsel.

The Surrogate's Roles and Responsibilities

The surrogate's primary responsibility is to interpret the physician's recitation of the patient's medical condition and recommended treatment in light of what the surrogate has reason to believe are *the patient's* relevant values, preferences, and life goals. This is the "substituted judgment" standard for surrogate decision making. Unless the surrogate has been instructed differently by the patient, he or she ought to try to the best of his or her ability to express treatment preferences that reflect the patient's goals and values, and not the surrogate's, if there is a conflict between them. If the surrogate is not certain what the patient would prefer in a given situation, or if, despite a good faith effort on the part of all who are in a position to know, there is simply no evidence whatsoever of the patient's likely preference, the surrogate ought to make the decision that appears to be, from an objective point of view, in the patient's best interests. Ordinarily this is determined by weighing, in the most informed manner possible, the likely benefits (to the patient) of various proposed treatments—or no treatment—against their likely burdens (again to the patient). This is (not surprisingly) the "best interests" standard for surrogate decision making.

Physicians and other members of the health care team have potential roles to play in helping surrogates do their job. Their most obvious role is to provide clear and helpful prognostic information and descriptions of proposed treatments according to the protocols outlined in the previous section. But they may also be able to enhance the surrogate's ability to represent the patient's interests and preferences by engaging in dialogue with the surrogate about the patient. The content of that dialogue will be suggested by the discussion in the next section of the most useful elements of an advance directive for health care.

A Realistic Process of Advance Care Planning

Most commentators agree that policies to encourage people to use advance directives to prepare for future end-of-life decision making have been largely unsuccessful.[28,29] As noted above, only a minority (between 20%–30%) of American adults have filled out an advance directive. Evidence suggests that even for those who have them, advance directives do not influence decision making. Most particularly, if people expect that filling out an advance directive will ensure that the medical decisions made during their future incapacity will match the choices they themselves would have made had they been able to participate in those decisions themselves, they will almost certainly be disappointed.

Common difficulties are that the documents cannot be located when they are needed, they are too vague to give useful guidance in the patient's actual circumstances, or the patient's stated preferences are ignored in favor of a course of action that physicians and/or family members believe is more in accord with the patient's present best interests. Hickman et al.[29] have listed some of the main factors that may explain these difficulties. These include:

1. An overemphasis on the patient's legal rights to refuse medical care, as opposed to the more general objective of enhancing people's ability to influence their care according to their goals and values;
2. Insufficient efforts by health professionals to educate patients as to realistic outcomes of various medical interventions;
3. Overemphasis on patients' preferences for specific medical interventions, rather than the effort to ascertain the patient's views about goals and values, and about what constitutes an acceptable quality of life;
4. The assumption that the planning process is complete as soon as an advance directive has been filled out, rather than viewing the process as ongoing and subject to periodic reassessment and revision of the patient's goals in light of changing medical circumstances;
5. Failure to involve family members or other important people in the patient's life in discussions about preferences for medical care;
6. Absence of system-wide policies and procedures to ensure that patients' preferences for care are known and respected wherever the patient may be receiving care;
7. Low community awareness of issues related to end-of-life planning;
8. State advance directive laws that introduce barriers into the advance planning process.

Three Basic Problems

As significant as Hickman and colleagues' barriers are for explaining the lack of public enthusiasm for the advance care planning process, there are three basic problems with advance directives that frequently lead to frustration and disappointment even when patients have gone to the trouble of creating one. All three are related to the nature of medical care for the critically ill, and the existential predicament of the person facing death. Stated briefly, and somewhat too simply, they are:

(1) Unpredictability. Because of the probabilistic and uncertain nature of prognosis, it is extremely unlikely that the scenarios a healthy person imagines when filling out his or her advance directive—either sitting at the kitchen table or in the doctor's office—will match the actual circumstances the patient or surrogate will face in the future. The more general the terms of the

advance directive, in order to capture a range of possibilities broad enough to fit an unknown and unknowable future, the less use they will be in providing specific guidance about treatment preferences. This is a structural problem that no preprinted advance directive form—no matter how elaborately or imaginatively it has been constructed—can solve.

(2) Uncertainty. Related to the unpredictability of the time and manner of death in general is a more specific uncertainty as to the potential benefit of any particular medical intervention or treatment that might be used near the end of the incapacitated person's life. Consider, for example, treatments such as antibiotics, oxygen therapy, blood transfusions, or even more invasive procedures such as kidney dialysis. All of these are typically among the items that, in advance directives, people indicate the desire *to refuse* in the case of terminal illness. Yet each of these, while not capable of reversing the dying process, may be very useful for more particular goals such as alleviating pain, clearing mental confusion, or simply keeping a person alive long enough for family or friends to gather at the bedside for a final farewell. The question, "If you were mentally incapacitated and terminally ill, would you want blood products or antibiotics?" (for example) is practically meaningless when asked far in advance.[30]

(3) Ambivalence. The desire for a gentle death, free of tubes and machines, coexists in most of us with the powerful desire to stay alive. It is very difficult to predict how, in the moment of truth, a particular patient will respond to even a tiny chance of success for a life-prolonging treatment, when the alternative to trying the treatment is likely to be imminent death. The difficulty of extrapolating a patient's real-time choices from previous discussions is compounded by the "framing effect," in which those choices will be strongly influenced by the way the alternatives are actually described.[31]

A Realistic Approach

It is a disservice to patients and families to represent advance care planning as a method of assuring the ability to exert control over the medical treatments they will receive at the end of life. Nevertheless, proponents of advance care planning frequently urge people to complete an advance directive, or a durable power of attorney for health care, precisely to "take charge" of their future medical care or, with respect to some dreadful twilight state between life and death in an Intensive Care Unit, to "make sure this can never happen to you." They encourage people to believe that if they are incapacitated, but have planned in advance and filled out the proper documents, the treatment decisions that will be made for them will match the decisions they themselves would make if, miraculously, they could be restored to full capacity, process all currently relevant medical information, and then decide which treatments should be applied. For all of the reasons mentioned above, this is misleading overstatement.

There are, however, some very realistic and meaningful goals that advance care planning *can* help people achieve. One goal is to promote honest and open communication about important values and life goals within families, and between patients, families, and health professionals, in the face of serious illness. This type of communication is often of great intrinsic value, whether or not it bears any relation to specific treatment choices. Another goal is to arrange for future medical decisions to be made, in case of future incapacity, by someone whose love and care the principal trusts—not on the assumption that this individual will infallibly make the "right" decision (if "right" means matching exactly the decision the principal would have made)—but because, since *any* surrogate is likely to be "wrong," it is often of great comfort to know that the decision maker is someone who really cares about you and is probably going to do his or her best to serve your best interests. Finally, advance planning is an opportunity to reflect on those qualities of life that make life worth holding onto and, conversely, those qualities that might be worse than death, and to communicate those values to a surrogate, who can then compare the likely outcomes of real-time medical alternatives to those benchmarks, and make choices in their light.[32]

A reasonable and useful advance care planning document should probably contain information along the following lines. Beyond their value in suggesting what an advance directive should contain, these items are also intended to suggest some of the questions that physicians can ask—directly of patients in advance, or to help surrogates fulfill their roles in order to fashion a treatment plan more likely than not to respect patient values.

1. Identification of a preferred surrogate decision maker, and at least one back-up.
2. Statement of the extent of the surrogate's authority, and how much flexibility the surrogate has in responding to real-time circumstances in ways that might depart from any specific instructions.
3. Evidence that the surrogate is aware of his or her appointment and understands the scope of his or her authority.
4. A statement from the principal describing the qualities and aspects of life that the principal considers necessary for a minimally acceptable quality of life, accompanied by instructions to the surrogate to request the application or continuation of *any and all* medical treatments that have a reasonable likelihood—according to accepted medical judgment—of restoring to the principal that quality of life for a reasonable period of time. Similarly, the surrogate is instructed to decline or insist on the withdrawal of *any and all* medical treatments if those treatments do not have a reasonable chance—according to accepted medical judgment—of achieving or maintaining that quality of life for a reasonable period of time.
5. In general the document should *not* specify particular treatments that the principal does or does not want. The statement in (4) should provide sufficient guidance for the physician to make these specific treatment decisions in light of the principal's overall criteria for an acceptable quality of life, combined with the principal's preference for resolving medical uncertainties—see (7). However, there may be some special circumstances in which particular treatments should be mentioned; for example, a Jehovah's Witness may wish to decline blood or blood products; or a person who has previously been resuscitated and placed on a mechanical respirator may have become convinced by the experience that he or she would never want it to be repeated; or in states that require the administration of artificial nutrition and hydration unless they are explicitly included among treatments to be withheld. Otherwise, the broad statement of values (4) and preference for resolution of uncertainties (7) should suffice for most people.
6. A statement of the principal's willingness to undergo trial periods of medical treatments when physicians are uncertain of their likely benefit, as defined in (4), accompanied by a clear statement of the surrogate's authority to stop those treatments after the agreed-upon trial period has ended.
7. A statement of the principal's preference either that genuine medical uncertainties be resolved in favor of *more* aggressive treatment or *less* aggressive treatment, with a clear additional statement that the surrogate has the ultimate authority to resolve disagreements between conflicting medical opinions.
8. A statement by the principal that he or she wants all necessary measures to maintain comfort and to treat pain, and that when medical treatments are deemed incapable of achieving the goals defined in (4), pain and other symptoms should be treated aggressively even if adequate treatment carries the risk of hastening death. The statement should include the desire for treating physicians to consult with qualified specialists in

pain management and palliative care whenever they or the surrogate deems it appropriate.

It should be said in conclusion that many, many people experience end-of-life decision making that is smooth and uncomplicated, and for many, many survivors the death of a loved one, while sad, is neither chaotic nor traumatic. When things go awry, or people are anguished and bewildered by events that seem to be tumbling out of control, it is usually not the fault of a missing or poorly worded living will or durable power of attorney for health care. Recall the perspectives of Hinton and Burt in the introduction. Death carries enormous power to frighten us and to discombobulate the best laid plans. Despite our rhetoric of *management* of symptoms, or of *directing* our health care providers to do (or not to do) this or that, we do not control death. In its presence we bear witness, and do the best we can.

RESPONDING TO DEMANDS FOR NONBENEFICIAL TREATMENT

The ethical consensus respecting a competent adult's right to *refuse* medical treatment—even life-sustaining treatment when the refusal is contrary to the physician's professional judgment—does not extend to the patient's or family's right to *demand* medical treatments that, in the physician's professional judgment, offer no prospect of patient benefit. This difference in the moral and legal status of refusals and demands occasionally gives rise to conflicts that are among the most vexing and emotionally draining that can occur in end-of-life care. Taken to their limit these conflicts can be so destructive, not only of the physician–patient–family relationship but of the atmosphere and milieu of the patient's dying that loved ones will take with them in memory, that prevention is the physician's foremost ethical responsibility. Preventive measures are not always successful, but their chances can be improved through systematic analysis of the nature of a conflict in its early manifestations ("differential diagnosis"), and a range of communication and conflict resolution strategies.

The Ethical Basis of the Conflict

Ethically, the difference in physicians' obligations toward refusals of treatment and demands for treatment stems from the way ethics and law customarily interpret the concepts of autonomy and self-determination. In bioethics, respect for personal autonomy and self-determination is rooted in the ideas of privacy and bodily integrity. The idea is that—with very few exceptions, such as a potential public health emergency—a person ought to be able to control what is done to, with, or for his or her own body. This is the foundation for the requirement of informed consent, and for the patient's right to say "No" to the physician's recommendations for (even life-saving) treatment. Courts have tested the claim of patient self-determination, or the patient's right to say "No," against potentially competing claims such as the state's interest in preserving life, the interests of third parties (e.g., spouses or minor children), the integrity of the medical profession, and the prevention of suicide. In every case almost all courts have come down in favor of self-determination. The competing interests have been uniformly seen as too abstract, too remote, or too weak to override the individual's interests in preventing the violation of his or her bodily integrity and in limiting the power of others to enforce values or life goals that he or she does not share.[33]

The matter is quite different for the person who demands a particular treatment. (This distinction applies equally to the context of requests for physician-assisted death, which are discussed in the next section.) Here it is no longer a question of an individual protecting his or her bodily integrity by drawing a boundary and saying: "Do not cross." Respecting this essentially negative right (the right to be let alone) requires physicians and everyone else simply to do nothing. The person who demands a treatment, however, would compel the physician, and potentially many other people, to act affirmatively to supply the treatment. Many more public and professional interests and resources are implicated in the positive satisfaction of a demand than in the negative respect for a refusal. And, especially when the demand is for a treatment that, according to accepted medical opinion, will not benefit the patient, ethical opinion is far more deferential to competing societal and professional interests than in the case of patients who are asserting their negative right to be let alone.

It is worth noting in this last connection that only a very few courts have explicitly addressed the question of patients' demands for life-saving treatment against widely accepted medical opinion, and up to now no clear judicial trend has emerged.[34] Among the most likely reasons for the relative lack of such cases is hospitals' reluctance, despite their desire to support physicians' professional judgment, to bear the costs and potential damage to their public image of going to court to force the removal of life-sustaining treatment over a family's vehement protests. However, as noted above, there are other, better reasons to avoid recourse to the very public, adversarial forum of a court of law to resolve these conflicts. Preserving a therapeutic relationship and protecting the sacred personal environment of the deathbed are very worthy motivations for the physician's efforts to find a more constructive resolution.

The Clinical Context of the Conflict

Many clinical scenarios have the potential to bring doctors into conflict with patients or their families over the continuation of medical treatments of little or no likely patient benefit; for example, continuous blood transfusion for the patient with inoperable bleeding, full resuscitation efforts for the elderly patient with sepsis and multiorgan failure, additional courses of high toxicity anticancer treatment for the patient for whom both standard and experimental therapies have failed to slow the spread of the disease. The paradigm case, however, continues to be the noncommunicative, ventilator-dependent patient, kept alive by mechanical means while suffering inexorable bodily deterioration and discomfort with little prospect of improvement. This is the patient who, in K. Danner Clouser's words—as vividly applicable today as when he wrote them 30 years ago—"is on the borderline between treatment and torture, where therapeutic hope has vanished, and pain without point has taken over. The doctor's time-honored admonition to preserve life and lessen pain is at a stupefying impasse."[35]

Faced with a family's continuing insistence that "everything be done," including, if necessary, chest compressions and electric shocks to the heart in order to keep the patient alive, the medical team chafes in resentment at another "family that doesn't get it." Every evening, when the family arrives at the ICU the same routine plays out: a physician from the team recites the grim medical facts, points to the patient's deteriorating body, and urges the family to allow them to withdraw the ventilator so the patient can die peacefully. The family listens to the explanations—the descriptions of failing organs, alarming laboratory values, hopelessly long odds—and insists that everything be done. The team wonders why a supposedly loving family is being so selfish and cruel, and how it is possible for the obstinacy of one family to commandeer enormous medical resources that could and should be put to much better use. The family wonders why the doctors keep badgering them with their litany of doom and gloom when they should simply be about their business of keeping their loved one alive, and how it is possible that the hospital can be so indif-

TABLE 13.1

CONFLICTS OFTEN RESOLVABLE

- Lack of comprehension
- Emotional barriers to processing information
- Disagreement about the patient's preferences
- Narrow understanding of "hope" and "caring"
- Mistrust of health care team
- Team conflict and mixed messages

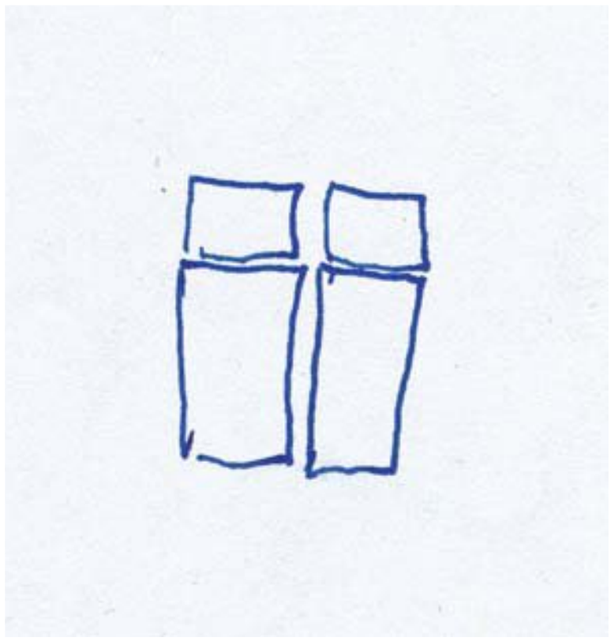

FIGURE 13.1 Physician's sketch of infant heart in apocryphal story of miscommunication.

ferent to the value of the life which the family has entrusted to it.

Differential Diagnosis of the Conflict

The frustrated medical team's epithet, "The family doesn't get it," is often shorthand for a common diagnosis of the cause of the impasse; namely, that for all of the medical team's efforts to be clear about the patient's serious medical condition and grim prognosis, the family has yet to fully comprehend. With every passing day, with its presentation of facts, laboratory values, and statistics, the team's hypothesis appears to be confirmed by the family's implacable opposition to changing the patient's level of care. Perhaps, the team reflects, we are using too many big words. Perhaps this is not a very well educated family. Maybe English is not their native language. The team redoubles its efforts to educate the family about the seriousness of the situation, only to remain stuck with the same result.

In fact there are several possible explanations for the conflict between the doctor and the family, of which a lack of intellectual understanding is only one, and not the most common in any event. But if lack of understanding is *not* the principal source of the conflict, then repeated efforts to lecture the family about the medical facts are no more likely to resolve the impasse than a course of antibiotics is likely to succeed in treating a viral infection. From the outset, therefore, an ethics of prevention requires careful discrimination among the possibilities. Tables 13.1 and 13.2 suggest a differential diagnosis of physician–family conflicts surrounding medically nonbeneficial treatments.

The principal difference between the two tables is that, in principle at least, all of the issues in Table 13.1 are amenable to resolution through sensitive, therapeutic dialogue, whereas the issues in Table 13.2 represent potentially intractable clashes of values or worldviews. Therefore, a good first step for the team is to try to elicit as specifically and clearly as possible all apparent sources of disagreement, sorting them if possible into the two categories, and choosing strategies of mediation or conflict resolution accordingly.[36]

In Table 13.1, for example, even though problems of intellectual comprehension are infrequently at the bottom of profound disagreements about life-sustaining treatment, the team has the responsibility (always implicit in the ideal decision-making process outlined above) of communicating information about the patient's illness in a language and in a setting that are optimally conducive to patient/family comprehension. It is worthwhile cultivating the skill of inquiring, in a noncondescending way, whether a family can repeat back to the team the essence of the information the team has tried to convey. (An apocryphal story recounts the experience of a surgeon who hastily sketched the chambers of a baby's heart for a new mother, in an effort to explain the need for a valve repair, in a schematic diagram similar to what's shown in Figure 13.1, only to hear the mother report to the father that their baby's problem was that it had been born with a square heart.) Genuine misconceptions and misunderstanding usually can be corrected with appropriate educational strategies.

Other issues in Table 13.1, however may deserve more consideration. For example:

- What may appear to be lack of intellectual comprehension may be a manifestation of emotional barriers to taking in information. The information may be too threatening, too unexpected, or too evocative of a deepest dread to be absorbed without the protective shields of numbing or denial. Most situations permit periods of supportive accompaniment of the shell-shocked, grief-stricken family before pressing forward with the team's recommendations to change the focus of care. Communication strategies discussed above, particularly under the SPIKES and NURSE mnemonics, can be of great value in this setting.
- The team and family may have different understandings, or evidence, of the patient's likely preferences. The patient may have expressed one view to the doctor, and another to the family. Language in an advance directive may suggest one thing to the team, but something quite different to family members who were present when the document was filled out. A tension-lowering approach in this setting is for someone (perhaps an ethics consultant) to open a physician–family conference with the statement, "Everyone in this room is trying to do exactly the same thing, which is to give [your husband, father, brother] the care that he would want if he could speak with us now. Our challenge is to figure out what that is. Let's go over what each of us knows about his likely preferences at this point, and how we learned this information."
- Patients as well as physicians may equate "hope" exclusively with hope for cure or prolongation of life, and "care" with the provision of maximal medical treatment. Efforts to expand hope include achievable goals more consistent with the patient's condition, and suggestions to the family of ways to express love and care through their presence, voice, and

TABLE 13.2

CONFLICTS OFTEN INTRACTABLE

- Disagreement on legitimate goals of medical care
- Disagreement on acceptable probabilities of success, or trade-offs between potential benefits and burdens
- Disagreement on an acceptable quality of life
- Waiting for a miracle

TABLE 13.3

CHECKLIST FOR THE TEAM

- Do team members agree on diagnosis and prognosis?
- Have team members and family compared sources of information about the patient's preferences?
- Is the team speaking to the family with one voice?
- Has the team identified a spokesperson with the greatest rapport and credibility in the eyes of the family?

touch, may offer the family emotional space to adjust their expectations of the medical team.

- Especially for families from marginalized, economically disadvantaged communities, the recommendation to limit intensive medical care can appear to repeat long-standing patterns of social injustice and deprivation. The medical team may represent one more agent of an oppressive power structure. In this setting, the family is unlikely to trust the team's recommendations, even when they are made in good faith on the basis of solid scientific evidence. If the team suspects this dynamic may be at work, explicitly naming the lack of trust and offering to call in more trusted individuals from the family's community may diffuse the conflict and promote eventual agreement on a treatment plan.
- Perhaps most common of all preventable or remediable sources of conflict, especially in the ICU, are mixed messages to the family about the patient's condition. The attending physician may prepare the family for the patient's inevitable death based on the overall combination of downward-trending prognostic indicators, only to have a specialist consultant come by later to tell the family that "the [lungs, kidneys, blood counts] look a bit better today." A team that repeatedly sends mixed signals to the family should not be surprised when the family holds fast to the most optimistic statements, and insists on staying the course. The most urgent task is for the team to arrive at its own internal consensus.

A brief checklist (see Table 13.3) can be part of a preventive ethics strategy to help the team first ascertain whether it is in fact dealing with a Table 13.1 type of conflict, and, second, maximize its chances of resolving it.

Table 13.2 conflicts are more difficult to resolve solely within the context of therapeutic dialogue. This is because the terms of the disagreement reflect value differences or worldviews that are not necessarily amenable to rational persuasion, or which supply disputants with individually convincing yet mutually incompatible interpretations of agreed upon facts. Institutional policies for mediation, which may include mandatory consultations with an ethics committee, and—if these efforts fail to break the impasse—offers to transfer the care of the patient either to another physician or to another institution, are options of almost last resort.[36] In the extreme case, none of these options is feasible. The institution may then be faced with the choice of going to court to obtain judicial authorization to stop the treatment—with no certainty of success but the virtual certainty of cementing the family's enduring resentment. Alternatively, it may recognize that there are (fortunately rare) instances where, for reasons of compassion, "professional medical judgment" and "the rational use of medical resources" may yield to a family's indomitable will. Though the team may view the patient's dying as needlessly prolonged and even horrible, in the circumstances of a family's passionate intransigence it may be the least poor outcome.

PHYSICIAN-ASSISTED DEATH

The vast attention paid to physician-assisted death in discussions of ethics at the end of life is far out of proportion to its actual significance in the experiences of most dying patients and their families. For most people, far more important issues are related to maintaining the energy and stamina to pursue valued activities and relationships amid the burdens of illness and obtaining timely, skilled help with pain, anxiety, and other symptoms. Even in Oregon, whose Death with Dignity Act legalizing physicians' prescriptions of lethal doses of medication for terminally ill patients spawned fears of a "suicide mecca" in the Northwest, the 46 deaths in 2006 that occurred under the law amounted to one-seventh of 1% of all deaths in the state that year.[37] Nevertheless, the issue commands attention, in part because of legitimate public concerns about the quality of care that our society makes available to the dying, and because requests for physician-assisted death confront physicians with troubling questions about the proper boundaries of medical practice and the nature of their duty to relieve suffering.

Terminology

As with many contested social practices, the language used to describe the various ways physicians can be involved in hastening the time of a patient's death has evolved through many phases and fashions, with people's preferred language often reflecting their prior moral evaluation of the practices in question. Thus, the literature abounds in discussions of the differences between "killing patients" and "allowing patients to die" or the differences between "passive euthanasia" and "active euthanasia,"[38] and—more recently—the preference of organizations such as the American Public Health Association[39] and the American Academy of Hospice and Palliative Medicine[40] for the term "physician-assisted death" rather than "physician-assisted suicide." What seems to be at issue in the debates about terminology is the recognition that *how we characterize* an action (or an omission) often predetermines judgments of its moral status.

Because "killing" is nearly universally condemned in all but very carefully circumscribed situations, proponents of physician actions (or omissions) that hasten a patient's death take pains to argue that those actions or omissions are not instances of "killing." Similarly, because "suicide" carries wide social stigma and is often associated with mental illness, patients who make use of physician-provided lethal prescriptions and the physicians who provide them prefer to characterize what they are doing in terms other than committing or aiding in "suicide." In fact, there is usually room for reasonable people to disagree about the most accurate characterization of many actions. This is one reason why, as mentioned at the beginning of this chapter, the public consensus on many aspects of end-of-life care (including, of most pertinence here, the idea that respecting patient wishes for aggressive symptom management that foreseeably hastens death is neither assisted suicide nor active euthanasia) masks considerable uncertainty and debate within society.

For convenience, the rest of this section will employ the term "physician-assisted death" to refer to a spectrum of actions and omissions by which physicians may have a more or less direct role in bringing about the death of an incurably ill patient sooner than the patient might have died without the physician's involvement. There is a fairly strong public and professional consensus (with the qualifications previously mentioned) about the moral status of many points along the spectrum.

Ethical Considerations Along the Clinical Spectrum

There are at least six reasonably distinct actions or roles that a physician might take in the care of a terminally ill patient that could advance the timing of the patient's death. Two lie at oppo-

site ends of the ethical and legal spectrum. Respecting the competent patient's wishes to forego or remove life-sustaining treatment is universally accepted ethically and legally in the United States. Administering a lethal injection with the intent of immediately ending the patient's life ("active euthanasia") is universally rejected legally in the United States, and—though not universally condemned ethically—commands the least widespread support in the ethical literature. In between are four actions that remain somewhat controversial though in varying degrees, always allowing for the fact that characterizing an action as one of these four is itself often a morally significant choice.[41,42]

These four intermediate actions include:

- Aggressive symptom management, usually with opiates and sedatives, despite the risk of hastening the patient's death. The paradigm case is the use of large doses of morphine for pain relief that have the effect of causing fatal respiratory depression. In fact this is an extremely *unlikely* side effect of skillful opioid administration to a patient who has been receiving chronic opioid therapy for pain relief for a period of time. Nevertheless, the scenario is frequently brought up in discussion of the "rule of double effect." This is the notion, originating in Catholic moral theology, that an action with foreseeable but unintended bad effects (here the death of the patient) may under certain conditions be undertaken with the primary intent of bringing about its good effect (here, the relief of pain). The extensive debate over the philosophical coherence and clinical applicability of the rule of double effect is beyond the scope of this chapter.[43–45] For present purposes it is sufficient to note that the basic concept of treating patient suffering aggressively with appropriate medical therapies, even at the risk of the patient's earlier death as a side effect of the therapy, is well accepted clinical practice and appears also to have received the sanction of at least some justices of the U.S. Supreme Court.
- Sedating the consenting, terminally ill patient to the point of unconsciousness to protect the patient from otherwise intractable physical or emotional suffering, while also withholding artificially provided nutrition and hydration. This sits on the borderline between the previous action (and its common justification via the rule of double effect) in combination with the universally accepted practice of respecting patient refusals of medical treatment, on the one hand, and the far more controversial action of injecting patients with a lethal dose of medication. The argument against the practice is that, while the sedatives themselves are not administered in an intentionally lethal dose as in the case of "active euthanasia," in combination with the withholding of nutrition and hydration the patient's death is as inevitable as it would be at the higher dose. That it takes place more slowly, in this view, should not affect the characterization of the action as ("slow") active euthanasia.[46] To this comes the rejoinder that, unlike active euthanasia, with its clear intent for immediate death, "terminal sedation"—as the practice is commonly known—is in principle always reversible (sedatives can be lightened to give the patient the opportunity to interact and change course if desired), and remains focused on alleviation of discomfort, not on bringing about the patient's death.
- Counseling the patient about voluntarily stopping eating and drinking and, if the patient decides to do this, providing medication as needed to alleviate possible discomforts or anxiety over the ensuing period of the patient's death from dehydration. This is another borderline action. On the one hand, it has been advocated as a solution to the moral conundrum posed by physician-provided prescriptions for lethal injection because the patient is solely responsible for his or her lack of nutrition and hydration, and his or her death is simply the result of the patient's exercise of the well-accepted right to be free of bodily intrusion. It is further argued that the determination required on the patient's part to persist in refusal of eating or drinking until death is a safeguard against subtle manipulation or coercion of the patient. On the other hand, the physician clearly has played some significant role. Without the physician's education of the patient about the option, his or her assurances of providing comfort measures, and actually providing them, many people would probably never consider this option at all, much less pursue it to its conclusion.
- Providing a prescription for a lethal dose of medication at the patient's request, and counseling the patient about how to take the medication so as to ensure a painless death, after ensuring the patient's mental competence, providing information about palliative care as an alternative, and requiring both oral and written requests separated by a waiting period. This is the Oregon Death with Dignity Act. As with the previous action, the patient takes all of the decisive steps to bring about his or her death, and may decide at many points to change his or her mind (indeed, of the 65 patients who received prescriptions in Oregon in 2006, 35 took the medication, 19 died of their disease, and 11 were still alive at the end of the year).[37] By calculating the effective dose, writing the prescription, and counseling the patient on how to ingest the medication, however, the physician is complicit in the patient's death in a way that he or she would not be were the patient to end his or her life in a completely private act.

Two Levels of Response: Social Policy and Clinical Care

There are two important levels of response to the issue of physician-assisted death: the level of social policy (i.e., which actions along the clinical spectrum should be legally permitted or prohibited) and the level of clinical care (i.e., how individual physicians should respond to their patients who request help in advancing the time of their death).

Social Policy

At the level of social policy there are once again two positions at the ends of a spectrum, with ongoing, active debates about positions in between.[38] One end is occupied by advocates of a thoroughgoing libertarianism: the choice to end one's life at the time and in the manner of one's own choosing is so bound up with personal privacy and self-determination that no limits should be set on the actions of fully informed, mentally competent adults, and least of all of a physician to help a terminally ill, suffering patient achieve a swift and painless death. The other end views physicians' direct involvement in assisted death—at least in the forms of providing prescriptions or injecting lethal medication—as so contrary to the role and professional identity of the physician, and so destructive of important societal values, as to require universal and permanent legal prohibition.[47] Physicians, on this view, should abstain from the practice even where it is legally permitted.

The most active debate takes place between these extremes. The essential dispute is this: Given the improvement in the science and technique of palliative care and pain management over the last 20 years or so (much of which is documented elsewhere in this volume), is the number of people whose physical or existential anguish near the end of life is beyond the reach of effective palliation large enough to justify the societal risks that could accompany widespread legalization of physician-assisted death in its most direct and active forms? Those who say no—and at the state level that would include, as of now, all states in the U.S. except Oregon—worry that the possibilities for various types of abuse in a permissive legal system outweigh the benefits to the very small number of people who truly have no other options.

These abuses might include acts of desperation by people without reliable access to medical care of any sort, much less state-of-the-art palliative care; subtle coercion of people to take advantage of legal means to end their lives, playing on their common desire not to be a burden on others; or misguided compassion of caregivers who are ignorant of comfort measures and social supports that could have provided the patient with more options for maintaining dignity and comfort.[2]

Those who say yes would argue that these hypothetical, even if theoretically plausible, worries should not outweigh the actual suffering of identifiable people who are ravaged by disease and dying in uncontrolled misery or humiliation. Given what even most opponents concede, that there are indeed some patients (small though their number might be) whose suffering is not remediable with standard measures of palliative care, proponents of legalization believe the more active forms of physician assistance should be available—and socially permissible—as a last resort.[48] They contend that the Oregon experience itself should reassure skeptics that safeguards against abuse can work;[49] and that, even if legally prohibited, physician-assisted death in its active forms is and will be carried out, and that legalization will allow a more public, well-regulated practice to take the place of the "euthanasia underground."[50]

Clinical Care

Regardless of the resolution of these issues at the social and political level, individual physicians should be prepared to deal compassionately and therapeutically with patients who raise the possibility of physician-assisted death. Opponents and proponents of legalization of the more active forms of physician involvement usually agree that excellent palliative care—the full array of active management and support of physical, psychosocial, and spiritual distress—is the standard of care for the seriously ill patient near the end of life. Quill and Arnold[51] outline a set of responses within the physician–patient relationship and the therapeutic dialogue that can help assess and respond to patients, independent of the physician's personal moral beliefs or the legal environment of his or her practice. They recommend that the physician who receives a request from a patient to help hasten death:

- **CLARIFY** what the patient is communicating: General thoughts about the desirability of ending his or her life? Wondering about the future if his or her condition deteriorates? Asking for help right now?
- **SUPPORT** the patient by giving reassurance that whatever the patient feels or desires, the physician is prepared to work together to find a mutually acceptable solution.
- **EVALUATE** the patient's mental state and decision-making capacity; whether the request seems commensurate with the level of unrelieved suffering; whether there is evidence of treatable depression.
- **EXPLORE** the many possible sources of intolerable suffering; for example, poorly controlled physical symptoms, loneliness, sleep disturbances and exhaustion, psychological or spiritual anguish.
- **RESPOND** to the emotions associated with the patient's request. Take them seriously while also trying to separate your own emotions from those of the patient.
- **INTENSIFY TREATMENT**, with the help of a multidisciplinary team, of any potentially reversible elements of the patient's suffering.

Only when all of these steps have been completed, Quill and Arnold recommend, should the physician respond directly to a patient's persistent request for hastened death. Physicians who believe that affirmative assistance is justified beyond steps that fall within ethically or legally accepted practice have a genuine moral dilemma. Some may feel compelled to inform the patient that, despite their sympathy and solidarity, they cannot cross a particular legal or ethical boundary, but may be willing to refer the patient to another physician. Others may be willing to, in Quill's words—cited in a very valuable essay by John Arras[52] —"take small risks for people [they] really know and care about."

CONCLUSION: BEYOND THE PATIENT–PHYSICIAN DYAD

Good care for a dying patient depends on more than the skillful efforts of the most conscientious physician. Dying is both an intensely private and an inherently social process. The ramifications of the patient's illness spread throughout his or her social network, both in space—to family, intimate friends, workmates, and so on—and in time—lasting throughout the grief and bereavement of the survivors. Palliative care, which sets itself the task of ministering not only to the patient but also to the "family as the unit of care," necessarily raises ethical and policy questions beyond the patient–physician dyad.

Some of these issues are closely connected to some of the familiar topics of clinical ethics, such as protecting the confidentiality of medical information or weighing the preferences or needs of family members against potentially incompatible wishes of the patient (e.g., the patient who insists on remaining at home to die even as family members are pushed beyond their physical or emotional limits by the demands of home-based care). Issues such as these push against an individualistic ethic that places the physician's obligations to the best interests of his or her patient above all other moral considerations,[53] and they often call for skills of negotiation and mediation that are not typically included in the interviewing and communication skills training in medical schools.

Other issues touch on broader questions of public policy and the allocation of society's resources. Excellent palliative care requires *systems* of care that can match the particular needs of patients and their families to appropriate resources, across all the sites of care typical of the prolonged, chronic illnesses that precede most deaths in our society.[54,55] These include, at a minimum:

- Systems to elicit and document meaningful information from patients about their values, preferences, and goals for medical care, and to make sure the documentation accompanies the patient wherever they are in the health care system;
- Systems to assure quality standards for the provision of palliative care in health care institutions, including hospitals, nursing homes, and personal care facilities;
- Systems to train health professionals in the principles and practices of palliative care;
- Systems for family and caregiver support that help families participate meaningfully in the lives and care of their dying loved ones without sacrificing their own physical, mental, and financial well-being;
- Systems for financing care that reward professionals for the time-intensive nature of patient and family support and communication in palliative care.

As has been mentioned more than once in this chapter, the enormous disruptive power of death makes it impossible for even the best systems and most dedicated individuals to ensure that every person dies according to their ideals and hopes for meaning, dignity, and comfort. And the physician is only one actor—albeit a very significant one—in the universal human process of coming to terms with life's ending. Families, faith communities, neighborhoods, civic groups, employers, professional caregivers, and many others have the opportunity and responsibility to help people die in ways that affirm the values and qualities that make life itself worthwhile. The best social policies, laws, and regulations that address the care of the dying will be those that make the efforts of all of these people easier rather than harder.

CHAPTER 14 ■ LAWS AND POLICIES AFFECTING PAIN MANAGEMENT

AARON M. GILSON

INTRODUCTION

Prevalence of Unrelieved Pain is a Public Health Problem

In *Illness as Metaphor*, author Susan Sontag wrote:

> Illness is the night-side of life, a more onerous citizenship. Everyone who is born holds dual citizenship, in the kingdom of the well and in the kingdom of the sick. Although we all prefer to use only the good passport, sooner or later each of us is obliged, at least for a spell, to identify ourselves as citizens of that other place.[1]

Of course, with sickness and disease often comes the experience of pain. In fact, pain is one of the most common physical complaints upon a person's admission into the health care system, and moderate to severe pain is frequently reported to be experienced throughout hospitalization, during treatment, and even after discharge. The National Institutes of Health (NIH) estimate that 100 million Americans suffer from chronic pain, including pain associated with the disease of cancer,[2] and recent research suggests that the prevalence of pain in people with cancer can range from 14% to 100%, depending on chronicity, severity, and site of the disease.[3] In addition, the prevalence of chronic noncancer pain in patients seen in the primary care setting shows an approximate range of 5% to 33%,[4] and a 2006 American Pain Foundation (APF) survey found that fewer than 40% of people with severe chronic noncancer pain reported that their pain was under control.[5] The costs of pain, both emotional and financial, can be enormous.[6] Untreated or undertreated severe pain at any stage of disease or condition can limit a person's functioning, productivity, and ability to interact socially; sometimes pain even destroys the will to live.[7] A 2003 study published in the *Journal of the American Medical Association* indicated that unrelieved pain annually exceeds $61 billion in lost productivity,[8] while a previous NIH estimation exceeded $100 billion per year in lost productivity and wages and in medical expenses.[9] The financial cost of chronic pain is considered similar to that of cancer or cardiovascular disease.[10] Increasingly, unrelieved pain is recognized as a significant public health problem in the United States.

Issues of public health demand a public health approach to develop informed and organized responses to these health problems.[11] A public health approach is intended to protect the community and enhance the health and quality of life of this population by making available effective and economical interventions.[12] Utilizing a social systems perspective, which incorporates input from various levels of the government (including administrative agencies), health care, education, and welfare systems, often is necessary to guide effective interventions.[13] As inadequate pain management becomes accepted as an important public health issue, efforts to rectify this situation will necessarily involve the systematic utilization of methods to measure outcomes of improved treatment. Some of the most frequent outcome measures, including reduction in pain scores and indicators of quality of life enhancement, must be considered alongside more long-term objectives that denote optimal levels of health status. Before such approaches and outcomes can be conceptualized and achieved, however, the numerous factors that can combine to result in unrelieved pain for patients with chronic diseases or conditions must be understood.

Barriers to the Effective Use of Opioid Analgesics for Pain Management

Unlike most countries in the world, the problem of unrelieved pain in the U.S. is not a function of needed medications being unavailable. However, patients who experience chronic severe pain often do not have access to prescription opioid analgesics, which are the only medications currently indicated for treating this level of pain. This situation relates directly to the equity of health care services. Access to effective pain management requiring prescription opioids remains inequitable, and the reasons for this represent a variety of issues.

Health care organizations and national experts suggest that a number of diverse factors can interfere with the medical use of opioid analgesics for the treatment of pain and can negatively impact patients' access to effective pain relief. Most studies have focused on issues in the patient or clinical domains, such as: (1) patient and family perceptions about the use of opioids for pain relief[7,14–20]; (2) patient characteristics such as race or ethnicity, substance abuse history, or the community in which they live[21–31]; and (3) knowledge and attitudes of health care professionals about the legitimate use of opioids.[28,32–45]

When treating pain with opioid analgesics, clinicians must determine how to maximize benefit and minimize harm, which they have generally not been trained to do. Health care practitioners' willingness to manage chronic pain with opioids often is impacted by unfamiliarity with pain management in general and with the relevant medications in particular, as well as by the perceived likelihood of iatrogenic harm to the patient and risk of regulatory or criminal sanctions resulting from prescribing the medications. As a result, there remains an urgent need to enhance the skills, awareness, and confidence of health care providers, and to explore the motivations and challenges to get both practitioners and patients involved in initiatives promoting pain management services.

Many of the clinical and patient factors previously mentioned can contribute to the high prevalence of unrelieved pain in the U.S., including characteristics of the health care system and health care professionals. Restrictive federal and state policies relating to drug control and health care practice (referred to as regulatory barriers) also are recognized as potential impediments to pain management, especially considering the extent that practitioners know of and adhere to such policies. Since the early 1990s, national health care organizations have frequently voiced concern about the possible detrimental effects of regulatory barriers. In 1994, the Agency for Health Care Policy and Research (now the Agency for Health Care Research and Quality) published clinical

practice guidelines for cancer pain relief, which recognized the existence of regulatory barriers, and recommended that drug abuse prevention laws not hamper the appropriate use of opioids for cancer pain.[46] Around that time the American Cancer Society sponsored a workshop to define priorities in cancer pain-related research that included policy and regulatory issues.[47] The American Cancer Society (ACS) later convened a Cancer Pain Management Policy Review Group to discuss regulatory challenges facing cancer pain management, with an emphasis on ensuring access to appropriate treatment given the recent national attention on the nonmedical use of pain medications. The Review Group developed several policy statements about various aspects of cancer pain management,[48–50] including a description of regulatory barriers affecting quality pain treatment.[51] In the last few years, the ACS,[48] as well the Institute of Medicine (IOM)[52] and the NIH,[53] have called for studies to improve pain management and identify the legal and regulatory impediments to using opioids for pain relief. For the U.S., this involves an understanding and examination of both federal and state laws.

Policies Governing the Use of Opioid Analgesics for Pain Management

Governments, both federal and state, can create and change public policies that influence health. Laws reflect governmental decisions that are largely influenced by social values, but provide the legal basis for actions that affect public health, including pain management. For example, given the increasing recognition of pain relief as a basic human right,[54] health care facility licensing standards (e.g., for hospitals, nursing homes, residential care units, and hospices) recently are making the assessment and relief of pain a regulatory mandate and, therefore, a treatment expectation for the patients who require these services. The World Health Organization (WHO) embraces the incorporation of human rights principles, acknowledging the need to "balance effective responses to disease risks" with respect for fundamental individual freedoms.[55] However, a patient receiving effective pain relief currently is viewed more as a right in the moral sense, but generally is not supported by law.

Legislative bodies typically create laws (i.e., statutes) that are broad and general, and depend on the relevant regulatory agency to interpret and implement the laws. In fact, legislatures that avoid making considerably detailed law would likely require less frequent amendments to such laws, because the accompanying regulations contain the professional or technical details that would need to be revised periodically to keep pace with changing practice standards. For medicine, the legislature grants authority to the state medical board to define and implement its laws through regulation (or administrative rules); regulations must be consistent with legislative provisions. Even given this structured process, pain-related law has not kept pace with advances in medical and scientific understanding. Although professional boards generally have frequently revised their pain management policies in reaction to updated professional standards, legislation has been slow to change. This has particular implication for pain management issues related to opioid prescribing, where such legislation tends to have extensive detail and may not reflect current medical standards (see the section State Pain Policy Development: An Emerging Trend).

In 2007, the journal *Pain Medicine* published B. Todd Sitzman's President's Message to the American Academy of Pain Medicine readership, entitled "Guiding Principles for the Pain Medicine Physician—In a Not So Ideal World."[56] According to Dr. Sitzman, an ideal clinical world for practicing pain medicine physicians would be characterized by, among other things:

> no governmental or third-party oversight; addiction to prescribed analgesics would not exist; . . . and for good measure, professional liability and attorneys would not exist.[56]

As Dr. Sitzman recognizes, health care professionals must practice in an environment of legal and regulatory influences, and where some patients with pain also have an addictive disease. Although practitioners generally do not receive training in legal and regulatory issues related to prescribing opioid analgesics, and are not familiar with the federal and state laws that govern their practice, there has been an increasing call for clinicians to acquire knowledge of the policies under which they practice.[57,58] This chapter attempts to create a resource to address this need by describing the three layers of laws creating the policy framework for both the diversion and legitimate medical use of opioid analgesics: (1) international treaties governing drug control; (2) federal statutes and regulations governing drug control, which includes the legal parameters for prescribing controlled substances; and (3) state statutes and regulations governing drug control and health care practice, including prescribing controlled substances. The chapter also discusses other legal and regulatory influences on prescribing practices, and provides recommendations to practitioners about what they can do in their state to improve pain management.

INTERNATIONAL TREATIES: ESTABLISHING BALANCE BETWEEN DRUG CONTROL AND MEDICAL USE

Treaties form the basic legal framework to control international and domestic production and distribution of drugs that have a recognized abuse liability. The drugs subject to these more rigorous controls are therefore referred to as "controlled substances," and include, but are not limited to, opioid analgesics. The principal treaty establishing controls for opioid analgesics used to treat severe pain is the Single Convention on Narcotic Drugs of 1961 (Single Convention).[59] It should be understood that the term "narcotic," which includes opioid analgesics, is now primarily used in legal contexts, such as in reference to the international drug control treaty or relevant laws; "narcotic," which generally is defined as an agent that produces stupor or insensibility, is no longer considered "useful in a pharmacological context" when describing opioid medications.[60] The Single Convention establishes a number of basic requirements for a country's laws and regulations to create effective measures against drug abuse and diversion. Many of these measures relate directly to the health care setting, including:

- A country's government must duly authorize everyone involved in the medical distribution of narcotic drugs,
- Medical prescriptions must be used to provide narcotic drugs to patients and may be issued only by health care professionals duly authorized under national law, and
- Authorized personnel are responsible for security, record-keeping, and reporting (Article 30: Trade and Distribution).[59]

Although established as international law aimed at preventing drug abuse, this treaty also recognizes that many controlled substances are indispensable to public health and that there is a need to ensure their availability for legitimate medical and scientific purposes.[59] Becoming a party to this treaty obligates a government to take steps to make controlled substances available in adequate amounts to effectively treat medical conditions. Most, but not all, of the world governments are parties to the Single Convention, including the U.S., which means that they formally accept the obligation to develop a legislative and administrative framework to implement the treaty's objectives.[61]

The long-standing dual obligation of country governments to (1) establish a system of controls to prevent abuse, trafficking, and diversion of controlled substances, and (2) simultaneously assure their medical availability is referred to as "balance." Balance maintains that opioid analgesics, although designated as

controlled substances, also are essential drugs, are absolutely necessary for adequate pain relief, and must be accessible to patients who need them for medical purposes. Within this framework, the ''controlled substances'' status of these medications is not meant to diminish their medical usefulness or create the perception that practitioners should avoid their use. Moreover, the principle of balance does not sanction medication use outside an established system of control, recognizing that only properly licensed health care practitioners can use opioid analgesics for legitimate medical purposes in the course of professional practice. Governments that achieve and implement balanced policy continue to maintain an opioids supply sufficient to meet medical demand, and empower practitioners to prescribe, dispense, and administer opioids in the course of professional practice and in response to individual patient needs.

The International Narcotics Control Board (INCB), a United Nations-affiliated agency responsible for monitoring governments' implementation of the Single Convention, has historically observed, and continues to note, that the global medical need for opioid analgesics is not being fully met.[62–64] Opioids remain insufficiently available to meet medical needs throughout the world for many reasons, including severely restrictive (or unbalanced) drug control policies[65–67]; the overriding concern about drug abuse and addiction also has motivated the creation of laws that hamper the appropriate medical use of opioids, including for the treatment of cancer pain[65,68]:

> . . . the reaction of some legislators and administrators to the fear of drug abuse developing or spreading has led to the enactment of laws and regulations that may, in some cases, unduly impede the availability of opiates. The problem may also arise as a result of the manner in which drug control laws and regulations are interpreted or implemented.[62]

Recently, the Council of Europe,[69] WHO HIV/AIDS,[70] the INCB,[71] and the UN Economic and Social Council[72] have called for governments to identify and address regulatory barriers in their narcotics control policies.

For example, a common requirement found in international drug control policies has been and continues to be Multiple Copy Prescription Programs (MCPPs), which the Single Convention encourages when a country's government considers such a control measure necessary or desirable (Article 30(2)(b)(ii)).[59] MCPPs typically require physicians to issue prescriptions using a special form so that a designated regulatory or enforcement agency can monitor the prescribing and dispensing of certain drugs. MCPPs are designed and enacted primarily to prevent forgery of narcotic prescriptions and can vary in type, from the use of prescription pads with counterfoil or carbon pages, to an extreme where the physician must complete the same required prescription information repeatedly on a number of separate forms. These serialized prescription forms are government-issued, but they may be difficult to obtain and can increase the health care and social stigma associated with opioid medications.[73,74] As early as 1990, the WHO Expert Committee on Cancer Pain Relief and Active Supportive Care addressed how special government-issued prescription forms can impact prescribing:

> Record-keeping and authorization requirements should not be such that, for all practical purposes, they eliminate the availability of opioids for medical purposes. Multiple-copy prescription programmes are cited as means of reducing careless prescribing and 'multiple doctoring' (patients registering with several medical practitioners in order to obtain several prescriptions for the same, or similar drugs). There is some justification for (this), but the extent to which these programmes restrict or inhibit the prescribing of opioids to patients who need them should also be questioned.[75]

More recently, some governments have concluded that MCPPs create burdens to physicians' practice that can unduly limit access to covered medications, and have changed the requirements of these programs to respond to these problems—this has occurred recently in Austria,[76] Italy,[77] and in numerous states in the U.S.[73,78] These positive programmatic changes do not undermine MCPPs' drug control capacities, but rather make it less likely that they hinder patient care. Other ways that countries have established overly restrictive drug monitoring and control systems include establishing extremely short medication supply limits (e.g., 3 days)[79] and only allowing physicians with certain specialties to prescribe.[80]

It is apparent that the international narcotics control treaty is intended to maintain drug availability for medical purposes, which the World Health Assembly[54,81,82] recently reaffirmed. However, some countries have implemented the treaty too strictly, which makes the use of opioid drugs for pain management difficult if not impossible—such countries do not have balanced drug control or professional practice policies. Given this reality, it is important to understand the current status of U.S. statutes and regulations. The next section describes the extent that the U.S. is continuing to balance its obligation to prevent medication diversion and abuse against its responsibility to ensure the appropriate medical use of opioid analgesics.

FEDERAL LAW: PRESERVING BALANCE BETWEEN DRUG CONTROL AND MEDICAL USE

The Federal Food, Drug, and Cosmetic Act

Under the authority of the Federal Food, Drug, and Cosmetic Act of 1962 (FFDCA), the Food and Drug Administration (FDA), which is part of the Department of Health and Human Services, is responsible for promoting public health by ensuring that all new drugs, including opioids and other controlled substances, are safe and effective for marketing and for human use under medical supervision.[83] The FDA's approval decisions for marketing a particular drug always involve an assessment of the benefits and risks, including its abuse liability. The drug manufacturer must provide to the FDA all relevant data related to safety by the time a new drug application is submitted.[84] When the benefits of a drug are considered to outweigh its risks, and when the labeling instructions allow for safe and effective use, only then does the FDA consider the drug safe for approval and marketing.

When reviewing a new drug application, a determination can be made that the manufacturer also must submit plans for a risk evaluation and mitigation strategy (REMS). The REMS contains steps to address morbidity and mortality, and requires a timetable to assess the strategy at 18 months, 3 years, and 7 years after the strategy is approved.[85] Additional elements of the strategy can include a communications plan to health care practitioners about the drug, such as: (1) sending letters, (2) disseminating information about the REMS to explain certain safety protocols or to encourage implementation by health care practitioners of applicable components of the REMS, and (3) use professional societies to disseminate information about serious drug risks and protocols to enhance safety.[85]

The FDA also is responsible for reviewing product labeling, and for ensuring that post-marketing promotional materials are consistent with the approved labeling. Historically, the FDA's statutory authority applied primarily to pre-marketing testing and, after drug approval, the agency's role was limited. However, in September 2007, the FFDCA was expanded to comprise active post-market risk identification for approved drugs,[86] which includes ongoing analysis of drug safety data from disparate data sources as well as adverse event surveillance using electronic data from the Federal government and the private sector. Once enacted, this collaborative process is designed to improve the quality

and efficiency of post-marketing drug safety risk-benefit analysis, and to allow for the public disclosure of safety and effectiveness data in a timely and systematic manner.

Once the FDA approves a medication, a physician can prescribe, and a pharmacist can dispense, that medication for "off-label" uses (i.e., uses not included in the approved labeling) if there is a recognized medical basis for those uses.[87,88]

> Once (an approved) new drug is in a local pharmacy after interstate shipment, the physician may, as part of the practice of medicine, lawfully prescribe a different dosage for his patient, or may otherwise vary the condition for use from those approved in the package insert, without informing or obtaining the approval of the Food and Drug Administration. This interpretation of the Act is consistent with the Congressional intent as indicated in the legislative history of the 1938 Act and the Drug Amendments of 1962. Throughout the debate leading to the enactment, there were repeated statements that Congress did not intend the Food and Drug Administration to interfere with medical practice and references to the understanding that the bill did not purport or regulate the practice of medicine as between the physician and the patient.[89]

The FDA again corroborated this statement in their FDA Consumer Magazine.

> New uses for drugs are often discovered, reported in medical journals and at medical meetings, and subsequently may be widely used by the medical profession. . . . When physicians go beyond the directions given in the package insert it does not mean they are acting illegally or unethically and Congress did not intend to empower the FDA to interfere with medical practice by limiting the ability of physicians to prescribe according to their best judgment.[90]

As this statement suggests, evidence supporting effective off-label use usually results from post-marketing studies or from an accumulation of case reports by independent investigators. The FFDCA does not restrict a physician's prescribing either to recommended doses or to labeled indications, which is a clear message contained in the forward to the *Physician's Desk Reference*.[91] Off-label uses simply reflect a physician's lawful ability to prescribe for a medical purpose and in the interest of the patient according to his or her best knowledge and judgment.[92]

Of course, prescribing decisions, including whether the medication is intended for a labeled or off-label indication, are part of medical practice. The FFDCA is intended neither to regulate medical practice[93] nor to interfere with the authority of a licensed health care practitioner to use controlled substances for a legitimate medical purpose.[94] It is the responsibility of the states, and not the federal government, to regulate professional health care practice. However, both the state and the federal governments share drug control responsibilities.

Federal Controlled Substances Law

Controlled substances laws provide an additional layer of control over the distribution of prescription drugs that have an abuse liability (i.e., use criteria related to the potential to produce psychological or physical dependence), establishing a closed distribution system to minimize their abuse, trafficking, and diversion. The federal Controlled Substances Act (CSA),[95] part of the Comprehensive Drug Abuse Prevention and Control Act of 1970,[96] is the principal drug control law in the U.S. and conforms to the international treaties—it establishes criminal penalties for the illicit possession, manufacture, and trafficking of controlled substances and prohibits their nonmedical use, while at the same time recognizing that they are necessary for public health and that their medical availability must be ensured. The CSA creates a comprehensive regulatory framework assuring that controlled substances are only produced and distributed through proper channels and for proper medical purposes. In fact, the CSA is a culmination of more than 50 pieces of federal legislation adopted since 1914 relating to drug control and diversion.[96]

The CSA specifies five classification schedules for controlled substances, each carrying different penalties for unlawful uses. A drug's medical usefulness and abuse liability form the basis for the decision to assign it to a particular schedule.[97] Schedule I drugs have no currently accepted medical use, no accepted safety for use under medical supervision, and a high potential for abuse (e.g., ecstasy, heroin, LSD, marijuana, methaqualone, and peyote), and are available only for scientific research. Drugs that have an FDA-approved medical use are placed in Schedules II through V according to potential for abuse in the following manner:

- Schedule II drugs have the highest potential for abuse, and include such opioids as codeine, fentanyl, hydromorphone, meperidine, methadone, morphine, and oxycodone, as well as nonopioids such as short-acting barbiturates (e.g., pentobarbital), amphetamines (e.g., methamphetamine, methylphenidate, and cocaine).
- Schedule III drugs have a lower abuse potential than Schedule II drugs, and include opioids such as hydrocodone- or codeine-combinations with aspirin or acetaminophen, as well as nonopioids such as buprenorphine, intermediate-acting barbiturates (e.g., butalbital), and the synthetic cannabinoid dronabinol.
- Schedule IV drugs have a lower abuse potential relative to drugs in Schedule III, and include opioids such as dextropropoxyphene, and pentazocine, as well as nonopioids such as benzodiazepines (e.g., alprazolam and diazepam), long-acting barbiturates (e.g., phenobarbital), and certain nonamphetamine stimulants (e.g., pemoline).
- Schedule V drugs have a lower abuse potential compared to drugs in Schedule IV and include compounds or preparations containing limited quantities of opioids such as codeine or opium, which may be used for over-the-counter preparations to treat cough or diarrhea, respectively, as well as antidiarrheals containing diphenoxylate and difenoxin.

Under federal law, the Drug Enforcement Administration (DEA) is the primary federal agency responsible for enforcing the CSA and, thus, has regulatory authority over controlled substances. The DEA is an agency of the federal Department of Justice, headed by the Attorney General of the United States.

To conduct research with, or manufacture, distribute, handle, dispense, administer, or prescribe, controlled substances, a person or business must be registered with the DEA (and, in some cases, also with the relevant state agencies).[98,99] Licensed and registered practitioners can prescribe, dispense, and administer controlled substances only for legitimate medical purposes and in the usual course of professional practice[100,101]; the DEA and federal courts have interpreted this to mean that prescriptions must be issued "in accordance with a standard of medical practice generally recognized and accepted in the United States."[102] Registrants' distribution of Schedule I and II controlled substances are made using a special order form (DEA Form 222) to monitor all transfers of these controlled substances within the "closed" system.[103,104] Prescriptions for Schedule II medications must be written and may not be refilled,[105,106] while five refills are permitted for drugs in Schedules III and IV.[107,108] Federal law allows oral or faxed (but not electronic) transmission of prescriptions for Schedule II controlled substances in medical emergencies under specific circumstances.[109] Federal law also allows for the partial dispensing and faxing (but not oral or electronic data transmission) of prescriptions under certain circumstances.[110] There are penalties, both criminal and civil, for violating federal requirements.

Although prescriptions for certain controlled substances must be in writing, and refills are limited, the fact that a drug has been approved for medical use does not change when it becomes a controlled substance. This principle is conveyed by the CSA statement that:

> [M]any of the drugs included within this title have a useful and legitimate medical purpose and are necessary to maintain the health and general welfare of the American people.[111]

Overall, the legislative history, as well as language contained in the CSA itself (and its related regulations), makes it clear that efforts to prevent drug abuse and diversion are not to interfere with legitimate medical practice and appropriate patient care.[112]

The CSA Ensures Availability of Controlled Substances for Medical Purposes

The CSA authorizes the DEA to establish production quotas for a number of opioids and other controlled substances as a means to stem diversion resulting from excessive unused supplies.[113] Such quotas, however, must maintain sufficient supplies to accommodate all medical and scientific needs.[101] Despite this apparent standard, 20 years ago the DEA set a very low quota for methylphenidate to restrict its production in an effort to control diversion.[114] As a result, the methylphenidate supply was inadequate to treat patients with attention deficit disorder and narcolepsy, which are legitimate medical uses. An official statement was promulgated in response to this action, establishing the principle of an ''undisputed proposition'' of drug availability:

> The CSA requirement for a determination of legitimate medical need is based on the undisputed proposition that patients and pharmacies should be able to obtain sufficient quantities of methylphenidate, or of any Schedule II drug, to fill prescriptions. A therapeutic drug should be available to patients when they need it. To accomplish this, a smooth flow of distribution is required . . . the harshest impact of actual or threatened shortages falls on the patients who must take methylphenidate, not on the manufacturers to whom the quotas directly apply. Actual drug shortages, or even threatened ones, can seriously interfere with patients' lives and those of their families.[114]

Following this statement, the DEA recalculated the methylphenidate quotas to accommodate its demand for medical purposes. The DEA has since expressed a willingness to grant additional quotas for opioids necessary to treat medical conditions including pain[115,116] and has not significantly reduced manufacturing quotas as a means to address the nonmedical use of prescription medications.

The CSA Does Not Regulate Medical Practice

Again, the federal government does not have the authority to regulate medical practice. This authority belongs to the states and is based on the police power in state constitutions, and underlies the medical practice acts that are designed to protect the public health and safety.[117] The CSA is not intended to supersede the authority of the FFDCA and provides no authority for the DEA to define or regulate medical practice,[95] including the treatment of pain in people with addictive disease and the indications for which a drug may be prescribed.

The DEA's enforcement authority is intended to relate to clinicians involved in unlawful distribution of controlled substances that is outside legitimate health care practice (i.e., behaviors that are clearly criminal in nature). To this end, a prescription for a controlled substance is only lawful when issued for a legitimate medical purpose and in the usual course of professional practice.[100] David Brushwood, a pharmacist and attorney and Professor in the College of Pharmacy at the University of Florida–Gainesville, interprets a useful distinction between the phrases ''legitimate medical purpose'' and ''course of professional practice,'' which define the boundaries of practitioner investigations and prosecutions for the DEA:

> A practice that is not medical is neither legitimate nor legal under the DEA regulation. A practice that is medical is legitimate and is legal under the DEA regulation. DEA does not regulate within medical practice but simply discerns whether a practice is medical or nonmedical . . . The DEA regulation has nothing to do with the credentials or qualifications of a health care provider. It has everything to do with the *activities* of the health care provider. If those activities are not professional health care activities, then they are illegal under the DEA regulations; if they are professional health care activities, they are legal. DEA has no authority to pass judgment on the merits of a professional practice. Its role is limited to determining whether a practice is a professional practice.[118]

Further evidence that the CSA was not intended to interfere with legitimate medical practice is found when Congress enacted a law in 1978 to implement another international treaty (i.e., the Convention of Psychotropic Substances of 1971).[119] Consequently, the control of psychotropic substances such as benzodiazepines became a responsibility within the CSA to:

> . . . ensure that the availability of psychotropic substances to manufacturers, distributors, dispensers, and researchers for useful and legitimate medical and scientific purposes will not be unduly restricted . . . and nothing in the Convention (on Psychotropic Substances) will interfere with ethical medical practice in this country as determined by the secretary of Health and Human Services on the basis of a consensus of the American medical and scientific community.[120]

The CSA Distinguishes Treatment of Addiction from Treatment of Pain

Under the CSA, it is not lawful to prescribe opioids for the purpose of treating addiction; this practice requires separate registration by the federal government as an Opioid Treatment Program (OTP), for the purpose of maintenance or detoxification of opioid addiction.[121] The use of medications approved for the purpose of addiction treatment, such as methadone and buprenorphine, must comply with federal and state regulations. Methadone, however, can be prescribed as an analgesic according to the same laws for prescribing any other Schedule II opioid.

The accurate application of terminology is central to shaping a balanced policy on drug control, especially in the U.S. where using opioids to maintain addiction (without a separate registration) is illegal. Addiction often is erroneously perceived as reflecting the development of physical dependence or tolerance, which are expected physiological consequences of using opioids for a prolonged period. Practitioners who consider these related, but separate, phenomena as synonymous can inappropriately label a pain patient as an ''addict'' and increase the risk of inadequate pain treatment. Given this situation, one must carefully differentiate between treating a patient's pain and maintaining or detoxifying a person with an addictive disease, and to understand and use terms correctly.

The CSA defines ''addict'' as:

> an individual who habitually uses any narcotic drug so as to endanger the public morals, health, safety, or who is so far addicted to the use of narcotic drugs as to have lost power of self-control with reference to his addiction.[122]

This definition is characterized by the use of circular, imprecise, and archaic language but, since the main component is loss of control and harm, it seems inapplicable to a patient with pain being treated with opioids. However, the CSA definition does not conform to the WHO's International Classification of Diseases concept of ''dependence syndrome,''[123] the American Psychiatric Association's Diagnostic and Statistical Manual classification of ''substance dependence,''[124] or the definition by the Liaison Committee on Pain and Addiction's (a consensus committee of the American Academy of Pain Medicine, the American Pain Society, and the American Society of Addiction Medicine).[125] Despite the CSA definition of ''addict'' not being considered a potential barrier to adequate pain relief, because it would not pertain to a

legitimate patient, the language should be updated to conform more completely to current terminology and standards.

Although not contained in the CSA, in 1970 a definition of "drug dependent person" was added to the federal Public Health Service Act (now the Public Health and Welfare Act).[126] The Interstate and Foreign Commerce Committee of the House of Representatives[96] considered the adopted definition to be similar to the WHO's terminology of the time. "Drug dependent person" was defined as:

> a person who is using a controlled substance . . . and who is in a state of *psychic or physical dependence, or both*, arising from the use of that substance on a continuous basis. Drug dependence is characterized by behavioral and other responses which include a strong compulsion to take the substance on a continuous basis in order to experience its psychic effects or to avoid the discomfort caused by its absence [emphasis added].[126]

Although indeed similar, there is a critical interpretive distinction between the resulting U.S. legal term and the WHO term from which it was adopted. Unlike the U.S. definition, the WHO conceptualization did not provide the opportunity for physical dependence alone to characterize drug dependence. In 1998 the WHO reaffirmed this conceptualization when they replaced the term "drug dependence" with "dependence syndrome" and further emphasized the bio-psycho-social nature of compulsive drug seeking.[127] Even given the medical and scientific evolution of addiction-related terminology that has occurred in the last 30 years, the 1970 Public Health and Welfare definition continues to have the potential to legally codify as "drug dependent" a patient with pain who has been taking opioids for a prolonged period.

Despite the inconsistent and incorrect use of addiction-related terminology in federal law, it must be stressed that it remains lawful under federal laws to use opioids to treat pain in patients, even when they have a history of substance use or current addictive disease. For example, in 1993 the DEA initiated action to revoke an Ohio physician's prescribing authority because prescriptions were issued to patients who were "known" drug abusers and drug traffickers. A DEA administrative law judge ruled, however, that the physician's controlled substances prescriptions were lawful because they were issued for legitimate medical purposes (e.g., pain relief, muscle spasm, and anxiety).[128] This ruling represents the critical distinction between a practitioner's ability to prescribe controlled substances to treat pain, even though the patient has an addictive disease, and clearly criminal behavior in which controlled substances are distributed without regard to their purpose or ultimate use. Such a judgment upholds the fundamental principle that, when considering the legality of a particular prescribing practice, the determination must be based on the purpose of the prescribing and not solely on the type of patient being treated. A later section will address how this critical distinction relates to more recent criminal investigations and prosecutions of health care professionals for their prescribing practices.

Regulations Implementing the CSA Recognize Opioids as Appropriate to Treat Intractable Pain

Controlled substances regulations promulgated by the DEA in Chapter II of the Code of Federal Regulations (CFR) clearly state that practitioners who use opioids to treat intractable pain over an extended period are considered to be acting within the course of professional practice:

> This section is not intended to impose any limitations on a physician or authorized hospital staff to . . . administer or dispense (including prescribe) narcotic drugs to persons with intractable pain in which no relief or cure of is possible or none has been found after reasonable efforts.[129]

This CFR provision was adopted in 1974, during a time when the concept of intractable pain was beginning to be accepted into the medical lexicon. In the intervening years, however, it became apparent that the phrase "no relief . . . has been found after reasonable efforts" could be interpreted to mean that the medical use of controlled substances is not reasonable and therefore should be used *only* after attempting and failing other treatments.[78] Given this ambiguity, and its potential negative impact on patient care, the term "chronic pain" has been used with increasing frequency to denote pain that persists beyond the expected time of healing but can vary over time in relation to its severity or extent of associated disability.[130] Nevertheless, this statement from federal regulations provides further support for the need to recognize and maintain a clinical and legal acceptance of prescribing controlled substances for pain.

The CSA and Regulations Do Not Limit Prescription Amount or Duration

As stated previously, federal law establishes requirements for what constitutes a lawful controlled substance prescription. At this time neither the CSA nor the CFR sets limits on the amount or duration of medication for which a practitioner can prescribe, administer, or dispense at one time. This still seems to hold true even after December 19, 2007, when the DEA amended the CFR to allow practitioners to issue multiple prescriptions of a Schedule II controlled substance, each issued on the same date and filled sequentially (called a "prescription series").[131]

A prescription series is a method for a practitioner to provide a patient with a large enough amount of a Schedule II medication, for example for a 3-month supply, without using a single prescription. Rather, the practitioner can now issue several prescriptions, each for one-third of the total amount needed. These prescriptions, each issued on the same day and containing written instructions for the date on which they are to be dispensed, would be delivered to the pharmacist and then dispensed sequentially on the dates indicated on the prescriptions. This procedure allows patients access to the medications they need and results in fewer doses dispensed at a time, thereby reducing the potential for diversion. A practitioner's ability to specifically issue a prescription series for Schedule II controlled substances was not previously authorized within the CSA; the CSA, when adopted in 1970, did not address this practice because chronic pain was not a treatment priority at that time.[132]

The DEA said it wanted to reassure health care professionals and patients that it is legal for practitioners to provide a prescription series to individual patients during a single office visit,[132,133] and now authorizes multiple prescriptions for "a total of up to a 90-day supply of a Schedule II controlled substance."[131] The DEA has clarified that allowing a 90-day prescription series does not alter the fact that the CSA and the CFR do not limit the quantity or number of days for which a single prescription for a Schedule II controlled substance can be written.

> The (Final) rule in no way changes longstanding federal law governing the issuance of prescriptions for controlled substances . . . the CSA and DEA regulations contain no specific limit on the number of days worth of a schedule II controlled substance that a physician may authorize per prescription.[131]

In addition, the DEA has verified that the new prescription series rule does not establish additional practice standards to which health care professionals must conform, especially in relation to a practitioner's responsibility to minimize the potential for medication abuse and diversion.[134]

> Under this Final Rule, practitioners who prescribe controlled substances are subject to the same standard in preventing diversion as they always have been under the CSA and DEA regulations. Section 1306.12(b)(iii) of this Final Rule is intended to make clear that a practitioner may not simply comply with the other requirements of

> this Final Rule while turning a blind eye to circumstances that might be indicative of diversion. Thus, section 1306.12(b)(iii) merely underscores that the longstanding requirement of providing effective controls against diversion remains in effect when issuing multiple schedule II prescriptions in accordance with this Final Rule.[131]

The intent of the CFR amendment is laudable, with the DEA wanting to reaffirm a practitioner's legal authority to issue a prescription series for Schedule II medications.[131,132,135] Multiple prescriptions for sequential dispensing permits health care professionals to better manage chronic pain in stable patients while exercising improved control over potential medication abuse and diversion, which is consistent with the principle of balance.[136] The DEA also recognizes the need to maintain balanced policy:

> . . . DEA, through its enforcement of the CSA and its implementing regulations, must prevent the diversion and abuse of controlled substances while ensuring that there is an adequate supply for legitimate medical purposes. DEA supports the intent of this Final Rule to address patients' needs for schedule II controlled substances while preventing the diversion of those substances.[131]

Indeed, the prescription series regulation is an important recent federal step to improve the regulatory environment for both diversion control and pain management and palliative care.

STATE LAWS: NEEDING TO IMPROVE BALANCE BETWEEN DRUG CONTROL AND MEDICAL USE

Both federal and state laws govern the prescribing, dispensing, and administering of controlled substances. In addition, states are solely responsible for regulating health care practice, including medical, pharmacy, and nursing practice. State policies are generally not as balanced as international treaties and federal law.[137] For example, most state laws do not specifically recognize controlled medications as important to public health, which is a concept inherent in federal law.[111] Some state policies also place greater restrictions than do federal laws on the prescribing and dispensing of opioids, which can ultimately interfere with medical decision-making that should be based both on the expertise of the practitioner and the individual patient needs, rather than on governmental requirements. Policy impediments at the state level are known to contribute to inadequate pain management.[48,51,52,137–148] In response to this knowledge, both international organizations[65,75,149,150] and national organizations[51–53] have called for studies to improve pain management by identifying and addressing the legal and regulatory impediments to using opioids for pain relief. A number of governmental and national authorities, such as Congress,[95] the National Conference of Commissioners on Uniform State Laws,[144,145,151] and the Federation of State Medical Boards of the U.S., Inc. (the Federation)[138,139] have recommended controlled substances or medical practice policy that is balanced.

State Pain Policy Development: An Emerging Trend

Since the late 1980s, there has been an increasing number of state pain-specific policies, such as Intractable Pain Treatment Acts (IPTAs) and health care regulatory board regulations and guidelines or policy statements (Fig. 14.1). Such policy adoption typically promotes the safe and appropriate use of controlled substances and creates more balanced state policies, but in some cases has led to additional restrictions and requirements with the potential to create barriers to the effective treatment of pain. For example, IPTAs are statutes that create immunity from regulatory sanctions for physicians who prescribe opioids to patients with intractable pain, and thus are intended to improve access to pain management; however, many IPTAs impose additional requirements and restrictions on prescribing opioids to such patients.[137,152–154] IPTAs often imply that opioid use for "intractable pain" is outside of ordinary medical practice, which produces greater rather than less government regulation when treating pain with controlled substances. For physicians who prescribe to patients whose pain does not satisfy the definition of "intractable pain," there is question about whether an IPTA provides immunity. IPTAs also tend to not contain clear statements supporting enhanced pain management and access to care.

Some advocates have recently recognized the potential negative impact of these characteristics on patient care and have worked with the legislature to remove ambiguities and restrictions from their state's IPTA. Iowa and Michigan became the first states, in 2002, to delete the term "intractable pain" from law. More recently, Arizona, California, North Dakota, Oregon, Rhode Island, and Texas repealed a number of restrictive provisions from their IPTAs, including removing the term and definition of "intractable pain"; the resulting laws now govern treatment for all types of pain.

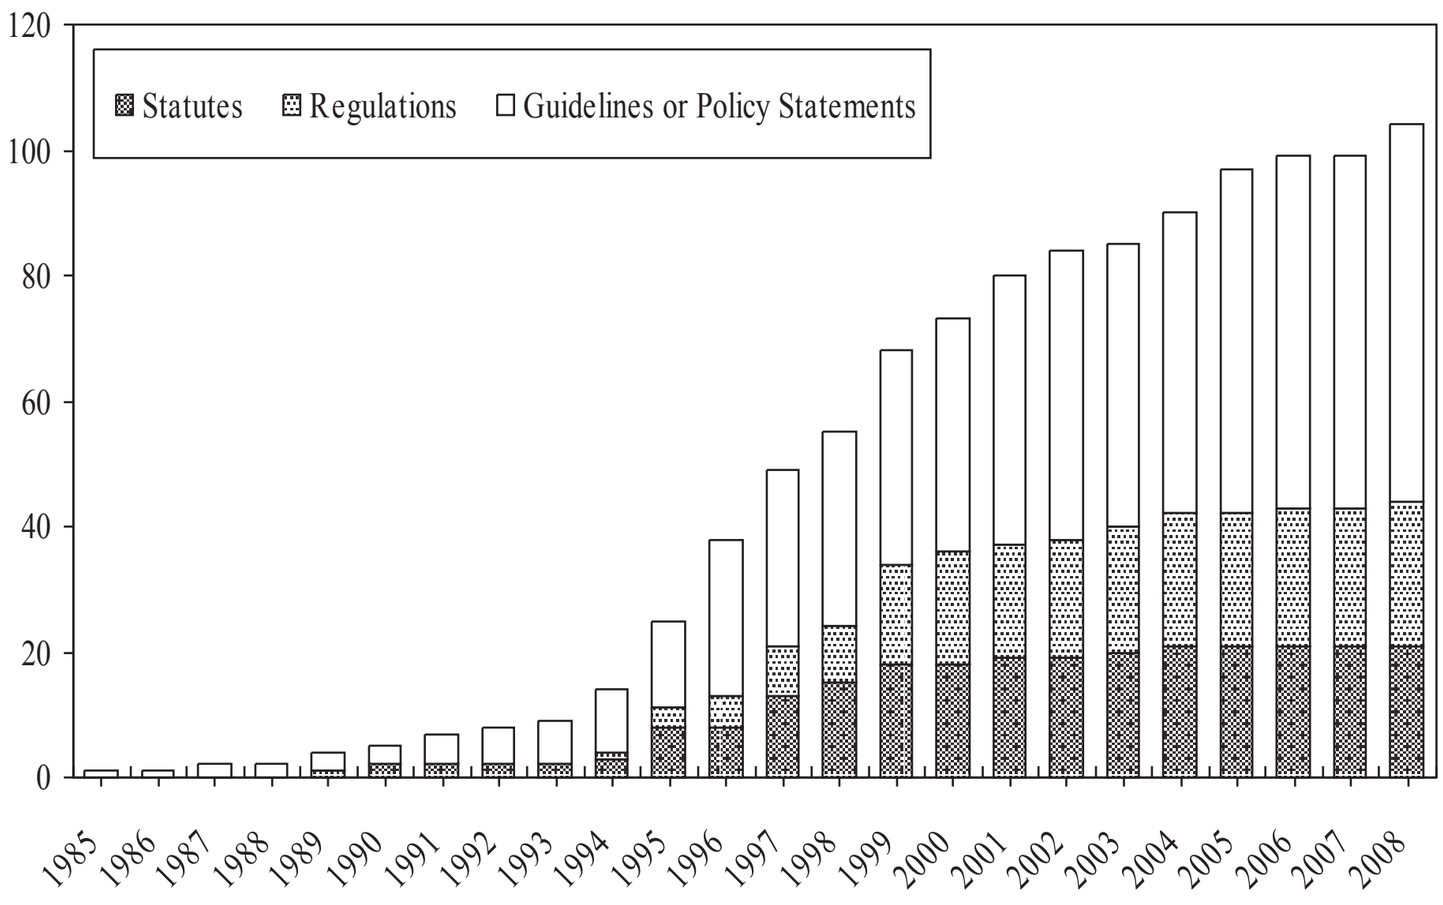

FIGURE 14.1 State pain policies, 1989-2008.

As an alternative approach to creating legislation, which often is difficult to modify to keep pace with evolutions in medical and scientific understanding, many states have instead chosen to develop health care regulatory board guidelines or regulations to encourage better pain management and to address physicians' fear of investigation and sanction.[137,155] Early reports have shown that concerns about regulatory scrutiny are prevalent and can hinder the availability of opioids for patient pain relief.[156–159] Since prescribing for pain management has become a more prominent part of professional practice, physicians have reported a reluctance to prescribe controlled substances out of a concern about regulatory oversight.[160–163] Fear of disciplinary action for opioid prescribing has been documented for a variety of other health care practitioners, including general practice physicians,[34,164–166] oncologists,[45] pain specialists,[167,168] medical residents,[44] pharmacists,[34,39] and nurses.[15,34,37,169] To directly address these concerns, for the past 20 years, health care regulatory boards have promulgated regulations, guidelines, and policy statements perpetuating the message that pain management and the appropriate use of controlled substances is an accepted part of professional practice; a typical goal of such policies is to reassure clinicians that they have nothing to fear from their licensing agency if reasonable professional practices are followed when using controlled substances for patient care.

Much of this recent policy activity was prompted by state medical board members' participation in pain management workshops sponsored periodically by the Pain and Policy Studies Group (PPSG) and the Federation since 1994.[36,170] The workshops emphasized the need for positive policy as a vehicle for providing guidance to licensees about using controlled substances for effective pain relief.

State medical boards' issuance of recommendations for pain management was aided considerably when, in 1998, the Federation adopted a policy template to promote consistency in state medical board policy, entitled *Model Guideline for the Use of Controlled Substances for the Treatment of Pain* (Model Guideline).[138] In May 2004, the Federation revised the Model Guideline as the *Model Policy for the Use of Controlled Substances for the Treatment of Pain* (Model Policy).[139] The Model Policy is substantially the same as the 1998 guideline, but encourages state boards to consider the failure to treat pain as worthy of disciplinary sanction; undertreated pain previously had been identified as an important clinical topic to address in state policy.[171] As of 2008, 32 states have adopted or adapted either the Model Guideline or Model Policy.

Evaluating the Quality of State Pain Policy

A criteria-based policy research methodology recently was developed to evaluate federal and state drug control and health care regulatory policies related to pain management, palliative care, and end-of-life care.[78,136,172–174] The basis for this policy evaluation was the aforementioned principle called balance, which is a fundamental and long-standing national and international principle of drug regulation and medical ethics. Balanced state policies do not establish barriers to appropriate health care practice and patient care, and will support pain management, including the use of controlled substances as an essential part of quality medical practice.[136] The principle of balance was used to derive 16 evaluation criteria. Each criterion relates to one of two categories: (1) positive provisions—policy language that can *enhance* pain relief, and (2) negative provisions—language that can *impede* pain relief (Table 14.1 contains each criterion). A complete description of the criteria, the evaluation methodology, and individual state policy profiles that contain the policy language from each state that satisfies each criterion, can be found in "Achieving Balance in Federal and State Pain Policy: A Guide to Evaluation" online at http://www.painpolicy.wisc.edu.

The most recent series of policy evaluations,[78,136,174] which were conducted in 2006, 2007, and 2008 and supported by grants from the ACS and the Susan G. Komen for the Cure, as well as through a cooperative agreement with the Lance Armstrong Foundation, provide the findings described in this section.

