In the ICU patient with suspected bacteremia or overwhelming infection due to Gram-negative bacilli, therapy should be chosen with knowledge of local ICU resistance patterns and include agents that the patient has not recently received. Pharyngeal colonization with Gram-negative bacilli rapidly develops in patients in the ICU, and initial therapy of nosocomial aspiration pneumonia requires the addition of an antipseudomonal penicillin, carbapenem, or cephalosporin, usually in combination with an aminoglycoside or fluoroquinolone [10]. In patients with *Pseudomonas aeruginosa* infections, the intensivist should consider using higher dosages or continuous infusions of piperacillin or piperacillin/tazobactam with or without an aminoglycoside [11]. The addition of the aminoglycoside to extended-spectrum penicillins is controversial [12] but has been shown to provide broader Gram-negative coverage and synergistic killing against *P. aeruginosa*.

β-Lactamase–Inhibitor Combinations

Clavulanic acid, sulbactam, and tazobactam are β-lactamase inhibitors that bind irreversibly to β-lactamases derived from *S. aureus* and anaerobes, as well as some β-lactamases from Gram-negative bacilli. Thus, the combination of one of these

TABLE 77.1

EXAMPLES OF PARENTERAL PENICILLINS

Penicillin	Indication	Dose based on creatinine clearance			
		>80 mL/min (normal)	50–80 mL/min	10–50 mL/min	<10 mL/min
Penicillin G	Meningitis	2 million U q2h	4 million U q4h	4 million U q4h	2 million U q6h
	Endocarditis	3–4 million U q4h	3–4 million U q4h	3 million U q4h	2 million U q6h
Ampicillin	Meningitis	2–3 g q4h	2–3 g q6h	2–3 g q8 h	2–3 g q12h
	Endocarditis	2 g q4h	2 g q6h	2 g q8 h	2 g q12h
Nafcillin or oxacillin	*Staphylococcus aureus* bacteremia, meningitis	2 g q4h	2 g q4h	2 g q4h	2 g q4h
	Skin, soft tissue infections	1–2 g q4–6h	1–2 g q4–6h	1–2 g q4–6h	1–2 g q4–6h
Piperacillin (use with an aminoglycoside for *Pseudomonas*)	*Pseudomonas aeruginosa*	3 g q4h or 4 g q6h	3 g q4h or 4 g q6h	3–4 g q8h	3–4 g q12h
	Enterobacteriaceae	3–4 g q6h	4 g q6h	3–4 g q8h	3–4 g q12h
Piperacillin plus tazobactam (use with an aminoglycoside for *Pseudomonas*)	*Enterobacteriaceae*	3.375 g q4–6h	3.375 g q6h	2.25 g q6h	2.25 g q8h
Ampicillin plus sulbactam	*Enterobacteriaceae*	3 g q6h	3 g q8h	3 g q12h	3 g q24h

β-lactamase inhibitors with ampicillin or piperacillin results in a drug combination that is active against β-lactamase–producing strains of *S. aureus*, *Bacteroides* sp, *Haemophilus influenzae*, *Neisseria gonorrhoeae*, and enteric Gram-negative bacilli such as *Escherichia coli* and *Klebsiella* and *Proteus* spp. However, chromosomally mediated β-lactamases of other Gram-negative bacilli are unaffected by these β-lactamase inhibitors, and therefore these combinations are ineffective against many isolates of *P. aeruginosa*, *Enterobacter cloacae*, *Citrobacter freundii*, and *Serratia marcescens*.

Formulations of β-lactamase combinations available parenterally include ampicillin–sulbactam and piperacillin–tazobactam. Piperacillin–tazobactam can be effective in the treatment of mixed infections, such as nosocomial pneumonia, intra-abdominal infections, and synergistic skin soft tissue infections. However, depending on local resistance patterns, the lack of efficacy against multiple-resistant Gram-negative bacilli commonly found in the ICU warrants monitoring of local resistance patterns and using a carbapenem, or adding an aminoglycoside as part of a combination regimen to ensure broad efficacy against nosocomial Gram-negative bacilli [10,13].

The usual suggested dosages of the available combinations are given in Table 77.1. For treatment of *P. aeruginosa* infections, the dosage of piperacillin–tazobactam should be increased to 3.375 g IV every 4 hours or 4.5 g IV every 6 hours for pneumonia. The pharmacology of the β-lactamase inhibitors is similar to that for other β-lactams: Clearance is by renal mechanisms, and dosage adjustments must be made with these combinations in the setting of renal impairment. Continuous infusion of piperacillin/tazobactam after a bolus has a pharmacodynamic advantage for organisms with relatively high minimum inhibitory concentrations (MICs) to piperacillin and in patients on continuous venovenous hemofiltration (CVVH) [11].

CEPHALOSPORINS

Cephalosporin antibiotics exhibit relative safety and an antibacterial spectrum that includes activity against Gram-positive and Gram-negative bacteria. Examples of parenteral cephalosporins that are currently available are listed in Table 77.2. Cephalosporins are not active against MRSA, *Enterococcus* spp, or *Stenotrophomonas maltophilia*. Many strains of *Enterobacter* possess an inducible chromosomal β-lactamase and may become resistant during therapy [14].

First-Generation Cephalosporins

First-generation cephalosporins exhibit a virtually identical spectrum of antibacterial activity, and they differ only in their pharmacokinetic properties. These agents are active against staphylococci (β-lactam–susceptible staphylococci) but are not effective against enterococci, *Listeria monocytogenes*, MRSA, or the majority of coagulase-negative staphylococci. Community-acquired strains of *E. coli*, *Proteus mirabilis*, and *Klebsiella pneumoniae* often are susceptible to the first-generation cephalosporins, but in general, third-generation agents are far more potent against Gram-negative bacilli and are preferred in the treatment of such infections in ICU patients. Nosocomial isolates of *Enterobacteriaceae* usually are resistant to first-generation cephalosporins, as are *Pseudomonas* and *Acinetobacter* spp.

Second-Generation Cephalosporins

Second-generation cephalosporins (e.g., cefuroxime) have only limited activity against hospital-acquired Gram-negative bacilli and therefore are not recommended for treatment of Gram negatives in the ICU setting.

Third-Generation Cephalosporins

Third-generation cephalosporins exhibit an expanded spectrum and increased potency against Gram-negative organisms, especially *Enterobacteriaceae* [15]. A number of these agents, particularly ceftazidime, are less active than first-generation cephalosporins against Gram-positive cocci. However, ceftriaxone has significant activity against *Streptococcus*

TABLE 77.2

EXAMPLES OF PARENTERAL CEPHALOSPORINS AND RELATED β-LACTAMS

Antibiotic	Dosage based on creatinine clearance			
	>80 mL/min (normal)	50–80 mL/min	<10–50 mL/min	10 mL/min
First-generation cephalosporins				
Cefazolin	1–2 g q8h	1–2 g q8h	1 g q8–12h	1–2 g q24h
Second-generation cephalosporins				
Cefuroxime	0.75–1.50 g q8h	0.75–1.50 g q8h	0.75–1.50 g q12h	0.75–1.50 g q24h
Third-generation cephalosporins				
Cefotaxime	1–2 g q6–8h	1–2 g q6–8h	1 g q8–12h	1–2 g q24h
Ceftriaxone	1–2 g q12–24h	1–2 g q24h	1–2 g q24h	1–2 g q24h
Ceftizoxime	1–2 g q8–12h	1–2 g q8–12h	1–2 g q12h	1 g q24h
Ceftazidime	1–2 g q8h	1–2 g q8h	1–2 g q12–24h	1 g q48h
Newest-generation cephalosporins				
Cefepime	1–2 g q8–12h	1–2 g q8–12h	1 g q12–24h	0.5–1.0 g q24h
Monobactams				
Aztreonam	1–2 g q8h	1–2 g q8h	1 g q8–12h	1–2 g q24h
Carbapenems				
Imipenem/cilastatin	0.5–1.0 g q6h	0.5–1.0 g q6–8h	0.5–1.0 g q8–12h	0.25–1.0 g q12h
Ertapenem	1 g q24h	1 g q24h	0.5 g q24h	0.5 g q24h
Meropenem	1 g q8h	1 g q8–12h	1 g q12h	1 g q24h
Doripenem	0.5 g q8h	0.5 g q8h	0.25 g q8–12h	Unknown

pneumoniae and other oral streptococci, and has been recommended for use in severely ill patients with community-acquired pneumonia (CAP), bacterial meningitis, and bacterial endocarditis [16–18].

The activity of most third-generation cephalosporins against *P. aeruginosa* is variable and unpredictable; only ceftazidime and cefepime, a fourth-generation cephalosporin, are considered active against this organism and should be used in combination with an aminoglycoside when infection with *P. aeruginosa* is likely [19]. If a third-generation cephalosporin is used as a single agent, gaps in coverage may occur, including (a) enterococcal superinfection; (b) *P. aeruginosa* infections in neutropenic patients; (c) emergence of broad-spectrum resistance by means of chromosomally mediated inducible β-lactamases during cephalosporin monotherapy of deep-seated infections by species of *Enterobacter*, *Providencia*, *Serratia*, *Pseudomonas*, and *Acinetobacter*; (d) intra-abdominal or intrapelvic infections likely to involve *Bacteroides fragilis*; and (e) *S. aureus* bacteremia, endocarditis, or meningitis. Thus, in ICU patients, third-generation cephalosporins generally should be used empirically as part of combination therapy or as specific single-agent treatment of Gram-negative bacillary infections involving organisms documented to be susceptible to the agent in vitro.

Newer Cephalosporins

Cefepime, a fourth-generation cephalosporin [20], has activity against Gram-positive organisms similar to that of cefotaxime and ceftriaxone and activity against *Pseudomonas* similar to that of ceftazidime. Compared with third-generation cephalosporins, cefepime has a lower affinity for β-lactamases and is not an inducer of chromosomal β-lactamases. The pharmacokinetics of cefepime are similar to those of ceftazidime: $t_{1/2}$ is 2.1 hours, and 80% to 90% of the dose is recovered in the urine. For treatment of infections due to *P. aeruginosa*, cefepime (often in conjunction with an aminoglycoside) should be dosed every 8 hours, but for moderate infections due to more susceptible species, it can be dosed every 12 hours (see Table 77.2).

Adverse Reactions

Cephalosporins are relatively nontoxic agents. The most commonly noted adverse effects are hypersensitivity reactions, including rashes, fever, interstitial nephritis, and anaphylaxis. In patients with documented penicillin allergy, the risk of cross-reactive allergic reactions to the cephalosporins is cited as 5% to 10%, and generally it is felt that cephalosporins should be avoided in patients with a history of documented anaphylaxis or immediate hypersensitivity (urticaria) reaction to the penicillins, but can be given to patients with a history of other types of reactions to penicillins, including morbilliform rash and fever. Enterococcal superinfections occur with any of the extended-spectrum cephalosporins because none of these agents has significant activity against enterococci [15,20].