TABLE 14.1

CRITERIA USED TO EVALUATE STATE PAIN POLICIES

Positive provisions: Criteria that identify policy language with the potential to enhance pain management

1. Controlled substances are recognized as necessary for the public health
2. Pain management is recognized as part of general medical practice
3. Medical use of opioids is recognized as legitimate professional practice
4. Pain management is encouraged
5. Practitioners' concerns about regulatory scrutiny are addressed
6. Prescription amount alone is recognized as insufficient to determine the legitimacy of prescribing
7. Physical dependence or analgesic tolerance are *not* confused with "addiction"
8. Other provisions that may enhance pain management
   Category A: Issues related to health care professionals
   Category B: Issues related to patients
   Category C: Regulatory or policy issues

Negative provisions: Criteria that identify policy language with the potential to impede pain management

9. Opioids are considered a treatment of last resort
10. Medical use of opioids is implied to be outside legitimate professional practice
11. Physical dependence or analgesic tolerance are confused with "addiction"
12. Medical decisions are restricted
    Category A: Restrictions based on patient characteristics
    Category B: Mandated consultation
    Category C: Restrictions regarding quantity prescribed or dispensed
    Category D: Undue prescription limitations
13. Length of prescription validity is restricted
14. Practitioners are subject to additional prescription requirements
15. Other provisions that may impede pain management
16. Provisions that are ambiguous
    Category A: Arbitrary standards for legitimate prescribing
    Category B: Unclear intent leading to possible misinterpretation
    Category C: Conflicting (or inconsistent) policies or provisions

Policy Evaluation Findings

Policy language was identified that promotes appropriate pain management and can enhance patient access to effective pain care; such language is common in the policies from state regulatory agencies, rather than from legislative statutes. The frequency with which states' policies contained such language in 2008[136] is as follows:

- Recognizes medical use of opioid as legitimate professional practice (in all states)
- Recognizes pain management as part of general medical practice (in 46 states)

- Addresses practitioners' concerns about regulatory scrutiny (in 40 states)
- Encourages pain management (in 39 states)
- Distinguishes addiction from physical dependence or analgesic tolerance (in 37 states)
- Recognizes that medication amount or duration are insufficient to determine legitimacy of a prescription (in 34 states)

Policy language that appears less frequently than the above concepts, but that also promotes effective pain control and patient care, was identified and relates to three broad domains: (1) health care practice issues (e.g., recognizes inadequate pain treatment as substandard medical practice that is subject to professional disciplinary action, recognizes that the goals of pain treatment should include improvements in patient functioning and quality of life, and recognizes the need for a multidisciplinary approach to pain management); (2) patient characteristics (e.g., recognizes that a patient's prior history or current status of drug abuse does not necessarily contraindicate appropriate pain management, and exempts certain patient populations from undue prescription requirements); and (3) regulatory or policy issues (e.g., establishes a legal responsibility for health care facilities to ensure that pain management is an essential part of patient care, and specifically acknowledges that drug control policies should not interfere with legitimate medical use of controlled substances). A state's drug control policy is considered unbalanced when it lacks these positive messages, because it focuses disproportionately on the abuse potential of opioids while failing to recognize their medical benefit when used appropriately.

In addition, some state policies, which were adopted to prevent drug abuse and substandard prescribing practices, can create unnecessary additional requirements that unduly restrict health care decision making and establish excessive burdens on caregivers and patients. In 2008, a number of state policy provisions did not conform to and even conflicted with current standards of professional practice, including language that:

- confuses physical dependence with addiction, thus suggesting that pain patients being treated with opioids may be "addicts" (in 16 states)
- prohibits prescribing to patients with addictive disease or a history of substance abuse, even if they have pain (in 8 states)
- requires a specialist consultation for every patient who is prescribed Schedule II controlled substances (in 8 states)
- places arbitrary limits on the amount of pain medications that can be prescribed and dispensed at one time (in 8 states) (see Table 14.2 for specific restrictions for each state)
- restricts opioids from being used unless other treatments have failed (in 6 states)
- places overly restrictive limits on the amount of time (less than 2 weeks) that a Schedule II prescription is valid (in 4 states) (see Table 14.3 for specific restrictions for each state)

These evaluations also consider laws that create and implement Prescription Monitoring Programs (PMP), which are primary diversion control mechanisms in the U.S., specifically at the state level. Until relatively recently, PMPs were characterized by the use of MCPPs, which are multiple-copy government-issued serialized prescription forms (usually required in triplicate or duplicate). The prescription forms were required for Schedule II medications only (i.e., the only medications indicated for severe pain) and the programs were administered by state law enforcement, such as the state Department of Justice. Their purpose was to provide law enforcement and prescribers and dispensers with information on "doctor shoppers," "scammers," and dishonest physicians. Unfortunately, prescription information collected by the programs was not real-time and often took months or even years to compile, which severely undermined their ability to actively monitor diversion or abuse activity. MCPPs focused exclusively on Schedule II medications, and used unique forms that practitioners had to order only from the government to prescribe those medications. As a result, the programs tended to stigmatize both the medications and the practitioners who prescribed them.[50] Research demonstrated that this stigmatization often motivated practitioners to prescribe lower-scheduled medications to avoid being monitored[74,175–179]; this phenomenon is called the "substitution effect."[74] Of course, lower-scheduled medications are not indicated to relieve severe pain, so the substitution effect usually meant a potential for undertreatment. On the other hand, law enforcement has tended to interpret decreased prescribing of Schedule II medications as evidence that the program was effective in reducing diversion.[180–182]

MCPPs largely have been replaced by Electronic Data Transfer (EDT) programs that collect prescription information about more than Schedule II controlled substances (usually Schedules II, III, and IV).[183–185] Monitoring multiple schedules minimizes a potential substitution effect because there are few other medications with which they could be replaced. EDT programs tend to be administered by state health agencies, such as the Pharmacy Board, and the policies that implement the programs generally emphasize that this effort to reduce abuse and diversion are not meant to interfere with appropriate patient care. The information from these programs is collected in a more timely fashion, although it is usually not real-time. However, there is still no generally available evidence to demonstrate the programs' effects either on practitioner prescribing or on incidents of medication abuse and diversion.

As of this writing, more than 38 states have legislation creating a PMP that is an EDT system for a variety of medication schedules. Over half of these programs were created in the last 3 years, as a result of federal funding under the Harold Rogers Prescription Drug Monitoring Program,[186] as well as the prospect of funding under the National All-Schedules Prescription Electronic Reporting Act (NASPER).[187] Both programs were designed to provide grants to states to develop PMPs. However, NASPER funds are contingent on the programs being EDT and applying to medications in Schedules II–IV; states can create programs with different characteristics, but they are not fundable under NASPER. Federal law mandates that the Secretary of Health and Human Services evaluate the safety and efficacy of the programs established through NASPER. In this context, "safety" refers to the extent that the programs avoid creating barriers to prescribing to patients for legitimate medical purposes, such as for pain management. "Efficacy" means the ability of the program to validly identify instances

TABLE 14.2

STATES WITH LAWS RESTRICTING SCHEDULE II PRESCRIPTION QUANTITY OR DURATION

Delaware	100 dosage units or 31-day supply
Massachusetts	30-day supply
New Hampshire	100 dosage units or 31-day supply
New Jersey	120 dosage units or 30-day supply
New York	30-day supply
Rhode Island	250 dosage units or 30-day supply
South Carolina	120 dosage units or 30-day supply
Utah	One-month's supply

Delaware	7 days
Hawaii	3 days
Illinois	7 days
Vermont	10 days

of abuse and diversion. Although there seems to be less chance for EDTs to restrict patient care, especially when compared to MCPPs, there has yet to be documentation available to the general public detailing either the safety or efficacy of these programs.

In addition to the discrete occurrences of policy language that can either enhance or impede the adequate treatment of pain with opioid analgesics, some state policies contain requirements or concepts that are contradictory and can create ambiguous practice expectations. For example, as identified previously, policies in 37 states correctly define addiction as a psychological/behavioral disorder that is not synonymous with either physical dependence or tolerance. Laws in 16 states also have an archaic and incorrect definition, which could legally classify patients being treated chronically with opioids, only because they are physically dependent, as "addicts." As a result, 13 states have at least one policy that correctly defines addiction and another that defines the concept incorrectly. There is no clear guidance for practitioners in these states about how patients with pain who are being treated with opioids should be viewed, given the inconsistencies among the legal, regulatory, and health care classification. Achieving balanced policy often depends on potentially discrepant practice standards being identified and made consistent.

A Progress Report Card to Measure Changes in the Quality of State Pain Policies

The criteria-based evaluation of state pain policy also serves as the basis for a methodology to quantify a state's policy based on its quality, which can then be used to compare all states and track policy changes over time.[188–191] Using policy data from the state profiles, each state now has been assigned a grade for 2000, 2003, 2006, 2007, and 2008. The grades, and the methodology used to calculate the grades, are contained in the most recent report, entitled "Achieving Balance in State Pain Policy: A Progress Report Card", and is available online at http://www.painpolicy.wisc.edu.

Grades range from A to F, using mid-point grades (e.g., B+, C+, D+) to characterize more precisely each state's overall combination of positive and negative provisions. A high grade means a state had many positives and few negatives. An A is achieved only when a state has a high number of positive provisions and no instances of restrictive or ambiguous language, while an F would result if a state had many negative provisions and no positive language. Higher grades are associated with state policies that are more balanced and consistent with modern medicine. A lower grade means that a state's policies contain potential barriers to patient pain relief (i.e., provisions that contradict current medical knowledge, are not consistent with the policy guidance recommendations from authoritative sources, and fail to communicate the appropriate messages about pain management to professionals, patients, and the public).

Progress Report Card Findings

Results show that the quality of pain policies varies greatly across states but has continued to improve over time. Between 2003 and 2006, 35 states made changes to their policies, but 19 states had policy change sufficient to produce improvement in their grade.[188] Of these 19 states, Rhode Island made the greatest improvement, increasing from a D+ to a B in this 3-year period; this state also was unique because all the improvement resulted from legislative policy change. The Rhode Island legislature added positive language to its IPTA, and repealed a number of unduly restrictive requirements from its IPTA and CSA.

Between 2006 and 2007, the first time policy change was evaluated over a single year, 23 states showed some degree of policy change and, in 8 of those states, the change was sufficient to improve their grade.[190] Kansas and Wisconsin achieved an A. California and Wisconsin demonstrated the greatest improvement: California increased from a C to a B, while Wisconsin increased from a B to an A. As with Rhode Island in 2006, California realized its grade change primarily by repealing restrictive or ambiguous language from its IPTA. Alternatively, Wisconsin's grade improved because its medical board adopted a positive pain management policy statement. By 2007, 12% of states scored around the average (a grade of C), while 86% scored above the average, and only 2% fell below the average; no state received a grade of D or F. Alternatively, Georgia remained the only state with the lowest grade (D+) and the least balanced policies.

Between 2007 and 2008, seven states changed their policies enough to improve their overall grade.[191] Oregon achieved the highest grade (A), and joined Kansas, Michigan, Virginia, and Wisconsin as having the most balanced policies in the country. An A means that there is prevalent language in statutes or regulatory policies, or both, that promote safe and effective pain management, as well as there being no language that can restrict medical decision making or patient access to appropriate pain care. The five states achieving an A comprise approximately 10% of the U.S. population. Alternatively, states with a B or B+ make up around 50% of the U.S. population (owing to the large populations of California, Florida, and Ohio), while almost 40% live in states that have a grade of C or C+ (owing primarily to Illinois, New Jersey, New York, Pennsylvania, and Texas). Georgia demonstrated the largest improvement, increasing from a D+ to a B. This was accomplished primarily through the medical board repealing its 1991 pain policy (the oldest existing medical board pain policy) with a guideline that repealed three existing negative provisions and contributed seven positive provisions. By 2008, 88% of states scored above the average grade of C in 2008, while no state scored a D+, D, or F (see Table 14.4). This finding is quite an improvement over those obtained in 2000, the first year that this policy evaluation was conducted, when only 49% of states received above a C.

No states' grade decreased over the entire 8-year evaluation timeframe; for the most part, states have avoided adopting new policies that could impede pain management and the medical use of controlled substances. In fact, in 2008 and for the first time since the policy evaluations began in 2000, state legislatures and regulatory agencies have completely avoided adopting policy language that could create barriers to chronic opioid treatment for pain relief.

The Importance of Improving State Pain Policy

The messages and requirements contained in state policies that govern health care practice, including opioid analgesic prescribing, can influence medical decision making and, ultimately, patient pain relief. Health care licensing boards that create and implement policies recognizing pain management as part of quality medical practice and patient care can counter the concern professionals have about regulatory investigation or sanction for prescribing pain medications. Patients and patient advocates also can use the presence of such policy to support appropriate pain treatment and to justify activities to improve pain management practices. Conversely, restrictive and ambiguous health care board policies can create a regulatory environment that hampers adequate patient pain relief. Achieving more balanced pain policy, as evidenced by higher state policy grades, is a necessary part of an overall multifaceted plan to improve pain and symptom management while stemming prescription medication abuse and diversion.[136,191,192]

The last decade was a time of notable improvement in the quality of many states' drug control and professional practice policies. Generally, the substantial policy change witnessed in

Kansas	A	North Carolina	B	Wyoming	C+

recent years has contributed to an abundance of positive messages about effective pain management, including statements to reduce licensees' concern about regulatory scrutiny with prescribing opioid analgesics. Much of this improvement results from individual health care regulatory boards taking advantage of the Federation's Model Guideline or Model Policy. In addition, health care regulatory boards (e.g., medical, osteopathic, pharmacy, and nursing) in some states have worked together to adopt joint guidelines for pain management, palliative care, and end-of-life care.[78,136,174] Such policies tend to emphasize the value of a multidisciplinary approach to treating pain, recognize that the goal of pain treatment should include improvements in patient functioning and quality of life, and assure that a broader variety of health care practitioners should not fear disciplinary action from their licensing board. The trend of state medical boards to adopt policies about pain management (e.g., regulations, guidelines, or policy statements), either separately or collaboratively, has resulted in an overall substantial improvement in the quality of state pain policies.[192]

Activities by health care professionals, pain, cancer, and end-of-life care initiatives, state agencies, and patient groups also have led to state pain policy changing for the better.[137,141,193] Many of these initiatives have as one of their goals to positively affect pain management practices of clinicians in their state by removing policy barriers that can restrict patients' access to adequate pain relief.[158,194,195] Improving pain, palliative care, and end-of-life care policy also has been part of the activities of national organizations such as the Alliance of State Pain Initiatives (ASPI),[196] the ACS,[48,197] the American Society of Law, Medicine & Ethics,[198] the IOM,[52] the National Association of State Controlled Substances Authorities,[199] the National Association of Attorneys General,[200] and the NIH.[53,146]

For most states to achieve greater balance and consistency in their pain policies, more effort must focus on removing long-outdated restrictive or ambiguous language from state law, some of which has been present for 30 years or more. Repeal from law of archaic restrictive language seems to have received less attention compared to the work of professional licensing boards to adopt positive policy. For example, between 2000 and 2008 there was only a 27% reduction in restrictive or ambiguous language, whereas there was a 75% increase in positive language during the same period.[191] Although states can enact laws or other governmental policies that are stricter than federal law, and must be allowed to vary in their approaches to public policy, the creation of undue restrictions is not obligatory in laws designed to control drug diversion or regulate professional practice. It is clear that professional and regulatory organizations recognize the necessity of attaining balanced policies governing pain management practices, including prescribing opioid analgesics. Support for balanced policy also was recently reiterated by national law enforcement; when the DEA issued its new regulation regarding the prescription series, it recognized the dual purpose of the new rule to maintain an adequate supply of medications to patients with legitimate medical needs while improving the potential to control their abuse and diversion.[131] Maintaining such an approach will ensure that patient care decisions requiring medical judgment are not overly limited by governmental laws solely aimed at preventing drug abuse and diversion.

THE NEED TO IMPLEMENT AND COMMUNICATE POLICY

Changing state policy, like addressing any other single factor, is not usually sufficient in and of itself to guarantee patient access to effective pain relief and symptom control, but it should be considered a necessary activity when trying to attain a positive professional practice and regulatory environment for treating pain. Policy improvement is not the final objective, but rather the critical first step. Regulatory policy will have the greatest potential to impact practice when coupled with a sustained commitment by the health care licensing board to communicate and properly implement it. To be most effective, new state regulatory policy must be disseminated widely and repeatedly to licensees and the public, and implemented consistently by the relevant board members, and regulatory administrators, investigators, and attorneys, or it will have little practical value and no effect on patient pain care.

Health care regulatory boards (i.e., medical, osteopathic, pharmacy, and nursing) increasingly are recognizing the importance of communicating newly adopted policy and have developed efforts to educate practitioners about the boards' expectations for proper pain management with controlled substances, and that health care professionals who responsibly treat pain should not fear their licensing agency. A number of state regulatory boards have created ways to widely disseminate and communicate their positive policy messages to practitioners, including California, Kansas, Maryland, Minnesota, North Carolina, Ohio, and West Virginia. Educational methods include video presentations that are mandatory viewing for all new licensees, sections on the boards' websites dedicated to pain management and policy issues, and adopting laws that require health care regula-

tory agencies to periodically educate their licensees about the appropriate use of controlled substances to treat pain. Such methods suggest that many boards are serious about confronting unrelieved pain and understand that communication is an essential component of policy change.

THE NEED TO CONTINUALLY AVOID POTENTIALLY RESTRICTIVE STATE POLICY

Despite there being sustained improvements since 2000 in state statutes and regulatory policies addressing pain management and the use of controlled substances,[136,191] a recent multidisciplinary Guideline from Washington[201] could create a precedent for states to adopt potentially restrictive treatment policy for chronic noncancer pain; although clinical practice guidelines do not meet the inclusion criteria for the PPSG policy evaluation methodology, this practice guideline warrants further dialogue and examination about its possible impact on patient care. The "Interagency Guideline on Opioid Dosing for Chronic Non-cancer Pain" was created by the Interagency Workgroup on Practice Guidelines (IWPG) representing the Departments of Corrections, Health, Labor and Industry, Social and Health Services, and Health Care Authority, and is not meant to apply to the treatment of cancer pain or pain at the end of life. After emphasizing the association between the "dramatic increase" in medical consumption of morphine and other opioids and rises in accidental deaths associated with opioid use, the practice guideline contains a purpose statement, which is to assist:

> . . . the practitioner in prescribing opioids in a safe and effective manner when instituting opioids for chronic non-cancer pain; when transitioning opioid treatment from acute to chronic non-cancer pain; and when weaning opioid if an opioid trial fails to yield improvements in function and pain [and] . . . managing opioid treatment for patients who are already above 120 mg morphine equivalents (MED) total daily opioid doses.[201]

Many recommendations are then provided to assist physicians in treating patients with chronic noncancer pain, including routine monitoring of treatment outcomes and consulting with other health care practitioners when needed. However, the guideline states that rarely, and only with a pain management consultation, should the total daily dose of opioid exceed 120 mg oral morphine equivalents for chronic noncancer pain. Such a condition has been perceived by many to establish a limit on the amount of medication that can be prescribed by practitioners who do not specialize in pain management.[202–205] Concern about this recommendation becoming a treatment standard largely relates to there being no scientific data to support 120 mg/day MED as a ceiling dose or as having sufficient treatment efficacy for patients with severe chronic pain, and the difficulty in identifying a practitioner who specializes in pain medicine, the reimbursement of these services[202–205]; in fact, experts commonly recognize that few patients with chronic pain have access to a pain specialist, given the dearth of such professionals.[206]

In addition, the Washington Interagency Guideline contains specific recommendations that, while similar, are more stringent than those contained in the Federation's Model Policy. For example, practitioners are suggested to consider prescribing opioids for any patient:

- only after other treatments have failed
- when treatment goals include improvements in both functioning *and* pain scores
- after establishing numerous risk management procedures, such as using single a prescriber/pharmacy, a signed opioid treatment agreement, and random urine drug screens

Although such clinical approaches can and should be used at a physician's discretion, based on individual patient circumstance, seeming to require them for every patient runs counter to the approach of the national medical regulatory agency.[138,139,207] As a result, physicians and other health care providers in Washington could perceive this as unduly restrictive policy, and that failure to conform to the policy expectations when treating pain patients with opioids will prompt greater regulatory or legal oversight.

Perhaps the most disquieting aspect of this guideline is that it is promoted as an effective response to the abuse and diversion of prescription pain medications. It implies that health care professionals and misprescribing are the primary sources of illicitly used opioids, despite there being a question whether this causal attribution exists. In fact, there are few systematic studies identifying the mechanisms contributing to opioid diversion (e.g., prescribing practices, employee pilferage, pharmacy thefts, home and medicine cabinet burglaries, and Internet sales), or the extent to which such sources are each part of the overall problem. Initiatives to safely and successfully address diversion are essential, but only to the extent that they do not have the potential to undermine clinical decision making and their ability to adequately treat patients with legitimate medical conditions.

Soon after the Interagency Guideline was introduced, media coverage characterized the policy launch under the heading "Washington State weighs limiting narcotic doses,"[206] believing that the guideline "recommends a total maximum daily dose of 120 mg of morphine or its equivalent." An interviewed pharmacist echoed this belief, stating objection to the dose limit set by the guidelines and considering it inadequate for the types of patients he treats.[206] For the first year of its existence, the opioid guideline is considered "educational" only, which allows for an official process of obtaining feedback from Washington state health care professionals before it can be implemented. A primary goal of this "educational" process is "seeing research that demonstrates the safety and effectiveness of dosage above 120 mg morphine equivalents per day."[208,209] During this time, the IWPG also plans to assess the "adequacy of specialty consultation."[209] Ostensibly, these measures were put into place to support the laudable goal of

> [making] sure any interventions to prevent problematic use don't adversely affect the vast majority who are appropriately using their medications.[208]

Hopefully, to accurately meet this stated objective, additional evidence will be presented and considered about whether guideline implementation, and the perception of its contents, creates barriers for health care practitioners who provide pain management services using opioids. For any new policy considered for adoption, there has to be attention to new requirements that are placed on practice, and whether they could be restrictive. This is a concern that always needs to be kept in mind when trying to maintain balance: That in a state's continued efforts to improve pain management and drug control through policy adoption, unintentional limitations, or ambiguities are not created. It would be regrettable if a practice guideline designed to protect patient safety and prevent harm to public health from prescription opioid diversion instead contributed to the public health problem of unrelieved pain and inadequate patient care. Although this policy is the first of its kind, other states already have expressed interest in using it as a template.

HOW HEALTH CARE REGULATORY BOARDS AND LAW ENFORCEMENT CAN AFFECT PRACTITIONERS' USE OF CONTROLLED SUBSTANCES

Health care professionals who prescribe, dispense, or administer controlled substances are subject to: (1) federal and state laws

governing their use of controlled substances, and (2) state laws and regulatory policies governing their professional practice, including their use of medications. Federal and state laws prohibit the nonmedical use of controlled substances, set potential penalties and sanctions for violations and are enforced by local, state, or federal law enforcement. State licensing boards establish minimum expectations (or standards) for health care practice and the use of controlled substances to treat pain, and can discipline practitioners for unprofessional conduct. Given this reality, not only is it important for practitioners to understand the legal and regulatory framework for opioid treatment of chronic pain, but it remains essential to realize what attitudes and beliefs the regulatory and law enforcement communities hold about the appropriateness of pain management and the use of opioid analgesics. How do regulators and law enforcement view practitioners who use opioids to treat pain, especially when the treatment involves chronic prescribing or patients with an addictive disease?

Pain Management and Medical Regulators: An Evolving Acceptance of This Health Care Practice

Since 1991, the Federation and the PPSG have cosponsored a series of national surveys of board members to assess across time changes in their knowledge and attitudes about issues related to the use of controlled substances for pain treatment. The surveys were initiated to determine the extent that physicians' reported concerns about regulatory discipline for their prescribing practices were warranted.[170,210] Many respondents to the earliest survey doubted that extended opioid prescribing for patients with chronic pain was legal and medically acceptable, especially when the patient had a history of substance abuse.[211] Medical regulators also tended to view "addiction" as synonymous with "physical dependence" or "tolerance," which could lead to the perception that any patient being treated with opioids is addicted. A second survey, conducted in 1997, showed encouraging improvements in beliefs and knowledge, but deficits remained in many regulators' concepts of what constitutes accepted prescribing practice and addiction.[35] The third survey, from 2004, was conducted to determine whether state board members' views about prolonged opioid use for pain have continued to improve over time, especially given the frequent policy adoption promoting appropriate and effective pain management.[36]

The 2004 survey contained 45 items, excluding the demographic variables, but only results for the most relevant items are discussed here. A number of survey items related to various aspects of clinical practice:

- 57% did not know that federal law imposes no limits on the amount of Schedule II controlled substances that can be prescribed at one time
- 9% did not believe, and 21% did not know, that physicians can lawfully prescribe methadone for pain
- 46% believed addiction was common when opioids are used for an extended period for pain relief
- 41% considered prescription amounts greater than those recommended in the *Physician's Desk Reference* or Product Package Insert as excessive and possibly inappropriate
- 35% did not know that federal law considered the medical use of controlled substances to treat intractable pain as acceptable practice
- 28% would doubt that a prescription order for more than one opioid for a single patient was legitimate

Interestingly, 37% of regulators reported that they were not familiar with the Federation's Model Guidelines, despite the fact that their own national organization actively disseminated the policy and even updated it in 2004 (before this survey was conducted).

Board members in 2004 were statistically more likely than those from the previous two surveys to correctly characterize addiction as compulsive use despite harm, and did not view it solely as "physical dependence." In addition, when asked to judge the legality of prescribing opioids for more than several months for several clinical scenarios, respondents in 2004 were more likely to view this practice as both lawful and medically acceptable for patients with cancer or noncancer pain, and even when the patient had a history of substance abuse. However, not surprisingly, when the patient scenario included a history of substance abuse, a much lower percentage of respondents considered this practice to be legal and acceptable. Only 21% of board members viewed prolonged opioid prescribing to a patient with chronic noncancer pain and a history of drug abuse as lawful, but this result compares favorably to the 1% of medical regulators considering it lawful in 1991.

Such findings suggest that, while most medical board members recognize the need for adequate pain relief, and maintain beliefs that are consistent with currently accepted medical practice standards, some continue to possess knowledge deficits and attitudes that do not conform to the Federation's promulgated standards. These deficits can have potentially profound implications for clinical practices involving opioid use, especially creating an environment of uncertainty for practitioners faced with treating pain in a patient with a history of substance abuse or an addictive disease. Regulators who hold these misconceptions can adversely influence disciplinary determinations.

Pain Management and Law Enforcement: Distinguishing Criminal Conduct from Unprofessional Practice

As stated previously, state licensing boards regulate professional practice and medical boards oversee physician practice, including controlled substances prescribing, to determine whether there are violations of statutes and regulations.[192] The CSA's legislative history demonstrates health care professionals' overriding concern that the drug control law ultimately would give law enforcement inappropriate authority over medical and scientific decisions[112]; abundant professional testimony resulted in Congress establishing a procedure in which the federal health agency (now the Department of Health and Human Services) makes medical determinations under the CSA. This history makes it clear that the federal government is obligated to create criteria for drug control, including the legal parameters for prescribing controlled substances, and to investigate intentional criminal conduct (e.g., issuing prescriptions *not* for a legitimate medical purpose and in the usual course of professional practice), while state administrative agencies regulate health care practice. Consequently, the responsibility to investigate physicians' clinical decisions to prescribe opioids belongs to the medical board.

However, the perception of increased law enforcement activity may be undermining a medical regulatory climate characterized by positive board policy that has developed in recent years. The 2004 national survey of medical board members described in the previous section showed that 11% of respondents believed that federal, state, or local law enforcement agencies, including the DEA, are more likely than their own boards to investigate a physician's improper prescribing practices.[36] Another 35% of board members viewed law enforcement as more involved in federal and state investigations and prosecutions of physicians due to their opioid prescribing practices.[36] This and other evidence[212] calls into question whether more prominent law enforcement involvement is superseding the generally more balanced health care regulatory environment that exists today. The DEA continually asserts that less than 1% of registered physicians have been criminally prosecuted for prescribing controlled substances,[213–215] and such prosecutions are related to conduct that is clearly crimi-

nal in nature (e.g., selling prescriptions, exchanging drug for sex, etc.). Despite these assurances, reports of law enforcement's unwarranted intrusions into legitimate health care persist.[215] Media coverage focusing on allegations, convictions, and acquittals of clinicians for manslaughter and murder, in relation to opioid prescribing and dispensing, perpetuates fear of possible criminal sanction.[216,217]

Cases involving questionable prescribing must be evaluated to determine whether the relevant practice is intentional criminal conduct or substandard professional practice.[58,218,219] Such a distinction remains critical to assure proper jurisdiction: good faith professional practice, even if poor, should insulate a practitioner from criminal prosecution[220]; both state and federal case law supports this distinction.[221] If a practitioner's conduct is intentionally outside legitimate professional practice, law enforcement interventions from federal, state, or local agencies seem warranted.[118] That is, a prescription issued or dispensed other than in good faith (i.e., the practitioner knew or intended that the prescription would not be used for a legitimate medical purpose) could form the basis for criminal sanctions.[118,213] It is likely that potentially unwarranted criminal charges against practitioners will become less frequent when investigations clearly and consistently consider criminal behavior as distinct from unprofessional conduct. Such a course of action ultimately can reduce the perception that pain management with opioids is at the periphery of legitimate professional practice, rather than being an integral treatment option.

PRACTITIONERS CAN IMPROVE PAIN MANAGEMENT POLICY IN THEIR STATE

Since the late 1990s especially, there seems to have been an evolution in the pain management field about how restrictive policy is viewed, from being a ''condition'' that is unavoidable and intractable to a ''problem'' about which something can be done.[221] Achieving balanced state policies governing pain management, through repealing restrictive or ambiguous language particularly in statutes and regulations and by adopting positive legislative or administrative policies, requires a strategic approach. Collaborating with members of the legislature or administrative agencies often is necessary for successful change. Increasingly, health care professionals have assumed a leadership role in helping shape state policy that avoids restrictive policy language and promotes effective pain care for patients.

With the objective of balanced state pain policy, the initial step is to recognize the potential impact that policy can have on pain management practice by understanding the policies' content; the types of policies determined to be in need of improvement can often dictate the path to take. Attempting to change statutory law requires legislature engagement, while improving regulatory policy involves collaborating with the relevant health care administrative agency such as the medical, pharmacy, or nursing board. A practitioner can begin this partnership either independently or as a member of an advisory committee. Also termed a task force or pain commission, an advisory committee is a legislatively mandated ad hoc group typically created to scan the legislative, regulatory, and health care environment to set an agenda to identify and remedy the particular issues in a state that create barriers to adequate pain treatment, which traditionally have included the development of educational programs for health care practitioners. Such barriers to patients' pain relief can vary considerably from state to state. Effective advisory committees usually comprise a multidisciplinary team of professionals (both governmental and nongovernmental), including members from a variety of health care professions and specialties.

The goals of advisory committees recently have included efforts to repeal restrictive or ambiguous provisions and to adopt positive policy as a means to enhance pain treatment. A diverse committee composition often is beneficial when wanting to enlist support from legislators, regulators, or other advocates willing to sponsor amendments to law to create more balanced state pain policies. Advisory committees also can function to educate policy makers about how certain provisions in current statutes and regulations have the potential to adversely impact patient care, which can serve to reduce the frequency of restrictive or ambiguous policy provisions in the future. As a result, successful collaborations between committee members and legislators can influence the legislative agenda within a state to diminish or avoid establishing barriers to the management of chronic pain for people with cancer or noncancer conditions.

Advisory committees are not the only forum in which practitioners can develop an understanding of, and effectively advocate for, balanced pain policy. Stakeholders have access to a variety of PPSG policy-related resources, including the policy evaluation reports that detail the content and quality of all states' statutes, regulations, and health care policies and that offer example language that can be incorporated into current policy to strengthen its messages regarding safe and effective pain relief. Also, national organizations such as APF or ASPI, the individual Pain Initiatives that are active in most states, or other unique state-level initiatives, can be valued resources for guidance. Such initiatives can be contacted to advise about resource mobilization, or to help identify state-level efforts currently underway to improve pain policy and to suggest a state legislator or regulator who can sponsor requests for policy reform.

Either alone, in conjunction with a state pain initiative, or as a member of a legislatively created advisory committee, practitioners now more than ever before are playing a successful role in improving statutes and regulations to optimize the appropriate medical use of opioid analgesics to treat chronic pain. Regardless of the forum used, however, any effort at policy change must avoid inadvertently creating additionally restrictive policy. Historically, as with IPTAs, some laws created to improve patient access to controlled substances ultimately impede medication use because they contain undue limits or treatment ambiguities. State-level stakeholders, including health care professionals, recently have recognized the reality that laws can create barriers to treating pain and have sought to repeal such limiting requirements, but such efforts are time-intensive and the first approach is not always successful and may require further windows of opportunity for action. Of course, it is expected that there will be less need to repeal language that can impede pain management when current or future policy development precludes potential barriers.

CONCLUSION

Controlled substances remain essential to maintain the quality of life for many patients experiencing severe chronic pain from cancer or noncancer origins. To navigate successfully through an environment characterized by heightened professional and societal concern about diversion and abuse of prescription controlled substances, we must remain cautious not to minimize or ignore the important role of opioid analgesics as an effective therapeutic modality, or to stigmatize patients with a chronic illness or condition who benefit from the prolonged use of opioid medications. We also must avoid stigmatizing those health care professionals who appropriately prescribe, dispense, or administer opioids. It is possible to contemporaneously address the dual public health problems of undertreated pain and prescription medication abuse/diversion without sacrificing either.

Given recent progress to reduce barriers in state policy, the principle of balance will likely continue to provide a useful framework for improving state policies governing health care practice and controlled substances prescribing. Practitioners, as well as members of regulatory and law enforcement agencies, have been working at an unprecedented level in recent years to achieve more

balanced state pain policy and to systematically implement such policy. The medicolegal concept of balance also can be used to conceptualize the appropriate roles and responsibilities of health care professionals, members of regulatory agencies, and law enforcement officials when considering cases of pain treatment or stemming the potential for drug diversion. A practitioner's medical responsibility is pain relief, but he or she also plays an essential role in monitoring for the abuse and diversion of the medications that are prescribed and for identifying possible comorbidities that would inform treatment considerations. Conversely, drug control is chiefly a responsibility of law enforcement, and such efforts must not interfere in medication availability, health care practice, or patient care. From this national and international principle, it is clear that the actions of members of health care, regulation, and law enforcement often overlap in the areas of medication availability for pain relief and efforts to minimize abuse and diversion. Likewise, U.S. drug laws and regulations have a dual purpose: to provide ample authority to address diversion problems without impeding the use of controlled substances in the medical care of patients.

Pain policy that does not contain archaic medical concepts and restrictive provisions, but does recognize pain management as a part of quality medical practice and attempts to address concern about unwarranted investigation for appropriate prescribing, coupled with training for practitioners about prescribing to relieve chronic severe pain, will realize the greatest benefit to public health. Practitioners also would benefit from guidance about treating patients with pain who have a history of substance abuse or other comorbid conditions that create a more complex clinical situation. Such sustained activities have the potential to contribute substantially to enhanced treatment of patients suffering from chronic pain conditions.

Since the early 1990s, the Federation periodically has sponsored educational workshops for medical regulators, and medical boards in all but four states have issued at least one policy concerning the treatment of pain. These policies have communicated positive messages to physicians about prescribing opioids for pain relief. To capitalize on state medical boards' momentum to promote the appropriate use of controlled substances for pain management, in 2007 the Federation sponsored preparation of a handbook entitled "Responsible Opioid Prescribing: A Physician's Guide."[207] The Handbook is conceptualized as a companion document to the Federation's Model Policy, and provides a description for practitioners about how they can effectively accomplish in their everyday clinical practice the recommendations made for each of the outlined seven treatment steps: (1) evaluation of the patient, (2) treatment plan, (3) informed consent and agreement for treatment, (4) periodic review, (5) consultation, (6) medical records, and (7) compliance with controlled substances laws and regulations. The Federation plans to make a copy of this handbook eventually available to all physicians licensed in each state. It is anticipated that the handbook will become a valuable educational tool to inform practitioners about addressing the clinical, regulatory, and policy issues inherent in treating chronic pain with opioids.

Availability of the policy information and policy change tools described in this chapter can facilitate further improvement in statutes and regulations across the U.S., and engender greater practitioner knowledge about the requirements and restrictions contained in the policies under which they practice. Increased practitioner understanding of their states' statutes, regulations, and other health care policies, and the extent to which health care regulators officially recognize the legitimacy of effective pain management using controlled substances, has a great potential to reduce concerns about scrutiny for such practice. Notable progress in the policy environment was made in the last 8 years, and will likely continue given the increased interest and resources in this area. More than ever before, we are poised to enter an era when state drug control laws and regulations and health care regulatory board policies create few significant barriers to appropriate and effective prescribing of controlled substances for pain relief.

CHAPTER 15 ■ LITIGATION INVOLVING PAIN MANAGEMENT

BEN A. RICH

INTRODUCTION

In recent years, issues arising in the context of pain management have increasingly been raised in the context of law and public policy. Indeed, one of the major professional journals, *Pain Medicine*, now has an entire section devoted to this area of activity (i.e., forensic pain medicine). While technically forensic pain medicine encompasses all instances in which pain medicine and the law converge, this chapter will focus on the area of convergence that is most often associated with the term forensic—litigation. The other aspects of law and public policy affecting pain management are covered in Chapter 14.

American jurisprudence is divided into two broad categories

of jurisdiction—state and federal—and four distinct domains within both categories: administrative, civil, criminal, and constitutional. Cases involving pain management have arisen in all four domains, and in this chapter we will consider the important cases in each and identify the important lessons for practitioners. We will begin with administrative proceedings, all of which involve disciplinary actions by state medical licensing boards against physicians. In reviewing these cases, it will become clear how the pendulum has been shifting in the last decade from concerns about so-called ''over-prescribing'' of opioid analgesics to cases in which physicians have been charged with unprofessional or substandard practice for their failure to demonstrate a minimally sufficient level of knowledge or skill in the assessment and management of pain. These proceedings reflect a policy trend among medical boards to emphasize the important role of pain management in patient care. That trend is more fully discussed in Chapter 14.

The aspect of civil litigation that most often involves health care professionals is medical malpractice. Such claims are a species of tort claim in which an injured party, the plaintiff, asserts that they have sustained damages as a result of the negligence of the other party, the defendant. Medical malpractice claimants, in order to be successful, must establish four essential elements. The first element is the existence of a duty owed by the defendant to the plaintiff. The generic characterization of such a duty is ''due care.''[1] In professional liability cases this translates to compliance with the prevailing standard of care. However, a health care professional–patient relationship must exist before such a duty may be deemed to have arisen.

The second element is breach of the duty owed, hence in medical malpractice litigation a material departure from the standard of care. A dispute as to what constitutes the relevant standard of care by which the defendant professional's conduct is to be evaluated is usually the critical issue in a medical malpractice case, and the outcome often depends on whose expert witness or witnesses are deemed by the jury to be most convincing. Consequently, medical malpractice cases have come to be characterized as little more than a ''battle of the experts.'' Traditionally the usual custom and practice of physicians in the same or similar situations to the defendant has set the standard of care. Evidence of compliance by the defendant physician with the custom tended to create an irrebuttable presumption that the applicable standard of care had been met. Over the last several decades there has been a gradual trend by the courts toward a recognition of instances in which the custom and practice of clinicians has lagged noticeably far behind advances in medical science and technology, or physicians have failed to adopt safer or more effective clinical practices such as those advocated by national clinical guidelines. In such situations, the courts have acknowledged that rigid and unreflective adherence to the customary practice might demonstrate a failure to exercise appropriate clinical judgment. We will consider that issue further in the section of the chapter pertaining to civil litigation.

The third element of a tort claim is damage or injury. The breach of a duty of due care that fails to produce an injury or other harm is, from a strictly legal perspective, of no consequence. It is characterized in the law as *damnum absque injuria* (a wrong without injury). Such circumstances may be of interest to risk managers and quality improvement personnel, but they do not give rise to tort liability. The intriguing aspect of harm in the context of pain management is whether subjecting patients to unnecessary pain through substandard care would be deemed by juries as on the same level as medical errors that produce demonstrably physical injury or even death. The cases we will examine confirm that this is indeed the case, at least for patients who were at the end of life.

Finally, the plaintiff must establish that the breach of the duty of care by the defendant was the proximate (direct and immediate) cause of the damage or injury he or she sustained. In the cases we will be considering, the plaintiff must persuade the jury that pain management consistent with the standard of care would have, to a reasonable degree of medical probability, ensured that the patient did not suffer.

In the fourth section of the chapter we will review criminal prosecutions by both the state and federal governments that concern the prescribing of opioid analgesics for terminal or chronic noncancer pain patients. Finally, in section 5, we will consider three U.S. Supreme Court cases in which Constitutional issues are raised in the context of cases related to pain management and/or end-of-life care.

ADMINISTRATIVE PROCEEDINGS

Until recently, disciplinary actions by state medical licensing boards involving the prescribing of opioid analgesics targeted the phenomenon of ''overprescribing,'' and it was the leading cause of both investigations and disciplinary actions.[2] Some of these actions were well-founded efforts to punish physicians who prescribed controlled substances inappropriately or without a legitimate medical purpose, thereby endangering their patients and/or society. Others, however, sought to punish physicians who were engaged in a good faith effort to manage chronic noncancer pain, and demonstrated either a dismissal by the boards of the plight of chronic pain patients or an ignorance of the risks, side effects, and benefits of opioid analgesia.[3] We will consider two cases from the second group in which the practices of the accused physicians were ultimately vindicated by state appellate court decisions.

In the Matter of DiLeo

Dr. Lucas DiLeo, a general practitioner, prescribed opioid analgesics for some of his patients with significant chronic nonmalignant pain. One of these patients, for example, was an iron worker who had fallen over 40 feet onto concrete and sustained 153 fractures, 93 in the face, as well as shattering his knees, ankles, and left femur. He underwent 10 operations, and continued thereafter to suffer with chronic pain. In 1992 the Louisiana Board of Medical Examiners filed an administrative complaint against Dr. DiLeo alleging that his prescribing of opioids to seven patients (an eighth patient was treated for obesity with a combination of Didrex and Xanax) was not for a legitimate medical purpose, demonstrated incompetence, and fell outside acceptable standards of medical practice.

The Board's expert witness, Dr. Linda Stuart, a board certified family practitioner and addiction specialist, did not question that the seven patients receiving opioids had serious pain problems nor did she challenge the doses prescribed as excessive. However, she did testify that in her opinion opioid analgesia was provided for too long a period of time, thereby posing an unacceptable risk of addiction and withdrawal symptoms. She acknowledged, however, that there were different schools of thought on this issue in the medical profession. As for the obesity patient, Dr. Stuart questioned the prescribing of Didrex and Xanax at the same time, since she considered the former to be a stimulant while the latter was a depressant.

Five of Dr. DiLeo's patients testified on his behalf, as did a physician whose specialty was internal medicine/endocrinology. The medical board ruled against Dr. DiLeo, and that ruling was affirmed by a trial court. The Louisiana Court of Appeals reversed and dismissed all charges against him after finding that no evidence had been presented by the Board to support Dr. Stuart's assertion that the duration of Dr. DiLeo's prescriptions was excessive. Indeed, the Court of Appeals held that the Board had failed to present any evidence as to what the relevant standard of medical practice was for prescribing opioids for chronic pain.

In the absence of such evidence, the unsupported assertions of Dr. Stuart were insufficient to justify the disciplinary measures imposed on Dr. DiLeo, and the charges against him were deemed by the court to be arbitrary, capricious, and an abuse of the Board's discretion.[4]

Hoover v. Agency for Health Care Administration

Katherine Hoover, MD was a board certified internist who had a number of chronic pain patients in her practice. For some of them she elected to prescribe opioid analgesics for an extended period of time. The state medical board took a dim view of this, and initiated disciplinary proceedings for "inappropriately and excessively" prescribing Schedule II drugs to seven patients. The board's case against Dr. Hoover consisted of two physicians who had reviewed pharmacy computer printouts documenting the prescriptions written for these patients by Dr. Hoover, and their opinions that the dosages she had prescribed were "excessive, perhaps lethal." None of these patients had, in fact, suffered any adverse effects from the prescriptions written by Dr. Hoover. Rather, they rallied to her support because she had diligently and successfully worked to manage their pain and restore their ability to function, whereas other physicians had either discounted their reports of pain or refused to prescribe opioids.

The board's experts did not review the medical records for any of these patients. Also, upon cross-examination, these "experts" acknowledged that they did not treat chronic pain patients in their practice. Indeed, under the more stringent standards for expert testimony that have developed in the last 10 years, one could reasonably argue that the medical board's experts were not really experts in pain management. The hearing officer in the case may have taken the same view, since she ultimately ruled that the evidence presented at the hearing supported a conclusion that Dr. Hoover's care of these patients was entirely appropriate. Nevertheless, the Board of Medicine took the remarkable step of disregarding the hearing officer's findings and conclusions, and imposed sanctions that included an administrative fine of $4000, CME on the prescribing of "abusable drugs," and 2 years of probation.

Dr. Hoover appealed, and in a scathing opinion by a three-judge panel of the Florida Court of Appeals, the ruling of the medical board was reversed. Noting a disturbing pattern and practice by the medical board, the opinion declared: "the board has once again engaged in the uniformly rejected practice of over-zealously supplanting a hearing officer's valid findings of fact regarding a doctor's prescription practices with its own opinion in a case founded on a woefully inadequate quantum of evidence."[5] Elsewhere in the opinion, the court referred to the board's "draconian policy of policing pain prescription practice." Similar to the decision by the Louisiana Court of Appeals in DiLeo, the Florida court noted that the medical board had failed to introduce competent, credible evidence of the standard of care by which Dr. Hoover's prescribing practices could be evaluated.

One very important implication of the DiLeo and Hoover cases is that the courts will not simply sit back and allow medical boards to declare what the standard of care is in any particular clinical situation. Rather, the board must present persuasive evidence in support of the prevailing standard of care. Moreover, such cases as these appear to represent an "ethic of underprescribing" on the part of state medical boards that persisted for decades.[6] It was the deeply engrained and pervasive nature of this ethic that prompted some state legislatures to adopt the intractable pain treatment acts (IPTA) that are discussed in Chapter 14. The thrust of such legislation was to send a message that the public policy of the state should not be to discourage physicians from providing effective pain management to patients with chronic nonmalignant pain, even if in some cases that would involve the extended use of opioid analgesics. The Hoover case suggests how difficult it was to surmount the prevailing ethic in some boards, since that case was brought shortly after the State of Florida had enacted an IPTA. The medical board rationalized its attempt to discipline Dr. Hoover by arguing that she had treated the patients in question prior to the effective date of the Florida law. The Florida Court of Appeals critiqued the cramped and legalistic way in which the Board attempted to flaunt the statute, noting that what the Board failed or refused to recognize was that the public policy of the state did not support its approach to punishing physicians who dared to prescribe opioids to patients with chronic noncancer pain.

Beginning in the mid-1990s, a few state medical boards adopted policies on pain management that were intended to reassure physicians that the board was not, in fact, hostile to good pain management practice, and sought to outline how physicians could care for such patients in a manner that was consistent with good medical practice. Then, in 1998, the Federation of State Medical Boards (FSMB) promulgated model guidelines for the use of controlled substances for the treatment of pain.[7]

The gradual dissemination of medical board policies promoting effective pain relief as an essential component of quality patient care signaled the beginning of a paradigm shift. Heretofore, the idea that if there could be such a thing as overprescribing of opioids, then as a matter of logic and consistency there must be an opposite side to the coin (i.e., underprescribing of opioids) seemed to be unintelligible to many medical boards. The inconsistency between perception and reality was truly remarkable. Whereas the medical literature in the 1980s and 1990s was replete with data indicating that pain was significantly undertreated in almost all patient care settings, no medical board had ever encountered a case in which underprescribing was deemed to constitute incompetent or unprofessional conduct.[8]

Oregon Board of Medical Examiners (OBME) v. Bilder

Paul A. Bilder is a pulmonary specialist who in the late 1990s was practicing in a small Oregon community. In 1999, the OBME initiated disciplinary action against Bilder following an investigation of complaints concerning his alleged failure to properly manage the pain and other distressing symptoms of six patients over a period of 5 years. The disciplinary action ultimately led to a Stipulated Order in which Bilder agreed to certain remedial measures.[9] Two of the six were elderly patients with metastatic cancer who were enrolled in hospice. In each instance the hospice nurse requested an increase in the dosage of pain medication in what turned out to be the last hours of the patient's life which Dr. Bilder refused to provide because he considered the amount requested excessive. In the other three cases, he refused to provide morphine or similar pain medication to a patient with CHF who was DNR and gasping for breath. The other three cases involved patients who were ventilator-dependent because of COPD or pneumonia. Dr. Bilder ordered paralytic agents but refused to order anti-anxiolytics or pain medication.

By the terms of the Stipulated Order, Dr. Bilder agreed to a 10-year probation, a formal reprimand, successful completion of the Board's Physician's Evaluation Education Renewal Program and an approved course in physician–patient communication, as well as continuing psychiatric treatment with regular reports from the treating psychiatrist to the Board. The Oregon Board once again found it necessary to take disciplinary action against Dr. Bilder 2 years later for similar instances of failure or refusal to appropriately respond to clear indications of patient suffering.[10]

Accusation of Eugene Whitney, MD

In 2003, California became the second state to take disciplinary action against a physician for failure to provide appropriate pain

relief. The patient in question was an 85-year-old man with advanced mesothelioma. The care of Lester Tomlinson in the last weeks of his life was the subject of both civil litigation and medical board disciplinary action. The civil litigation will be discussed in the next section of this chapter.

Mr. Tomlinson spent 5 days in a local hospital receiving treatment for pneumonia and pleural effusion. He was then transferred to a skilled nursing facility (SNF) and came under the care of Eugene B. Whitney, MD, for the duration of his stay, which ended with his death approximately 3 weeks later.[11] The care of Mr. Tomlinson at the SNF generated a great deal of contention between the members of his family (wife and daughter) and the caregivers. Each administration of pain medication, which began on the fourth day following his transfer from the hospital, was precipitated by a complaint from the family that he was in pain. Medication orders progressed from Restoril to Vicodin to various strengths of Duragesic patch. Only after the family specifically requested morphine for Mr. Tomlinson's increasing pain did Dr. Whitney discontinue the Vicodin and ordered Roxanol 20 mg, 10 mg orally every 6 hours.

Dr. Whitney saw Mr. Tomlinson only once during that period of time, 2 days after the first administration of Roxanol. He found the patient to be in pain and ordered MS Contin oral solution 10 mg every 4 hours as needed. As noted in the medical board charges against Dr. Whitney, MS Contin comes in tablet form only, and should be provided on a regular schedule, not on an ''as needed'' basis. Dr. Whitney discontinued the prior order 2 days later and instead ordered MS Contin 5 mg every 2 hours for breakthrough pain. As further noted in the medical board accusation, halving the dose of an opioid analgesic and doubling the frequency of administration will not increase the analgesic potency. Nursing notes at the SNF in the subsequent 2 days until Mr. Tomlinson's death indicate uncontrolled pain and anxiety.

The Medical Board of California charged Dr. Whitney with unprofessional conduct and incompetence for his failure ''to understand the unique properties of Roxanol solution and MS Contin tablets and to prescribe the medications properly.''[11] The Board and Dr. Whitney entered into a Stipulation for Public Reprimand, the terms and conditions of which require that he obtain continuing medical education in pain management, the prescribing of opioid analgesics, and communication with patients and families.[12]

At this point it is still too early to conclude that the medical board actions against Drs. Bilder and Whitney represent any sort of paradigm shift in philosophy and practice of medical boards generally in regard to opioid prescribing by their licensees. Two cases do not constitute a trend. Nevertheless, the Federation of State Medical Boards Model Policy concerning controlled substances for pain relief, updated and expanded in 2004, contains language that is strongly suggestive of a new paradigm. The Model Policy makes the following assertions:

- the state medical board will consider inappropriate treatment, including the undertreatment of pain, a departure from an acceptable standard of practice;
- the state medical board views pain management to be important and integral to the practice of medicine;
- the inappropriate treatment of pain includes nontreatment, undertreatment, overtreatment, and the continued use of ineffective treatments.[13]

As of mid-2007, a majority of state medical boards had adopted the model policies or promulgated policies that emphasized the need to incorporate sound pain management practices into patient care.[14] To some extent the shift in attitudes about the role of pain management in patient care, and the influence of those new attitudes in the formulation of medical practice guidelines and policies, can be traced to a few dramatic legal cases. We turn now to these cases and their role in informing public attitudes and public policies about pain and its management.

CIVIL LITIGATION

Despite growing evidence in the clinical literature that pain is often undertreated, and a medical malpractice crisis purportedly arising out of a plethora of malpractice claims yielding significant monetary damage awards, prior to 1990 there had never been a malpractice suit seeking damages for failure to provide appropriate pain relief.

While somewhat speculative, there are several possible explanations of this curious state of affairs. First, the phenomenon of widespread undertreated pain was not well known outside of the health professions. It had yet to become a featured topic in the print or electronic media. Moreover, laypersons held the erroneous belief that pain was the inevitable result of traumatic injury, serious illness, or a major surgical procedure. Finally, the generally high repute in which health care professionals were held presupposed that they would most certainly not allow a patient to experience unnecessary pain or suffering. The pervasiveness of pain in the clinical setting must, on this view, result from the sheer intractability of the pain associated with major illness, and most certainly with the process of dying. From this perspective, the case we now consider is all that more remarkable in its outcome.

Estate of Henry James v. Hillhaven Corporation

Henry James was a 75-year-old man who carried the diagnosis of stage III adenocarcinoma of the prostate with metastasis to the lumbar sacral spine and left femur. In December of 1986 and January of 1987 he spent nearly 2 months in a local hospital receiving treatment for a pathological hip fracture. During that hospitalization, in addition to bone debridement and radiation therapy, Mr. James was evaluated by hospice and received Roxanol 150 mg every 3 to 4 hours around the clock for his pain. Progress notes indicate that his pain was well controlled on this regimen.

After a very short stay at home, he was admitted to a nursing home owned and operated by the Hillhaven Corporation. The continuing orders for pain medication included 150 mg per day of Roxanol, along with 2 tablets of Tylenol every 4 hours as needed and Darvocet-N 100 mg. His family had ensured that he received the medication when he was at home, and made certain that the nursing home staff was aware of it upon his admission.[15]

In preparation of the SNF admission documents, a nurse offered the opinion that Mr. James was addicted to morphine and on that basis declared her intent to significantly reduce the amount of opioid analgesia and replace it with a tranquilizing agent. Remarkably, she was able to effectuate this change in the pain management regimen without the review and approval of the patient's physician. His family learned about the change only after he had been discharged from the facility and was interviewed by investigators for the North Carolina Department of Human Resources, the licensing agency for the facility. Their investigation revealed that at no time during his 23-day stay did he receive pain medication as ordered.[15]

Thereafter, the family consulted an attorney and suit was filed against the nurse and the facility for failure to properly treat Mr. James' pain.[16] In order to prevail in such a case, the plaintiff (Mr. James' estate) had to establish by a preponderance of the evidence that (1) a recognized standard of care for the management of his pain existed, (2) the standard was violated by the defendants, and (3) the departure from the standard of care caused him to

experience pain. If the jury answered each of those questions in the affirmative, then it must proceed to determine what several weeks of unnecessary pain should be worth in monetary damages. During the course of the trial expert witnesses called by the plaintiff challenged the position taken by the nurse at the Hillhaven facility that the dose of morphine prescribed for Mr. James was excessive and not necessary to control his pain.[17]

The jury answered each of the questions in the affirmative and awarded the plaintiff compensatory damages of $7.5 million. However, the jury did not stop with that award. In a civil action, when a defendant's conduct is sufficiently egregious to meet certain criteria, punitive damages may be awarded. The purpose of such damages, as the term suggests, is not to compensate the plaintiff, but rather to make a negative example of and punish the defendant. The jury in this case assessed another $7.5 million in punitive damages. Apparently, the jurors were convinced that there is or ought to be something like a right to effective pain relief, at least for patients in the circumstances of Mr. James, and that the defendant corporation and/or its agent consciously disregarded that right and in the process subjected an elderly, dying patient to unnecessary pain and suffering. In a subsequent section of this chapter we will consider two cases in which the U.S. Supreme Court appears to adopt a similar position as a matter of constitutional law.

Several years after the verdict and subsequent out-of-court (and confidential) settlement of the *James v. Hillhaven* case, North Carolina joined a number of other states in enacting tort reform legislation. Consequently, the same result could not be achieved today even in the same or a very similar case. Punitive damages are now capped at three times the amount of compensatory damages or $250,000, whichever is greater. Furthermore, punitive damages cannot even be sought unless the plaintiff can prove by clear and convincing evidence (a higher burden of proof than a preponderance of the evidence) one of the following aggravating factors: (1) the defendant acted out of malice, (2) fraudulently, or (3) in willful and wanton disregard of the rights or safety of the defendant. Punitive damages could not be recovered from a corporation (such as Hillhaven) unless the officers, managers, or directors participated in or condoned the conduct that constituted the aggravating factors.[18]

William Bergman v. Wing Chin, MD and Eden Medical Center

William Bergman was an 85-year-old man in severe pain when he arrived at the Emergency Department (ED) of Eden Medical Center. He had been taking the Vicodin prescribed by his physician, but without receiving adequate relief. He was given morphine by the ED physician, and experienced significant relief. In order to do a more extensive workup, he was admitted to the hospital and came under the care of a hospitalist, Wing Chin, MD. Out of concerns about the side effects of morphine, in particular respiratory depression, Dr. Chin discontinued it and wrote a standing order for Demerol, 25–50 mg every 4 hours "as needed." This order remained in place throughout the 5-day hospital stay, during which the nurses charted pain levels in the range of 7–10 on the standard 10-point scale. On the date of Mr. Bergman's discharge, his numerical pain score was noted to be a 10; nevertheless, Dr. Chin planned to send him home with a prescription for Vicodin. When Mr. Bergman's daughter protested, Dr. Chin ordered another administration of Demerol and a fentanyl patch.

During the hospitalization, the medical work up was strongly suggestive of lung cancer, although Mr. Bergman refused to consent to a lung biopsy that Dr. Chin believed was indicated in order to make a definitive diagnosis. Despite a diagnosis Dr. Chin deemed less than definitive, shortly following his discharge Mr. Bergman came under the care of a hospice nurse, who prevailed upon another physician in the community to write a prescription for morphine after she found the fentanyl patch to be inadequate to manage Mr. Bergman's pain. He died 3 days following discharge. No autopsy was performed. The cause of death was considered to be complications from lung cancer.[19]

The children of William Bergman became convinced that the last days of their father's life were severely compromised by a clinical failure to provide effective pain relief. Their conviction resulted in part from a review of his medical record by an expert secured through the assistance of the organization Compassion in Dying (now Compassion and Choices). The family initially filed a complaint against Dr. Chin with the Medical Board of California. In an interesting approach to the case, the Board's own investigation and independent expert review confirmed that the pain relief Dr. Chin provided to Mr. Bergman was inadequate. Nevertheless, the Board notified the family that it would not take any adverse disciplinary action against Dr. Chin based upon only one episode of inadequate patient care. Displeased by this response, and with continuing support from Compassion in Dying, the Bergman family secured legal counsel and filed a civil action against Dr. Chin and Eden Medical Center. The medical center settled with the plaintiffs prior to trial.

The complaint against Dr. Chin that was tried to a jury was unusual in that it was not a straightforward medical malpractice claim. Such a claim could not have any chance of success in California because, as a result of tort reform legislation, damages for pain and suffering resulting from medical malpractice can only be recovered by the patient; they are not deemed to "survive" such that they can be recovered following the patient's death by the personal representative. The only challenge to the medical care provided by Dr. Chin related to his alleged failure to properly manage Mr. Bergman's pain, hence the only damages that could be awarded would be for unnecessary pain and suffering. However, if the pain and suffering can be proven to have resulted from acts or omissions that constitute "elder abuse," under California law the personal representative of the "victim" of the abuse can recover damages. Consequently, the Bergman family's suit against Dr. Chin and the hospital alleged elder abuse.

Another complicating factor about an elder abuse claim in California is that it carries an elevated burden of proof. Rather than a mere preponderance of the evidence, the plaintiff must establish by "clear and convincing evidence" that the defendant was guilty of recklessness, fraud, or malice in perpetrating physical, financial, or fiduciary abuse or neglect.[20] Prior to this case, no physician had ever been accused of elder abuse, and the claim that failure of a health care professional to provide effective pain management might constitute a violation of the statute was an even further stretch. From all appearances, the trial of the case proceeded as would a typical medical malpractice claim. The plaintiffs offered the testimony of two physician expert witnesses, both of whom testified that there were serious problems with the type, dose, and schedule of administration of analgesia to Mr. Bergman while a patient at Eden Medical Center. In rebuttal, Dr. Chin called two physician expert witnesses who testified that in their opinion the measures he employed in an effort to manage Mr. Bergman's pain did not constitute a material departure from the custom and practice of similar physicians caring for patients like Mr. Bergman.[21]

During the course of the trial, despite Dr. Chin's contention that there was no conclusive evidence that Mr. Bergman had lung cancer, the judge allowed the plaintiffs to introduce into evidence the Agency for Health Care Policy and Research Clinical Practice Guideline *Managing Cancer Pain*. That evidence tended to bolster the testimony of the plaintiff's experts that Dr. Chin's pain management strategy was deficient in significant ways. The guideline provides, for example:

- Treatment of persistent or moderate to severe pain should be based on increasing the opioid potency or dose;

- Medications for persistent cancer-related pain should be administered on an around-the-clock basis with additional "as needed" doses, because regularly scheduled dosing maintains a constant level of drug in the body and helps prevent recurrence of the pain;
- Meperidine (Demerol) should not be used if continued opioid use is anticipated.[22]

Dr. Chin testified that he had no familiarity with these or with the Medical Board of California's 1994 guidelines and policy on pain management. He also stated that he did not take the nurses' notes on Mr. Bergman's pain levels into account because he did not have any confidence in that form of pain assessment.

The nurses involved in the care of Mr. Bergman testified on behalf of Dr. Chin that whenever Mr. Bergman reported pain in the moderate to severe range, they administered another 25 mg dose of Demerol consistent with the standing order. Interestingly, however, they testified that the reason the medical record did not reflect what they insisted to have been consistent achievement of pain relief in response to these administrations was that at Eden Medical Center pain was charted "by exception." In other words, pain was only noted when it was outside of normal limits. Such an approach begs the question of what constitutes an authoritative source for the "normal limits" of pain for any particular patient. This charting anomaly worked against the defendant, because the medical record was replete with pain levels in the moderate-to-severe range each day, but not in the mild to nonexistent range that would have supported their claim that the opioids administered to Mr. Bergman during his hospitalization were sufficient to meet his needs.

Ultimately, the jury reached a verdict in favor of the plaintiffs, and awarded $1.5 million in damages. They came within one vote of awarding an additional amount in punitive damages. The trial judge reduced the award to $250,000 on the theory that the statutory cap on monetary damage awards for medical malpractice claims applied even though this claim was filed pursuant to the elder abuse statute. The judge awarded nearly $1 million in attorney fees and litigation costs to the plaintiffs as well. Outstanding posttrial issues were resolved by confidential agreement between the parties; hence, no appeal was taken by either side.

News of the verdict in the Bergman v. Chin case shook the medical community. The stark contrast between the reaction of the Medical Board of California to the allegations in the case and that of the lay jury seemed to support an observation by the physician Eric Cassell nearly 20 years earlier: "The relief of suffering, it would appear, is considered one of the primary ends of medicine by patients and lay persons, but not by the medical profession."[23] Because the verdict came in the context of an elder abuse claim against Dr. Chin, it seemed particularly punitive in nature, and raised the issue of how to most appropriately and effectively "rehabilitate" physicians whose knowledge, skills, and/or attitudes were not conducive to the effective assessment and management of pain. We will revisit this issue after the discussion of the Tomlinson case that follows.

Tomlinson v. Bayberry Care Center, et al.

We have previously discussed the Tomlinson case in the context of the elder abuse claims filed against both the acute and long-term care facilities in which the patient received care in the last month of his life, as well as the physicians who were responsible for that care in both clinical settings. The claims in that case bore a striking resemblance to the claims in the Bergman v. Chin case.[24] Perhaps because of the jury verdict in the prior case, as noted, all of the defendants in Tomlinson settled prior to trial. Interestingly, as alluded to previously, the Medical Board of California took a much different position in dealing with the complaint by the Tomlinson family against Dr. Eugene Whitney, who was the responsible physician when Mr. Tomlinson was in the skilled nursing facility (Bayberry Care Center) than it did with regard to the complaint filed by the Bergman family against Dr. Chin. The Medical Board of California sanctioned Dr. Whitney for his failure "to understand the unique properties of Roxinol solution and MS Contin tablets and to prescribe the medications properly" pursuant to a stipulated disciplinary order he entered into with the Board. He was required to undergo an extensive evaluation of his professional knowledge and skills and work with the Board in developing a detailed remediation plan.[26] Also, the California Department of Health Services issued a Notice of Deficiency against Bayberry Care Center based upon the many problems with the care Mr. Tomlinson received at that facility.[25]

Just as one can speculate that the defendants in the elder abuse claims by the Tomlinson family were motivated to settle prior to trial because of the earlier jury verdict against Dr. Chin, it is also tempting to suggest that the decision of the Medical Board of California to take disciplinary action against Dr. Whitney in response to the complaint filed against him by the Tomlinson family was influenced by the highly negative public response to the Board's refusal to take similar action against Dr. Chin, particularly when a lay jury deemed the same conduct not just malpractice but elder abuse and the California legislature was motivated to pass a law mandating continuing medical education in pain management for California physicians. It is certainly possible that one influenced the other, but there is no way to authoritatively establish that proposition.

CRIMINAL LITIGATION

Criminal prosecutions of health care professionals for acts or omissions resulting in death or grave harm to patients are exceedingly rare.[26] By far the most common means of imposing sanctions on health professionals for negligent or even reckless patient care are those we have already considered—disciplinary action by state licensing boards or professional liability (malpractice) claims. The exceptional case that prompts a criminal prosecution is almost invariably one involving the death of the patient and conduct by the professional that is considered egregious in nature or in the extent to which it departs from a consensus view of what constitutes the parameters of responsible professional conduct.

Since our focus is necessarily on pain management and palliative care, we will consider several instances in which physicians have been prosecuted in either state or federal court. Some of the more high profile state prosecutions have involved the care of dying patients, whereas those in federal court have been pursuant to the Controlled Substances Act and involved prescribing opioids for chronic noncancer pain patients. We begin with a highly instructive state prosecution.

State v. Naramore

In 1994, the Attorney General of Kansas filed a two-count criminal complaint against L. Stanley Naramore, D.O. Both counts related to his care of patients almost 2 years before who were facing terminal conditions. Early in 1996 a jury returned guilty verdicts related to each count and the court sentenced Dr. Naramore to concurrent terms of 5 to 20 years. We will focus on the case that gave rise to the first count, and on the subsequent reversal of both convictions by the Kansas Court of Appeals.

The patient, Ruth Leach, was a 78-year-old woman suffering from advanced breast cancer that had metastasized to her bones, lungs, and brain. While a patient at St. Francis Hospital in the small Kansas town by the same name, her condition continued to deteriorate and the fentanyl patches no longer controlled her pain. She was restless and agitated, and the nurse on duty suggested to the family that Dr. Naramore be called and asked to

prescribe stronger pain medication. Upon arriving at the hospital, he examined Ruth Leach and spoke with her two adult children. Together they reached a decision to increase her pain medication in an effort to control her pain. Naramore explained that there was a risk of depressed respiration. He then administered 4 mg of Versed and 100 micromilligrams of fentanyl. Thereafter, the nursing notes indicate that the patient's respiration slowed and grew irregular.

From this point on the accounts of what transpired take on a curious, disjointed quality. To the extent they are accurate, it is not difficult to understand why there was a failure to maintain a consensus among the family and caregivers concerning the goals of care and how each subsequent action would be consistent with the reasonable pursuit of those goals.

The patient's son, who had training as an emergency medical technician, is reported to have asked Dr. Naramore if his mother was dying, and Naramore was said to have observed that she was, but that the effects of the fentanyl could be reversed by the administration of Narcan. This statement suggested to the patient's son and the nurse on duty that an overdose of pain medication must have been given. Thereafter, when Dr. Naramore began to prepare for continuing IV infusion of analgesics, the son insisted that he not administer any more, and was quoted as saying: "I'd rather my mother lay there and suffer for 10 more days than you do anything to speed up her death." In an effort to dissuade the son, Dr. Naramore told him: "it just gets terrible from here on out . . . the next few days are going to be absolutely terrible."[27] When the son remained intransigent and assured Dr. Naramore that he would hold the doctor accountable for anything that happened, Dr. Naramore withdrew from the case. The next day Ruth Leach was transported to another hospital, where she was given morphine for her pain and died 3 days later of her underlying terminal illness.[28]

As a result of the events described above, Ruth Leach's family became convinced, and they in turn persuaded the Kansas Attorney General, that Dr. Naramore had intended to hasten her death through administration of excessive doses of analgesics. Dr. Naramore was charged with attempted first-degree murder of Ruth Leach. At the same time, he was charged with second-degree murder of another patient from about the same time period, Chris Willt.

In order to convict a defendant of attempted first-degree murder, the jury must find that the prosecution has proven beyond a reasonable doubt that the defendant: (1) performed an overt act toward the commission of the crime; (2) did so with the intent to commit the crime of first-degree murder; and (3) failed to complete the commission of that crime. The elements of murder in the first degree include intent to kill a person, the intentional performance of an overt act toward that end that is both deliberate and premeditated.[27]

The prosecution presented several medical experts whose testimony supported the charge that Dr. Naramore had attempted to murder Ruth Leach. The Director of Emergency Medicine at the University of Kansas Medical Center testified that in his opinion Ruth Leach was near death after the administration of Versed and fentanyl, and that she would have died if the morphine Dr. Naramore had ordered had in fact been administered. This view was similarly expressed by a specialist in anesthesiology and critical care medicine at the University of Vermont College of Medicine who had previously practiced in Kansas. He testified that a dose of Versed combined with that of the fentanyl were excessive and in short order would have caused the patient to stop breathing. An additional respiratory depressant such as morphine would simply have added to the certainty of her death.

In his defense, Dr. Naramore called several expert witnesses. One of these, a physician who had cared for Ruth Leach for 5 years prior to her death, noted that she had received a variety of medications for her pain, none of which had brought it under control. He found it to be "phenomenal" that anyone would accuse Dr. Naramore of trying to kill her under these circumstances. A family physician from another small Kansas community said that if Dr. Naramore had actually intended to kill Ruth Leach he would have used 10 times the dosage administered. He characterized the care provided as "concerned and compassionate."

Another witness for Dr. Naramore was the president of the Kansas Association of Osteopathic Medicine and a family medicine practitioner. He believed that Dr. Naramore's efforts to control Ruth Leach's pain and distress at the end of her life were exemplary. Finally, another family physician who served on the peer review committee for Blue Cross/Blue Shield of Kansas testified that given her significant history of opioid analgesia and the extent of her distress at the time, the dosages of Versed and fentanyl were reasonable and in no sense an overdose.

The convictions of Dr. Naramore for the attempted murder of Ruth Leach and for the second-degree murder of the other patient were reviewed and reversed by the Kansas Court of Appeals. In its opinion, the Court of Appeals made numerous references not only to the expert witness testimony on his behalf at trial, but also to *amicus curiae* (friend of the court) briefs filed on behalf of Dr. Naramore by the Kansas Association of Osteopathic Medicine, the American Osteopathic Association, and the Kansas Medical Society. The court also noted that it had done its own substantial research on the subject of palliative care for terminally ill patients. Its review of the case law revealed "no criminal conviction of a physician for the attempted murder or murder of a patient which has ever been sustained on appeal based upon evidence of the kind presented here."[27]

In arriving at its decision that the criminal convictions must be reversed, the Court of Appeals noted and relied heavily upon the several expert witnesses who testified not only that Dr. Naramore's care of Mrs. Leach could not be reasonably characterized as indicative of an intent to kill her, but that in their professional judgment the care he provided was medically appropriate under the circumstances and hence within the applicable standard of care. The following language of the court is highly instructive and hence merits direct quotation:

> We have made a thorough review of the record [of the trial court proceedings], which contains a wealth of undisputed evidence and expert medical testimony. We find that no rational jury could find criminal intent and guilt beyond a reasonable doubt based on the record here. When the issue is whether there is reasonable doubt, a jury is not free to disbelieve undisputed facts. What occurred here is generally known. The jury was not free to disbelieve that there was substantial competent medical opinion in support of the proposition that Dr. Naramore's actions were not only noncriminal, but were medically appropriate.
>
> . . . When there is such strong evidence supporting a reasonable, noncriminal explanation for the doctor's actions, it cannot be said that there is no reasonable doubt of criminal guilt . . . All three *amicus* briefs . . . note that if criminal responsibility can be assessed based solely on opinions of a portion of the medical community which are strongly challenged by an opposing and authoritative medical consensus, we have criminalized malpractice, and even the possibility of malpractice. The instant case is a very good example of this.[27]

The above-quoted language of the court, and subsequent statements in the court's decision regarding the absence of any jury instructions "relating to the medical and moral responsibilities of care givers for the critically or terminally ill patient" are of considerable consequence because of their implications for a wide range of criminal prosecutions of physicians for care provided in an effort to manage the pain and adverse symptoms associated with terminal and serious chronic conditions.

Not only have state criminal prosecutions of health care professionals been relatively infrequent[28]; as illustrated by the Naramore charges, some of those have not been carefully screened by prosecutors prior to their initiation, so that even if they result in a conviction at trial, they do not survive the appel-

late review process. At the end of this chapter we will consider a set of recommendations for further insulating health care professionals from the risk of such prosecutions.

FEDERAL CRIMINAL PROSECUTIONS

Recent federal criminal prosecutions of physicians pursuant to the Federal Controlled Substances Act (CSA) for prescribing practices in the care of chronic noncancer pain patients are not entirely aberrational. They follow in the history and tradition of earlier cases, and the appellate courts reviewing these cases cite the earlier decisions profusely as correctly interpreting and applying the intent of the Congress when enacting the CSA. It therefore behooves us to review key elements of one such precedent-setting case before taking up the contemporary examples.

United States v. Rosen (1978)

Although Dr. Isadore Rosen was prosecuted under the CSA for prescribing controlled substances to patients for weight loss as part of an "obesity practice," and not for pain management, the language of the appellate court decision and its analysis of the CSA are often cited in later cases involving the prescribing of controlled substances for pain. Also, the prosecution of Dr. Rosen was based in large measure on the testimony of undercover law enforcement agents who came to him posing as patients seeking to lose weight. The use of such tactics generally gives rise to a claim of "entrapment" by the defendant; that is, that the government agents induced him to engage in one or more unlawful acts that he was not otherwise contemplating and in which he never would have engaged but for their inducement. As often happens, the court in *Rosen* easily disposed of this defense by noting "When a person is shown to be ready and willing to violate the law, the providing of an opportunity therefore by undercover agents or police officers is not entrapment."[29]

In order to convict Dr. Rosen of the 25 counts of distributing controlled substances in violation of the CSA with which he was charged, the government had to prove the following three elements of the offense beyond a reasonable doubt:

1. That he distributed or dispensed a controlled substance;
2. That he acted knowingly and intentionally; and
3. That he did so other than for a legitimate medical purpose and in the usual course of his professional practice.

Dr. Rosen conceded the first two elements, but asserted as to the third that each of the agents who came to him posing as patients presented symptoms for which the drugs he prescribed or dispensed were medically appropriate. It is important to note that while the prescribing of certain types of medications for the purpose of weight reduction is subject to some controversy, for purposes of this decision the court noted that all of the drugs prescribed by Dr. Rosen have legitimate therapeutic uses.

The crux of Dr. Rosen's argument on appeal of his criminal conviction was that the trial court relied on what it considered to be evidence of substandard medical practice as a basis for finding criminal intent. This point is critical as it will arise in the discussion of more recent prosecutions under the CSA. If the third element listed above is deemed to have been established beyond a reasonable doubt by the evidence, then the courts treat the physician not simply as a negligent, or even in some instances a reckless physician, but simply as a drug dealer. The court in Rosen reviewed a number of earlier convictions under the CSA and identified the following list of "red flags" suggesting that a physician may be acting illegitimately or outside the course of professional practice.

1. An inordinately large quantity of controlled substances was prescribed.
2. Large numbers of prescriptions were issued.
3. No physical exam was given.
4. The physician warned the patient to fill the prescriptions at different pharmacies.
5. The physician issued prescriptions to a patient known to be delivering the drugs to others.
6. The physician prescribed controlled substances at intervals inconsistent with legitimate medical treatment.
7. The physician used street slang rather than medical terminology for the drugs prescribed.
8. There was no logical relationship between the drugs prescribed and treatment of the condition allegedly existing.
9. The physician wrote more than one prescription on occasions in order to spread them out.[30]

The routine followed by Dr. Rosen's weight loss "clinic" included many of these red flag elements according to the testimony of the government agents who posed as patients seeking to lose weight. In particular, Dr. Rosen did not take a medical history or perform a physical exam other than to have the patients weighed and their blood pressure taken on the first visit by a staff member who was not a nurse. He provided no instructions on how to take the medications or warnings of risks or side effects to be concerned about, nor did he schedule follow-up appointments. Based upon this and other evidence at trial, the court of appeals ruled that the government had met its burden of proof that Dr. Rosen's prescribing or dispensing of controlled substances to the undercover agents was not in good faith for legitimate medical purposes in the course of his professional practice.

United States v. Hurwitz

Dr. William Hurwitz was a medical doctor who operated a pain medicine practice in McLean, Virginia. So widespread was his reputation as a liberal prescriber of opioids that many of his patients came from great distances—39 states—seeking medications from him that other physicians would not prescribe. In 1992, he was reprimanded by the District of Columbia medical board because of his "liberal" prescribing practices, and in 1996 the Virginia board revoked his license, and subsequently reinstated it with ongoing monitoring of his prescribing practices. Ostensibly that monitoring was still taking place when, in 2004, a federal grand jury indicted him on 62 counts, including drug trafficking resulting in death and serious bodily injuries, health care fraud, and criminal forfeiture. He was subsequently convicted on 50 of those counts and sentenced to 25 years in prison.[30] Throughout the criminal process, Dr. Hurwitz was portrayed by the federal prosecutor and officials of the Drug Enforcement Administration as "no different from a cocaine or heroin dealer peddling poison on the street corner."[30] At the trial, however, several nationally prominent experts in pain medicine testified on behalf of Dr. Hurwitz. During the trial, immediately following the testimony of the government's chief expert witness, six former presidents of the American Pain Society (APS) took the unprecedented step of sending a letter to the trial judge expressing their deep concerns about "serious misrepresentations" that had been made by the government's expert, who was also a past president of the APS.

When Dr. Hurwitz appealed his convictions to the Fourth Circuit Federal Court of Appeals, the American Academy of Pain Medicine, the American Pain Foundation, and a group of nationally prominent experts in pain management, among others, filed *amicus curiae* (friend of the court) briefs in support of his appeal. These briefs asserted, among other points, that "seriously erroneous rules of law and scientific theories [were] relied upon to convict [Dr. Hurwitz]."[32]

It is important to understand the significance one can reasonably attach to the willingness of these prominent organizations and individual members of the pain medicine community to go on record in this case. The government's position was that Dr. Hurwitz's prescribing of controlled substances had absolutely nothing to do with pain management. It was drug trafficking, pure and simple. The persons to whom he dispensed or prescribed these drugs were not patients, but rather drug seekers who sought either to feed their addiction or further disseminate them in the illicit market for prescription drugs.[32] The thrust of the argument on the other side was not that Dr. Hurwitz was practicing exemplary medicine, or in some instances even prescribing within the minimal standard of acceptable care for chronic pain patients, but rather that however far out of the mainstream his prescribing practices were, he was nevertheless a physician and not a drug dealer. The appropriate societal sanctions for physicians who practice negligently are medical malpractice liability claims or disciplinary action by licensing boards. In egregious circumstances, appropriate sanctions might include the permanent revocation of licensure. Nevertheless, physicians who practice substandard medicine are nonetheless physicians, and their patients remain patients in need of medical care, even if in some instances the care they require is for addiction.

The Fourth Circuit Court of Appeals reversed the Hurwitz conviction and remanded the case to the District Court for a new trial. In doing so, it sought to make clear where the trial judge had erred, and how the retrial should be conducted so as to provide Dr. Hurwitz with a fair trial. At the end of the new trial, he was convicted of 16 counts of drug trafficking and sentenced to 57 months in prison. Taking into consideration the amount of time he has already spent, it is likely that he will be released in late 2008 or early 2009.

United States of America v. McIver

Dr. Ronald McIver had approximately 1,000 patients in his South Carolina practice, most of whom saw him because of problems with chronic noncancer pain. In response to reports from the Columbia, South Carolina police department about Dr. McIver's prescribing practices, the DEA initiated an investigation of his practice in 2002. Based upon investigatory findings that among McIver's patients there were those who regularly received prescriptions for what were characterized as "massive quantities" of oxycodone, Dilaudid, OxyContin, methadone, and morphine, he was indicted on 15 counts of drug trafficking related to his treatment of 10 patients, 9 of whom testified for the government at his trial. The remaining patient was deceased, the cause of death having been characterized as an "oxycodone overdose."[33]

The major thrust of the prosecution's case at trial was based upon the expert testimony of a Dr. Steven Storick, an anesthesiologist who the court deemed to be duly qualified as an expert in pain management. After reviewing the medical records of the patients in question, he concluded that Dr. McIver's treatment of several of them fell outside the parameters of legitimate medical practice. For example, in the case of a patient with a history of substance abuse, Dr. Storick asserted that prescribing opioids to such a patient was "like pouring gasoline on a fire." A medicaid patient who sought treatment from Dr. McIver for fibromyalgia traveled almost 3 hours to see him, paid for his services in cash, and filled prescriptions for methadone, OxyContin, oxycodone, and morphine costing thousands of dollars. The patient testified that she sold the methadone and morphine, and was addicted to oxycodone. With regard to her treatment, Dr. Storick testified that Dr. McIver's conduct was "way outside the course of legitimate medical treatment."[33]

The jury convicted Dr. McIver of multiple counts of unlawful distribution of a controlled substance, and one that resulted in death. He was sentenced to 30 years in prison. On appeal to the Fourth Circuit Court of Appeals, the same court that granted Dr. Hurwitz a new trial, Dr. McIver's counsel attacked Dr. Storick's testimony as reflective of a hostile and suspicious approach to the care of chronic noncancer pain patients in that he insisted upon objective signs of tissue damage before prescribing opioids, and he refused to acknowledge that physicians could be deceived by some patients' reports of pain and yet still be legitimately prescribing opioids for them based upon a reasonable belief that they had significant pain.

The appeal also challenged the jury instructions, which Dr. McIver claimed suggested to the jury that he could be convicted if he "deviated drastically from accepted medical practice." The Court of Appeals, in affirming the conviction, disagreed, noting that the jury was instructed that the prosecution must prove not only that the defendant acted "outside the course of professional practice" but also that he acted "for other than a legitimate medical purpose."[34]

Before concluding the discussion of these federal prosecutions of physicians who were at the far liberal end of the prescribing continuum, it may be helpful to delineate the parameters of that entire continuum, and perhaps even to suggest where, as a matter of law and public policy, the line should be drawn between "the bounds of medicine" and the realm of drug dealing and trafficking by health care professionals. The thrust of the argument goes something like this: Just as we do not criminally prosecute clinicians whose failure or refusal to provide pain relief subjects some of their patients to physical and mental anguish, neither ought we to criminally prosecute clinicians whose excessive prescribing creates or exacerbates some of their patients' addiction disorders or propensity to engage in drug dealing under the guise of being a pain patient. In the most egregious instances at both ends of the continuum, the appropriate public policy stance is to suspend or permanently revoke their professional licensure.

Currently, however, at least clinicians at the far liberal end of the prescribing continuum, such as Hurwitz and McIver, prosecutors, and judges (through approved jury instructions) invite juries to act as though no real physician–patient relationship existed. As suggested by the Kansas Court of Appeals in the Naramore case, whenever the criminally charged clinician is able to present expert testimony that what he or she did was within the "bounds of medicine," the mere fact that the prosecution can offer expert testimony maintaining that it was not should never be sufficient for a conviction. Such a conflict of testimony should necessarily create the reasonable doubt that precludes a jury verdict against a criminal defendant.

CONSTITUTIONAL CASES

Several decisions by the Supreme Court of the United States in the last 10 years have addressed issues related to the treatment of pain. Each case also involved highly controversial ethical and political issues: physician-assisted suicide and medical marijuana. As is typical of the Supreme Court, the rulings in each case were not an effort to decide which side was correct on the ethics or the politics, but rather to determine what was consistent with the Constitution and a reasonable interpretation and application of federal statutes.

The first of these, the companion cases of *Washington v. Glucksberg*[36] and *Vacco v. Quill*[37] decided in 1997, directly involved the question of whether there was a constitutional right on the part of dying patients to be able to acquire lethal doses of medication from willing physicians for purposes of hastening their death. In the process of unanimously ruling that there was no such constitutional right, five of the nine justices joined in two concurring opinions that have been interpreted as a recognition by a majority of the court of a constitutional right on the part of terminal patients to receive palliative care.[37] The language from these companion cases most consistently cited for this prop-

osition include the following passage from the concurring opinion by Justice O'Connor:

> The parties and amici agree that in these states [Washington and New York] a patient who is suffering from a terminal illness and who is experiencing great pain has no legal barriers to obtaining medication, from qualified physicians, to alleviate that suffering, even to the point of causing unconsciousness and hastening death.

combined with language from a separate opinion by Justice Breyer:

> Were the legal circumstances different [than in Washington and New York]—for example were state law to prevent the provision of palliative care, including the provision of drugs as needed to avoid pain at the end of life—then the law's impact upon serious and otherwise unavoidable physical pain (accompanying death) would be more directly at issue. And as Justice O'Connor suggests, the Court might have to revisit its conclusions in these cases.

The focus upon pain and suffering at the end of life by the concurring justices may simply be a consequence of the fact that a right to lethal medication was asserted by the plaintiffs in these cases only as to patients with terminal illness. However, a right to appropriately aggressive palliative care as opposed to a lethal prescription, especially if defined quite broadly as the relief of pain and suffering, might be of even greater significance for a patient with severe chronic noncancer pain than for a terminally ill patient, since it could persist for years or decades rather than merely weeks or months. Only future cases will illuminate whether there might be constitutional protection from unreasonable governmental barriers to pain relief for such patients.

The constitutionality of the Oregon Death With Dignity Act (ODWDA), pursuant to which the state of Oregon legalized and regulated physician-assisted suicide (referred to by its proponents as physician aid in dying) was not directly at issue in either *Glucksberg* or *Quill*. However, those decisions by implication upheld the ODWDA since they determined that there is neither a constitutional right to nor a constitutional prohibition of such a practice. Consequently, it is a matter for each individual state to determine as part of its authority to regulate the practice of health care professionals.

In 2001, Attorney General John Ashcroft issued an Interpretive Rule (IR) of the federal Controlled Substances Act (CSA), maintaining that prescribing a controlled substance for the purpose of assisting a patient in ending their life, even pursuant to a state statutory scheme such as the ODWDA, contravened the CSA and rendered the prescriber vulnerable to federal prosecution. Since all lethal prescriptions written pursuant to the ODWDA were federally controlled substances, the Ashcroft IR would essentially nullify the Oregon law. The State of Oregon immediately challenged the IR in federal court and obtained first a temporary restraining order and subsequently an injunction prohibiting enforcement of the IR pending resolution by the courts. When Ashcroft resigned as Attorney General, his successor Alberto Gonzales decided to continue the legislation. By then, review of adverse rulings by the federal district and Ninth Circuit Court of Appeals had been sought and the case was pending before the U.S. Supreme Court.

The central issue decided by the Supreme Court in Gonzales v. Oregon was: "who decides whether a particular activity is 'in the course of medical practice' or 'done for a 'legitimate medical purpose.' "[38] The Attorney General claimed authority under the CSA to define standards of medical practice at least insofar as the prescribing of scheduled drugs. Taking into consideration the legislative history of the CSA, the Supreme Court majority ruled that the intent of Congress was to combat a national problem of recreational drug abuse by ensuring that scheduled narcotics were secured within the health care setting through the prescribing by licensed practitioners for legitimate medical purposes. Nothing in the language or the legislative history of the CSA suggests that Congress intended to confer on the Attorney General, in his capacity of law enforcement, to usurp the usual authority of the individual states in regulating the practice of medicine, which includes the writing of prescriptions. For this and other reasons discussed at length by the Court, the IR was held to exceed the authority of the Attorney General under the CSA.

The last case we will consider, which was decided before *Gonzales v. Oregon*, was *Gonzales v. Raich*. The plaintiffs in this case, Angel Raich and Diane Monson, were California residents suffering from a variety of serious medical conditions. Raich carries at least ten diagnoses, including an inoperable brain tumor, seizure disorder, and several chronic pain syndromes. Monson suffers from severe chronic back pain and muscle spasms related to a degenerative disease of the spine.

California is one of ten states that have enacted legislation insulating seriously ill patients or their physicians from prosecution under state law for cultivating or possessing cannabis for use by the patient pursuant to the physician's written recommendation or approval. The plaintiffs in this case argued that they were being treated by board-certified family practitioners who had determined after prescribing a wide variety of standard medications that marijuana is the only drug available that provides effective relief of their symptoms.[40] As a Schedule 1 drug, the CSA recognizes no legitimate basis for patients such as Raich and Monson to possess or use marijuana, even though their physicians authorized it pursuant to the California statute. The plaintiffs filed suit against Attorney General Ashcroft and the administrator of the DEA in federal district court seeking declaratory and injunctive relief preventing the federal government from prosecuting them under the CSA. The crux of their argument was that enforcement of the CSA against them required that interstate commerce be implicated in their acquisition and use of medical marijuana. The district court ruled against the plaintiffs, finding that the Commerce Clause of the Constitution applied to them despite the fact that the marijuana they used was grown in California.

The Ninth Circuit Court of Appeals reversed the district court, holding that the plaintiffs' intrastate, noncommercial cultivation, possession, and use of marijuana for personal medical purposes on the advice of a physician does not constitute drug trafficking. Much of the court's discussion involved arcane legal principles and Supreme Court precedents. Ultimately, it was these very principles and precedents that provided the basis for the Supreme Court's reversal of the Ninth Circuit. Simply stated, the Court held that "Congress' power to regulate interstate markets for medicinal substances encompasses the portions of those markets that are supplied with drugs produced and consumed locally. . . . The CSA is a valid exercise of federal power, even as applied to the troubling facts of this case."[39] Thus the Court's ruling in *Raich* cannot be understood as a pronouncement on the clinical question of whether the known risks and purported benefits of medical marijuana use ever justify a physician recommending it to patients when standard therapies are found to be inadequate.

LESSONS FROM THE LITIGATION

Generalizations that meet minimal criteria of accuracy and practicality concerning the lessons one should learn from the varieties of litigation surveyed in this chapter are both difficult and dangerous. They are difficult because of the wide variation in cases; for example, state and federal courts, some patients who were dying, others facing chronic noncancer pain, still others who were addicted to prescription drugs or simply "planted" as a part of ongoing investigations by law enforcement. They are dangerous when they constitute gross oversimplifications of complex phenomena that have only superficial similarities. Nevertheless, some attempt at synthesis is both necessary and appropriate.

- Lesson 1: A new medical ethos has clearly emerged, grounded on the recognition that timely and effective assessment and

management of all types of pain is essential to sound patient care. Nationally recognized clinical practice guidelines and organizational policies (such as the Joint Commission) affirm this basic proposition.

- Lesson 2. Evidence- or consensus-based guidelines and policies reinforce the proposition that there are recognized standards of care for the management of acute, chronic noncancer, and pain associated with terminal illness. These standards apply to all clinicians who care for patients with pain, and not merely pain medicine or palliative care specialists.
- Lesson 3. Material departures from these standards render clinicians vulnerable to a variety of adverse legal consequences. Egregiously conservative approaches to opioid analgesia may result in civil liability for undertreatment of pain or professional licensing board sanctions. Excessively liberal approaches to the prescribing of opioids, particularly when a reasonable clinician would have recognized red flags or other warning signs, may result in criminal prosecution at the state or federal level.
- Lesson 4. Prudent practitioners should ensure that their knowledge, skills, and attitudes (at least insofar as they affect professional practice) are informed by the current authoritative clinical practice guidelines and policy statements. When that is the case, their approach to pain management will reflect a reasonable balance between effective pain management for their patients and due diligence to ensure that their prescribing practices are neither harming their patients nor contributing to the phenomena of prescription drug abuse and diversion.
- Lesson 5. As with any other aspect of patient care, timely, accurate, and thorough documentation in the medical record that reflects not only what was done, but also what informed the decision on what to do and what alternatives were considered is absolutely essential. In every legal setting, incomplete, inaccurate, or untimely documentation of professional conduct is problematic, sometimes devastatingly so.
- Lesson 6. Clinicians who heed lessons 1–5 above are not at any serious risk of adverse legal action arising out of their responsible efforts to relieve the pain of their patients.

CHAPTER 16 ■ OPIOID POLICY, AVAILABILITY, AND ACCESS IN DEVELOPING AND NONINDUSTRIALIZED COUNTRIES

DAVID E. JORANSON, KAREN M. RYAN, AND MARTHA A. MAURER

INTRODUCTION

More than two decades ago, an expert committee of the World Health Organization (WHO) concluded that most pain due to cancer could be relieved if health professionals would use a relatively simple analgesic method and if patients could have access to opioids such as oral morphine.[1] The WHO analgesic method also has been endorsed for relief of pain due to HIV/AIDS.[2]

United Nations (UN) health and regulatory agencies repeatedly have appealed to health professionals, their organizations, and governments to cooperate in order to implement the WHO analgesic method and remove barriers that block patient access to opioid pain medications.[3–7] Although drug regulations and opioid availability have improved in some countries, the vast majority of cancer and AIDS patients in the developing world, and many in developed countries, still lack access to these essential medications. This chapter focuses on opioids that are indicated for moderate to severe pain associated with cancer and AIDS, such as morphine, oxycodone, and fentanyl.

A further disparity exists in reported medical consumption of opioid analgesics between developed nations with a small proportion of the global population and the large and growing population of developing countries. With the shifting burden of cancer and AIDS to developing countries, the public health problem of inadequate availability of pain medications is deepening.[8,9]

Health professionals who manage pain must know about the regulation of opioid analgesics. Just as effective clinical management of pain rests on a body of knowledge, treatment methods, and communication between the clinician and patient, so the task of ensuring access to pain medications in any country depends on knowing the role and responsibilities of national governments and on communication between drug regulators and health professionals.

This chapter outlines the body of knowledge about government drug control policy and the methods that are being developed to assist health professionals and governments to improve opioid analgesic availability and access. ''Opioid availability'' refers to whether a country has stocks of opioid analgesics either at the manufacturer or retail level of the drug distribution system. The term may be used in referring to the presence of opioids within a country, or at any point throughout the drug distribution system, including in the health care facilities that provide medical care for patients. Alternatively, ''opioid accessibility'' refers to patients' ability to obtain the opioid pain medications they need for pain relief. Clearly, patient access is not possible unless opioids are available in a country. Therefore opioids may be legally available within a country or even a health care facility, but patients may not be able to access them for a variety of reasons. Cooperation of governments with pain and palliative care experts and their national and international organizations is emphasized.

PAIN RELIEF IS PART OF CANCER AND AIDS CONTROL

The global incidence and prevalence of cancer and HIV/AIDS is a public health problem of great concern. The WHO estimates that there are 22 million people with cancer in the world. Each year approximately 10 million individuals are diagnosed with cancer, and more than 6 million die from this noncommunicable disease. Experts predict that these numbers will double by 2020, with major impacts on developing countries where it is estimated that the majority of new cases and deaths from cancer, including children, will occur.[8,9] The global occurrence of HIV/AIDS is also a critical public health problem. The Joint United Nations Programme on HIV/AIDS (UNAIDS) indicated that in 2007, 33.2 million people were living with HIV/AIDS, a communicable disease, and 2.1 million people died from AIDS.[10]

During the course of their disease, people living with AIDS and cancer survivors experience pain as well as a variety of other symptoms that will negatively impact the quality of their lives.[11] Those nearing the end of life are likely to experience even more severe symptoms.[2,12–15] Common symptoms of cancer include pain, fatigue, anxiety, constipation, cough, depression, dyspnea, and nausea.[1] Patients with cancer or AIDS often have severe pain, particularly during the late stages of the disease.[13,15–19] In the developing world, most cancers are diagnosed in late stage.[16,17] Pain can be due to the disease itself, the treatment of the disease, or another concurrent disorder.

Pain and Palliative Care

Palliative care, including the critically important component of pain management, is a model of care aimed at relieving symptoms of disease and its treatment and improving the patient and family's quality of life throughout the course of the disease. The WHO has long recognized that relieving pain and other symptoms in cancer[1] and AIDS[2,20] is a necessary part of palliative care, including for children.[21]

Palliative care and pain relief medicines should be available and accessible to all individuals who have pain and other symptoms.[2,12] In 2002[22] and 2003,[9] the WHO emphasized that palliative care be part of any national program aimed at reducing the overall burden of cancer, and that it is the government's public health responsibility to develop a policy and program to address palliative care needs in the country. The WHO has expanded its recommendations to include HIV/AIDS control programs: ''Palliative care is an essential component of a comprehensive package of care for people living with HIV/AIDS because of the variety of symptoms they can experience—such as pain . . .''[2]

There is a strong international imperative that palliative care, including pain management, should be included in national cancer and HIV/AIDS control efforts. The WHO has reaffirmed the necessity of including palliative care as a critical component of

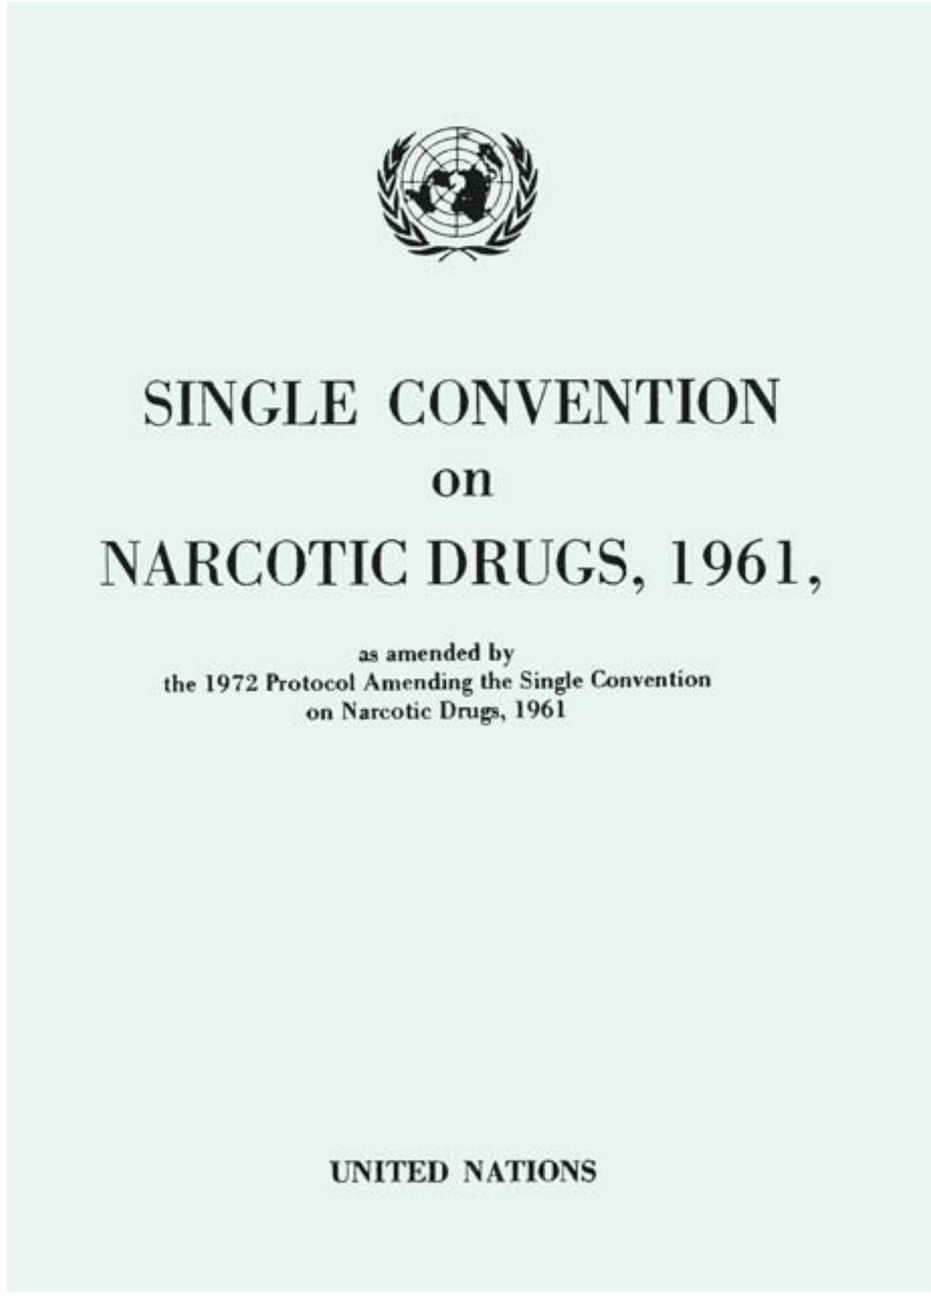
cancer or AIDS control efforts in a country.[23,24] At the country level, national policies should provide a policy framework for developing and expanding health care services to reach patients who need disease treatment as well as relief of pain and other symptoms.

In 2007, the WHO published a guide for developing effective national cancer control programs that include palliative care. This guide reiterated that national palliative care plans must include policy to provide for the medications necessary to manage symptoms associated with cancer, including opioid analgesics for pain.[25]

OPIOIDS ARE ESSENTIAL MEDICINES

There are many useful therapies for treating cancer pain, including pharmacological and nonpharmacological approaches. Opioid analgesics, and in particular orally administered morphine, are regarded by international health experts as the gold standard for relieving moderate to severe pain due to cancer or AIDS. The WHO Expert Committee on the Selection and Use of Essential Medicines has designated morphine and other opioid analgesics as *essential medicines*, which are those medicines that ". . . satisfy the priority health care needs of the population. They are selected with due regard to public health relevance, evidence on efficacy and safety, and comparative cost-effectiveness. Essential medicines are intended to be available within the context of functioning health systems at all times in adequate amounts, in the appropriate dosage forms, with assured quality and adequate information, and at a price the individual and the community can afford. The implementation of the concept of essential medicines is intended to be flexible and adaptable to many different situations; exactly which medicines are regarded as essential remains a national responsibility."[26]

The first WHO essential medicines list, issued in 1977, identified 208 essential medicines for treating the global disease burden, and included morphine to treat pain, thereby recognizing its benefit to public health.[27] In 2007, the 15th edition celebrated the 30th anniversary of the Model Essential Medicines List.[28] This list identified 340 essential medicines and included only morphine, immediate and sustained release, as an opioid analgesic appropriate for the treatment of moderate to severe pain. Currently, 156 of 193 WHO member states have official essential medicines lists.



In 2005, the WHO Cancer Control Program requested that the International Association for Hospice and Palliative Care (IAHPC) recommend a list of essential medicines specifically for palliative care. In 2006, a committee of the International Association for Hospice and Palliative Care Board members and external advisors from 29 pain and palliative care organizations guided the process of identifying the medications to treat the most prevalent symptoms in palliative care. The effort focused on efficacy and safety of medications, with the presumption that cost considerations will be made at the national level. The committee recommended 33 essential medicines (14 are also on the WHO list of essential medicines); the list can be online accessed at http://www.hospicecare.com/resources/pdf-docs/iahpc-list-em.pdf.
The list includes four opioid analgesics to treat moderate to severe pain: transdermal fentanyl, methadone, morphine (both immediate and sustained release preparations), and oxycodone. If accepted, this list would expand WHO's list of essential medicines to treat moderate to severe pain, which presently includes only morphine (both immediate and extended release). The WHO will be conducting cost effectiveness analyses and evidence-based reviews of the recommended medications to determine whether it will adopt this list of essential medicines for inclusion in its list for palliative care. Meanwhile, the IAHPC encourages countries to use the list as a model when developing their own lists of essential medicines according to resources and needs.

OPIOID ANALGESICS ARE CONTROLLED DRUGS

Opioid analgesics, in addition to being medicines that are essential for relieving pain, have a potential for abuse and drug dependence. They are "controlled" by an international law called the Single Convention on Narcotic Drugs, 1961, as amended by the 1972 Protocol Amending the Single Convention on Narcotic Drugs, 1961 (Single Convention) (see Fig. 16.1)[29] as "narcotic drugs," a legal term that will be used where the context requires. This chapter addresses opioid analgesics that are agonists with no ceiling effect that can relieve moderate to severe pain, such as morphine, fentanyl, oxycodone, and hydromorphone. This chapter does not address codeine, which is not a pure agonist, or other partial or mixed agonists, such as buprenorphine and pentazocine, which are controlled under the Convention on Psychotropic Substances, 1971.[30]

Nearly every government, or party, in the world has formally acceded to the Single Convention. As of 2006, 181 countries were Parties to the Single Convention, representing 99.6% of the world's population. In so doing, each has agreed to adopt laws, regulations, and administrative procedures to carry out the aims of the Single Convention. The Single Convention establishes obligations to which national governments have acceded, to control opioids and also to make them available for medical purposes.

The premise of the Single Convention rests on the recognition that the consequences of addiction to narcotic drugs pose a threat to society that governments must address: ". . . addic-

SINGLE CONVENTION

on Narcotic Drugs, 1961

UNITED NATIONS

FIGURE 16.1 The United Nations Single Convention on Narcotic Drugs, 1961.

tion to narcotic drugs constitutes a serious evil for the individual and is fraught with social and economic danger to mankind."[28] The Single Convention establishes an international government framework of prohibitions and requirements concerning the legitimate production, manufacture, and distribution that is intended to prevent illicit trafficking, nonmedical use of narcotic drugs, and diversion, which is the illegal movement of controlled medications from the licit distribution system into the illicit market. The most restrictive category under the Single Convention is Schedule I, which includes narcotic drugs considered to be highly addictive and liable to abuse. Morphine and other opioids such as fentanyl, oxycodone, and pethidine are controlled in Schedule I.

According to the Single Convention, several UN organizations have roles in the procedure to schedule drugs. The WHO Expert Committee on Drug Dependence has the responsibility of providing recommendations to the Commission on Narcotic Drugs regarding scheduling drugs.[31] This role is critically important as scheduling decisions can have major implications for the availability of drugs for medical care.

The principal *international* requirement is that legitimate trade in narcotic drugs is regulated, including the cultivation of opium and manufacture of medicinal opioids such as codeine and morphine. To prevent diversion, an import-export system is established to limit trade to the amounts necessary for medical use; trade is regulated by the International Narcotics Control Board (INCB) in Vienna, Austria.

The INCB was established in 1968 as an independent and quasi-judicial monitoring body to implement UN international drug control conventions.[31] The 13 members of the INCB are elected by the Economic and Social Council of the UN and serve as individuals rather than representatives of their governments. The WHO nominates three members who have medical, pharmacological, or pharmaceutical experience. The INCB's responsibilities in regard to opioids include: (1) to ensure, in cooperation with governments, that adequate supplies of drugs are available for medical and scientific uses and to prevent diversion of drugs from licit sources to illicit channels; (2) to administer the system whereby governments must estimate the amounts of narcotic drugs required for medical and scientific purposes; (3) to monitor licit distribution of narcotic drugs using governments' reports of amounts consumed, in an effort to coordinate a supply sufficient to meet, but not exceed, demand; (4) to analyze information provided by governments, UN bodies, and other international organizations to ensure that governments adequately implement the provisions of the treaty; (5) to maintain a "permanent dialogue" with governments, working closely with them to comply with their obligations under the international drug control treaty; (6) to recommend, when appropriate, additional technical and/or financial assistance for those countries needing support in carrying out obligations of this treaty; (7) to ask for explanations of apparent violations of the treaty, propose corrective measures to governments that are not fully adhering to the treaties, and assist governments to overcome difficulties. If the INCB determines a government has not taken measures to remedy a serious situation, it may call the matter to the attention of the Commission on Narcotic Drugs and the Economic and Social Council of the UN. As a last resort, the treaty empowers the INCB to recommend that governments stop trade with a defaulting country.[31]

The Single Convention establishes several *national* obligations, among them that governments must regulate all entities that handle controlled drugs. The goal is to create a closed distribution system, including security and record keeping. Prescribing and dispensing to individuals must be done only for medical purposes by medical professionals authorized under national law, using "medical prescriptions." Distribution outside of the regulated system is prohibited in order to prevent diversion of controlled drugs from medical to nonmedical uses. There is little if any diversion of narcotic drugs from the licit international trade, despite the large number of transactions involved; most diversion of narcotic drugs occurs within domestic circuits.[32] Efforts to prevent diversion should be balanced so as not to interfere in medical practice and patient care.[33,34]

Examples of efforts to lessen the risks of abuse and diversion include risk management plans before marketing of new controlled drugs[35,36]; guidance for clinicians on how to safeguard controlled drugs[37]; education for clinicians about how to assess patients for abuse and drug dependence as well as for pain; and ethics guidelines for how pain medicine specialists can balance the benefits and risks of opioid treatment.[38]

CONTROLLED MEDICINES SHOULD BE AVAILABLE

In addition to controlling drugs to prevent their diversion and nonmedical use, the Single Convention stipulates a second obligation to ensure adequate availability of narcotic drugs for medical and scientific purposes. The Single Convention clearly recognizes the importance of narcotic drugs as analgesic medications, and asserts that medical access to opioids for relief of pain is to be assured by governments, since they are obligated to conform their laws to the Single Convention, ". . . the medical use of narcotic drugs continues to be indispensable for the relief of pain and suffering and that adequate provision must be made to ensure the availability of narcotic drugs for such purposes."[39]

The drug availability obligation is no less important than drug control, but it is poorly understood and implemented by health professionals and governments. There is no indication that the medical value of controlled drugs is lessened as a result of scheduling under the Single Convention. Scholars of international narcotic drug policy have concluded that the Single Convention, as amended, recognizes that the basic purpose of international drug control is to reduce the availability of drugs for nonmedical purposes, but "that this should not affect or limit their therapeutic use."[40]

Government Mechanisms to Ensure Adequate Drug Availability

The INCB recognizes *both* drug control and drug availability obligations of governments:

> One of the objectives of the Single Convention on Narcotic Drugs, 1961 . . . is to ensure the availability of opiates, such as codeine and morphine, that are indispensable for the relief of pain and suffering, while minimizing the possibility of their abuse or diversion.[3]

To accomplish this objective, the Single Convention requires that governments adopt laws, regulations, and administrative procedures to implement two specific mechanisms that are intended to ensure adequate availability of opioid analgesics in countries, while preventing nonmedical use. First, governments must annually establish an estimate of the amounts of opioids that will be required for all medical and scientific needs for the coming year. Licit trade in narcotic drugs can be lawfully conducted only within this amount. If imports exceed a country's estimated requirements, exporters are obligated to refrain from further trade with the country. Governments are encouraged to develop valid estimation methods, to establish estimates that take increasing demand into consideration, to cooperate with health professionals to obtain information about unmet needs, and to increase the estimate whenever necessary to always satisfy medical needs. Second, governments must report the amounts of each narcotic drug consumed (i.e., distributed to the retail level), to allow identification of consumption that either exceeds or falls short of the estimate.

Implementation of Drug Availability: The Competent National Authority

Each Party to the Single Convention is expected to establish a drug control program not only to prevent illicit trafficking and diversion, but also to ensure the adequate availability of narcotic drugs for medical and scientific purposes[5] and to designate an agency called the Competent National Authority (CNA) to implement the functions required by the Single Convention. This office is usually located in the pharmaceutical department of the Ministry of Health, the national drug control or public security agency, or the functions may be divided between agencies. The CNA is the principal national administrative authority for carrying out the estimation and statistical reporting procedures that are necessary for ensuring that opioid analgesics are adequately available for medical and scientific purposes. Guidelines for estimating the amounts of opioids required for medical and scientific use and for reporting consumption statistics are useful for those who want to understand the administrative procedures to be followed by CNAs.[41,42] The INCB provides guidelines for CNAs to comply with the Single Convention, including the administration of effective mechanisms to ensure opioid availability.[43]

DISPARITIES IN OPIOID CONSUMPTION

The Single Convention requirement that national governments report annual consumption statistics provides a unique source of data to describe global and national opioid consumption trends and to study disparities. Consumption means the amounts of opioid analgesics distributed for medical purposes to the "retail" level in a country (i.e., to those institutions and programs that are licensed to dispense to patients, such as hospitals, nursing homes, pharmacies, hospices, and palliative care programs). The INCB uses consumption statistics to: (1) monitor compliance of governments with the provisions of the Single Convention; (2) identify trade discrepancies between importing and exporting countries, (3) detect imbalances between quantities of medications available and disposed within a country; (4) identify trends in the worldwide availability of opioids and other drugs for medical needs; and (5) monitor and maintain a global balance of supply and demand of opioids for medical and scientific needs.[42]

Opioid consumption statistics have several useful applications for those who study and improve opioid availability to: (1) identify whether a country has available opioids that can relieve moderate to severe pain, (2) learn whether the amounts indicate any substantial current consumption or progress over time,[14] and (3) evaluate the outcome of efforts to improve opioid availability.

Consumption statistics provided in INCB reports have several limitations that should be considered when using them as an indicator of opioid availability:

1. Some governments report late, do not report for a particular year or period, or make inaccurate reports, which results in incomplete or invalid information for that year. Consequently, the amounts for the most recent year may be underreported; these deficiencies may be corrected in subsequent years.
2. The INCB's published reports do not provide data on small quantities; instead, the symbol "<<" signifies that a country reported between 0 and 0.499 kg, and also rounds up to 1 kg reported amounts that were reported between 0.5–0.999.[32] Although not available from the INCB's published reports, consumption of small amounts can nevertheless be important, especially in countries with small populations or in those which are just beginning to address their needs.
3. Consumption statistics do not distinguish between clinical uses for opioids, as in methadone for treatment of pain or drug dependence, or fentanyl for analgesia or anesthesia.
4. Consumption statistics do not distinguish between programs that use opioid analgesics such as hospitals and hospices.
5. Consumption statistics do not indicate which products or dosage forms of an opioid are available within a country (i.e., whether an opioid is in oral, parenteral, or transdermal form).
6. Consumption statistics are not a valid clinical indicator of the quality of pain control in a country.

Morphine Equivalence Metric

The WHO has considered a country's annual consumption of morphine to be an indicator of the extent that opioids are used to treat severe cancer pain and an index to evaluate improvements in pain management.[13,14] The WHO and the INCB have long recognized that pain is inadequately treated owing to low consumption of morphine in most countries, and great disparities between countries.[44,45] Additional opioid analgesic medications and formulations such as fentanyl, hydromorphone, and oxycodone have been introduced in global and national markets over the past 20 years and should be taken into consideration when studying opioid consumption in a country, region, and globally. To what extent does consumption of morphine alone compared with other opioids adequately describe a country's medical use of opioids?

To address this question, the Pain & Policy Studies Group/WHO Collaborating Center for Policy and Communications in Cancer Care (PPSG/WHOCC) developed a metric called morphine equivalence (ME) for each principal opioid used to treat moderate to severe pain that is expressed in terms of morphine equivalence and adjusted for population. The ME allows an equianalgesic comparison of the consumption of morphine with other opioid medications at the national, regional, and global levels.[45] A total ME statistic combines consumption of several principal opioid analgesics into one metric. The following study drugs were selected to calculate the total ME because they are the opioids that are indicated for severe pain: fentanyl, hydromorphone, methadone, morphine, oxycodone, and pethidine. We used conversion formulas established by the WHO Collaborating Centre for Drug Statistics Methodology in Oslo, Norway.[46] These data were obtained directly from the INCB, thereby eliminating the small quantity limitation; the other limitations of opioid consumption statistics apply to ME data.

Global Trends

The 30-year trend ending in 2005 in Figure 16.2 shows that prior to 1986, morphine ME was very low and stable throughout the world; it was paralleled by total ME. After WHO announced its cancer pain relief three-step analgesic ladder in 1986 and encouraged use of oral morphine, morphine ME began to increase; total ME increased more rapidly and diverged from morphine ME. With the emergence of additional opioids and dosage forms in the mid-1990s, total ME increased even more, so that morphine ME became less and less of a valid indicator of global opioid consumption. In 1986, global morphine ME was 50% of total ME, compared to 14% in 2005. In recent years, fentanyl, methadone, oxycodone, and hydromorphone, respectively, accounted for the greatest portion of opioid consumption, at least for the global aggregate data.

Of interest is the long-term decline in consumption of pethidine (meperidine), likely due to increasing recognition of the potential risks associated with accumulation of the toxic metabolite norpethidine. Pethidine has been used in many countries mainly by injection for postoperative pain because of a perception that its very short duration of action reduces the risk of dependence. Pethidine is no longer recommended by the WHO for the treat-

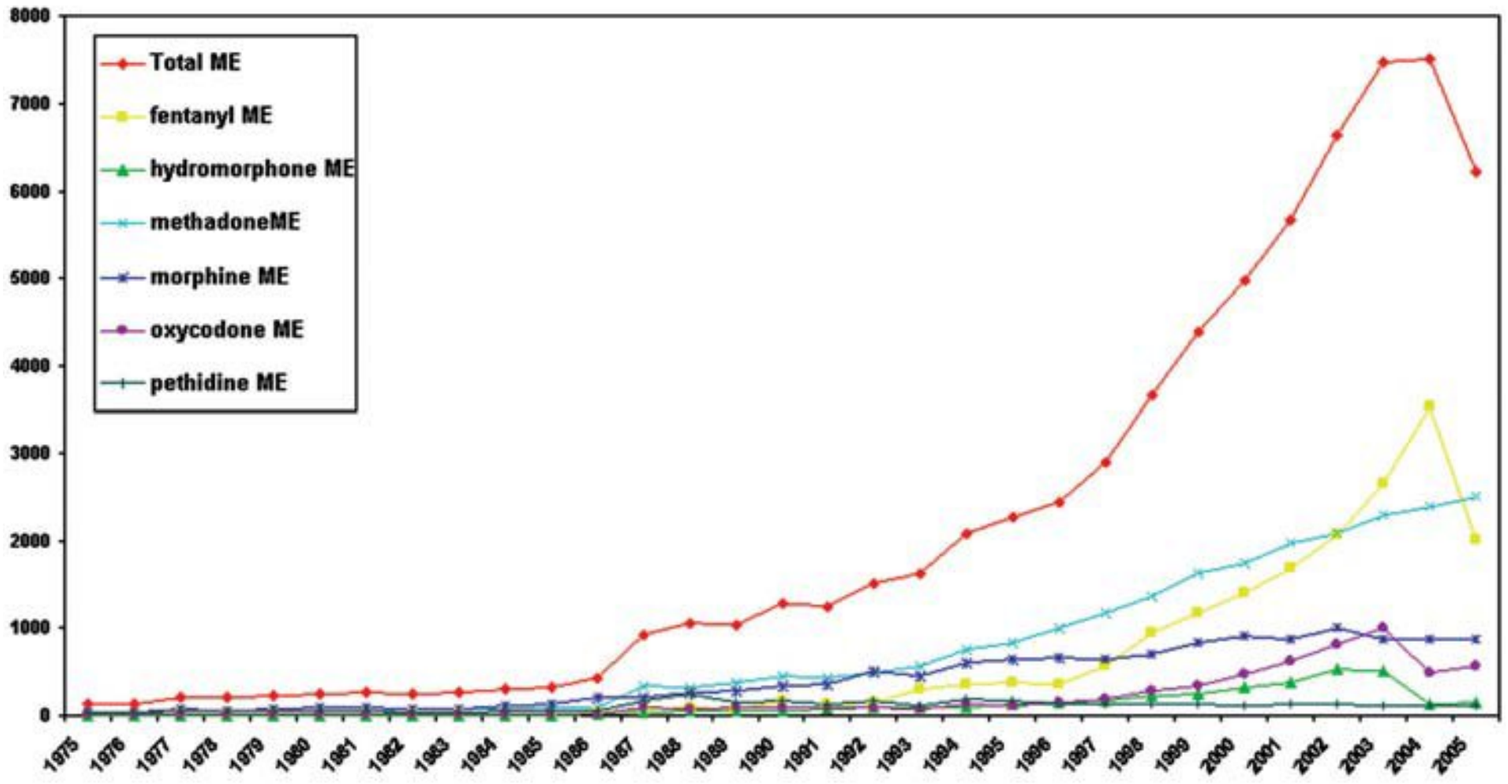

FIGURE 16.2 Global opioid consumption, ME by drug and total ME, mg/capita.

ment of pain[28] although it continues to be used. Programs that move away from pethidine should ensure that other suitable opioids are accessible; if pethidine is available, there should be no regulatory barrier to this transition, as pethidine and other opioids such as morphine are controlled in the same schedule and should be subject to the same international and national controls.

Disparities in Consumption Among High- and Low-Income Countries

At the national and regional level, there are great disparities in the amount of morphine consumed between high- and low-income countries. The INCB has consistently reported that a small number of high-income countries consume most of the morphine in the world, while the remaining countries, which have over 80% of the world's population, consume a small fraction.[47] Is this striking disparity unique to morphine consumption, or are there similar disparities for total ME?

Major disparities in ME are also evident when geographic regions are compared. Table 16.1 shows the milligram per capita total ME for six regions compared to the global total ME for 1975, 1986, and 2005. Global total ME increased fourfold between 1975 and 1986 and 14-fold from 1986 to 2005. Similarly, each of the regions experienced increases in total ME during the 30-year period; however, there were striking disparities between the regional total ME as a percentage of the global total ME. The total ME for Africa, a region with mostly low-income countries, was consistently the smallest percentage of total global ME and experienced a slight decrease between 1986 and 2005. The regional total ME for Asia, Central and South America, and the Middle East, also regions with predominantly low-income countries, were similar to Africa, representing relatively small percentages of the global total ME and experiencing decreases in the percentage of total global ME between 1986 and 2005. In contrast, Europe, a region with a number of high-income countries, had the largest percentage of total global ME throughout the 30-year period, with a substantial increase in the last 20 years. In 2005, these data showed that Europe and the four high-income countries of Australia, Canada, New Zealand, and the United States represented over 85% of the global total ME.

Country Comparisons

In some countries, morphine alone continues to be a valid indicator of total ME but not in others. Two European countries are compared: the Russian Federation and Belgium. In the Russian Federation, the low and relatively stable consumption of morphine ME has paralleled that of total ME. In Belgium, fentanyl ME has always accounted for the increasing trend in total ME. These differences are interesting and no doubt related to social, cultural, or economic differences between the countries.

Additional studies using the ME statistic are needed to further examine the role of opioid consumption as an indicator of treating pain over the past 20 years. What other events in the pain management/palliative care field may have influenced the changes in the consumption of strong opioids? What are the countries

TABLE 16.1

GLOBAL AND REGIONAL TRENDS IN TOTAL ME (MG/CAPITA)

Year	Africa Total ME	Middle East Total ME	Central and South America Total ME	Asia Total ME	Australia, Canada, New Zealand, U.S. Total ME	Europe Total ME	Global Total ME
1975	3.21 (2%)	7.66 (6%)	8.29 (6%)	10.08 (8%)	41.58 (34%)	53.10 (43%)	123.92
1986	8.99 (2%)	23.05 (5%)	72.63 (16%)	50.16 (12%)	99.6 (23%)	175.38 (41%)	430.93
2005	31.46 (1%)	141.717 (2%)	97.41 (2%)	212.95 (3%)	1551.66 (25%)	4189.31 (67%)	6218.61

Values in parentheses indicate the region's percentage of the global total ME for that year.
Percentages added across rows may not total 100% due to rounding.

for which morphine consumption alone was the most and least accurate, and what might this signify? What are the strong opioids that account for most of the global and regional increase in consumption? The ME statistic may be a useful tool to examine these types of questions at the global, regional, and national levels.

Finally, we identified an important contribution for fentanyl and methadone in the total ME increase over time. Future studies should correct for these medications' other clinical indications to focus solely on their use for pain relief, especially methadone's use for addiction treatment. This procedure will ultimately provide a much more precise measure of national opioid consumption for pain treatment.

BARRIERS: HEALTH PROFESSIONALS AND GOVERNMENTS

A number of factors, or barriers, contribute to inadequate availability of opioid analgesics[49]; their presence and severity vary from country to country. Weakness of health care infrastructure and problems in access to basic services is a typical constraint to obtaining pain relief and palliative care that is found especially, but not only, in developing countries, and in countries with remote areas and challenging geography. This chapter concentrates on the opioid-related barriers involving health professionals, government drug regulatory policies, and drug distribution systems.

Since national laws control drug availability and access, it is useful to know how government drug regulators perceive the issues relating to opioid availability. The INCB surveyed government drug control authorities about barriers in their countries; Table 16.2 lists these barriers.[5] Although the survey was conducted in 1995, the barriers are similar to those of today. Approximately 10 years later, Help the Hospices surveyed health care professionals and hospice or palliative care staff from Asia, Africa, and Latin America about barriers to accessing pain relieving medications and, in particular, oral morphine.[50] Sixty-nine surveys were returned, representing 31 countries and all 3 regions. The barriers to accessing oral morphine can be summarized by the following: (1) excessively strict national laws and regulations; (2) fear of addiction, tolerance, and side effects; (3) poorly developed health care systems and supply; and (4) lack of knowledge on the part of health care professionals, the public, and policy makers.

TABLE 16.2

BARRIERS IDENTIFIED BY 1995 INCB SURVEY

- Fear of addiction to opioids
- Lack of training of health care professionals about the use of opioids
- Laws or regulations that restrict the manufacturing, distribution, prescribing, or dispensing of opioids
- Reluctance to prescribe or stock opioids stemming from fear of legal consequences
- Overly burdensome administrative requirements related to opioids
- Insufficient amount of opioids imported or manufactured in the country
- Fear of diversion
- Cost of opioids
- Inadequate health care resources, such as facilities and health care professionals
- Lack of national policy or guidelines related to opioids

It is important to identify the barriers in a country, distinguish between them, and choose intervention strategies that can be effective. For example, it would be ineffective to use professional education to change strict prescription regulations; changing strict regulations could be part of an effort to alleviate physicians' fears of addiction and of being investigated, but would not do much to change the low priority of pain management or address reimbursement issues. A survey has been developed to gather information about barriers.[51] Once identified, for example, using a convenience survey of participants at a conference, barriers can be studied, prioritized, and categorized: (1) knowledge and attitudes about pain, opioids, and addiction; (2) opioid regulatory policy; (3) the drug distribution system; and (4) cost of opioid analgesics.

Knowledge and Attitudes About Pain, Opioids, and Addiction

Incorrect knowledge about pain, opioids, and addiction often underlies attitudes and can result in medical and institutional practices that block access to opioid analgesics. If professionals who are responsible for regulating drugs are misinformed about addiction, now referred to as *dependence syndrome* in the WHO International Classification of Diseases–10,[52] or have outdated attitudes about the benefits and risks of opioids, they may not be able to accept that there is an unmet need for opioid analgesics and be reluctant to examine regulatory policies for barriers.[1] The International Association for Pain and Chemical Dependency (IAPCD) provides an international forum for considering the relationship between pain and addiction.[53] IAPCD is an international organization with the objective of fostering communication and cooperation among professionals in health care, law enforcement, policy, and regulation in an effort to improve pain management for all patients, including those with a history of, or current, addictive disorders.

Inadequate Education of Health Professionals

The governments who responded to the 1995 INCB survey frequently identified insufficient education of health professionals as a barrier to opioid availability.[5] If health care professionals do not understand the importance of pain management, or how to assess and treat pain, they may be reluctant to care for pain patients or lack the confidence to prescribe medications like morphine. Indeed, given the major advances in knowledge about pain, opioids, and addiction, it is likely that what health professionals and the public learned 20 years ago is inaccurate by today's standards.

Exaggerated Fears of Opioid Dependence Syndrome

The barrier identified most frequently by government narcotic regulators in the 1995 INCB survey was concern about addiction to opioids.[5] Overstated concerns about the risk of dependence syndrome and side effects preventing adequate treatment of pain or regulatory reform is a phenomenon that has been called "opiophobia."[54,55] Early definitions of dependence syndrome were developed by experts in addiction before opioid pain management became a priority. These experts believed that mere exposure to morphine produced dependence syndrome,[56] and that physical dependence, expected in extended use of opioids, was the principal characteristic of dependence syndrome and therefore to be prevented.[52] New knowledge about pain and dependence syndrome has led to official recognition that diagnosis of drug dependence depends on the principal characteristics of compulsive behavior and continued use despite harm, whether or not physical dependence or tolerance is present.[57] Despite evidence that addiction or dependence syndrome—when defined and applied correctly—is not inevitable or even common when opioids are used

to relieve pain in patients without a history of substance abuse, fears of addiction continue to impact the treatment decisions of health care professionals resulting in suboptimal pain relief.[58] There is no question that some individuals are susceptible to addiction/dependence syndrome, so a competent assessment of the patient including substance abuse history is indicated, as well as monitoring for warning signs.

Misunderstanding of Side Effects

Patients and families sometimes fear that using opioids to manage pain will result in side effects that cannot be managed.[58] Several side effects are associated with the medical use of opioids, including constipation, fatigue, nausea, vomiting, itching, drowsiness, confusion, and sedation.[13] Health care professionals and patients should realize that side effects are predictable and should be anticipated and treated.[59] Most patients will experience a reduction in many of the side effects, such as sedation and nausea, within the first week of opioid therapy. Constipation does not diminish so clinicians should always advise patients to begin a bowel regimen with opioid therapy.[59] When side effects persist despite treatment, adjustment of the dose and trials of other opioids are indicated.

Fear That Opioids Will Hasten Death

Some fear that the use of opioids for pain at the end of life in terminally ill patients will hasten death owing to the side effect of respiratory depression. This has been shown to be more a myth than reality.[60] Respiratory depression can be a concern when opioids are administered by poorly trained physicians, when the patient has not used opioids previously and the starting dose is too high, when the dose exceeds what is necessary to relieve a patient's pain, when the dose is increased too rapidly, or when the patient does not adhere to the directions for use. However, studies have found that incremental dose increases to relieve pain are safe when pain is severe.[61] If respiratory depression occurs during treatment, it can be reversed by the administration of an opioid antagonist medication such as naloxone, which should be available. Rather than shortening patient survival, some studies suggest that adequate relief from pain can improve quality of life and possibly survival.[61,62]

Health Care Professionals Fear Legal Sanction

The INCB survey showed that governments realize that health care professionals fear legal sanctions. This is a significant barrier leading to reluctance to prescribe opioid analgesics. The WHO has also recognized that health care professionals may be reluctant to prescribe or stock opioid medications if they make a mistake or perceive a risk of losing their professional license, or even criminal prosecution based on misunderstanding of pain, opioids, and addiction.[13] Consequently, it is important that the WHO[13,63] and the INCB[5] have recognized that overly restrictive laws and regulations impede adequate opioid availability in some countries.

Government Regulatory Policy

Clearly, governments' main responsibility is to protect public health and safety; so it is reasonable and necessary for governments to take steps to prevent harm caused by diversion of opioid analgesics to nonmedical uses. But the relevant policies and activities should not interfere in medical practice and patient care. The Single Convention establishes a number of basic requirements for national laws and regulations to establish a "closed" distribution system to prevent diversion:

- everyone involved in the industrial production and medical distribution of narcotic drugs must be authorized to do so by the government;
- medical prescriptions, the format to be decided by governments, must be used to provide opioids to legitimate patients, and only for medical purposes;
- "counterfoil" prescription forms with several copies may be used but they are not required; and
- security, record keeping, and reporting requirements must be observed.[39]

A lack of understanding about how international law intends there to be a balance between controlling diversion and drug availability can lead to overly restrictive regulation of opioid medications. Pain and palliative care advocates should also avoid making opioids available *without* a control system; this would also be unbalanced and could lead to public health and safety consequences.

It should be noted that the systems established by governments to regulate prescription and distribution of opioids were designed before the value of the oral use of opioid drugs for cancer pain management was recognized. These systems were developed to prevent the diversion and abuse of opioids and not to prevent the use of opioids for pain relief.[1]

It is clear that some countries have gone beyond the minimum control measures required by the Single Convention and have established very stringent controls, especially in relation to drug prescription and distribution.[1] The INCB has recognized that some legislators and administrators have overreacted to drug abuse and have enacted laws, regulations, and administrative policies that impede the availability of opiates for medical purposes.[3] These include complex prescription forms and prescription books that must be obtained from the government with considerable difficulty, restrictions that limit the diagnoses of eligible patients, limitations on prescription amount to a few days, limitations on daily dose, and elaborate licensing requirements for palliative care programs. In countries with states, as in India and the U.S., some states have enacted restrictive laws and regulations that interfere with opioid distribution and patient access to opioid pain medications.[64,65]

The Single Convention clearly recognizes that governments have the right to regulate narcotic drugs more strictly than required by the Single Convention. The 34th WHO Expert Committee on Drug Dependence (ECDD) discussed the impact of unduly strict national laws on the medical availability of controlled medications, acknowledging there are countries where stricter measures are applied than are required by the Conventions. While recognizing that this is permissible, the ECDD said that governments should bear in mind that the aims of the Single Convention are to ensure availability for medical use as well as to prevent abuse. The ECDD called on national authorities to carefully consider whether ". . . .any such measure currently in force could be modified to permit access for patients in need."[66]

Drug Distribution Systems

In any country, opioid medications must first be approved and then procured by importation or domestic manufacture from narcotic raw materials or drugs seized by law enforcement. A system of government-regulated distributors then distributes to the retail level of pharmacies, hospitals, clinics, nursing homes, hospices, and palliative care programs, where registered health care professionals prescribe and dispense them to patients. The entire system of medication acquisition and disbursement is referred to as the drug distribution system. Figure 16.3 illustrates the key components of a drug distribution system and Table 16.3 presents examples of drug distribution system barriers.

Cost of Opioid Analgesics

The cost of opioid analgesic products has been identified by international organizations and researchers as a barrier to opioid availability and access.[67–69] Comparative studies have reported

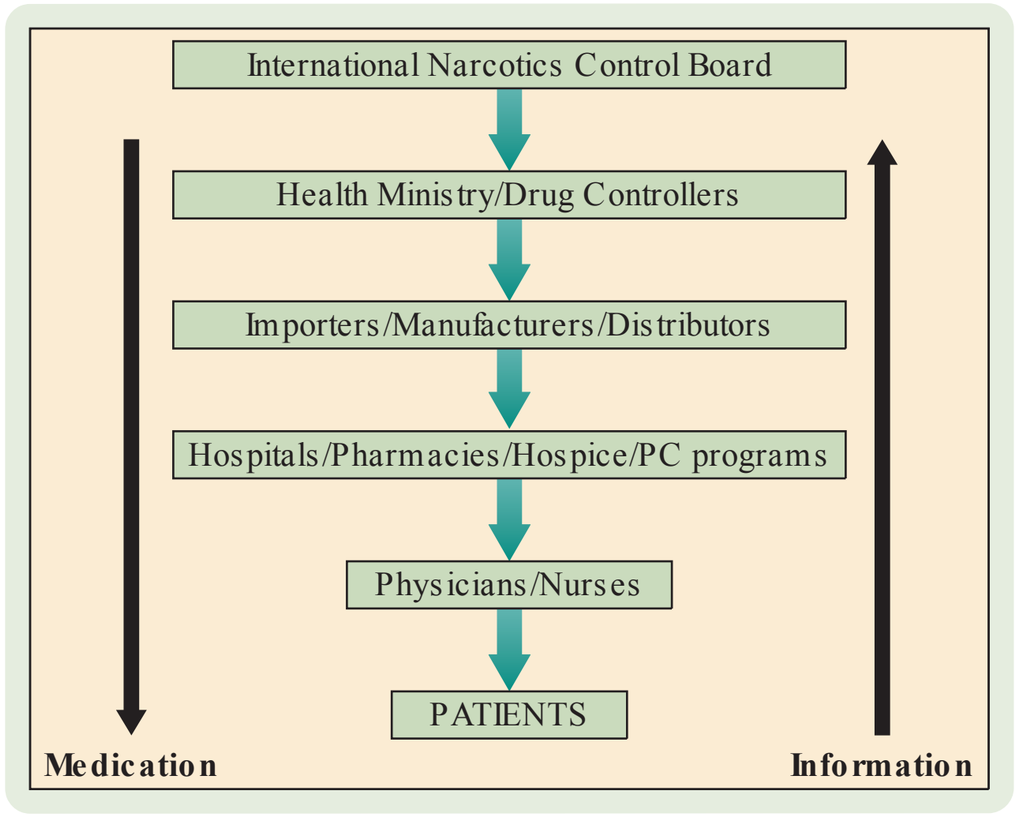

FIGURE 16.3 Drug distribution system.

wide variability in the cost of opioids analgesics throughout the world. One study of developed and developing countries found the cost of opioids relative to income was significantly higher in developing countries than in developed countries.[69] Another comparative study of codeine, fentanyl, morphine, and tramadol in nine developed Western European countries found great variability in the cost of opioids. The wholesale price of morphine was consistently the lowest of all the opioids in each of nine countries over the 3-year study period.[69] A recent survey of cancer pain treatment in Latin American countries revealed that a patient's inability to pay for opioid medications was one of the central reasons they are not prescribed.[68]

UNITED NATIONS' RECOMMENDATIONS

Although there have been efforts to inform health professionals and their organizations about the need to work with government,[50,70] this subject is not well understood among most health care professionals and their organizations because it is not ordinarily included in medical education. A brief historical review of the recommendations of UN bodies shows they have made a number of useful observations and recommendations to governments and health professionals, including that they should cooperate with each other to ensure adequate availability of opioids for medical purposes including pain relief throughout the world. Indeed, representatives of national governments, acting through their membership in UN bodies such as the Economic and Social Council and its Commission on Narcotic Drugs, and the World Health Assembly, have for a number of years requested governments to evaluate their national drug control policies for impediments and to improve the availability of opioid analgesics for medical purposes.

Beginning in 1989, a consultation between the INCB and the WHO Cancer Unit, then led by Dr. Jan Stjernsward, produced an authoritative recognition of the opioid availability problem and a strong recommendation that governments should act to evaluate their national laws. The INCB requested governments throughout the world to "examine the extent to which their health-care systems and laws and regulations permit the use of opiates for medical purposes, identify possible impediments to such use and develop plans of action to facilitate the supply and availability of opiates for all appropriate indications."[3]

In 1990, the WHO Expert Committee on Cancer Pain Relief and Active Supportive Care made a recommendation similar to that of the INCB, requesting that national governments should conduct a "regular review [of legislation], with the aim of permitting importation, manufacture, prescribing, stocking, dispensing and administration of opioids for medical reasons, . . . [and] review of the controls governing opioid use, with a view to simplification, so that drugs are available in the necessary quantities for legitimate use."[4]

In 1995, the INCB returned to the subject of opioid availability for pain relief and conducted a survey to determine whether governments had responded to its 1989 recommendations. The responses of the 65 responding governments were analyzed and published along with several pointed conclusions and recommendations including that "governments that have not done so should determine whether there are undue restrictions in national narcotics laws, regulations or administrative policies that impede prescribing, dispensing or needed treatment of patients with narcotic drugs, or their availability and distribution for such purposes, and should make the necessary adjustments."[5] The INCB outlined its expectations for governments under the Single Convention: "A national drug control programme should have legislative authority reflecting the provisions of the 1961 Convention, delegation of responsibility for implementation, including administrative responsibility for managing import and export licenses, estimating medical requirements, reporting required statistics and supervising adequate controls over distribution. Controls over the professionals and medical facilities that distribute narcotic drugs should ensure accountability and prevent diversion while making narcotic drugs available to the patients who need them. Controls should not be such that for all practical purposes they eliminate the availability of narcotic drugs for medical purposes."[5]

The INCB called specific attention to the role of health professionals, recommending that their organizations, including the International Association for the Study of Pain (IASP), teach students and practitioners about the medical use of opioids, their adequate control, and the correct use of terms related to dependence.[5] The INCB further recommended that IASP and other nongovernment organizations establish ongoing communication about national requirements, unmet medical needs, and impediments to availability with the CNAs in their countries. Such recommendations are consistent with the ethical responsibilities of physicians to comply with all laws and regulations but also to work toward changing them if they interfere in the practice of medicine and patient care.[38]

The INCB requested and received a number of comments from

TABLE 16.3

EXAMPLES OF DRUG DISTRIBUTION SYSTEM BARRIERS

- Government has not made procurement arrangements for the importation or domestic manufacture of needed opioids.
- There are delays in government decision making about procurement.
- Government's official estimate of type and quantity of opioids required is insufficient.
- The government's method for estimating opioid requirements does not take into consideration the actual needs.
- Manufacturers and distributors do not distribute opioids in a timely way.
- The number of health professionals, pharmacies, and patient care facilities authorized to procure and dispense opioids to patients who need them is insufficient.
- Governments do not have the systems in place to guarantee a safe and effective transfer of medications from wholesalers to retailers.

national chapters of the IASP including from Canada, Chile, Colombia, Hungary, Japan, Kenya, Malaysia, New Zealand, the Philippines, Republic of Korea, Russian Federation, Singapore, Slovakia, the United Kingdom, and the U.S. Summaries of these comments were included in the INCB's report (see http://www.incb.org/pdf/e/ar/1995/suppl1en.pdf)

One INCB recommendation in particular was to the WHO to develop "methods that can be used by government and non-government organizations to identify impediments to the appropriate medical availability of narcotic drugs."[5] Subsequently, the WHO revised its seminal publication *Cancer Pain Relief*[1] to include a Guide to Opioid Availabilty[13] and designated the Pain and Policy Studies Group (PPSG) at the University of Wisconsin to be a WHO Collaborating Center (WHOCC), with terms of reference to develop methods to improve opioid availability. The PPSG/WHOCC drafted international guidelines for evaluating national opioids control policy. In 2000, the WHO and the INCB approved them, emphasizing that governments should use the guidelines to examine their laws and regulations and health care systems to identify impediments and to ensure that opioid medications are always available to patients when they are needed.[73] The WHO also proposed that governments encourage health care workers to report to the appropriate authorities any instance in which oral opioids are not available for cancer patients.[1]

In 2005, the UN Economic and Social Council adopted a resolution about the treatment of pain using opioids,[6] found online at http://www.un.org/docs/ecosoc/documents/2005/resolutions/Resolution%202005-25.pdf. It recognizes that medical use of narcotic drugs is indispensable for the relief of pain and suffering, that low national consumption of opioids is a matter of great concern, and that opioids such as morphine should be available at all times in adequate amounts and appropriate dosage forms to relieve severe pain. A resolution by the World Health Assembly[7] in the same year called for the development of a funding mechanism to facilitate the actions necessary to improve the availability of opioids for the treatment of pain.[72] See online at http://www.who.int/gb/ebwha/pdf_files/WHA58-REC1/english/A58_2005_REC1-en.pdf and http://www.who.int/medicines/areas/quality_safety/Framework_ACMP_withcover.pdf

Taken together, these findings and resolutions form an unmistakable and uncontroversial imperative from the highest level of international and national government health and regulatory authorities in the world that governments and health professionals should work together to identify and remove impediments to the adequate availability of opioids for medical purposes.

METHODS AND EXAMPLES

There are several approaches to consider when implementing the United Nations' recommendations to review drug control policies and address identified barriers to opioid availability. The following section outlines approaches, methods, tools, and resources that national governments or palliative care advocates can use to develop and implement a national project to improve opioid availability.

The specific activities and the order in which they are carried out may not be the same in every country because of differing national situations. We discuss a general approach for a national project, but the activities outlined should be considered flexible and be adapted to a country's situation. Some of the activities may already have occurred, or may need to be repeated to garner broader support and new steps or stakeholders may emerge as the project develops. A national project usually begins as a result of leadership of one or more professionals in pain management, palliative care, or drug regulation.

We present public health and policy data relating to hospice and palliative care services. This is complemented by material drawn from the social and cultural analysis of end of life issues, including ethnographic, historical and ethical perspectives. You will find data here for over 61 countries in Eastern Europe, Central Asia, Africa, South America and the Middle East in ways which facilitate cross-national and regional comparison and analysis." eolc-observatory.net/global_analysis/index.htm

Assessing the Country Opioid Availability Situation

An important initial step when beginning an effort to improve opioid availability is to collect and review available information about a country's pain and palliative care situation, such as how much opioid medication is currently being used, and if there are activities underway to improve opioid availability. There are a number of resources that can provide this type of information, such as the Country Profiles on the PPSG/WHOCC website, which will be discussed in greater depth in the next section. Sometimes a more formal needs assessment has been accomplished,[72] however, it is very important to assess those factors that relate directly to the unmet needs for opioid analgesics and how they are controlled and distributed. Table 16.4 offers suggestions for identifying the extent and nature of existing efforts by regional or national organizations toward improving palliative care or opioid availability in a particular country. With increasing interest in opioid availability in many parts of the world, it is important for the planners to identify those who are interested or already involved in order to exchange information and coordinate activities.

Identification of Barriers to Opioid Availability

After an assessment of the situation and stakeholders in a country, the next step in the process may be to identify the regulatory barriers to adequate opioid availability. The WHO Achieving Balance Guidelines is the central resource; it offers a framework for understanding and specific criteria for assessing regulatory barriers. The criteria are recommended by international authorities.[74] The Guidelines were approved by a group of international experts in pain management and drug regulation and were reviewed and endorsed by the INCB, so they constitute the highest level of international health and drug regulatory consensus.

The WHO Guidelines are based on the principle of "Balance" which is derived from the Single Convention. This principle asserts that governments' obligation to control narcotic drugs is not only to prevent drug abuse, but also to ensure the availability of opioid analgesics for medical purposes. Controls aimed at preventing drug abuse and diversion must not interfere with the adequate availability of opioid analgesics for patients' pain relief; drug abuse controls that interfere in opioid availability and patient access to effective pain care would be considered out of balance and should be identified and corrected.

Sixteen guidelines are recommended for use in assessing the adequacy of national drug control policy and administration, and encourage governments and health care professionals to cooperate in a study process using the guidelines. Each guideline or criteria is explained and documented; the guidelines should be used to evaluate the adequacy of: (1) policy language in laws and regulations, (2) administration of the estimates and statistics system, and (3) the functioning of the system that distributes opioid pain medications.

The Guidelines contain a Self Assessment Checklist (SAC) that can be used to familiarize the planners with the nature of the evaluation criteria, to guide an assessment activity within a group of interested parties, and to summarize findings.[74] Once barriers are identified, additional information and review may be necessary to refine the analysis so that it is specific enough to discuss with regulators and to guide strategic planning of interventions.

Other methods to identify barriers may be used as well, such as interviews with key informants or focus groups with those who are familiar with patient care, unmet needs, and the national regulatory framework (e.g., clinicians, pharmacists, and regulators).[45]

Mechanisms of Change

Making change in national policy usually requires a government mechanism to allow the needs and action plans to be discussed and agreed upon. A direct dialogue between health professionals and government regulators can result in modifications to regulatory policy. Sometimes a more formal mechanism such as a task force or commission is needed to convene the stakeholders and guide a strategic planning process. A task force or commission appointed by the government can be a powerful mechanism, since government willingness to examine policy is a necessary component of changing government policy. Less formal methods such as a committee or task force of a nongovernment organization may be a good place to begin to study the problem, review relevant literature, raise awareness, and formulate a preliminary analysis. In any case, thoughtful fair leadership is always needed from one or more individuals who have the time, energy, credibility, communication ability, and willingness to listen and guide a process. The relevant body should prepare a report of its deliberations, including information about the needs, barriers, results of the policy evaluation, and recommended changes. The recommendations do not need to be limited to government regulations, and may include other aspects of national policy and program that are relevant to meeting the needs of people with cancer and HIV/AIDS. Needs assessments, such as the WHO Achieving Balance Guidelines, can provide a structure for the deliberations. The report should reflect a consensus so that points of disagreement, which could block later progress, are resolved early in the process. The following examples illustrate successful mechanisms that guided the policy change process in Italy and Uganda.

Italian Ministerial Workgroup

In 1998, health care organizations publicly requested the Italian Ministry of Health and other nongovernment organizations to address barriers to opioid availability by amending the opioid prescribing laws.[75] The Drug Department of the Ministry of Health responded by appointing a multidisciplinary workgroup of physicians, pharmacists, and representatives of the Ministry of Health who had experience in cancer, pain management, palliative care, opioid legislation, and pharmacology. The objectives of the workgroup were: (1) to recommend changes to the Italian national opioid prescribing law, (2) to identify and make available the drugs necessary for pain relief, and (3) to develop educational information on cancer pain management to educate the public and health care professionals.[76] Leadership was provided by leading palliative care physicians who reached out to the PPSG/WHOCC for technical assistance.

Ugandan Ministry of Health Study Group

In 1998, the Ugandan Ministry of Health invited staff from Hospice Africa Uganda, a nongovernment organization that had pioneered community-based palliative care in rural and urban Uganda, to be technical experts in a pilot study looking at the viability and safety of using morphine to treat chronic pain at the community level.[77] The study involved semi-structured interviews with key informants, direct observation of morphine distribution throughout the country, and audits of clinical care quality. The Ministry's leadership and involvement with the study enhanced the government's awareness of the need to make policy change.

The Strategic Plan

Developing a strategic plan to address barriers to opioid availability is a critical phase in a national project. The strategic planning process typically begins after the leaders have reviewed the literature, and used the BOAT and the SAC and/or other techniques to identify barriers.

In an effort to make a strategic plan realistic and achievable, the plan should focus on three to five of the most important opioid availability/access problems in a country which, if successfully addressed, would contribute to significant immediate and sustained improvements in patient access to pain medications. A strategic planning process requires some preparation, and can take place during a national event such as a workshop or commission, or in a regional workshop where country teams meet separately to develop and then share their strategic plans for comment.

Regional Workshops

Several workshops to improve opioid availability have been organized cooperatively between the WHO, PPSG/WHOCC, and national and/or regional nongovernment organizations that have an interest in relieving pain due to cancer and HIV/AIDS.[20,78–84] These 3-day regional workshops involved carefully selected teams of health care and regulatory professionals, including a representative of the CNA, from five or six countries in the same region. Drawing together countries in a particular region allows for participants to learn together about the methods to improve opioid availability, as well as common challenges and opportunities among the participating countries. These workshops culminate in a strategic planning process and specific action plans, and sometimes result in country teams working to implement a national project to address barriers to opioid availability. Leadership, availability of resources, and technical cooperation are critically important to successful follow-up implementation of strategic plans.

National or State Workshops

A national or state workshop involving the stakeholders (e.g., regulators, expert health care practitioners, and patient care pro-

grams) can be a useful mechanism to initiate or continue the dialogue that is needed to improve opioid availability for medical needs. A workshop can be an opportunity to increase awareness by reviewing relevant literature, exchanging information among the stakeholders about pain management, palliative care, laws and regulations, and need for opioids leading to a report. Workshop participants can develop an action plan to submit to the government for its approval and action. The following example highlights a recent national workshop in Colombia.

Colombia

The CNA in Colombia is the Fondo Nacional de Estupefacientes (FNE) of the Ministry of Health. In cooperation with the PPSG/WHOCC and the WHO, the Fondo convened a national workshop of drug regulators and palliative care physicians in November 2007 to examine the procurement and distribution systems for opioid analgesics throughout the country. The goal was to improve these systems so that patients have better access to these essential pain medications from a well-functioning distribution system. The workshop, hosted by the Universidad de la Sabana, included representatives from the Ministry of Health (MOH), the WHO, the Pan American Health Organization (PAHO), the PPSG/WHOCC, the Colombian National Cancer Institute (INC), the International Association for Hospice and Palliative Care (IAHPC), the Colombian Chapter of the International Association for the Study of Pain (ACED), and the Colombian Association for Palliative Care. This workshop yielded excellent communication between health care practitioners and regulators from the 32 states in 6 national regions. Six regional break-out sessions were used to identify problems and obstacles as well as solutions. The six groups reported on their findings in a plenary session, where a strategy session was held to discuss possible solutions and to decide on recommendations to be presented to the FNE.

Implementation of Policy Changes

Improving national policy by itself is not sufficient to improve opioid availability and patient access. It is critically important to work with relevant government and nongovernment organizations to implement policy changes: this may include communication of policy changes to the public via the media (e.g., newspaper articles, radio announcements); for example, education of health care professionals, drug regulators, and law enforcement, including how the policy changes will impact their professional responsibilities. The following example from Kerala, India, illustrates the importance of translating policy changes into practice to positively affect patient care.

Kerala, India

In 1999, a task force appointed by the Kerala Health Secretary was successful in simplifying the state morphine rules, and a national policy was changed which exempted palliative care programs from the requirement to have a ‘‘drug license’’ to dispense morphine (which requires employing a pharmacist, a substantial cost to the program).[64] The policy improvements enhanced the efforts of the Pain and Palliative Care Society, a nongovernment organization based in Kerala, to expand greatly the number of palliative care clinics throughout the state to reach patients in rural and remote areas. The number of palliative care clinics in Kerala increased from 21 in 2000 to 68 in 2006.[85]

Case Example–Romania

The following example summarizes a recent national policy project to improve opioid availability and accessibility in Romania. This example highlights a series of activities and tools that were used by the Romanian leaders to achieve policy change and embark on implementation.

Regional Workshop

In 2002, the PPSG/WHOCC, the WHO European regional office (EURO), and the Open Society Institute (OSI) sponsored a 3-day regional workshop in Budapest, Hungary,[45] entitled *Assuring Availability of Opioid Analgesics for Palliative Care*. The workshop was attended by teams of health are professionals and drug regulators from six Eastern European countries: Bulgaria, Croatia, Hungary, Lithuania, Poland, and Romania.

Strategic Planning

During the workshop, the six country teams used the WHO Guideline’s SAC to identify barriers to opioid availability and develop an action plan for addressing those barriers. The team of Romanian health care professionals and drug regulators identified lack of morphine in most hospital pharmacies, severe restrictions on the out-patient use of opioids, and a complex regulatory system for prescribing opioids.[45]

Readiness for Policy Change

The workshop organizers had limited resources for follow-up and decided to choose one country on which to concentrate. Romania was identified as the country with the most potential for making policy changes because (1) it had many regulatory barriers that restricted patient access to opioids, (2) it had palliative care leaders who were highly motivated to work on making changes, and (3) the Ministry of Health, where the Competent Authority was located, was willing to establish a palliative care commission to evaluate national drug control policy and provide recommendations for change.[45]

Establishing a Mechanism: A Ministry of Health Commission

A Commission was a critical factor contributing to the successful policy change process in Romania. Following the regional workshop in 2002, the Romanian Ministry of Health appointed a Commission of Pain and Palliative Care specialists to study the narcotics control policies using the WHO Guidelines. The Commission requested assistance from the PPSG who assisted with the review and analysis of policies. A report of recommended policy changes was prepared and presented to the Minister of Health. This report became the basis for the changes in law and regulations that followed.[45]

Policy Change

The Minister of Health directed the Pharmaceutical Department to draft new legislation removing barriers that had been identified according to the Commission’s recommendations. The proposed law was adopted by the Romanian Parliament in 2005. A team from the Ministry of Health CNA and the Commission came to the University of Wisconsin in 2004 to concentrate on drafting a regulation to implement the new law. The regulations, from which remaining barriers were removed, were approved in 2006 and became effective in 2007.[86]

Implementing Policy Changes

A process to implement the new law and regulations began with a meeting in Bucharest in 2006. All the major stakeholders, including representatives of palliative care, cancer, HIV/AIDS, the CNA, medical education, and the anti-drug law enforcement agency convened for a day to discuss how the new law and regulations would be successfully implemented. The meeting, titled ‘‘Implementing a modern and balanced opioid legislation in Ro-

mania,'' was attended by approximately 40 people, including the Vice Chair of the Parliament Commission for Health. The meeting provided an opportunity to educate all parties about opioids for treating pain under the new law and regulations. It was also an opportunity to clarify any questions and to clear any doubts so there would be a consensus.

Educational Program

The Palliative Care Commission also recognized that it was necessary to develop a national education program and a curriculum to re-educate health care practitioners about how to prescribe opioid analgesics under the new regulations so as to improve pain management. A new Curriculum Planning Committee, including experts in palliative care and pharmacy from the University of Wisconsin, was developed to prepare a training of trainers program to reach physicians and pharmacists throughout the country. It consists of 20 hours of classroom teaching on two consecutive weekends and 6 hours of clinical practice in each participant's own setting. The courses include interactive case studies, are recognized by the Ministry of Health, and are nationally accredited for continuing medical education by the College of Physicians and Pharmacists.[86] In the first year, approximately 2,200 physicians were trained (D. Mosoiu, personal communication, October 30, 2007).

NEW RESOURCES FOR NATIONAL POLICY PROJECTS

Several new resources are being developed to support policy reform activities and to accelerate the rate of change in the world.[87]

International Pain Policy Fellowship

The PPSG/WHOCC has learned that making policy and systems change in a country is more likely to be successful if three criteria are met:

1. A demonstrated unmet need for opioid analgesics for pain management due to regulatory barriers.
2. A committed pain or palliative care ''champion'' to work with the PPSG and also the government.
3. A demonstrated government commitment to address regulatory barriers.

In order to expand leadership for change in more countries, the PPSG/WHOCC developed an International Pain Policy Fellowship (IPPF), supported by a grant from the Open Society Institute's International Palliative Care Initiative. The IPPF seeks to provide candidates with the knowledge and skills necessary to develop and implement a project to improve the availability of pain medications for pain relief and palliative care in their respective countries. The 2-year Fellowship is intended for health professionals (for example pharmacists, oncologists, AIDS clinicians, pain and palliative care physicians), health care administrators, policy experts, or lawyers from low- or middle-income countries who have an interest in drug policy advocacy to improve availability of opioid analgesics for pain relief and palliative care.

The Fellowship consists of (1) education regarding the role of international drug control treaties, governments, health care professionals, and opioid analgesics in the treatment of pain; (2) a 1-week training session at the University of Wisconsin Paul P. Carbone Comprehensive Cancer Center in Madison, Wisconsin; and (3) follow-up technical assistance to the Fellows for the duration of the 2-year Fellowship. The training curriculum covers the relationships between disease, pain, palliative care, inadequate opioid availability; examines the international legal framework for drug control, national government responsibilities to ensure drug availability, and examples of regulatory barriers; and provides resources for evaluating national policy as well as examples of their use. This specialized curriculum, based in large part on the WHO Guidelines, ''Achieving Balance in National Opioids Control Policy,'' addresses the dual, often competing, characteristics of opioid analgesics: their necessity for pain relief but also their potential for abuse.

The application process is competitive, based on demonstrated national leadership to develop pain management and/or palliative care; the strength of commitment to improving opioid availability in their country; position in national cancer, AIDS, pain, or palliative care association(s); and potential ability to develop a working relationship with government officials. Those selected as finalists are invited to a telephone interview for more in-depth discussions and examination of the potential for a successful Fellowship.

The inaugural IPPF was held in October 2006 with eight Fellows from Argentina, Colombia, Nigeria, Panama, Serbia, Sierra Leone, Uganda, and Vietnam. Additional funding provided by the United States Cancer Pain Relief Committee allowed seven members of an International Expert Collaboration in palliative care and opioid availability to attend the training session to assist PPSG/WHOCC staff to present the curriculum, guide the discussions, assist with country Action Planning, and follow up. These global experts have maintained follow-up communication and mentoring, in conjunction with PPSG/WHOCC staff, during the remainder of the 2-year Fellowship.

At the end of the week, the Fellows prepared detailed national Action Plans that will guide their activities to improve patient access to opioid analgesics for the next 2 years, in collaboration with the PPSG/WHOCC.

In September 2007, the *New York Times* published a series about the global undertreatment of pain including in India[87] and Sierra Leone.[89] One article highlighted the situation in Sierra Leone, including the work of the International Pain Policy Fellow, who is the founder and Executive Director of Shepherd's Hospice in Freetown. He is implementing his action plan to improve patient access to pain medication. Working with the government, he is making progress to import oral morphine at the hospice to provide patients with appropriate pain management, he has trained his staff on the appropriate uses and handling of morphine, and he is taking part in a national Palliative Care Task Force.

These Action Plans are ambitious, each addressing unique and dynamic national environments characterized by political changes (such as national elections) and other unforeseen factors that impact national health care priorities. Consequently, the PPSG/WHOCC obtained funding from the Lance Armstrong Foundation to reconvene the 2006 class of fellows to discuss progress and challenges as they work toward the objectives outlined in their national Action Plan. The 3-day meeting allowed for (1) an update and discussion with each country on progress and barriers in the past 12 months; (2) break-out into small groups to revise the Action Plan, if necessary; (3) a report from each Fellow on their Action Plan revisions for the remainder of their Fellowship; and (4) preliminary exploration of the meaning of cancer survivorship in developing countries. This type of meeting can capitalize on the inevitable changes in national landscape that will occur during a 2-year period by providing a real-time forum to review and respond to both their achievements and challenges, and to utilize the collective experiences of the entire group that may allow Fellows to share methods for handling a particular obstacle that may be common among them.

IPPF Progress

Vietnam. On 27 March 2007, a national workshop, ''Workshop on Supply, Management and Use of Opioids in Palliative Care'' was held in Hanoi, Vietnam. The workshop, which included a broad range of stakeholders from throughout the country, was

successful in accomplishing the following stated objectives: (1) to enhance understanding of the Principle of Balance in national narcotics control policies and the WHO- and INCB-supported narcotics policies, and (2) to agree on the action plan for 2007–2008 to ensure the availability of opioids used in palliative care. Participants divided into small working groups to discuss the action plan and to assign tasks. A consensus was reached that revisions and enhancements should be made to the current regulation on the supply, management, production, and use of opioids in palliative care. The following day, the Ministry of Health formally approved the new Action Plan. The Ministry of Health will now develop new prescribing regulations for opioids to improve availability which include the following policies aimed at improving availability as well as control:

1. The prescription length for opioids for terminal cancer and AIDS patients will be increased from 7 to 30 days.
2. The maximum dose of opioid prescriptions which was 30 mg will be eliminated.
3. The requirement for physicians and pharmacies to maintain opioid prescription records will be reduced from 5 to 2 years.
4. Opioids will be available in all districts throughout the country. If a district has no pharmacy that stocks opioids, the pharmacy of the district hospital will be required to stock opioids.
5. The Drug Administration of Vietnam (DAV) within the MoH revised its regulations on Procurement, Purchase, Distribution, Storage & Dispensing of Narcotic and Psychotropic Drugs following WHO, INCB guidelines.
6. The DAV will regulate conditions for production, importation, exportation, storage, distribution, and retailing of opioids and psychotropic drugs.
7. Any pharmacy that meets the standards of ''Good Pharmacy Practice'' (GPP) and ''Good Store Practice'' (GSP) will be able to sell opioids and psychotropic drugs. (In the past, only very few pharmacies could do this.)
8. Requirements for reporting of controlled medication supply and distribution and of estimated need will be revised in line with a newly designed, decentralized supply chain.
9. Templates for reporting, estimation, and bookkeeping will be revised to be in line with the improved management system.

Planning is underway for the second class of International Pain Policy Fellows in 2008.

Internet Course

Another way to accelerate change is to make the body of knowledge and experience more easily accessible to an international audience. Funded by the National Hospice and Palliative Care Organization (NHPCO), the PPSG/WHOCC developed a Web-based course about national drug control policies' impact on access to opioid analgesics for pain relief that will be available free of charge in 2008. The aim of the course is for learners to understand the body of knowledge encompassing the evaluation and improvement of national policies that govern the medical availability of opioid analgesics for cancer and AIDS patients. The course is intended for an international audience of health care professionals, local and national policy advocates, government drug regulatory personnel, national health policy advisors, and medical scholars. The course is accessible via the PPSG/WHOCC Web site (http://www.painpolicy.wisc.edu/on-line_course/welcome.htm).

Essential Elements of National Drug Control Policy

A question often encountered during the course of the PPSG/WHOCC's policy evaluation work in a number of countries is whether there exists a balanced model law that could be adopted or adapted to simplify drafting of new legislation. Although several model laws have been produced by UN agencies, PPSG/WHOCC has found none that address adequately the obligation to ensure drug availability. Further, our experience shows there is great variability among national laws. Each country has its own cultural history and health care systems. Their laws are so unique that wholesale replacement with a one-size-fits-all is not likely to be accepted. Consequently, the PPSG/WHOCC developed, in consultation with the WHO, the UN Office of Drugs and Crime, and the INCB, a report about the ''essential elements'' of a modern national opioids control policy that will present reasonable expectations for national policies, based on the obligations that were established in the Single Convention and the subsequent official interpretations of the drug control conventions and expert guidance from international health and regulatory bodies. See report at http://www.painpolicy.wisc.edu/internat/model_law_eval.pdf.

PPSG/WHOCC Web Site Resources

Some important parts of the body of knowledge regarding opioid availability are not easily accessible. The PPSG/WHOCC has established an international section of its website (http://www.painpolicy.wisc.edu) to provide worldwide public access to key resources and information. The international section contains most of PPSG/WHOCC's international publications and links to other important articles about opioid availability; monographs that present the opioid consumption trends globally, regionally, and nationally; as well as links to other relevant resources and organizations pertinent to specific countries. The 2000 WHO guidelines, ''Achieving Balance in National Opioids Control Policy,'' in 23 languages, are readily accessible from the home page and from each country page.

Country Profiles

A new and useful place to begin learning about the status of opioid consumption in a country is the Country Profile on the PPSG website. These profiles include: (1) the country population and a map, (2) the country's status of adherence to the Single Convention and whether the country has reported consumption statistics and submitted estimates to the INCB, (3) the contact information for the Competent National Authority, (4) opioid consumption statistics, and (5) links to relevant national resources regarding pain, palliative care, and opioid availability.

CONCLUSION

Deepening disparities between high-, low-, and middle income countries in the extent of availability of opioid pain medicines means that pain and suffering in the world is an increasing public health problem. This is cause for alarm and should precipitate concerted action by health professionals, their organizations, and their governments. Actions should be guided by an understanding not only of the need for pain medicines, but also the barriers, the drug control policy framework, and how to work with government drug regulators.

However, health care professionals from any country are not likely to know about these topics because they have not generally been included in basic professional education or continuing education about pain and palliative care. The purpose of this chapter is to outline the body of knowledge, methods, and experience that is relevant to understanding and improving national opioid availability and patient access to pain medicines.

How can this information be applied? Pain and palliative care specialists often are involved in the planning and delivery of training and education for colleagues in other countries, where avail-

ability and access to opioid pain medicines is likely to be limited. Each of these occasions presents an opportunity, if not an ethical imperative, for the visiting professional to learn about the national opioid situation and to address availability and access issues knowledgeably and appropriately.