Dosage

When used in the treatment of severe infections in ICU patients, all cephalosporins should be used, at least initially, at maximal doses and short dosing intervals (Table 77.2). In patients with severe impairment of renal function, dosages of all cephalosporins except ceftriaxone must be adjusted to avoid accumulation [20].

CARBAPENEMS

Four carbapenem antibiotics—imipenem, meropenem, ertapenem, and doripenem—are approved for clinical use [21–23]. Imipenem is a carbapenem and is administered in combination with cilastatin, a specific enzymatic inhibitor of a renal dehydropeptidase, which inhibits metabolism of imipenem by the kidney, increasing the $t_{1/2}$ and decreasing the nephrotoxicity of imipenem. Imipenem exhibits activity against Gram-negative

bacilli at least equal to that of the third-generation cephalosporins (including anti-*Pseudomonas* potency equal to that of ceftazidime); against Gram-positive cocci similar to that of oxacillin, nafcillin, and cefazolin; and against anaerobic bacteria equal to metronidazole or clindamycin. MRSA are resistant to imipenem. *Enterococcus faecalis* appears susceptible in vitro, but *Enterococcus faecium* usually is resistant and imipenem should not be regarded as effective therapy for serious infections caused by enterococci. Among nonfermentative Gram-negative bacilli associated with nosocomial infections, *S. maltophilia*, *Burkholderia cepacia*, and *Flavobacterium* spp usually are resistant to imipenem. Resistance to imipenem arises infrequently (most commonly with *P. aeruginosa*) during therapy, usually via alteration in porin channels in the bacterial cell outer membrane, resulting in diminished intracellular concentrations of the drug, and the organism usually remains susceptible to other β-lactams if the organism is susceptible initially.

The usual dosage of imipenem/cilastatin is 2 g per day in four divided doses, with up to 4 g per day in life-threatening infections by less susceptible organisms (e.g., *P. aeruginosa*). Dosage adjustment (see Table 77.2) is necessary for patients with renal dysfunction because serum concentration-related myoclonus and seizures can occur. Treatment of highly resistant Gram-negative bacilli (e.g., *P. aeruginosa*, *E. cloacae*, and *Acinetobacter* sp) with imipenem may involve initial coadministration of a second agent, such as an aminoglycoside.

Adverse reactions to imipenem include rash and fever. The frequency of cross-reactivity with other classes of β-lactams is estimated to be approximately that observed with penicillins and cephalosporins. Risk of seizures can be minimized by adjustment of dosing in the elderly and in patients with reduced renal function; usage should be avoided when possible in patients with a history of seizures or central nervous system (CNS) lesions.

Meropenem and ertapenem are broad-spectrum carbapenem antibiotics similar to imipenem [21,22]. Meropenem is more active against Gram-negative rods, including *Pseudomonas* spp, and slightly less active against Gram-positive cocci, including *S. aureus*. Ertapenem is not active against *Pseudomonas* sp or *Enterococcus* spp but has activity against extended-spectrum β-lactamase (ESBL) producing *Klebsiella*. The standard dosing for ertapenem is 1 g IV every 24 hours and for meropenem 1 g IV every 8 hours (see Table 77.2). Meropenem and ertapenem are excreted via the kidney, but, in contrast to imipenem, their renal metabolism is negligible and cilastatin is not coadministered [22]. Meropenem and ertapenem seem less likely than imipenem to cause seizures.

Doripenem is a novel carbapenem with a broad spectrum of activity against Gram-positive pathogens, anaerobes, and Gram-negative bacteria, including *P. aeruginosa* [23]. Doripenem exhibits rapid bactericidal activity with two- to fourfold lower MIC values for Gram-negative bacteria, compared with other carbapenems. It has significant in vitro activity against *Enterobacteriaceae* (including ESBL strains), *P. aeruginosa*, *Acinetobacter* spp, and *B. fragilis*.

Doripenem is dosed at 500 mg IV every 8 hours, and dose and/or interval needs to be adjusted based on creatinine clearance (see Table 77.2). A low risk of seizures has been demonstrated in clinical studies [23].

AZTREONAM

Aztreonam is a monobactam, differing from penicillins and cephalosporins in that it has a monocyclic rather than a bicyclic nucleus, granting aztreonam little cross-allergenicity with other β-lactams. Although skin rashes occur occasionally with this drug, aztreonam has been given safely to patients with immediate hypersensitivity-type reactions (anaphylaxis, urticaria) to penicillins or cephalosporins [24].

Aztreonam has no activity against Gram-positive or anaerobic bacteria. Against most facultative aerobic Gram-negative bacilli, aztreonam exhibits a spectrum and potency much like that of third-generation cephalosporins including activity against some strains of *Pseudomonas* spp. The usual dosage of aztreonam is 1 to 2 g IV every 6 to 8 hours. Aztreonam is cleared by the kidneys, and dosage must be reduced in patients with renal insufficiency.

AMINOGLYCOSIDES

Aminoglycoside antibiotics are bactericidal agents of value in the treatment of Gram-negative infections in ICU patients [25]. Aminoglycosides in common clinical use in the critically ill patient include gentamicin, tobramycin, and amikacin. Streptomycin occasionally is used for enterococcal or mycobacterial infections.

Pharmacology

All available aminoglycosides exhibit similar pharmacologic properties: (a) absorption from the gastrointestinal (GI) tract is negligible, and adequate serum levels are obtained only by the IV or intramuscular routes; (b) volume of distribution is similar to that of total volume of extracellular fluid and therefore can be somewhat unpredictable under conditions of abnormal extracellular fluid such as dehydration, third-space losses, congestive heart failure, or ascites; (c) protein binding is minimal; (d) penetration into the cerebrospinal fluid (CSF) is poor even in the presence of meningeal inflammation; (e) drug levels in bronchial secretions are only two thirds of those in serum and are poor in vitreous fluid, prostate, and bile; (f) excretion is predominantly by glomerular filtration, and $t_{1/2}$ of the aminoglycosides in the presence of normal renal function is approximately 2 to 3 hours (longest for amikacin) and is prolonged in patients with renal impairment, approaching 24 hours in those with end-stage renal failure; (g) all aminoglycosides are dialyzable, and greater efficacy of removal occurs with hemodialysis (approximately 60% to 75% cleared in 6 hours) than with peritoneal dialysis; and (h) aminoglycoside activity is reduced under conditions of reduced pH and oxygen tension, such as in purulent, particularly anaerobic, fluids, and tissues [25].

Spectrum of Action and Indications for Therapy

The primary clinical indication for aminoglycoside therapy is serious infection caused by Gram-negative bacilli. Aminoglycosides are also used in combination with a cell wall agent for therapy of enterococcal endocarditis. Another indication is treatment of mycobacterial disease. Although more toxic than penicillins and cephalosporins, aminoglycosides provide the broadest range of potent, bactericidal antibiotic activity against Gram-negative bacilli, particularly when multiple-resistant enteric Gram-negative bacilli (e.g., *Enterobacter* sp) or nonfermentative Gram-negative organisms such as *Pseudomonas* and *Acinetobacter* spp are considered possible pathogens.

Resistance to aminoglycosides generally emerges slowly and infrequently. However, resistance to aminoglycosides has increased dramatically among *Enterococcus* spp, and currently in many hospitals, up to one fourth of isolates are gentamicin

resistant [26]. Some high-level gentamicin-resistant isolates remain susceptible to high levels of streptomycin [27].

Gentamicin and Tobramycin

In many ICUs, gentamicin (or tobramycin) resistance is prevalent among local isolates of Gram-negative bacilli, and amikacin may be preferred in the initial management of Gram-negative bacillary infections, pending results of microbiologic studies and susceptibility testing. In addition, gentamicin in combination with ampicillin, penicillin, or vancomycin is indicated for treatment of endocarditis due to enterococci or viridans group streptococci and can be used with vancomycin and rifampin for treatment of prosthetic valve endocarditis caused by coagulase-negative staphylococci.

Tobramycin is more potent than gentamicin against *P. aeruginosa* in vitro and, along with amikacin, may be effective against gentamicin-resistant strains of this organism. However, the frequency of cross-resistance is unpredictable and may be alarmingly common [28]. In addition, tobramycin is less active than gentamicin against some organisms, such as *Serratia* and *Acinetobacter* spp.

Amikacin

Amikacin is the semisynthetic aminoglycoside most resistant to aminoglycoside-inactivating enzymes. For most gentamicin-resistant Gram-negative bacilli such as multiresistant ESBL-producing *Klebsiella*, amikacin is the most active aminoglycoside and should be the empiric aminoglycoside of choice in hospitals or ICUs in which gentamicin and tobramycin resistance is prevalent.

Adverse Reactions

Unlike β-lactam antibiotics, aminoglycosides are characterized by a narrow therapeutic–toxic ratio, and therapy with these agents can be associated with considerable toxicity. Hypersensitivity reactions such as fever and rash are uncommon but have been reported in up to 3% of patients who receive these drugs. Anaphylaxis has been observed on rare occasions. Neuromuscular blockade has been described uncommonly and appears to be of concern only in patients with myasthenia gravis or severe hypocalcemia or those who are receiving neuromuscular blocking agents. Ototoxicity appears to occur with equal frequency (up to 10% of patients) among the modern aminoglycosides [25]. Vestibular damage has been described more commonly with gentamicin and tobramycin, whereas impairment of auditory acuity seems more common with amikacin [25]. Ototoxicity occurs unpredictably (either early or late in therapy), is related only partially to elevated serum levels, most closely correlates with duration of therapy and total dosage administered, and often is irreversible. Patients expected to receive aminoglycoside therapy for extended duration and who are conscious and communicative should be questioned periodically about symptoms of eighth cranial nerve dysfunction, such as tinnitus, diminished auditory acuity, lightheadedness, and dizziness.

Nephrotoxicity has been reported to occur in 2% to 10% of all patients receiving aminoglycoside therapy and in up to 10% to 25% of critically ill patients. However, renal damage usually is mild and reversible promptly with cessation of therapy. Aminoglycoside-induced nephrotoxicity appears to be related to dose and duration of therapy as well as to serum concentrations, especially elevated trough levels. It is seen more commonly in elderly patients, those with preexisting renal disease, those with diminished tissue perfusion caused by cardiogenic or peripheral vascular factors, and patients receiving other nephrotoxic agents. The most useful laboratory tests that are available to reduce and detect aminoglycoside nephrotoxicity are the serum creatinine levels and determinations of trough serum aminoglycoside concentrations.