This approach might result in presentations that include a discussion of the pharmacology of analgesics with emphasis on the opioids that are necessary to relieve severe pain, discussion of the types of barriers that may interfere in pain relief, explanation of national governments' obligation to ensure *adequate* opioid availability and the role of the Competent National Authority, encouragement to address the barriers, and where to find resources that can be used to improve opioid availability and access.

Although the body of knowledge about the control and availability of opioid analgesics may not be well known, the process of working with individual countries to improve opioid availability borrows from a method with which health professionals are very familiar. The elements of the medical model can be applied to solving problems in opioid availability: evaluation, diagnosis, and a treatment plan. Indeed, health care professionals and governments in India, Romania, and Uganda have worked together to diagnose opioid availability barriers and implement action plans to remove the barriers. New efforts to diagnose and treat barriers are being led by International Pain Policy Fellows in other low- and middle income countries.

There are hopeful signs of progress in some countries, but it is not likely that this progress—which is still in an early developmental phase—is sufficient to gain on the deepening global disparities in access to pain relief medications. Greater leadership will be needed from international drug control bodies, national governments, and from individual health professionals and their organizations.

CHAPTER 17 ■ MEDICAL EVALUATION OF THE CHRONIC PAIN PATIENT

GORDON IRVING AND PAM SQUIRE

INTRODUCTION

Evaluation of a patient with acute pain is usually straightforward. A simple history of the presenting painful condition, physical evaluation, and appropriate investigation is standard and in most cases adequate. Persistent pain with a limited focus such as osteoarthritis of one or two joints without significant comorbidities can also be relatively straightforward and a limited pain assessment is appropriate. Chronic pain, however, is much more complex, with patients often developing anxiety and depression. They may also exhibit somatic preoccupation as well as a tendency to develop other life problems. The pathological cause of the pain (the pain generator) may be unknown (as in fibromyalgia). The intensity of the pain may seem to be out of proportion to any obvious pathology. Faced with a disease they do not understand and anxious about hurting themselves further, many patients will avoid activities that may exacerbate their pain, which eventually leads to feelings of unworthiness and poor self-esteem. Compounding these issues, the medications themselves may contribute to reduced functionality.

The effect of these complex interplays between pain and its comorbidities results in a life that spirals downward, often becoming pain-centered with life deterioration of such severity that many of these patients admit to suicidal ideation. Failure to identify and address all factors contributing to the patient's ''total pain'' will prevent the implementation of effective treatment strategies, often leading to mutual frustration between patient and physician. The objective of a pain assessment is to determine all of these relevant factors. The initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT)[1,2] were published primarily to improve and standardize methodology in clinical trials but can be modified for practicing clinicians.[3] This chapter utilizes some of the IMMPACT recommendations and suggests a format to document the evaluation in a way that facilitates both sharing and transfer of information between health care professionals. Time efficient, validated tools designed to expedite an assessment done in either a multidisciplinary clinic or by a solo practitioner assessment have been included. Sourcing information for these tools is available at the end of the chapter.

PROCESS OF ASSESSMENT

A multidisciplinary team best evaluates complex chronic pain patients. However, in today's health care environment, the time to evaluate complex pain patients is often limited and assessments are commonly completed by a solo practitioner. In this chapter, interview techniques to reduce this burden and patient completed questionnaires have been included or Internet referenced. Pain assessments using electronic questionnaires that integrate into existing electronic medical records (EMRs) are becoming more common. Any Web-based questionnaire should allow drop down boxes if an answer is positive, enabling greater detail to be asked. Ideally, it should also allow integration with the practitioner's EMR and the patient's own personal electronic health record if they have one. The use of Web-based or paper questionnaires should save the practitioner time and enable more focused questioning.

Initial and follow-up assessments will be handled differently, depending on whether the practitioner is a primary health care giver or a pain specialist.

A detailed examination of the patient presenting with specific pain syndromes (e.g., low back pain, headaches, complex regional pain syndromes) will not be addressed in this chapter. These are described in the chapters allotted to those problems. Details of the psychological and psychiatric assessments will also be covered in other chapters. In this chapter, the authors present a general guide to the clinician.

General Guidelines

Assessment and treatment of a patient with complex pain begins with the recognition that a complete pain cure is unlikely. The best results are achieved by utilizing approaches that involve both the available community resources as well as the patient taking more responsibility in their own therapy. Involvement by the patient in decision-making and goal setting is important. Improving the patient's physical and mental functioning is the goal.

Time Allotment

This depends on the type of practice. A pain specialist may allot 30 to 90 minutes to assess a new patient; the busy primary care practitioner may only have 15 to 20 minutes. The use of a physician extender (either a self-completed questionnaire or another person who can document this information for the physician) can speed up the encounter by having the patient's history available before the practitioner enters the examination room. Alternatively, the assessment can be divided and information can be completed over several different visits.

An initial comprehensive questionnaire can be sent to the patient prior to the consultation (see Appendix), or a Web-based one developed. Asking the patient to arrive 20 to 30 minutes early prior to the initial appointment enables relevant paperwork and insurance verification to take place, and gives time for the patient to complete questionnaires if not already done. A companion, preferably a significant other, should accompany the patient when possible for the initial evaluation and when optimizing or initiating new therapies. By having this individual sit at the patient's side, much information can be gathered about the couple's relationship by body language as well as by visual and verbal expression. The companion may also contradict or confirm whether a therapy is working, either verbally or by gesture.

Successful evaluation of a patient with complex pain by a clinician is facilitated by the development of a mutually trusting relationship. Patients should have the feeling that they have been listened to, their fears have been acknowledged, and that the practitioner is ''there for them.'' This latter statement does not imply the practitioner has to feel the suffering of the patient.

The practitioner should remain empathic, not sympathetic, to the patient's issues.

OUTLINE OF A MULTIDIMENSIONAL ASSESSMENT FOR PERSISTENT PAIN HISTORY

The following format for documentation of a multidimensional pain assessment is recommended for complex patients. It serves to ensure that all the various dimensions of pain have been assessed and serves, when dictated in this format, to facilitate communication with other treating clinicians.[4,5]

Pain History

- Details of pain history and associated symptoms
- Details of previous consults and investigations
- Previous treatments tried and details of the outcomes
- Current medications, including over-the-counter medications and other treatments.

History of Past Health Relevant to the Presenting Problem

- Those comorbidities that could influence the manifestation of the pain syndrome (dementia, diabetes)
- Those comorbidities that could influence treatment (renal failure, cardiovascular disease, sleep disturbance)

Psychiatric Comorbidity

- Anxiety, depression, bipolar disorder, posttraumatic stress disorder (PTSD), adult attention deficit hyperactivity disorder (ADHD)

Psychosocial Factors

- Individual personality features which impact pain (catastrophizing, health-related anxiety, pain-related fear and associated avoidance behaviors)
- Factors that may contribute to pain interruption of life (solicitous spouse, meaning of the pain)
- Other factors (specific family or cultural issues, employment history, litigation issues, financial situation, family and/or community support)
- Pain coping strategies
- Relevant family history, including sexual abuse and adverse childhood events

Risk of Addiction

- Screening—if opioids or cannabinoids are currently being used, requested, or will be considered; determine if the addiction risk is low, medium, or high[6]
- Smoking history[7,8]
- Previous drug and/or alcohol exposure and related outcomes (attendance at drug or alcohol detoxification or rehabilitation programs or legal or social problems)
- Family history of drug, alcohol, or psychological/psychiatric problems[9]

Assessment of Function

- To determine the impact of the pain on a person's life and provide a baseline for follow-up assessment
- It should cover all of the relevant areas and usually includes impact of pain on domains such as employment, social, recreational, family, or home responsibilities. It should assess self care, sleep, and ideally evaluate the overall quality of life

Goals

- Determine patient goals to direct treatment and evaluate effectiveness of therapeutic interventions

Physical Examination

- Mental status examination as appropriate
- General physical examination and, if appropriate, look for evidence of substance abuse/misuse and document its presence or absence
- Focused pain examination, paying attention to musculoskeletal and neurological examination
- Further investigations or consults as needed and consider:
  - urine drug testing
  - medication logs
  - diaries to assess pain, sleep, activity, or other relevant behaviors
  - informed consent documentation, opioid or behavioral contracts.

Follow-Up Visit

- To review goal achievement
- To review "homework" (pain diaries, medication logs)
- To interview a significant other
- Need to document (5As):
  - Analgesic response both to pain score and function
  - Activity response
  - Adverse events (to treatment)
  - Aberrant drug-related behavior if potentially addictive medications such as opioids and /or cannabinoids are prescribed
  - New Action plan of care

THE PAIN HISTORY

It is important to document medical etiologies of all contributing pain diagnoses. The pain may be categorized according to the taxonomy of the International Association for the Study of Pain (IASP).[10] The mechanism, if known, date of onset and overall severity, and factors that worsen or improve pain should be noted. Having a routine when evaluating a patient ensures capture of all the relevant data. It can be formally done during an interview by having the history form outlined with headings or captured by a questionnaire. For children or patients with cognitive impairment, a caregiver should be present to provide additional information.

The Short Form of the McGill Pain Questionnaire (SF-MPQ)[11] is a self-report measure of pain quality. The Brief Pain Inventory (BPI)[12] is another self-reporting tool that includes a pain diagram and several scales to assess pain severity and interference with function and is recommended by IMMPACT.

The acronym OPQRST has been suggested as a mnemonic for assessing each individual pain problem.

O = Onset
P = Provocative/Palliative
Q = Quality/Character (Does it have neuropathic features?)
R = Region/Radiation
S = Severity/Intensity
T = Timing of pain (Continuous or intermittent?)

O: Onset of Pain

How pain began is often informative.

In many cases the initial acute pain is well documented with an understandable etiology. In other cases, there does not appear to be an obvious organic cause. In these cases the physician has to be careful not to ascribe the pain to psychogenic causes but to accept the patient's description.[13]

P: Provocative/Palliative

Assessing what provokes or relieves the pain provides valuable clues to the diagnosis.

Leg and back pain due to spinal stenosis has a characteristic pattern of worsening with walking or standing, with the pain being totally relieved with sitting or lying. Neuropathic pain can present with spontaneous pain or pain provoked by different stimuli such as cold, light touch, or the brushing of sheets. It is usually improved with heat, often the opposite of inflammatory pain.

Q: Quality or Character

Neuropathic pain symptoms include numbness, tingling, pins and needles, electric shocks or shooting pain, and hot or burning pains. Questionnaires to identify neuropathic pain (and differentiate it from nociceptive pain) include the LAANS scale,[14,15] The Neuropathic Pain Questionnaire,[16,17] painDetect,[18] the DN4[19] and ID-Pain,[20] and the Neuropathic Pain Scale.[21] Associated symptoms are often important in formulating a diagnosis. A severe recurrent bilateral headache accompanied by photophobia, phonophobia, nausea, and vomiting in an otherwise healthy female suggests a migraine. In patients with suspected neuropathic pain it is important to ask about associated symptoms involving activation of the sympathetic nervous system. Inquire about changes in hair and nail growth, sweating, skin color and temperature, or swelling. The latter four may not be evident on the day of examination as they are often intermittent. They can sometimes be documented by photograph if the patient is able to provide this. Many patients with complex regional pain syndromes will have subtle motor abnormalities. They may volunteer weakness but not mention tremor, dystonia, or motor incoordination unless specifically asked. Patients with neuropathic pain may also experience altered and sometimes bizarre sensations and, since many pain patients struggle to have their pain believed, they may not volunteer certain information. For example, they may hesitate to describe formication (a sensation of bugs crawling under their skin), or a sudden feeling of cold water running down one leg, for fear of appearing "crazy." Asking directly about these types of symptoms is helpful.

R: Region/Radiation

The different sites of pain can be visually represented by having the patient draw their pain on a pain diagram. Neuropathic characteristics can be represented at the same time by using symbols or adding colors to the diagram (i.e., red for burning, green for tingling, blue for numbness) (Fig. 17.1).

Name _____ Date _____

Please color the areas where you experience pain. Use one of these five coloring pens to shade the specific type of pain that you are experiencing. Then circle with a pen all areas of pain and starting with the worst, number the areas in order of severity.

Red - burning
Green - tingling
Blue - numbness
If you have other pain sensations name them here and color as black or yellow
Yellow - aching
Black - _____

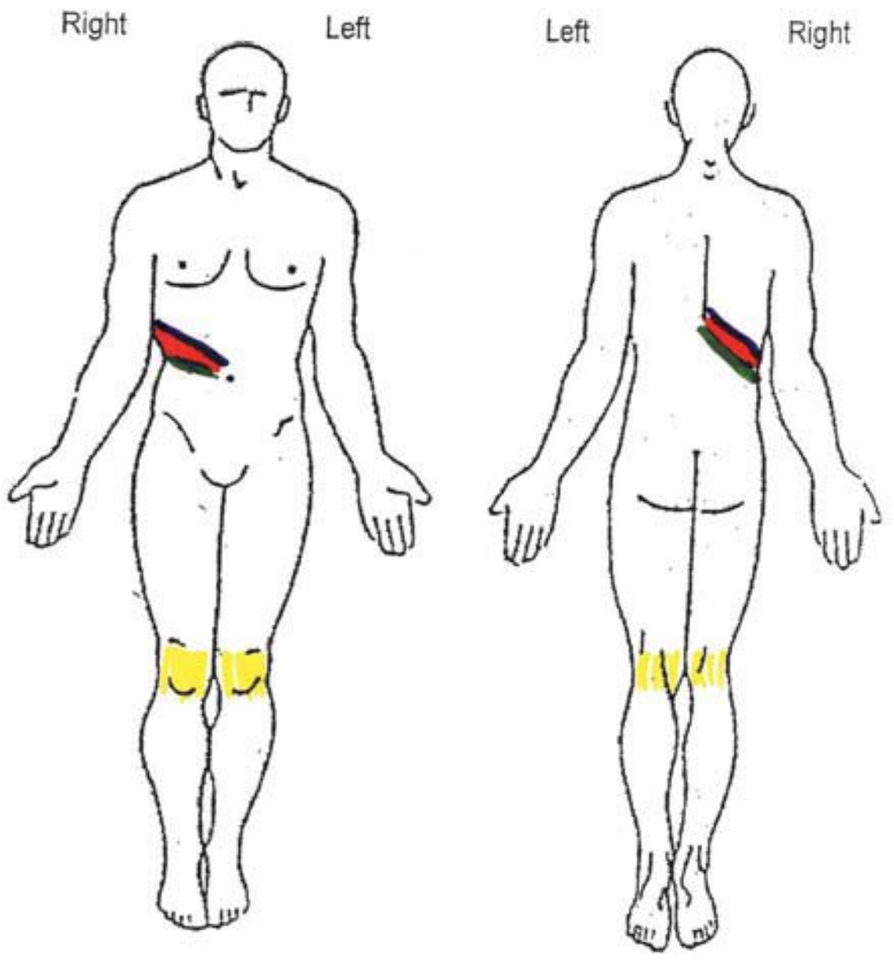

FIGURE 17.1 The pain diagram of a patient with postherpetic neuralgia and bilateral osteoarthritis of the knees.

S: Severity/Intensity

There are several different rating scales validated as measures of pain severity. The one chosen should be appropriate for the patient's abilities and preferences. The Numeric Rating Scale (NRS) is the most commonly used. A patient simply rates pain on a scale between 0 and 10 where "0" represents no pain and "10" represents the "worst pain imaginable." The visual analogue scale (VAS) consists of a 10-cm line anchored at the 0 end with the words "no pain" and at 10 with "the worst imaginable pain." The patient then makes a mark on the line consistent with their pain rating.

Many physicians have difficulty when patients rate their pain score with a number that seems to be at odds with their demeanor and functionality. Acknowledging to the patient that you believe they must have significant pain and then offering further anchors to the scale often results in a different rating that may be more meaningful in follow-up. The following script may be helpful in a patient who has rated their pain as 15/10:

"I believe you have pain that is severe and it is obviously very distressing to you but I am not quite sure how to interpret your rating because I do need a number between 0 and 10. If I say 0 means absolutely no pain and 10 out of 10 pain would be severe burns to most of your body or the pain you would feel if your hand was caught in a meat grinder, where would you rate your pain?" A patient who initially described their pain as 15/10 will often adjust their rating when belief, acknowledgment, and new anchors are provided.

Infants, children, the elderly, and others with cognitive impairment all require pain assessment scales designed to address their individual needs. Many different scales have been developed for these special populations and the reader is directed to separate chapters in this book for more detail.

T: Timing of Pain

The timing of pain can provide diagnostic clues to pain etiology. Neuropathic pain is often spontaneous. Patients report episodes of severe pain without any provocation while nociceptive pain, such as osteoarthritis of the hip, is usually not severe unless provoked by use. The typical timing of cluster headaches differentiates it from the ice pick headache and the intermittent nature of trigeminal neuralgia would differentiate it from herpes zoster pain of the fifth cranial nerve.

Previous Treatments Tried and Details of the Outcomes

The initial questionnaire should allow the patient to list all the therapeutic modalities they are currently using or have used in the past. These could include prescription medications, nonprescription or complementary formulations, as well as interventions such as biofeedback, physiotherapy, massage therapy, anesthetic pain blocks, or surgeries. It is important to determine which ones the patient feels are useful as well as which were ineffective or produced intolerable side effects.

Current Medications Including Over-the-Counter and Other Treatments

A complete list of the patient's present medication should be recorded and any changes documented at each follow up. This is especially important if the patient is seeing other specialists who are prescribing medications as this poses an increased risk for unsuspected drug interactions. Inquire about other alternative therapists treating and/or prescribing nonprescription medications, herbs, or supplements. Many of these interact with prescribed medications or create other side effects and should be documented (for specific information go to the Memorial Sloan-Kettering Cancer Center Web site at www.mskcc.org/aboutherbs)

HISTORY OF PAST HEALTH RELEVANT TO THE PRESENTING PROBLEM

Medical history relating to the possible etiology of the pain is important as it may predict other pain problems either currently or in the future (i.e., multiple sclerosis or Parkinson's). Document history of comorbidities that could influence either the manifestation of the pain (i.e., dementia) or treatment choices (i.e., liver or renal insufficiency).

Many comorbidities occur in patients suffering chronic pain. Common relevant comorbidities include:

- **Dementia**: This may alter the manifestation of pain. Simple tests such as the mini mental status should be available to give to patients who are suspected of being in the early stages of dementia. Pain and depression scales should be appropriate for the degree of cognitive impairment. It is important to have a caregiver present at the evaluation in these situations.
- **Renal or hepatic compromise**: These will obviously affect many metabolic functions and reactions to medications. Initial baseline laboratory tests should be considered before commencing or continuing to prescribe many medications.
- **Sleep disturbance**: The relationship between pain and sleep dysfunction can be complex and over 70% of patients with chronic pain report sleep disturbance.[22] Most patients report that sleep is interrupted due to pain and many develop unhealthy sleep patterns. A sleep history should always be asked with questions to identify sleep apnea, restless leg syndrome, and monoclonic leg movements. Patients with PTSD may have significant sleep disturbance from nightmares. Effective treatment of sleep disturbance will involve assessing and treating all of the contributing factors.

PSYCHIATRIC COMORBIDITIES

Anxiety and depression are common and may decrease the patient's tolerance to pain, in turn reducing their coping ability. There are many different assessment tools for depression. Ideally, a tool validated for chronic pain patients should be used. The IMMPACT committee[23] recommended using the Beck Depression Inventory (BDI). A change of $\geq$5 points on the BDI was recommended by IMMPACT to be considered a reasonable estimate of a clinically important change when assessing treatment efficacy in follow-up.

Other validated easy to use depression tools include the Hamilton Depression Scale, the Zung Self-Rating Depression Score, and the Hospital Anxiety and Depression Scale (HADS).

The HADS can also be used for anxiety as can the General Anxiety Disorder Scale (GAD7) and the Beck Anxiety Inventory.

Other psychiatric comorbidities that may affect pain management and should be assessed include bipolar disorder, PTSD, and ADHD.

PSYCHOSOCIAL ASSESSMENT

Psychosocial factors are important variables in the comprehensive assessment of chronic pain. Numerous relevant factors have been described and there are multiple assessment tools and measures to evaluate them. Unfortunately, at present there is no consensus in the literature to direct the clinician regarding choice of these measures. Using a "prototypical" pain assessment battery, Davidson et al.[24] determined that a 7-factor model could be extracted. The dimensions they determined should be measured included pain and disability, pain description, affective distress, support, positive coping strategies, negative coping strategies, and activity.

Two key individual personality features that impact pain include catastrophizing and health related anxiety. Persons who catastrophically misinterpret innocuous bodily sensations, including pain, are likely to become fearful of pain, which results in at least two processes. First, pain-related fear is associated with avoidance behaviors and the avoidance of movement and physical activity in particular. Avoidance also means withdrawal from rewarding activities such as work, leisure, and family. Second, pain-related fear is associated with increased bodily awareness and pain hypervigilance. Hypervigilance, depression, and disuse are associated with increased pain levels and, hence, would exacerbate the painful experience.

Validated tools to screen for these features include the Pain Catastrophizing Scale (PCS) and the Tampa Scale of Kinesophobia (TKS).[25] Patients with higher scores should have further assessment. Another simple option is to simply have the patient list their fears. There is evidence that identifying and modifying the patient's specific fears can improve outcomes.[26]

Other factors that may contribute to pain interruption of life include the influence of others (e.g., a spouse that is particularly solicitous), litigation issues, financial security, and status of health care coverage. If a patient has to pay a significant amount of money out of pocket for his or her medications, the prescription may not be filled. A brief employment history should focus on whether the patient is able to return to the previous employment, if they enjoyed their job, and if they are considering or actively retraining for other employment. Whether the patient is receiving wages while off work and whether or not a lawyer is involved may influence return to work. These factors have a major effect on successful pain management and should not be overlooked on the initial evaluation. The family or community support system of the patient is important in assessing the individual's social isolation.

The Multidimensional Pain Inventory Interference Scale (MPI)[27] is a 60-item self-reporting tool. It assesses pain patients' affective, cognitive, and behavioral responses to pain. IMMPACT suggests utilizing this tool.[1,2]

Coping strategies can be assessed by using the Chronic Pain Coping Index (CPCI),[28] a 65-item measure of cognitive and behavioral coping strategies.

If available, a referral to a clinical psychologist specializing in pain should be made if one or more of the following factors have been identified: pronounced emotional disturbance; pain behavior enabled by the family; possible secondary gain; failure to respond to several treatment modalities; reports of pain severity or functional impairment which seem inconsistent with disability; or excessive use of health care services.[29]

RISK OF ADDICTION SCREENING

The disease of addiction exists as a spectrum disorder and can complicate the management of a patient with persistent pain. Assessment of addiction risk is covered in this textbook in a separate chapter and the reader is referred there for further details. Standard assessment tools to define risk are listed in Table 17.1, as are other resources to assist with urine drug testing and follow-up documentation of high-risk individuals.

ASSESSMENT OF FUNCTION

Pain can affect functioning through its effect on physical, emotional, and cognitive functioning. Pain interrupts memory tasks, specifically ones that require attentional resourcing for controlled processing of information.[30] Simple tasks may therefore not be as impaired by pain as tasks that require more complex attention.

Assessment of loss of functionality can be assessed using different functionality questionnaires including the Pain Disability Index (PDI)[31] and the last 7 questions of the BPI. Disease-specific tools can also be used, such as the WOMAC scale for osteoarthritis, the Roland score for low back pain, or the Fibromyalgia Impact Score for fibromyalgia. These and others can be found in Wittink and Carr's source book.[32] Utilizing these self-reporting tools allows some objective documentation of functionality change, which is helpful in determining treatment efficacy and tracking outcome.

GOALS

Goal setting seeks to determine which specific social, recreational, or occupational tasks or roles are important to the patient. Examples of tasks in these categories include going out to see a movie (social), skiing (recreational), or being able to lift heavy objects (occupational). Roles in these domains could include active participation as a church committee member (social), soccer coach (recreational), or as a mother or lawyer (occupational). Determining appropriate goals is an important part of the pain assessment as it will help to direct treatment. People resist coercion, therefore when getting the patient to identify achievable goals, it is important to influence and not control. Goals need to be measurable, for example "to walk 3 blocks" not "exercise more." They should reflect the patient's current abilities. Identifying up to three goals is a reasonable starting point.

If a patient cannot achieve his or her goals, the practitioner should reassess the goals made, find out what barriers prevented the patient from completing their goal, and assist in reframing the goal to something more achievable in the short term. The goal, however, should always be one that the patient identifies. Evaluation by a psychologist may provide some helpful insights when constructing or re-evaluating goals.

If treatment goals are not met and the PDI or BPI score does not improve, it may be reasonable to assume current treatment is not effective and should be changed. Documenting that a patient has achieved or exceeded goals and has achieved a drop in the PDI score over 6 months can corroborate treatment efficacy.

PHYSICAL EXAMINATION

The examination is usually a focused examination based on the patient's history. The goal is to determine the etiology of the pain (if possible) and to determine, if appropriate, the presence or absence of neuropathic pain and physical signs of substance abuse or misuse. The following evaluation outline for a physical examination is suggested.

General Exam: Observe, Identify, and Document

- Mental status—consider a mini mental status exam if there are concerns about cognitive impairment. Comment on mood, displays of emotion, or evidence of impairment (slurred speech, difficulty remaining alert) and any smell of substance of abuse on breath, body, or clothes
- General appearance (whether it matches photo ID may be appropriate to comment on depending on the specific situation)
- Blood pressure, heart rate, weight, and height
- Stance and gait
- Mobilization aids (what, how, and why they are used)
- Signs of substance abuse including needle marks on lower arm, leg, or bottom of feet; rhinorrhea; red palms; spider veins on chest; and pupil diameter
- Evidence of any tremors, muscle atrophy, trophic changes, or deformities

Site of Pain

Perform a focused examination of the musculoskeletal system.

LOOK for:

- Positional relief postures (i.e., avoids weight bearing on one buttock, turns body instead of neck, prefers to stand and lean)
- Pain distraction signs (i.e., permanent heating pad burn marks, excessive teeth wear from clenching or grinding, joint damage in hand from chronically exerting excessive pressure on a painful area)
- General posture (i.e., head forward posture, exaggerated lumbar lordosis)
- Alignment of spine, shoulders, pelvis, and legs
- Symmetry
- Deformities, visible muscle spasm, atrophy, hypertrophy, scars, and birthmarks
- Leg length asymmetry

FEEL for:

- Bony landmarks
- Tenderness, swelling, crepitus, contour or bogginess of joint, muscle, ligament, bursa, or bone
- Trigger points (some clinicians quantify these with a pressure algometer)
- Evidence of damage to the local myotomal segment which includes:
  - Denervation sensitivity of the local spinal segment resulting in:
    - Trophedema. This can be documented by the matchstick test—trophedema is nonpitting to digital pressure, but if the end of a matchstick is pushed into the skin it will form a clear-cut indentation that persists for several minutes.
    - Peau d'orange effect of the skin in the area affected

MOVE to assess:

- Individual joints for swelling, crepitus, redness, warmth, and range of motion (active/passive)

- Muscle tone
- Muscle weakness
- Specific maneuvers (i.e., the impingement test to assess the shoulder, the hip flexion adduction internal rotation (FAIR) test of the hip to assess the piriformis muscle)

Neurological Exam

LOOK **for or ASK ABOUT:**

- Signs of sensory avoidance (specific clothing to avoid clothes brushing, wearing dark glasses in the examination room, poor oral hygiene in patients with mouth pain)
- Skin lesions (i.e., scarring from varicella zoster, foot ulcers with diabetic neuropathy)
- Swelling of the painful area (neurogenic edema) (ask if this occurs if not present, as in many patients this can be an intermittent feature)
- Changes in skin color (again, ask if this occurs if not present as in many patients this can be an intermittent feature. A photo by the patient can also provide documentation of these signs)
- Altered sweating (ask about if not present)
- Trophic changes (loss of hair, thinning skin, cracked dry skin, altered nails)
- Secondary changes associated with chronic peripheral neuropathy (e.g., Charcot neuropathic foot destruction with necrotic arthropathy and chronic ulcers on the plantar surface)
- Evidence of autonomic dysfunction (especially with complex regional pain syndrome or peripheral diabetic polyneuropathy)
- Involuntary movements: tremors, myoclonus, tics, dystonia, fasciculations, or others
- Specific tests (i.e., Adson's test for thoracic outlet syndrome, straight leg raising for lumbar radiculopathy)

FEEL **for:**

- Temperature differences between affected and unaffected areas (some clinicians document this objectively with a temperature probe)
- Edema, swelling, tenderness

MOVE **to assess:**

- Cranial nerves
- Gait
- Balance and coordination; finger tapping, rapid alternating movements, finger nose and heel-shin testing, Romberg
- Tone:
  - Spasticity = eliciting the "clasp knife phenomenon," which predominates in the upper limb flexors and the lower limb extensors
  - Rigidity = uniform resistance that worsened during the range of movement; usually worsens with distraction
  - Paratonia = describes increased resistance because the patient has difficulty consciously relaxing the muscle. This usually improves with distraction.
  - Hypotonia = decreased tone
- Motor function (Table 17.2):
  - Pronator drift: With the patient standing with both arms extended and palms up (supinated) look for one arm to drift downward and begin to turn palm down (pronate). A positive test is a subtle indicator of upper motor neuron weakness (in which supination is weaker than pronation)

TABLE 17.2

SENSORIMOTOR NERVE DISTRIBUTION

Movement	Nerve root	Key sensory area	Peripheral nerve
Hip flexion	L2–L3	L2 = Medial midthigh L3 = medial knee	Femoral
Knee extension (deep knee bend)	L3–L4	L4 = medial calf (test just above medial malleolus) L5 = lateral calf and dorsum foot (test area above second toe)	Femoral
Ankle dorsiflexion (heel walk)	L4–L5	L4 = medial calf L5 = lateral calf and dorsum foot	Peroneal
Hip extension (compare buttock squeeze)	L4–L5	As above	Gluteal
Knee flexion	L5–S1	S1 = posterolateral foot and ankle (test base of 5th toe)	Sciatic
Ankle plantarflexion (toe walk)	S1–S2	S2–posterior thigh and popliteal fossa	Tibial
Anal sphincter weakness (finger squeeze during exam)	S2–S4	S3–S5–perianal area	
Shoulder abduction	C5	C5–lateral upper arm/lateral epicondyle	Axillary
Elbow flexion	C5–C6	C6–thumb	Musculocutaneous
Elbow extension	C6–C7	C7–middle finger	Radial
Wrist extension	C6–C7		Radial
Wrist flexion	C7–C8	C8—5th finger	Median
Finger flexion	C8		Median
Finger extension	C8		Radial
Finger abduction	T1	T1–ulnar forearm/medial epicondyle	Ulnar

- In the arms, test resisted shoulder abduction C5, elbow flexion C5–C6, elbow extension C6–C7, wrist extension C6–C7, wrist flexion C7–C8, finger flexion C8, finger extension C8, and finger abduction T1. In the legs, test hip flexion L3–L4, hip extension L4–L5, knee flexion L5–S1, knee extension L3–L4, ankle dorsiflexion L4–L5, and ankle plantar flexion S1–S2.
  Score power by
  0 = No contraction
  1 = Visible muscle twitch but no movement of the joint
  2 = Weak contraction insufficient to overcome gravity
  3 = Weak contraction able to overcome gravity but no additional resistance
  4 = Weak contraction able to overcome some resistance but not full resistance
  5 = Normal; able to overcome full resistance
- Reflexes:
  - C5–C6 roots the biceps and brachioradialis reflexes:
  - C6–C7 roots (mainly C7) the triceps reflex
  - L3–L4 roots (mainly L4) the knee jerk
  - S1 roots the ankle jerk
  - Score reflexes by
    0 = No observable reflex
    1 = Trace reflex
    2 = Normal reflex
    3 = Brisk reflex
    4 = Nonsustained clonus (two or less beats of clonus)
    5 = Greater than three beats of clonus or sustained clonus
    Anal "wink" reflex in a patient with suspected cauda equina syndrome (scratch the perianal skin about 2 cm away from the anus and look for muscle contraction to cause an "anal wink")

Patients with peripheral neuropathy may have diminished or absent reflexes. If they do not, look carefully for evidence of upper motor neuron dysfunction.

Signs of Upper Motor Neuron Dysfunction

- Hyperreactive reflexes
- Spasticity
- Positive Babinski sign
- Positive pronator drift sign
- Weakness that is predominant in the arm extensors and leg flexors

Signs of Lower Motor Neuron Dysfunction

- Absent or hyporeactive reflexes
- Tone normal or reduced
- Negative Babinski sign
- Atrophy and fasciculations
- Weakness that is predominant in arm flexors and leg extensors

Mixed upper and lower motor neuron dysfunction can present with hyperreflexia and spasticity mixed with depressed reflexes and weakness in patients with cervical myeloradiculopathy.

Bedside Method for Quantitative Sensory Pain Testing

Many clinicians find it useful to have the patient complete a colored pain diagram as it helps to direct the sensory testing (see Fig. 17.1 or Appendix 4). Using the diagramed symptoms of neuropathic pain, determine if the area of pain, tingling, or numbness colored by the patient is associated with sensory changes.

Patients are examined for the following modalities:

Light Touch

Lightly brush the skin. This can be performed at the bedside with a cotton wisp, cotton-wool tip, Q-tip, foam brush, or paint brush. In cases of decreased light touch, testing begins in the area of reduced or absent sensation and is slowly advanced until the sensate area is reached. With areas of increased sensitivity, testing should start over the normal skin and move toward the sensitive area. Once the patient feels any change in sensation the point on the skin is marked.

Drawing the area of abnormality on the skin can help to determine the pattern of loss (single nerve territory, polyneuropathy, or nondermatomal). If light touch is normal it is still important to test for pinprick and temperature, as these tests evaluate different small fiber components of the nerve.

VIBRATION: TESTING

Vibration sense is often tested with a 128-Hz tuning fork. Test over the bony prominences moving from distal to proximal. In subjects with distal symmetric polyneuropathy, the tuning fork is placed over the interphalangeal joint of the big toe. If no vibration is noted, move to the medial malleolus and repeat the exam. If still unable to sense vibration, the test is repeated over the patella. For the hands, test over the second distal interphalangeal joint, and move proximally to the ulnar styloid and lateral epicondyle if no vibration is felt.

Punctate/Pinprick

This can be evaluated with a safety pin, unbent paper clip, or a more standardized device such as a Neuropen. The size and angle of the sharp tool can significantly affect the intensity of the stimulus and can produce differing clinical evaluation results. The Neuropen has a standardized probe tip and is designed to allow production of a consistent stimulus. Perform the testing in the area with the abnormal positive or negative sensations.

Warm and Noxious Heat Testing

For bedside testing, thermal evaluation can be done by heating the round end of a tuning fork in warm or hot water. There are no commercially available small devices for standard bedside testing of warmth or heat pain. It is difficult to get the tuning fork to the correct temperature for heat pain testing. This test is most useful to confirm the involvement of small fibers when evaluating for a possible small fiber neuropathy. This most often occurs in a patient whose pain drawing suggests a peripheral neuropathy but in whom sensation to vibration and light touch was normal.

Cool and Noxious Cold Testing

For cool testing a tuning fork is held under cool water and applied to the area of altered skin sensation. For cold pain the tuning fork is immersed in ice water. Comparison is made with the established control site. Have the patient report the sensation. (Does it actually feel cool? In some patients it feels paradoxically hot.)

REDUCED SENSATION: Have the patient express the degree of loss by utilizing a simple 1 to 100 scale of a dollar. Ask "If

this is a dollar (stimulating the normal area), then how much is this worth? (now stimulating the area of sensory loss). Responses of 90 cents reflect a very different degree of loss than a reply of 10 cents.

INCREASED SENSATION: In the case of a sensation that should have been painful (pinprick, noxious heat or cold) have the patient grade the pain in the normal area first (0–100) and then grade the abnormal area which they should rate as higher than the normal area.

Record **dysesthesia** if the nonpainful stimulus was felt as increased but not painful and write a description of the sensation (e.g., numb, pins and needles).

Record **hyperalgesia** if the stimulus was a normally painful stimulus (pinprick, heat or cold pain) but it produced more pain than the unaffected normal test site. Grade intensity (0–100).

Record **allodynia** if the stimulus was nonpainful (brush, vibration, warm, cool) and either the threshold was normal or decreased (stimulus intensity reported as the same or more than the normal site) and the patient reported pain from the stimulus. Grade intensity (0–100).

Record **hyperpathia** if the stimulus threshold is increased (stimulus intensity reported as less than the normal site) and the patient reports it as painful. Grade intensity (0–100).

Further Investigations or Consults

Other investigations may include specific radiological or EMG testing, a sleep study, specific or baseline laboratory investigations, or urine toxicology screening. Referral to appropriate specialists for further assessments should be requested as needed.

FOLLOW-UP VISITS

Ideally the first follow-up visit should be within a few weeks to allow assessment of treatment efficacy and tolerability and review of any testing, consults, or "homework" requested. A follow-up form given to the patient to complete prior to being seen may be helpful. It should include questions about the goals achieved and efficacy of any therapy started (see Appendix).

The 5A's have been suggested as a useful acronym to document follow-up visits and evaluate the efficacy therapy. These are Adverse events (to treatment), Affect (mood), Activities (progress toward goals/functionality outcomes), Aberrant drug–related behavior if opioids are prescribed, and Action taken.[33]

CONCLUSION

Assessment and reassessment must be built into every treatment plan. Patients should leave each visit, whether an initial visit or a follow-up, with a definite and agreed plan. Patients should also be repeatedly reminded that it will take effort on their part to reach relevant goals (see Appendix).

Nonadherence, or questioning an agreed treatment plan, occurs in up to 50% of patients, but merely repeating the original reasoning will often be ineffective. Patients need to be involved in a discussion about any concerns or objections they may have to the treatment plan as it evolves. For any trial of treatment, a reasonable time to expected improvement must be defined early on (e.g., up to 3–4 weeks for an antidepressant to work, 2–3 weeks before improvement in pain may be felt with the same drug). With physical therapy it may take three to four sessions for ongoing improvement. If there are no recognizable improvements after the agreed upon trial time, that particular therapy should be changed or stopped.

Working with a chronic pain patient can be immensely satisfying, as the practitioner sees a patient begin to take more responsibility for their often disabling, all-encompassing pain, and improve their quality of life and function. Having an organized way of getting the patient to give a comprehensive history and validating their pain but not being drawn into their "stories" is a skill that takes time to develop, but being prepared by using some of the suggestions outlined in this chapter and appendix should speed up the "learning curve." Equally important from the practitioner's point of view is to not do it alone, but involve the patient, their significant other, and other community resources. An integrative approach provides the best possible outcome for patients with chronic pain.

APPENDIX 1: INITIAL PAIN QUESTIONNAIRE

Name Date
Age

Please list your main areas of pain, how long you have had pain in each area, and how severe the pain is on average (e.g., low back pain 10 years moderately painful).

Area	how long years	months	Mild pain/moderate pain/ severe pain
1			
2			
3			
4			
5			

Briefly describe how each of the pain problems you listed above started (e.g., "after surgery to my knee,""after a car accident").
Area 1
Area 2
Area 3
Area 4
Area 5

Surgical History

Have you had any surgeries directly related to your pain problem(s): Yes No

If yes, complete the information.

Name and year of surgery (e.g., lumbar fusion, 1985; knee surgery, 1998):

1 Year
2 Year
3 Year
4 Year
5 Year

Have you had other surgeries NOT related to your pain problems? Yes No

If yes please complete the following information:

Name and year of surgery (e.g., appendectomy 1993, tonsillectomy 2001).

1 Year
2 Year
3 Year
4 Year
5 Year

Allergies

Are you allergic to any medication? (An allergy means a rash, swelling, difficulty in breathing. It does NOT mean causing a stomach upset or dizziness): Yes No

If yes, please list them:

Present Medication

How satisfied are you with your present pain medications?
5-point scale from extremely satisfied to extremely dissatisfied
Please list all prescription medications you are taking that are NOT for pain (e.g., blood pressure, cholesterol, heart, blood thinners) and how many times a day:

Name Dose Times per day Date started Prescribing doctor

Please list all other nonprescription medications you are taking (e.g., Tylenol, Advil, Aleve, vitamins, herbal supplements, homeopathic remedies).

Pain Medication

What pain medications have you taken in the past? Your pharmacist may be able to help you with a list.

Opioid (Narcotic) Medication (Vicodin, Percocet, Darvocet, Morphine, Fentanyl, Demerol, Methadone

Have you been given opioid (narcotic) medication for your pain?
Yes No

If yes have they improved your activity or general level of function?
No a little bit somewhat quite a bit very much

Do you feel your doctor is reluctant to prescribe opioids?
Yes No

Are you concerned about addiction if you are prescribed opioids:
Yes No

Are any members of your family concerned about addiction if you are prescribed opioids? Yes No

Past Medical History

Have you had any of these conditions either now or in the past?

Heart and Blood Vessels

High blood pressure
Angina
A heart attack
Congestive cardiac failure

Lungs

Shortness of breath easily
Asthma

Liver/Kidneys

Hepatitis
Other liver problems
Kidney problems
Bladder problems

Metabolic/Intestinal Tract

Diabetes
Thyroid disease
Acid reflux
Stomach ulcer
Dark black stools
Blood in stools
Have you had an unexplained weight loss of more than 10 pounds in the last 6 months?

Nervous System

Loss of balance
Seizures
Stroke
Paralysis
Peripheral neuropathy

Muscles and Joints

Neck/back problems
Joint pains

Other

Cancer
HIV

Psychological

Anxiety
Panic disorder
PTSD
ADHD (Adult hyperactivity disorder)
Bipolar
Schizophrenia
Depression
Any history of addiction or substance abuse: Yes No

Please note, if you answer yes to this or other similar questions it will NOT mean you don't receive the best treatment your provider can give you, nor will it necessarily mean you don't get strong pain medicine (narcotics) but it will help him or her to offer you the safest treatment plan the two of you together can determine.
If yes was it to:
Alcohol
Prescription drugs?
Other drugs?
Exposure to toxins such as asbestos, dyes, printing rubber, arsenic, etc.?

Are you pregnant now? Yes No

If all your pain was gone how healthy would you be (100% being full health)_____%
ER visits

In the PAST YEAR have you been treated in the Emergency Room for your pain problem YES NO
If yes 1 2–3 4–6 7–10 More than 10 times

Health care visits

In the past 3 months how many times have you been to your regular health care provider or specialist for your pain problem

(MD, ARNP, PA) 0 1 2–3 4–6 7–10 More than 10 times

In the past 3 months how many times have you been to your physical therapist for your pain problem 0 1 2–3 4–6 7–10 More than 10 times

In the past 3 months how many times have you seen an alternative health care provider for your pain problem (chiropractor, homeopath, naturopath, acupuncturist) 0 1 2–3 4–6 7–10 More than 10 times

Pain Score

Click the number that best describes your baseline or constant level of pain over the past few days when taking your pain medication:
0 1 2 3 4 5 6 7 8 9 10
No pain worst possible pain

Click the number that best describes your worst level of pain over the past few days, when taking your pain medication:
0 1 2 3 4 5 6 7 8 9 10
No pain worst possible pain

How many times on average over the past few days did your worst pain occur?
1–2 3–4 5–6 7–8 More than 8

Have you ever had the following types of treatment for your PRESENT pain problem(s) and what was the result?
No Improved No change Worse

Occupational Therapy
Physical therapy
Passive (heat, gentle massage, ultrasound)
Mobilizations
Exercises
TENS
Chiropractic manipulations
Deep tissue massage
Psychological counseling for pain
Biofeedback
Trigger point injections
Joint injections
Epidural steroid injections
Facet joint injections
Nerve blocks
Other local anesthetic or steroid injections

Have you had any of the following tests for your pain:

Blood tests	No	Yes
X rays	No	Yes
MRI	No	Yes
Cat (CT)Scan	No	Yes
EMG	No	Yes
Bone Scan	No	Yes
Myelogram	No	Yes
Discogram	No	Yes
Ultrasound	No	Yes

Social History

This is important for physicians who treat your pain to know because HOW you grew up affected how your pain sensing system developed and your current environment and state of mind can affect both your pain and how easy it is to cope with it.

Did you have a happy childhood? Yes No

Have you ever been sexually and or physically abused? Yes No

If yes was it before you were an adult? Yes No

Do you currently feel threatened in your environment? Yes No

Have you ever seriously considered or attempted suicide? Yes No

Do you have a suicide plan at the moment? Yes No

Are you: married, divorced, widowed, single, living with someone?

Do you have any children? Yes No
If yes how old are they? _____

Do you smoke? Yes No

If yes
Less than half a pack a day
Half to one pack a day
One or more packs a day.

Is the best smoke of the day the first one in the morning?
Yes No

If you are a former smoker when did you stop?

Do you drink alcohol? Yes No

If yes
Less than 6 drinks per week?
7–24 drinks per week?
Over 24 drinks per week?

Do you binge drink?

Do you drink to decrease your pain Yes No

Have you or your doctor ever thought you had a problem with pain medication? Yes No

In the past 10 years have you ever tried street drugs? Yes No

If yes
Marijuana
Cocaine
Heroin
Other

Are you using any of these drugs presently?

Family History

Do you have any members of your immediate family who suffer from
Chronic pain Yes No
Diabetes Yes No
Headaches/migraines Yes No
Severe arthritis Yes No
The same pain complaints as you have Yes No
Any family history of addiction or substance abuse Yes No

If yes was it to
Alcohol?
Prescription drugs?
Other drugs?

Work History

What is your occupation? Are you:
Employed full time
Employed part time
Unemployed because of pain
Unemployed because of other reasons

Retired because of pain

In school or retraining because of pain

Homemaker

How satisfied are you with your current job?
Very satisfied, Neutral, Very dissatisfied

Do you have problems getting along with your co-workers?
No Yes

Do you have an attorney working on your injury claim?
No Yes

If you are not working at present do you think you will be able to return to the same sort of job that you were doing before your pain?
No Yes Not applicable

Are you actively considering a change of employment or a retraining program?
No Yes Not applicable

Overall, on a scale of 0–10 how close are you to returning to work (10 means ready to work full time, 0 means you are not even close to work at any job)
0 1 2 3 4 5 6 7 8 9 10

Do you suffer from headaches? ☐ Yes ☐ No

IF YES

In the past two weeks did you suffer from headaches? (one possible answer)

- ☐ I had mild headaches which came infrequently
- ☐ I had moderate headaches which came infrequently
- ☐ I had moderate headaches which came frequently
- ☐ I had severe headaches which came infrequently
- ☐ I had headaches almost all the time

Type of headaches (mark the ones that best describe your main headaches)

- ☐ Are your headaches one sided? Yes No
- ☐ Are they worsened by, or do they cause you to avoid physical activity? Yes No
- ☐ Do they cause you to feel sick or to vomit? Yes No
- ☐ Does bright light or any noise make the headache worse? Yes No

Constipation
Do you suffer from constipation (less than 3 bowel movements a week) Yes No

Do you suffer from all over body pains or have you been told you suffer from fibromyalgia? ☐ Yes ☐ No

Sleep History

Have you been told you snore a lot? Yes No

Have you been told you often gasp for breath or stop breathing during sleep? Yes No

Have you been diagnosed with sleep apnea? Yes No

Are you a restless sleeper? Yes No

Do you often have problems with restlessness (creeping, crawling or other uncomfortable feelings) in the legs keeping you awake?
Yes No

Does your bed partner report that your legs jerk during sleep?
Yes No Don't know

Do you feel rested when you wake up in the morning?
Yes No

Do you use any of these substances regularly in the four hours before going to bed?
Alcohol
Caffeine (coffee, tea, sodas)
Tobacco
Decongestants

Beta blockers (for blood pressure or heart problems, such as atenolol, propranolol)

Have you ever had a sleep study? Yes No

Physical Function and Quality of Life Questions

Mood Disorders

Has there ever been a period of time when you were not your usual self and (while not using drugs or alcohol). ☐ **Yes** ☐ **No**

...you felt so good or so hyper that other people thought you were not your normal self, or you were so hyper that you got into trouble? ☐ Yes ☐ No

Has a health professional ever told you that you have manic-depressive illness or bipolar disorder? Yes No

Depression Questionnaire

During the past month have you often been bothered by feeling down, depressed, or hopeless? Yes No

During the past month have you often been bothered by having little interest or pleasure in doing things? Yes No

Anxiety

Over the last 2 weeks, how often have you been bothered by the following problems?

		Not at all	Several days	More than half of the days	Nearly every day
1	Feeling nervous, anxious or on edge	0	1	2	3
2	Not being able to stop or control worrying	0	1	2	3
3	Worrying too much about different things	0	1	2	3
4	Trouble relaxing	0	1	2	3
5	Being so restless that it is hard to sit still	0	1	2	3
6	Becoming easily annoyed or irritable	0	1	2	3
7	Feeling afraid as if something awful might happen	0	1	2	3

If you checked off any problems, how difficult have these problems made it for you to do your work, take care of things at home, or get along with other people?

Not difficult at all	Somewhat difficult	Very difficult	Extremely difficult
○	○	○	○

PTSD

In the past month have you:

Had repeated, disturbing *thoughts,* or *images* or flashbacks of a stressful experience? Yes No

Several times avoided *having feelings* related to a stressful experience? Yes No

ADHD
Check the box that best describes how you have felt and conducted yourself over the past six months.
Never Rarely Sometimes Often Very often

1. How often do you have trouble wrapping up the final details of a project once the challenging parts have been done?
2. How often do you have difficulty getting things in order when you have to do a task that requires organization?
3. How often do you have problems remembering appointments or obligations?
4. When you have a task that requires a lot of thought, how often do you avoid or delay getting started?
5. How often do you fidget or squirm with your hands or feet when you have to sit down for a long time?
6. How often do you feel overly active and compelled to do things, like you were driven by a motor?

Pain Disability Index [PDI]

The rating scales below are designed to measure the degree to which aspects of your life are disrupted by chronic pain. In other words, we would like to know how much your pain is preventing you from doing what you would normally do, or from doing it as well as you normally would. Respond to each category by indicating the *overall* impact of pain in your life, not just when the pain is at its worst.

For each of the 7 categories of life activity listed, please circle the number on the scale, which describes the level of disability you typically experience. A score of 0 *means no disability at all,* and a score of 10 *signifies that all of the activities in which you would normally be involved have been totally disrupted or prevented by your pain.*

Family / home responsibilities: This category refers to activities related to the home or family. It includes chores or duties performed around the house (e.g., yard work) and errands or favors for other family members (e.g., driving the children to school).
0 1 2 3 4 5 6 7 8 9 10
No disability Worst disability

Recreation: This category includes hobbies, sports, and other similar leisure time activities.
0 1 2 3 4 5 6 7 8 9 10
No disability Worst disability

Social Activity: This category refers to activities which involve participation with friends and acquaintances other than family members. It includes parties, theater, concerts, dining out, and other social functions.
0 1 2 3 4 5 6 7 8 9 10
No disability Worst disability

Occupation: This category refers to activities that are a part of or directly related to one's job. This includes nonpaying jobs as well, such as that of a home maker or volunteer worker.
0 1 2 3 4 5 6 7 8 9 10
No disability Worst disability

Sexual Behavior: This category refers to the frequency and quality of one's sex life.
0 1 2 3 4 5 6 7 8 9 10
No disability Worst disability

Self-Care: This category includes activities which involve personal maintenance and independent daily living (e.g., taking a shower, driving, getting dressed, etc.).
0 1 2 3 4 5 6 7 8 9 10
No disability Worst disability

Life-support Activity: This category refers to basic life-supporting behaviors such as eating, sleeping, and breathing.
0 1 2 3 4 5 6 7 8 9 10
No disability Worst disability

Goals for Treatment

Please put down four things in your life which you can't do or have difficulty doing because of your pain, and which you would most DEARLY like to do if the treatments decrease your pain by 50%.
These four things can't be vague or general such as "to be free of pain" or "to be whole again." They have to be activities which can be measured and which someone else could see you doing. For instance if you have been very inactive and wish to change this write "walk 3 blocks" instead of "increase exercise."

1 _____
2 _____
3 _____
4 _____

APPENDIX 2: FOLLOW UP/ PROGRESS NOTE

What new medications (prescribed and over the counter) are you taking for your pain (how much and how often?)

_____

_____

How would you best describe your pain? (please check all that apply)
Dull, throbbing, aching shock-like, numb, or tingling burning

Has the sort of pain changed since your last visit? No Yes

Please rate your pain by circling the one number that best describes your pain on the average over the past few days (while taking your pain medication)
1 2 3 4 5 6 7 8 9 10

Please circle the number that best describes your pain at its worst in the last 24 hours
1 2 3 4 5 6 7 8 9 10

How many times did your pain get to its worst level during the last 24 hours?
1–2 3–4 5–6 7–8 More than 8

What makes your pain worse?
Standing Walking Sitting Bending Ice Heat
Other _____

What makes your pain better?
Standing Walking Sitting Bending Ice Heat
Other _____

Did the pain medicine cause a problem

	No	Mild	Moderate	Severe
Nausea				
Constipation				
Drowsiness				
Confusion				
Dry mouth				
Headache				
Weight gain				
Sexual problems				

(Brief Pain Inventory) To what degree has pain interfered with the following activities (1 = no interference, 10 = maximum interference

Your sleep	1....2....3....4....5....6....7....8....9....10
General activity	1....2....3....4....5....6....7....8....9....10
Mood	1....2....3....4....5....6....7....8....9....10
Walking ability	1....2....3....4....5....6....7....8....9....10
Normal work (at home and outside)	1....2....3....4....5....6....7....8....9....10
Relations with others	1....2....3....4....5....6....7....8....9....10
Enjoyment of life	1....2....3....4....5....6....7....8....9....10

Did you achieve your physical goals since your last visit? (These are activities that pain had stopped you doing?)
No Didn't try Almost achieved Achieved Achieved and more

What new goals are you setting yourself to be achieved by the next visit?

Do you need refills of your pain medications Yes No

Please list problems in order of importance you want to discuss with your health care practitioner.

APPENDIX 3: GOAL SETTING

A goal is something we would like to do in the next month to 6 months, such as walking, water exercise, visiting family, doing things with friends, or controlling your diabetes.
Goals are generally too big to work on all at once, so start one step at a time and with smaller goals. For example, your pain will have limited your physical activity so it is important to exercise, but doing too much all at once may make your pain worse temporarily. You might start with deciding what type of exercise to do, then where to go to exercise, how much time I will spend exercising when first starting, and maybe asking a friend or family member to exercise with you.
Decide what goals to make **this month** and how to do it.
Important points about goals, they should be something:

1. You want to do—not what your doctor, nurse, family, or anyone else thinks you should do.
2. Realistic—something you think you can REALLY do this month.
3. Specific—for example, doing more exercise is not specific, but walking 10 minutes twice a day IS.
   What? Walking more
   How much? 10 minutes
   How often? Twice a day: 4 times a week
4. How confident are you that you can succeed? This usually means a level of 7 or more on a confidence scale (0 = don't think I can do it to 10 = I definitely think I will complete the goal)

Goal Setting Worksheet

Date: _____

Use the following worksheet to assist you in identifying your goals.

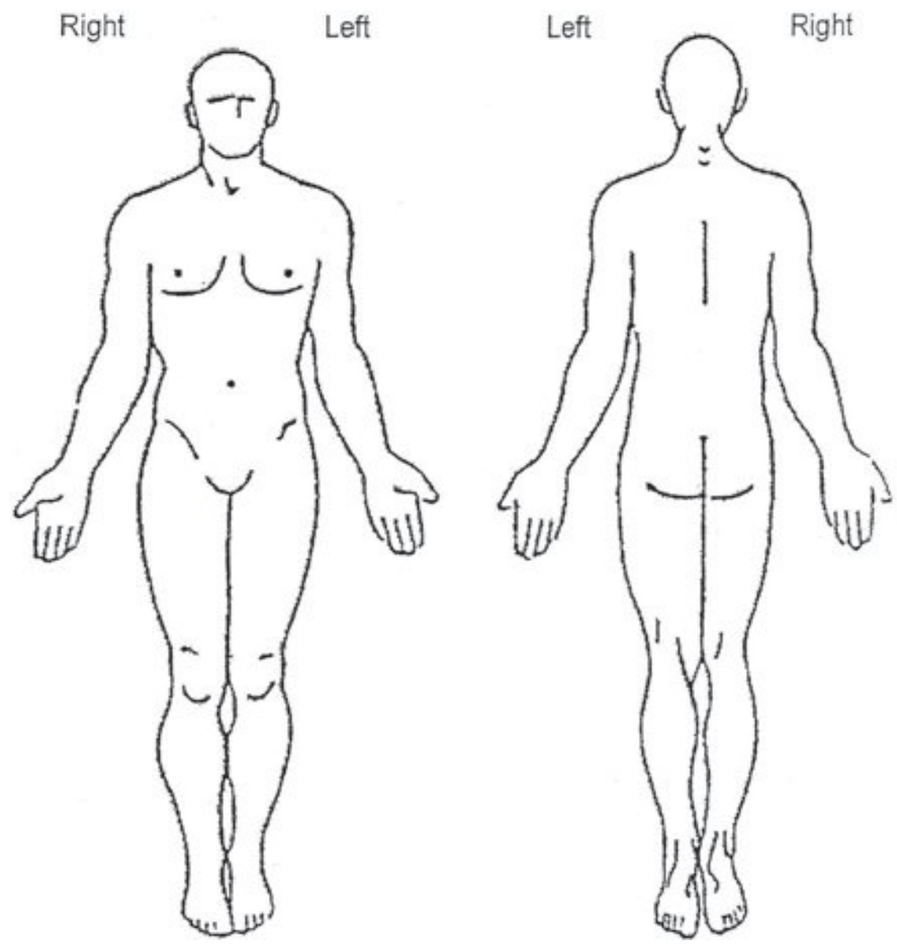
1. Choose one of the activities below:
To improve my pain I will:
1. Choose one of the activities below:
   _____ Work on something that's bothering me.
   _____ Stay more physically active!
   _____ Take my medications as prescribed.
   _____ Improve my food choices.
   _____ Reduce my stress.
   _____ Cut down on smoking.
   _____ Other

2. Choose your confidence level:
This is how sure I am that I will be able to meet my goal over the next month.

1 _____ 5 _____ 10
Not sure Somewhat sure Very sure

3. Chosen Goal one:
What: _____
How much/often: _____
Confidence level =

Chosen Goal Two:
What: _____
How much/often: _____
Confidence level =



APPENDIX 4: PAIN DIAGRAM

Name _____ Date _____
Please color the areas where you experience pain. Use one of these five coloring pens to shade the specific type of pain that you are experiencing. Then circle with a pen all areas of pain and, starting with the worst, number the areas in order of severity.

Red — burning
Green — tingling
Blue — numbness

If you have other pain sensations, name them here and color as black or yellow

Yellow — _____
— _____
Black

CHAPTER 18 ■ ELECTRODIAGNOSTIC EVALUATION OF ACUTE AND CHRONIC PAIN SYNDROMES

DOUGLAS G. CHANG AND ELAINE S. DATE

INTRODUCTION

Before a clinician can treat pain effectively, the utmost must be done to identify what condition is being treated, and identify what may be causing pain. For this purpose, electrodiagnostic studies are important in the evaluation of acute and chronic pain syndromes. They give valuable, quantitative information on the physiologic health and functioning of nerve and muscle. They help localize injuries, quantify the extent of injury, suggest age of injury, and give valuable prognostic information that can change treatment protocols. They can monitor interval progression. All of this complements the static, anatomic structural information provided by radiological imaging studies. In other words, radiological imaging can identify anatomy that may or may not be the cause of symptoms. Electrodiagnostic studies can quantify symptoms (e.g., show evidence of spinal nerve root compression) but cannot identify the anatomic cause (e.g., infection, tumor, or disk herniation). Together, electrodiagnostic and radiologic studies are extensions of the physical exam and serve to refine the differential diagnosis suggested by a clinical presentation.

Common reasons for ordering electrodiagnostic studies include symptomatic complaints (weakness, pain, numbness and/or tingling in an extremity) and physical examination findings (focal neurological deficits in deep tendon reflexes, strength or sensory losses). Typical clinical scenarios involve radiculopathies, entrapment syndromes, trauma, and metabolic pathology seen in diabetes and alcoholism. Other important scenarios include rheumatologic disease, neuromuscular disease, and various infectious and neoplastic neuropathies. Further details about these conditions can be found in several electrodiagnostic textbooks.[1,2,3,4,5,6]

Practically, electrodiagnostic studies should be thought of when the diagnosis is in doubt, either during the initial patient presentation or as the result of nonresponse to treatment. The studies can evaluate the possibility of additional lesions (e.g., concomitant nerve entrapment syndromes, peripheral neuropathies, and so-called ‘‘double crush syndromes’’), be used to follow the interval progression of both operative and nonoperative treatments, and provide pre-operative baselines. The objectives of this chapter are to introduce basic principles of electrodiagnosis. Hopefully, this will provide information on when to order electrodiagnostic tests, and help interpret and utilize the resulting electrodiagnostic reports.

TERMINOLOGY

Electrodiagnostic studies involve two components: nerve conduction studies (NCS) and needle electromyography (EMG). Al-

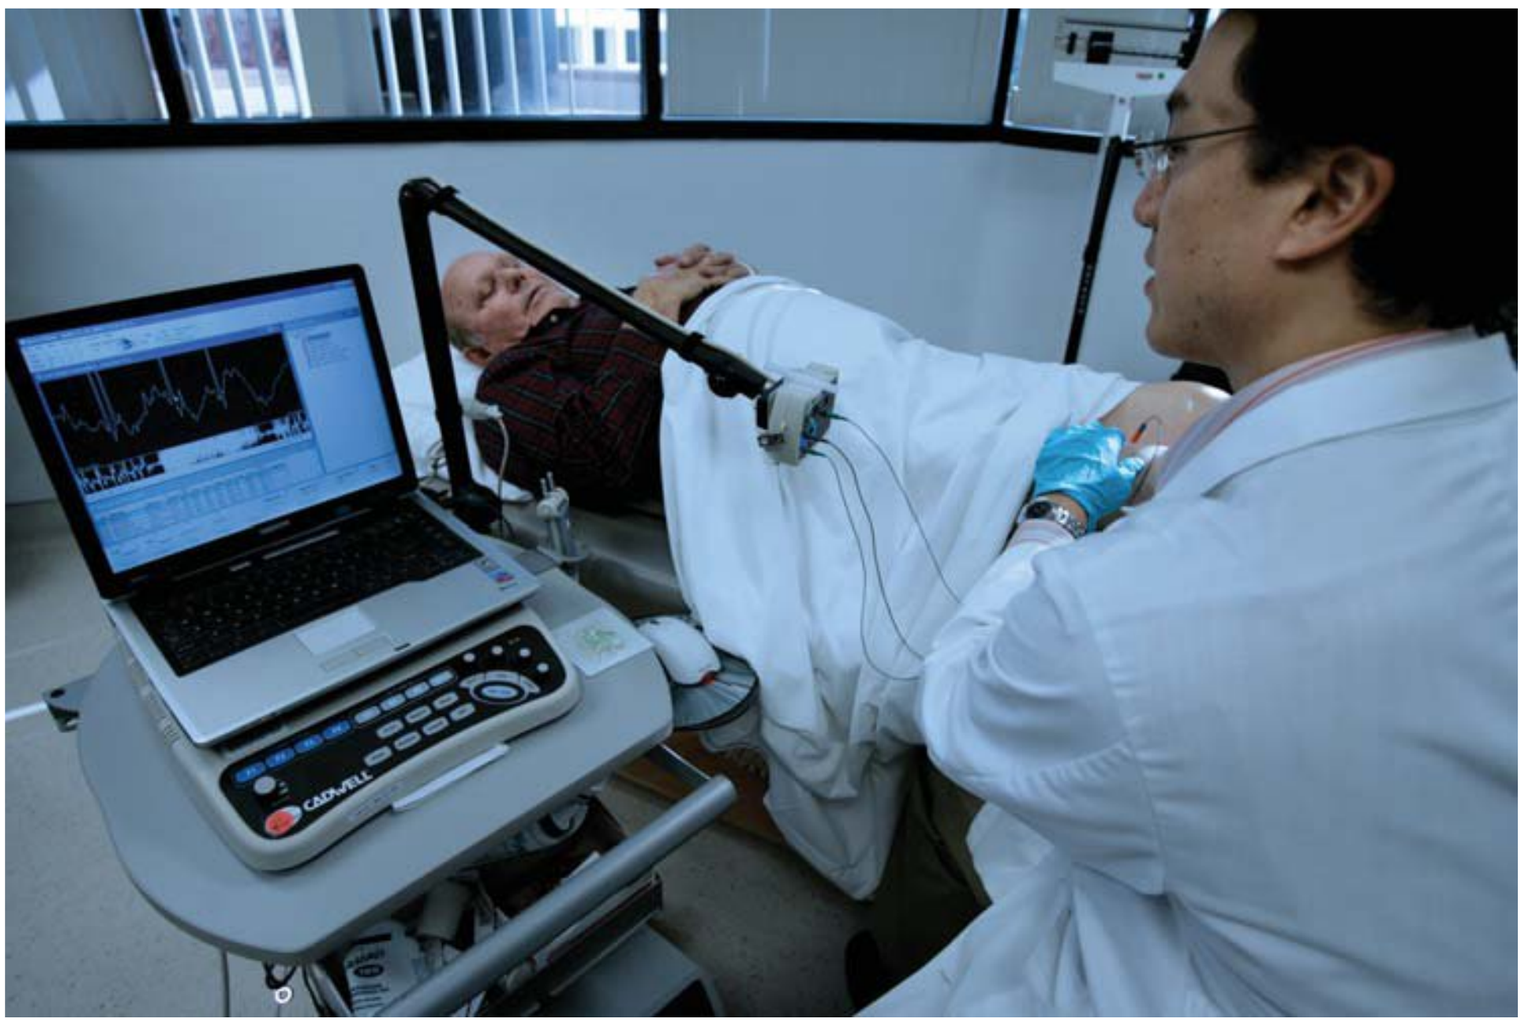

FIGURE 18.1 A typical configuration for an electrodiagnostic study. In this figure, a monopolar electrode (*orange*) is inserted into the right vastus medialis of a subject. On the computer monitor (*left*) appear the motor unit potentials from voluntary muscular contractions. The equipment for a nerve conduction study would vary slightly from this picture; instead of a needle electrode, there would be recording electrodes.

though the term EMG strictly refers to the direct needle examination of muscle, EMG is often used generically to refer to electrodiagnostic studies as a whole. A typical setup is depicted in Figure 18.1.

Nerve conduction studies involve electrical stimulation to evaluate peripheral nerve function. Electrical conduction abnormalities can suggest injury to myelin (from slowed conduction velocity or delayed response), axons (with diminished amplitude response or temporally dispersed waveforms), or the neuromuscular junction (diminished amplitude response with repetitive stimulation). The distribution of abnormalities distinguishes focal from diffuse global processes.

So-called "late responses" are variations of nerve conduction studies. Two common studies are the "H-reflex" and "F-wave." The H-reflex is an electrically measurable analog of the ankle deep tendon reflex. The H-reflex and ankle deep tendon reflex are specific for the S1 monosynaptic spinal reflex arc. In the H-reflex, an electrical stimulus is applied to the tibial nerve behind the knee, which elicits a wave of depolarization that travels proximally on Ia afferents. The wave traverses the spinal reflex arc, synapses on the anterior horn cell, and elicits an efferent volley, causing depolarization of the calf muscle. The H-wave may be delayed or lost bilaterally in large nerve fiber pathology, and unilaterally with unilateral S1 nerve root lesions that may have occurred in the indeterminate past. Therefore it cannot distinguish acute from chronic injury. It will be abnormal with advanced age, tibial or sciatic nerve injuries, and peripheral neuropathies.[7]

F-waves are late responses from the axons of motor neurons in a peripheral nerve as well as the spinal cord. The F-wave may be obtained from practically any muscle, but typically is used to evaluate cervical spinal nerve root function via the median nerve. The clinical utility is not agreed upon,[1] but it may be helpful with three scenarios. These are diabetic neuropathy, Guillain-Barré syndrome, and multifocal motor neuropathy with conduction block. F-waves are usually abnormal in radiculopathies only when significant disease is present. Many practitioners do not suggest routine F-wave studies in the workup of focal entrapment neuropathies such as carpal tunnel syndrome.[1]

Somatosensory evoked potentials (SSEP) measure conduction between a large peripheral nerve and the cerebral cortex or spinal cord. SSEP is sensitive to certain lesions in the central nerve system pathways, such as may occur in multiple sclerosis, spinal cord injury or tumor, and compressive myelopathies. It has poor detection of radiculopathies and the CNS motor pathways.[7]

EMG OVERVIEW

EMG Procedure

Electromyography studies involve insertion of a needle electrode, typically about 23 gauge to 25 gauge in size, into muscle tissue and recording the resultant electrical activity (as seen on the computer monitor in Figure 18.1). The muscle is examined while at rest and during contraction. This provides information about muscle motor unit health and function. Various muscles are examined, and the pattern of pathology seen across all the muscles gives information about the overall disease process.[8] Each muscle is routinely examined in four stages (during initial needle insertion, at rest, and during minimal contraction and maximal contraction). Several findings are described. In the first stage there is insertional activity; in the second stage we look for abnormal spontaneous activity. The third stage evaluates the motor unit potentials (amplitude, configuration, and recruitment). In the fourth stage, the interference pattern is examined.

Stages of the EMG Examination and Typical Findings

Insertional activity is a volley of electrical potentials that is provoked by the initial mechanical irritation of needle insertion and movement. It lasts a few milliseconds. If muscle fibers have degenerated, there are fewer electrically excitable cells available. As a result, there is reduced insertional activity.

Secondly, the electrical activity of the muscle at rest is examined. Normally there should be electrical silence when needle movement ceases. Abnormal spontaneous activity arises from persistent electrical potentials that occur despite the lack of needle movement. It is a sign of unstable muscle membranes. The abnormal spontaneous activity can take the form of fibrillation potentials, positive sharp waves, and complex repetitive discharges

FIGURE 18.2 Involuntary needle electromyography action potentials at rest (negative values are above the baseline). **(A)** Insertion potentials are seen in the first 250 ms of this record. They were produced as the needle sliced through muscle fibers. The insertion potentials are followed by a train of positive sharp waves. A single positive sharp wave is also illustrated. **(B)** Fibrillation potentials. The sharp spikes are seen against a background of positive sharp waves. A single fibrillation potential is also illustrated.

(Fig. 18.2). Spontaneous and benign endplate spikes and endplate noise can also be observed occasionally.

In the third stage, the subject is asked to contract the muscle minimally to study the motor unit potentials (MUP). A muscle motor unit is defined as all the muscle fibers innervated by a single motor neuron (Fig. 18.3). The motor unit potential is the electrical discharge of the contracting motor unit. MUP amplitude, duration, shape, and discharge frequency is recorded (Fig. 18.4).

These parameters are usually commented upon in an electrodiagnostic report and carry clinical implications. The findings can be described as "normal," "myopathic," or "neuropathic." MUP amplitude can be decreased with loss of muscle fibers (e.g., myopathy), axonal neuropathy, or motor neuron disease. It can be increased because of reinnervation with spatially larger motor units (e.g., recovery from neuropathy). MUP duration can be decreased with atrophy of muscle fibers (seen in myopathy), or increased with reinnervation with spatially dispersed muscle fibers (seen in recovery from neuropathy or myopathy).

In the fourth stage, the subject is asked to gradually increase the force of muscular contraction up to maximal effort. The number and firing rates during recruitment are evaluated. With progressively forceful contraction in normal muscle, the recruitment

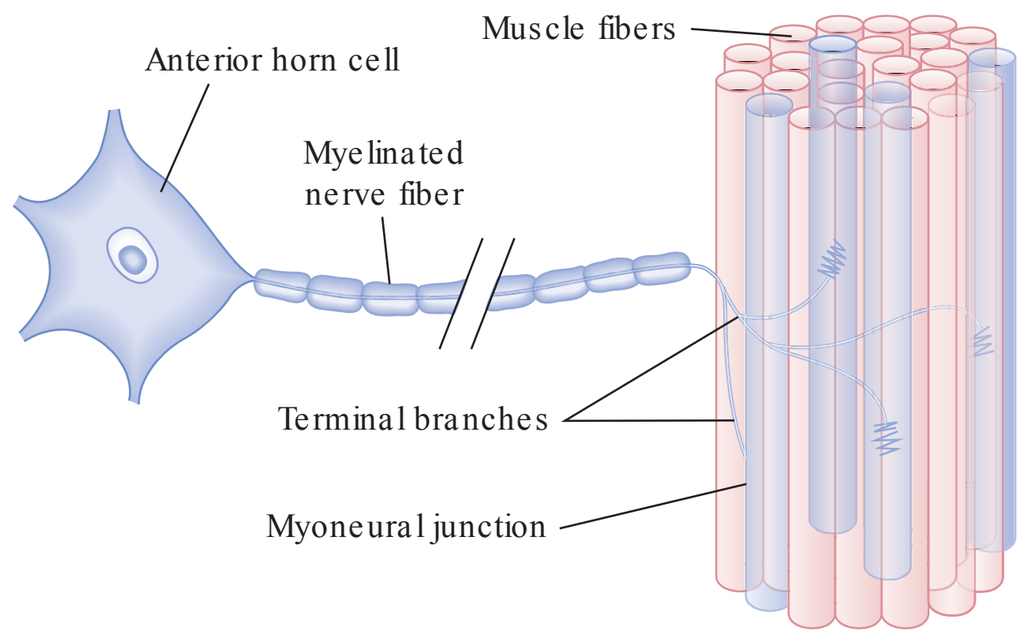

FIGURE 18.3 The components of a single motor unit. The muscle fibers of the unit (*shaded*) are interspersed among fibers of other units. The myoneural junctions are located approximately midway between the ends of the muscle fibers.

FIGURE 18.4 Samples of motor unit action potentials recorded by monopolar needle electrodes. **(A)** Normal triphasic wave. **(B)** Polyphasic (eight phases) wave of longer duration and of similar amplitude. **(C)** Large amplitude potential with a triphasic basic component and a small late component, a satellite potential (*). Note amplitude calibration in **C** compared with that in **A** and **B**.

of muscle fibers follows a pattern: An individual muscle fiber will fire and reach a frequency of 15 to 20 Hz, at which point a second fiber will be recruited. The second fiber will reach a frequency of 15 to 20 Hz and then a third fiber is recruited, and so on.

The actual analysis of recruitment patterns is rather subjective and can be difficult. Modern computerized analysis of the waveforms is helpful, but the whole process also depends on the patient's effort. Because of pain, language, comprehension, or personal motivation level, the patient may not be able to comply with the instructions to provide a slow and progressively forceful contraction while a needle electrode is embedded in the muscle belly. Maximal contraction in normal muscle reveals the discharge of many MUPs, which flood the screen. The interference pattern at maximal contraction is evaluated subjectively from the observed density of electrical spikes, along with their amplitude, frequency, and sound.

In disease states, there are characteristic patterns of firing, recruitment, and interference that suggest either muscle denervation (neuropathies) or muscle fiber destruction (myopathies). Neuropathic disease processes denervate the motor unit acutely. This is followed by re-innervation from collateral sprouting of nearby surviving motor units. As a result, the motor units become bigger because the fewer surviving neurons assume control over more and more of the muscle fibers. When the bigger motor units fire, there is an observable pattern of muscle fiber recruitment that is termed a "neurogenic" recruitment pattern. This is also called "decreased recruitment" or "reduced recruitment." There are decreased numbers of MUPs, firing later at increased rates, in order to meet the force demanded of the muscle.

On the other hand, the so-called myopathic recruitment pattern (also called "early" or "increased" recruitment) comes from the fact that insufficient force is generated by any given motor unit, and additional motor units are recruited earlier or more rapidly than expected. The observation is that there are too many motor units firing for the amount of contraction requested. There is an increased number of MUPs, firing faster, and earlier in the myopathic disease state.

Summary of EMG Findings

The EMG findings in upper and lower motor neuron disorders and myogenic lesions are summarized in Table 18.1, which was adapted from Kimura.[2] The exact findings seen in a given subject depend on the disease process itself, as well as the timing of the electrodiagnostic exam in relation to the disease process. In normal muscle, there is brief insertional activity, no spontaneous activity, motor unit potentials (MUPs) of 0.5 mV to 1.0 mV and 5 msec to 10 msec duration, and full interference pattern.

In neuropathic lesions, the EMG findings show normal to increased insertional activity, normal (silent) to abnormal spontaneous activity (with positive sharp waves and/or fibrillation potentials), MUPs that are normal to large amplitude with increased duration, complex configuration, and limited recruitment. During maximal contraction (stage 4) there is a reduced interference pattern.

In myopathic lesions, the EMG findings show normal to increased insertional activity and sometimes there are myotonic discharges. There can be normal (silent) to abnormal spontaneous activity (with positive sharp waves and/or fibrillation potentials). The MUPs have small amplitudes with early recruitment and myotonic discharges may be seen. The interference pattern is full but of low amplitude.

NERVE CONDUCTION STUDIES OVERVIEW

The intraneural anatomy of the nerve fiber gives our bodies a functional reserve that protects us against catastrophic loss with partial nerve injuries. The peripheral nerves are similar to insulated cables, and are composed of individual nerve fibers traveling together in bundles, called fascicles. However, the internal organization of the peripheral nervous system is unlike a cable, and does not have the somatotopic organization seen in the brain and spinal cord of the central nervous system. In the peripheral nervous system, the fascicles exchange nerve fibers in an interwoven course along the nerve (see Fig 18.5).[6] Therefore, a partial nerve injury in the peripheral nervous system does not result in a Brown-Sequard–like scenario that might result from a partial injury in the central nervous system spinal cord. In the peripheral nervous system, a partial nerve injury will often result in partial function of most muscles because of spared fascicles. Furthermore, each of the nerves distal to the injury will have at least some abnormality that will be detectable. It is the intraneural

TABLE 18.1

TYPICAL EMG FINDINGS SEEN IN NORMAL, NEUROGENIC, AND MYOGENIC LESIONS

EMG Stage	Normal	Neuropathic lesion	Myopathic lesion
1. Insertional activity	Normal (brief)	Normal–increased	Normal–increased Myotonic discharges
2. Spontaneous activity	Normal (silent)	Normal (silent) Fibrillation potentials Positive sharp waves	Normal (silent) Fibrillation potentials Positive sharp waves
3. Motor unit potentials	0.5–1.0 mV amplitude 5–10 msec duration Normal recruitment	Normal to large amplitude Normal to increased duration Normal to limited recruitment	Small amplitude Early recruitment Myotonic discharges
4. Interference pattern	Full	Reduced	Full Low amplitude

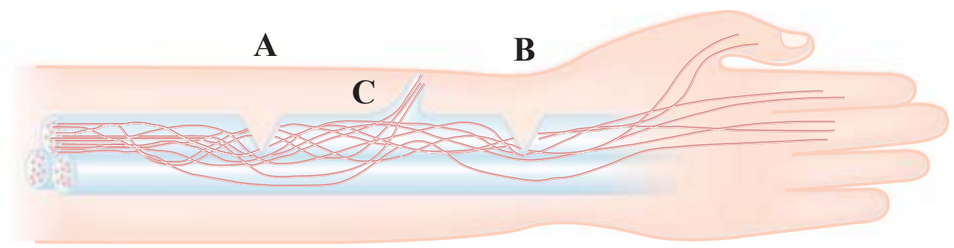

FIGURE 18.5 Typical mammalian nerve, involving the movement of axons from one fascicle to another during their course. Here lesions at A and B may be easily distinguished electromyographically by the fact that lesion A produces changes in the distribution of branch C, whereas the lesion at B does not. (Redrawn from Pease WS, Lew HL, Johnson EW. *Johnson's Practical Electromyography*. Philadelphia: Lippincott Williams & Wilkins; 2007.)

anatomy that permits partial function after a nerve injury and allows electrodiagnostic studies to pinpoint a lesion.

Nerve conduction studies test the integrity of the peripheral nervous system, both sensory and motor. The techniques are standardized, and there are banks of reference data.[8] Reference data are established in age-matched normals without neurological complaints. However, subjects at the extremes of age or limb size may not fall within these norms. In these cases, the sensitivity of NCS can be increased if a contralateral asymptomatic limb is used for the control.[6]

In motor nerve testing, the peripheral nerve is stimulated by passing electrical currents through the skin to produce synchronized muscle contraction "downstream," or distally. The motor response is recorded with surface recording electrodes (Fig. 18.6) placed over the muscle being studied. The recording is referred to as a compound motor action potential (CMAP), with the key parameters being onset latency and amplitude. Latency is the time between the stimulus and observed response. It measures conduction in the fastest nerve fibers. Amplitude (and area) is a result both of the total number of fibers conducting electrical signal and their degree of synchrony (see Fig. 18.7). Conduction velocity of a nerve is determined by measuring the distance between two stimulation sites along the course of a nerve, and comparing the latency measurements. Surface stimulators consist of two electrodes placed 1.5 to 3.0 cm apart (Fig. 18.8).

Sensory nerve testing involves techniques and analysis similar in concept to motor testing, although there are a few differences. The electrodes come in different shapes and forms (see Fig. 18.8). Sensory nerves may be tested in an antidromic fashion, stimulating the nerve proximally and recording a response distally (Fig. 18.9). They may also be tested in an orthodromic fashion, stimulating the nerve distally and recording the response proximally. The response from either technique is referred to as a sensory nerve action potential (SNAP).

Neural pathology may be identified by examining the CMAP and SNAP parameters (Fig. 18.10). In general, demyelinative neural pathology will lead to prolonged latency measurements and slowed conduction velocity. A long demyelinated nerve segment will have conduction velocities less than 20 m/second.[6] On the other hand, with axonal pathology there is no slowing of conduction in individual fibers. Instead there is loss of axons, which results in decrements of the CMAP amplitude. In actuality, many disease states, such as a compression neuropathy, will result in a combined demyelinative, axonal loss picture of varying proportions. Also, if the pathology is severe, absent responses can occur with either process.

Pathology of the myelinated neuron comes in three patterns: conduction slowing, segmental conduction block, and full-length conduction loss. Conduction slowing can be seen in demyelination, remyelination, and reinnervation. Conduction block occurs at a specific location along the nerve. It is frequently caused by local trauma, ischemia, autoimmune, metabolic, or vascular disease. Axons are spared, and the segments above and below the lesion will conduct signals normally.

Axon loss occurs in various disease states and injuries. Many diseases result in partial axon loss. Some examples include diabetic neuropathy, vitamin E deficiency, alcoholic neuropathy, chronic renal failure with uremia, and hereditary neuropathies such as Charcot-Marie-Tooth disease. Complete axon loss, following a stab wound, for example, results in a characteristic pic-

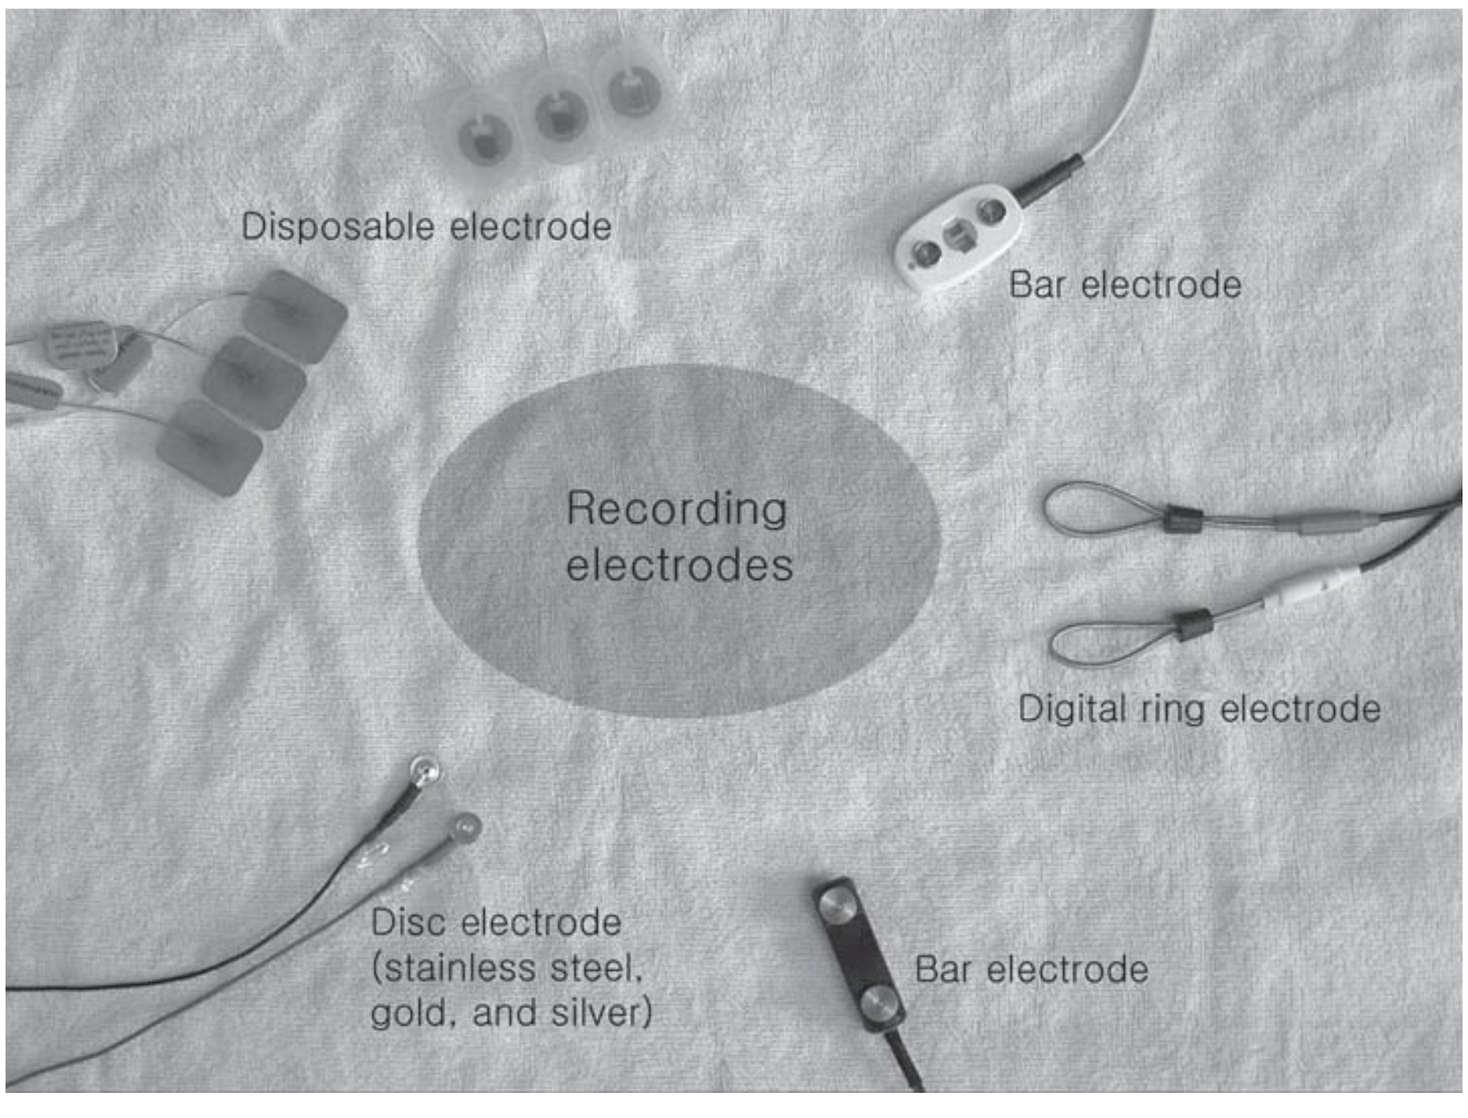

FIGURE 18.6 Different types of surface recording electrodes. (From LeeHJ, DeLisa JA. *Manual of Nerve Conduction Study and Surface Anatomy for Needle Electromyography*. Philadelphia: Lippincott Williams & Wilkins; 2005.)

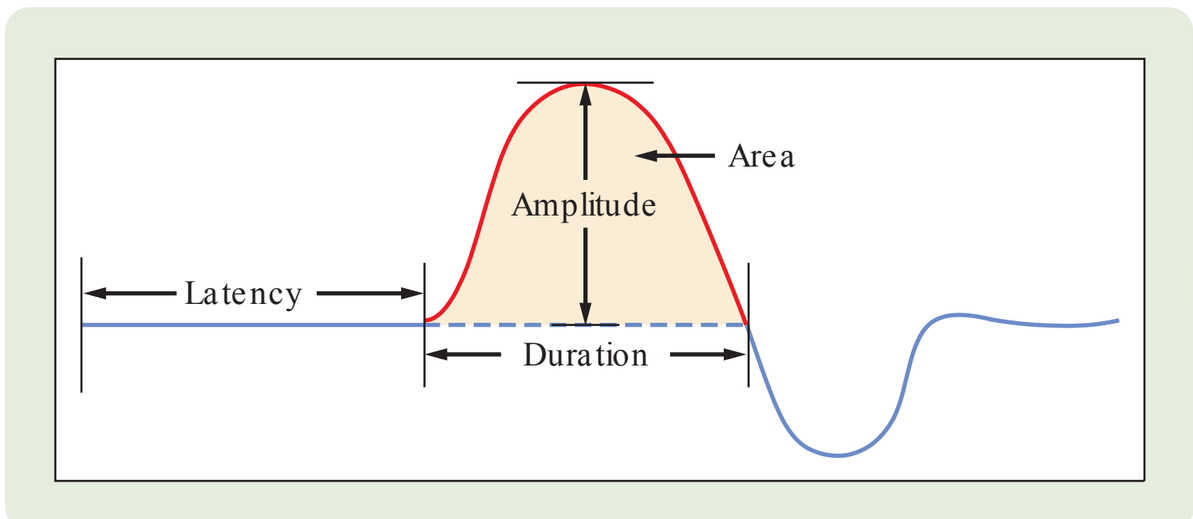

FIGURE 18.7 CMAP parameters. (Redrawn from Lee HJ, DeLisa JA. *Manual of Nerve Conduction Study and Surface Anatomy for Needle Electromyography*. Philadelphia: Lippincott Williams & Wilkins; 2005.)

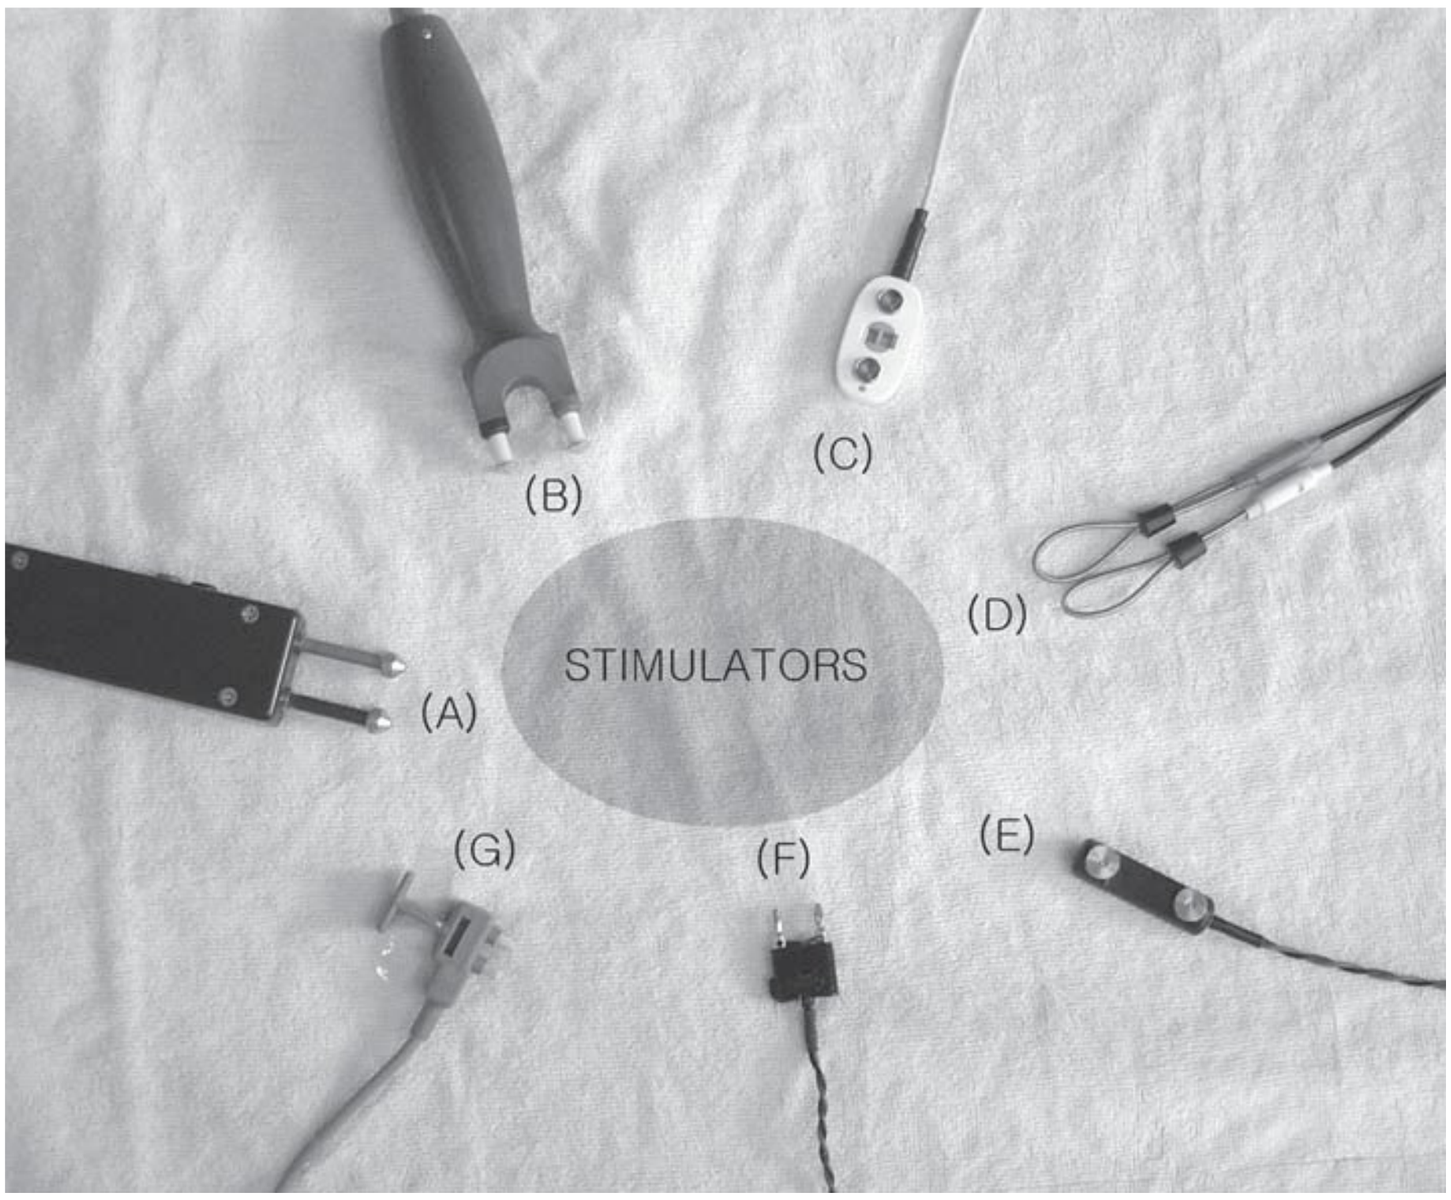
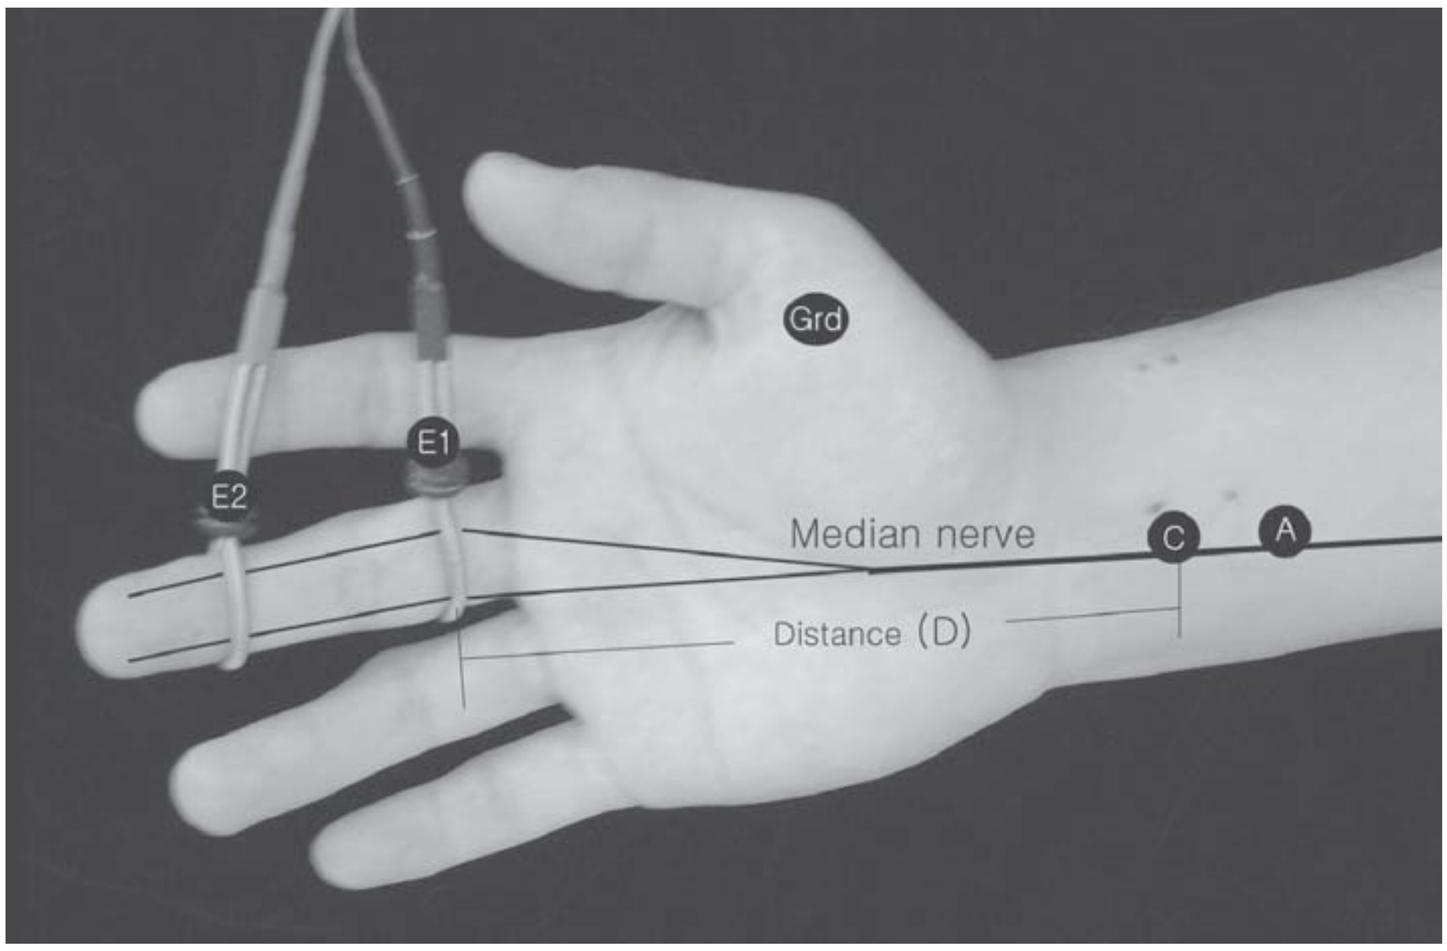
ture. For 3 to 7 days after complete axonal injury, the distal nerve will continue to conduct because there are enough stored materials and energy sources for independent function.[6] After this period, the conduction of the distal nerve will fail completely because of neural dissolution, a process known as Wallerian degeneration.

Regeneration of the injured distal nerve segments can occur as long as the nerve cell body is intact. Additionally, there must be some connective tissue integrity about the nerve fiber to provide a permissive environment and conduit for regeneration. In a frankly severed nerve, surgical approximation is required to permit regeneration. After interruption of the axons, the cell body requires about a month before regeneration occurs. Thereafter, the regrowth occurs at a rate of an inch per month. Motor nerves may then require yet another month after the regenerating nerve establishes connection to the muscle in order to establish new myoneural junctions.

PATIENT PREPARATION

The patients should be placed in the most comfortable position possible on an exam table or chair, with pillows and blankets. To reduce anxiety and fear of pain, provide an opportunity to counsel and educate the patients about the procedure. Expose the area to be studied and clean the skin with an alcohol pad. It is helpful to inform patients not to use heavy lotions or creams on their skin. An important environmental factor is temperature, to the extent that every EMG report should report the skin temperature among the test data. The patients must be kept warm to avoid temperature artifacts in the study. Cool limbs will result in slowed nerve conduction and latency measurements, and increased amplitudes. This may have nothing to do with any neural pathology. A wrist temperature of 32° C and ankle temperature of 29° C is considered standard. Many laboratories have warmer requirements. Temperature regulation can be accomplished with





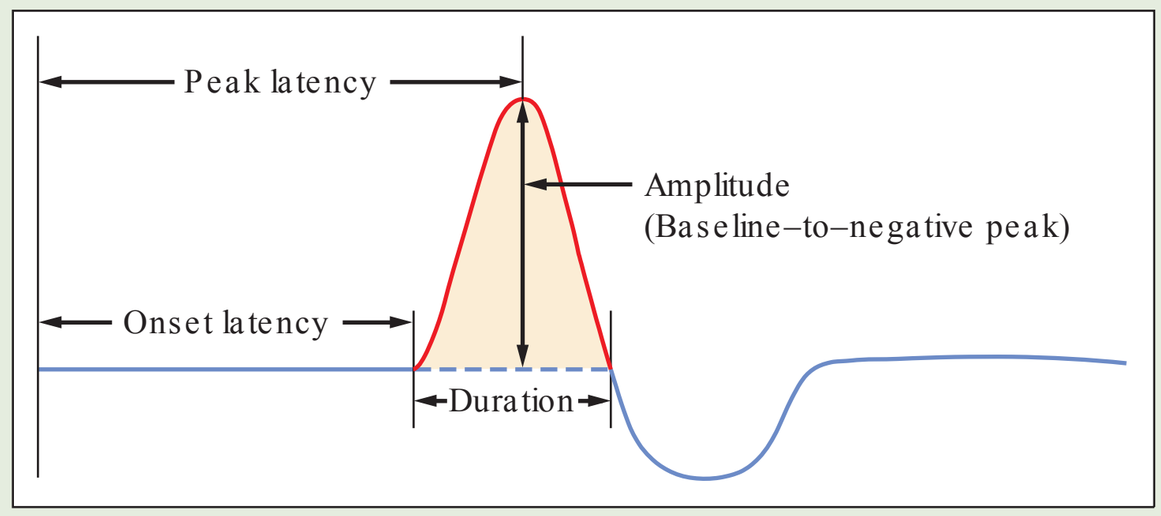


FIGURE 18.8 Different types of stimulators. (From Lee HJ, DeLisa JA. *Manual of Nerve Conduction Study and Surface Anatomy for Needle Electromyography*. Philadelphia: Lippincott Williams & Wilkins; 2005.)

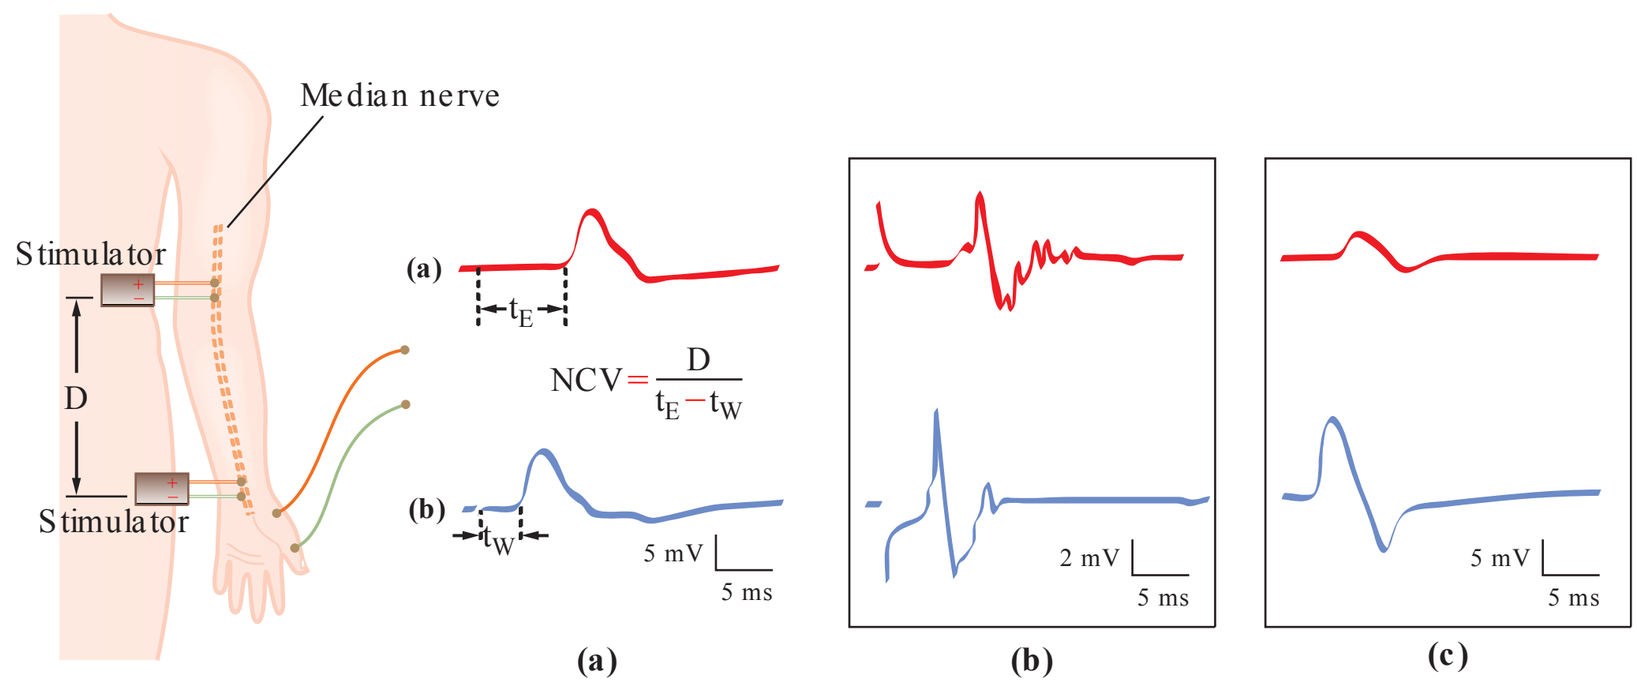

FIGURE 18.10 Schematic representation of the determination of median nerve motor conduction velocity (NCV) from the elbow to wrist, illustrating three different types of responses: t_E and t_W are the latencies from time of stimulation to time of onset of response of the muscle, from elbow and wrist stimulation, respectively. *D* is the distance between the two points of stimulation. (**A**) A normal response. Note that the amplitude of the response from the elbow and wrist stimulations are essentially equal, as are the wave shapes. (**B**) Temporal dispersion associated with segmental demyelination. Note the smaller amplitude of the response on elbow stimulation compared with stimulation at the wrist, as well as distortion of the wave when the elbow response is compared with the wrist response. (**C**) Partial neurapraxic block between the two points of stimulation. Note the much smaller response from elbow stimulation without distortion of wave form when compared with the response on wrist stimulation.

a combination of heating pads, blankets, and heat lamps. Sometimes a patient can be asked to exercise or drink hot beverages. Last, temperature correction factors exist to normalize the electrophysiologic data obtained from suboptimal studies.[1,8]

SPECIAL CONSIDERATIONS

For patients, the EMG experience is generally an uncomfortable one. Perception of pain is affected by various psychological factors (advice from friends, fear of needles, sound emanating from the medical instrumentation speaker, unfamiliarity with the test). Certainly, the puncture of skin by the electrode and movement through the tissue fascia contributes most of the pain. Some areas are more painful than others; the most painful are the cervical and lumbosacral paraspinal muscles and the hand intrinsics. Concentric needles, favored by electrodiagnosticians trained in neurology, are more painful than the monopolar, Teflon coated needles, favored by those trained in the field of physical medicine and rehabilitation. Rarely, a short-acting benzodiazepine may be required for anxious patients.

There are no absolute contraindications to a focused EMG exam, but the risk–benefit ratio should be weighed. Relative contraindications include bleeding risk in patients with mild thrombocytopenia, whose platelet counts are below 50,000/mm.^{3} In patients with anticoagulation there are some special considerations. Coumadin should be stopped 3 days prior to the needle exam. A follow-up check of serum coagulation parameters is usually not necessary. Treatment dose, subcutaneous low molecular weight heparin should be stopped 12 hours prior to the study. Other strategies include gentle use of a small EMG needle (e.g., 30 gauge) and being selective about which muscles to test (avoiding deep muscles that are difficult to manually compress or muscles that are near vital blood vessels or nerves). No particular precaution is needed with patients on prophylactic heparin or other medications such as aspirin, clopidogrel, and nonsteroidal anti-inflammatory medications.[9]

Pneumothorax is a rare but potentially catastrophic complication of EMG studies. Some caution should be used when studying the muscles of the shoulder girdle (e.g., serratus anterior, supraspinatus, rhomboid) and paraspinals near the cervicothoracic junction.

With regard to NCS examinations, there are precautions advised in patients with implanted pacemakers and cardioverter-defibrillators. There are no known complications of nerve conduction studies in patients with regular, implanted pacemakers.[9] General guidelines suggest that NCS studies be performed more than 6 inches away from the pacemaker, using a stimulus duration of 0.2 ms or less, and a stimulus rate less than 1 Hz. For patients with an implantable automatic cardioverter-defibrillator, there is a greater theoretical risk and a consultation with a cardiologist is recommended. One option is to deactivate the device and provide cardiac monitoring during the study.[9]

The only other medication consideration is stopping the use of pyridostigmine in patients being tested for a neuromuscular junction disease such as myasthenia gravis or Lambert-Eaton syndrome.

Last, after the needle EMG examination, a patient's serum creatine phosphokinase (CPK) may be mildly elevated for up to 3 days. This may affect the workup for myopathy.

PATHOLOGICAL CONDITIONS

The EMG-NCS examination can provide diagnostic information to help clarify the diagnosis. It is useful in several situations, such as radiculopathy, focal nerve entrapment syndromes, trauma, and peripheral neuropathies due to such conditions as diabetes, hypothyroidism, or alcohol abuse. It is vital for the diagnosis of other conditions such as neuromuscular junction disease (e.g., myasthenia gravis, Lambert-Eaton syndrome, botulism), neuropathies (e.g., Guillain-Barré syndrome, amyotrophic lateral sclerosis), and myopathies (e.g., the inheritable dystrophies and inflammatory myositis conditions). Although pain management clinicians need to be mindful of these important conditions, these diseases are not regularly encountered in a typical pain management practice. Therefore, for the sake of brevity, the ensuing discussion will not focus on these conditions. Only a brief summary will be presented at the end of the section. Further details are described in common neurology and electrodiagnostic medicine texts.[1,2,3,4,5,6]

Radiculopathies

With many patients suspected of having a radiculopathy, there is little practical value from electrodiagnostic testing. This is the case for a younger patient with a consistent history of radicular pain, a neurological exam with focal deficits, and advanced radiological images showing spinal stenosis at the appropriate neurological level. However, many patients do not have such a tidy presentation. With a more complex presentation, electrodiagnostic testing is extremely valuable. This is not an uncommon presentation: an older patient with confounding past medical (e.g., diabetes) and surgical (e.g., carpal tunnel release) history, scattered neurological exam findings, and spine imaging with various stages of degenerative change identifiable at several levels.

The electrodiagnostic nerve conduction findings in a radiculopathy are explainable with an anatomic discussion (see Fig. 18.11). Spinal radiculopathies usually involve stenosis of the spinal nerve roots at a location that lies proximal to the dorsal root ganglion (DRG). The peripheral nerve cell bodies of the sensory neurons reside in the DRG and send their nerve fibers distally. Usually in the case of a radiculopathy, there are normal sensory nerve conduction studies because of this anatomy. (The site of stenosis is proximal to the entirety of the sensory nerve cell bodies and tracts.) In contrast, motor nerve function can be compromised in cases of severe radiculopathy. The site of stenosis may impact the spinal cord anterior horns, which affect the motor nerve cell bodies and result in axon loss in the motor nerve fiber tracts. This loss can appear with amplitude loss in the motor nerve conduction studies. For example, a severe L5 radiculopathy could result in decreased CMAP amplitude in the deep peroneal nerve conduction studies to the extensor digitorum brevis. In general, however, radiculopathies do not result in observable abnormalities in the nerve conduction studies.

Needle EMG exam is a very specific investigation in cases of radiculopathy, with poor sensitivity. The EMG diagnosis of an acute or subacute radiculopathy depends on the observation of abnormal spontaneous activity, with positive sharp waves and fibrillation potentials. Such spontaneous activity should be seen in two peripheral muscles that share the same nerve root origin, but are innervated by different peripheral nerves. An example involves the abducens pollicis brevis (APB) and first dorsal interosseus (1st DI) muscles of the hand. Both of these muscles originate from the C8 and T1 nerve roots. However, the APB is innervated by the median nerve, whereas the 1st DI is innervated by the ulnar nerve. The diagnosis of acute radiculopathy can also be made with the observation of abnormal spontaneous activity in one peripheral muscle and one proximal trunk muscle, such as the paraspinal muscles. An example would be the APB and the lower cervical spine multifidus muscles. Nerve root innervation of the muscles has some degree of individual anatomical variation. Nevertheless, there are commonly accepted tables to guide the electromyographer (see Table 18.2). A reasonable radiculopathy screen should involve at least five muscles in an affected limb, with consideration for the proximal trunk musculature as well.[10]

The needle EMG examination does not have good sensitivity,

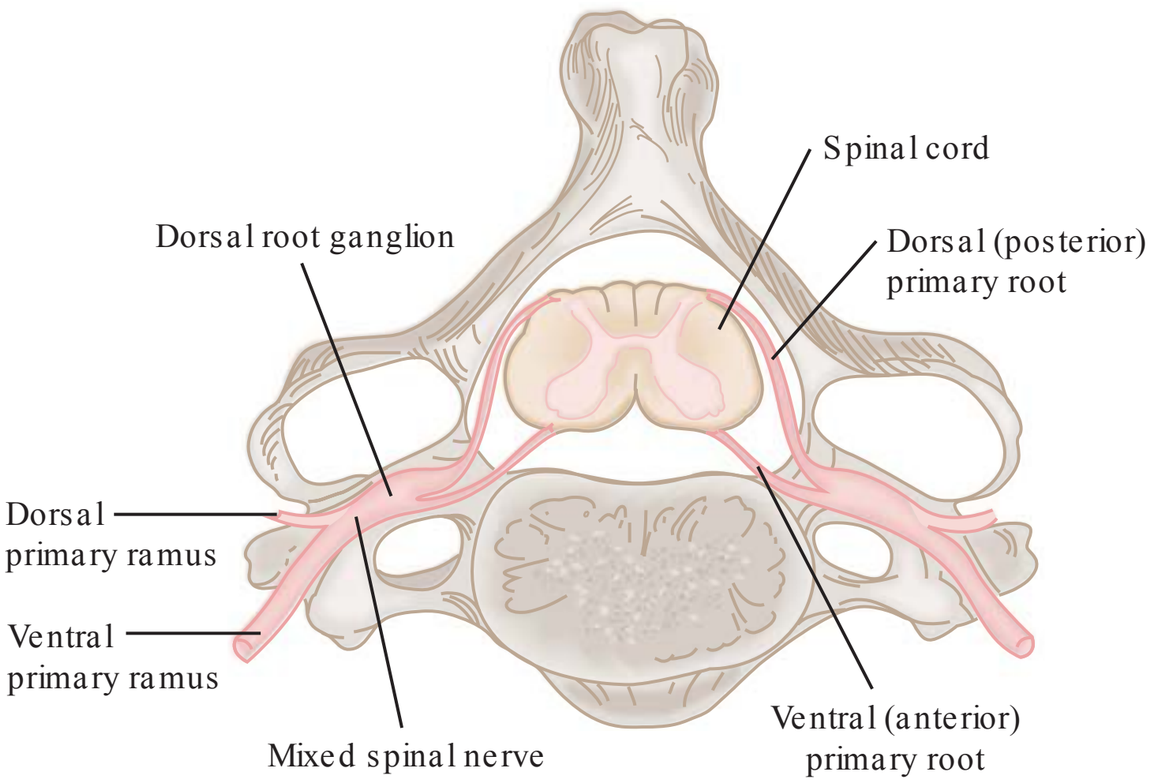

FIGURE 18.11 Relationship between the spinal cord, roots, and the ventral and dorsal rami. Note that the dorsal root ganglion is at the intervertebral foramen. (Redrawn from Pease WS, Lew HL, Johnson EW. *Johnson's Practical Electromyography*. Philadelphia: Lippincott Williams & Wilkins; 2007.)

and an exam that does not uncover abnormal spontaneous activity should not be taken as evidence that the patient is not suffering from a radiculopathy. There are several reasons why a needle EMG exam might not show muscle abnormalities in the presence of a true radiculopathy. A false negative result can arise from sampling errors. For example, there are several L5 innervated muscles to examine with a needle electrode. The electromyographer may choose to examine the peroneus longus (L5) and anterior tibialis (L4, L5) muscles, but the muscle abnormalities could be limited to the flexor digitorum longus and medial head of the gastrocnemius (L5, S1). There may not be representative muscle groups to sample; for example, in a C3 radiculopathy. Furthermore, a given muscle should be sampled with a needle placed in four or five different locations within the muscle. The ability of the patient to cooperate (by keeping relaxed during an uncomfortable needle exam) can introduce muscle noise artifacts that make it difficult to see or hear subtle spontaneous muscle activity. The timing of the EMG needle exam can also affect results. Abnormal spontaneous activity disappears with time even though clinical symptoms persist. The likelihood of false negative exams increase with cervical spine radiculopathies lasting longer than 6 months, and with lumbosacral radiculopathies lasting longer than 12 to 18 months.[10,11] Proximal muscles heal faster than distal muscles, and false negative results are more likely in a high cervical or high lumbar radiculopathy than with a radiculopathy affecting a lower nerve root.

False-positive examinations are rare. The false-positive problem arises from the diagnosis of a radiculopathy, when there is actually a more systemic problem such as a polyradiculopathy, plexopathy, or motor neuron disease. The false-positive problem comes either from a deficient study (not sampling enough muscles during EMG or performing adequate NCS), or from testing too early in the disease process before widespread findings are apparent.

TABLE 18.2

REPRESENTATIVE MUSCLE NERVE ROOT AND PERIPHERAL NERVE INNERVATION

Muscle	Spinal cord level	Peripheral nerve
Upper limb		
Supraspinatus	C5, C6	Suprascapular
Deltoid	C5, C6	Axillary
Biceps brachii	C5, C6	Musculocutaneous
Brachioradialis	C5, C6	Radial
Pronator teres	C6, C7	Median
Triceps brachii	C6, C7, C8	Radial
Extensor indicis proprius	C7, C8	Radial
Abductor pollicis brevis	C8, T1	Median
Dorsal interossei	C8, T1	Ulnar
Abductor digiti minimi	C8, T1	Ulnar
Lower limb		
Adductor longus	L2, L3, L4	Obturator
Vastus medialis	L2, L3, L4	Femoral
Anterior tibialis	L4, L5	Deep peroneal
Gluteus medius	L4, L5, S1	Superficial gluteal
Peroneus longus	L5, S1	Superficial peroneal
Flexor digitorum longus	L5, S1	Tibial
Biceps femoris short head	L5, S1	Sciatic (peroneal)
Gastrocnemius	S1	Tibial

Entrapment Syndromes

Carpal Tunnel Syndrome (CTS)

A common nerve entrapment scenario is carpal tunnel syndrome, which results from compression of the median nerve under the transverse carpal ligament, which provides the "roof" of the carpal tunnel in the palmar wrist. This may result in a median nerve neuropathy. The clinical scenario is well described. Patients may complain of pain, numbness, and tingling of the entire hand or in a distribution limited to the median nerve dermatome. Radiation of symptoms into the forearm is not uncommon. Nocturnal exacerbation is typical, when it is presumed that the wrist is held in extreme flexion or extension during sleep. Predisposing factors include previous Colles' fracture, rheumatoid arthritis, diabetes, gout, pregnancy, thyroid conditions, multiple myeloma, and tuberculosis. However, most patients are otherwise healthy. On physical exam, the symptoms may be exacerbated by tapping on the carpal tunnel of the wrist (Tinel's sign) or by prolonged wrist flexion (Phalen's sign). Patients may also complain of neck pain. Clinical series do demonstrate some increased association between cervical spine degenerative disease, ulnar nerve pathology

at the cubital tunnel, and median nerve pathology at the carpal tunnel.[5] Thus, an electrodiagnostic examination is helpful to determine which factors may be contributing most to a patient's symptomatology.

Carpal tunnel syndrome is fundamentally a clinical diagnosis. In the syndrome, electrodiagnostic studies will demonstrate conduction abnormalities of the sensory and/or motor nerve branches of the median nerve only. In mild cases, abnormalities of the sensory nerve SNAPs will precede abnormalities of the motor nerve CMAPs, although the reverse may occur. If the SNAPs are recorded between the wrist and digits, an abnormality may not be localized to the wrist. The abnormal SNAPs could also be the result of proximal compression (e.g., pronator teres syndrome) or a diffuse neuropathy. Any of these conditions would produce distal abnormalities. A better localizing feature would be slowing of the CMAP distal latency, and normal forearm conduction velocity. In severe cases, slowing of the median motor nerve conduction velocity is seen in the forearm. This slowing, occurring proximal to the wrist, may be due to retrograde changes in the nerve. Severe cases of carpal tunnel syndrome may demonstrate axonal loss in the distal median nerve innervated muscles (i.e., abducens pollicis brevis [APB]).

For these reasons, CTS evaluation should include sensory and motor nerve conduction studies of both the ulnar and median nerves. The sensory exam of choice is *antidromic*, meaning the electrical stimulus is applied proximally on the median nerve and the recording is made distally. If this exam is "normal," a short segment *orthodromic* sensory exam is indicated because the orthodromic studies have less likelihood of false negative results with higher sensitivity.[12] With regard to the ulnar nerve, electrodiagnostic studies show that 15% to 40% of patients with CTS also have objective evidence of ulnar nerve dysfunction.[1] The likely explanation is that many CTS patients may have a predisposition to multiple entrapment neuropathies, or a more generalized peripheral neuropathy.

Last, the CTS evaluation should also include needle exam of the APB to determine the presence of axon loss. The needle EMG exam is less sensitive than NCS in the evaluation of CTS, because the pathology is mainly demyelination. (Demyelinative processes affect the sensory nerve responses with slowing and prolongation of the SNAP latency.) The needle exam is usually not too revealing in most CTS cases until late in the disease. If there is evidence of membrane instability in the APB, then it is important to sample another C8–T1 innervated muscle to evaluate for a cervical radiculopathy. The first dorsal interosseus muscle is a good muscle to sample because it is a C8–T1 muscle innervated by the ulnar nerve. Also, needle sampling of C6–C7 innervated muscles (e.g., pronator teres or flexor carpi radialis) can be helpful, because C6 and C7 radiculopathies commonly present with thumb and hand pain. Last, 11% of patients with CTS have a concomitant cervical radiculopathy,[1] a phenomenon termed "double crush syndrome."

Several schemes have been established to diagnose and rate the severity of carpal tunnel syndrome.[1] However, there are no universally accepted criteria or standards. The diagnosis is fundamentally a clinical decision. The severity can be rated with electrodiagnostic findings according to one scheme[1] as mild (median sensory nerve abnormalities), moderate (median sensory and motor nerve abnormalities), and severe (median sensory and motor nerve abnormalities, along with needle EMG abnormalities). A reasonable treatment approach could utilize splinting for mild cases, splinting and steroid injections for moderate cases, and surgery for severe cases.

Case example: A 56-year-old female with mild central canal stenosis at C3–C4 and C5–C6, with moderately severe right C5–C6 neuroforaminal stenosis (Fig. 18.12) was treated with three cervical epidural steroid injections during the course of a year. The shots were mildly helpful in treating her bilateral hand and forearm pain. Because of the muted benefit of epidural injections, an electrodiagnostic study was ordered.

FIGURE 18.12 Sagittal T-2 image of the cervical spine, showing multilevel degenerative disk disease with mild central canal stenosis at C5–C6 and C3–C4. Axial images (not shown) demonstrate moderate to severe right neuroforaminal stenosis at C5–C6.

Evaluation of the left median nerve compound motor action potential (CMAP) had normal amplitude with decreased latency and normal conduction velocity across the forearm. The right median nerve CMAP had decreased latency, amplitude, and conduction velocity. These results demonstrated a bilateral median nerve sensorimotor mononeuropathy. On the left there was evidence of demyelination, on the right there was evidence of demyelination with axon loss. Both sides are consistent with a diagnosis of moderate carpal tunnel syndrome. The EMG exam refocused the treatment plan.

Traumatic Syndromes

Trauma can cause a nerve injury in just about any part of the body. Some of the more common scenarios are presented in Table 18.3, adapted from Liveson.[5] Nerve resection can occur with fractures or penetrating injuries. Traction injuries are commonly seen with dislocations or vaginal and obstetrical procedures. Compression injuries may result from blunt trauma, hematomas, compartment syndromes, or positioning issues during surgery.

During the acute phase (within 4 weeks of injury), the electrodiagnostic exam is used to identify injury location, the possibility of muscle paralysis, and nerve continuity. It can be important in the acute phase to identify outright nerve injury, as opposed to pain inhibited function or cognitive impairment (e.g., an obtunded patient). If no volitional motor activity is observed with the needle EMG exam, then there is no nerve conduction to the muscle. This could be because of complete severance of the nerve, or temporary conduction block (neurapraxia). If some motor unit potentials are seen, then there is neural continuity to the muscle. Nerve conduction studies give information about neural transmission.

In the chronic phase, the needle EMG becomes very useful. If nerve transaction or axon death exists, then there will be observable membrane instability with abnormal spontaneous activity. The nerve interruption is complete if membrane instability is present and no voluntary motor unit potentials are present. The location of the injury can be identified by strategically examining muscles along the course of a particular nerve. In the chronic

TABLE 18.3

ANATOMIC SITES SUSCEPTIBLE TO TRAUMATIC NERVE INJURY

Traumatic event	Vulnerable nerve
Upper limb	
Penetrating neck wound, traction injury at birth	Brachial plexus
Shoulder dislocation, intramuscular injection	Axillary
Humerus (spiral groove) fracture, pressure	Radial
Elbow subluxation, fracture, dislocation	Ulnar
Humerus, elbow, radioulnar joint fractures	Median
Lower limb	
Regional anesthesia (femoral block)	Femoral
Hip, pelvic fracture	Sciatic (peroneal > tibial)
Knee injuries	Peroneal
Ankle fractures	Tibial, peroneal

phase, nerve conduction studies permit the distinction between temporary conduction block and complete axon interruption. Serial examinations over time can document interval progress and healing.

Peripheral Polyneuropathies

There are many different types of acquired peripheral polyneuropathies involving infectious, toxic, metabolic, pharmacologic, hereditary, auto-immune, nutritional, systemic illness–related, malignant, and endocrine disorders.[13] Most polyneuropathies cause distal, symmetrical weakness and/or sensory loss. The sensory deficit is frequently most severe in the distal extremities (“stocking-glove” distribution). Occasionally, a polyneuropathy will preferentially affect the proximal limbs. The disorder may present over a variable time course, and the predominant neurological deficit may involve motor, sensory, autonomic, or combinations thereof.

Leprosy

Leprosy (Hansen disease) is the most common cause of polyneuropathy worldwide. In this disease, *mycobacterium leprae* invades Schwann cells, endoneurium, and perineurium. Three manifestations of the disease are recognized: lepromatous, borderline, and tuberculoid. The host’s immunologic status determines which form of the disease develops. Patients may develop generalized symmetric sensorimotor polyneuropathies, mononeuropathies, and mononeuropathy multiplex.[1]

Diabetic Neuropathy

The most common cause of neuropathy in the United States is diabetes.[6] The common etiology involves chronic hyperglycemia; however, there appear to be diverse causes. The precise mechanism is not known, but direct axonal injury due to hyperglycemia, autoimmune injury with antineural antibodies, and increased intraneural pressure and ischemia seem to be contributing factors.[14] Additionally, patients with renal failure independent of diabetes develop a sensorimotor neuropathy due to uremia. About half of the patients with diabetes have a distal symmetric polyneuropathy. It is most common in patients older than 50 years. Patients experience sensory complaints with dysesthesias, painful paresthesias, and sensory loss in the distal extremities. Early signs include decreased perception of vibration and pain. In progressed cases, proprioception is affected and there is weakness in the distal muscles. Painless injuries and loss of balance are common. Later, proximal weakness can occur.

Most asymptomatic, neurologically intact diabetic patients have conduction velocities that are mildly slow, around the lower limit of normal.[6] As the severity of the neuropathy advances, sensory amplitudes disappear in the lower extremities. Motor amplitudes become reduced. Abnormal temporal dispersion and partial conduction block are not common. Needle EMG findings will show abnormal spontaneous activity in the distal muscles.

A pure autonomic neuropathy is rare, but some degree of autonomic involvement is present in most patients. Autonomic symptoms may involve sudomotor (dry skin), papillary (poor dark adaptation), cardiovascular (orthostatic hypotension), urinary (incontinence, impotence), or gastrointestinal (constipation).

There are several other presentations of diabetic neuropathies. Some diabetic patients will have a polyneuropathy affecting mainly the small-diameter sensory fibers (A delta and C fibers) that manifests as painful paresthesias. Another presentation is diabetic neuropathic cachexia, which involves a precipitous and profound weight loss. It is rather uncommon. Mononeuropathies are more common in diabetics (refer to the previous entrapment neuropathy section). A diabetic femoral neuropathy may present with pain, weakness, and atrophy of muscles innervated by the femoral nerve. The presentation of a diabetic polyradiculopathy resembles a radiculopathy due to spinal degeneration (see the previous radiculopathy section).[15] The neuropathy usually begins with severe, unilateral pain in the low back, hip, and thigh. However, multiple spinal nerve roots are involved and there is weakness in the expected myotomal distributions. Coexisting symmetrical polyneuropathy often is present.

The presentation of a patient with diabetes can arise from a combination of degenerative musculoskeletal and nervous system etiologies. The electrodiagnostic exam helps to refine the diagnosis, direct treatments, and establish treatment expectations.

Disorders of Muscle

Myopathy refers to a problem in skeletal muscle. A myopathy usually presents with symmetrical proximal weakness. The sensory exam is normal. Deep tendon reflexes are depressed. Muscle atrophy and weakness is present. Occasionally, the lost muscle is replaced by fat and pseudohypertrophy (increase in the apparent muscle size) results. Myopathies are generally painless, but some cases are painful with muscle tenderness. Hereditary myopathies include the muscular dystrophies, dystrophic myotonias, congenital myopathies, metabolic myopathies, and mitochondrial myopathies. Acquired myopathies involve inflammatory, infectious, endocrine, electrolyte disturbances, malignancy, toxins, and systemic disease.[1]

Duchenne Muscular Dystrophy (DMD)

One devastating example of a hereditary muscle disorder is Duchenne muscular dystrophy (DMD). It is an X-linked disease affecting boys that usually results in death before the age of 20. A milder form is Becker muscular dystrophy. Both dystrophies involve a defect in the gene product dystrophin.

Myotonic Dystrophy

Another type of heritable myopathy is myotonic dystrophy. The molecular defect involves myotonin protein kinase. There is distal muscle weakness and atrophy, and a characteristic facial appearance involving additional atrophy of the temples and jaws. Car-

diac abnormalities present in more than 50% of patients. Endocrine abnormalities, such as testicular atrophy and diabetes, are common. A key feature is *myotonia*, delayed relaxation of skeletal muscle after contraction (e.g., inability to relax grip after a handshake). Serum creatine kinase levels are usually normal. Motor and sensory nerve conduction studies are usually normal. Needle EMG will reveal a striking finding called the myotonic discharge, which involves waxing and waning of both the amplitude and frequency of motor units.

Disorders of Neuromuscular Junction

Myasthenia Gravis

Disorders of the neuromuscular junction are rare. In myasthenia gravis, the density of postsynaptic acetylcholine receptors is reduced at the neuromuscular junction. The geometry of the end plate is also disturbed. As a result, the amplitude of the endplate potential is reduced and may fail to reach the necessary threshold to produce a muscle action potential. The patient experiences easy fatigability and weakness. An initial effort may produce strong muscular contraction, but subsequent efforts get progressively weaker. In one variation, the disorder is ocular, affecting all eye muscles. The diagnosis rests on a form of nerve conduction testing called repetitive nerve stimulation. Treatment is directed at blocking acetylcholinesterase in order to prolong neurotransmitter function. Immunosuppressive therapies, including thymectomy, may be of benefit.

CONCLUSION

The basics of electrodiagnostic studies were outlined in this chapter. The technical aspects of nerve conduction studies and electromyographic needle exam were presented. Patient preparation factors were identified. Radiculopathies, entrapment syndromes, trauma, polyneuropathies, and a few myopathic conditions were discussed. The approach has been practical and applied, with the anesthesiology pain management audience (who may never have performed an EMG) in mind. Neurology and physical medicine and rehabilitation ‘‘purists’’ might find this review too brief. Everyone, regardless of background, is directed to more comprehensive textbooks dedicated exclusively to the art and practice of electrodiagnosis.

There are limitations and subjective aspects to every electrodiagnostic exam. However, in the end, electrodiagnostic studies help to refine and clarify the diagnosis, set expectations, and can radically change treatment plans. The bottom line is that electrodiagnostic studies are an important tool that must not be overlooked by physicians who treat pain.

CHAPTER 19 ■ DIAGNOSTIC IMAGING OF PAIN

ASAKO MIYAKOSHI AND KENNETH R. MARAVILLA

INTRODUCTION

Pain is a major indication for imaging examinations. Imaging protocols are tailored based on acuteness, character, and location of the pain and the presumed diagnosis. Since, most of the time, the differential diagnoses of acute pain are relatively limited based on history and physical examination but can be of surgical emergency, primary imaging study for the patient with acute pain will typically confirm or exclude the presumed diagnosis based on history and physical examination (acute fracture, intracranial hemorrhage, aortic dissection, pneumothorax, pneumoperitoneum, etc). For patients with recurrent or persistent pain whose diagnosis remains obscure after routine imaging workup, the role of imaging could be expanded. Specialized imaging techniques can help detect subtle evidence of disease, direct therapy, and help identify patients for surgical or radiological intervention.

A comprehensive discussion of radiographs, computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, and radionuclide examinations for evaluation of pain should include almost all radiological subspecialties. This is beyond the scope of this chapter and can be found in most general radiology textbooks. This chapter is dedicated to the evaluation of the pain in the nervous system and reviews the imaging approach to several

regional pain syndromes as well as imaging techniques that can be used to select surgical candidates among patients with back pain, tic douloureux, and peripheral nerve entrapment syndromes. Techniques and indications for MRI of the cranial nerves and posterior fossa vasculature, discography for nonradicular back and neck pain, and high-resolution MRI of the brachial plexus and peripheral nerves are discussed.

HEADACHE

Headache is a common symptom. Choosing the patient who should have a cranial imaging study can be challenging (see Chapter 62). The diagnostic yield of neuroimaging examinations in patients with headache and a normal neurologic examination, or in patients with typical migraine, is low (Table 19.1).[1] Specific clinical features associated with significant intracranial abnormality, however, should prompt neuroimaging: Acute onset of an extremely severe headache, including thunderclap headache, worsening subacute headache, headache associated with focal neurologic signs or cognitive impairment (in patients without a history of migraine), new headache in patients older than age 50, and headache in immunocompromised patients or patients with known malignancy.[1–4] Patients over the age of 65 with new onset of pathologic headache have a 15% incidence of serious intracranial disease, including temporal arteritis, tumor, and infarct. In contrast, patients younger than age 65 have only a 1.5% incidence of detectable underlying pathology.[5]

Acute Headache

Severe, acute headache, especially if associated with neurologic abnormality or depressed sensorium, suggests possible subarachnoid hemorrhage (SAH). The devastating consequences of untreated ruptured aneurysm require prompt exclusion of SAH in this setting. Diagnosis is best made by CT demonstration of hyperdense blood in the subarachnoid space or detection of xanthochromic cerebrospinal fluid (CSF) on lumbar puncture in patients with a negative CT examination.[6] CT sensitivity for detection of SAH is reduced as the time interval from hemorrhage increases.[1] If SAH is present, subsequent imaging is directed at detecting an aneurysm (Fig. 19.1) or arteriovenous malformation (Fig. 19.2). Venous sinus thrombosis (Figs. 19.3 and 19.4),[7,8] benign perimesencephalic SAH,[9] arterial dissection[10,11] (Fig. 19.5), and migraine can also present as severe acute headache.

Imaging the patient with suspected SAH should begin with nonenhanced CT. Cisterns and sulci must be carefully examined for hyperdense acute blood, which can be subtle if the amount of hemorrhage is small, or if the study is performed more than 24 hours after the bleed occurred. Nonenhanced CT has a sensitivity of 98%[6] within 12 hours, or on a more recent study, 100% on emergency CTs.[12] In patients with high suspicion for SAH who have a negative CT, lumbar puncture should be performed for the uncommon but possible false negative CT.[6,13] In the absence of SAH, nonenhanced CT can detect signs of other pathologies, including increased density within a thrombosed dural venous sinus, venous infarction, and edema associated with intracranial mass lesions. If subtle abnormalities are found on nonenhanced CT, further imaging evaluation includes contrast-enhanced CT or MRI. In the absence of SAH, MRI is a more sensitive technique to evaluate the patient for other causes of headache, including dural venous sinus occlusion, venous infarct, and intracranial infection. If SAH is detected, CTA or DSA is generally used to further evaluate the location and features of an aneurysm or arteriovenous malformation.

Magnetic resonance angiography (MRA) and CT angiography (CTA) are useful for rapid, noninvasive diagnosis of intracranial vascular lesions. CTA is a dynamic, CT-based angiographic technique in which thin slice images are obtained rapidly and continuously during the first pass of the arterial phase of an intravenous contrast infusion. Using state-of-the-art multidetector CT, axial images covering the entire cerebral vessels can be acquired in a few seconds. Using rapid computer processing, planar and three-dimensional (3D) reconstructions can be created to display the enhanced blood vessels in a manner analogous to the projection images from catheter angiography. CTA can be easily performed immediately following the initial noncontrast CT while the patient is still on the CT table. MRA is also possible to obtain, but it is more time consuming and may not be suitable when the patient is unable to hold still and requires close monitoring. The quality of CTA in detecting aneurysms is comparable to digital subtraction angiography (DSA). However, DSA is considered to be superior to CTA for detecting small aneurysms ($<$5mm), especially with 3D rotational angiography. 3D rotational angiography also allows for more precise evaluation and measurement of aneurysms.[14–19] CTA or MRA can assist in the rapid diagnosis or exclusion of aneurysms and arteriovenous malformations in the acutely ill patient. These images are also used to clarify subtle findings in patients with questionable abnormalities on noncontrast CT. Similarly, carotid dissection can be detected by imaging the upper cervical vasculature with the above-described imaging techniques (see Fig. 19.5).[20,21]

Chronic Headache

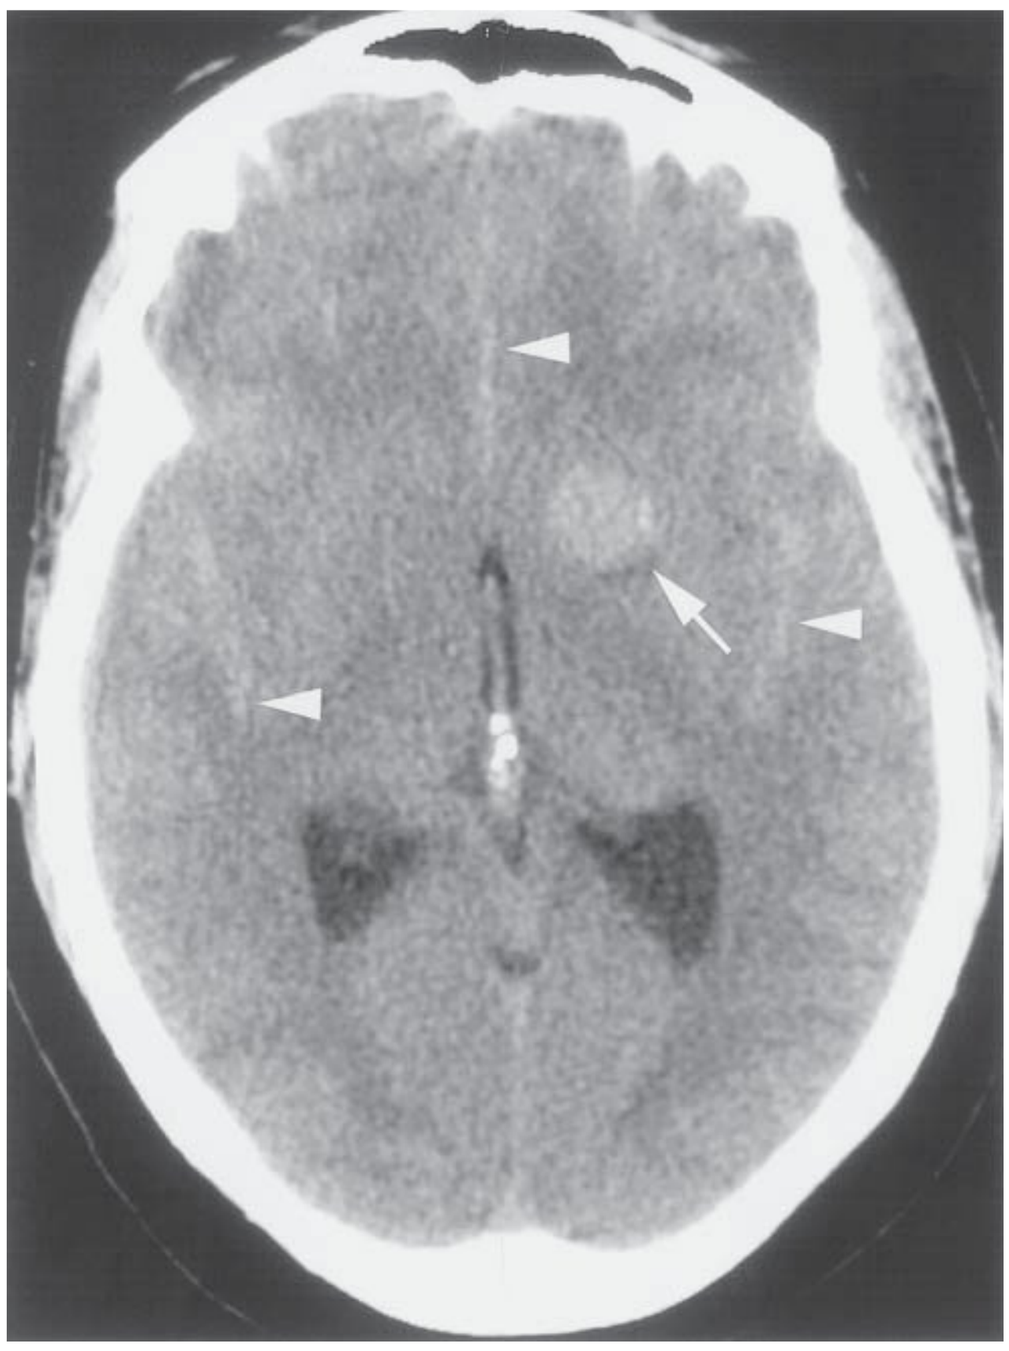

Image findings are unrevealing in most cases of isolated chronic headache. Intracranial lesions can present primarily with headache, but usually are associated with other neurologic signs or symptoms.[22] When headaches are caused by underlying pathologic disorders, the differential diagnosis is broad. Serious primary conditions include intraparenchymal, dural, or skull base tumors[23]; unruptured aneurysms[24]; abscesses; arterial dissection[25]; venous sinus thrombosis; and arteriovenous malformations. A normal CT or MRI without intravenous contrast excludes most intracranial masses, and can reassure the clinician and justify continued clinical observation and symptomatic treat-

ment. If the clinical evaluation points toward metastasis, abscess, or a vascular process, then contrast-enhanced CT or MRI is an appropriate study. Conventional plain-film radiography may be used as a screening method for various pathological conditions of the sinonasal cavities. However, CT scanning remains the study of choice for the imaging evaluation of acute and chronic inflammatory diseases of sinonasal cavities.

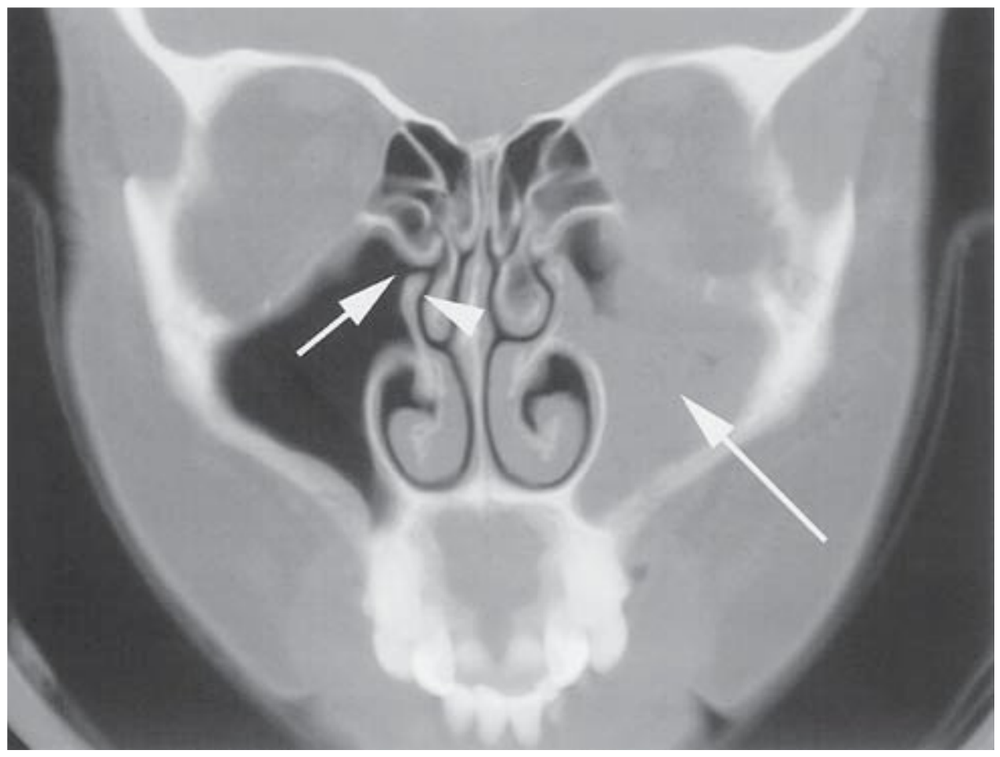
Acute Sinusitis

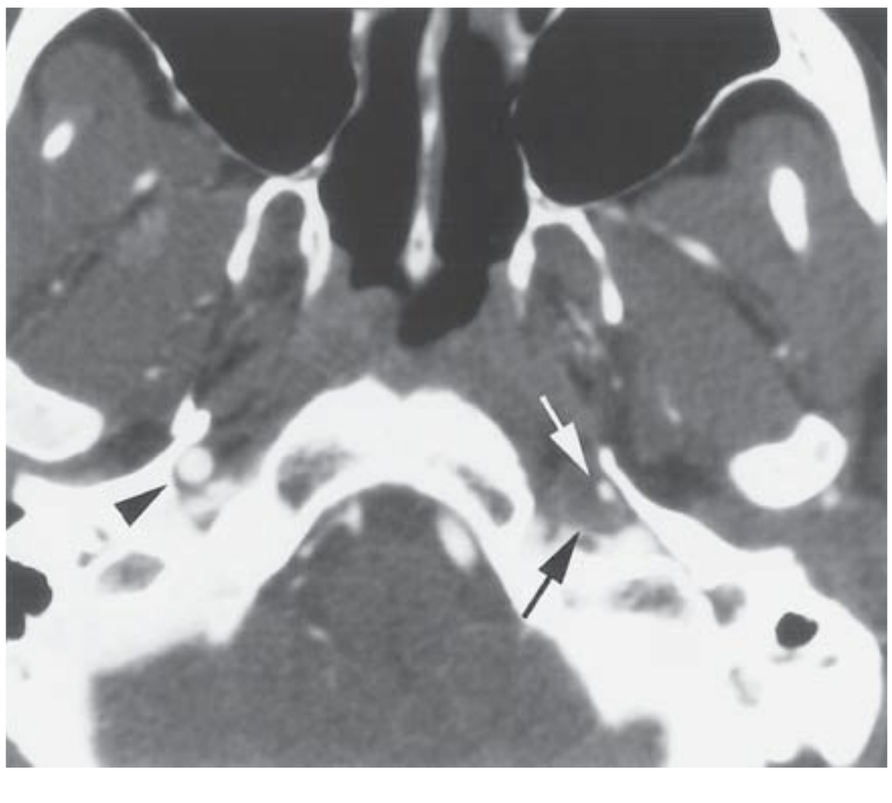
Acute sinusitis is a common cause of headache or facial pain. Conventional plain radiography may be used. It is specific but not sensitive in detecting sinus mucosal abnormalities.[26,27] Screening sinus CT is more sensitive than plain radiography and is now used routinely at our center. Designed as a rapid, limited CT examination targeted only at the paranasal sinuses, this study can be performed at only a modestly increased cost compared with plain films. CT has the additional advantages of evaluating the middle ear and mastoid air cells, as well as the subtle bony and mucosal changes reflecting chronic sinusitis. In the patient with recurrent sinusitis, thin section, high resolution coronal CT assists in planning of endoscopic sinus surgery (Fig. 19.6).[28]

Intracranial Hypotension

The syndrome of CSF hypotension is characterized by positional headache and variable symptoms of nausea, vomiting, and visual, auditory, or vestibular disturbances. Normal CSF pressure in the

FIGURE 19.4 Venous sinus thrombosis with bilateral thalamic infarcts in a 24-year-old woman with 4 days of headache followed by several hours of nausea and depressed consciousness. Nonenhanced computed tomography shows low attenuation changes in both thalami, with increased attenuation in the internal cerebral veins (*arrow*) and straight sinus (*arrowhead*).





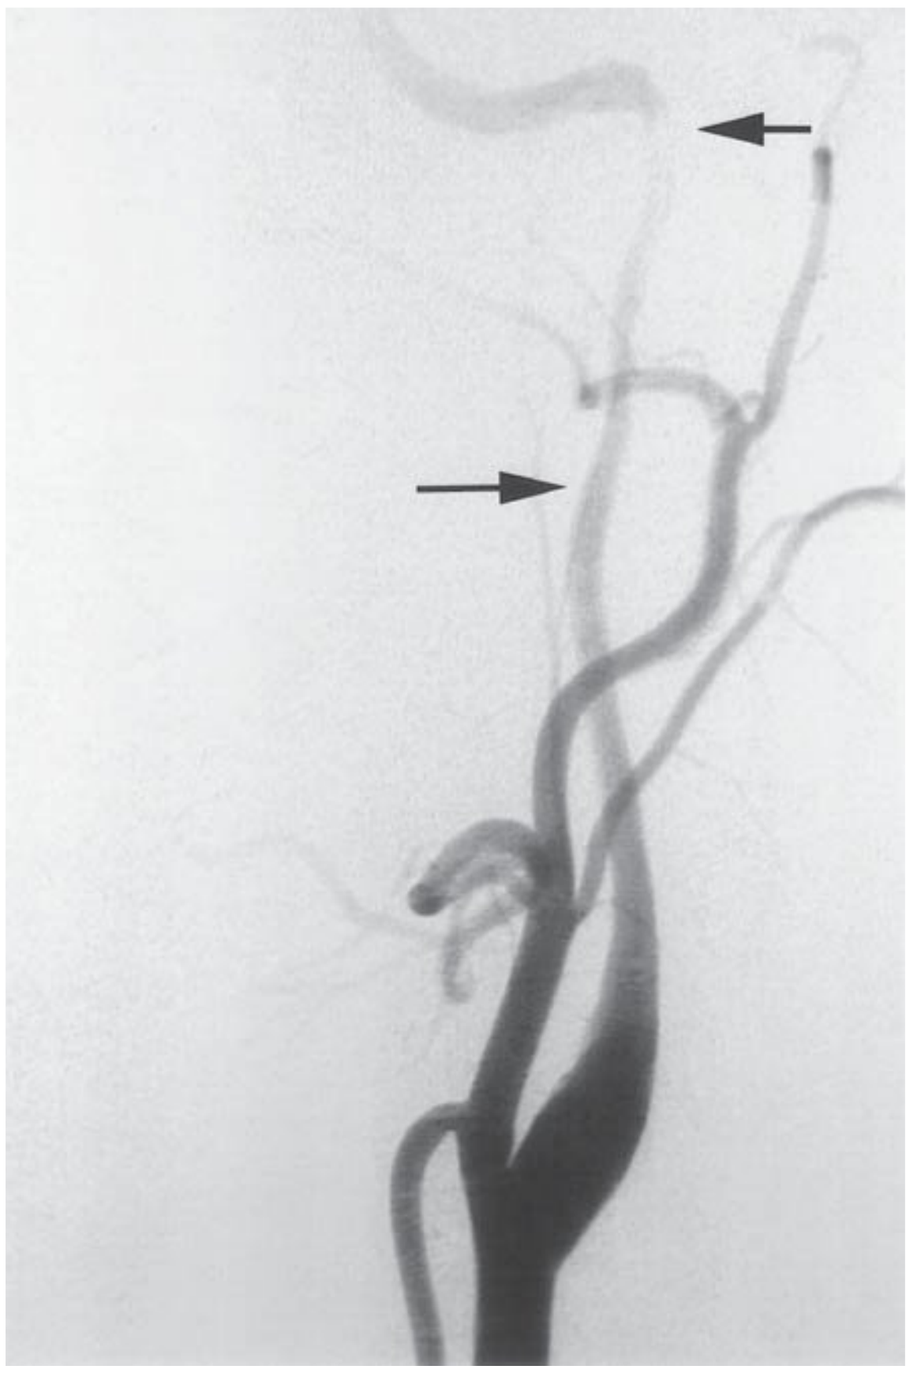


FIGURE 19.6 Chronic sinusitis. Coronal, nonenhanced screening sinus computed tomography through the face shows opacification of the left maxillary sinus caused by chronic inflammation (*long arrow*). The ostiomeatal unit (*short arrow*) and uncinate process (*arrowhead*) are clearly demonstrated on the opposite side.

FIGURE 19.5 Internal carotid artery dissection in a 37-year-old man with headache and left pupillary constriction. **(A)** Computed tomographic angiography at skull base shows decreased caliber of left internal carotid artery (*white arrow*) at the skull base. Intramural hematoma surrounds the narrowed lumen (*black arrow*). Normal right internal carotid artery (*arrowhead*). **(B)** Left internal carotid arteriogram shows smooth narrowing of distal cervical internal carotid with near complete occlusion at the skull base (*arrows*).

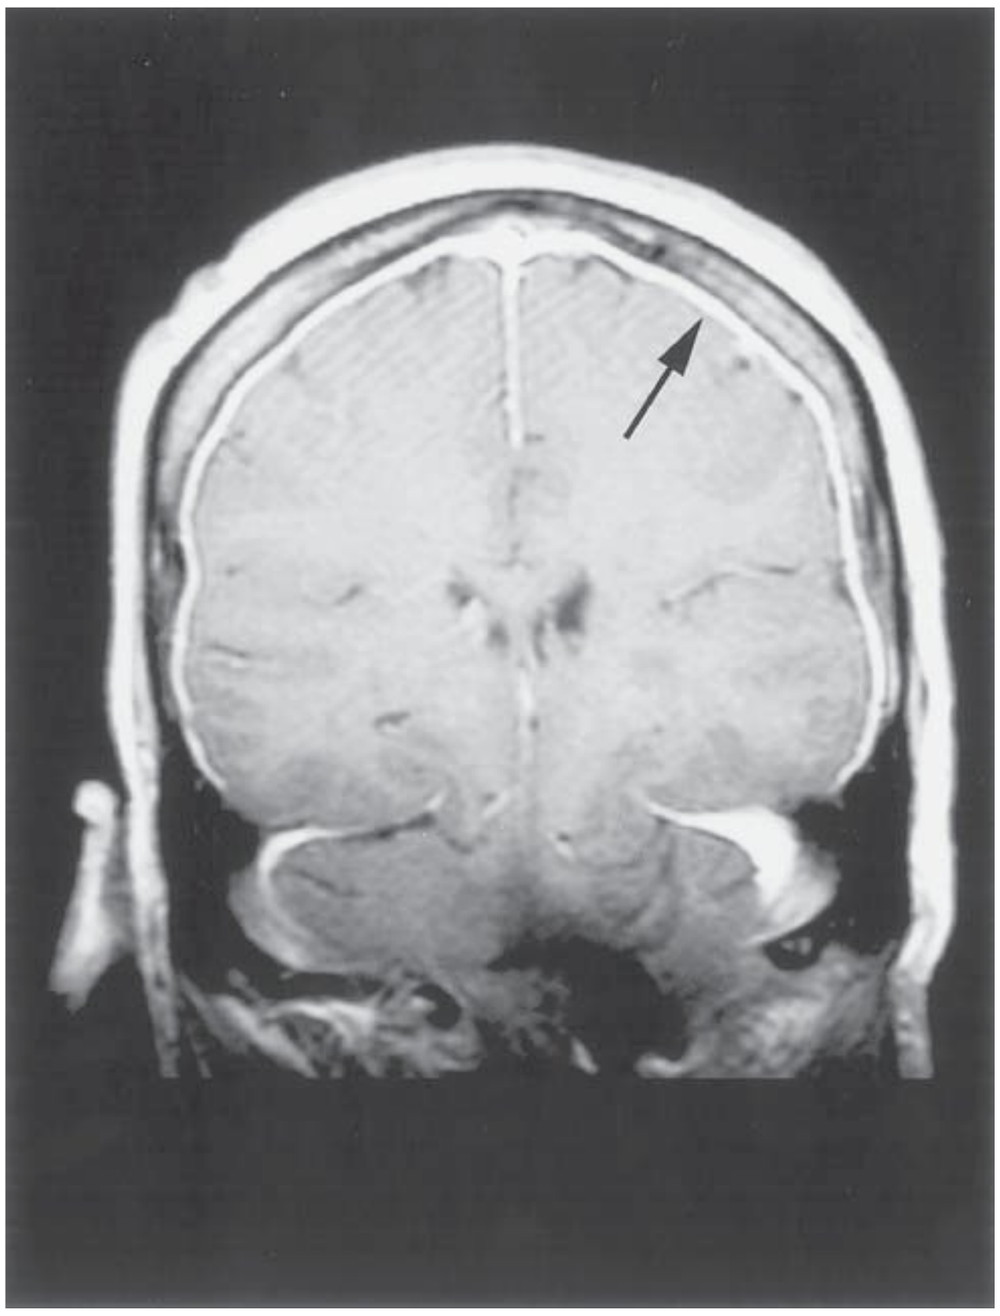

FIGURE 19.7 Cerebrospinal fluid hypotension caused by overshunting. A 54-year-old woman with ventriculoperitoneal shunt. Diffuse dural thickening and enhancement (*arrow*) caused by shunt valve with insufficient resistance. Similar findings may be seen in patients with postlumbar puncture, dural tears, or posttraumatic cerebrospinal fluid leaks.

recumbent position, and in the absence of prior lumbar puncture, is between 7 and 18 cm H_2O. CSF hypotension can be caused by spontaneous development of a CSF leak[29] or may result from diagnostic lumbar puncture, epidural anesthesia, myelography, head injury, or overdrainage of CSF shunts.[30]

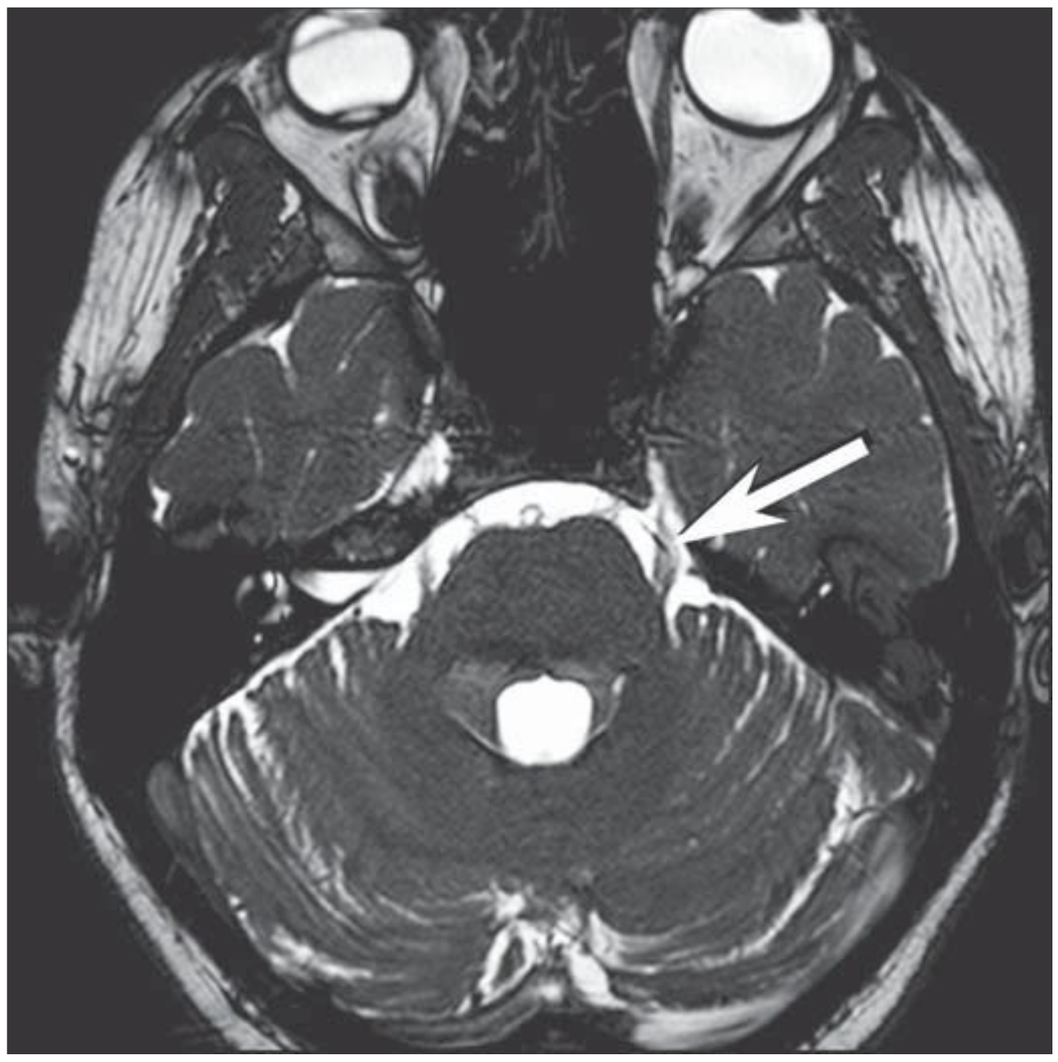
Spontaneous, posttraumatic, and postlumbar puncture CSF hypotension probably reflects chronic leakage of CSF through a dural defect.[31] Cranial MRI with gadolinium demonstrates smooth, continuous enhanced dural thickening, subdural effusions, and downward vertical displacement of the brain (Fig. 19.7). In some cases, the dural thickening may extend inferiorly to involve the spinal canal as well. These findings may disappear with resolution of CSF hypotension after successful treatment by blood patch, epidural saline injection, or surgical repair of the defect.[32–34] Headache with MR findings of diffuse enhanced dural thickening, not explained by prior surgery or infection, should prompt a diligent search for occult spontaneous CSF leak. An occult, spontaneous leak may occur through the skull base, or, less frequently, via a spinal dural defect. Recently, MR myelography has been attempted and seems promising as a noninvasive test to detect the source of the leak in spontaneous intracranial hypotension.[35–38] On MR myelogram, epidural collection, engorgement of a venous plexus, and irregularity of the nerve sleeve at the leakage site can be seen.