Therapy and Determination of Serum Levels

Recommended dosage schedules and desired serum concentrations for the aminoglycosides are shown in Table 77.3. The use of the once-daily dosing method for aminoglycosides (see Table 77.3) may reduce nephrotoxicity and enhance efficacy against Gram-negative bacilli [30,31]. These agents induce a postantibiotic effect, and, hence, are suited for less frequent dosing. Postantibiotic effect is uncertain for Gram-positive bacteria, and the desired peak and trough levels are lower when you are using aminoglycosides for synergistic activity against Gram-positive pathogens.

In patients with impaired renal function, serum concentrations (and serum creatinine and blood urea nitrogen values) should be monitored to ensure safe and effective concentrations. Trough concentrations should be monitored frequently (and dosage/frequency adjusted accordingly) in patients with fluctuating cardiovascular function/fluid volumes or renal function and in those who are anticipated to receive prolonged therapy [25]. Trough serum concentrations should be less than 1 μg per mL (or undetectable) when large doses are given at intervals of 24 hours or greater.

In patients undergoing hemodialysis, it can be estimated that approximately two thirds to three fourths of a dose (i.e., 1 mg per kg gentamicin or tobramycin or 5 mg per kg amikacin) is required at the end of each hemodialysis session, and serum concentrations (trough before dialysis, peak after supplemental dose given) should be monitored. In patients undergoing peritoneal dialysis, instillation of the aminoglycoside into the dialysate at a therapeutic concentration (i.e., 4 μg per mL = 4 mg per L for gentamicin and tobramycin; and 20 μg per mL = 20 mg per L for amikacin) eliminates a serum-dialysis concentration gradient and minimizes loss of drug through dialysis.

FLUOROQUINOLONES

Fluoroquinolones are broad-spectrum agents that exert their antimicrobial activity by inhibiting deoxyribonucleic acid (DNA) synthesis by binding to two enzymes, bacterial DNA gyrase and topoisomerase IV, enzymes that introduce superhelical twists into double-stranded bacterial DNA. Fluoroquinolones broadly in use include ciprofloxacin, levofloxacin, and moxifloxacin.

These agents are active and generally bactericidal against susceptible enteric Gram-negative bacilli (including enteric pathogens such as *Salmonella* and *Shigella* spp), *H. influenzae*. Resistance to these agents among Gram-negative bacteria such as *P. aeruginosa*, *Acinetobacter* spp, and *Aeromonas hydrophila* is increasing and non–lactose-fermenting Gram-negative bacilli such as *B. cepacia*, *Pseudomonas fluorescens*, and *S. maltophilia* are often resistant to the quinolones. Of the quinolones, ciprofloxacin has greatest potency against *P. aeruginosa*. Activity of quinolones against aerobic Gram-positive cocci is variable, and activity against methicillin-susceptible *S. aureus* and coagulase-negative staphylococci has diminished; MRSA commonly are resistant [32]. Although, in general, streptococci (particularly *S. pneumoniae*, *Streptococcus pyogenes* [group A streptococcus], and enterococci) exhibit poor susceptibility to older quinolones, moxifloxacin and levofloxacin are considered efficacious in treatment of pneumococcal pneumonia. Moxifloxacin has in vitro activity against *B. fragilis*, but there is little clinical experience with

TABLE 77.3

RECOMMENDED DOSAGE REGIMENS AND SERUM CONCENTRATIONS OF AMINOGLYCOSIDES IN INTENSIVE CARE UNIT PATIENTS BASED ON CALCULATED CREATININE CLEARANCE[a]

Drug/renal function	Route	Loading dose (mg/kg)	Regimen (mg/kg)	Target serum concentration (μg/mL)[b]		
				Peak[c]	Trough[c]	8 h after dose
Traditional regimen						
Gentamicin, tobramycin						
>80 mL/min	IV, IM	2.0–2.5	1.3–1.7 q8h	4–8	1.0–1.5	
60–79 mL/min		2.0–2.5	1.3–1.7 q12h	4–8	1.0–1.5	
40–59 mL/min		2.0–2.5	3 q24h	4–8	1.0–1.5	
30–39 mL/min		2.0–2.5	2 q24h	4–8	1.0–1.5	
10–29 mL/min		2.0–2.5	2–3 q48h	4–8	1.0–1.5	
<10 mL/min		2.0–2.5	1–2 q48h	4–8	1.0–1.5	
Amikacin	IV, IM					
>80 mL/min		7.5–10.0	7.5 q12h	20–25	5–10	
60–79 mL/min		7.5–10.0	5.0 q12h	20–25	5–10	
40–59 mL/min		7.5–10.0	7.5 q24h	20–25	5–10	
30–39 mL/min		7.5–10.0	5.0 q24h	20–25	5–10	
10–29 mL/min		7.5–10.0	7.5 q48h	20–25	5–10	
<10 mL/min		7.5–10.0	5.0 q48h	20–25	5–10	
Once-daily dosing[d]						
Gentamicin, tobramycin						
80 mL/min	IV	Not needed	5–7 q24h	NA[e]	Undetectable (<0.3)	2–6
60–79 mL/min	IV	Not needed	5–7 q36–48h (based on serum concentration at 6–14 h after dose)	NA[e] [29]	Undetectable (<0.3)	6–11
Amikacin	IV	Not needed	15–20 q24h	NA[e]	Undetectable (<0.3)	6–18

[a] Creatinine clearance; for women, multiply the result by 0.85.
[b] Lower concentrations are desired when using aminoglycosides for treatment of gram-positive infections
[c] Serum for peak levels should be drawn 30 minutes after a 30-minute infusion, and trough levels should be obtained within the 30 minutes before the next dose.
[d] Patient exclusions—age <12 y, pregnancy, burns >20% body surface area, ascites, dialysis, endocarditis, creatinine clearance <60 mL/min.
[e] NA—with once-daily dosing, peak concentrations are high transiently and measurement of peaks is not applicable.

its use against this pathogen. Quinolones have activity mycobacteria, including *Mycobacterium tuberculosis*, *Mycobacterium kansasii*, and *Mycobacterium fortuitum*, but susceptibility results should be used to guide therapy. Levofloxacin and moxifloxacin are more active than ciprofloxacin against *Mycoplasma* sp, *Chlamydophilia trachomatis*, and *Ureaplasma urealyticum*. All demonstrate activity against *Legionella pneumophila*.

The $t_{1/2}$ of the fluoroquinolones is relatively long (3 to 4 hours for ciprofloxacin and levofloxacin, and 9 to 10 hours for moxifloxacin). Levofloxacin is cleared primarily by the kidneys and require dosage adjustment for patients with renal insufficiency. Moxifloxacin is cleared by the liver, and dosage adjustments in renal failure are unnecessary. Some component of hepatic excretion occurs with ciprofloxacin, and major dosage adjustment (50% of dose, 12-hour interval) is required only at creatinine clearance rates of less than 20 mL per minute [33]. The fluoroquinolones are not eliminated by hemodialysis or peritoneal dialysis.

Although available oral fluoroquinolone formulations can achieve adequate serum and tissue concentrations to treat infections outside the urinary tract, parenteral therapy is preferred in the acute management of serious infections in the ICU, as oral absorption may not occur due to problems with intestinal motility or perfusion. Ciprofloxacin, moxifloxacin, and levofloxacin are available in IV preparations. GI tract absorption of fluoroquinolones can be impaired by concomitant administration of antacids, sucralfate, and multivitamins containing zinc or iron.

Adverse Reactions

In general, the fluoroquinolones are safe and well tolerated. The most common adverse reactions include GI tract symptoms (nausea, vomiting, dyspepsia, abdominal pain, and diarrhea), CNS symptoms (insomnia, restlessness, headache, dizziness, confusion, and, rarely, seizures), tendon rupture, and occasional hypersensitivity reactions (rash, pruritus, and drug fever). Ciprofloxacin increases serum concentrations and potentiates the effects of theophylline, warfarin, and cyclosporine.

Indications

The fluoroquinolones are indicated in the treatment of (a) complicated urinary tract infections involving susceptible Gram-negative bacilli; (b) prostatitis; (c) bacterial pneumonia, especially due to Gram-negative bacilli, *H. influenzae*, *Legionella* sp, or high-level penicillin-resistant *S. pneumoniae*; (d) bacterial diarrhea of diverse causes, including traveler's diarrhea and enteritis due to *Shigella*, *Salmonella*, and *Campylobacter* spp; (e) invasive (malignant) external otitis; (f) intra-abdominal and intrapelvic infections (in combination with anaerobic coverage); (g) outpatient treatment of CAP; and (h) septic shock due to urinary tract infections in combination with a β-lactam agent. In treating nosocomial pneumonia, it must be remembered that the older fluoroquinolones (e.g., ciprofloxacin) have limited activity against streptococci and

no activity against anaerobes, and addition of an agent active against these organisms should be considered. In addition, resistance to fluoroquinolones is becoming increasingly common in *S. aureus* and among Gram-negative bacilli, especially *P. aeruginosa*.

VANCOMYCIN

Vancomycin is bactericidal at low concentrations against most Gram-positive cocci and bacilli, including *S. aureus* (including MRSA), coagulase-negative staphylococci, *S. pneumoniae* (including drug-resistant strains), viridans group *Streptococcus* spp, *Streptococcus bovis*, *Clostridium* sp, and *Diphtheroid* spp [34]. Although most enterococci are inhibited by low concentrations of vancomycin, bactericidal killing of these organisms requires the addition of an aminoglycoside such as gentamicin or streptomycin [7,35]. Resistance to vancomycin is an emerging problem, particularly in strains of *E. faecium*. The first strain of *S. aureus* with reduced susceptibility to vancomycin was reported in 1997 from Japan [36].

Because of poor absorption from the GI tract and severe pain with intramuscular injection, vancomycin is given IV for the treatment of systemic infections. Oral vancomycin is used only in patients with antibiotic-associated colitis caused by *Clostridium difficile*. Oral metronidazole is preferred for this process in non-ICU patients due to emerging problems with vancomycin-resistant organisms. In severely ill patients with *C. difficile* infection, oral vancomycin or a combination of oral vancomycin and IV metronidazole is recommended [29].

Vancomycin is excreted primarily by the kidneys. In patients with normal renal function, serum $t_{1/2}$ of IV-administered vancomycin varies from 2.7 to 13.3 hours, and peak and trough serum concentrations are unpredictable. The usual recommended dose for adults with normal renal function is 2 to 3 g per day in divided doses every 8 to 12 hours. The dose should be administered IV over 60 minutes. For complicated infections in seriously ill patients, a loading dose of 25 to 30 mg per kg (based on actual body weight) may be used to achieve target concentration rapidly, followed with 15 to 20 mg per kg per dose every 8 to 12 hours. Nomograms are available to guide vancomycin dosing in patients with varying degrees of renal insufficiency [37]. Serum trough concentrations should be monitored in patients with reduced renal function or unstable hemodynamics; monitoring of peak concentrations usually is not helpful. For pneumonia due to MRSA and meningitis, dosing to achieve higher troughs of 15 to 20 μg per mL should be used. For endocarditis dosing to achieve troughs of 10 to 15 μg per mL are recommended [38].

Adverse Reactions

Because there is no cross-reaction, vancomycin is the drug of choice in the therapy of serious Gram-positive infections in patients who are allergic to penicillins and cephalosporins. Vancomycin is associated with hypersensitivity reactions such as rash and fever in approximately 3% to 5% of patients. Rapid IV administration of vancomycin can produce a histamine-associated reaction characterized by flushing, tingling, pruritus, tachycardia, hypotension, and an erythematous rash over the upper trunk and face. This red-person syndrome is a histamine-release phenomenon, not a manifestation of hypersensitivity, and can be avoided by slow IV administration of the drug (i.e., at a rate no faster than 15 mg per minute or 0.5 g over 60 minutes and 1 g over 60 to 90 minutes) or by pretreatment with antihistamines [39]. Neutropenia occurs occasionally [40]. Ototoxicity appears to occur uncommonly in patients who receive vancomycin, usually in association with elevated serum levels (at least 50 μg per mL), and generally is reversible with discontinuation of therapy. Nephrotoxicity occurs rarely in patients who receive vancomycin alone, is usually associated with elevated serum vancomycin levels, and is more common in patients with recent concomitant aminoglycoside administration.

TELAVANCIN

A glycopeptide analog of vancomycin, telavancin, shows promise as alternative treatment for patients with serious infections caused by Gram-positive pathogens [41]. Telavancin exhibits low potential for resistance development and is active against resistant pathogens, including MRSA. Telavancin is currently approved only for treatment of complicated skin and skin structure infections (cSSSIs). Similar to vancomycin, it demonstrates activity in vitro against a variety of Gram-positive pathogens, including but not limited to MRSA and penicillin-resistant *S. pneumoniae*. Modifications to vancomycin's structure expanded telavancin's spectrum of activity in vitro to include organisms such as glycopeptide-intermediate *S. aureus* (GISA), vancomycin-resistant *S. aureus* (VRSA), and vancomycin-resistant enterococci (VRE). Dose of 10 mg per kg per day is recommended for patients with normal renal function. Since telavancin is cleared extensively by the kidneys, dosage adjustments will be required in patients with moderate-to-severe renal impairment. Renal toxicity was reported more frequently with telavancin than with vancomycin in two phase III clinical trials (3% vs. 1%). Potential teratogenicity of this agent must be considered in women who are pregnant or may become pregnant.

THERAPY OF ANAEROBIC INFECTIONS

As reviewed previously, excellent efficacy against anaerobes is provided by carbapenems as well as β-lactam/β-lactamase combination agents. Additional agents with anaerobic activity include metronidazole and clindamycin.

Metronidazole

Metronidazole is highly active against obligate anaerobes. Although orally administered metronidazole is absorbed nearly completely, critically ill patients with infections other than *C. difficile*–associated diarrhea should receive therapy by the IV route. Metronidazole is administered at 500 mg (7.5 mg per kg) IV every 8 hours [42]. Metronidazole is metabolized by the liver; no dose adjustment is required in patients with renal insufficiency, but dosages must be reduced in individuals with severe hepatic insufficiency. Penetration into CSF and brain is excellent. Reported serious adverse events include neutropenia, pancreatitis, peripheral neuropathy, and hepatitis. Metallic taste occurs commonly, and up to 12% of patients have minor GI tract side effects. A disulfiram-like reaction can occur with concomitant alcohol intake.

Metronidazole is active in vitro against anaerobic Gram-negative bacilli and is probably the most potent agent for treatment of infections caused by *B. fragilis* [5]. Metronidazole must be used in conjunction with an agent active against aerobic organisms in the treatment of intra-abdominal, intrapelvic, and pulmonary infections where aerobic organisms can be expected to be concurrent pathogens. It has become the drug of first choice for treatment of *C. difficile*–associated diarrhea because of limitations on the use of oral vancomycin in an attempt to decrease selective pressure for the emergence of VRE, although

oral vancomycin, often with IV metronidazole, is preferred in critically ill patients [43].

Clindamycin

Clindamycin is active in vitro against a wide variety of anaerobic bacteria. It has been used with great success in the treatment of anaerobic infections of the head, neck, and lungs/pleural space. The use of clindamycin in addition to penicillin is recommended in the treatment of necrotizing fasciitis due to β-hemolytic *Streptococcus* spp because of its apparent activity against organisms that are present in very high inoculum [44]. Clindamycin-resistant strains of *B. fragilis* group are becoming more prevalent, with 29% of isolates resistant in 2001 versus 10% in 1988 [45].

Usual parenteral therapy with clindamycin for severe infections consists of 600 to 900 mg IV every 8 hours (25 to 40 mg per kg per day) [46]. Because clindamycin is metabolized by the liver and excreted in inactive form in bile, no adjustment in dosage is required in patients with renal insufficiency.

The most important side effects of clindamycin are gastrointestinal. The incidence of diarrhea during therapy with clindamycin has been reported to range from 3% to 30%. Pseudomembranous colitis due to *C. difficile* has been reported to occur in up to 10% of patients who receive clindamycin [29,47].

MACROLIDES

The macrolides are bacteriostatic antibiotics that act on the 50 S ribosome subunit. The most common use of macrolides is to treat primary atypical pneumonia due to *Mycoplasma pneumoniae*, *Chlamydophilia pneumoniae*, or *Legionella* spp; pharyngitis due to *S. pyogenes*; *Bordetella pertussis* infections; enteritis due to *Campylobacter* spp; and eradication of the diphtheria carrier state.

Erythromycin is the oldest agent in current use in this class, and now used less frequently than azithromycin or clarithromycin. Erythromycin is used occasionally in the ICU setting to enhance gut motility [48].

Azithromycin is available in oral and IV preparations and clarithromycin in an oral form [49]. In addition to sharing the microbiologic spectrum of activity of erythromycin, azithromycin is more active against *C. trachomatis* but is less active than erythromycin or clarithromycin against staphylococci and streptococci. Clarithromycin shares the antimicrobial spectrum of erythromycin but is more active against Gram-positive cocci. Both agents have activity against *Mycobacterium avium-intracellulare* and *Mycobacterium chelonae* and are used prophylactically and therapeutically for disseminated *M. avium* complex infection in patients with advanced human immunodeficiency virus (HIV) disease. These agents are bacteriostatic and not usually used as first-line agents for treatment of Gram-positive infections in the ICU.

Oxazolidinones

Linezolid, the first available oxazolidinone antimicrobial, exerts its action by inhibiting the initiation of protein synthesis by stopping assembly of bacterial ribosomes [50,51]. Linezolid has bacteriostatic activity against MRSA, VRSA, and VRE and is bactericidal against penicillin-resistant *S. pneumoniae*. It is approved for treatment of nosocomial pneumonia and cSSSIs caused by *S. aureus* (including MRSA). It is available for IV or oral use at a dosage of 600 mg every 12 hours and has excellent oral bioavailability. Dosage adjustments are not necessary for patients with renal insufficiency [52]. The oxazolidinones have the potential for interaction with monoamine oxidase inhibitors, selective serotonin receptor uptake inhibitors (SSRIs), adrenergic agents used to support blood pressure in the ICU, and foods that contain a high tyramine content, with potential to trigger the serotonin syndrome, which can involve cognitive, autonomic, and somatic manifestations, and present variously as confusion, agitation, coma, autonomic instability, flushing, low-grade fever, nausea, diarrhea, diaphoresis, myoclonus, rigidity, and rarely myoclonus and death [53]. Reversible thrombocytopenia may occur if treatment is given longer than 14 days. Resistance may develop in enterococci with long-term use and has been described in *S. aureus* [54,55].

Quinupristin/Dalfopristin

Quinupristin/dalfopristin is a combination of two streptogramin antibiotics used in combination to treat vancomycin-resistant *E. faecium* infection and other Gram-positive bacteria including *S. aureus* [56]. This agent is given by the IV route, and, due to a high incidence of phlebitis, has to be administered through a central vascular catheter. It has bacteriostatic activity against *E. faecium*. The dose is 7.5 mg per kg every 8 hours for serious infections and 7.5 mg per kg every 12 hours for skin and skin structure infections. This drug is reserved for patients with difficult-to-treat infections. Quinupristin/dalfopristin has been used in a few patients with meningitis, and CSF concentrations appear to be higher than the MIC for susceptible organisms. Myalgias and arthralgias occur in up to 10% of patients and may limit its use [57].

Daptomycin

Daptomycin, a cyclic lipopeptide antimicrobial agent with rapid, concentration-dependent bactericidal activity against aerobic and facultative Gram-positive microorganisms, is active against a range of Gram-positive bacteria, including many multidrug-resistant isolates. Daptomycin is approved for treatment of cSSSIs caused by susceptible strains of *S. aureus* (including MRSA), *S. pyogenes*, and other streptococcal and *Enterococcus species* [58]. The dosage of daptomycin for soft tissue infections is 4 mg per kg every 24 hours by IV infusion given over 30 minutes for patients with a creatinine clearance greater than 30 mL per minute. A dose of 6 mg per kg every 24 hours is recommended for bacteremia and right-sided endocarditis caused by susceptible strains of *S. aureus* (including MRSA). In the lung, daptomycin is bound to surfactant, and it is not clinically effective for pneumonia [59]. The drug is excreted primarily via the kidney with low potential for interference with hepatically metabolized drugs. If the creatinine clearance is less than 30 mL per minute, the dosage interval should be extended to 48 hours. Reported adverse effects include diarrhea, vomiting, sickle-cell crisis, hypersensitivity reactions, dermatitis, myalgias, and creatinine kinase elevations [60,61].

Tigecycline

Tigecycline is the first antibiotic in the glycylcycline class and is a minocycline derivative [62]. Tigecycline is one of the few new antimicrobials with activity against Gram-negative bacteria including multiresistant *Acinetobacter* spp and organisms that produce ESBL. In addition, it is active against Gram positives such as MRSA and enterococci including VRE. Tigecycline is approved treatment of cSSSIs and complicated intra-abdominal

infections. Tigecycline is available only for IV administration, given as a 100-mg initial dose, then 50 mg every 12 hours. The most common treatment adverse effects are nausea and vomiting which occur generally during the first 2 days of therapy.