FACIAL PAIN

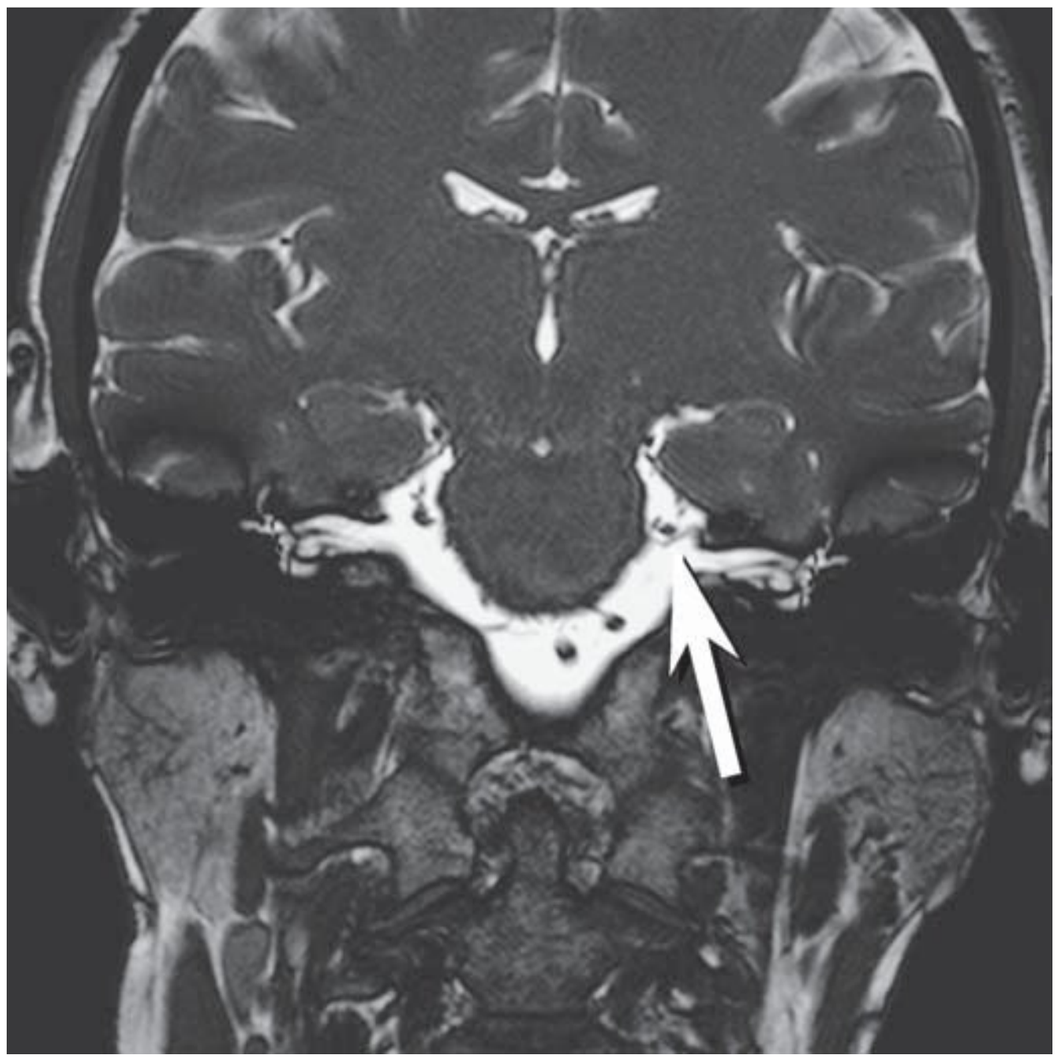
Intractable trigeminal neuralgia (tic douloureux) can be related to irritation of the nerve from a branch of the superior, anterior, or posterior inferior cerebellar artery that contacts the cisternal portion of the fifth cranial nerve near its exit from the pons[39] (see Chapter 67). Surgical intervention with placement of a prosthesis to separate the offending vessel from the root entry zone of the cranial nerve is often effective in relieving symptoms.[40] Diagnosis of vascular loops in the prepontine cistern and cerebellopontine angle was difficult before the development of MRI. Thin section balanced steady-state free precession gradient-echo techniques (BFFE, FIESTA, true FISP), MRA, and multiplanar or 3D reformatting can accurately demonstrate cisternal vessels and nerves in the posterior fossa and aid in identification of surgical candidates.[41–45]

The diagnosis of vascular loop syndrome is made by demonstration of a blood vessel contiguous with, or preferably distorting, a cranial nerve close to its origin from the brainstem at the root entry zone. This portion of the nerve is sensitive to irritation from pulsations in the contacting artery. The diagnosis is based on appropriate clinical symptoms as well as definitive MRI/MRA findings, because 49% asymptomatic patients show vascular loops contacting the cranial nerve origins.[44] Diffusion tensor imaging may be useful to support the diagnosis. Asymmetric decrease of fractional anisotropy in the affected nerve could be visualized[46] (Fig. 19.8). Image findings alone do not justify surgical treatment, which is based on symptom severity and failure of medical therapy. Other causes of trigeminal nerve dysfunction include mass lesions near the trigeminal nerve such as meningioma, schwannoma, arachnoid cyst, cholesteatoma, and epidermoid cyst.[47,48] These can be diagnosed by conventional cranial MRI and CT.

Vascular loops can compromise other cranial nerves in the basal cisterns. Chronic vertigo can be caused by posterior fossa vessels contacting the root entry zone of the eighth nerve (see Fig. 19.9) and compression of the intracisternal seventh nerve can result in hemifacial spasm. High-resolution MRI/MRA can be used to identify potential vascular loop syndromes causing these symptoms.



SPINAL PAIN

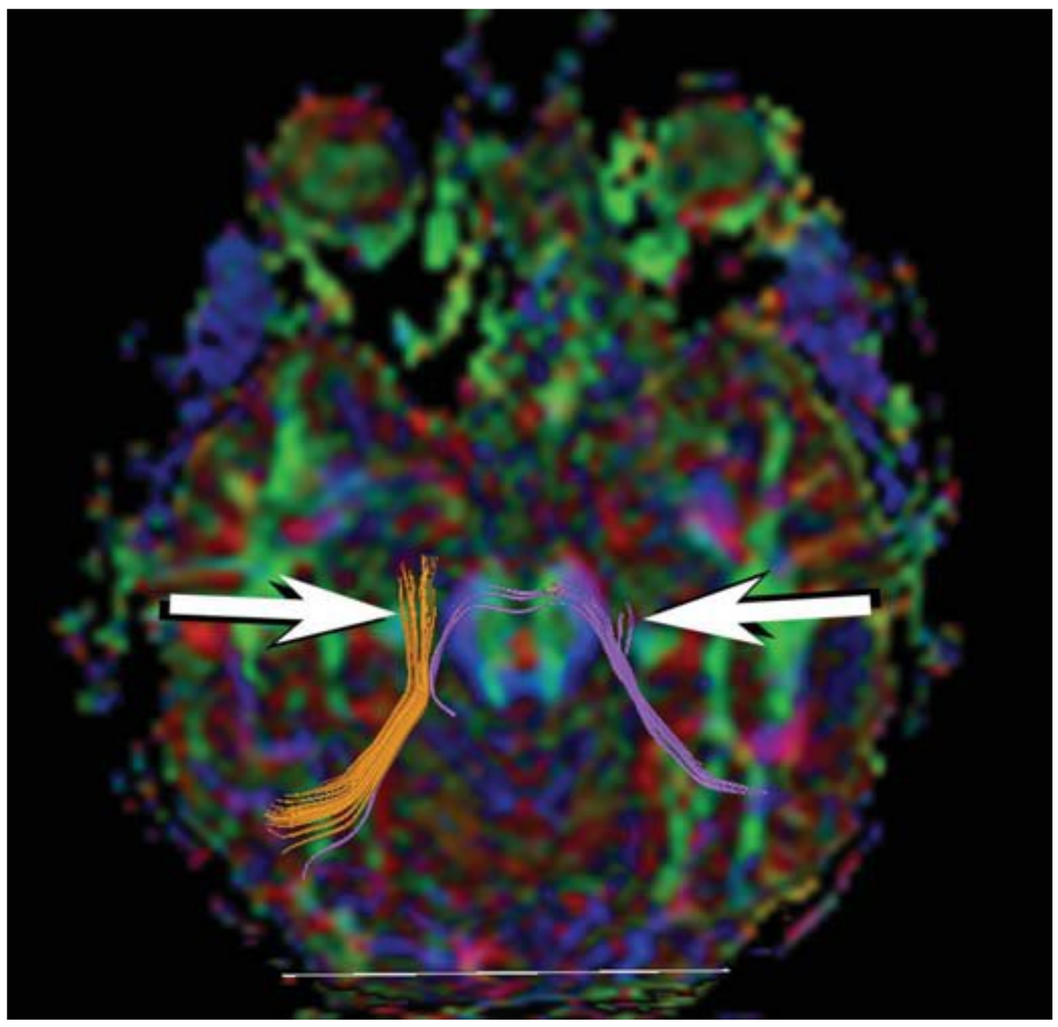


Overview

Technical advances in surgical fusion of lower lumbar vertebrae have resulted in safer, less invasive operations and have generated renewed interest in diagnostic tests that might predict a favorable surgical outcome for the back pain patient.[49–51] Conventional MRI, CT, and CT myelography can accurately evaluate spinal canal or neuroforaminal stenosis, lumbar disc protrusion, extrusion, or sequestration in the patient with pain and radiculopathy[52] (Fig. 19.10). Gadolinium-enhanced MRI can distinguish between postsurgical scar and recurrent disc herniation in the patient with prior back surgery and persistent or recurrent pain.[53] Scar tissues have a blood supply and demonstrate contrast enhancement, whereas herniated disc does not have a direct blood supply and only minimally enhances by diffusion of contrast. The difference of the enhancement is more conspicuous by using an ionic contrast medium.[54] Although CT and MRI are helpful to depict degenerative changes and disc pathology, because of the prevalence of degenerative changes, annular tears, and disc bulge and focal protrusion in asymptomatic patients, CT or MRI findings alone do not prove that a given disc is the cause of the individual patient's pain.[55] The less common findings of moderate or severe central stenosis, root compression, and extrusions are likely to be diagnostically and clinically relevant.[56]

Benign versus Malignant Compression Fracture

Water-fat in-phase and opposed-phase gradient recalled-echo sequences are promising in differentiating pathologic compression fractures from benign compression fractures.[57] In this method,



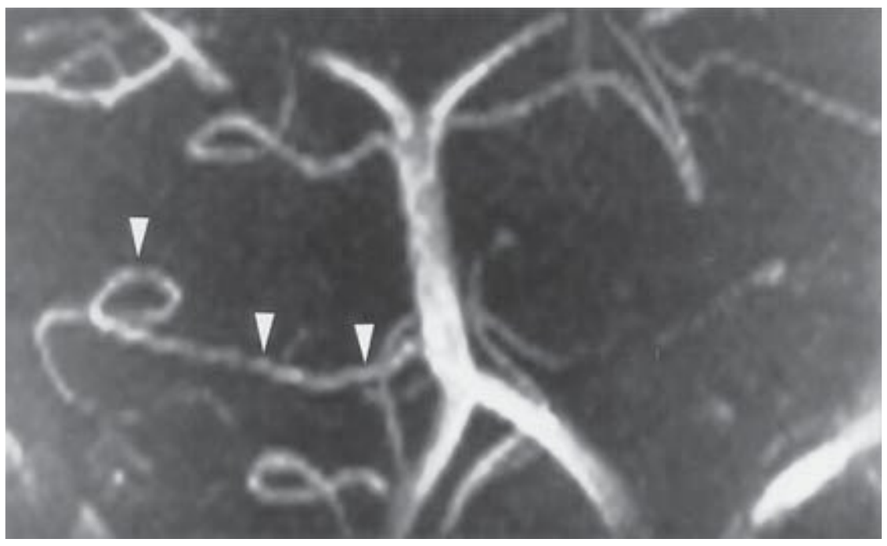


FIGURE 19.8 Vascular loop compression of the trigeminal nerve. **(A)** Axial balanced fast field echo (BFFE) image and **(B)** coronal BFFE image demonstrate the left superior cerebellar artery branch runs immediately inferior to the cisternal segment of the left trigeminal nerve (*arrows*) with possible compression. **(C)** Diffusion tensor imaging (DTI) clearly delineates the asymmetry of the trigeminal nerves (*arrows*) with decreased anisotropy on the left (*right arrow*), which is suggestive of vascular compression.

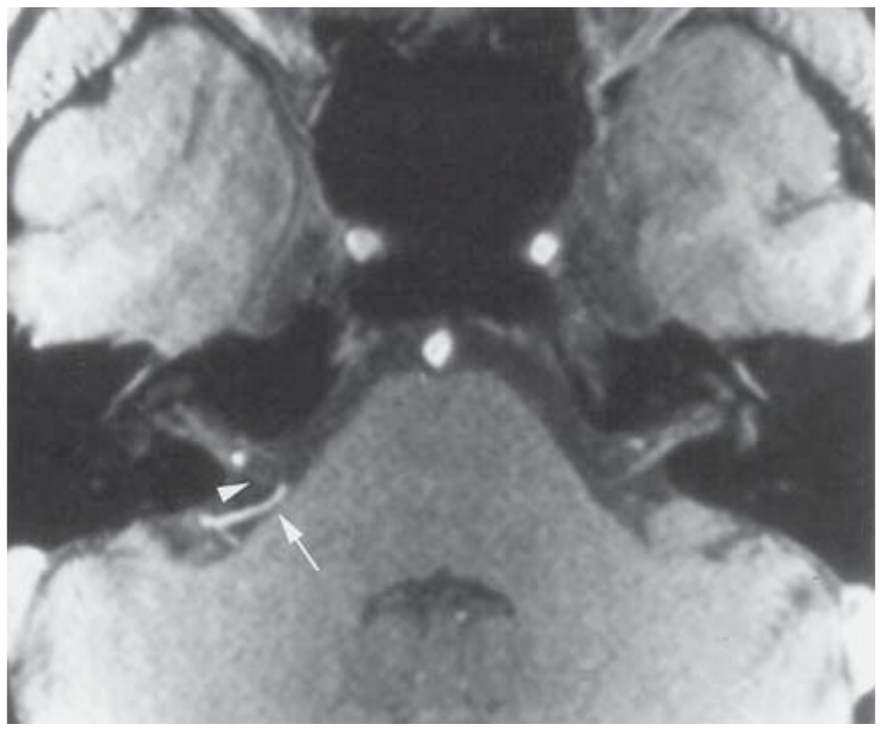
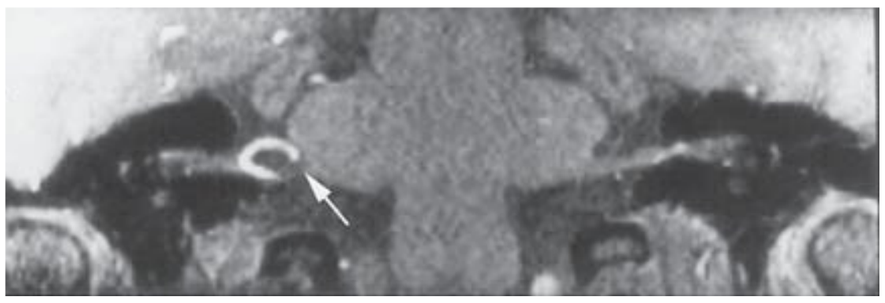


signal intensity ratio on opposed-phase images compared to in-phase images of >0.8 suggests malignancy since malignant processes replace normal fatty marrow.

Discogenic Pain



Before the advent of spinal CT and MRI, discography was the only radiologic technique for directly assessing the anatomy and integrity of the intervertebral disc. From this anatomic standpoint, CT and MRI have replaced discography.[58] The current role of discography is as a provocative test, with the aim of selecting patients with a greater likelihood of improvement after spinal fusion procedures. Discography involves injection of radiographic contrast material into an anatomically abnormal (suspect) disc and one or two normal (control) discs, and recording the patient's reported pain sensations during injection (Fig. 19.11).[59] A positive test result is indicated by reproduction of the patient's symptoms during injection of a morphologically abnormal disc, without similar discomfort on injection of control disc levels.[60] Discography is a unique provocative test for discogenic pain, but patients' reporting symptoms during disc injection can be affected by psychological factors as well as the interview technique.[61,62] The discographic identification of a painful disc also does not guarantee that the patient will respond to surgical fusion at that level.[63,64] Concordant pain could be present in patients with mild low back pain who do not seek treatment.[65] Because ongoing controversy exists as to the accuracy and value of discography,[66–68] its utilization largely depends on each clinician. Discography is probably best indicated before proposed sur-

gical therapy in the setting of severe, intractable back pain without radiculopathy or CT or MRI evidence of disc herniation. In this setting, discography may help to establish the levels of symptomatic disc disease.

LIMB PAIN AND MAGNETIC RESONANCE NEUROGRAPHY

Magnetic Resonance Neurography

Magnetic resonance neurography (MRN) is targeted to the peripheral nervous structures using a high resolution matrix. Images are obtained along the courses of the nerves of interest. The primary purpose of MRN is to delineate any abnormality of the nerve and detect the cause. The current indications include mass, compressive neuropathy, nerve entrapment syndromes, unexplained neuropathy or plexopathy, traumatic nerve injury, and posttreatment nerve evaluation. With the advance of available surgical techniques, accurate presurgical evaluation of the nerve abnormality is becoming more and more important. MRI of the cervical or lumbar spine and MRN of the brachial or lumbosacral plexus and peripheral nerves permit direct visualization of the nervous structures and can confirm the presence of neural irritation, edema, or compression.[69–73] Pathologic states caused by variant anatomy, prior trauma, scar tissue or mass lesion, and musculoskeletal causes of pain can be excluded (Figs. 19.12 to 19.14). MRI of distal musculature can provide evidence of denervation in the distribution of a given peripheral nerve (Figs. 19.15

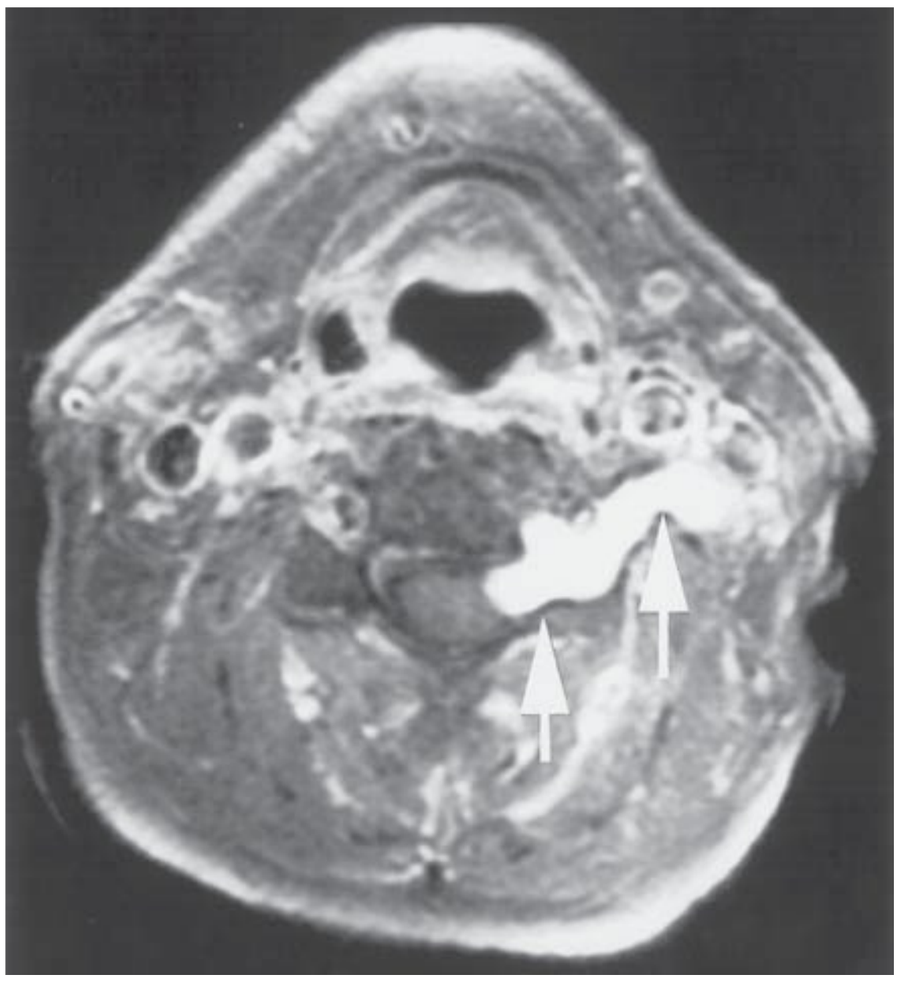

FIGURE 19.12 C-5 schwannoma. An 81-year-old man with 4 years of left upper extremity pain and dysesthesia. Axial and coronal short tau inversion recovery images reveal a dumbbell-shaped high signal intensity extradural mass involving the left C-4/5 neural foramen (*arrows*).

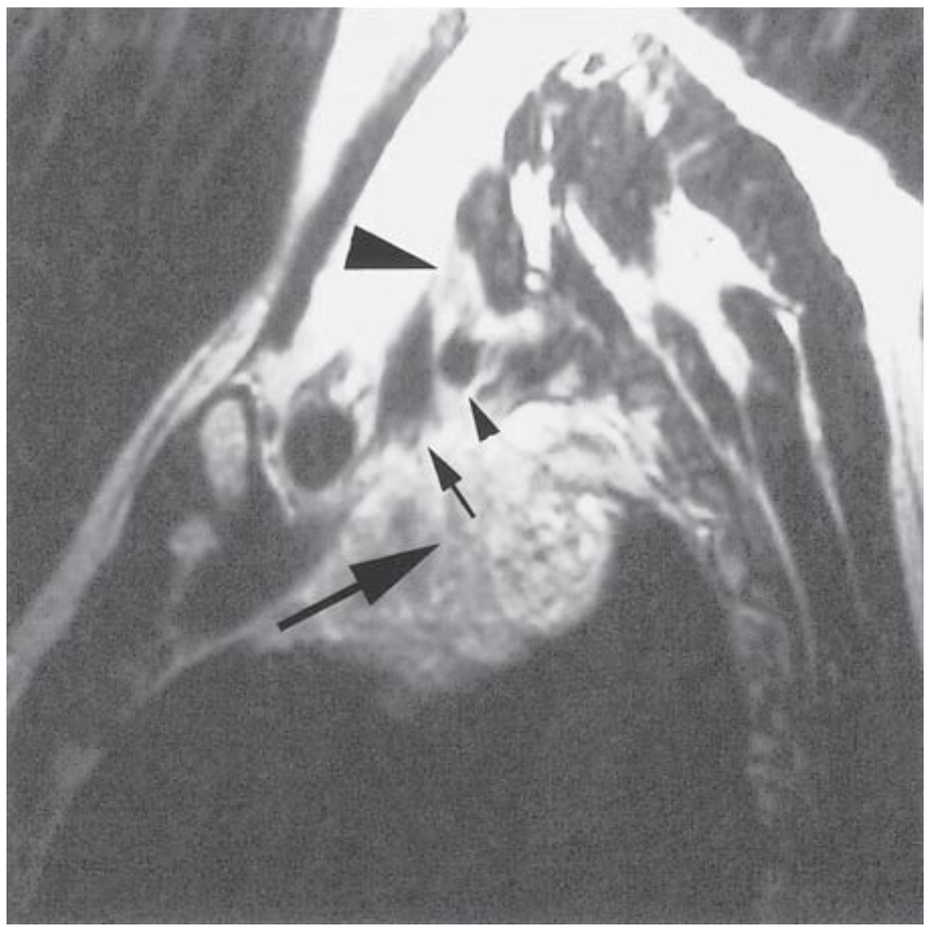

FIGURE 19.14 Pancoast's tumor. A 42-year-old man with mild cough. Posterior superior mediastinal mass was identified on plain radiograph. Sagittal T2 images demonstrate the pulmonary apex mass (*long arrow*) that abuts but does not surround the subclavian artery (*small arrowhead*). At surgery, the mass was found to be a lung cancer. Small arrow: anterior scalene muscle; large arrowhead; brachial plexus.

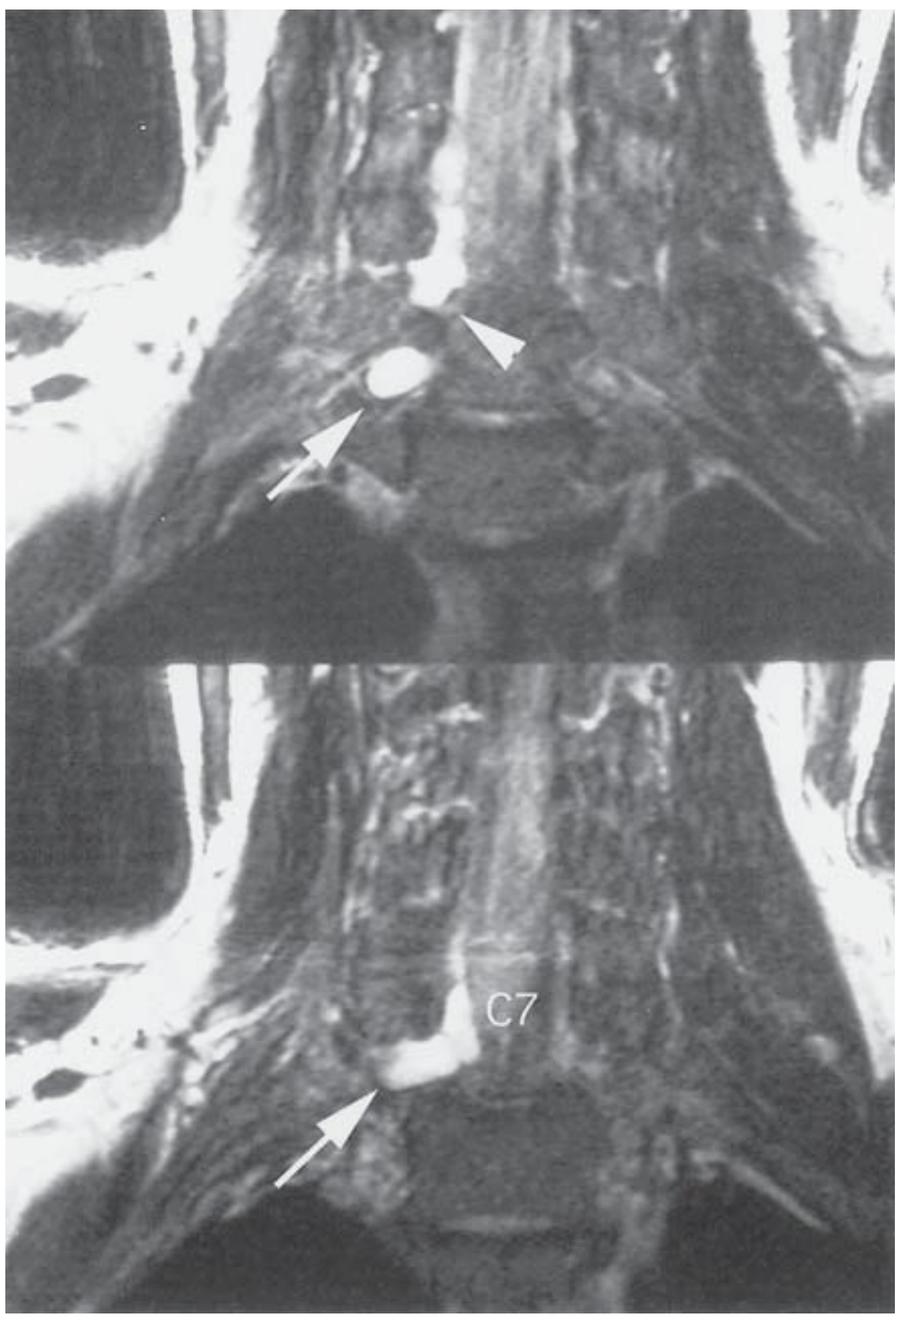

FIGURE 19.13 Nerve root avulsion. A 25-year-old man with traumatic injury to the right brachial plexus following a motorcycle accident that resulted in a flail upper extremity. After the accident he suffered from daily, intermittent, lancinating pain. Electromyography demonstrated absent cortical and brainstem response to stimulation of median and ulnar nerves and upper trunk of brachial plexus (C-6–8 roots). Coronal T1 and short tau inversion recovery images show proximal meningeal diverticuli at C-6, C-8, and T-1 (*arrow*) as well as abnormal signal in the right brachial plexus.

and 19.16).[74–76] In rat models, increased T2 signal is seen in the denervated muscles within 48 hours after a denervation event. This peaks at about 2 to 4 weeks. If there is nerve regeneration, the abnormal muscle signal resolves in 6 to 8 weeks. But without regeneration of the nerve, denervation changes of the muscle progresses and eventually causes muscle atrophy with fatty infiltration and resolution of high T2 signal several months later.[75,77–79]

Neurogenic pain involving the neck, shoulder, and the upper extremity can result from cervical nerve root compression, bra-

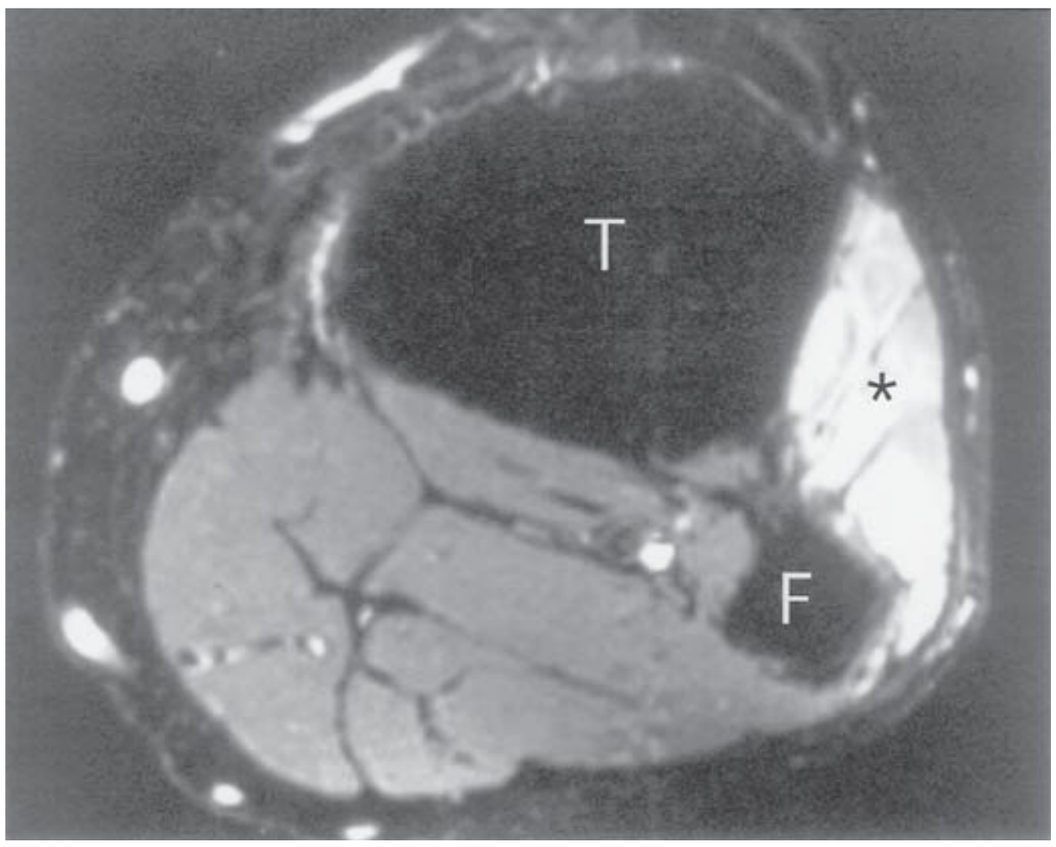

FIGURE 19.15 Subacute denervation in the distribution of the peroneal nerve. This axial short tau inversion recovery image of the proximal calf at the level of the fibular head (*F*) and the tibial metaphysis (*T*) demonstrates markedly hyperintense signal intensity within the anterior compartment muscles (*asterisk*). Note the muscles of the posterior calf for comparison, which show normal signal intensity. This illustrates the typical appearance of acute and subacute denervation that in this case followed severe injury to the left common perineal nerve.

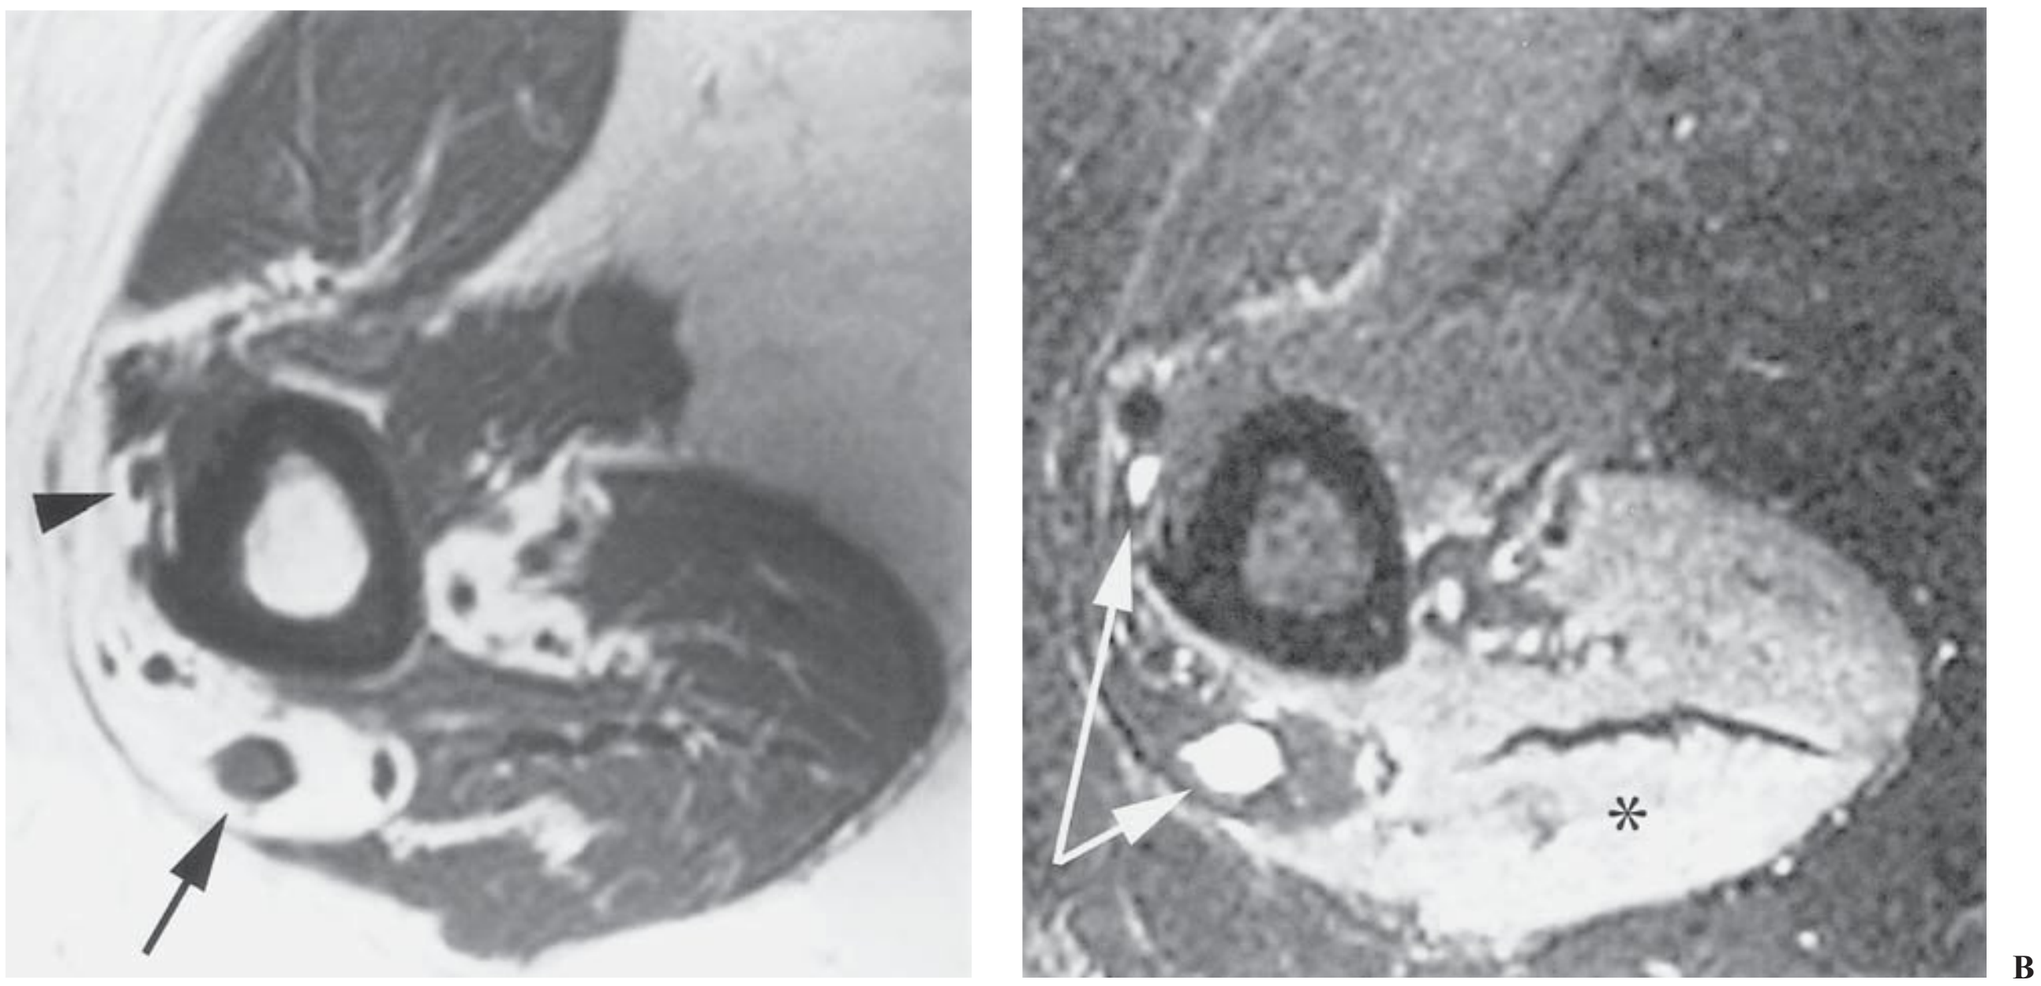

FIGURE 19.16 Ulnar and radial nerve injury. This patient suffered a severe left brachial plexus injury, with radial and ulnar neuropathy. (**A**) T1-weighted axial image through the left upper arm showing location of the radial (*arrow*) and ulnar (*arrowhead*) nerves. T1 sequences generally demonstrate anatomic relationships better than corresponding short tau inversion recovery sequences. (**B**) Short tau inversion recovery image showing increased signal in radial and ulnar nerves (*arrows*) as well as increased signal in triceps muscle (*asterisk*).

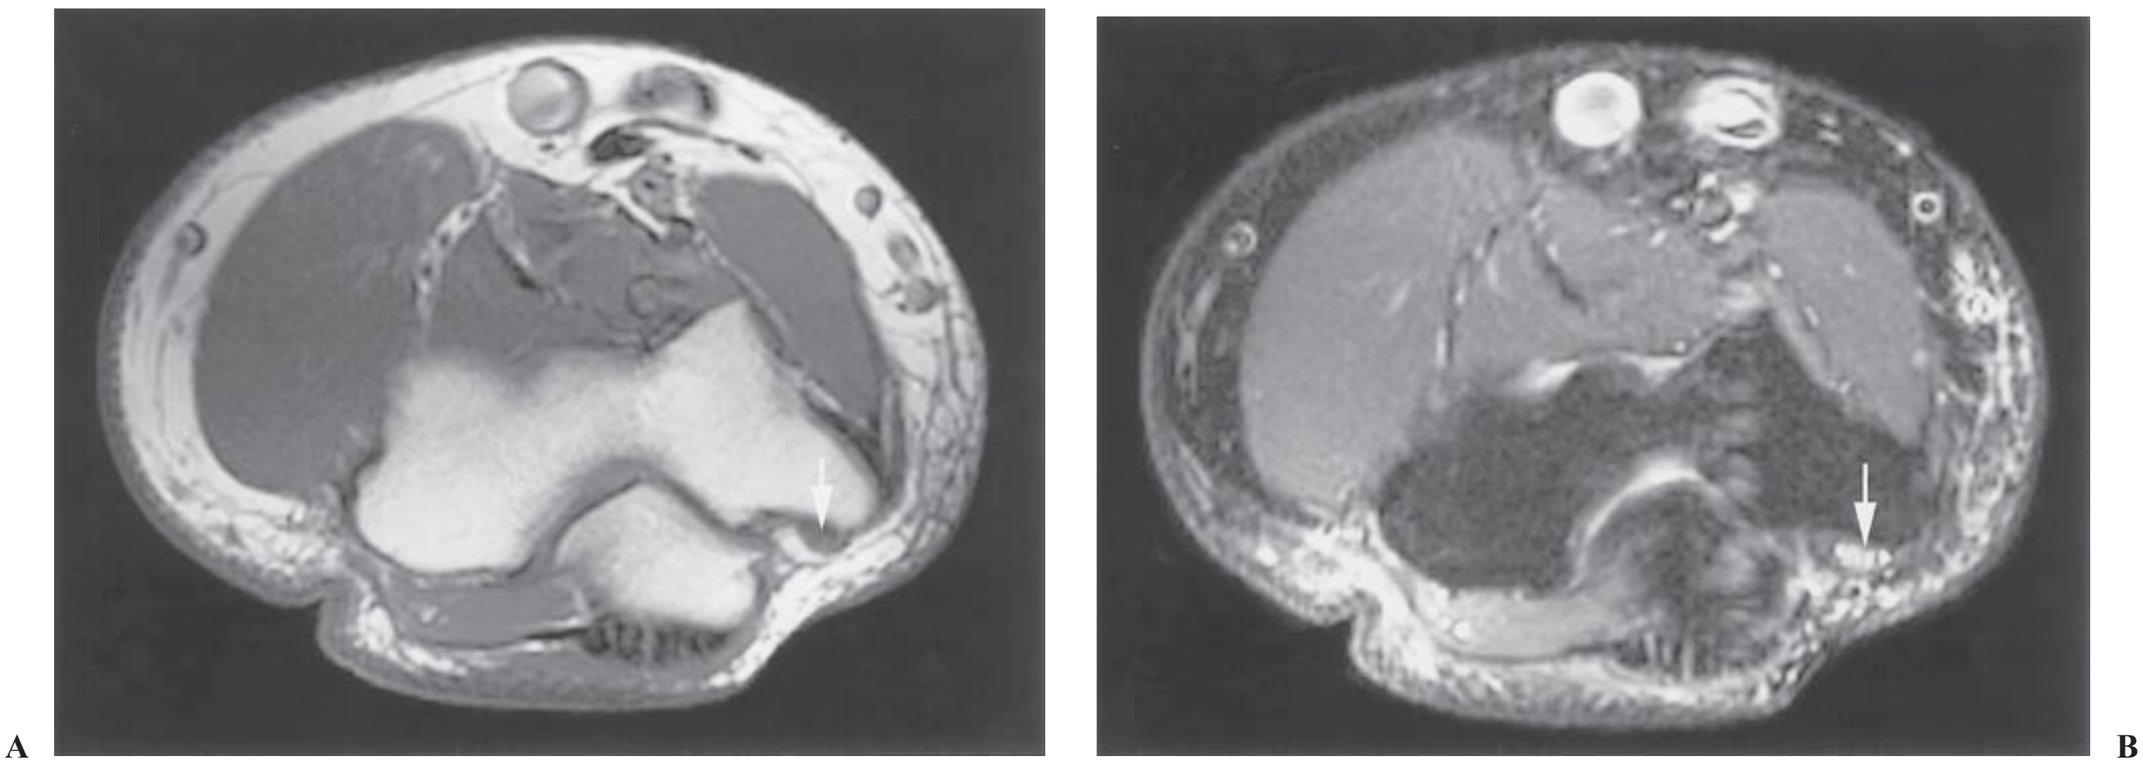
chial plexopathy, thoracic outlet syndrome (TOS), ulnar nerve entrapment at the elbow, or median nerve compression at the carpal tunnel.



Neurogenic pain involving the lower back, hips, and legs can result from lumbar nerve compromise, lumbosacral plexopathy, and an abnormality along the sciatic nerve (see Chapters 40, 69, and 71). MRN is particularly useful for patients with unexplained neuropathy, for whom surgical intervention is planned, or when the anatomic site of abnormality remains unclear after clinical examination and electrodiagnostic studies.[72,80] However, because only a relatively small field of view (FOV) can be imaged with high spatial resolution, it is necessary to clinically establish the site of a suspected neuropathic lesion as accurately as possible before using MRN. Imaging is then focused on the site of maximum clinical suspicion.

Brachial plexus, cervical root, or lumbosacral MRI is optimally performed using a phased-array RF coil and a large matrix size. These specialized receiver coils obtain detailed images by combining high signal-to-noise information from multiple coil elements to produce a very detailed image.[72] Coronal and sagittal T1-weighted images provide superb anatomic definition. Frequency selective fat saturation fast spin echo T2 and short tau inversion recovery (STIR) sequences are sensitive to changes in normal signal intensity within the roots, trunks, and cords of the brachial plexus and lumbosacral plexus. The former has better signal-to-noise ratio. STIR sequences suppress signal from fat more homogeneously, increasing the conspicuity of abnormal nerves. It is often helpful to image both sides of the patient simultaneously for comparison with the asymptomatic side.[81] Optimal MR neurography at the elbow, wrist, arm, thigh, knee, and ankle also requires high-resolution surface coils, a large matrix size, T1, fast spin echo T2, and STIR sequences. Imaging is conducted in the axial plane (perpendicular to the nerve) and either in the coronal or sagittal plane. Normal nerves demonstrate iso- or slightly high T2 signal compared to muscles. Fasciculated appearance can be seen especially within a large nerve such as the sciatic nerve due to interfascicular adipose tissues. Abnormal changes in peripheral nerves identified by MR neurography include focal or generalized enlargement of the nerve, increased signal on T2 and STIR sequences, loss of fascicular architecture, enhancement after administration of gadolinium, and displacement or compression of the nerve by soft tissue or osseous masses.[72,73,80] Acute and subacute denervation of musculature supplied by peripheral nerves is evident as increased signal on T2 and STIR sequences, loss of muscle volume, and sometimes enhancement after gadolinium administration. Chronic denervation results in marked loss of muscle mass together with fatty infiltration. The increased T2 changes seen in acute and subacute denervation are not seen. Axial T2 or STIR images of the abnormal musculature supplied by an injured peripheral nerve can identify denervation and are an indirect but effective means of determining the affected nerve and level of injury (see Figs. 19.15 and 19.16).[69] The 3D T1-weighted data set may also be used for better anatomical evaluation of the nerve.[82] Extremity pain, dysesthesia, and weakness can result from entrapment of nerve roots, compression, injury, or infiltration of the brachial, lumbar, or sacral plexi and compression of peripheral nerves at several sites.[83,84] Anatomical diagnosis is not always clear and may require imaging of the spine or trunk as well as the affected extremity.

In summary, cervical spine MRI, CT, or CT myelography can demonstrate intervertebral disc herniation, spinal canal and neuroforaminal stenoses, and degenerative changes in evaluating radiculopathy. Contrast-enhanced MR can identify spinal cord and vertebral tumors in addition to postoperative scars. Brachial plexus and pelvic MRI, using high-resolution phased array coils, can define the course of nerve roots, trunks, divisions, and cords in the patient with plexopathy, as well as detect masses, traumatic injuries, and inflammatory changes[81] (see Figs. 19.12 and 19.13). Direct imaging of peripheral nerves at common sites of entrapment can confirm the location of repetitive stress injury or tumor, and help clinicians select patients who might benefit from decompressive surgery (Fig. 19.17; see Fig. 19.16).[80]

Thoracic Outlet Syndrome

Thoracic outlet syndrome (TOS) is a group of disorders associated with the nervous and vascular structures from the base of

A B

FIGURE 19.17 Ulnar entrapment. Axial T1 (**A**) and short tau inversion recovery (STIR) (**B**) images of the right elbow taken at the level in which the ulnar nerve passes through the cubital tunnel. (**A**) On this T1-weighted image, a normal sized right ulnar nerve is nicely demonstrated surrounded by perineural fat (*arrow*). (**B**) The STIR image, however, demonstrates abnormally increased hyperintensity within the nerve that is abnormal (*arrow*) and that, in the presence of appropriate symptoms, is an indication of ulnar nerve entrapment.

the neck to the axilla (see Chapter 40). Most patients have a controversial syndrome characterized by variable supraclavicular and upper extremity pain, dysesthesia, and weakness without the presence of an anomalous cervical rib or objective physical examination or electromyographic findings of nerve abnormality.[85] Because musculoskeletal inflammatory conditions, complex regional pain syndromes, and distal compressive neuropathies can have similar symptoms, the diagnosis of TOS can be extremely difficult. Although decompression of the inferior brachial plexus and subclavian vessels by transaxillary resection of the first rib has been successful in management of some patients with TOS, generally after a trial of physical therapy, the decision to operate is rarely straightforward. There are three forms of TOSs: arterial, venous, and neurogenic. Neurogenic TOS is considered to be most common, consisting of more than 90% of all TOS cases. But more than one form may coexist.[86] Neurogenic TOS is difficult to diagnose. Patient symptoms are subtle and confusing, but generally show chronic progression. It is usually considered to be associated with chronic compression and entrapment. Primary use of EMG is to exclude other peripheral neuropathies, rather than to rule in TOS. A minority of patients (less than 10%) have a predominately vascular form of TOS with symptoms resulting from subclavian artery compression or venous insufficiency and possible thrombosis.[87] Arterial TOS is due to compression of the subclavian artery or axillary artery and typically presents with upper extremity arterial insufficiency symptoms or embolic episodes, and ultrasound or arteriography demonstrates subclavian artery aneurysm, arterial thrombosis, or distal emboli. Venous TOS (Paget-Schroetter syndrome) is due to thrombosis caused by compression of the subclavian or axillary vein and typically presents with upper limb swelling, pain, and cyanosis. It is significant in that it can result in pulmonary embolism.

The role of imaging in suspected TOS is not clearly established at present and more investigation is required to evaluate the validity of imaging.[88]

If cervical radiographs visualize the cervical ribs, the diagnosis is easily made. And it is usually due to arterial compression. But most cases of neurogenic TOS are not associated with cervical ribs. Neurogenic TOS may be imaged with MR neurography of the brachial plexus which may show an angular deformity of the course of the brachial plexus trunks as they pass through the area of the scalene triangle with or without accompanying increase in T2 signal of the affected nerve(s).

Ultrasound is useful for vascular evaluation including dynamic evaluation of vascular systems in different arm positions and in a seated position and detects arterial stenoses even when the MRI is negative.[89] Significant (>70%) stenosis can also be seen in 19% of the normal population with abducted arm position. Ultrasound can demonstrate thrombosis in the subclavian-axillary venous system. Its sensitivity is over 90% with variable specificity.[90–92] However, ultrasound is largely operator dependent and the clavicle may limit the observation window.

CT is useful in evaluation of bony and vascular structures but inferior to MRI in regard to soft tissue evaluation. CT scanning in neutral and elevated arm position is useful to evaluate vascular compression especially with reformatted multidimensional or 3D reconstructions.[93, 94] However, this requires radiation to the patients and iodine contrast.

MRI is an emerging modality in evaluation of thoracic outlet syndrome.[95,96] It is noninvasive, does not require radiation, and demonstrates good soft tissue delineation. Panegyres and colleagues reported sensitivity of 79% and specificity of 87.5% for the detection of distortion or displacement of the brachial plexus or subclavian vessels.[95] Contrast enhanced MRA is also useful to evaluate vascular compression,[97] especially with abducted arm position.[98–100] However, arterial compression can be seen in the normal population (0% to 1.39%). Venous compression is seen more frequently in normal populations (41.7% to 47%). Therefore, clinical correlation is important. Scanning in two positions is also useful to evaluate neural compression. Nervous compression on the provocative position is only seen in patients but not in controls.[101,102] The costoclavicular distance also significantly decreases by the provocative position in patients.[101–104]

Piriformis Syndrome

Piriformis syndrome is nondisc origin leg pain caused by compression of the sciatic nerve by the asymmetrically enlarged piriformis muscle or by an associated fibrous band. On MR, abnormal T2 high signal can be present in the affected sciatic nerve.[105,106] Filler reported that piriformis muscle asymmetry and sciatic nerve hyperintensity at the sciatic notch exhibited a 93% specificity and 64% sensitivity on MR in distinguishing patients with piriformis syndrome from those without who had similar symptoms.

Peripheral Nerve Entrapment Syndromes

Carpal tunnel syndrome is the most common form of nerve entrapment and is the result of median nerve compression at the carpal tunnel (see Chapter 71). Clinical features, usually sufficient for diagnosis, include paresthesia and hyperesthesia in the median nerve distribution, radiation of pain along the volar aspect of the forearm, nocturnal pain, exacerbation with repetitive movements, and atrophy of the thenar muscles. Carpal tunnel syndrome is most often caused by repetitive injury of the median nerve within a compromised carpal tunnel volume, but can also be caused by focal space-occupying lesions, local inflammatory processes, or metabolic derangements related to systemic illness.[107,108] Proximal nerve entrapment in the cervical spine, thoracic outlet, and along the course of the median nerve can mimic carpal tunnel syndrome. The pronator syndrome and the anterior interosseous syndrome are distal median nerve compression syndromes in which the nerve is compressed by the two heads of the pronator teres, or after the branching of the anterior osseous nerve, along the interosseous membrane, respectively. Both of these syndromes can produce symptoms identical to carpal tunnel syndrome.[72]

Although ultrasound and CT have been used to evaluate anatomy of the carpal tunnel and visualize the median nerve,[109] MR is superior to these technologies in confirming the diagnosis of carpal tunnel syndrome, by virtue of its greater contrast sensitivity and its ability to detect abnormal signal intensity changes within a compressed median nerve. A coronal T1 scout image allows selection of axial scan levels through the wrist. Axial T1 and STIR (or T2) images should be obtained at the distal radiocarpal joint, proximal carpal tunnel, distal carpal tunnel, and metacarpal bases. Dedicated phased-array coils are valuable in increasing image quality to better demonstrate these small structures (Fig. 19.18).[69]

Findings in carpal tunnel syndrome include increased girth of the median nerve proximal to the carpal tunnel, flattening of the nerve within the tunnel, increased bowing of the flexor retinaculum, and increased signal intensity of the median nerve on T2 and STIR sequences. Ganglion cysts, lipomas, posttraumatic or degenerative bony deformities, and other soft tissue tumors are easily identified on MRI. Thickening or separation of tendons with increased signal changes on T2 or STIR sequences indicates tenosynovitis. Often idiopathic, it can also be caused by trauma, rheumatoid arthritis, and chronic infection. Amyloid, gout, acromegaly, hypothyroidism, and other systemic diseases associated with carpal tunnel syndrome are generally diagnosed on the basis of clinical, laboratory, and plain film findings.[110–113]

Additional entrapment syndromes are also found with the ulnar nerve in the cubital tunnel at the elbow and Guyon's canal in the wrist[114] with common symptoms being tingling sensation on the ring and little fingers. On MRN of the elbow, abnormal signal and enlargement of the nerve can be seen.[115] Common peroneal nerve entrapment around the fibular head can be seen as T2 high signal within the nerve.[76] High-resolution, surface coil MRI can be diagnostic, but its application requires careful attention to the anatomy of the particular nerve involved.[69]

IMAGING GUIDED INJECTION

Imaging studies play an important role in the facilitation of diagnostic and therapeutic nerve blocks, vertebroplasty, and kyphoplasty (see Chapters 99 to 103). Accurate placement of needles for the injection of local anesthetic or neurolytic substances can be confirmed by radiographs, fluoroscopy, or CT scanning. These imaging techniques can prove the localization of a needle at a specific anatomic site and confirm the actual nerve or nerve root that is being blocked. The injection of a contrast agent with a local anesthetic solution can reveal the distribution of the agent used and confirm which nerves have been exposed to the anesthetic solution. This is particularly important when a surgical decision is based on the responses to nerve blocks. These techniques are particularly useful in patients whose anatomy has been distorted by disease processes or prior surgical procedures. The development of open magnet MR scanning may lead to an increase in the use of this imaging technology in the performance of image guided nerve blocks.

Radiography is commonly used to confirm the placement of needles in the performance of facet joint blocks, paravertebral somatic nerve blocks, or transsacral blocks. Fluoroscopy is used in the placement of epidural electrodes or catheters. Surgical procedures such as gangliolysis of the trigeminal nerve or radiofrequency rhizolysis or spinal nerves are performed with fluoroscopy. CT scans are commonly used for celiac plexus block. Modern imaging techniques facilitate the use of nerve blocks by providing proof of the exact location of the needle or the spread of injectate.

For vertebroplasty, the role of imaging procedures includes

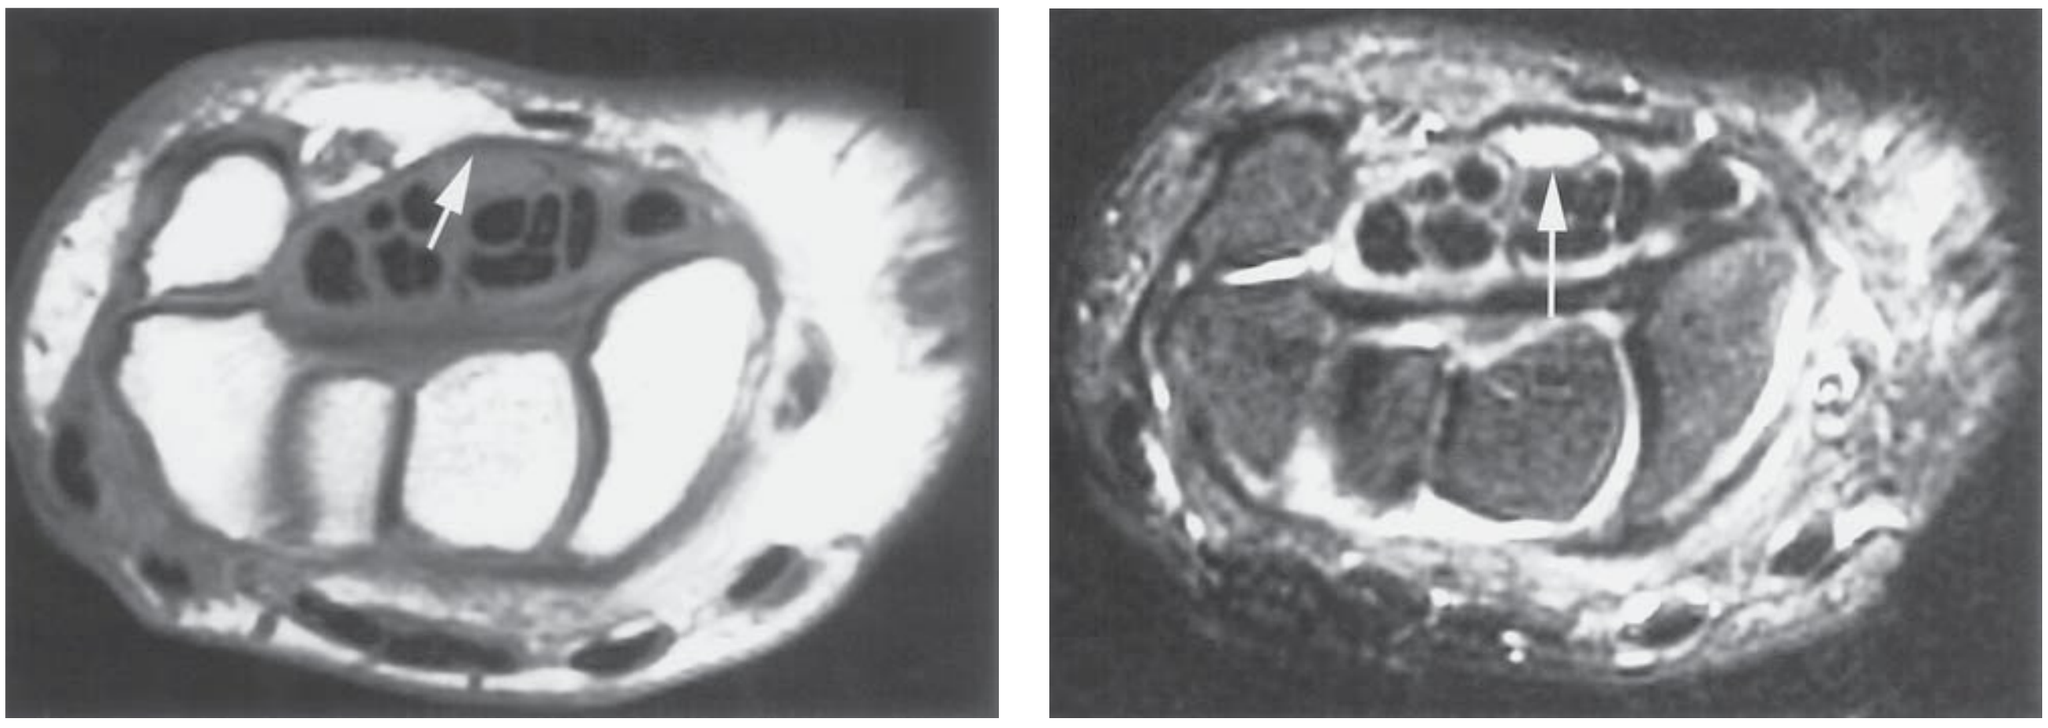


FIGURE 19.18 Carpal tunnel syndrome secondary to tenosynovitis. **(A)** Axial T1 image through the carpal tunnel shows increased girth of the median nerve and bowing of the flexor retinaculum (*arrow*). **(B)** Corresponding axial short tau inversion recovery image shows increased signal in the median nerve (*arrow*), as well as high signal fluid surrounding the tendon sheaths.

preprocedural evaluation to assess for the degree of the vertebral compression, exclude findings which contraindicate the procedure such as unstable fracture, neural foraminal involvement, and osteomyelitis of the target vertebra.

FUTURE APPLICATION OF PAIN IMAGING

Recent advances in functional brain imaging have started to reveal the complex process of the pain mechanism. Patterns of brain activation with various pain syndromes are being explored and the responses of individuals with chronic pain versus control subjects undergoing identical painful stimuli are beginning to reveal some interesting findings. How these will influence management of patients with chronic pain is yet to be defined.

CONCLUSION

Diagnostic imaging in patients with acute pain has a clearly defined role in establishing or confirming a pathologic diagnosis and directing medical, surgical, or radiologic intervention. Patients suffering from chronic, recurrent, or intractable pain from degenerative disease, anatomic variations, chronic inflammatory conditions, neoplasm, and postoperative or posttraumatic scarring may benefit from specialized imaging examinations for the determination of etiology, treatment planning, and prediction of the outcome of directed therapy.

CHAPTER 20 ■ MEASUREMENT OF PAIN

MARK P. JENSEN

INTRODUCTION

Valid and reliable pain assessment is essential for successful pain care. Adequate assessment is also necessary to determine the efficacy of pain treatments in clinical trials, and for understanding the mechanisms of those effects. The clinician or researcher who wishes to use the most useful measures and strategies for pain assessment is faced with a large, and growing, number of options and decisions. The purpose of this chapter is to make those decisions easier.

The chapter begins with a brief discussion of several important issues that clinicians and researchers need to consider when choosing from among pain measures and designing pain assessment procedures, including: (1) evaluating the reliability, validity, and utility of pain measures; (2) determining the number of pain problems to assess; (3) choosing the pain domain(s) to assess; and (4) selecting the time period of assessment (e.g., current pain experience versus recall of pain over the last day, week, or longer). The bulk of the chapter then reviews the available psychometric information regarding measures of six pain domains: pain intensity, pain affect, pain quality, pain site, pain's temporal characteristics, and pain interference. Next, the chapter briefly discusses strategies for assessing pain in special populations (e.g., infants and young children, the demented geriatric patient, or other patients who might have difficulty expressing themselves verbally). It ends with a summary of recommendations.

Validity, Reliability, and Utility in the Context of Pain Assessment

No measure is perfect. No one measure assesses all pain domains, nor is any single measure useful in all settings and with all populations. Moreover, because of the imperfection of available instruments, it is theoretically possible to modify any existing measure to improve it further, or to develop new and better measures to replace existing ones. As a result, new pain assessment procedures and measures are constantly being developed and published. Thus, the clinician or researcher seeking to find the best measure for his or her needs should not only be aware of the existing pain assessment literature, but should also know how to evaluate new measures as they are published.[1] The following section seeks to facilitate this task by briefly summarizing the three key issues that should be considered when evaluating any pain measure: *validity, reliability,* and *utility*.

Validity

Validity refers to the appropriateness, meaningfulness, and usefulness of a measure for a specific purpose. It is generally seen as the most important consideration in the evaluation of a measure.[2] Validity always needs to be evaluated with respect to the specific purpose a measure or instrument will be used for; measures are not inherently "valid" or "invalid" in and of themselves. For example, a hammer is not inherently valid. It is valid (useful) for driving nails into wood, but invalid for washing dishes.

Rarely, if ever, can the validity of a measure be determined with a single study. Rather, support for the validity of a measure is usually established over time and with a series of studies. When evaluating the validity of a potential measure, the clinician or investigator should consider *content*, *construct*, and *criterion* validity.

Content Validity. Content validity concerns the degree to which the items of a measure represent a defined universe or domain of interest. For example, if a measure of a patient's *usual* pain or *average* pain over the last month is needed, then a single rating of current pain would not usually be considered to have content validity for assessing this construct, because pain can vary so much from one moment to another. Similarly, if a measure of the impact of pain on a patient's life is needed, and a measure includes items that ask only about pain's impact on sleep and mobility (but not other important daily activities), the measure would not generally be viewed as adequately representing the domain of pain interference. Thus, a critical question that every test user should ask is whether or not a potential measure assesses or represents all of the key components of the domain of interest. If the measure does not meet this standard, it does not have content validity.

Construct Validity. Construct validity refers to how well the items of a measure perform as measures of the domain or construct of interest. Two measures can have similar content validity—that is, both may contain items that assess the critical components of some pain construct—but have different construct validity. For example, if two measures ask about pain interference with the same set of activities, yet respondents are asked to indicate the extent of interference with each activity using different response levels (for example, yes/no response in one measure versus 0–10 scales in the second), the latter measure may evidence more precision than the former. The more precise measure may represent the construct better, and have more construct validity than the less precise one, despite the fact that the two measures

have similar content validity. Similarly, if the language used in the items of one measure is clear and succinct and the other confusing and complex, the former measure would likely contain less error than the latter measure, and therefore better represent the construct of interest. Thus, factors other than content validity will impact how the scores obtained from different measures behave, especially with respect to their associations with other important pain-related measures and the precision with which they represent the domain of interest. Evidence for the construct validity of a measure generally comes from studies that demonstrate strong associations between a measure's score and other measures of the same construct, and weak to moderate associations with measures of other constructs.

Criterion Validity. Criterion validity refers to a measure's associations with one or more key outcome criteria. Usually, the most important criterion of a pain measure is the responsivity of the measure to the effects of a pain treatment, or to changes in pain over time, because pain measures are most often used for detecting these differences and changes. Pain measures that are proposed to be used as outcome measures in clinical trials should therefore have evidence that they are able to detect treatment effects or show expected changes in pain over time.

But not all pain measures are designed to assess treatment efficacy. A number of measures of pain quality, for example, and as described later in this chapter, were designed to distinguish from among different types of pain (e.g., neuropathic versus nociceptive). The validity of such measures should be determined by their ability to perform the task they were designed for or that they will be used for; their validity as measures of treatment efficacy need only be of concern when or if they are being considered for that specific purpose.

Reliability

Reliability refers to the extent to which the score from a test is free from errors of measurement. Many factors, other than a patient's experience of pain, could potentially influence his or her response to a pain measure or scale. Such factors could include the specific assessment setting (e.g., home versus clinic), assessment burden (e.g., single assessment versus a daily diary), the person administering the measure (e.g., research assistant, nurse, spouse, primary health care provider), other subjective experiences and feelings (e.g., being more or less fatigued or upset), motivational factors (e.g., desiring to appear stoic, wanting a prescription for a specific medication), ethnicity or culture, and previous learning experiences (e.g., the consequences of reporting of higher versus lower pain levels), among many others. The variability in a pain score (the ''variance'') that is associated with these other factors, and that is not associated with the specific domain of interest, is considered error variance. Although no measure is 100% reliable, the best measures demonstrate relatively little influence of these other factors and potential sources of error.

Higher error variance means lower reliability. Unlike validity, which is considered with respect to the proposed use of the measure, reliability is usually considered to exist within a measure. However, it is also possible for a measure to be more reliable in some settings or with some populations then in others. For example, as described in more detail later in this chapter, Visual Analogue Scales of pain intensity (where the respondent is asked to make a mark on a line that represents the perceived magnitude of pain) have been found to be more difficult for patients with cognitive deficits than with patients who do not exhibit cognitive deficits. These measures, then, might be considered to be inadequately reliable in populations at risk for cognitive deficits, although evidence indicates that they are adequately reliable in otherwise healthy adults. Thus, it is important that the reliability of any measure be established for the specific population with whom the measure will be used, or at least in samples of individuals who are similar to the population with whom the measure will be used.

Utility

Finally, issues of reliability and validity need to be considered in light of a measures' utility, given that there is often a trade-off among these. For example, to maximize the content validity of a measure of pain interference, one would want the measure to assess the pain interference of all, or nearly all, of the possible (100s? 1,000s?) activities a person could engage in. Such a measure, although it would have clear content validity, would not be practical; no one would use it. Similarly, to maximize the content validity of a measure of a patient's usual pain over the course of the last month, one might ask the patient to report on his or her current pain every hour for 30 days, and then average those responses into a single index of average pain. But few patients would be willing to perform this assessment task, and the costs of ensuring complete data for such a measure would be prohibitively expensive for most clinicians and many researchers. Deciding on which measure(s) to use for a particular application often comes down to selecting the measure that is both adequately valid and most practical.

How Many Pain Problems Should Be Assessed?

Patients often have more than one pain problem. For example, the majority of individuals with spinal cord have chronic pain, and the majority of these report pain at more than one site.[3] Clinicians and those researchers who do not limit their sample to the (few) patients with only one pain problem are faced with the difficult task of determining the number of pain problems to assess in any one patient or study participant. If only one ''primary'' pain problem is assessed at a clinic visit, but on the next visit a different ''primary'' pain problem emerges as the most distressing, then it would be very difficult to track the effects of pain treatment from one clinic visit to the next.

Similarly, researchers who limit the number of pain problems assessed to just one primary problem run the risk of underestimating the magnitude of pain and its impact in their research findings. On the other hand, it may not be practical to assess every pain problem in every patient seen in the clinic or in every participant of a research study. These considerations suggest that, in many situations, patients should have the opportunity to report on more than one pain problem, but not necessarily always be required or expected to report on every pain problem that they have at every assessment point.

But how many pain problems should be assessed? Two? Five? More? One approach to deal with this issue is to begin by assessing pain ''in general''; for example, asking patients to consider all of their pain problems together when rating the overall average magnitude or intensity of their pain and the impact of pain on their lives. This is a practical solution, especially for assessing pain interference, since it may be very difficult for patients to identify the unique contribution of each different pain problem to interference with different activities. Moreover, assessing global pain intensity and interference allows the clinician or researcher to have a single primary measure of these two key pain domains, making analyses and tracking over time easier.

However, limiting assessment to only pain ''in general'' may oversimplify assessment, and also interfere with determining the true effects of pain treatment. For example, if a pain treatment reduces the pain associated with one pain problem (headache) but not another (low back pain), the specific effect of the treatment on headache pain might be less noticeable or even lost altogether if a measure of ''general'' pain intensity is used. So, in many situa-

tions, allowing for the assessment of more than one pain problem would be useful.

Unfortunately, however, there is not yet a clear consensus in the field concerning the best number of pain problems to assess. In the clinical setting, it probably makes sense to assess as many of the pain problems that are of concern to the patient. If the patient experiences eight unique pain problems, and views each as a significant problem that contributes to dysfunction, then perhaps each of these should be assessed, at least at the initial evaluation, and then tracked at subsequent clinic visits as appropriate.

When determining how many pain problems to assess in a research study, the number of problems that should be assessed would vary as a function of the research question(s) being asked and the specific population being studied. One reasonable option would be to select the number of pain problems to assess that would capture the majority of patients in the population. For example, in persons with spinal cord injury, it has been recommended that investigators should consider assessing basic information (such as pain location and intensity) for up to three presenting pain problems.[4] In this instance, three was chosen as a way to balance the need for a thorough assessment against the need to minimize assessment burden, keeping in mind that the majority of persons with spinal cord injury and pain report three or fewer pain problems.[3] Although it is unlikely that a single upper limit of pain problems can be identified that should be assessed in every research project and with every patient population, each investigator should at least consider this issue when developing assessment protocols.

Which Pain Domain(s) Should Be Assessed?

Clinicians and researchers have long recognized that pain is a multidimensional experience that includes a number of measurable qualities such as intensity, affect (global bothersomeness of the pain experience as well as the impact of pain on emotional functioning), sensory quality, spatial quality (location), temporal quality, and impact on or interference with daily activities.[5,6] Although the focus of pain assessment in clinical and research settings has often been, and continues to be, on pain intensity,[7] there has been an increased interest in the assessment of pain's other domains.[8]

It is important that clinicians and investigators consider assessing more than just pain intensity for a number of important reasons. First, limiting assessment to only pain intensity leaves clinicians and researchers in the difficult position of having limited information about the presenting pain problem(s). In a clinical situation, changes in a pain domain not assessed might end up being critical for understanding the effects of a pain treatment (for example, if pain qualities are not assessed, and a treatment reduces the ''aching'' and ''deep'' qualities of a pain problem, but perhaps not average pain intensity overall; or if a treatment produces a decrease in the impact of pain on sleep or other areas of functioning, even when there has been a minimal impact on pain intensity). For this reason, anyone interested in assessing pain should at least consider all of the pain domains when determining which ones to assess, and perhaps only avoid those domains they are certain will not be important to treatment (for clinicians) or understanding (for researchers).

One of the factors that might determine the selection of fewer domains and measures (e.g., perhaps choosing to assess just pain intensity and pain quality) over a more comprehensive assessment (e.g., including measures of pain site, pain interference, and the temporal qualities of pain, as well as perhaps more general measures of psychological and physical functioning) is whether the pain problem being assessed is more acute or chronic. Acute pain, which may be defined as pain resulting from current or very recent damage to tissue, includes pain from medical procedures (e.g., injections, lumbar punctures, surgery) as well as both major and minor physical injuries. Because many acute pain problems tend to resolve quickly in most individuals, their impact tends to be transitory. In this situation, and if the focus of treatment is on just one or two pain domains (e.g., pain intensity, mood), then it may be appropriate to assess only one or two pain domains.

Chronic pain, on the other hand, tends to be more complex than acute pain. Patients' responses to chronic pain can vary a great deal, and its impact can be quite variable. For chronic pain, then, in both clinical and research settings, and in order to ensure a thorough understanding of the pain problem, more pain domains, and perhaps more measures that assess these domains, are often required.

Recall Ratings versus Summary Scores From Multiple Ratings Using Diaries

Often, the clinician or researcher wishes to have a measure of a patient's usual, least, or worst pain during a specific period of time. A single measure or rating of current pain is not likely going to be an adequate index of usual pain, given that pain can vary from one moment to another. So what is the best way to assess usual pain? Currently, the two viable options are: (1) ask the respondent to provide multiple ratings of current pain on pain diaries during the epoch of interest (e.g., four times/day for 7 days), and then compute the average, worst, and least pain levels from the ratings obtained, or (2) assess pain once, but ask the respondent to provide a *recall* rating of their average, worst, and least pain over the epoch of interest (e.g., asking respondents to rate their average, worst, and least pain intensity during the past week). Deciding between these two options has significant implications for the cost of a study and the reliability and validity of the obtained scores. However, each approach has strengths and weaknesses, and pain assessment experts have not yet reached a clear consensus on which option should be recommended.

Support for the first approach, using multiple assessment from diary data (most often obtained electronically using palm-top computers or automated telephone recordings) comes from studies that have demonstrated (1) a biasing impact of recent pain and worst pain (also known as ''end'' and ''peak'' effects) on recall ratings[9–11] and (2) the ability of electronic diaries (through the use of palm-top computers that can obtain ratings throughout the day, and download the ratings onto a server) or phone diaries to obtain multiple pain ratings over time, making it possible to average these ratings into a highly reliable measure of average pain.[12,13] These considerations provide a strong incentive to use diary assessments. In general, when diaries are required, electronic or phone diaries are preferred over paper-and-pencil ones, given the frequency with which patients use paper-and-pencil diaries inappropriately.[14,15] Because of the reported strengths of diary approaches, there has been a recent significant increase in the use of this approach to collect data in clinical trials.[16–19]

However, there are three findings from studies of diary pain assessment, and one practical issue, that make some investigators hesitant to embrace a diary approach to pain assessment, especially for use in clinical trials. First, as a practical issue, diary data are expensive. The financial cost of the hardware and software associated with data collection via electronic diaries may be beyond the means of some investigators. Related to this, there is also a cost in terms of patient assessment burden. It is not yet clear how many times per day a patient needs to report pain in order to adequately capture their usual pain experience. Some procedures require only one assessment per day[14,20–22] but it is more common to ask patients to provide three[22] or even more (four to six times[16,18,23]) ratings per day. This requires a significant effort on the part of patients. To the extent that much less costly recall ratings (that only require one assessment) may be adequately valid (and data suggest that they are, see later), investi-

gators may save substantial resources and significantly decrease the patient assessment burden, if recall ratings are used instead of diary ratings.

A second problem with diary data is that using this approach will result in missing data. The reported percentages of missing data points from electronic diary studies range from 6%[15] to 17%.[24] The reported rates of study participants who provide incomplete data (that is, at least some missing data during the study period) range from 17%[14] to 46%.[20] The primary reason reported for missing electronic data is that the patient did not hear the alarm or cue asking for the assessment.[25] Other reasons given include: the alarm going off at an inconvenient time, the participant being too busy to respond, technical difficulties with the computer, emotional reasons, and pain being too severe at the time of assessment.[25] When data are missing, investigators need to either remove subjects from the analyses (which limits the generalizability of the findings and runs the risk of resulting in findings that overstate the impact of treatment) or use some approach to impute the missing data (that is, estimate what the missing ratings might have been, had all subjects provided complete data). A variety of data imputation procedures can be used for clinical trial data, such as ''last observation carried forward,'' which involved taking the most recent rating obtained, and replacing all missing values with that rating.[16] A more conservative approach is to replace missing values with pretreatment ratings. Regardless of the approach used, however, data imputation adds error; imputed data are estimates only. And there is no evidence that the error added with data imputation is any less then the error that exists in recall ratings. In fact, the error added by the need to impute missing scores could potentially be greater than that associated with recall bias, so the use of diary data over recall ratings could potentially result in a more costly and effort-intensive assessment procedure that is ultimately also less reliable.

A third issue is that the use of electronic diaries limits the subjects who can participate in a study. For example, in one electronic diary study that approached 52 possible participants, 6 refused participation outright, one did not have the motor ability to hold the computer stylus, and 5 had visual problems that interfered with their ability to read the computer display.[20] By limiting the participants in clinical trials to those who are able and willing to use electronic diaries, their use in these trials limits the generalizability of the study findings.

Also, research supports the conclusion that recall ratings are adequately valid for most research purposes. Although research does indicate that there can be both peak and end effects that bias recall ratings, these effects tend to be small.[9] Moreover, research indicates that the correlations between recalled average pain (in the previous 7 days) and actual average pain during that same period (as assessed by diaries) are quite strong (correlation coefficients range from 0.68 to 0.99[26–32])—well within a range that indicate they carry valid variance as measures of average or usual pain. In short, recall ratings reflect actual average pain, and are therefore valid indicants of that pain.

Finally, and perhaps most critically, the research finding that provides the most support for the validity of recall ratings as outcome measures in pain clinical trials is indisputable: recall ratings are responsive to the effects of pain treatments known to impact pain. Hundreds, if not thousands, of clinical trials have shown that effective treatments for chronic pain result in reductions in recall ratings of average pain.

In summary, although data from pain diaries could potentially be more valid as measures of average pain than recall ratings are among those who provide complete data, scores from such data could also result in more measurement error (when data need to be imputed), create problems with generalizability (when subjects who cannot complete diaries or those who provide missing data are excluded), or both. Although some of the sources of error in recall ratings are now better known, those associated with peak (most pain) and end (most recent pain) effects tend to have only small effects on recall ratings. Most importantly, research consistently shows that the bulk of the variance of recall ratings is related to actual pain scores, and that recall ratings are responsive to treatment effects. Thus, recall ratings can be used as valid measures of usual pain in clinical trials.

MEASURING PAIN'S DOMAINS

Measuring Pain Intensity

The single pain domain assessed most often in clinical and research settings is pain intensity, or the magnitude of felt pain.[33] The three most commonly used scales to assess pain intensity are (1) the Visual Analogue Scale (VAS), (2) the Numerical Rating Scale (NRS), and (3) the Verbal Rating Scale (VRS) (Fig. 20.1). The results from research across many different pain populations yield fairly consistent findings concerning the psychometric properties of these measures[5,8] and may be summarized as follows:

1. Each of these measures is adequately valid and reliable as a measure of pain intensity in most settings.
2. For both VAS and 0–10 NRS scales, changes (decreases) between about 30% to 35% appear to indicate a meaningful change in pain to patients across patient populations.
3. For 0–10 NRS scales, the rating chosen has a specific meaning in terms of the impact of pain on functioning. In most samples, ratings in the 1–4 range have a minimal impact on pain, and can be viewed as representing ''mild'' pain. Once ratings reach 5 or 6, patients report that pain has a greater impact on functioning; these ratings can be viewed as ''moderate'' pain. Ratings ranging from 7–10 have the greatest impact on functioning, and can be viewed as representing ''severe'' pain.
4. When examined, single-item measures of pain intensity appear to have adequate test-retest stability (often, but not always, greater than 0.80) over short periods of time.
5. There are fairly consistent differences between available measures in terms of their failure rates. VASs usually show higher

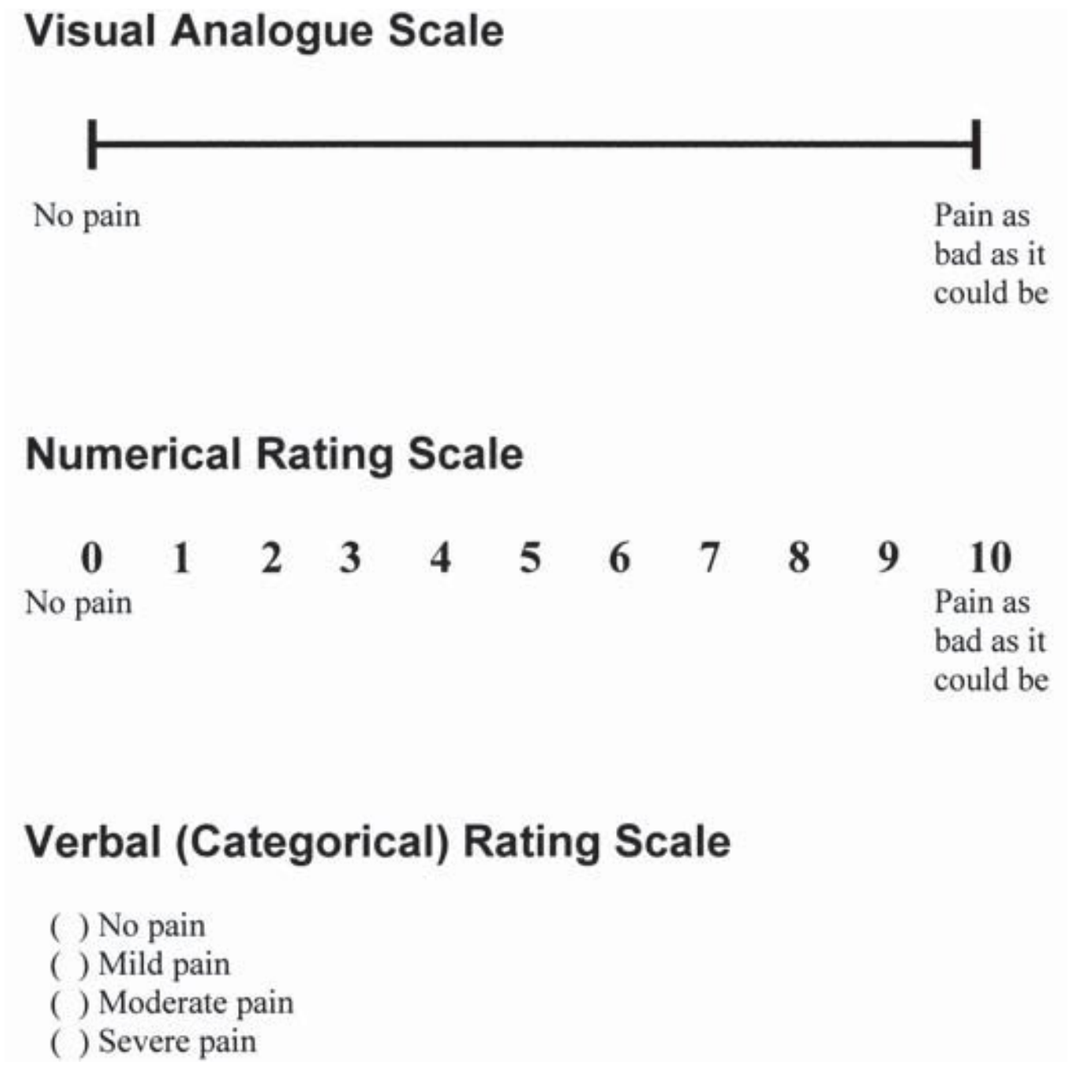

FIGURE 20.1 The Visual Analogue Scale (VAS), Numerical Rating Scale (NRS), and Verbal Rating Scale (VRS).

failure rates than NRSs and VRSs, and NRSs tend (when differences are found) to show slightly greater failure rates than VRSs, probably related to the increased complexity of matching a sensation to a line length versus a number or verbal descriptor.
6. In terms of preferences, patients tend to prefer VRSs and NRSs over VASs.