THERAPY OF FUNGAL INFECTIONS

Invasive and disseminated fungal infections are increasingly common in ICU patients, especially those who receive immunosuppressive therapy or broad-spectrum antibiotics; in patients with lymphoreticular malignancies or transplants; and in individuals with advanced HIV disease. Newer antifungals of the triazole class (fluconazole, itraconazole, voriconazole, and posaconazole) and echinocandin class (caspofungin, micafungin, and anidulafungin) have become available for the treatment of systemic mycoses. However, amphotericin B remains important for empiric initial therapy for life-threatening fungal infections when the infecting organism is not yet identified or is resistant to triazoles.

Amphotericin B

Amphotericin B is a polyene antibiotic, insoluble in water, and solubilized by the addition of sodium deoxycholate, forming a colloidal dispersion. Its mechanism of action is due to its binding to ergosterol, a sterol present in the cell membrane of susceptible fungi, resulting in altered membrane permeability and causing leakage of cell components and resultant cell death. Amphotericin B is effective against most species of fungi that are pathogenic in humans [63]. Either amphotericin B deoxycholate or one of the liposomal preparations is the initial drug of choice for empiric therapy of life-threatening, invasive, or systemic fungal infections including mucormycosis, cryptococcosis, histoplasmosis, and coccidioidomycosis and is effective for blastomycosis and extracutaneous sporotrichosis. Although *Candida albicans* generally is susceptible to amphotericin B, non-*albicans* species of *Candida* often are less susceptible, and fluconazole or an echinocandin is the drug of choice once the infecting species is identified and susceptibility is known. Amphotericin B preparations have variable activity that is evident against *Aspergillus* spp, *Zygomycetes* spp, *Scedosporium boydii*, *Fusarium* spp, and dematiaceous fungi. The combination of amphotericin B plus flucytosine is synergistic against *Candida* sp and *Cryptococcus neoformans* and is used to treat meningitis due to these fungi.

Amphotericin B for IV administration should be prepared in 5% dextrose because saline solutions result in drug precipitation. The drug is highly protein bound and is distributed into many tissues (liver, spleen, lung, muscle, kidney, skin, and adrenals); because penetration into CSF is poor, intrathecal/intracisternal administration or the use of triazoles may be necessary for some CNS mycoses. The metabolism of amphotericin B is obscure, but renal and hepatic insufficiency has little effect on serum levels of the drug and hemodialysis does not affect serum levels.

Amphotericin B usually is given by IV infusion once a day over 2 to 6 hours, at a concentration of 0.1 mg per mL. Daily and total doses are adjusted according to the fungal species, sites, and extent of infection and the individual tolerance of the patient. A test dose of 1 mg (in 25 to 100 mL 5% dextrose) is infused over 30 minutes. For patients who are critically ill with apparently rapidly progressive fungal disease, the full daily dose of 0.5 to 1.0 mg per kg can be given immediately following the test dose. For patients who exhibit poor tolerance with the test dose or subsequent increased doses, amphotericin B dosing can be increased in a gradual fashion, with increase in the dosage by 5 to 10 mg per day until the final daily dose is reached. The usual duration of amphotericin B therapy for systemic mycoses is 4 to 12 weeks, to a total dose of 1 to 2 g. For infections caused by less susceptible fungi (e.g., *Aspergillus* spp, *Zygomycetes* spp [*Mucor*], and *Coccidioides immitis*), treatment warrants daily doses of up to 1.0 to 1.5 mg per kg and a total dose of 2 g. Cryptococcosis can be treated successfully with reduced (0.3 mg per kg per day) dosages of amphotericin B plus flucytosine (150 mg per kg per day orally) for 6 weeks.

Adverse Reactions

Adverse effects of amphotericin B most frequently include infusion-associated constitutional symptoms such as fever, chills, hypotension, and tachypnea, most common and most severe with the first few doses of the drug and during escalation of dosage and can be minimized by increasing daily dosage slowly (if the clinical situation permits) or by pretreatment with acetaminophen, hydrocortisone (25 to 50 mg IV), or meperidine (25 mg IV). Dantrolene (10 mg IV) has been used successfully as an alternative or adjunctive agent in patients with severe rigors [64]. Nephrotoxicity occurs frequently with amphotericin B deoxycholate therapy, and thus patients with renal insufficiency or administration of other nephrotoxic agents should be given one of the liposomal preparations. Potassium levels should be monitored closely and supplementation with potassium begun as soon as serum potassium decreases toward the low end of normal range. Mild anemia occurs commonly during amphotericin B therapy, but thrombocytopenia, leukopenia, and severe hepatitis are rare.

Alternative lipid preparations of amphotericin B have become available in an attempt to decrease renal toxicity [65]. The lipid formulations are notably more expensive than amphotericin B deoxycholate but are advantageous in patients with, or at risk of, renal insufficiency, those on other nephrotoxic medications, or those whose renal function worsens during treatment with amphotericin B. The ability to deliver a higher dose with the lipid complex than with amphotericin B alone has resulted in reports of patients responding to the lipid formulation at high dose (5 to 10 mg per kg) when traditional therapy with amphotericin B had been ineffective [65].

Flucytosine

Flucytosine is an orally administered pyrimidine analog with a narrow spectrum of action, generally used in combination with an amphotericin preparation for therapy of *C. neoformans* and *Candida* meningitis. Most strains of *C. neoformans* and *Candida* sp are susceptible initially, whereas most other fungi that are pathogenic for humans are resistant. The use of combination therapy with flucytosine allows a reduction in dosage and duration (0.3 mg per kg per day for 6 weeks) of amphotericin B in the treatment of cryptococcal meningitis and improves efficacy in the treatment of *Candida* meningitis because of its excellent penetration into this site. The drug is cleared by the kidneys, with a serum $t_{1/2}$ of 3 hours in patients with normal renal function and 85 hours in anuric patients. The usual recommended dosage in patients with normal renal function is 150 mg per kg daily in four divided doses; the interval between doses should be doubled (every 12 hours) when the creatinine clearance rate is 20 to 40 mL per minute and quadrupled (every 24 hours) when the creatinine clearance rate is 10 to 20 mL per minute. The serum level of flucytosine should

be monitored, particularly in patients with renal impairment, and the dose should be adjusted to maintain a level of 50 to 100 μg per mL. Leukopenia is the most serious complication of flucytosine therapy and occurs most commonly in patients with renal insufficiency and when serum levels exceed 100 μg per mL. GI tract intolerance (nausea, vomiting, anorexia, or diarrhea), hepatitis, and rash occur occasionally.

TRIAZOLES

Fluconazole

Fluconazole is a water-soluble triazole available for IV and oral use and exhibits good activity in vitro against *Candida* spp and *C. neoformans* [66]. As with all the triazoles, its mode of action is mediated through inhibition of ergosterol synthesis. Oral absorption is excellent, resulting in serum levels nearly as high as with IV administration and is independent of gastric acidity. Fluconazole penetrates well into bodily fluids, including CSF (50% to 90% of serum concentrations) and the eye. Fluconazole has a long (30 hours) $t_{1/2}$; because of its renal clearance, adjustments must be made in dosing in patients with renal impairment. For patients with oropharyngeal or esophageal candidiasis, the usual dosage (oral or IV) of fluconazole is 200 mg on the first day of therapy, followed by 100 mg once a day; therapy is continued until clinical findings resolve and for a total of 2 to 3 weeks. Fluconazole (800 mg loading dose, then 400 mg once daily) is effective in the treatment of systemic or hepatic candidiasis due to susceptible strains of *C. albicans* [67]. Non-albicans species of *Candida* may be less susceptible. For severe systemic mycoses (i.e., coccidioidomycosis, cryptococcosis) or candidemia, the usual daily dosage is 800 mg then 400 mg IV daily. Side effects of fluconazole are relatively minor and uncommon, with GI tract symptoms (nausea) most frequent. Mild, transient elevation of serum transaminase levels occurs occasionally. Fluconazole inhibits the metabolism and potentiates the effects of warfarin, phenytoin, cyclosporine, tacrolimus, and oral hypoglycemic agents.

Itraconazole

Itraconazole, a broad-spectrum triazole antifungal with notable activity against *Aspergillus* sp, *H. capsulatum*, *C. immitis*, and *Sporothrix schenckii*, is available for IV or oral use [68]. Itraconazole is widely distributed in most tissues but with poor levels in CSF. Clinical experience indicates that itraconazole has a role in the treatment of sporotrichosis, blastomycosis, histoplasmosis, paracoccidioidomycosis, and chromomycosis and may be of use in treating patients with coccidioidomycosis, cryptococcosis, or aspergillosis who have failed prior therapy with amphotericin B or other azoles. Daily dosage is 200 to 800 mg orally, with the higher doses indicated in patients with CNS infection. Clearance is by hepatic metabolism, and no adjustment of dosage is required in patients with renal failure. Like voriconazole, the IV form of itraconazole includes cyclodextrin to improve solubility, and as cyclodextrin is cleared by the kidney, the IV formulation should not be used if the creatinine clearance is less than 30 mL per minute. Itraconazole is well tolerated, with occasional GI tract symptoms (abdominal discomfort, nausea, and diarrhea) or minor elevation of liver chemistry values noted. Itraconazole requires an acidic environment for optimal GI tract absorption. Absorption of the elixir form of the drug is greater than with the capsules, and absorption is better with multiple daily dosing. Itraconazole has only a minimal effect on the synthesis of androgens or cortisol but appears to be able to produce a picture of mineralocorticoid excess with hypokalemia, edema, and hypertension.

Voriconazole

Voriconazole is a second-generation, broad-spectrum triazole that is a synthetic derivative of fluconazole. Voriconazole is active against strains of *Candida krusei* and *Candida glabrata* that are inherently fluconazole resistant and against strains of *C. albicans* that have acquired resistance to fluconazole. Voriconazole has a broad activity against many species of *Aspergillus* spp, including *Aspergillus terreus*, which often is resistant to amphotericin B [69]. It is a drug of choice for invasive aspergillosis and refractory infections with *Pseudoallescheria/Scedosporium* and *Fusarium* spp.

Voriconazole is available in oral and IV formulations. The standard loading dose is 6 mg per kg repeated in 12 hours. Patients who weigh more than 40 kg should receive 200 mg every 12 hours for maintenance therapy and the dosage should be adjusted in patients with mild-to-moderate liver disease. Because the azoles are metabolized by the hepatic cytochrome P450 systems, a variety of drug interactions can occur; however, voriconazole generally is well tolerated. Reported toxicities include elevations in liver enzymes, rash, and, in a third of patients, transient ocular toxicity [70]. The IV form contains cyclodextrin and should be used for short periods (<2 weeks) in patients with renal insufficiency due to accumulation of the metabolites.

Posaconazole

Posaconazole is a second-generation triazole approved for the treatment of oropharyngeal candidiasis, including infections refractory to itraconazole and/or fluconazole [71]. It is approved also as prophylaxis for invasive *Aspergillus* and *Candida* infections in patients older than 13 years who are at high risk of developing fungal infections, such as hematopoietic stem cell transplant recipients with graft-versus-host disease and neutropenic patients with hematologic malignancies [72,73]. Limited clinical experience suggests efficacy for the treatment of infections due to Zygomycetes and as salvage therapy for patients with invasive aspergillosis and coccidioidomycosis. Posaconazole currently is available only as an oral tablet or suspension and requires administration with food or a nutritional supplement to assure adequate bioavailability. Dose adjustment is not required in the presence of renal or hepatic insufficiency. Although not a substrate of hepatic CYP450 3A4, posaconazole inhibits this enzyme and thus has the potential for significant pharmacokinetic interactions with drugs metabolized by this isoform. Its use in combination with CYP450 substrates that prolong the QTc interval is contraindicated, as is its use with ergot alkaloids. The recommended dosage for posaconazole antifungal prophylaxis is 200 mg (5 mL) three times daily. Recommended therapy of oropharyngeal candidiasis is a loading dose of 200 mg (100 mg twice daily), followed by 100 mg daily for 13 days. Refractory oropharyngeal candidiasis may be treated with 400 mg twice daily with the duration based on clinical response and the patient's underlying disease. Experimental treatment of invasive fungal infections with posaconazole at doses 200 mg orally four times daily and maintenance therapy at 400 mg orally twice daily is based on pharmacokinetic data; however, package labeling does not include this indication [74]. The most common adverse effects associated with the use of posaconazole include headache, fever, nausea, vomiting, and diarrhea.

ECHINOCANDINS

Caspofungin/Micafungin/Anidulafungin

Caspofungin, micafungin, and anidulafungin are echinocandins, a class of antifungal agents that act on the fungal cell wall by inhibiting glucan synthesis. Echinocandins are available only for IV administration and are active against most species of Candida.

Caspofungin can be used for refractory cases of invasive aspergillosis for patients intolerant of voriconazole and amphotericin B. All of these agents may be used to treat candidemia with similar success but with fewer side effects than amphotericin B [58]. These agents are highly protein bound and distribute into all major organ sites including the brain; however, concentration in uninfected CSF is low. For caspofungin, the recommended dosage for adults is 70 mg as a loading dose, then 50 mg per day. Dose alteration is recommended in the presence of moderate hepatic insufficiency. Caspofungin is metabolized by the liver, and dose adjustment is required when it is given with other drugs that alter cytochrome P450 activity. In general, caspofungin is well tolerated with the most frequently reported adverse effects being increased serum transaminases, GI upset, and headaches. Caspofungin is classified as pregnancy category C and should be used during pregnancy only if the potential benefit outweighs the potential fetal risk.

These three agents exhibit a fungicidal effect against most *Candida* sp and have become the drugs of choice for empiric therapy of candidemia in the ICU. However, they are not active against *C. neoformans* and it is important to consider the possibility of cryptococcal disease when using them empirically. They have a fungistatic effect against *Aspergillus* spp. Micafungin appears comparable to fluconazole as antifungal prophylaxis in patients undergoing hematopoietic stem-cell transplantation [75,76] and anidulafungin has been used in neutropenic children. Absence of antagonism in combination with other antifungal agents suggests that combination antifungal therapy is an area that needs further study, particularly for severe aspergillosis and candidiasis [77].

Trimethoprim–Sulfamethoxazole

Trimethoprim–sulfamethoxazole (cotrimoxazole) works through sequential, two-stage inhibition of folate synthesis. It has activity against Gram-positive and Gram-negative bacteria, *Nocardia* spp, and *Pneumocystis jiroveci* (previously known as *P. carinii*). Trimethoprim–sulfamethoxazole can be used in the therapy of Gram-negative infections, including those caused by *Enterobacter* spp in the ICU patient. Sometimes this agent is effective against β-lactam–resistant nosocomial bacteria including MRSA. The dose for serious bacterial infections is 8 to 10 mg per kg per day (of the trimethoprim component), divided every 6 to 12 hours.

Trimethoprim–sulfamethoxazole is the drug of choice for *Pneumocystis* pneumonia [78,79]. In moderately to severely ill patients, it is administered IV or orally at a dosage of 15 to 20 mg per kg per day of the trimethoprim component in three to four divided doses for a total course of 14 days in non-AIDS patients and at a dosage of 15 mg per kg of the trimethoprim component daily (or 75 mg per kg of the sulfa component daily) for 21 days in patients with AIDS. Failure to obtain satisfactory response in 5 days (7 days in individuals with HIV infection) warrants change to an alternative regimen (see HIV chapter 85 for *Pneumocystis* pneumonia therapy). Adverse reactions to trimethoprim–sulfamethoxazole occur in approximately 10% to 15% of patients who are uninfected with HIV-1 and in up to two thirds of patients with AIDS. The most common problems are neutropenia or thrombocytopenia, or both (particularly in patients with advanced HIV-1–induced immunodeficiency or receiving zidovudine); rash or fever; nausea or vomiting; and abnormalities of hepatic enzymes.

Pyrimethamine–Sulfadiazine

For the treatment of systemic and invasive (including encephalitis) toxoplasmosis in the compromised host, the alternate double-antifolate combination of pyrimethamine–sulfadiazine usually is used. Pyrimethamine is administered orally with a loading dose of 200 mg, then at 75 mg daily (with folinic acid 5 mg daily) together with sulfadiazine orally at 6 g daily in four divided doses. Adverse reactions occur in similar frequency and type as with cotrimoxazole. Alternative therapy for CNS toxoplasmosis is clindamycin (900 mg IV every 6 hours) plus pyrimethamine [80].

THERAPY OF VIRAL INFECTIONS

As viral infections have become more common and more severe in an era of expanding populations of immunocompromised hosts, several antiviral agents have become available (Table 77.4). Nevertheless, antiviral therapy remains problematic and limited in scope as compared with antibacterial treatments. Antiretroviral therapy is discussed in Chapter 85.

Acyclovir and Related Compounds

Acyclovir is a nucleoside analog of guanosine with antiviral activity against herpes viruses, particularly herpes simplex virus (HSV) types 1 and 2 and varicella-zoster virus (VZV) [81]. Administered as a prodrug, acyclovir requires phosphorylation to a monophosphate form by a virus-generated thymidine kinase and then to a triphosphate form by host cellular enzymes. Because cytomegalovirus (CMV) lacks a thymidine kinase, acyclovir has limited activity against this virus.

Acyclovir is available in topical, oral, and IV preparations, with the last route preferred for serious infections in critically ill patients and for milder illnesses in those unable to take medications by mouth. Dosage varies according to the condition under treatment. After oral administration, absorption is slow and incomplete, with oral bioavailability of only 15% to 30%. Serum $t_{1/2}$ is 2 to 3 hours in patients with normal renal function. Because 85% of clearance is renal, dosage must be reduced in patients with impaired renal function. Acyclovir is well tolerated. Reversible renal impairment, due to crystalluria, occurs occasionally, usually in patients who are receiving high doses by rapid IV infusion or those who are elderly, dehydrated, or have antecedent renal insufficiency. At high doses, especially IV, neurologic reactions (confusion, delirium, hallucinations, seizures, and tremors) have occurred in approximately 1% of patients. Occasionally, patients have nausea, vomiting, or rash.

Intravenous acyclovir at 10 to 12 mg per kg every 8 hours is the drug of choice for HSV encephalitis (for a course of 14 to 21 days), for congenital HSV infection (10 to 14 days), and for VZV infections (chickenpox or shingles) in immunocompromised patients (7 to 10 days). Acyclovir at 5 mg per kg IV every 8 hours is effective against mucocutaneous HSV in immunocompromised patients.

Valacyclovir, a prodrug for acyclovir, is more completely absorbed than acyclovir and is hydrolyzed rapidly to acyclovir in the intestinal wall and the liver [82]. In general, it is well tolerated, but thrombocytopenia and hemolytic-uremic syndrome

TABLE 77.4

ANTIVIRAL THERAPY

Antiviral agent	Indication	Dose	Route	Duration of treatment	Adjust for renal failure
Acyclovir	Herpes simplex virus				
	Encephalitis	10–12 mg/kg q8h	IV	10–14 d	Yes
	Neonatal infection	10 mg/kg q8h	IV	10–14 d	Yes
	Mucocutaneous disease	5 mg/kg q8h	IV	7–10 d	Yes
	Herpes varicella-zoster	10 mg/kg q8h	IV	7–10 d	Yes
Ganciclovir	Cytomegalovirus				
	Induction	5 mg/kg q12h	IV	14–21 d	Yes
	Maintenance	5 mg/kg qd or	IV	Indefinite	
		6 mg/kg 5 d/wk	IV	Indefinite	
		3,000 mg qd	PO	Indefinite	
Foscarnet	Cytomegalovirus				
	Induction	60 mg/kg q8h or	IV	14–21 d	Yes
		90 mg/kg q12h	IV		
	Maintenance	90 mg/kg qd	IV	Indefinite	
Cidofovir (+ probenecid premedication)	Cytomegalovirus	5 mg/kg q wk IV	IV	14 d	Contraindicated in patients with baseline creatinine >1.5 mg/dL or increase to >2.0 mg/dL
	Induction	5 mg/kg q 2 wk		Indefinite	
	Maintenance				

have been reported in immunocompromised patients. Other side effects are similar to those of acyclovir and include encephalopathy, fevers, seizures, and rash. Acyclovir, or valacyclovir, is used prophylactically in patients who are undergoing bone marrow or solid organ transplantation.

Famciclovir, a prodrug for penciclovir, is active against VZV and HSV. Side effects are similar to those of acyclovir. Both of the newer oral agents, famciclovir and valacyclovir, are dosed three times a day orally rather than the five times a day that is needed with acyclovir for VZV infections.