Recommendations for Assessing Pain Intensity

Given the empirical support for the validity and reliability of VASs, NRSs, and VRSs as measures of pain intensity, any of these could reasonably be employed in most clinical settings or as outcome measures in clinical trials. Primarily because of (1) differences in failure rates between these measures in some populations (supporting NRSs and VRSs over VASs),[34] (2) the evidence that some people can differentiate between more than just four or five levels of pain between from "no pain" and "extreme pain,"[35,36] and (3) the potential benefits of standardizing pain intensity assessment to allow for increased comparisons between studies, the field has recently moved toward recommending that clinicians and researchers consider first using the 0–10 NRS (see Fig. 20.1) over other pain intensity measures.[8]

Of course, there may be times when the 0–10 scale may not be appropriate. This scale requires the respondent to match his or her pain experience to a number, a task that may not be that easy for the very young, the extremely elderly, or individuals who are very ill. In these cases, and perhaps others, alternative pain intensity measures may be needed (see final section on assessing pain in special populations).

Measuring Pain Affect

The affective quality of pain includes both the general unpleasantness and/or bothersomeness of the pain sensation, as well as the many varieties of affect (fear, anger, sadness, frustration, feelings of hopelessness) that pain can produce—especially as it becomes chronic. The most common measures of general, global pain unpleasantness are single-item rating scales (VASs, NRSs, and VRSs) that use endpoints that reflect extreme levels of unpleasantness (e.g., for a 0–10 NRS or 100 mm VAS, "not bad at all" for the 0 rating or 0 mm mark, and "the most unpleasant feeling possible for me" for the 10 rating or 100 mm mark[37]). In general, these measures have proven useful in highly controlled laboratory studies that seek to differentiate intensity from affective components of pain.[37,38]

On the other hand, outside of the laboratory setting, patients appear to treat single-item VAS, NRS, and VRS measures of pain unpleasantness much like measures of pain intensity, so that the two are often indistinguishable from one another in clinical populations.[39,40] Moreover, one might question the content validity of single-item measures of affect, given the complex and multidimensional nature of emotional experience.

Pain affect can also be assessed using multiple-item scales, the most common of which are the affect subscale of the McGill Pain Questionnaire (MPQ[41]) and its associated short form, the MPQ-SF[42] (Fig. 20.2). The original MPQ contains 78 descriptors that are categorized into 20 subgroups, 5 of which assess the impact of pain on affect. The five affective domains are: tension (assessed using "tiring" and "exhausting" descriptors), autonomic (assessed using "sickening" and "suffocating" descriptors), fear (assessed using "fearful," "frightful," and "terrifying" descriptors), punishment (assessed using "punishing," "grueling," "cruel," "vicious," and "killing" descriptors), and affective miscellaneous (assessed using "wretched" and "blinding" descriptors).[41] Within each domain, when administered the MPQ, respondents are asked to circle or mark the single descriptor within each group that most accurately reflects or describes their pain. Descriptors are then ranked according to their position in the word set. The Pain Rating Index (PRI), which can be computed for each of the four primary MPQ subscales, including the affective subscale, is the sum of the rank values of these descriptors.

The short form of the MPQ (MPQ-SF) contains 15 descriptors, 4 of which come from the MPQ Affective subscale ("tiring-exhausting," "sickening," "fearful," and "punishing-cruel").[42] However, unlike the MPQ, which requires respondents to select a single descriptor from each category list that best describes their pain, respondents to the MPQ-SF are allowed to rate the severity of each item individually on a four-point Likert scale (0 = none to 3 = severe). A severity or intensity score can then be calculated for the Affective subscale (as well as for Sensory and Total scale scores, see next section on pain quality assessment). Research has shown that the correlations between the corresponding scales on the MPQ and MPQ-SF are high (*rs* range, 0.68 to 0.92).[42–44]

There is a substantial amount of data supporting the validity of the MPQ and MPQ-SF Affective subscales. First, like the other MPQ and MPQ-SF scales, the Affective subscale has been shown to be responsive to pain treatment.[45–47] Additional support for the validity of the MPQ-Affective scale as a measure of the affective component of pain, specifically, was reported by Ahles and colleagues, who found that this scale was more strongly associated with measures of psychological distress than with measures of pain intensity.[48] Also, Kremer and colleagues reported that patients with cancer report a greater affective component of their pain on the MPQ-Affective scale than patients with low back pain, consistent with the hypothesis that cancer pain may be associated with higher levels of affect (e.g., be more worrisome and cause more fear) than low back pain.[49] Given the strong associations between the original MPQ and SF-MPQ Affective scales, it is likely that the findings for the Affective MPQ scale would likely be similar for the SF-MPQ, although research confirming this has yet to be performed.

Recommendations for Assessing Pain Affect

Although single-item measures of pain affect or pain bothersomeness have demonstrated validity in highly controlled laboratory studies, supporting their use in this setting, they have shown less discrimination (from single-item measures of pain intensity) in clinical populations. Thus, with clinical populations, when an index of pain affect is needed, clinicians and researchers should strongly consider administering the MPQ or MPQ-SF Affective items. The MPQ Affective scale, having a longer history than the MPQ-SF, has more empirical support for its reliability and validity. However, given the strong associations between the MPQ and MPQ-SF scales, their high degree of item overlap, and the relative brevity and greater simplicity of the MPQ-SF for scoring, adequate evidence exists to support the use of the MPQ-SF as well.

Measuring Pain Quality

The experience of pain consists of much more than its magnitude or intensity and affective components. Pain is also often described using a number of different qualities, such as "burning," "aching," and "tender," among many others. Although historically clinicians and researchers have focused on pain intensity as the single most important pain domain to assess,[33] there has been a recent upsurge of interest in the assessment of pain qualities. The two primary purposes of such measures are: (1) to help diagnose the pain problem and (2) to more thoroughly describe the pain experience and determine the effects of pain treatments on that experience.

Using Pain Quality Measures as Diagnostic Aides

A growing body of research supports the conclusion that different pain qualities are associated with different causes, sources, or

Short-Form McGill Pain Questionnaire (SF-MPQ)

A. PLEASE DESCRIBE YOUR PAIN DURING THE LAST WEEK. *(Check off one box per line.)*

	None	Mild	Moderate	Severe
1. Throbbing	0 ☐	1 ☐	2 ☐	3 ☐
2. Shooting	0 ☐	1 ☐	2 ☐	3 ☐
3. Stabbing	0 ☐	1 ☐	2 ☐	3 ☐
4. Sharp	0 ☐	1 ☐	2 ☐	3 ☐
5. Cramping	0 ☐	1 ☐	2 ☐	3 ☐
6. Gnawing	0 ☐	1 ☐	2 ☐	3 ☐
7. Hot-burning	0 ☐	1 ☐	2 ☐	3 ☐
8. Aching	0 ☐	1 ☐	2 ☐	3 ☐
9. Heavy (like a weight)	0 ☐	1 ☐	2 ☐	3 ☐
10. Tender	0 ☐	1 ☐	2 ☐	3 ☐
11. Splitting	0 ☐	1 ☐	2 ☐	3 ☐
12. Tiring-Exhausting	0 ☐	1 ☐	2 ☐	3 ☐
13. Sickening	0 ☐	1 ☐	2 ☐	3 ☐
14. Fear-causing	0 ☐	1 ☐	2 ☐	3 ☐
15. Punishing-Cruel	0 ☐	1 ☐	2 ☐	3 ☐

B. PLEASE RATE YOUR PAIN DURING THE LAST WEEK.

The following line represents pain of increasing intensity from "no pain" to "worst possible pain". Place a vertical mark (|) across the line in the position that best describes your pain **during the last week.**

No Pain — **Worst Possible Pain**

Score in mm
(Investigator's use only)

C. CURRENT PAIN INTENSITY

0 ☐ No pain
1 ☐ Mild
2 ☐ Discomforting
3 ☐ Distressing
4 ☐ Horrible
5 ☐ Excruciating

Questionnaire Developed by: Ronald Melzack

types of pain. In one study supporting this conclusion, Chang and colleagues[50] induced skin pain and muscle pain in human subjects through the use of intracutaneous and intramuscular injection of capsaicin into the left forearm, respectively. Although ratings of global pain intensity were very similar for both the skin and muscle pain, capsaicin injection into skin and muscle produced distinctly different pain qualities, as described by the subjects. When capsaicin was injected into the skin, subjects described their pain as sharp, cutting, and burning; pain induced by intramuscular capsaicin injection was described as throbbing, pulsing, and tingling. The results of this study support the idea that different pain mechanisms or sources of pain produce different pain sensations, and that these differences can be reliably assessed through the assessment of specific pain qualities. Also, it is generally thought that different nociceptors and fibers underlie different pain sensations, with the myelinated A-delta fibers responsible for localized "sharp," "stinging," and "shooting" pain, and the unmyelinated C-fibers responsible for less localized dull pain sensations.[51–53]

To date, five measures of pain quality have been developed that are specifically designed to assist in the diagnosis or classification of pain. They include: (1) the Leeds Assessment of Neuropathic Symptoms and Signs,[54] (2) the Self-Report Leeds Assessment of Neuropathic Symptoms and Signs,[55] (3) the Neuropathic Pain Questionnaire,[56] (4) the Neuropathic Pain Questionnaire–Short Form,[57] and (5) the Neuropathic Pain Diagnostic Questionnaire (DN4).[58]

Leeds Assessment of Neuropathic Symptoms and Signs. The Leeds Assessment of Neuropathic Symptoms and Signs (LANSS)[54] was perhaps the first measure designed specifically to distinguish neuropathic from nociceptive pain. It has two components: a pain questionnaire and a sensory testing component. The pain questionnaire consists of five items that ask respondents to indicate, yes or no, if their pain could be described as: (1) "[consisting of] strange, unpleasant sensations . . . like pricking, tingling, pins and needles"; (2) "[making] . . . the skin in the painful area look different from normal . . . like mottled or looking more red . . ."; (3) "[making] . . . the affected skin abnormally sensitive to touch . . ."; (4) "[coming] . . . on suddenly and in bursts for no apparent reason . . . like electric shocks, jumping and bursting . . ."; (5) "[feeling] . . . as if the skin temperature in the painful area has changed abnormally . . . like hot and burning . . ." The sensory testing component asks a clinician to test for allodynia (by lightly stroking a nonpainful and the painful area with cotton wool) and to test for altered pin-prick threshold (by comparing the patient response to a 23-gauge needle mounted inside of a syringe barrel placed gently on the skin in a nonpainful and then in the pain area). Each response is weighted, and the weights of all positive responses are summed to create a total score, with a score of less than 12 indicating an unlikelihood that neuropathic mechanisms are contributing to the patient's pain, and a score of 12 or greater indicating that neuropathic mechanisms are likely to be contributing to the patient's pain.

The LANSS showed a high rate (85%) of accurate classification for neuropathic versus nonneuropathic pain in the original development sample that was replicated in a cross-validation sample (82% accuracy).[54] This high level of accuracy was subsequently replicated in additional samples of patients (one sample with cancer[59] and a second with mixed chronic pain conditions[60]). The internal consistency of LANSS is high (Cronbach's alpha = 0.74),[54] indicating adequate reliability, and the LANSS items have also demonstrated an ability to discriminate between patients with fibromyalgia and patients with rheumatoid arthritis.[61] Finally, although the LANSS was not designed to be a measure of treatment outcome, one study demonstrated significant beneficial effects for transcranial magnetic stimulation for central (poststroke) and peripheral (trigeminal neuralgia) pain using the LANSS as an outcome measure.[62]

However, the LANSS has also been criticized as being difficult to administer, and concerns have been raised about using a sharp needle for assessing pin-prick threshold differences.[63] Specifically (1) the allodynia item was viewed as ambiguous given that this item does not provide an option for scoring patients with both sensory deficits and no allodynia and (2) using a sharp needle for pin-prick detection may pierce the skin in patients with fragile skin. In response to these concerns, the LANSS developer clarified that (1) if the patient has sensory deficits in the painful area and does not report allodynia, the allodynia item should be scored as "0" and (2) clinicians need not use a sharpened needle to detect differences in pin-prick threshold if this is deemed as unsafe for a particular patient—dulled (but sterile) pins could be used instead. The important issue for this item is whether a difference in sensation or threshold exists between the painful and a nonpainful area when a pin-prick is applied to both. Also, of four studies that have provided cross-validation psychometric data concerning the LANSS, three did not report significant difficulties using this measure.[60–62] One study reported that 6 of 26 patients required assistance with the five pain quality items (but did not report any difficulties with the sensory items).[59] In this latter study, if the pain quality being assessed was not clearly present (i.e., if either the patient or clinician was unsure), it was scored as absent. The resulting accuracy for discrimination of the LANSS when scored in this way was still high (86%).[59]

Self-Report Leeds Assessment of Neuropathic Symptoms and Signs. One potential drawback to the LANSS, that could limit its use in some clinical and research settings, is that it requires a trained clinician to administer. To address this limitation, a self-report version of the LANSS (S-LANSS) has been developed.[55] The S-LANSS includes the same five pain quality items of the LANSS. However, the sensory items were modified to allow patients to self-administer them by: (1) gently rubbing the painful and a nonpainful area with their index finger for the allodynia item and (2) gently pressing the painful and a nonpainful area with a finger tip to assess static allodynia. The S-LANSS has demonstrated an ability to correctly classify 75% of 200 patients with mixed chronic pain problems as having neuropathic versus nociceptive pain.[55] When administered by a clinician, however, its accuracy rate increased to 80%.[55] Finally, the internal consistency of the S-LANSS (Cronbach's alpha = 0.76) supports its reliability as well as the conclusion that the S-LANSS items tap into the same underlying dimension.

Neuropathic Pain Questionnaire. The Neuropathic Pain Questionnaire (NPQ)[56] has 12 items that assess two global affective pain domains (unpleasant and overwhelming pain) and 10 specific pain descriptors (burning, sensitive, shooting, numb, electric, tingling, squeezing, freezing, increased pain due to touch, increased pain due to weather changes). The items were selected from a larger pool of items specifically because of their ability to discriminate between patients with neuropathic and nonneuropathic pain.

When completing the NPQ, respondents are asked to rate each item using a 0 to 100 severity scale. The ratings are then weighted based on their demonstrated ability to discriminate between pain types; items with better discriminative ability are given more weight. The weighted scores are then summed into a total, with total scores below 0 suggesting nociceptive pain, and scores of 0 or above suggesting neuropathic pain. The sensitivity and specificity of the NPQ for discriminating neuropathic from nociceptive pain were found to be 75% and 78% in the scale development sample, respectively. Cross-validation yielded a sensitivity of 67% and a specificity of 75%.[56]

Neuropathic Pain Questionnaire–Short Form. A short form of the NPQ has also been developed (NPQ-SF),[57] with the idea that this could be used in settings where subject assessment burden is

a primary concern (e.g., survey research). A discriminant function analysis was used to select only those items from the pool of 12 NPQ items that contributed statistically significantly to the ability to classify patients with neuropathic versus nonneuropathic pain. Three items emerged from these analyses: numbness, tingling pain, and increased pain due to touch. In the scale development sample, these three items had a 73% classification accuracy rate, indicating that NPQ-SF was only slightly less accurate in its predictive power than the original NPQ, despite its brevity.[57]

Neuropathic Pain Diagnostic Questionnaire. The Neuropathic Pain Diagnostic Questionnaire (DN4)[58] is the most recently developed measure that was designed to discriminate between neuropathic and nonneuropathic pain. It is administered by a clinician, and begins by asking patients if they do or do not experience their pain as having burning, painful cold, or electric shock qualities. Patients are then asked to indicate if they do or do not experience tingling, pins and needles, numbness, or itching in the same area that they experience pain. Finally, and similar to the LANSS, the evaluating clinician determines if hypoesthesia (decreased sensitivity) to touch or to pinprick exists in the painful area, and whether lightly brushing the area elicits pain. In the initial study, the DN4 yielded a very high level of accuracy (86%; sensitivity, 83%; and specificity, 90%) for distinguishing patients with and without neuropathic pain.[58]

Pain Quality Scales as Descriptive and Outcome Measures

Pain quality measures may also be used to describe the pain associated with different pain conditions, as well as to identify the effects of pain treatments on various qualities of the pain experience. To the extent that different pain qualities are linked to different pain mechanisms, then understanding the effects of pain treatments on those qualities may be used to better understand the mechanisms of pain treatments. In addition, given the evidence (reported later) that different pain treatments have different effects on various pain qualities, pain clinicians could potentially use pain quality assessment for helping to select from among different treatment options. For example, clinicians may offer patients reporting their pain as primarily ''aching'' those treatments shown to impact ''aching'' pain most effectively, while providing patients who describe their pain as ''electrical'' with treatments that have been shown to reduce ''electrical'' pain sensations.

To date, five measures have been developed to assess pain quality, and have been used as outcome measures in clinical trials. They include (1) the McGill Pain Questionnaire (MPQ),[41] (2) the Short-Form McGill Pain Questionnaire (MPQ-SF),[42] (3) the Neuropathic Pain Symptom Inventory (NPSI),[64] (4) the Neuropathic Pain Scale (NPS),[65] and (5) the Pain Quality Assessment Scale (PQAS).[66]

McGill Pain Questionnaire. The MPQ was introduced previously in the context of assessing pain affect. In addition to assessing affective pain domain, the 78 MPQ descriptors can also be scored to assess sensory pain (10 sensory categories, such as temporal, punctuate pressure, and thermal pain, assessed using 42 descriptors), evaluative pain (one category, assessed using five descriptors), and miscellaneous pain (four categories that do not clearly fall into sensory or affective components, assessed using 17 descriptors).[41]

As described previously, respondents are asked to select the single descriptor from each of the 20 categories (the number of descriptors listed per category varies from 2 to 6) that best describes his or her pain, and the rank order of the descriptors in each category are summed to compute sensory, affective, evaluative, miscellaneous, and total scores.

Support for the usefulness of the MPQ comes from the fact that it has been used in hundreds of studies, and has been translated into at least 20 languages.[67] Moreover, a three factor (sensory, affective, and evaluative domains) structure of the MPQ has been confirmed in two studies,[68,69] although the high degree of association among these subscales suggests some limitations in discriminative validity of the primary MPQ scales.[68] Also, and of primary importance, the MPQ scales have demonstrated validity as outcome measures given their responsivity to changes produced by pain treatments.[47,75,76]

A number of studies have examined the reliability of the MPQ. In populations of patients with cancer pain, studies have found that responses to the MPQ are generally consistent over the time span of several days.[77–79] In a study with patients with low back pain, Love and colleagues[78] found adequate test-retest stability for the MPQ scale scores (total: r = 0.83; sensory: r = 0.76; affective: 0.78) over the course of several days.

Despite the many strengths of the MPQ, it also has some limitations. First, although it only takes about 5 minutes to complete by someone familiar with the measure, the MPQ includes a large number of descriptors that are rarely used by some individuals with pain; 78 descriptors suggests a very high degree of content validity, but this many descriptors may not be needed to adequately describe pain quality in many populations. Pain quality measures with fewer items may be adequately thorough, while also still providing adequate content validity. Indeed, this limitation may be one reason that the short-form version of the MPQ, described later, was developed.

A second limitation of the MPQ concerns the way it is scored. Although it probably makes sense to combine multiple affective responses into a composite Affective scale, there may be limitations in combining a large number of different sensory descriptors into a composite sensory scale. Primary among these is the possibility that such a procedure does not allow investigators to detect the impact of treatments on specific pain descriptors. A significant effect of a pain treatment on the MPQ sensory pain scale could have been due to its modest effects on many different pain qualities, or a large effect on just a few. One of the important reasons to assess pain quality in clinical trials is to determine the effects of treatment on specific pain qualities; scoring the MPQ descriptors into composite scales does not allow for this.

Also, because it is unlikely that pain treatments impact all pain qualities in the same way, the use of composite pain quality scores, based on many different items (recall that the MPQ sensory scale assesses 10 quality domains using 42 descriptors), runs the risk of reducing one's ability to detect significant effects. When using composite measures in clinical trials that include items that are not affected by treatment, or are affected only minimally, the effect size for the total scale is reduced. Indeed, when differences are found, the MPQ scale scores tend to be less responsive to treatment effects than single-item pain intensity ratings.[80–82]

Short-Form McGill Pain Questionnaire. The Short-Form McGill Pain Questionnaire (SF-MPQ) was developed as a measure that balances the need for pain quality data against the need to minimize assessment burden (see Fig. 20.2).[42] As previously mentioned in the Affect section, the SF-MPQ consists of 15 descriptors, each of which can be rated on a four-point severity scale from ''none'' to ''severe.'' The 15 items were selected based on their frequency of endorsement by patients with a variety of pain disorders. Eleven of the descriptors assess sensory pain (throbbing, shooting, sharp, cramping, gnawing, hot-burning, aching, heavy, tender, and splitting), and, as described previously, four items assess affective pain.

Evidence supporting the validity of both SF-MPQ scales includes data showing a strong association between the sensory and affective scales scored from the SF-MPQ and the original MPQ sensory and affective subscales.[42–44] Also, a number of studies have demonstrated that the SF-MPQ is responsive to pain treatments, providing additional critical support for the validity

of the SF-MPQ as an outcome measure.[83–85] Finally, because each SF-MPQ item is individually rated, SF-MPQ responses could theoretically be used in clinical trials to look at the specific effects of pain interventions on particular pain qualities, although this strength of the SF-MPQ has yet to be capitalized on.

Limitations of the SF-MPQ include the fact that some descriptors common to neuropathic pain (e.g., electrical, tingling) are not included in the measure, limiting its utility in individuals with neuropathic pain. An additional limitation of the SF-MPQ concerns scoring. As discussed previously with respect to the MPQ, if the items are combined into scale scores, these scores may be less sensitive to treatment effects than are individual ratings of pain intensity or individual descriptor ratings. This makes the SF-MPQ scale scores, perhaps, less useful than global pain intensity ratings or even the individual SF-MPQ items as outcome measures.

Neuropathic Pain Symptom Inventory. The Neuropathic Pain Symptom Inventory (NPSI)[64] includes 12 items that were selected to assess four global domains of neuropathic pain (spontaneous ongoing pain, spontaneous paroxysmal pain, evoked pain, and paresthesias/dysesthesia). Respondents rate the severity or intensity of each descriptor item on 0 to 10 numerical rating scales. Two additional items assess the temporal qualities of pain (number of hours of spontaneous pain in the past 24 hours, number of paroxysms during the last 24 hours).

As reported in the initial development study, short-term (3 hours) and long-term (1 month) test-retest stability of the NPSI items were shown to be very high, as measured by intra-class correlation coefficients (short-term: range 0.87–0.98; long-term: 0.78–0.98). Also, validity for the evoked pain items was evidenced through their significant associations (*r*s range 0.66–0.73) with related clinician scores of pain evoked by brushing, pressure, and cold stimuli. Changes in the NPSI total score were also found to be associated significantly with patient and provider ratings of global improvement over a one-month period. However, to date, no other studies using the NPSI have been reported.

Neuropathic Pain Scale. The Neuropathic Pain Scale (NPS) was developed as a measure of neuropathic pain to both (1) describe neuropathic pain qualities in different pain populations, and (2) document the impact of pain treatments on pain qualities in clinical trials.[64] The NPS includes 10 items, two that assess global pain intensity and unpleasantness, and eight that reflect specific pain domains (six pain qualities and two spatial characteristics) likely to be reported by patients with neuropathic pain syndromes:

Respondents rate each item on a scale from 0 to 10, with 0 being "no ____" or "not ____" and 10 corresponding to "the most ____ sensation imaginable." An eleventh item allows patients to report the temporal nature of their pain (constant with intermittent increases, intermittent, or constant with fluctuation). Rather than combining the individual item ratings into scale scores, the NPS items were intended primarily to be used for assessing distinct pain qualities, which could then be used to create a profile of a person's pain quality experience. A growing body of research supports the validity of the NPS for describing neuropathic pain conditions,[86–88] distinguishing between pain diagnoses,[55,64,86] predicting treatment outcome,[89] and other symptoms,[90] and detecting treatment effects.[64,71,91–97]

The NPS has also shown utility for identifying the pain qualities affected by different pain treatments.[65,71,93,97] For example, a recent study examined the effectiveness of the NPS for assessing changes in pain qualities in three groups (peripheral neuropathic pain, low back pain, and osteoarthritis) of patients treated with open label lidocaine patch 5%.[93] Although significant changes in almost all NPS pain qualities were found, significantly larger changes were seen for NPS items measuring sharp and deep pain than for items measuring cold, sensitive, or itching pain.[93] In another study, controlled-release oxycodone was found to be associated with decreases in sharp, dull, deep, and surface pain, but had little impact on hot, cold, itchy, or sensitive pain in patients with painful diabetic neuropathy.[66] In a sample of patients with mixed neuropathic pain conditions, intravenous lidocaine and phentolamine were found to have similar effects on 8 of 10 NPS items, although lidocaine had a greater effect on global pain unpleasantness and deep pain.[65] Finally, one study showed that tizanidine for neuropathic pain impacted the hot, cold, and sensitive NPS items (as well as global intensity and unpleasantness) after 2 weeks of treatment, and then impacted sharp, dull, and deep pain NPS items after 8 weeks, indicating that the NPS may be used to show how treatments impact various pain qualities over time.[96]

Another strength of the NPS is its brevity, which makes it potentially useful in survey research and in settings where assessment burden may be a significant issue. Also, the NPS has been translated into 24 languages, and so may be useful for cross-cultural research comparing neuropathic pain conditions and treatments across cultures.

Although the NPS was originally designed to be scored to create a "profile" of sensation severity across different pain qualities, it is possible to combine the items into composite scores. Galer and colleagues,[91] for example, created four different NPS composite scores when examining the effects of a lidocaine patch 5% in a sample of patients with postherpetic neuralgia: an average of all 10 items (NPS10), an average of the eight specific descriptors excluding the global ratings of pain intensity and unpleasantness (NPS8), an average of the eight items that do not reflect allodynia (i.e., excluding the "sensitive" and "surface" items; NPS NA), and an average of four items thought to reflect nonperipheral pain mechanisms ("dull," "deep," "sharp," and "burning" items; NPS4). However, concerns about the use of composite scores from pain quality measures, raised above with respect to the MPQ, are also relevant here; use and interpretation of composite pain quality scores, regardless of the measure used for item selection, needs to proceed with caution.

The primary limitation of the NPS is associated with one of its strengths—its brevity. The NPS does not assess a number of pain qualities that are commonly reported by patients with some neuropathic pain conditions, such as shooting, electrical, and tingling pain. Also, the NPS does not assess some pain qualities experienced by individuals with nonneuropathic pain, limiting its utility in populations with musculoskeletal problems, such as individuals with low back pain or arthritis.

Pain Quality Assessment Scale. The Pain Quality Assessment Scale (PQAS; Fig. 20.3)[5,98] was developed to make available a measure that had the strengths of the NPS, but without its primary limitation. It uses the existing 10 NPS items as a starting point, but then also includes 10 additional items to create a measure capable of assessing the most common pain qualities seen across a variety of chronic pain conditions.[66] In addition to the original NPS items, the PQAS includes the following pain qualities to make it possible to assess additional common neuropathic and nociceptive pain qualities: tender, shooting, numb, electrical, tingling, cramping, radiating, throbbing, aching, and heavy. Like the NPS, the PQAS includes an additional item to differentiate between three primary temporal patterns of pain: intermittent (i.e., variable pain with some pain free periods), variable (variable pain without pain-free periods), and stable (i.e., constant pain with little variation). Thus, the final 21-item PQAS was intended to be comprehensive enough to capture the majority of a patient's pain experience, yet also be brief enough to minimize assessment burden.

All of the data that support the validity of the NPS also support the PQAS, since the NPS items are contained in the PQAS. In addition, in the first published report using the PQAS items, it was found that all 10 of the new PQAS items (i.e., the non-NPS

PAIN QUALITY ASSESSMENT SCALE (PQAS)

Instructions: There are different aspects and types of pain that patients experience and that we are interested in measuring. Pain can feel sharp, hot, cold, dull, and achy. Some pains may feel like they are very superficial (at skin-level), or they may feel like they are from deep inside your body. Pain can also be described as unpleasant.

The Pain Quality Assessment Scale helps us measure these and other different aspects of your pain. For one patient, a pain might feel extremely hot and burning, but not at all dull, while another patient may not experience any burning pain, but feel like their pain is very dull and achy. Therefore, we expect you to rate very high on some of the scales below and very low on others.

Please use the 19 rating scales below to rate how much of each different pain quality and type you may or may not have felt ***OVER THE PAST WEEK, ON AVERAGE.***

Place an "X" through the number that best describes your pain. For example:

0	1	2	X	4	5	6	7	8	9	10

1. Please use the scale below to tell us how **intense** your pain has been over the past week, on average.

No pain	0	1	2	3	4	5	6	7	8	9	10	The most **intense** pain sensation imaginable

2. Please use the scale below to tell us how **sharp** your pain has felt over the past week. Words used to describe sharp feelings include "like a knife," "like a spike," or "piercing."

Not sharp	0	1	2	3	4	5	6	7	8	9	10	The most **sharp** sensation imaginable ("like a knife")

3. Please use the scale below to tell us how **hot** your pain has felt over the past week. Words used to describe very hot pain include "burning" and "on fire."

Not hot	0	1	2	3	4	5	6	7	8	9	10	The most **hot** sensation imaginable ("burning")

4. Please use the scale below to tell us how **dull** your pain has felt over the past week.

Not dull	0	1	2	3	4	5	6	7	8	9	10	The most **dull** sensation imaginable

5. Please use the scale below to tell us how **cold** your pain has felt over the past week. Words used to describe very cold pain include "like ice" and "freezing."

Not cold	0	1	2	3	4	5	6	7	8	9	10	The most **cold** sensation imaginable ("freezing")

6. Please use the scale below to tell us how **sensitive** your skin has been to light touch or clothing rubbing against it over the past week. Words used to describe sensitive skin include "like sunburned skin" and "raw skin."

Not sensitive	0	1	2	3	4	5	6	7	8	9	10	The most **sensitive** sensation imaginable ("raw skin")

FIGURE 20.3 The Pain Quality Assessment Scale (PQAS). (Copyright © Jensen, Galer, and Gammaitoni, 2006. Reproduced with permission.) (*continues*)

7. Please use the scale below to tell us how **tender** your pain is when something has pressed against it over the past week. Another word used to describe tender pain is "like a bruise."

Not tender | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **tender** sensation imaginable ("like a bruise")

8. Please use the scale below to tell us how **itchy** your pain has felt over the past week. Words used to describe itchy pain include "like poison ivy" and "like a mosquito bite."

Not itchy | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **itchy** sensation imaginable ("like poison ivy")

9. Please use the scale below to tell us how much your pain has felt like it has been **shooting** over the past week. Another word used to describe shooting pain is "zapping."

Not shooting | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **shooting** sensation imaginable ("zapping")

10. Please use the scale below to tell us how **numb** your pain has felt over the past week. A phrase that can be used to describe numb pain is "like it is asleep."

Not numb | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **numb** sensation imaginable ("asleep")

11. Please use the scale below to tell us how much your pain sensations have felt **electrical** over the past week. Words used to describe electrical pain include "shocks," "lightning," and "sparking."

Not electrical | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **electrical** sensation imaginable ("shocks")

12. Please use the scale below to tell us how **tingling** your pain has felt over the past week. Words used to describe tingling pain include "like pins and needles" and "prickling."

Not tingling | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **tingling** sensation imaginable ("pins and needles")

13. Please use the scale below to tell us how **cramping** your pain has felt over the past week. Words used to describe cramping pain include "squeezing" and "tight."

Not cramping | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **cramping** sensation imaginable ("squeezing")

14. Please use the scale below to tell us how **radiating** your pain has felt over the past week. Another word used to describe radiating pain is "spreading."

Not radiating | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **radiating** sensation imaginable ("spreading")

15. Please use the scale below to tell us how **throbbing** your pain has felt over the past week. Another word used to describe throbbing pain is "pounding."

Not throbbing | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **throbbing** sensation imaginable ("pounding")

FIGURE 20.3 (*continued*)

16. Please use the scale below to tell us how **aching** your pain has felt over the past week. Another word used to describe aching pain is "like a toothache."

Not aching | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **aching** sensation imaginable ("like a toothache")

17. Please use the scale below to tell us how **heavy** your pain has felt over the past week. Other words used to describe heavy pain are "pressure" and "weighted down."

Not heavy | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **heavy** sensation imaginable ("weighted down")

18. Now that you have told us the different types of pain sensations you have felt, we want you to tell us overall how **unpleasant** your pain has been to you over the past week. Words used to describe very unpleasant pain include "annoying," "bothersome," "miserable," and "intolerable." Remember, pain can have a low intensity but still feel extremely unpleasant, and some kinds of pain can have a high intensity but be very tolerable. With this scale, please tell us how **unpleasant** your pain feels.

Not unpleasant | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **unpleasant** sensation imaginable ("intolerable")

19. Finally, we want you to give us an estimate of the severity of your deep versus surface pain over the past week. We want you to rate each location of pain separately. We realize that it can be difficult to make these estimates, and most likely it will be a "best guess," but please give us your best estimate.

HOW INTENSE IS YOUR *DEEP* PAIN?

No **deep** pain | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **intense deep** pain sensation imaginable

HOW INTENSE IS YOUR *SURFACE* PAIN?

No **surface** pain | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | The most **intense surface** pain sensation imaginable

20. Pain can also have different time qualities. For some people, the pain comes and goes and so they have some moments that are completely without pain; in other words the pain "comes and goes". This is called **intermittent** pain. Others are never pain free, but their pain types and pain severity can vary from one moment to the next. This is called **variable** pain. For these people, the increases can be severe, so that they feel they have moments of very intense pain ("breakthrough" pain), but at other times they can feel lower levels of pain ("background" pain). Still, they are never pain free. Other people have pain that really does not change that much from one moment to another. This is called **stable** pain. Which of these best describes the time pattern of your pain (please select only one):

( ) I have **intermittent** pain (I feel pain sometimes but I am pain-free at other times).
( ) I have **variable** pain ("background"pain all the time, but also moments of more pain, or even severe "breakthrough pain or varying types of pain).
( ) I have **stable** pain (constant pain that does not change very much from one moment to another, and no pain-free periods).

FIGURE 20.3 (*continued*)

items) were responsive to the effects of both lidocaine patch 5% and a corticosteroid injection in a sample of patients with carpal tunnel syndrome.[98] These findings indicate that the PQAS may be even more useful than the NPS for identifying the specific effects of pain treatments on different qualities of neuropathic pain, although more research is needed to determine if the new items continue to evidence validity as outcome measures in other neuropathic pain populations, as well as in populations of persons with nonneuropathic pain.

Recommendations for Assessing Pain Quality

There is clearly a very large interest in the development, if not the use of, pain quality measures. A fair number of such measures now exist, and additional pain quality measures and modifications of pain quality measures seem to be developed and published on a regular basis. At this point, the LANSS (or S-LANSS in survey research) has the most evidence supporting its validity as a measure for distinguishing neuropathic from nonneuropathic pain, and the NPS has the most empirical evidence supporting its validity as a measure of the distinct pain qualities impacted by pain treatments.

However, both the LANSS and the NPS have limitations, and it is likely that each can be improved further. Concerning the LANSS or S-LANSS, improvements could potentially be made by adding items or pain quality domains to these measures that have been shown to discriminate neuropathic from nonneuropathic pain in other studies measures. These include, for example, ''squeezing'' (from the NPQ and DN4), ''freezing'' (from the NPQ) or ''painful cold'' (from the DN4), and ''itching'' (from the DN4). Indeed, even though the NPS was not specifically developed to discriminate between neuropathic and nonneuropathic pain, five NPS items have been shown to differ between patients with these types of pain, and four of these (''sharp,'' ''cold,'' ''itchy,'' and ''surface'' pain) are not included on the LANSS.[55,99] Inclusion of items that reflect these pain qualities, and possibly others, may enhance the accuracy of the LANSS and S-LANSS even further.

Similarly, although the NPS has been used more than any other pain quality measure for identifying the specific pain qualities impacted by pain treatments, it has limited content validity. This limitation was what inspired the development of the PQAS, which includes pain qualities common to patients with neuropathic and nonneuropathic pain conditions. Thus, it is likely that the PQAS will ultimately prove more useful than the NPS, and might be considered over the NPS when a measure of pain's effects on specific pain qualities is needed, especially given the fact that all of the NPS items are included in the PQAS.

Ultimately, it is possible that pain quality scales (or subscales of measures such as the MPQ or PQAS) may be developed that are specific for each pain problem or pain type. Once the pain qualities most closely associated with low back pain, for example, are identified, it may be most practical to administer measures that just assess those qualities in samples of patients with low back pain. In a sample of persons with carpal tunnel syndrome, the pain qualities assessed by the PQAS that were reported as most severe (as defined by average ratings of 4.00 or more on a 0–10 scale) included sharp, tender, shooting, numb, electrical, tingling, cramping, deep, and surface pain.[98] Numb (average rating, 7.13/10) and tingling (average rating, 6.98/10) were particularly high in this sample. Moreover, as might be expected, the pain qualities that were rated as most severe pretreatment were the qualities that tended to show the greatest improvement with pain treatment.[98] Based on these findings, a PQAS Carpal Tunnel subscale (PQAS-CT) could be envisioned that included just these nine items, and a composite score made up of such a scale might be shown to be more responsive to effective pain treatment than a composite made up of all of the PQAS sensory items. But replications of research using the PQAS and other pain quality measures are needed to ensure that no critical pain quality is left out when diagnosis-specific measures are developed.

Measuring Pain's Spatial Characteristics

Pain can occur both at different body locations (e.g., head, leg), or at different depths (e.g., ''surface'' or ''deep'' pain). The two most common strategies used for assessing the body location of pain are the pain drawing and the pain site checklist. A pain drawing consists of an outline of a human form, and respondents are simply asked to mark or shade in the areas on the drawing which correspond to pain they are currently experiencing. Pain drawings are included in a number of standard pain questionnaires, such as the MPQ,[41] the LANSS,[54] and the original (non-short form) BPI.[100] One published pain drawing allows the assessor to use a template to score the patient's response, both for the specific area that has been shaded, as well as for ''pain extent'' (which reflects the total number of areas that have been shaded).[101]

A site checklist is a simple list of possible sites for pain, and the respondent is asked to indicate which site(s) are currently painful.[102] Like pain drawings, site checklists can be scored for both the specific site(s) chosen, as well as for ''pain extent'' (total number of sites chosen). The presence and severity of ''deep'' and ''surface'' pain can be determined by asking respondents to rate each (see the PQAS reflecting these in Fig. 20.3).

Although research suggests that scores derived from measures of pain site (i.e., ''pain extent'' as represented by the number or percent of body area involved) predict, in some patients, disability, pain interference, medication use, return to work, and psychological functioning, this same body of research indicates that these associations are not consistent and not always strong.[32] This suggests that measures of pain's spatial characteristics should not be used as proxy measures of psychopathology or disability.

On the other hand, pain drawings, pain site checklists, and measures of the relative depth of pain are well suited for descriptive purposes. For example, research in patients with spinal cord injury has used pain drawings and pain site to describe the frequency of pain experienced at different body sites, as well as the relationship between pain location or number of pain sites and other related variables.[102,103]

Recommendations for Assessing Pain Site

Pain drawings, pain site checklists, and severity ratings of pain's perceived depth have all been used successfully to describe the pain in different populations, and measures of the latter domain, as items from the NPS and PQAS, have demonstrated responsivity as outcome measures in clinical trials. Decisions about which to use in any one setting or with any one population will largely depend on the preference of the assessor, and practical issues concerning how the data will be used. Clinicians often prefer pain drawings, given that they provide a global overview of how patients experience the location(s) of their pain. However, when used in research, pain drawings require an additional step (usually with the aid of a template) to objectively determine the specific site(s) selected. Pain checklists may be more practical for the researcher, given that coding for the specific sites (e.g., legs, low back, head, etc.) is completed by the respondent once the checklist has been administered and completed.

Measuring Pain's Temporal Characteristics

The temporal aspects of pain, such as its variability, frequency, and duration, as well as its pattern across time (over minutes, hours, days, or months) can be assessed by asking patients to rate their pain on multiple occasions over time using pain diaries.

The specific temporal domains of interest can then be operationalized by computing scores from the diary ratings. Based on diary data, *pain variability* can be operationalized as the standard deviation of pain intensity ratings during a specific epoch, *frequency* of "breakthrough" pain as the number of times pain reached and exceeded a specific cutoff (e.g., 7 or more on a 0–10 scale for severe breakthrough pain, or 5 or more for moderate to severe breakthrough pain[104]), and *pain duration* as the number of hours that pain was rated as being above a specific cutoff, for example 5 or more on a 0 to 10 scale for duration of "moderate to severe" pain.[104]

Diary data can also be used to identify *temporal patterns*. Jamison and Brown,[105] for example, identified six different temporal pain pattern types (e.g., steady increase over the course of a day, steady decrease, curvilinear pattern, no consistent pattern) based on diary data. They found that the group of patients that showed no clear consistent pattern from one day to the next also reported the greatest emotional distress.[105] van Grootel and colleagues identified two primary patterns of pain intensity from diary data in a sample of patients with temporomandibular disorders: (1) those reporting higher levels of pain later in the day and (2) those reporting higher levels of pain in the morning; with the former group reporting higher overall levels of pain intensity, more difficulty falling asleep at bedtime, more widespread pain, and greater endorsement about the role of a physician in managing their pain problem.[106] These findings suggest the possibility that the time pattern of pain experience may play a role in how patients think about or manage their pain.

Another way to assess pain pattern is to describe different temporal patterns to patients, and allow them to select the description that best describes their pain. For example, an item from the PQAS (see Fig. 20.3) asks patients to indicate which of the following best describes their pain: (1) I have intermittent pain (I feel pain sometimes but I am pain-free at other times); (2) I have variable pain ("background" pain all the time, but also moments of more pain, or even severe "breakthrough" pain or varying types of pain); (3) I have stable pain (constant pain that does not change very much from one moment to another, and no pain-free periods). One study found that these temporal characteristics differed as a function of neuropathic versus nonneuropathic pain, with patients rated by physicians as having "possible" neuropathic pain being more likely to endorse having variable pain then patients rating as being "unlikely" to have neuropathic pain.[99]

Recommendations for Assessing Pain's Temporal Characteristics

Either diary-based measures or categorical scales may be used to assess pain's temporal characteristics. Categorical scales require less investigator effort than diary-based measures, but diary-based measures allow for greater flexibility in coding different temporal patterns then categorical scales. Both types of measures have some, albeit limited, support for their predictive validity. Neither has yet been used as outcome measures, so their utility for determining the impact of pain treatment has yet to be determined.

Overall, then, although the temporal dimension of pain can be assessed, there is not yet adequate empirical support for concluding that assessment of the temporal characteristics of pain provides information that is critical to understanding a patient's pain, or the impact of treatment on that pain. More research is needed to compare the utility and validity of measures of pain's temporal characteristics to draw conclusions about the clinical and research importance of this pain domain, and the best way(s) to assess it.

Measuring Pain Interference

Pain interference refers to the extent to which pain interferes with day-to-day functioning. The two most commonly used measures of pain interference are the Brief Pain Inventory Pain Interference (BPI) scale[100] (see Fig. 41.3) and the Interference scale of the West Haven-Yale Multidimensional Pain Inventory (WHYMPI).[107]

Brief Pain Inventory Pain Interference Scale

The BPI Interference scale includes seven items that assess the extent to which pain has interfered with: general activity, mood, walking ability, normal work (including both work outside the home and housework), relations with other people, sleep, and enjoyment of life. Respondents are asked to rate the degree of pain interference with each activity on 0 (does not interfere) to 10 (completely interferes) numerical scales. The responses to the seven items are then averaged to form the Pain Interference scale score.

Factor analyses of responses show that the seven interference items load together onto a single factor,[100,108–116] and that the scale has excellent internal consistency (with alphas ranging from .78 to .91).[104,109,110,113–115] One study used multidimensional scaling to determine the factors underlying the BPI Pain Interference items in a large sample of 1,843 persons with metastatic cancer.[117] These analyses yielded two underlying interference dimensions: interference with activity (walking, work, general activity, sleep) and affectivity-related interference (relations, mood, enjoyment of life), suggesting the possibility of alternate scoring and use of the BPI Pain Interference scale. However, this alternate scoring has yet to be used or tested in additional samples. The BPI Pain Interference scale is associated, as would be expected, with measures of pain intensity.[112,118,119] The BPI Interference scale has been increasingly used as an outcome measure in clinical trials, and evidence demonstrating changes in the BPI Interference scale score supports its validity for this purpose.[92,120–123]

Recently, the BPI Interference scale was slightly modified (with permission from the copyright holder of the BPI) so that it could be used in persons with physical disabilities.[124–126] Perhaps the most important modification was to change the wording of the interference with walking item to ask respondents to rate the degree of interference with "mobility (ability to get around)." This change makes it possible for individuals who have mobility restrictions unrelated to pain (i.e., who are wheelchair users) to rate the impact of pain on their mobility. Since many of these individuals would be unable to walk even if they had no pain, the original wording of this item would not be appropriate.

The other modification made was to increase the content validity of the scale by including items asking about pain interference with self-care, recreational activities, and social activities,[125] as well as items asking about interference with communication and learning new information or skills.[124,126] These five activity domains are important to many individuals with disabilities, and also reflect functioning domains defined as relevant and unique by the WHO's International Classification of Functioning, Disability, and Health.[127] Given the psychometric strength of the original BPI interference items, it is perhaps not surprising that the 10- and 12-item modified scales also have strong psychometric properties. First, the internal consistency of the modified scales are uniformly high (range, 0.89 to 0.96) in three samples of persons with disabilities, including individuals with cerebral palsy,[125] spinal cord injury,[126] and multiple sclerosis.[124] Second, like the original BPI Interference scale, the modified and expanded scales show strong associations with measures of pain intensity (correlation coefficients range, 0.61 to 0.66), consistent with what would be expected if they measured the extent to which pain interfered with functioning.[125,126] Finally, factor analyses of the modified and expanded items show that new items all load strongly on a pain interference factor that is related to, but also distinct from, a pain intensity factor.[124]

However, although the modification of the original walking BPI item makes it possible for individuals who have difficulties walking for reasons other than pain to respond to that item, and

the addition of items increases the content validity of the BPI, it is not clear that these modifications substantially improve other psychometric properties of the scale. For example, the internal consistency of a scale made up of 10 items (αs = 0.95 to 0.96[124,126]) is not that much larger than the original seven-item scale (α = 0.92 to 0.93[124,126]) in these same samples, suggesting that if scale brevity is important, the original 7 BPI items may provide as good a measure of pain impact as the expanded 10- or 12-item version.

West Haven Yale Multidimensional Pain Inventory Pain Interference Scale

Another measure of pain interference is the Interference scale of the West Haven-Yale Multidimensional Pain Inventory (WHYMPI).[107] The entire WHYMPI consists of three parts. Part 1 contains 20 items that assess five key pain-related domains: interference, support, pain severity, self-control, and negative mood. Parts 2 and 3 assess spouse responses to patient pain behaviors and participation in various life activities, respectively. The Interference scale contains nine items that assess the perceived degree to which pain affects: (1) four daily activities (social activities, work, daily activities, and chores), (2) satisfaction with three activities (social activities, family activities, work), and (3) social relationships (friendships, marital, and family relationships).

Support for the reliability and validity of the WHYMPI Interference scale as a measure of pain interference comes from a number of sources. First, factor analyses show that the nine pain interference items loaded together on a single scale that is distinct from the other WHYMPI scales.[107,128] The items show an excellent internal consistency (α range = 0.90 to 0.91),[107,128] as well as a high degree of stability (r = 0.86)[107] over a 2-week period. The WHYMPI Interference scale also shows an expected strong association with pain severity (rs range = 0.49 to 0.70).[128,129] Importantly, the WHYMPI Interference scale has also shown responsivity to change associated with treatment.[129–133]

Recommendations for Assessing Pain Interference

Both the BPI and WHYMPI of pain interference scales were constructed using sound scale development strategies, and each has support for its reliability and validity as a measure of pain interference. Also, each measure is relatively brief and easy to administer, complete, and score. However, to date, the BPI Interference scale has the most empirical support for its reliability and validity. Moreover, it has been translated into many different languages, and has been adapted for and validated in disabled populations, making it possible to compare pain interference across different cultures and populations. Thus, unless there is a clear reason not to use the BPI, it appears to be an excellent first choice when a measure of pain interference is needed both in the clinic and in research settings.

MEASURING PAIN IN SPECIAL POPULATIONS

Although the measures described and recommended for use in this chapter so far can be used by many patients in most settings, there are special populations that may require different measures or approaches. These include patients that are at risk for cognitive deficits (e.g., patients with head injuries, the elderly, the very ill) or who may not yet have reached an adequate developmental stage to understand the measure or the tasks that the measure requires (e.g., infants and toddlers). A detailed review of the many measures and procedures for assessing pain in special populations is beyond the scope of this chapter, and the interested reader is referred to other more detailed reviews to obtain information concerning the available options (for children[134,135]; for the elderly[136–138]; for individuals with limited communication abilities[137,139]; for individuals with cancer[140]). In general, when assessing pain in special populations who are unable to provide valid responses to standard measures, the clinician and researcher has two options: (1) to simplify the assessment strategy to a level that can be understood by the patient or (2) to depend on observation of behaviors known to reflect pain experience.

Simplified Measures of Pain

Simple Pain Measures to Consider

Of the two options to consider when selecting a pain assessment approach for special populations, the first option, using a simplified measure of pain, may be considered a better option to select whenever possible and practical given the facts that (1) only patients have direct access to their pain experience, and so are in the best position to describe this experience and (2) observational measures of pain behaviors show, at best, only moderate associations to patient reports of pain experience.[141]

Of the three primary pain intensity measures used most often in pain research and clinical settings, evidence indicates that VRSs tend to be easier for patients to understand and use than NRSs, and that NRSs are easier for patients to understand and use than VASs,[40,142–145] making simple VRSs (e.g., none, mild, moderate, severe) a natural choice to consider when a simple measure of pain is needed. Another measure to consider in this situation is a face scale. Face scales consist of line drawings of faces, each of which represent expressions that communicate different levels of pain and distress. Although a number of such scales have been developed, one that has many strengths is the Faces Pain Scale–Revised (FPS-R, Fig. 20.4). An earlier version of the FPS-R[146] as well as the FPS-R have been shown to be easier to comprehend by older patients and patients with dementia than either a VRS or a VAS,[147,148] suggesting that this measure may be useful when even simple VRSs are too complex for the patient or population being studied. Also, the instructions for the FPS-R are available in many languages (currently 34), and information about the FPS-R is readily available and kept updated on a website (www.painsourcebook.ca).

There is ample evidence supporting the reliability and validity of the FPS-R as a measure of pain intensity (see review[137]). For example, the FPS-R of pain intensity is strongly associated with other measures of pain intensity,[148,149] and shows adequate test-retest stability over a 2-week interval (r = 0.76).[148] Also, the FPS-R shows responsivity to treatments known to impact pain, including in a clinical trial involving children as young as 4 to 6 years old,[150] a trial involving children 5 to 12 years old,[149] and one that used the FPS-R in children aged 3 to 12 years old.[151] Interestingly, although the NRS tends to be preferred over other scales by older patients who are not cognitively impaired, the FPS-R is preferred over other pain measures by elderly patients who have cognitive impairments.[148] However, one study reported that over half of a sample of 6-year-olds had difficulty understanding and using the FPS-R,[152] suggesting that when designing a pain trial with very young children, either: (1) adequately large numbers of participants may be needed to overcome possible unreliability of the measure or (2) if limited numbers of possible participants are available, an alternative measure or procedure (such as a pain behavior observation procedure) may be needed.

A final option to consider in special populations is the "Box Scale," which is basically a Numerical Rating Scale presented with the numbers surrounded by boxes.[153] Respondents are asked to indicate on this scale the single number that represents their pain intensity level. Because of the way the measure is presented, respondents are given two cues to help them identify dif-

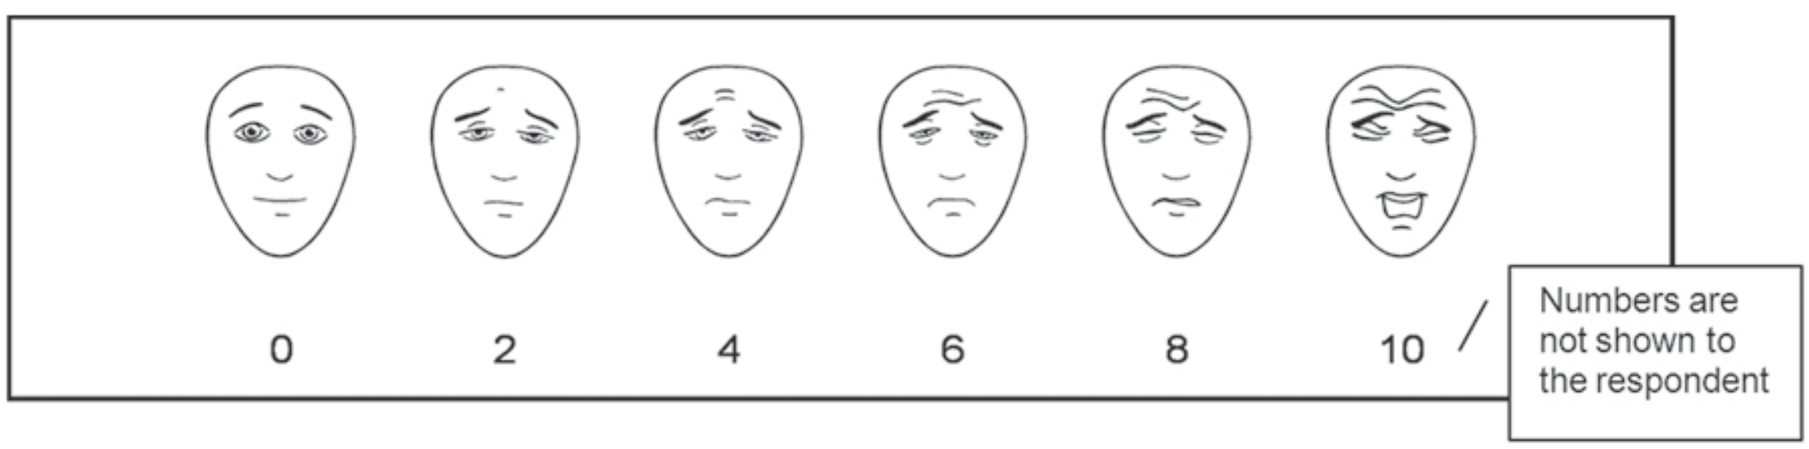

FIGURE 20.4 The Faces Pain Scale–Revised (FPS-R). Instructions to the respondent are: "These faces show how much something can hurt. This face [point to left-most face] shows no pain [or hurt]. The faces show more and more pain [point to each from left to right] up to this one [point to right-most face]—it shows very much pain. Point to the face that shows how much you hurt [right now]." Do not use words like "happy" or "sad." This scale is intended to measure how the respondents feel inside, not how their face looks. Numbers are not shown to the respondent; they are shown here only for reference. The instructions for administration are currently available in over 31 languages from www.painsourcebook.ca. (From Hicks CL, von Baeyer CL, Spafford PA, et al. The Faces Pain Scale – Revised. Toward a Common Metric in Pediatric Pain Measurement. *Pain* 2001;93:173–183. Used with permission from IASP®.)

ferent pain levels: both a number and a visual analogue. Although not a great deal of research has been performed using such measures, the research that has been performed suggests the possibility that box scales may be even easier for elderly individuals to comprehend and use than verbal categorical scales or faces scales.[153] More research is needed to explore this possibility, but until such research is performed, clinicians may wish to consider including box scales as an option when choosing a measure to use with a special client who has difficulties with other measures.

Selecting the Best Measure for a Patient or Population

One way to determine which measure to use in any one patient in the clinical setting is to begin by asking him or her to provide pain ratings using a number of different measures (for example, a NRS, a VRS, the FPS-R, and perhaps a box scale) for *six* domains of pain intensity: his or her own current pain, his or her own worst, least, and average pain during a specific period of time (e.g., the past 24 hours), the rating he or she would make on the scales that would represent mild pain, and the rating he or she would make on the scales that would represent severe pain. The patient's responses to the measures could then be examined to determine which scale(s) show(s) the most consistent response; that is, the scales for which his or her own least pain is rated lower than worst pain, ratings of his or her own current and average pain ratings fall within the least-worst range, and the ratings they selected as representative of "mild" and "severe" pain fall within an expected range (e.g., severe pain is rated higher than mild pain, and both are rated higher than the lowest possible response on the scale). Evidence indicates that even among individuals with severe dementia, the majority can provide a valid response to at least one type of scale, although the scale that is most useful for any one patient may differ between individuals.[147] Thus, by first trying different scales with patients who are at risk for having difficulties with standard measures, the clinician can determine for each patient that measure or scale that provides the most consistent response, and that the patient indicates is easiest for him or her to use. This is the scale that could then be used with that patient in future clinical encounters.

Selecting a measure to use in a clinical trial involving populations of patients who may have difficulty comprehending or using pain measures is more challenging, given that there is no single measure that is universally valid for every individual. In this situation, it probably makes the most sense to: (1) select the single measure that is most likely to be valid for the most study participants (for example, either a simple VRS or the FPS-R); (2) ensure that the measure is adequately explained to all study participants; (3) ensure adequate power (e.g., large sample sizes) to deal with possible decreases in reliability of assessment due to possible difficulties with the measure in some study participants; and (4) consider using ability to comprehend and use the measure (as determined, for example, by an ability to provide a consistent response when asked to rate current, least, average, most, "mild" and "moderate" pains, see previous discussion) as an eligibility criterion for participation in the study. If the study population of interest is known to include at least some participants who will not be able to provide a valid response on a self-report pain measure, and adequate sample sizes are not available to address possible increased unreliability in assessment because of this potential problem (or there is a need to determine the effects of the treatment even among those who are unable to validly describe their pain), then the use of pain behavior observation scales or procedures may be indicated.

Behavior Observation Measures

A large number of pain behavior observation scales and measures have been developed for use as proxy measures of pain when self-report scales cannot be used, for example, in preverbal children or in nonverbal adults. The field has not yet come to a consensus regarding which one of the available measures is the most valid and reliable in most populations. The interested reader is referred to the published reviews for the most up-to-date summary of the state of the science concerning these measures.[135,137,138,154]

Briefly, all of the available measures contain a list of behaviors commonly thought to be associated with the experience of pain, such as moaning, crying, furrowing one's brow, grimacing, and rubbing a body part, among many others. The scales often score the behaviors as being present or absent, but they sometimes ask the observer to rate the behaviors along a continuum of frequency or intensity. Item responses are then summed to create total pain behavior scores or subscales for specific classes of behaviors, such as vocal, social, and activity pain behavior subscales. One review of pediatric measures[135] recommended two scales for assessing pain intensity associated with medical procedures (the Face, Legs, Activity, Cry, and Consolability, or FLACC scale[155]; and the Children's Hospital of Eastern Ontario Pain Scale, or CHEOPS[156]), one for assessing postoperative pain in the hospital (FLACC), one for assessing postoperative pain at home (Parents' Post-operative Pain Measure, or PPPM[157]), one for assessing pain in critical care (the COMFORT scale[158]), and two for assessing pain related fear or anxiety (the Procedure Behavior Check List, or PBCL[159]; and the Procedure Behavioral Rating Scale–

Revised[160]). A review of pain behavior measures in elderly individuals with dementia concluded that two scales appear most valid and useful in these populations: the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC)[161]; and the DOLOPLUS 2.[162]

CONCLUSION

When considering which pain domains to assess for research or clinical purposes, investigators and clinicians must balance the need for a thorough assessment against the needs of the patient for minimal assessment burden. When determining this balance, all of the possible pain domains (intensity, affect, quality, temporal characteristics, and impact or interference) should at least be considered. Moreover, it is important to remember that many patients with pain often report more than one pain problem.

The ideal assessment, even when assessment needs to be brief, would probably involve assessing up to at least three ''primary'' or ''most bothersome'' pain problems, and include an evaluation of their intensities and locations. For assessing intensity of each pain problem or pain site, the data from a large number of studies in persons with chronic pain suggest that 0 to 10 scales of pain intensity (with 0 = no pain and 10 = pain as bad as you can imagine) have the most strengths and fewest weaknesses of the available measures.

To assess pain site, pain drawings have been used more often then site checklists in published research. However, pain site checklists are easier to score, given that pain drawings require a second step of scoring to determine the location(s) and extent of pain, and there is no evidence to suggest that patients' responses to site checklists are any less valid than their responses to pain drawings. For these reasons, a site checklist, providing that the sites listed are adequately comprehensive, may be more practical in many research situations, although clinicians may prefer pain drawings for the overall gestalt that such measures can provide concerning how the patient views pain in his or her own body.

Whether or not to assess the temporal pattern(s) of the different pain problems would be important (1) if altering the temporal pattern of pain is a goal of treatment or (2) if knowledge about the temporal pattern is needed to help diagnose the pain problem. The available data indicate that pain's continuous versus intermittent nature can predict important functional outcomes, with continuous pain associated with poorer outcomes, suggesting that some assessment of this aspect of pain may be useful. A simple categorical question (e.g., such as that included on the PQAS) appears to be adequate for assessing this characteristic of pain. More research is needed to determine the relative validity and utility of assessing other temporal characteristics of each pain problem.

Although pain does have an affective component, pain affect is not frequently measured in pain research. This may be due, in part, to the strong associations found between measures of pain intensity and pain affect; pain that is more severe usually bothers people more. There are, however, a number of situations in which it may be appropriate to assess pain affect in addition to pain intensity. For example, when evaluating the effects of treatments, such as cognitive-behavioral treatments, that might have a greater impact on the affective or suffering component of pain than on pain intensity. In these situations, because of its brevity and demonstrated validity, the pain affect scale of the short-form MPQ is probably the best choice.

Although more research is needed to identify the pain quality scales (and items) that best classify pain types (e.g., neuropathic vs. nonneuropathic), at this point, the LANSS has the most empirical support for this purpose. To assess pain qualities for describing pain or determining the effects of treatment on pain qualities, the NPS has the most empirical support. However, the NPS has limited content validity. Because the PQAS includes all of the NPS items, it also has support for its validity as a measure of pain quality in treatment outcome studies. However, the additional items in the PQAS means that it has greater content validity then the NPS, and so may prove to be more useful for many populations of persons with pain.

Research has confirmed what many clinicians and patients with chronic pain already know: Pain can have a significant negative impact on important activities. Assessing the critical domain of pain interference should be strongly considered by both clinicians and researchers. Clinicians could use this information to help target treatments (e.g., substantial impacts on mood might suggest the need for treatments that could address mood disturbances, while substantial impact on sleep would suggest the need for treatments that could help the patient sleep better), as well as track the efficacy of different pain treatments that are provided. Researchers could, and in many cases probably should, assess pain interference as a secondary outcome in clinical trials in order to determine whether or not the treatment being examined has any benefits on the patient's life beyond its effects on pain. For assessing this domain, the seven BPI pain interference items (with the ''walking'' item modified in samples of patients with physical disabilities so these patients can rate the interference of pain on ''mobility [ability to get around]'') appear to have the most strengths of the available measures.

In populations of patients who might have limited ability to communicate or to use the measures recommended above, clinicians can select from among the simpler measures, such as simple categorical scales or the FPS-R. Among patients who demonstrate an inability to understand or use these measures, then a very simple dichotomous question (''Do you have bothersome pain?'') or some of the validated pain behavior observation scales may be needed.

One final point can be made concerning the pain assessment: In any setting, it is critical to remember that we are ultimately assessing individuals—not pain. Many of the measures that we use have extensive support for their reliability and validity, and can provide numbers and ratings that can be used to help determine the efficacy of pain treatments, the need to continue or discontinue those treatments, and the possible need to provide additional treatments. But all of the numbers and ratings provided by patients and research subjects come from people, many of whom may be suffering a great deal. Measures, surveys, and questions can never replace the need to listen with compassion to the people we serve. The experience of a person reporting a pain level of ''7'' (out of 10) will rarely, if ever, be the same as the experience of another person reporting that same pain level. Much more important than obtaining a pain rating or score is an understanding of patients and their experience. We serve our patients best when we remember to take the time to listen.

CHAPTER 21 ■ PSYCHOLOGICAL AND PSYCHOSOCIAL EVALUATION

TATIANA D. STARR, LAUREN J. ROGAK, KENNETH L. KIRSH, AND STEVEN D. PASSIK

INTRODUCTION

Over the past 30 years it has become increasingly evident that psychological factors have a significant impact on the overall experience of chronic pain.[1–3] Chronic pain is more than ongoing and recurrent physical pain; it involves a persons' psychological and social well-being. Research examining behavioral and psychosocial evaluation in the context of persistent pain has led to new developments in psychological assessments, including the advancement and incorporation of well-validated measures to round out the multidisciplinary process of pain management.[4] Clinicians and researchers have also developed approaches that have the potential to significantly enhance patient adjustment to pain as well as aid in prevention and management of psychological and behavioral issues that arise as a result of chronic pain.[5–9] This chapter reviews the various psychosocial concepts which may be related to pain and should be targeted for effective assessment. We seek to touch on the prevalence, association, assessment, evaluation, and treatment of each relationship.

PSYCHOPATHOLOGY

It is well established that patients with chronic pain frequently present with a number of comorbid psychiatric conditions including depression, anxiety, and personality disorders.[10] Research has also demonstrated a significantly higher incidence of these disorders among chronic pain patients in comparison to other medically ill populations as well as the general population.[11] Additionally, an estimated 50% of individuals with chronic pain have comorbid depression and/or anxiety,[10] and although these disorders are viewed conceptually as two distinct conditions, the high prevalence of comorbidity and overlapping symptoms have the potential to complicate assessment.[12–14] The majority of self-report measures of depression and anxiety are highly correlated with each other and the lack of discriminant validity among these measures creates additional barriers toward assessment.[12–16] Complications associated with measurement of mood disorders have additional consequences when assessing these conditions in the chronic pain population. An assessment method that distin-

guishes between symptoms common to these mood disorders is essential in accurately guiding specifically tailored interventions as misunderstanding these interactions can lead to unsuitable treatment approaches.

Depression

There has been a growing interest in the relationship between depression and chronic pain due to the high prevalence rates encountered coupled with general lack of standard assessment and treatment methods.[17] The research on this association is vast but remains inconclusive. One small certainty is that there is an extraordinary amount of suffering experienced by chronic pain patients who struggle with depression. Whether depression was pre-morbid or manifested as a result of the pain condition, the burdens of coexisting pain and depression should not be ignored. Although there is more work to be done, there has been enormous progress in understanding, assessing, evaluating, and treating these patients.[17,18]

The diagnostic definition of depression was developed from a psychiatric framework and has not been adapted appropriately to apply to the chronic pain population, adding to diagnostic difficulties.[19] The broad range of depression assessment tools (i.e., self-report, structured and unstructured interviews, projective tests), makes it difficult to compare studies of patients with chronic pain and those with depression.[17] Although many theories of pain have been established, the biopsychosocial model may be the most useful as it addresses the integration of biological mechanisms, psychological and social factors, and addresses each as an individual facet while determining a multifaceted approach to evaluate and treat a patient comprehensively.[20]

Epidemiological studies[18] show that major depressive disorder (MDD) is shown in 5% to 10% of primary care settings. This represents an underestimation of the prevalence seen in pain populations, as many individuals have depressive symptoms that do not meet the full criteria to be diagnosed as MDD as outlined by the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV).[21] The implication is that these conditions are coexisting more commonly and have the potential to exacerbate one another. This also raises the issue that they may be treated together to maximize a healthy lifestyle.[22]

The overlap of pain and depression is seen in 30% to 60% of patients.[22] When the etiology for the pain is unknown, depression rates have been shown to be higher.[23] Additionally, those patients with chronic pain, defined as the presence of pain for most days within a month, are three times more likely to meet the diagnostic criteria outlined for depression as those without a diagnosis of chronic pain.[24] Research has also shown that the more severe, frequent, and enduring the painful condition, the more severe any corresponding depression will be.[25] Further, the extent of depressive symptoms has been correlated with level of acceptance of chronic pain as facilitated by a basic idea of the perception of what the future held, with poor acceptance leading to greater depth of depression.[26]

A close look at the association between prevalence rates of pain and depression raises the question as to why chronic pain patients are not all depressed.[27] The prevalence rates of pain and depression are high but not universal. Research comparing depressed, nondepressed, and mildly depressed pain patients proposes that difficulty in coping and negative perceptions of self-control are correlated with the advent of depression in pain patients.[28] Some research proposes two facets that may mediate the effects of pain and depression: a patient's perspective of the role of pain in their life and their ability to maintain control over the pain.[29,30] Thus, the more perceived control a person believes they have in life, and the smaller role they allow the pain to play, the less likely they will become depressed.[29,30]

Assessment and Evaluation

The body of literature on the diagnostic and treatment implications of comorbid depression and pain is growing rapidly. However, one issue always seems to emerge: due to the nature of each individual illness, pain can result from depression or depression can result from pain. This adds to diagnostic difficulties and complicates decisions regarding which illness might be considered primary and whether both issues need to be treated through medication trials. It is important to delineate the true diagnosis (or both if a comorbid diagnosis is appropriate) so that medications can be streamlined and given appropriately. For instance, the pain patient with increased agitation presenting with pseudo-depressed mood might see remarkable mood improvement simply from treating the pain condition aggressively. If the patient responds to the pain medication alone, we have spared them another medication (or set of medications) for depression and anxiety which would have potentially added side effects for no appreciable gain in mood or function. In either case, we do need to be aware of the interrelationships between pain and mood and ultimately focus on helping the patient integrate into a healthy way of living.[22,31]

In many cases, chronic pain patients are only followed by a primary care physician due to the fact that there are simply not enough chronic pain specialists and they are often concentrated in metropolitan areas. The high rate of comorbidity between chronic pain and mental disorders, including depression, is not standard knowledge for primary care physicians. Therefore, it is not a guarantee that a physician will recognize the symptoms of such disorders. Primary care physicians are then left to assess, evaluate, and proceed to the best of their ability when faced with a patient with this comorbidity.[31] Recognition of depression in the chronic pain patient has caused difficulty in the primary care setting.

Few diagnostic tools and structured interviews for diagnosing depression take into account the presence of chronic pain. Therefore, patients in pain may not show the "common" depressive symptoms.[19,22] They may present with those that aren't the direct markers of an MDD. Consequently, it has been seen that patients with comorbid pain and depression do not commonly present symptoms of dysphoria, anhedonia, hopelessness, melancholy,[22] guilt, or self-vilification[19] but show more somatic symptoms, feelings of sadness,[22] negative cognitive biases, and a self-focused and health-oriented perspective.[19]

Initial psychosocial screenings in patients with depression should include the emotional impact pain has on daily activities, past and present pain treatments (successes and failures), and their goals and expectations for relief of pain. The answers to these questions, as well as clinical judgment, will lead to a need for a comprehensive interview. This interview should go into more depth than the initial questions and may include details regarding how daily activities are affected (e.g., impact on interpersonal relationships, coping with physical and emotional symptoms, substance abuse, and historical and current psychological symptoms and diagnosis, if relevant).[27]

Pain-Related Anxiety, Catastrophization, and Anxiety Sensitivity

Pain-related anxiety is a complex psychological construct surrounding a variety of cognitive, behavioral, and physiological responses to the pain experience.[32,33] Anxiety is an important factor in predicting patient outcomes, particularly regarding how well the patient will adapt to their pain.[34–37] Research has demonstrated that anxiety precipitates muscular contraction, vasoconstriction, and pain-inciting chemicals that increase pain severity.[3] Pain-related anxiety has also been associated with cat-

astrophizing,[38] placing greater focus on bodily sensations[39] and avoidance of physical activities.[35]

Catastrophizing around pain refers to an appraisal process or an attempt to cognitively cope with pain.[47] A consistent finding in the past two decades is that catastrophizing during, and in anticipation of, pain may result in greater psychological distress and a more intense pain experience.[40–48] While positive coping attempts involve adaptive thoughts and behaviors to manage pain, catastrophizing involves negative or intrusive thoughts that exaggerate the severity of the pain and generates feelings of helplessness regarding how to control it.[45,47,49] Catastrophizing includes three components: magnification, rumination, and helplessness that lead to increased pain-related behaviors.[43] Such behaviors include higher rates of health care usage,[2] increased use of pain medications,[44] and prolonged hospitalization.[50] Patients who catastrophize report more intense pain, psychological distress, and disability compared to other patients.[43,44,47] The concept of pain catastrophizing has gained recognition as one of the most important predictors of pain, and it is estimated to account for approximately 7% to 31% of the variance among pain ratings.[51] It has also been found that catastrophizing is a stronger predictor of poor pain outcomes than depression.[20,48,52]

The term *anxiety sensitivity* refers to fear associated with symptoms related to anxiety that are based on the belief that these sensations have negative social, psychological, or somatic consequences.[53] This perspective represents a stable psychological construct that magnifies anxiety and fear in response to stimuli that is potentially anxiety-evoking.[54] Individuals with high anxiety sensitivity may be more susceptible to panic attacks. In the absence of effective emotional regulatory techniques, patients who perceive physiological sensations, such as an autonomic arousal, as a sign of danger or harm may experience heightened levels of anxiety.[55] Research assessing the relationship between chronic pain and anxiety sensitivity has shown evidence that individuals with chronic pain tend to experience higher levels of anxiety related to somatic symptoms.[56] In addition, those patients with heightened anxiety sensitivity have been found to report increased levels of persistent pain more frequently.[57] Heightened levels of anxiety sensitivity may also intensify pain sensations in patients when exposed to anxiety-producing stimuli.[58] Anxiety sensitivity has also been recently linked to the development of higher levels of pain-related fear, specifically fear of consequences associated with the experience of pain sensations. Elevated levels of anxiety sensitivity may then lead to avoidance of activities that may induce or increase pain.[59] Such avoidance over a long period of time may take a physical and emotional toll on the patient, leading to decreased socializing, diminished physical activity, and secondary behavioral problems (e.g., deconditioning and weight gain).[60] This response pattern tends to be cyclical, with emotional responsiveness and diminished physical capacity eliciting avoidance and reconfirming the patient's apprehension concerning their pain experience.[61]

Assessment and Evaluation

The emotional and cognitive responses to and in anticipation of pain are important factors in determining the extent of patients' distress and suffering. As such, self-report measures have been developed to gain a subjective assessment of the specific dimensions associated with pain-related anxiety, catastrophization, and anxiety sensitivity. These instruments help guide clinicians' understanding of the patient's emotional and cognitive responses to pain, and ultimately aid in developing a treatment plan to minimize distress and increase overall functioning.[35]

The Pain Anxiety Symptoms Scale (PASS) was developed to measure pain-related anxiety on four dimensions: (1) pain-specific appraisals; (2) cognitive symptoms; (3) physiological symptoms; and (4) escape and avoidance behavior.[35] Studies utilizing the PASS have indicated that patients with chronic pain exhibit higher levels of pain-related anxiety, tend toward overpredicting their pain intensity, cope poorly with painful sensations, and demonstrate greater somatic reactivity in expectation of pain-eliciting physical activities.[38] The primary function of the PASS is to facilitate the study of anxiety and fear associated with pain and to improve treatment outcomes. It may also have particular clinical utility in identifying empirical subtypes of chronic pain patients who may have different responses to treatment regimens. For example, patients found to manifest fear of pain primarily in the physiological response system may benefit more from an intervention such as relaxation training rather than cognitive restructuring.[35] The PASS[35] is also used to assess catastrophizing in chronic pain patients.[62] Although the PASS is generally not considered a catastrophizing measure, two of the subscales included are closely related. These scales (fear and cognitive anxiety) are also highly correlated with the six-item catastrophizing scale on the Coping Strategies Questionnaire.[62]

The Pain Catastrophizing Scale (PCS)[43] is used more frequently to assess pain catastrophizing. It was developed based on definitions of catastrophizing and measure it based on three dimensions including rumination, helplessness, and magnification.[62] The PCS can be useful in gaining a greater understanding of the psychological processes that lead to heightened physical and emotional distress in response to painful experiences. From a clinical perspective, the PCS could aid in identifying individuals who have greater susceptibility to aversive medical procedures such as surgery or chemotherapy.[63]

Anxiety sensitivity is frequently measured using the Anxiety Sensitivity Index (ASI).[64] Research has demonstrated that the ASI has utility in longitudinally predicting panic attacks[65] and heightened anxious responding.[66] The ASI is comprised of a hierarchical structure measuring three major factors including: (1) physical concerns (fears associated with adverse physical outcomes); (2) psychological concerns (fears associated with losing control cognitively); and (3) social concerns (fears associated with public display of anxious symptoms).[67–69]

It is common for chronic pain patients to experience anxiety about the meaning of their pain and how it will impact their daily lives now and in the future. The threat of severe pain can have such a profound effect that individuals may have difficulty disengaging from it, and such fears can lead to avoidance and inactivity, and ultimately greater disability.[70] The pain experience may instigate a set of increasingly negative thoughts and fears, and these processes, which are not driven solely by the actual sensory experience of pain, can have a tremendous influence on the patient's functioning and pain tolerance.[71–73] In fact, factors related to anxiety, including fear and avoidance, have been found to be stronger predictors of persistent pain than biomedical factors.[74] Clearly, pain-related anxiety, pain catastrophizing, and anxiety sensitivity all play important roles in amplifying the pain experience and such issues must be assessed and addressed in treatment.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) develops after a person experiences a traumatic event wherein a person's well-being feels threatened. The DSM-IV[21] categorizes the symptoms into three constructs: (1) re-experiencing the event (e.g., intrusive thoughts and reminders), (2) avoidance and emotional numbing (e.g., restricted affect), and (3) hyperarousal (e.g., insomnia). Additionally, symptoms manifest with intense fear, helplessness, and avoidance of stimuli.[21] A major distinction between PTSD and other psychiatric disorders is that it is necessitated by an initial stressor.[21] In the past, PTSD was only conceptualized as a disorder that occurred in war veterans and rape victims.[75] However, definitions of this initial stressor have expanded to an unending

range of events, some of which include serious medical illnesses, abuse, natural disasters, and violence.[21]

When looking at patients with PTSD, chronic pain has been seen as the most prevalent co-occurring physical problem.[76,77] There has been growing interest in the relationship between pain and PTSD, and the increased risk of chronic pain in PTSD patients.[76] A breakdown of the symptoms commonly associated with both these disorders demonstrates large overlap. For example, both are characterized with anxiety, avoidance, and increased somatic responses.[76] This symptom overlap is important to the understanding of the overall clinical picture of a patient who presents with both PTSD and chronic pain.

Assessment and Evaluation

PTSD is a disorder that is dependent on assessment and treatment since the debilitating symptoms do not recede on their own. People suffering with PTSD have been shown to be at an increased risk for suicide, social isolation, substance abuse, psychiatric disorders (depression, anxiety), insomnia, and medical illness (asthma, chronic pain).[78] Therefore, a comprehensive assessment and evaluation of each patient is essential in order to determine the frequency and severity of their symptoms which can aid in tailoring a treatment plan specific to their particular needs.

The Modified PTSD Symptom Checklist (MPSS) is a self-report scale used to measure general symptoms of PTSD.[79] The checklist is based on the diagnostic criteria of PTSD as outlined by the DSM-IV[21] and allows patients to rate the frequency and severity of their symptoms along either a four point scale (for frequency) or a five point scale (for severity).[80] A study employing this measure with a population of patients with comorbid PTSD and chronic pain found that chronic pain patients showed higher rates of frequency and severity in PTSD symptoms suggesting that these patients have a hyper-awareness and sensitivity to bodily sensations.[80] Findings such as this illustrate the need to further understand both disorders exclusively and mutually in order to provide the most effective treatment. Additionally, it is well-known that self-report measures, although beneficial, lack invaluable clinical judgment. Therefore, implementing a comprehensive psychosocial evaluation will give a clinician a more complete clinical picture and allow them to tailor treatments based on the more prevalent symptoms.

It is clear that negative moods play a significant role in influencing treatment motivation and compliance. For example, patients with pain-related anxiety may struggle with continuous fear of activities that they perceive as too dangerous or demanding, and patients with comorbid depression who feel hopeless may lack the motivation to seek treatment. An essential component of pain management requires clinicians to keep a watchful eye on patients' moods in order to provide optimal care.[81]

The frequent prevalence of PTSD and chronic pain, in conjunction with the negative impact they can have on each other by exacerbating symptoms and hindering treatment, shows the need for comprehensive assessment as well as further research. Hopefully, future research should include examination of a broader population. By assessing patients who suffer from comorbid PTSD and chronic pain in a multitude of settings (e.g., pain clinics, community settings, mental health clinics, outpatients, inpatients, and the general population), we will gain a greater understanding of each disorder, their relationship, and how to better treat them.