Ganciclovir

Ganciclovir is highly active against CMV, in part because of the high concentration of the triphosphorylated form of the drug in infected cells. The most problematic adverse effect is myelosuppression, particularly neutropenia. Other side effects include nausea and vomiting and CNS abnormalities. Ganciclovir is effective in the treatment of disseminated CMV and CMV retinitis, GI tract infection (colitis, esophagitis, and gastritis), and pneumonitis. In bone marrow transplant patients, the drug sometimes is used in combination with IV CMV hyperimmune globulin for the treatment of CMV pneumonitis [83]. Valganciclovir is a prodrug for ganciclovir [84]. It is more completely absorbed from the GI tract, achieving higher serum levels than possible with oral therapy with the parent drug.

Treatment with ganciclovir in AIDS patients with CMV retinitis usually involves induction therapy with 5 mg per kg IV twice a day for 14 to 21 days, followed by maintenance therapy with oral valganciclovir. It is given for 3 weeks or until serum CMV molecular assays are negative in immunocompromised patient with disseminated CMV infection. Ganciclovir and valganciclovir are cleared by the kidney and dosage adjustments must be made in patients with renal impairment, especially in light of the relationship between drug serum levels and myelosuppression. Valganciclovir is used as prophylaxis or preemptive therapy for CMV in transplant patients.

Cidofovir

Cidofovir is a nucleotide analog that is active against herpes viruses, including CMV, HSV, and VZV. It is a prodrug that is converted to cidofovir diphosphate by host cellular enzymes. In contrast to ganciclovir and acyclovir, activation by viral-encoded enzymes is not required, so it may be used to treat CMV infections when the virus is resistant to ganciclovir because of the UL97 mutation.

Foscarnet

Foscarnet (trisodium phosphonoformate) is an inorganic pyrophosphate analog that acts by inhibiting viral DNA polymerases of most human herpes viruses (particularly CMV) and reverse transcriptases of human retroviruses (particularly HIV-1) [83]. Foscarnet has been demonstrated to be effective in the therapy of CMV retinitis in patients with AIDS and has been used alone and in combination with ganciclovir to treat ganciclovir-resistant CMV in immunocompromised patients (especially transplant recipients) [85]. Foscarnet is associated with a significant (25%) incidence of nephrotoxicity. Therapy involves IV administration at a dosage of 60 mg per kg three times a day for induction and at 90 to 120 mg per kg once a day for maintenance therapy. Clearance is by renal excretion, and dosage adjustment is required in patients with renal impairment. Nonrenal adverse effects include nausea, vomiting, anemia, seizures, and metabolic abnormalities (hyperphosphatemia and hypophosphatemia, hypercalcemia and hypocalcemia, hypokalemia, and hypomagnesemia).

Anti-influenza Agents

Amantadine and rimantadine are oral antiviral compounds that inhibit influenza A, and zanamivir and oseltamivir are

neuraminidase inhibitors that inhibit both influenza A and B viruses. If initiated within 48 hours of the start of symptoms, all four agents may reduce the intensity of influenza infection in patients infected with susceptible viruses [86]. For patients who are immunocompromised or who have ongoing viral replication and progressive symptoms, therapy after 48 hours may also be beneficial, although supporting data are not available. Zanamivir is given by the inhaled route and oseltamivir by the oral route. The dose of oseltamivir is 100 mg per day and for zanamivir 20 mg by inhalation daily. Resistance to the antiviral agents has occurred in influenza viruses, and clinicians need to be aware of the susceptibility of prevailing influenza strains in the community to appropriately choose an agent for use in the ICU.

CHAPTER 78 ■ PREVENTION AND CONTROL OF HEALTHCARE-ACQUIRED INFECTIONS IN THE INTENSIVE CARE UNIT

MIREYA WESSOLOSSKY AND RICHARD T. ELLISON, III

INTRODUCTION

Preventing healthcare-acquired infections in intensive care units (ICUs) is a daily concern of physicians providing care for critically ill patients. Patients in ICUs are at increased risk for infection for multiple reasons, including their underlying illness, the use of medical devices for organ system support and hemodynamic monitoring, impaired nutritional status that contributes immune function compromise, and ongoing exposure to hospital antibiotic-resistant bacterial flora. The focus of this chapter is to review the general epidemiology of these infections, the factors contributing to their development, preventative strategies, and important characteristics of key healthcare-acquired pathogens.

EPIDEMIOLOGY OF HEALTHCARE-ACQUIRED ICU INFECTIONS

Studies performed over the last two decades have found that infections in ICU patients are both common and significant. Work by Craven and colleagues in the early 1980s at Boston City Hospital in adult medical and surgical ICUs found that

overall 28% of the patients developed at least one nosocomial infection, and once infected patients had threefold increases in mortality [1]. Similarly, in 1995, European investigators assessed the prevalence of nosocomial infections in a multinational survey of 1,417 ICUs in 17 nations on one single day (the EPIC Study), and found an overall prevalence of ICU-acquired infection of 21% [2]. A more recent study in a single US medical ICU performed over 20 months in 2000 to 2001 found that 42% of patients requiring at least 48 hours of ICU care had a microbiologically confirmed infection, and patients with infection had a 1.9-fold increased risk of in-hospital mortality ($p < 0.001$) [3].

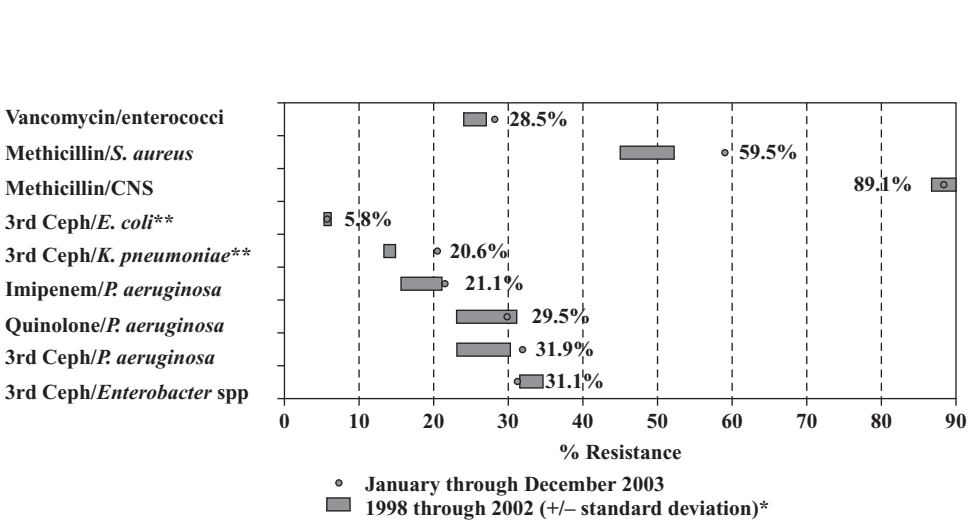
The types of infection seen in ICU patients have varied slightly over time and between types of ICU units, but several types of infections have predominated. In the Boston City Hospital study, the incidence of infections was higher in surgical ICU than in medical ICU patients; and pneumonia, surgical wound infections, urinary tract infections (UTIs), and bloodstream infections (BSIs) were the most frequent infections [1]. In the European Prevalence of Infection in Intensive Care (EPIC) study, the principal infections identified were ventilator-associated pneumonia (47% of infections), tracheobronchitis (18%), UTI (18%), and bacteremias (12%) [2]. Klevens and others, using a multistep approach, estimated 394,288 hospital-associated infections among adults and children in ICU in 2002 from US hospitals. The infection rate per 1,000 patient-days was 13.0: among all, UTI was the highest (3.38) followed by pneumonia (3.33) and BSI (2.71) [4]. The use of medical devices is a predominant cause of infection with the majority of episodes of nosocomial pneumonia associated with mechanical ventilation, healthcare-acquired infection (HAI) UTIs associated with urinary catheterization, and primary BSIs linked to central venous catheters.

Additional data through the National Nosocomial Infection Surveillance (NNIS) system of the Centers for Disease Control and Prevention (CDC) has assessed nosocomial infections in differing types of ICUs, and found that trauma/surgical and neurosurgical ICUs tend to have more nosocomial pneumonia than medical or coronary care ICUs; and that pediatric, trauma, and burn ICUs have more BSIs than medical ICUs [5,6]. The differences in infection rates noted are likely related to the size of the unit (small vs. large), the type of more predominant device use (urinary catheters, endotracheal tubes, and vascular catheters), the age group of the patients (pediatric vs. adults), and the most predominant illness of the patients (coronary, surgical, burn, medical, and pediatric).

Pediatric intensive care units differ from adult ICUs in many ways. First, they are typically combined units (medical and surgical). Second, their beds are not commonly physically separated as adults ICU beds. Third, pediatric patients usually have less comorbidity than adults. Data from the CDC NNIS system during the years 1992 through 1997 found a mean overall patient infection rate of 6.1%, with the principal infections being venous catheter–associated BSIs, followed by pneumonia and UTIs [6].

MICROBIOLOGY OF ICU INFECTIONS

The predominant causes of ICU infections are a limited number of bacterial and fungal pathogens. In general, the pathogens that are seen can be characterized as those that survive well in a moist environment (e.g., Gram-negative bacteria including *Enterobacter* strains, *Pseudomonas aeruginosa*, and *Acinetobacter* species), those that colonize the skin and produce biofilm to allow adherence to catheters and other devices (e.g., *Staphylococcus aureus* and coagulase-negative staphylococci), and those which are resistant to commonly used antibiotics (e.g., methicillin-resistant *S. aureus* [MRSA], vancomycin-resistant enterococci [VRE], multidrug-resistant Gram-negative bacteria, and *Candida* species). In the EPIC study, the predominant pathogens were *Enterobacteriaceae* (34.4%), *S. aureus* (30.1%), and *P. aeruginosa* (28.7%) [2]. It was notable that 60% of the *S. aureus* isolates were MRSA, and that coagulase-negative staphylococci (19.1%) and fungi (17.1%) were common [2]. During the last 12 years, there has been an increasing trend toward highly antibiotic-resistant pathogens in the ICU setting. Data from the NNIS system on US ICUs comparing data from 1998 through 2003 has shown a progressive rise in the prevalence of MRSA to 60%, as well as dramatic increases in the prevalence of *Klebsiella* strains resistant to third-generation cephalosporins and *P. aeruginosa* resistant to cephalosporins and imipenem (Fig. 78.1) [5].



In the NNIS pediatric ICU study noted previously, for primary BSIs, coagulase-negative staphylococci were the most common pathogens (38%) followed by Gram-negative bacilli (25%) [6]. For nosocomial pneumonia, *P. aeruginosa* (22%) was the most frequent pathogen followed by *S. aureus* (17%), and for UTI, Gram-negative aerobic bacilli were the most frequent pathogens (57%) followed by fungi, most frequently *Candida albicans* (14%).