ADJUSTMENT TO CHRONIC PAIN

Individuals with chronic pain face numerous experiences in which their pain serves to elicit responses that have a significant impact on their everyday functioning. Chronic pain does not imply incapacitation; although the effects of having a long-term painful condition can be disabling for some patients, others are able to live full, productive lives.[82,83] The primary goal of treatment for chronic pain is undoubtedly to eliminate or reduce the pain,[84] utilizing interventions that focus on prolonged analgesia of the physical symptoms.[85] However, total, lasting relief is uncommon and some patients show little to no improvement even in the short-term.[86] When patients are unable to achieve sufficient pain relief, their condition can become overwhelming and lead to decreased levels of functioning and greater disability. When this occurs, the treatment goals often shift focus from the physical aspect of the pain, and toward alternatives that take into account other influences that affect the patient's overall functioning.[87]

Responses to Pain: Coping and Acceptance

Recent evidence suggests that patients' overall level of functioning is strongly influenced by the way in which they respond to their pain.[82] Coping techniques in response to persistent pain have been a focal point of treatment over the past two decades.[88] These techniques have been found to yield positive outcomes,[89,90] and, as a result, have become widely accepted among the pain community, and have been utilized as the primary approach to pain adjustment.[91] Coping can be broadly defined as the deliberate effort to manage or alleviate the negative effect of stress.[92–94] In the context of chronic pain, coping has been referred to as a method to control either the level of pain, or the reaction to the pain.[91] Patients who view their pain as intolerable may make intense efforts to control the severity of their pain.[85] These efforts can be beneficial when they lead to sustained relief and improvement in functioning.[84] Conversely, they can also become problematic when they dominate other important aspects of the patient's life, creating additional undesirable side effects, or shifting the patient's priorities from valuable aspects of their life toward continuous efforts to reduce or eliminate their pain.[84] Problems associated with coping often stem from unsuccessful attempts to control or avoid the pain,[84] and repeated failures at achieving relief frequently leads to increased feelings of frustration and discouragement which only exacerbate the problem.[91]

Coping has also been conceptualized as a form of avoidance.[39,84,85] Previous research indicates a strong relationship between excessive avoidance of pain and increased discomfort and disability.[39,95,96] Patients who do not accept the fact that they have chronic pain are more likely to seek out any possible intervention to treat or reduce their pain. For these patients, this approach may not be in their best interest because they may exhaust all possible treatment options with a small chance of achieving lasting relief.[85]

Accumulating research is now supporting acceptance-based approaches to living with unrelieved chronic pain.[84] Acceptance is not a method of coping but, rather, a lifestyle that incorporates acknowledgment of pain, and a willingness to experience it.[82,85] Accepting pain means continuing to work toward living a satisfying and fulfilling life despite the pain and choosing to refrain from fruitless attempts to change, reduce, or eliminate the pain past what can be reasonably achieved.[82,85] This idea may be counterintuitive for many patients since our natural inclination is toward avoiding or controlling undesirable and distressing experiences. It is important, however, to note that acceptance neither means submitting to a life of suffering, nor is it a decision to give up all attempts to feel better. Rather, it promotes making a reasonable distinction between what can be controlled, and what can not.[82,84]

Research evaluating the impact of acceptance on patient functioning has demonstrated greater patient adaptation to pain beyond the effect of increased pain intensity or pain-related depression and anxiety.[85,97,98] Additionally, incorporating a perspective that focuses more on acceptance may lead the patient with

chronic pain to generally have a greater sense of self-control.[99] A number of studies have shown evidence that patients who accept chronic pain function significantly better, reporting less pain, emotional distress, and disability.[84,85,87,91] They also report better work status and have less frequent medical visits.[97]

Assessment and Evaluation

The majority of studies that examine coping with chronic pain have utilized the Coping Strategies Questionnaire (CSQ), which assesses five strategies for coping with pain: (1) ignoring the pain; (2) distancing from the pain; (3) distraction; (4) coping self-statements; and (5) praying.[88,100] Patients use a rating scale to indicate how frequently they use each strategy to cope with their pain.[88] A major concern with the assessment of these strategies is the emphasis on cognitive processes. Some research has indicated that praying, distancing from the pain, and distraction were unhelpful coping strategies and associated with increased difficulty in patient functioning[88] and increased pain.[91] Coping, as a psychological framework for chronic pain patients, has received criticism surrounding the paucity of empirical data clarifying which behavioral strategies in response to pain are helpful.[91] The CSQ, as well as other coping inventories, rely heavily on reporting thoughts, or attempts to change thoughts, rather than behaviors. This emphasis can be problematic because it may distance the respondent further from the perspective of overt behavior where a great deal of daily activity occurs and can significantly limit assessment methods.[91]

The most widely used measure of acceptance of chronic pain is the Chronic Pain Acceptance Questionnaire (CPAQ).[82] The CPAQ is a 20-item self-report measure that assesses acceptance on two domains: (1) activity engagement (e.g., "I am getting on with the business of living no matter what my level of pain is") and (2) pain willingness (e.g., "I would gladly sacrifice important things in my life to control this pain better").[97] In a study comparing the utility of the CSQ and the CPAQ in guiding treatment, the CPAQ was found to offer greater utility because of its inclusion of items that fit an activity-related treatment approach, including such aspects as awareness of pain without wrestling with pain, mindfulness, and moving away from controlling or changing the pain.[88] The development of the CPAQ has led to innovative treatment approaches focused on cognitive, emotional, and behavioral change.[88]

Individuals diagnosed with persistent pain are often confronted with the reality of their chronicity, often being told they have to "learn to live with the pain."[91] It has recently been argued that limiting unsuccessful coping strategies should be the primary focus of treatment.[101] Interventions aimed at disengaging patients from the perceived struggle associated with controlling their condition have significant potential for development in this area.[91]

There is a large degree of overlap between coping strategies and adopting an acceptance perspective. Perhaps the most effective approach to treatment would include a cooperative effort between both models of adjustment to chronic pain. Some research supports the idea that there is more than one path to adopting an acceptance perspective. For example, using cognitive behavioral strategies that focus on obtaining control over painful experiences may actually make the pain become more acceptable.[102] The outcome of greater acceptance may be due to decreased avoidance and increased pain exposure, thus leading patients to experience less emotional reactions and recognize that different circumstances may be associated with variable pain levels, and the pain may not be as debilitating as they had once believed.[85] The decision to cope with or accept pain is not a solitary choice. Learning to live with chronic pain is a continuous experience that requires a balance between control strategies and acceptance.

LIFESTYLE HABITS AND MOTIVATION TO CHANGE

Living with chronic pain requires major lifestyle adjustments. To this end, when faced with a persistent chronic pain condition, a decision must be made to learn how to incorporate the necessary adjustments into daily life. In both the chronic pain population and the general population, maladaptive lifestyle habits are common. These can include smoking, overeating, not exercising, gambling etc. These lifestyle habits, in conjunction with chronic pain, create added obstacles which must be resolved to help make a smoother transition more feasible. Psychological interventions tailored to these individuals help manage the effects of living with chronic pain and achieving a balance between these new obstacles in life.

The chronic pain population is unique. These patients are facing new challenges and are adding an unseen variable to their current lifestyle. Not only does the chronic pain condition vary from patient to patient, but each person presents with a unique lifestyle comprised of both good and bad habits. This causes difficulties for the treating physicians. In order for their primary care physician to help, these patients have to be ready to adopt a self-management perspective.[103] A way to start the intervention process is by implementing a patient-centered therapeutic approach. This technique is based on the patients' perspective about their pain and their lifestyle in general. The foundation is built on patients' present feelings as well as their expectations and future goals.[104] Within a patient-centered treatment approach, the primary responsibility is given to the patient who, in turn, is encouraged to set goals and work toward achieving those goals. It is the responsibility of the clinician to help foster the global goals and to help formulate techniques to manage the day-to-day experiences. In effect, the clinician takes on the role of a mentor and consultant. Furthermore, this role must be set with boundaries and limits. Specifically regarding advice giving, it is not the responsibility of the clinician to tell the patient what the goals are and how to achieve them. Rather, they should approach the patient with empathy and compassion when offering advice and employ reflective listening techniques.[105,106] Types of reflective statements include repetition and rephrasing what a patient is saying, continuation of thoughts and reflecting on the feelings they express. The success of reflective listening relates back to the idea that the patient is in the center of the therapy which becomes a collaboration rather than traditional treatment.[103,106]

The Stages of Change

Similarly to how the degree of pain varies with each patient, they also differ in their readiness and confidence to self-manage the pain.[107] In addition, cognitive behavioral interventions will not succeed when there is any resistance from the patient. The Stages of Change were developed to benefit those individuals who were not ready to change their lifestyle and to move along those that were on the path.[108] This is the most innovative construct coming from the Transtheoretical Model (TTM), a comprehensive protocol of therapeutic interventions.[103,106]

The literature pertaining to the Stages of Change model within the framework of patients with chronic pain reveals that, beyond living with chronic pain, these patients suffer from secondary negative consequences which they have the power to control, including social isolation and decreased physical stamina.[109] Utilizing a behavioral model and framework will allow these patients to make the necessary changes by reducing these secondary consequences. The five original stages of change are: (1) precontemplation (individual is not considering change and further may not recognize the need for change); (2) contemplation (the idea of changing behaviors is considered but not yet implemented); (3)

preparation (plans are set in motion to make changes in behavior); (4) action (a plan has been set and techniques are being employed); and (5) maintenance (the goal has been met and behavior has been changed, however it must be continuously worked on to keep this stable).[109] These stages are fluid, meaning that a person can move back and forth through them as they reach goals, reassess goals, or falter and regress.[108] Additionally, even successfully reaching a goal does not allow a person to skip a stage. Actual success is achieved when the person moves through each stage.[109]

Assessment and Evaluation

Readiness to change is defined as a process of behavioral change, as opposed to one isolated event. People can alter their levels of motivation, confidence to change, desire to receive help, or choice to internalize. All of these varied emotions and stages became the basis for the distinct stages.[108] There seems to be a correlation between a person's readiness to change and the ability to successfully change a behavior.[110] The idea of the TTM and using motivation as an approach to self-management is tied very tightly with the readiness of a patient. There is a vast amount of literature following this idea and deconstructing the theories and assessments in order to formulate the most effective way to apply this to the chronic pain population.[107,110]

The first and most widely recognized assessment of the Stages of Change is the University of Rhode Island Change Assessment Questionnaire (URICA).[111] This was developed initially to assess psychiatric outpatients' level of motivation to adopt specific treatment. Kerns and colleagues[107] adapted this for the chronic pain population into the Pain Stages of Change Questionnaire (PSOCQ). Some of the content was altered, but the biggest change was to remove the third stage, preparation. When adapted for a pain population, the focus of each stage remains mostly the same. In precontemplation, a patient sees their pain as strictly medical, thereby requiring only those related interventions. In contemplation, a patient may recognize that they can intervene on their own behalf aside from using the medical techniques. In action, a patient takes on a self-management approach and implements a plan to change their lifestyle. In the last stage, maintenance, patients have acquired the necessary skills to manage their chronic pain and have a lifestyle plan in place to follow.[112]

The motivational strategies that have been employed to work along with the Stages of Change center around assessing what the patient wants to change, what they want to get out of the therapy, and generating a picture of their ideal lifestyle, which should help to foster authentic self-management. Assessing and evaluating these goals early on and continuously coming back to them is mutually beneficial and will help to establish and maintain rapport between patient and physician. This also will help a patient keep to the set agenda and opens the door for the physician to ask a patient for clarification when needed. Use of direct, open-ended questions in this dialogue will prevent confusion and even conflict later on.

There are a number of specific strategies which can be useful, including the employment of open-ended questions and reflective listening.[113] These help to bring the patient to a higher level of confidence and recognition of the importance of self-management. This will lead to the formulation of an agenda that is specific to the patient. Also, examining the pros and cons of behavior change will bring about the negatives and positives associated with self-management and aid in minimizing the ambivalence a patient may be feeling. Third, the physician can elicit concerns about the status quo if a behavior is not changed. Bringing these concerns to the surface will endorse the need for change and consequences if the behavioral change is not pursued. Last, the physician can help to brainstorm solutions and aid in coming up with a multitude of ideas that will help maintain or increase a patient's confidence in their ability to change.[103]

Reverting back to the idea of a patient-centered therapeutic approach, goals and treatments will differ for each patient. In addition, the simple idea of readiness to self-manage is going to vary along a continuum as well. The Stages of Change was formulated with this exact idea in mind, focusing on the idea that a patient should find their place with the stages organically.

Habits are deeply ingrained in our daily lives and we must remember that making the decision to change, implementing a plan, and maintaining that change for any length of time is a difficult feat for anyone. When the additional obstacle of experiencing chronic pain is present, the need to adapt lifestyles is that much more difficult and important. In the chronic pain population, the patient must reach a level where they no longer see medical treatment as the only way to ease suffering.[103] This helps them to take back control of their lives and not allow the pain to overshadow their chosen lifestyle. Further research is needed to understand how a person succeeds and fails in this feat, using such techniques as the Stages of Change. This can lead to the formulation of a standard program where patients have a framework to use as a baseline for comparison and to monitor progress.

CHEMICAL HEALTH

Chemical Coping

Chemical coping is a construct that stemmed from the recognition of the grey area between perfect compliance and aberrancy in medication usage.[114] This idea was cultivated by Bruera and colleages[115] as a way to illustrate an archetype of maladaptive coping via substances. This construct was first applied to a sample of cancer patients with high rates of historical substance abuse, which was furthered by the distress associated with cancer.[115] More recently, this idea is being extended from cancer patients into chronic pain populations.[114]

There are distinctive traits associated with patients in the chronic pain population who might be considered chemical copers. Stress has been seen as a major catalyst in this population and chemical copers have a tendency to increase drug dose and deviate from the treatment path when stress seems unmanageable. Additionally, chemical copers do not tend to set psychosocial goals and are disinterested in nonpharmacological treatments.[114]

There are several associated features within the construct of chemical coping: (1) self-medication,[116] (2) sensation seeking, (3) alexithymia, and (4) somatization. The self-medication hypothesis purports that patients misuse substances in order to relieve feelings of physical or emotional distress and that they have an affinity toward specific pharmacological substances.[116] Sensation seeking is defined as an inclination toward a multitude of complicated and powerful experiences and a desire to go beyond the norm to obtain these feelings. Chemical coping is a strategy used to avoid feelings of distress, whereas the goal of sensation seeking is an alternative to everyday states of mind.[114] Alexithymia is present when a person has the inability to manage and comprehend their emotions and feelings. These patients present with somatic complaints and have little to no emotional connection thereby solely relying on physical feelings.[117] The last associated feature is that of somatization wherein physical complaints have no physiological basis. These patients are not always aware that they are misconstruing emotional distress as physical symptoms and are likely to be resistant to accepting this meassage.[118]

Impulsivity

Impulsivity is a complex behavioral construct that requires further examination within the chronic pain population.[119] Differ-

ent aspects of impulsivity include decreased ability to delay gratification, tendency toward the present moment, risk-taking, poor planning, proneness to boredom, sensation-seeking, reward sensitivity, adventuresomeness, acting without predetermined thought, and hedonism.[120,121] Due to the multidimensional nature of impulsivity, these aspects may manifest in varying behavioral degrees depending on the context in which they are presented. Since it applies to a diverse range of contexts, impulsivity is a common diagnostic criterion for many disorders in the DSM-IV,[21] and has also been implicated as a risk factor for disorders such as alcoholism, eating disorders, and pathological gambling.[120] Longitudinal studies have shown evidence supporting the idea that impulsivity is a risk factor in children for later development of substance abuse issues,[122,123] and cross-sectional studies have demonstrated an association between impulsiveness and substance use in a sample of college students.[124] Impulsiveness may also be linked to other types of impulse-control related behaviors including criminal activity and repeated aggression.[125] The relationship between impulsivity and substance abuse has also been examined in patient populations, demonstrating that patients who are substance abusers score higher on personality measures of impulsivity relative to control groups.[126–133]

A proclivity toward impulsive behavior has important clinical implications in chronic pain patients. This can become problematic because pain patients taking potentially abusable medications such as opioids may be at greater risk for abuse. There are a number of risk factors that have been associated with substance abuse that relate to impulsive behavior. Women with a history of preadolescent sexual abuse are at greater risk for substance abuse and mental disorders.[134–136] Trauma experienced as a result of this abuse can also lead to other psychological disorders such as PTSD[137] and personality disorders.[11] Chronic pain patients who present with a comorbid personality disorder such as borderline personality disorder (BPD) may be at particular risk for substance abuse.[11] Patients with BPD tend to have more intermittent patterns of drug abuse as a result of their characteristic impulsivity and frantic efforts to self-regulate their emotional distress and feelings of emptiness and boredom. This self-medicating, impulsive behavior is often chaotic in nature and in line with their other desperate attempts to act out, such as pursuing the self-regulating effects of food or interpersonal contacts.[138] Impulsive substance abuse has also been found to be largely associated with other psychological disorders including attention-deficit hyperactivity disorder (ADHD), depression, anxiety, obsessive compulsive disorder (OCD), schizophrenia, and bipolar disorder.[139]

Assessment

Self-report measures have been developed to assess impulsivity such as the Barratt Impulsiveness Scale (BIS-10)[133,140] and the Eysenck Personality Questionnaire.[141] However, there are a number of limitations associated with these instruments. First, these measures were generally developed to assess impulsivity in healthy volunteers, not in medically ill populations.[142] Additionally, when respondents are asked to rate items on long-term personality traits such as "I act on impulse," there is a large potential for bias.[143]

Impulsivity can be a predictor and risk factor when viewed within the framework of aberrant drug-taking behaviors. Markers of impulsivity include criminal behavior, history of personal or family substance abuse, history of childhood sexual abuse, and psychological disorders.[137,139] The Opioid Risk Tool (ORT) is a five-item self-report measure that evaluates risk potential for opioid abuse. It was developed based on empirical research linking the aforementioned markers to the level of risk associated with opioid abuse.[137] This measure has clinical utility in evaluating patients prior to initiation of opioid therapy thus allowing clinicians to classify patients into one of three categories; low, moderate, or high risk. The simplicity of the ORT allows the clinician to begin treatment while monitoring the underlying risk factors. Furthermore, the clinician is able to tailor treatment to meet the individual needs of each patient.[139]

In the pain population, chemical health should be part of the initial and ongoing assessment. The goal of psychotherapy in chronic pain syndromes needs to be focused on the differentiation between emotional and physical pain. This is especially true in individuals with tendencies toward chemical coping and impulsivity. This will allow the physician to combat repercussions faced as a result of pharmacological misuse as well as tend to the psychosocial components of living with chronic pain.[114]

CONCLUSION

Increasing attention on chronic pain has led to significant advances in assessment and treatment with greater understanding of the implications of psychological and psychosocial conditions within the chronic pain population. Although recent contributions have improved assessment and evaluation methods of these patients, further research is needed to determine a standard of care.

CHAPTER 22 ■ DISABILITY EVALUATION IN PAINFUL CONDITIONS

JAMES P. ROBINSON AND RAYMOND C. TAIT

INTRODUCTION

The third edition of *Bonica's Management of Pain* contains a chapter on disability assessment in patients with chronic pain written by one of the present authors (JPR).[1] It outlines fundamental conceptual dilemmas that must be faced by any individual or institution that grapples with the problem of how to compensate fairly people who report incapacitation from pain.

As discussed in the third edition, issues related to pain and disability are problematic at several levels. At a societal level, they challenge institutions charged with the responsibility of developing policies regarding disability benefits that bear on individuals who report incapacitating pain. At a much more concrete level, they confound clinicians who are faced with the challenge of whether or not to support requests by their patients for disability benefits and what metric they should apply if they decide to do so.

The present chapter builds on concepts discussed in the previous chapter on disability. In particular, we identify questions which bear on policies for determining pain-related disability and which are amenable to empirical study, and we review the small steps that have been taken to answer these questions. To some degree, these small steps begin to flesh out the concept of "disability science" described in the third edition chapter. The current chapter also summarizes the developments that have occurred in social policies relative to pain and disability during the 7 years since the latter chapter was written.

Finally, we briefly consider the types of decisions that treating physicians are required to make regarding their patients in order to comply with regulations established by disability agencies, and strategies that clinicians might follow when they make disability determinations for patients who they are treating. We note at the outset, however, that the challenges for clinicians are essentially identical to those that existed 7 years ago, secondary to a failure to address critical issues at the levels of policy formation and disability science.

The material contained in this chapter is most relevant to individuals with chronic pain who live in the United States, report incapacitation secondary to their pain, and seek disability benefits of some kind. The chapter focuses on disability programs in the United States for the simple reason that these are the ones with which the authors are most familiar. While the need to specify the jurisdictions considered in this chapter highlights the important fact that disability policies are extremely variable from one jurisdiction to another, the reader will also note that some of the issues raised in the following pages cut across jurisdictions and apply more broadly to the difficulties that clinicians and disability evaluators face when assessing a subjective phenomenon such as pain.

REVIEW OF KEY CONCEPTS

Impairment and Disability

Disability

Two concepts that are fundamental in the area of disability involve "impairment" and "disability." Unfortunately, these terms do not have unique definitions, because different disability agencies define them in slightly different ways. The two concepts are compared in Table 22.1.

In its broadest meaning, disability refers to an inability to carry out necessary tasks in any important domain of life because of a medical condition. For example, a C5 quadriplegic is disabled in the sense of being unable to carry out many basic activities of daily living (ADLs). This chapter focuses on the more restricted concept of work disability, which can be informally defined as the inability to carry out work-related tasks because of a medical condition.

It is important to distinguish between self-reported disability and disability as a social construct. In medical research, it is common for investigators to use self-reported disability as an outcome variable. For example, patients might be asked to complete the Roland-Morris scale, which assesses the extent to which they are limited in ADLs because of low back pain.[2] As a completely different matter, a patient with chronic pain might apply for work disability benefits from a workers' compensation carrier or some other agency that manages disability benefits. If the disability agency determines that the patient is eligible for benefits, he/she is granted the social status of being work disabled. As a consequence of this determination, he/she is exempted from selected customary societal obligations (i.e., working) and is likely to receive disability payments to compensate for lost income. This chapter focuses on the latter aspect of disability, work disability as a social construct.

Work disability can be subcategorized in several ways. The most important distinctions are between total and partial disability, and between temporary and permanent (or long-term) disability. Various disability agencies have programs tailored to these different categories of work disability. For example, the U.S. Social Security Administration (SSA) disability programs are designed for people who are permanently and totally disabled[3]; workers' compensation time loss benefits are paid to individuals who are totally, temporarily disabled; many private disability insurance policies provide benefits when an individual is disabled from performing his or her usual work, even if he or she is not totally disabled. In this chapter we will focus on permanent, pain-related disability.

Impairment

As with the term, disability, "impairment" does not have a unique definition. The American Medical Association's *Guides to the Evaluation of Permanent Impairment*, 5th edition (AMA Guides), provides one definition: "A loss, loss of use, or derangement of any body part, organ system, or organ function."[4] The World Health Organization (WHO) gives the following definition: "Impairments are problems in body function or structure as a significant deviation or loss."[5] The definition given in the 6th edition of the AMA Guides[6] is similar to the one used by WHO. Finally, the SSA offers the following definition: "Anatomical, physiological, or psychological abnormalities that can be shown by medically acceptable clinical and laboratory diagnostic

TABLE 22.1

IMPAIRMENT VERSUS DISABILITY

	Impairment	Disability
Typical Definition	A loss, loss of use, or derangement of any body part, organ system, or organ function†	The inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment(s) which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than 12 months‡
Purpose	Determine the extent to which organs/body parts of an individual are compromised	Determine limitations in an individual's ability to perform various activities because of a medical condition
Level of analysis	Organs or body parts	The whole person
Subtypes	Irrelevant	Temporary vs. permanent Total vs. partial Work-related vs. other domains (e.g., inability to perform ADLs)

techniques.''[7] The present essay focuses on impairment as conceptualized by the AMA Guides, 5th and 6th editions.[4,6]

Although these definitions of impairment differ somewhat, they all emphasize that impairments are biomedical abnormalities that can be analyzed at the level of organs or body parts. In fact, a critical distinction between impairment and disability is that they address limitations at different levels of analysis—impairment refers to a limitation in the function or structure of an organ or body part, whereas disability refers to a limitation in the behavior of a person. This distinction is reflected in the syntax used to describe impairments and disabilities. For example, one would say ''Ms. Smith's right leg is weak because of her polio'' to describe her impairment, and ''Ms. Smith is unable to walk up stairs'' to describe her consequent disability.

While it is possible to distinguish conceptually between impairment (meaning dysfunction of an organ or body part) and disability (meaning an activity limitation secondary to an impairment), the distinction is often unclear in actual practice. For example, the notion of a measurably dysfunctional organ does not readily apply to psychiatric impairments. It is also difficult to make the distinction in conditions in which incapacitation is attributed to pain.

Associations Between Impairment and Disability

As many observers have noted, evaluations of impairment and evaluations of work disability can yield discrepant results. At one extreme (e.g., a violinist with amputation of the second and third digits of the left hand), an individual can have modest impairment, but severe work disability. At the opposite extreme (e.g., Stephen Hawking), an individual can have severe impairment but little or no work disability. But disability agencies typically assume a strong link between impairment and disability. First, they construe impairment as a necessary condition for disability. The logic underlying this requirement is simple. Disability programs are designed to assist individuals who are unable to compete in the workplace because of a medical condition. In essence, disability programs attempt to partition individuals who fail in the workplace into two large groups: those who fail because of a medical condition, and those who fail for nonmedical reasons. The distinction is necessary because there are many potential nonmedical reasons that may restrict employment, including a lack of demand for a job applicant's skills or an applicant's lack of motivation. Disability programs require evidence that an applicant has a medical problem underlying his/her workplace failure. Impairment provides the needed evidence, since it can be viewed as a marker that an individual has a medical problem which diminishes his/her capability. Conversely, if an individual has no identifiable impairment, this implies that employment limitations may not be due to a medical condition.

Second, disability agencies typically assume that the severity of a patient's impairment correlates with the degree and/or probability of his/her being disabled from work. Even when an agency compensates for work disability and not for impairment, it will often seek information about a patient's impairment to rationalize its decision about whether or not to award disability benefits. In this chapter, we will use the term ''impairment'' when the emphasis is on medical evaluation of the severity of an individual's derangement of organs or body parts, and ''disability'' when the emphasis is on evaluation of an individual's ability to work.

Institutions Involved With Disability

Communities frequently provide assistance to individuals who are incapacitated. This type of helping behavior can be seen not only in modern societies, but also in primitive ones. Indeed, evi-

dence of such assistance even can be seen in communities of infrahuman primates.[8] During the last 100 years, the informal understandings that have existed in communities regarding help for the infirm have been supplemented or replaced by formal disability programs. The development of such programs–for example, the Social Security Disability Insurance (SSDI) and the Supplemental Security Income (SSI) programs run by the SSA—has changed the dynamics of disability. In order to receive benefits, an individual having a medical problem that hinders activity must submit an application to an agency that administers a disability program. Adjudicators from the agency then determine whether the applicant meets eligibility criteria for benefits. In order to make this determination, the adjudicators typically request medical information from the applicant's treating physicians. Due to this need for pertinent medical information, physicians are routinely drawn into the disability determination process. This is true not only for SSI and SSDI, but also for other disability systems such as workers' compensation, the Veterans Administration, and private disability insurance programs.

When assessing impairment or disability, the physician must do so within the guidelines of the system within which the disability determination is to be made. In the present chapter, the term ''disability agency'' is used to refer to any insurance company or governmental organization that evaluates disability applications or dispenses disability benefits. A detailed discussion of different disability agencies can be found elsewhere.[9] In the United States, the disability agencies that physicians are most likely to encounter are the SSA, the Veterans Administration, the workers' compensation system, and various disability programs administered by private insurance companies. It is important to be aware that these agencies differ markedly with respect to their missions, their definitions of key concepts, and the demands they make on physicians. This chapter makes frequent references to the 5th and 6th editions of AMA Guides.[4,6] As the title indicates, that book describes procedures that can be used to determine the severity of impairment for claimants with a wide range of medical disorders. The book is important to any discussion of pain-related disability for two reasons. First, it is the most comprehensive work available on the evaluation of impairment. Second, many disability agencies require that applicants for disability be evaluated according to principles set out in the AMA Guides. Hence, it is imperative that physicians who provide disability evaluations become familiar with the principles described in the AMA Guides. At the time of this writing, most disability agencies rely on the 5th edition of the AMA Guides. However, the recently published 6th edition will almost certainly supersede the 5th edition in the near future.

The Administrative Imperative

As noted previously, disability programs are run by bureaucracies that can have distinct, and often unique, imperatives. For example, the SSA, which runs the two largest disability programs in the United States, strives for uniformity, objectivity, and cost containment in its disability evaluation procedures.[10] However sensible these goals are from a bureaucratic standpoint, they often are at odds with the clinical realities of patients with chronic pain.[11] In particular, the administrative imperative for objectivity leads agencies to assume that incapacitation associated with an injury or illness is (or should be) ''transparent'' to a physician (i.e., that the activity limitations described by patients should be highly correlated with evidence of tissue damage or organ dysfunction objectively assessed by a physician).

The administrative requirement that impairment/disability decisions be based on objective medical evidence of derangement in an organ or body part conflicts fundamentally with the evaluation of incapacitation secondary to pain. People with chronic pain typically attribute their pain and activity limitations to dysfunction of an organ or body part. But these subjective reports often are difficult to assess, primarily because examination of the involved organ or body part often does not reveal objective abnormalities that make the pain reports inevitable.[12] It often appears to an observer that the affected organ or body part is capable of functioning, but that the claimant *does not use it normally* because of pain.[13]

CONCEPTUAL PROBLEMS IN EVALUATING PAIN-RELATED DISABILITY

The Fundamental Dilemma

A key feature of pain is its subjectivity. Physicians and other observers can make inferences about a claimant's pain, but cannot directly experience it. To examine the significance of this feature of pain, it is useful to consider two conceptually distinct factors that might be considered in impairment ratings: objective factors such as atrophy of a limb or reduced ejection fraction and subjective factors such as pain. While objective medical factors can be assessed via methods (e.g., laboratory assays or imaging studies) that are independent of the subjective experiences and communications of a claimant, the assessment of subjective factors requires an examiner to interpret the behavior and communications of the claimant and to use these sources of information to infer the claimant's subjective experiences.

Disability agencies clearly and consistently attach great weight to objective factors in the determination of disability. The agencies, however, are inconsistent with respect to the weight (and legitimacy) that they attach to subjective factors. For example, the SSA specifically requires adjudicators to consider pain when they evaluate applicants for SSDI or SSI programs.[14] In sharp contrast, the Washington State Department of Labor and Industries specifically mandates that pain should not be considered in disability determinations regarding injured workers.[15]

It is worth noting that the challenge of assessing subjective factors is not limited to conditions in which chronic pain plays a major role. Very comparable assessment issues arise when impairment associated with mental illness is assessed. There are no established laboratory or imaging studies that identify an individual who suffers from depression or schizophrenia. In diagnosing these conditions and determining the extent of impairment associated with them, an examiner is forced to rely primarily on the verbal and nonverbal behaviors of a patient.

Pain versus Other Manifestations of Disorders: The Embeddedness Problem

One conceptual problem in any discussion of pain-related impairment is that pain is not completely distinct from organ/body part dysfunction. Rather, it is usually most appropriate to construe pain as a ''component'' of a medical disorder. From this perspective, it is arbitrary to examine the significance of pain in isolation from the medical condition underlying the pain, just as it would be arbitrary to evaluate shortness of breath in isolation from congestive heart failure. It would seem conceptually appropriate to evaluate a medical disorder as an entity with characteristic signs, symptoms, and pathophysiology. An impairment rating based on such an evaluation would take into account all manifestations of the disorder, including pain. Many disability agencies follow this logic: that is, they construe pain as one of many manifestations of injuries or diseases. This conceptualization involves the implicit assumption that impairment ratings based on objective evidence of derangement of organs or body parts capture the burden of illness borne by an individual, including the burden imposed by pain.

Unfortunately, this apparently plausible approach to the assessment of pain in the context of impairment ratings can run into either of two complications. First, pain severity may not (and often does not) correlate well with objective indicators of organ/body part dysfunction. In fact, empirical evidence has consistently demonstrated a low concordance between self-reports of pain and behavioral functioning (such as ADLs) or physiologic indices.[16,17] In such situations, impairment ratings based strictly on objective findings are likely to fail to capture the burden of illness of the disorder.

A second and even more difficult situation involves conditions that are associated with severe pain but are not amenable to conventional impairment ratings because they are not associated with unequivocal objective findings. In these conditions, it is not possible to make impairment ratings on the basis of such findings. Common examples include headache disorders and fibromyalgia.

TOWARD A SCIENTIFIC APPROACH TO PAIN-RELATED DISABILITY

Progress Since the Third Edition of Bonica's Management of Pain

The chapter on disability evaluation in the 3rd edition discussed conceptual dilemmas associated with the evaluation of pain-related disability and noted the paucity of scientific data that might help resolve these dilemmas. Unfortunately, the last 7 years have witnessed little progress in "disability science" that might inform a more rational approach to pain-related disability. Several problems have impeded progress.

Although some of the conundrums relevant to pain-related disability are amenable to empirical research (see later), there is a paucity of published studies that address relevant issues. Moreover, we are not aware of any attempt to synthesize empirical data that might be relevant to pain-related disability, much less attempt to consider the significance of such data for policy. As a result, the debate between those who consider pain an important element of disability determination and those who do not continues to rely on rhetoric rather than scientific data. Unfortunately, the rhetoric has only served to polarize the respective positions.

There is also a dearth of conceptual papers relevant to pain-related disability in the medical literature. For example, although there has been heated debate about the appropriate way to treat pain in the 6th edition of the AMA Guide,[18] we are not aware of any published paper in which proponents and opponents have presented their arguments relative to the place of pain assessment in impairment/disability evaluations. While relevant papers have been generated within disability agencies,[15] these are generally not available to the broad academic and/or disability determination community.

In particular, we are not aware of any published paper that weighs the relative importance of two key issues relevant to pain-related disability. One is that pain appears to be *relevant* to the incapacitation of many individuals (see later). The other is that incapacitation associated with pain is *difficult to assess*. Those who advocate giving great weight to pain in disability determinations emphasize the first point; opponents emphasize the second.

Agencies with different policies regarding pain-related disability have not published results of research on the effects of their policies and appear not to have tracked them carefully.[19] Also, it appears that there is little communication among disability agencies, perhaps because they often operate with different disability determination policies. As a result, the debate regarding pain-related disability has not been informed by the various experiments of nature represented by policies of different disability agencies. For example, as far as we know, the SSA and the Washington State Department of Labor and Industries have not compared the effects of their very different policies regarding the determination of pain-related disability.

Despite these caveats, a few contributions to the problem of pain-related disability have appeared in the last 7 years. In particular, the AMA Guides 5th edition[4] and the AMA Guides 6th edition[6] provide detailed discussions of problems in assessing impairment associated with pain. Also, the primary authors of the chapter on pain-related impairment in the 5th edition subsequently published a paper addressing conceptual issues regarding the evaluation of pain-related impairment.[13] Two law professors have published a detailed discussion of SSA regulations related to pain, along with crucial legal judgments regarding these regulations.[20] Finally, Waddell[21] has published a fascinating historical review of efforts by various jurisdictions in Canada to address pain-related disability. Although we note attention in these disparate venues to the problem of pain in the determination of disability, we also note the rather scattered nature of this attention. Clearly, the problem is sufficiently complex and of sufficient importance to merit a more integrated approach, such as that commissioned by the Institute of Medicine 20 years ago.[11]

Empirical Approaches to Pain-Related Disability

Several empirical issues bear on the feasibility of awarding disability benefits to individuals with incapacitating pain (Table 22.2). Specifically, the following questions are relevant and amenable to research: (1) What is the epidemiology of incapacitating chronic pain? (2) What is the relative contribution of objective factors and subjective factors to incapacitation in various medical conditions? (3) How accurate are physicians in assessing the burden of pain-related illness that individuals actually face? (4) Do the awards currently being provided by disability agencies match the future burden of illness/injury of claimants who report incapacitating pain? In the following sections, we discuss the rather limited data that bear on these questions.

Epidemiology of Pain-Related Disability

Analysis of the epidemiology of pain-related disability is compromised by the fact that it is difficult to get relevant data from disability agencies. There are several reasons for this difficulty. One is that there are multiple disability agencies that develop their own methods for recording and storing data about disability applicants and beneficiaries. There is no central repository for such data. Hence, access to such data, if it were to occur, would be piecemeal at best. Second, relevant data from private disability agencies are generally proprietary and not readily shared with

TABLE 22.2

EMPIRICAL ISSUES THAT BEAR ON THE FEASIBILITY OF EVALUATING PAIN-RELATED IMPAIRMENT AND DISABILITY

1. What is the epidemiology of incapacitating chronic pain?
2. What is the relative contribution of objective factors and subjective factors to incapacitation in various medical conditions?
3. How accurate are physicians in assessing the burden of pain-related illness that individuals actually face?
4. Do the awards currently being provided by disability agencies match the actual burden of illness/injury of claimants who report incapacitating pain?

the public. Third, medico-legal records related to disability claims have a limited shelf life; not only do most lawyers that represent disability claimants destroy records within 3 years of claim settlement, many agencies do so, as well.

Finally, disability agencies generally do not record information about claimants in ways that facilitate the study of pain in the incapacitation of beneficiaries. Although, as noted previously, disability agencies differ in the manner in which they code medical information regarding claimants, their general tendency is to rely on traditional diagnostic categories such as those given in ICD-9. The categories in ICD-9 do not provide direct information about the role of pain in incapacitation. While at least one agency, the SSA, has instructed adjudicators to gather such information, these data have not been gathered systematically enough to be useful.[19]

In the face of these limitations, the best available strategy for investigating the role of pain in claimants' reports of incapacitation is to look for proxies—conditions in which activity limitations are governed primarily by pain, and where the pain that patients report is not closely associated with objective findings of organ/body part derangement. Of course, the determination that a condition designated by an ICD-9 diagnosis is a pain syndrome involves judgment, and disagreements are inevitable. But in the absence of better data, we will consider sprains/strains and lumbar spine conditions to be representative conditions in which pain is the dominant reason for incapacitation, and objective findings of loss of function of the affected body area are minimal or inconclusive.

In identifying sprains/strains as proxies for pain syndromes, we recognize that these can be very specific diagnoses based on definable injuries to ligaments or muscles. For example, a tear of the anterior cruciate ligament would be coded as a sprain. However, informal observation suggests that the latter example is relatively rare. In most instances, a diagnosis of sprain/strain is made when an individual complains of pain, but there are no clear-cut findings of injury in the symptomatic area. Thus, when a patient complains of pain in his/her spine, upper extremity, or lower extremity, an examining physician typically considers the possibility that the patient's symptoms might be the result of a definable musculoskeletal abnormality (e.g., fracture) or neurologic abnormality (e.g., carpal tunnel syndrome). If such well defined conditions are ruled out, a diagnosis of sprain/strain is often the default option.

We consider most diagnoses of lumbar spine disorders to be proxies for pain syndromes because the incapacitation of individuals is generally not attributable to measurable mechanical failure of the spine, or to a loss of neurologic function in a lower extremity. Rather, the individuals are incapacitated by pain as they try to engage in various activities.[1,13]

Useful data about sprains/strains and low back disorders come from the Bureau of Labor Statistics (BLS).[22] For example, in 2003, there were 1,315,920 work injuries and occupational illnesses in the United States that required a worker to take time off work. Of these, 43% were coded as sprains/strains, and 18% as back injuries. (These two categories overlap, since most back injuries are coded as back strains/sprains.) BLS data on claims that require prolonged time away from work (more than 30 days) indicate similar trends: 43% of such claims were for sprains/strains, and 21.4% were for back injuries. Finally, unpublished data from the Washington State Department of Labor and Industries from 2003[23] provide information on work injuries that lead to more than 120 days off work. Twenty-one percent of these claims were for sprains/strains of the back. Although these data do not directly address permanent disability, there is strong evidence that the probability of indefinite work disability is high among workers who miss substantial periods of time from work shortly after their injuries.[24]

In summary, the previous data indicate that disorders characterized by pain that is at best loosely correlated with objective findings account for a very substantial proportion of protracted work disability claims. These data underline the importance of developing systems to evaluate claims of incapacitation secondary to pain.

Relative Contributions of Objective versus Subjective Factors in Disability

As described previously, pain is typically "embedded" in various medical disorders. Thus, it is often the case that when individuals complain of persistent pain, the pain can plausibly be attributed to a medical condition that is associated with objective indicators of organ/body part derangement. For example, a patient with significant coronary artery stenosis would have understandable reasons for his/her complaints of chest pain. In conditions where objective indicators of organ/body part derangement typically occur in conjunction with characteristic pain, the severity of an individual's incapacitation could in principle be assessed either by (1) evaluating the severity of the objective indicators, (2) by gathering subjective data from him/her about the burden of illness imposed by the condition because of pain, or (3) by some combination of the two strategies. Which of the approaches provides data that are most closely associated with the degree of incapacitation that the individual demonstrates?

Once some indicator of incapacitation has been defined (e.g., ability to work, or ability to perform ADLs), the previous question can be framed as a problem in prediction, and can be modeled by the following regression equation:

$$\text{Predicted } Y = f(X_1, X_2, \ldots\ldots X_n; x_1, x_2, \ldots\ldots\ldots\ldots x_m)$$

Where:

Predicted Y = a claimant's predicted ability to perform ADLs

$X_1, X_2, \ldots\ldots X_n$ = the claimant's "scores" on indices of organ or body part derangement

$x_1, x_2, \ldots\ldots\ldots\ldots x_m$ = the claimant's "scores" for self-reported pain severity, and severity of limitations imposed by pain

This conceptualization of the problem of assessing the role of subjective factors (pain) versus indicators of organ/body part derangement in incapacitation invites empirical exploration. Specifically, for a given medical condition, it would be possible to investigate correlations between: (1) organ or body part indices and self-report variables; (2) organ or body part indices and incapacitation; and (3) self-report variables and indices of incapacitation. Correlations among these classes of variables will, of course, depend on the medical condition under consideration and on the specific measures used to assess relevant variables. At one extreme, objective measures of organ dysfunction/derangement might accurately predict the degree of incapacitation of individuals with a given medical disorder, and subjective data might add nothing to the predictive equation. Alternatively, it is possible that subjective data are needed to maximize prediction of incapacitation.

It is beyond the scope of this chapter to review research in this complex area in any depth. However, in the specific case of noncatastrophic low back pain, self-report measures demonstrate the following statistical properties: (1) they are only modestly associated with objective indicators of spine dysfunction and (2) they are substantially correlated with functional outcome measures such as ability to perform ADLs.[25–36] Thus, a system to predict functional status among low back pain claimants is likely to be more accurate if it incorporates self-report data in addition to indices of spine function than if it relies solely on objective indices of spine function.

Judging Pain and Disability: Bias and Accuracy

As has been noted previously, the subjective nature of pain and the frequent failure of pain reports to correlate with available medical evidence greatly complicate disability determination. Patients can report severe pain in the absence of medical evidence[37,38] and they can describe little or no pain despite obvious lesions.[31] The inherent difficulties in evaluating patients' reports about their pain are magnified when the patients become claimants for benefits from disability agencies that require objective evidence of impairment.[39] A key question amenable to empirical research is whether examiners are capable of accurately judging the burden of illness borne by individuals who report incapacitating pain.

Historically, concerns regarding judgments of pain-related disability have been framed as a problem of inter-rater reliability.[40–42] Much of the focus of these concerns has centered on low back pain, secondary to its uncertain pathogenesis, its prevalence, and its associated costs, both medical and societal.[39,43–45] Unfortunately, systematic efforts to improve inter-rater reliability among disability examiners have met with somewhat mixed success.[46] Indeed, there is increasing evidence that variability in disability determination decisions may be a function of more than inter-rater error.[47,48] In particular, the variability may reflect uncertainty that is inherent in judging subjective phenomena such as pain.

Decisions made in the context of uncertainty have received considerable scrutiny in recent years,[49,50] although little directly involves decisions made regarding pain-related disability. That literature suggests that such decisions often are influenced by intuitive, rather than rational-deductive processes.[51] Moreover, when phenomena lack clear and specific evidence (as is common with chronic pain), judges tend to discount their importance.[52] Because pain is highly reliant upon self-report and often lacking objective evidentiary support, it is not surprising that observers (both lay and medical) tend to underestimate pain when patients report severe pain.[53,54] Although the precise mechanisms underlying this tendency are unclear, there is little doubt that the tendency to discount high levels of pain is consistent and widespread.

Negative stereotypes also exist for patients with symptoms of chronic pain and can influence assessment processes,[55,56] especially for those involved in compensation/litigation proceedings.[57] When observers are asked to make judgments of pain and pain-related disability for patients who fall into the latter category, those stereotypes have been shown to operate: judgments of symptom severity are significantly lower for patients involved in litigation proceedings than patients who are not.[58] Similarly, negative stereotypes exist for patients who describe severe pain without supporting medical evidence, as is often the case for patients with diagnoses of lumbar sprain/strain. Judgments of pain intensity and pain-related disability for patients without supporting medical evidence are reliably and substantially lower than those for patients with such evidence.[59,60] Not only does each of the above factors influence ratings of pain and disability independently, the factors have an additive effect when they are combined. Hence, litigating patients who report high levels of pain without supporting medical evidence present a very disadvantaged picture to examiners charged with making disability determinations.[61]

Aside from the situational factors described, several patient features also may systematically influence the disability determination process, potentially undermining its validity for pain-related conditions. For example, there is growing evidence that the race of an applicant can influence impairment[47] and disability ratings.[48] Further, socioeconomic status (SES) may influence ratings, such that lower SES applicants may receive lower ratings than do those from higher SES levels.[62] Finally, while less studied with regard to disability, gender also has been shown to influence observer estimates of pain: research has shown that women are seen as more emotional and more likely to over-report pain than men.[63] If the proclivity to discount pain reports from women extrapolates to a similar tendency in regard to their reports of pain-related dysfunction, women may be another group that is at risk of receiving lower ratings when disability is determined.

In addition to patient and situational factors, several characteristics of the rater may influence his/her disability ratings. One involves the rater's experience. Raters with more experience seem to underestimate pain to a greater degree than do those with less experience.[64–66] The precise mechanisms associated with this predisposition are unclear, but may have something to do with the fact that highly experienced clinicians draw upon increased levels of exposure to severe pain among patients that they have seen, such that the anchor points that describe "severe pain" differ from those of less experienced clinicians. Similarly, there is some evidence that a physician's specialty also may moderate his or her ratings; those whose specialties expose them to patients with catastrophic injuries and/or illnesses may rate pain and disability at lower levels than those whose practices comprise patients with more commonplace problems.[60] Each of these findings may have implications for disability determination: physicians who perform disability determinations usually are highly experienced and many also are surgeons. Thus, disability examiners may have characteristics that predispose them to underestimate levels of pain and pain-related disability in patients who present with a primary complaint of pain.

The Detection of Deception

The previous discussion focuses on general factors that influence evaluators when they rate disability in patients with chronic pain. However, it does not specifically address one key issue that bears on these ratings: the ability of evaluators to determine when patients are exaggerating their incapacitation or are deliberately feigning incapacitation.

Deception must be seen against the broader background of social influence. Throughout their lives, people develop strategies to meet their needs by influencing others.[67] The strategies they develop may be explicit and carefully planned, but they are often implicit and unplanned. When individuals develop medical problems, they frequently find that their needs can be met only if they can influence the physicians and other professionals with whom they interact. At a very basic level, patients want to be respected and thought of as "legitimate" by these professionals.[68] This is particularly true for patients with primary complaints of pain, many of whom may have been accused of malingering or having psychiatric problems.[56] Patients who are sensitive to such issues appear to present themselves clinically in a manner that lessens the likelihood of such accusations; they appear to downplay emotional aspects of pain and to emphasize its biological determinants.[69] Similarly, patients with pain problems may feel that they need certain kinds of treatment, such as chronic opioid therapy. They can satisfy this need only if they can convince their physicians that such therapy is appropriate. Patients who are applying for disability have an obvious need to convince disability evaluators of the legitimacy of their claims.

It stands to reason that pain patients will adapt interpersonal strategies they have developed in the past to the task of influencing health professionals so as to meet their needs. These strategies are subtle enough so that it is difficult to enumerate them or to decide which strategies deserve the appellation "deception". To put the matter differently, while it is possible to identify extremes of patient behavior—one anchored by complete forthrightness, and the other by deliberate, planned deception—many patients occupy a "gray zone" somewhere in the middle. They demonstrate "exaggerated" pain behavior or report "excessive" incapacitation from their pain, but do not appear to be deliberately

falsifying information that they provide.[70–72] Terms like symptom magnification are often used to describe such presentations.

Outright deceit (malingering) by patients is a form of fraud.[73] There is a general consensus that patients who are malingering should not receive disability benefits. In practice, however, secondary to the subjective nature of pain and the uncertainties inherent in its evaluation, it is extremely difficult to discern outright deceit with confidence because that judgment ultimately resides in the eye of the beholder. Some physicians will find evidence of symptom magnification and suspect deliberate deception whenever a claimant reports symptoms or a degree of incapacitation that cannot be easily explained on the basis of objective findings. But as discussed, chronic pain poses a dilemma precisely because patients report incapacitation that cannot be fully explained on the basis of objective findings. To put the matter differently, pain patients almost always have symptom magnification relative to their objective findings, but this should not be automatically construed as evidence that they do not have valid claims.

There is an abundant literature on deception by patients with various medical complaints. Much of this comes from forensic settings. A few points deserve mention. First, frank malingering is a problem in patients with chronic pain, with prevalence estimates of up to 10%.[74] In particular, investigators have expressed concern that individuals with chemical dependency might present themselves as suffering from chronic pain in order to get opioids.[75] Second, evidence available from forensic research and other settings suggests that physicians are not particularly skilled at identifying deception on the part of pain patients.[75–78] Third, research on the ability of physicians to detect deception is hampered by conceptual ambiguity about what constitutes deception on the part of patients with chronic pain.

It is beyond the scope of this chapter to provide a detailed review of literature on the ability of disability evaluators to detect deception on the part of claimants with chronic pain. It is important to note, though, that a thorough analysis of the scientific basis for disability evaluation in the context of chronic pain would need to include a consideration of this literature.

Systemic Factors

While the research cited above raises concerns about the reliability and validity of disability determination examinations at the level of the individual claimant, those results do not obviate the need to examine disability determination processes at the systemic level. Indeed, the disability determination system is constructed in a manner that may mitigate the effects of a single examiner or examination. In fact, when substantive disagreement exists in regard to an applicant's level of disability, it is common for several medical opinions to be obtained, each of which is considered when an administrative law judge reaches a final determination.[79]

The issue of systemic fairness was examined for the State of California in a study commissioned through the RAND Institute for Civil Justice.[80] Because of the scale of the project, we will describe it in some detail. A crucial element of the study methodology involved the computation of actual earnings loss; this was derived from a comparison of the earnings of workers applying for workers' compensation benefits with a cohort of workers in similar occupations over the years of the study (January 1, 1991 to April 1, 1997). By comparing actual earnings loss with actual benefits, the study investigators were able to assess the equity of the system.

Study findings of most relevance to this chapter involved the "horizontal" and "vertical" equity of disability determinations for workers' compensation claims. Horizontal equity involved analysis of benefits relative to actual loss of earnings for workers who sustained injuries to different body parts (e.g., shoulder vs. low back). Horizontal equity would be demonstrated if the ratio between disability benefits and earning losses was the same for workers with different types of injuries. Vertical equity, on the other hand, involves the proportionality of benefits to different levels of actual earnings loss; vertical equity would be demonstrated if workers with a greater loss of earnings also received higher benefits than those with a lower loss of earnings.

Study findings relative to these metrics were mixed. In regard to horizontal equity, researchers found that injuries to some body parts (e.g., shoulders) were compensated at higher levels than injuries to other body parts (e.g., knee). For vertical equity, results appeared more encouraging: benefits correlated strongly with actual earnings loss. At a general level, therefore, the disability determinations seemed to reflect vertical equity in the California system.

The latter finding, however, masked significant inconsistencies in the data. Of particular note for this chapter, there was significant inconsistency in impairment ratings between physicians who were retained by applicants versus those retained by the defense. Further, those inconsistencies were greatest in conditions that required the subjective judgment of an examiner, typically involving multiple-impairment cases. While the report did not break out data specific to the issue of pain, its findings are of particular note relative to multiple impairments involving the back, for example, back and psychiatric disorders and back and lower extremity; both common among patients with chronic back pain. Among applicants with both back and lower extremity impairments, the average applicant rating exceeded the average defense rating by 86%. Among applicants with both back and psychiatric impairments, the difference averaged 94%. These data suggest that the factors described that operate at the level of the medico-legal encounter had systemic effects that apparently influenced final disability determination findings.

Related concerns are raised by other research more specific to disability applicants with low back pain. For example, a recent study followed these applicants approximately 2 years after claim settlement, collecting information regarding their functional status at that time.[62] The study found very little correlation between disability ratings and measures of functional status, including levels of pain severity, psychological distress, and disability/employment. Not only were the correlations between disability ratings and functional status weak, the correlations generally reflected an inverse relationship: claimants who had received higher disability ratings reported fewer functional problems. These data, although reflecting disability determination processes in only one state, nonetheless raise significant questions regarding the validity of current disability determination paradigms for applicants with pain as a primary cause of disablement.

Aside from the issues of equity and validity raised by the previous studies, other research suggests that systemic disparities may exist in the management of pain in workers with occupational injuries. Race/ethnicity and SES appear to be associated with levels of treatment, such that the rates of surgery and overall levels of medical care have been shown to be lower for African Americans and for lower SES applicants.[48,81] Moreover, because both surgery and level of medical care predict final disability ratings, the differences in treatment indirectly affected disability settlements for the latter groups. Further, race and SES also contributed directly to disability ratings, such that African American race was negatively associated with those ratings and SES positively associated with ratings. Finally, the clinical adjustment of African Americans and of poorer applicants was worse than that of their Caucasian and more affluent counterparts after their claims were settled.[82] Hence, the limited available data suggest that disability determination systems may disadvantage minority and lower SES applicants with low back pain in terms of treatment, claim settlement, and long-term outcomes.

Conclusion

While research that bears directly and indirectly on disability determination processes remains quite limited for patients with

pain, it is sufficient to raise substantial questions about the validity and equity of those systems. At the level of the medico-legal encounter, there is reason to believe that situational, patient, and provider factors contribute to systematic variability in ratings. At the level of the disability system, there is reason to believe that significant inequities are meted out to applicants with a primary complaint of pain, and those inequities may impact applicants at multiple levels: in the delivery of care, in claim settlement, and in postsettlement outcomes.

The scientific evidence is limited in a number of ways beyond its relative scarcity. First, the research is limited geographically. Because it has occurred primarily at the state level (e.g., California, Missouri), there is a real need for a broader examination of disability systems at a multi-state or national level. Second, research has focused primarily on workers' compensation systems; there is a need to examine other systems for disability determination (SSA disability, Veterans' Affairs, etc.). Finally, much of the research has focused on low back pain. While low back pain constitutes a substantial dilemma for disability determination systems (especially in the absence of verifiable objective impairment), it certainly is not the only condition for which pain represents the primary source of dysfunction. For example, fibromyalgia and other forms of musculoskeletal pain also are widespread causes of disability.[83–86] As such, these conditions also merit specific empirical attention if a more valid and equitable approach to disability determination is to be undertaken.

PAIN-RELATED IMPAIRMENT/ DISABILITY: CHALLENGES FOR THE CLINICIAN

Physicians play a crucial role in the roughly 7 million disability evaluations that are done annually in the United States. Sometimes physicians are hired by insurance companies or disability agencies to perform independent medical examinations on patients whom they are not treating. In other instances, physicians are asked (or required) to make disability judgments about patients whom they are treating.

Treating physicians have good reason to feel discomfort when they make disability judgments about their patients. In a general way, the process of disability evaluation places a physician in the middle, between his/her patient and a variety of disability agencies. In the best of circumstances, this often has the feel of fitting a round peg into a square hole, since the administrative categories established by disability agencies often do not match the clinical realities of patients. In the worst case, clinicians end up feeling caught in the crossfire between warring adversaries. They may perceive employees of disability agencies as unenlightened bureaucrats who make excessive demands for documentation and seem to lose the forest for the trees. At the same time, they may perceive their patients as reporting extraordinary amounts of incapacitation, and trying to enlist physicians as allies in their battles with disability agencies. It is beyond the scope of this chapter to discuss the multiple challenges that clinicians face as they interface between their patients and disability agencies. Detailed discussions of these issues are available.[12,87–90] We will thus confine ourselves to a few salient comments.

1. Treating physicians usually prefer to avoid the task of rendering judgments about whether their patients are disabled from work. Unfortunately, this is typically not an option. Disability agencies generally will not grant disability benefits to an applicant unless his/her treating physician supports the application. Thus, if a physician fails to complete disability forms for his/her patient, the patient is penalized.
2. The types of data required by physicians and the manner in which physician information is processed vary widely from one disability agency to another. In order to address a patient's requests fairly, a physician must be familiar with the disability agency with which he or she is interacting.
3. Disability agencies routinely insist that treating physicians base their judgments about disability on objective findings. As noted previously, if this demand is followed, patients incapacitated by pain would never receive disability. As discussed by Robinson,[12] treating physicians often need to reject the administrative demand for objectivity.

CONCLUSION

This chapter has focused on problems associated with disability evaluation for chronic pain at a societal level. We have described some of the dilemmas and controversies in this area, have outlined research issues that bear on the question of whether pain-related disability can be reliably and validly assessed, and have briefly discussed research on these issues. Our goal has been to demonstrate the possibility (and need) of performing empirical research on pain-related disability rather than to exhaustively review the research that has been done thus far. The research that we have reviewed supports the following conclusions: (1) incapacitation secondary to pain occurs frequently in the workplace; (2) in at least some highly prevalent conditions, it is necessary to consider subjective information (especially pain) in order to predict how incapacitated patients are likely to be; (3) the ability of clinicians to "decode" the verbal messages that patients provide about their pain and their burden of illness is limited; and (4) current systems for awarding disability benefits probably underestimate the burden of illness created by chronic pain.

In our opinion, policies regarding pain-related disability are in disarray. Disability agencies vary widely in the way they approach this problem. For example, the SSA requires adjudicators to consider pain when they evaluate disability applications, while the Washington State Department of Labor and Industries requires adjudicators *not* to consider pain. There appears to be little communication between agencies about the pros and cons of various policies regarding pain-related disability, and the medical literature on the subject is virtually nonexistent.

In our view, several steps must occur if rational policies regarding pain-related disability are to emerge (Table 22.3). First, there needs to be a dialogue about the problems associated with assessing pain-related disability. This dialogue will be productive only if it addresses both horns of the dilemma of pain-related disability simultaneously—the relevance of pain to work incapacity and the difficulty of assessing the burden of pain. Second, further research is needed on the empirical issues described previously, and other researchable questions regarding pain-related disability policy should be identified. Third, disability agencies need to assess the effectiveness of policies they have developed regarding

TABLE 22.3

STEPS NEEDED TO DEVELOP RATIONAL POLICIES REGARDING PAIN-RELATED DISABILITY

1. Dialogue among professionals about the problems associated with assessing pain-related disability.
2. Simultaneous consideration of the relevance of pain to work incapacity and the difficulty of assessing the burden of pain.
3. Further research on empirical issues that bear on the feasibility of assessing pain-related disability.
4. Assessment by disability agencies of the effectiveness of their current policies for evaluating pain-related disability.
5. Better communication among disability agencies regarding policies for evaluating pain-related disability.

pain-related disability; it would be advantageous if they could establish channels of interagency communication in conducting these assessments. A related point is that it is important that questions related to the determination of pain-related disability be addressed on a wider stage than has been the case thus far. Most research has been constrained by geographic limitations; studies on a national scope are needed if a piecemeal approach to this issue is to be avoided.

In the absence of rational policies regarding pain-related disability, it is difficult to provide guidance to the clinician who addresses pain-related disability in patients he/she treats. We have outlined a few rules of thumb that we believe will help such clinicians, and have referred to publications in which one of us (JPR) has discussed the practical problems of disability management by clinicians in more detail. However, we are convinced that clinicians will not get any respite until disability agencies come to terms with the problems of pain-related impairment/disability, and develop empirically driven rules and assessment methods that are consistent and acceptable to treating physicians.

CHAPTER 23 ■ MULTIDISCIPLINARY ASSESSMENT OF PATIENTS WITH CHRONIC PAIN

DENNIS C. TURK AND JAMES P. ROBINSON

INTRODUCTION

This chapter deals with the multidisciplinary assessment of patients with chronic noncancer pain. In order to be specific, especially with regard to the medical evaluation of chronic pain patients, we organize the discussion around a typical and common chronic pain problem (e.g., persistent cervical spine pain). We note, though, that many of the concepts in the chapter are relevant to the assessment of virtually any chronic pain patient. In particular, concepts related to the assessment of psychological factors, social factors, and functional limitations have wide applicability.

A key premise in this chapter is that multiple factors influence the symptoms and functional limitations of patients with chronic pain. As a consequence, we believe that evaluation along multiple dimensions, performed by professionals with a variety of skills, provides important insights into the factors governing the complaints of these patients and assists in treatment planning.

CONCEPTUAL ISSUES

Conundrums in the Assessment of Pain

How we think about symptoms such as pain influences the way in which we go about evaluating patients. Physicians and the lay public alike tend to assume that some underlying pathology is both a necessary and a sufficient cause of the symptoms reported and experienced by patients. Consequently, medical assessment usually begins with taking a thorough history and performing a physical examination, followed by, when deemed appropriate, laboratory tests and diagnostic imaging procedures in an attempt to identify or confirm the presence of an underlying pathology that *causes* the symptom (see later). In the absence of identifiable organic pathology, the physician may assume that the report of symptoms stems from psychological factors (i.e., personality

characteristics, psychopathology, malingering). A psychological evaluation may be requested to detect the underlying psychological factors that underlie the patient's reports. Thus, there is a duality where the report of symptoms is attributed to *either* somatic *or* psychogenic mechanisms. This dualistic perspective dates back at least to the 17th century and the philosopher René Descartes. The assumption that symptoms that cannot be explained by medical findings must originate from psychological distress is, albeit unfortunately common, overly simplistic and inconsistent with current scientific understanding. The dichotomous view is incomplete and, as described throughout this chapter, is not compatible with available research evidence or the current understanding of chronic pain.[1]

Over the years, research has revealed puzzling observations that challenge the presumed isomorphism between pain and organic pathology. For example, the exact pathophysiology underlying some of the most common and recurring acute (e.g., primary headache) and chronic (e.g., back pain, fibromyalgia [FM]) pain problems is largely unknown. Conversely, several studies using plain radiography, computed tomography (CT), and magnetic resonance imaging (MRI) reveal that more than 30% of *asymptomatic* individuals have structural abnormalities such as herniated discs and spinal stenosis that would be accepted as valid explanations of pain if the individuals had been symptomatic.[2–6] In the case of FM, although a number of endocrine, immunological, and neurochemical perturbations have been investigated, there is currently no consensus regarding the causal mechanisms for the symptoms reported.[7] Thus, we are confronted with a rather strange set of circumstances: people with no identified organic pathology who report severe pain and, conversely, others with significant pathology who are apparently pain free.

A Conceptual Model for Assessing Pain

The conundrums described suggest that multiple factors likely contribute to persistent pain and related disability. There is a growing consensus that these consist of (1) genetic composition,[8] (2) physical pathology associated with trauma or disease, (3) alterations in the peripheral and central nervous system attributable to initial insult (peripheral and central sensitization), (4) psychological contributors including prior learning history and available coping resources (e.g., emotional support, financial resources, acquired coping skills), and (5) environmental influences (e.g., response by significant others, disability compensation, features inherent in the workplace) that all likely interact. A comprehensive evaluation should provide information about each of these factors, although examination of unique genetic contributions is in its infancy at this time but will likely be gaining attention in the coming years. Thus, in this chapter we will describe a general strategy for assessing factors 2 to 5.

Pain Behavior

It is useful to begin a discussion of assessment of patients with chronic pain with the concept of pain behaviors. Pain is a subjective perception and there is currently no objective way to know about the experience of pain other than by patients' behavior. Pain behaviors include verbal behaviors (i.e., statements about pain). They also include nonverbal behaviors such as limping or wincing. These pain behaviors are sources of communication; they convey to others the presence and severity of pain.

The challenge for an examiner is how to interpret patients' pain behaviors. Although these behaviors are sometimes determined entirely by an abnormal biological process in the area of injury, they are typically also influenced by changes in nervous system encoding and processing of nociceptive signals, by a patient's beliefs and appraisals, emotional status, coping strategies, and by the social environment.

Classes of Variables Underlying Pain Behavior

We will return to more formal assessment of pain behaviors later in this chapter. For now, a useful way to conceptualize this challenge is to think of a prediction equation with multiple unknowns:

PB = f(Xa1, Xa2 . . . Xan1; Xb1, Xb2 . . . . . Xbn2; Xc1, Xc2 . . . . . Xcn3; Xd1, Xd2 . . . Xdn4)

Where PB = the pain behavior that a patient demonstrates, and predictor variables are organized into four categories, such that Xa1, Xa2. . .Xan1 refer to biomedical factors at the end organ where the patient reports pain; Xb1, Xb2 . . . . . Xbn2 refer to alterations in nervous system function (especially central nervous system sensitization) that perpetuate pain after nociceptive impulses from the end organ have diminished or ceased; Xc1, Xc2 . . . . . Xcn3 refer to psychological variables; and Xd1, Xd2 . . . Xdn4 refer to social or contextual variables that influence pain behavior.[9a]

The prediction equation emphasizes the multiplicity of factors that influence patients' expressions of pain and highlights the dilemma facing an evaluating physician. The dilemma is that it is extremely difficult to determine the weights that should be assigned to various factors for an individual patient. To make matters even worse, there is no consensus about what the possible variables within various categories are (e.g., to specify the types of psychological factors that may affect a patient's pain behavior).

In accordance with the model, the discussion is organized around the assessment of medical factors, central nervous system sensitization, psychological factors, and social factors in chronic pain patients. We also consider the assessment of the severity of functional incapacitation in these patients.

ASSESSMENT OF MEDICAL FACTORS

A careful medical evaluation is a basic element in a multidisciplinary evaluation of a patient with chronic pain. The general goals of such an evaluation are to: (1) make a medical diagnosis; (2) determine whether additional diagnostic testing is needed; (3) make a judgment about the extent to which medical data regarding a patient adequately explain his or her symptoms and the severity of his or her apparent incapacitation; (4) determine whether there is any medical or surgical treatment that has a reasonable chance of reversing the pathophysiologic processes underlying the patient's pain; (5) determine whether there are any symptomatic treatments that should be prescribed if a reversal of pathophysiology is not possible; and (6) establish the objectives of treatment.

The specific procedures that physicians perform and the differential diagnostic possibilities they entertain vary enormously with patients' symptoms and presumed medical disorders. For example, the medical evaluation of a patient with pelvic pain is entirely different from the evaluation of a patient with neck pain. Also, the medical evaluation of a pain patient depends on the chronicity of the patient's symptoms and the medical evaluations and diagnostic testing that the patient has already undergone.

In order to be reasonably specific, the discussion here focuses on the medical evaluation of patients with persistent neck pain following a "whiplash" injury. Although some of the procedures are specifically relevant to this patient population, many of them can be employed in the evaluation of virtually any chronic pain patient.

There is no uniformly accepted algorithm for evaluating neck pain patients. In fact, as will be discussed, physicians differ sharply about some aspects of such evaluations. The approach discussed later is summarized in Figure 23.1, which identifies key questions that should be asked in the evaluation of a patient with persistent neck pain.

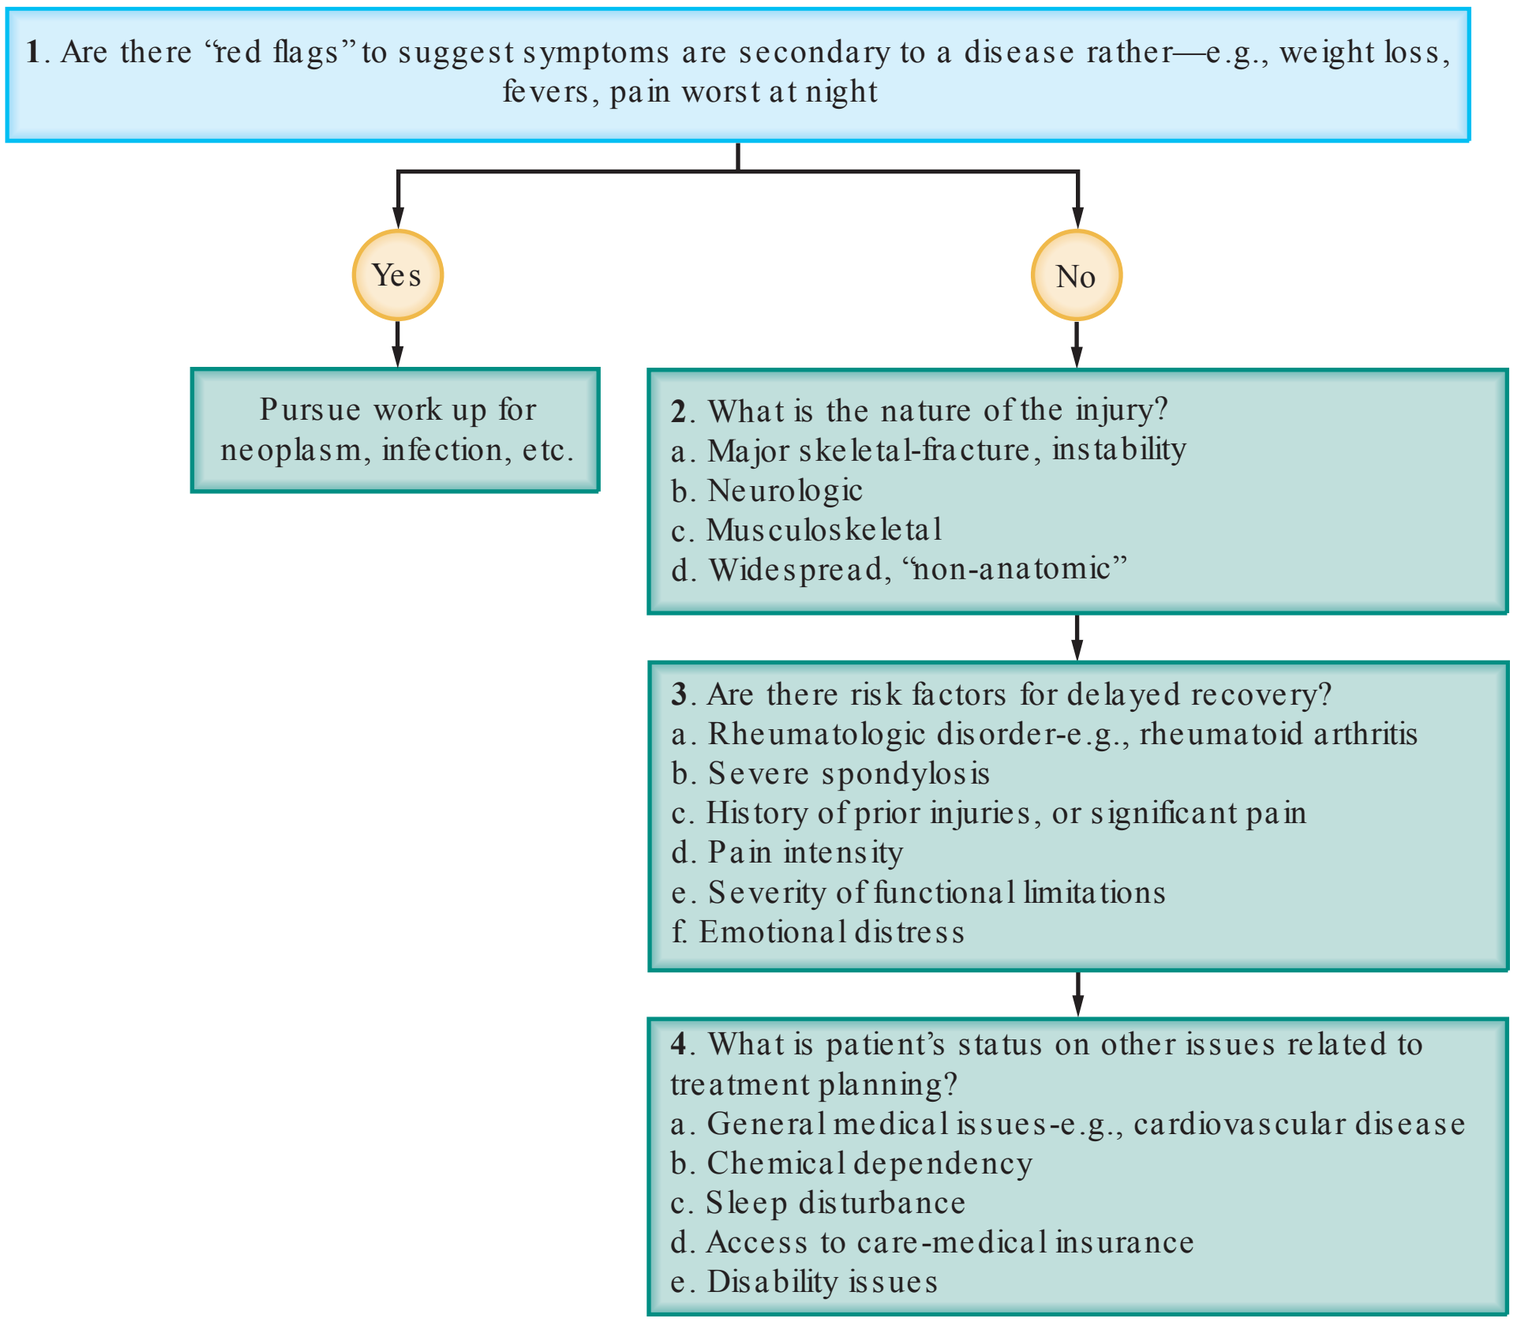

FIGURE 23.1 Key issues to address in the medical evaluation of chronic pain patients.

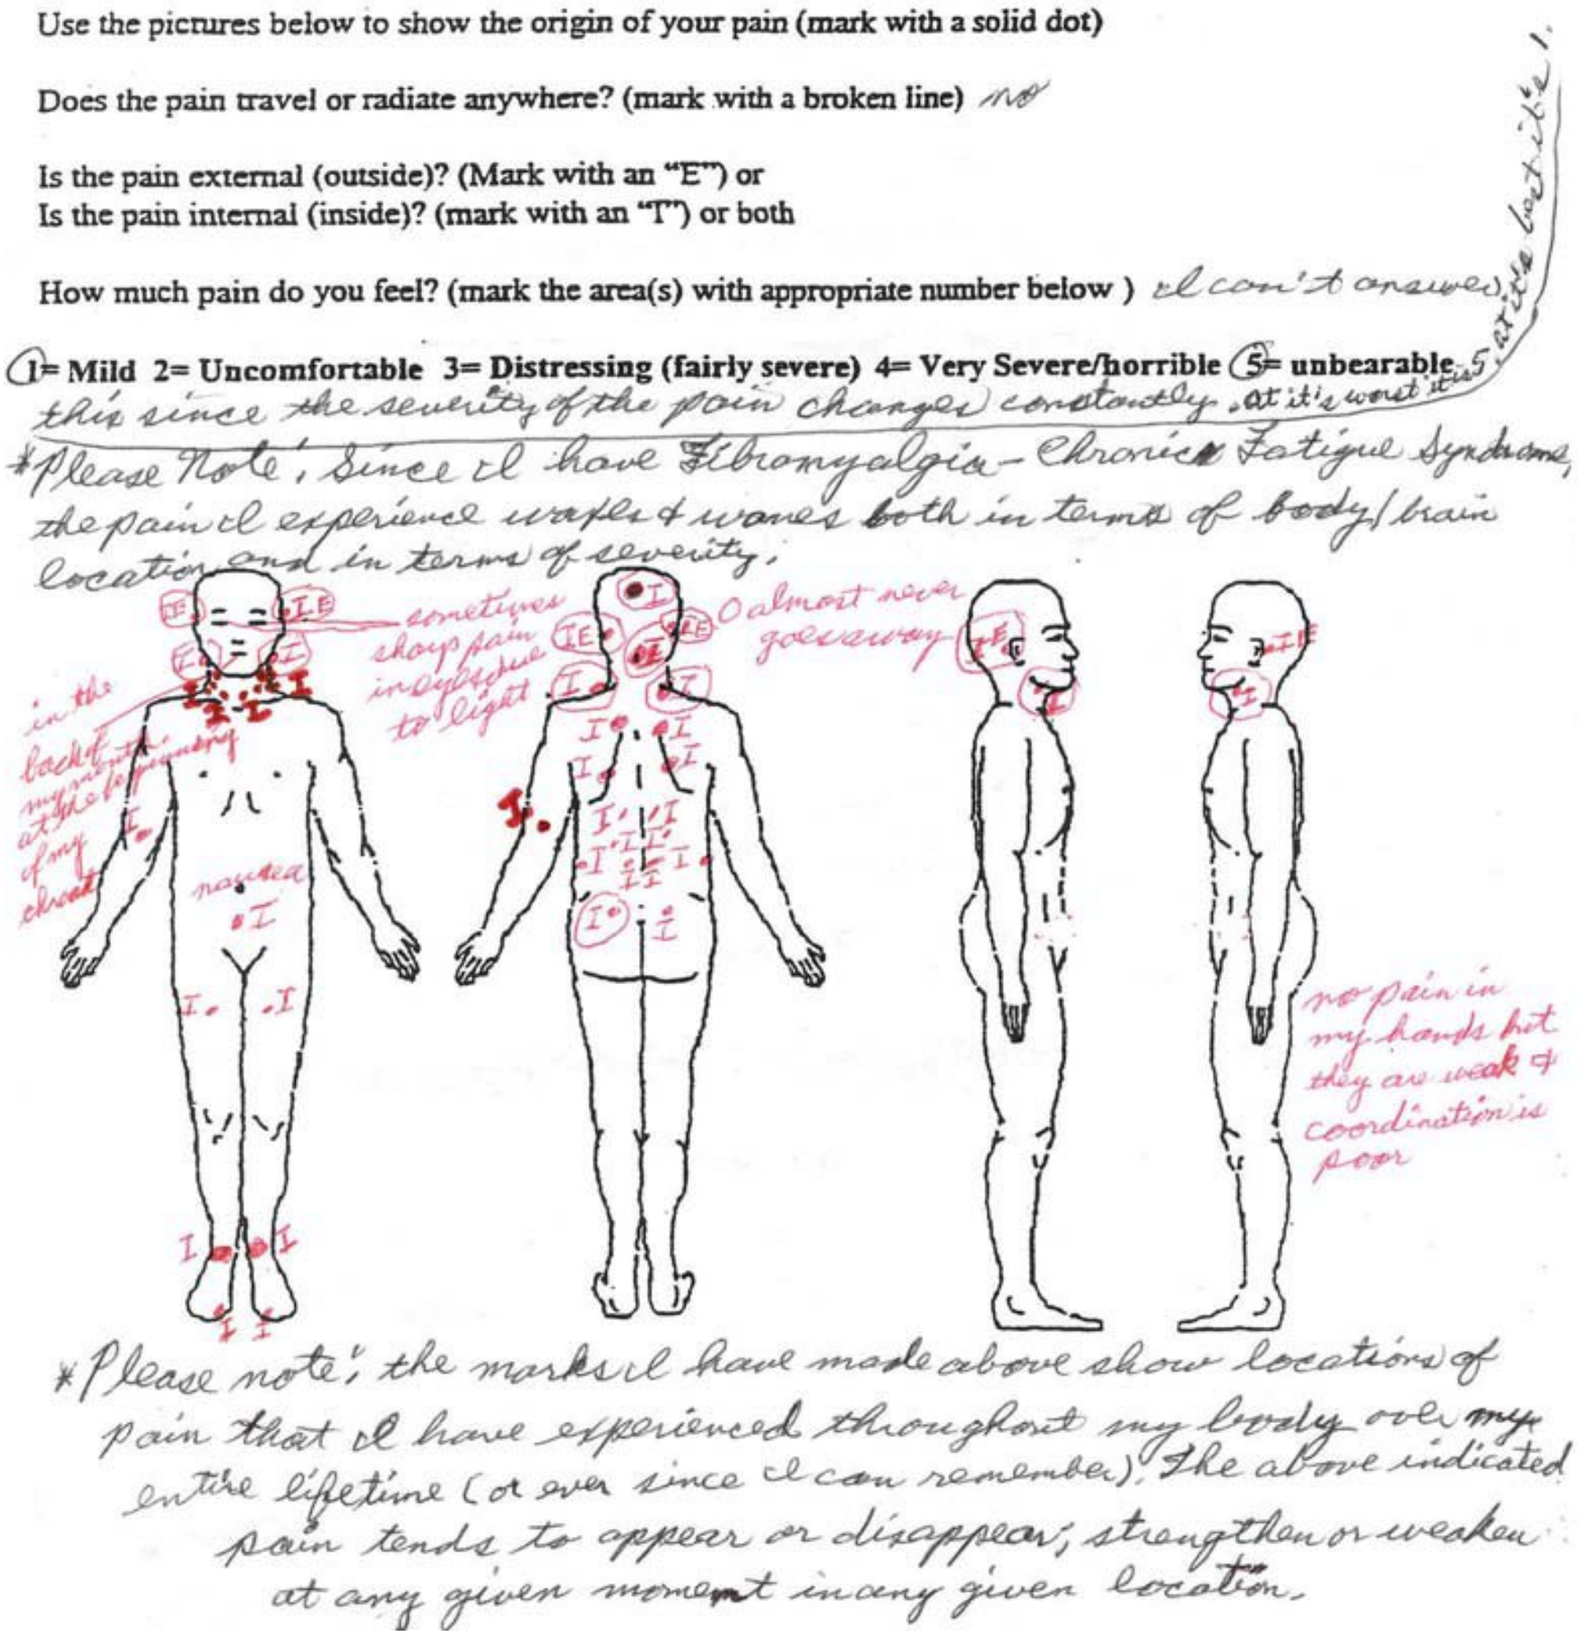

Are There Red Flags?

Although the assumption in this section is that the patient is undergoing evaluation for residuals of a neck injury, occasionally the physician will find that the patient has misattributed his or her symptoms, and is actually symptomatic because of a disease rather than because of any injury.

1. A general medical history that addresses issues such as weight loss or fevers should alert the physician to focus on the possibility of neoplasm or infection.[9]
2. If symptoms appear to be the result of injury, what is the nature of the injury?
   a. Neurologic disorders. The physician needs to be alert to clinical evidence of a cervical radiculopathy or a myelopathy. Evidence for these possibilities is obtained from the patient's history (e.g., pain and paresthesias into an extremity in a segmental distribution) and a careful neurologic examination.