In addition to these predominant pathogens, there are several situations where other pathogens are a concern in the ICU. A number of institutions have noted the emergence of extended-spectrum β-lactamases (ESBL) producing *Klebsiella* and *Escherichia coli* strains [7,8]. In addition, in a few institutions that have used carbapenems extensively (often to try to treat ESBL-positive Gram-negative bacilli), the carbapenem-resistant Gram-negative pathogens *Stenotrophomonas maltophilia*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, and *Burkholderia cepacia* have emerged [9–13]. Finally, the fungal pathogens *Candida parapsilosis* and *Malassezia furfur* have been seen in patients receiving total parenteral nutrition, the latter being seen only with lipid supplementation [14,15].

RISK FACTORS

The length of ICU stay is the predominant risk factor for nosocomial infection followed by the use of medical devices [2,3,6]. In the NNIS surveillance studies and subsequent studies by the CDC's current National Healthcare Safety Network (NHSN), nosocomial infection rates for nosocomial pneumonia, BSIs, and UTIs have correlated strongly with device use [4,16]. Other risk factors include the patient's underlying illness, selected medications, and the type of healthcare facility. In the EPIC study, seven risk factors were determined for ICU-acquired infection: increased length of stay (>48 hours), mechanical ventilation, diagnosis of trauma, central venous, pulmonary artery, urinary catheterization, and stress ulcer prophylaxis [2]. Teaching hospitals with higher rates of device utilization have had higher device-associated infection rates [4,16]. As in adult ICUs, the most important risk factors for nosocomial infection in pediatric ICUs appears to be the length of ICU stay and rate of device utilization [2,6].

A potential risk factor undergoing intense study at this time is hyperglycemia. Hyperglycemia is common in the ICU setting due to underlying disease, physiologic stress, and parenteral nutritional support. In vitro investigations suggest that hyperglycemia can impair polymorphonuclear leukocyte and monocyte phagocytic and bactericidal activities [17]. A large randomized trial performed in a single surgical ICU found that tight control of blood glucose during the ICU stay (maintaining blood glucose 80 to 110 mg per dL) reduced overall mortality, the incidence of bacteremias, and the number of patients who required more than 10 days of antibiotic therapy [18].

2003 No. of Isolates	Increase in Resistance (2003 vs. 1998–2002)
2,048	12%
4,100	11%
3,336	1%
1,355	0%
1,068	47%
1,392	15%
1,825	9%
2,119	20%
1,411	–6%

FIGURE 78.1. Selected antimicrobial-resistant pathogens associated with nosocomial infections in ICU patients, comparison of resistance rates from January through December 2003 with 1998 through 2002, NNIS System. CNS, coagulase-negative staphylococci; 3rd Ceph, resistance to 3rd-generation cephalosporins (ceftriaxone, cefotaxime, or ceftazidime); Quinolone, resistance to either ciprofloxacin or ofloxacin. *Percent (%) increase in resistance rate of current year (January–December 2003) compared with mean rate of resistance over previous 5 years (1998–2002): [(2003 rate – previous 5-year mean rate)/previous 5-year mean rate] × 100. **"Resistance" for *Escherichia coli* or *Klebsiella pneumoniae* is the rate of nonsusceptibility of these organisms to either 3rd group or aztreonam. [From the American Journal of Infection Control 2004; 32: 470–485. A report from the NNIS System. This report is public domain and can be copied freely.]

However, a subsequent study of the impact of tight glycemic control on outcomes in a medical ICU did not find the same benefit, and further investigation of both the risk of infection with hyperglycemia and optimal treatment is needed [19].

PREVENTIVE AND CONTROL MEASURES

A number of approaches have been found to help prevent ICU-associated infections. The comprehensive use of standard infection control practices as well as enhanced infection control precautions for selected pathogens, limiting the use of medical devices, and careful attention to architectural design are key components of strategies to prevent ICU infections. In addition, the implementation of targeted quality improvement programs for central vascular catheter infections and ventilator-associated pneumonia have been shown to be highly effective approaches to decreasing infection rates.

Infection Control Precautions

The CDC and the Hospital Infection Control Practices Advisory Committee have prepared guidelines on isolation precautions to prevent the transmission of microorganisms from colonized or infected patients to other patients, visitors, and healthcare workers [20]. The current guidelines were last updated in 2007 and recommend a two-tiered approach to patient care. Standard precautions are used for the care for all patients. Additional, more stringent transmission-based precautions are used for the care of patients who are suspected or known to be colonized or infected with specific pathogens that are readily transmitted through direct contact, through large respiratory droplets, or through smaller airborne particles. The current guidelines are summarized in Table 78.1.

A key component of these guidelines is the need for healthcare workers to practice good hand hygiene [20,21]. Approaches that have been shown to improve compliance with this practice have included the provision of water free alcohol-based hand rubs throughout institutions as well as intensified educational and monitoring programs on hand hygiene. Alcohols have excellent in vitro germicidal activity against Gram-positive and Gram-negative pathogens, fungi, and many viruses including human immunodeficiency virus, influenza virus, and respiratory syncytial virus.

There have been several additional approaches recently developed to further control of healthcare-acquired infection that should be considered in the ICU setting, particularly in the setting of high infection rates. The performance of daily bathing of patients with chlorhexidine gluconated using either impregnated clothes or dilute bathing solutions has been associated with reductions in rates of MRSA and VRE acquisition and central line–associated BSIs, potentially by decreasing the bioburden of microbial pathogens on the body surface [22–24]. Although not associated with alterations in infection rates, the institution of programs to monitor the actual performance of housekeeping staff has been found to improve the disinfection of the hospital environment in ICUs, including disinfection of computer stations [25]. Finally, equipment has been developed that allows for the use of total room disinfection with a hydrogen peroxide mist which can eradicate vegetative bacteria, fungi, spores, viruses, and prions. While its use as part of routine care remains unclear, it may be of value in controlling outbreaks due to *Clostridium difficile* or multidrug-resistant Gram-negative bacteria [26,27].

Architectural Design and Hospital Construction

Modern ICU design includes the use of single-patient rooms, adequate physical space for equipment and personnel, individual patient sinks, adequate hand hygiene stations, and adequate room ventilation with filtered air and at least six air changes per hour [28]. In addition, there are defined guidelines

TABLE 78.1

ISOLATION PRECAUTIONS

		Transmission based		
	Standard	**Airborne**	**Droplet**	**Contact**
Definition	Reduce risk of transmission of blood-borne pathogens and pathogens from moist body substances, and applies to all patients	Prevent transmission of disease by airborne droplet nuclei ($\leq$5 μm size)	Reduce risk of transmission of microorganism by droplets ($\geq$5 μm size) generated by the patient sneezing, coughing, talking, or performance of procedure	Reduce transmission of epidemiologic important organism from an infected or colonized patient through direct or indirect contact
Room		Private-negative pressure room with air exhausted to outdoors or through high-efficient filtration; door kept closed	Private room; door may remain open	Private room or cohorted with a patient with similar organism. Patient care items should be dedicated to a single patient
Mask	Mask, goggles, and face shields provide barrier protection to reduce the transmission of pathogens when splashes or spray of blood, body fluids, secretions, or excretions are likely	N95 mask or comparable respirator. Surgical mask should be worn by the patient during transportation outside the negative pressure room	Mask if entering the room	
Gown	Provide barrier protection, prevents contamination of clothing, and protects the skin of personnel from blood and body fluid exposures			
Gloves	Anticipated blood, body fluid, secretions/excretions, nonintact skin, contaminated items, and mucous membranes			
Hand hygiene	Before and after patient contact; immediately after glove removal; after contact with blood, body fluids, secretions/excretions, or mucous membranes			
Suspected or confirmed pathogens	Used for all patients independent of the presence of known pathogens	Tuberculosis Varicella (including disseminated zoster) SARS Measles Disseminated zoster Viral hemorrhagic fevers Smallpox Monkeypox Varicella Avian influenza	Meningitis due to *Neisseria meningitides* or *Haemophilus influenzae* Diphtheria (pharyngeal) Pertussis Mumps *Mycoplasma pneumoniae* Pneumonic plague Streptococcal (Group A) pharyngitis, pneumonia Influenza Rubella Parvovirus B19	MDR bacterial (MRSA, VRE, GISA, VRSA, Gram-negative bacilli) *Clostridium difficile* Viral hemorrhagic fevers Scabies Lice HSV (neonatal; disseminated) Disseminated zoster

GISA, glycopeptide-intermediate *Staphylococcus aureus*; MDR, multidrug resistant; MRSA, methicillin-resistant; *Staphylococcus aureus* SARS, severe acute respiratory syndrome; VRE, vancomycin-resistant enterococci; VRSA, vancomycin-resistant *Staphylococcus aureus*.

for the design of airborne isolation infection rooms for patients requiring management of tuberculosis or other infections readily transmitted by the airborne route.

Ongoing construction and renovation activities in healthcare facilities have also been recognized as significant risk factors for infections with environmental pathogens. There can be concerns with environmental Gram-negative organisms, particularly *Legionella* species. More frequently is a concern with disease due to environmental molds, in particular *Aspergillus* species [28,29]. United States healthcare institutions are now required to have procedures in place to ascertain that construction and renovation activities are performed in a manner that protects patients from being exposed to environmental pathogens [28].

Infection Control Surveillance Programs

In 1970, the CDC initiated the NNIS system as an approach to identifying secular trends in these infections. The program initially included 10 to 20 hospitals and expanded to nearly 300 hospitals. A subsequent study that analyzed healthcare-acquired infection rates at differing institutions before and after the distribution of infection rate data found that institutional infection rates diminished after institutions were made aware of their infection rates [30]. In addition, an analysis of ICU-associated, device-related infection rates during the 1990s for all the participating hospitals in the NNIS system showed a decreasing incidence of these infections, as institutions were

able to compare their infection rates with national standards [31]. These results have been mirrored in data on central line–associated BSIs reported through the NHSN system [16]. Disseminating data in a simple and routine manner, to those who need to know, enables clinicians to make decisions on the basis of scientific data and to alter practice (Table 78.2).

Quality Improvement Initiatives

A major advance in medical care in the last decade has been the adoption of quality improvement strategies used in other industries such as air transportation. The development of standardize approaches to the provision of care has been particularly effective in the prevention of device-related infections in the ICU stetting. Several institutions have documented a significant reduction in BSIs linked to central venous catheters after the implementation of quality improvement programs targeted against these infections [32,33]. Principal components of these programs have included, providing education on appropriate infection control practices to staff involved in central catheter placement and care, standardizing the location of catheter placement to preferentially use the subclavian location and avoid femoral lines when possible, centralizing the location of all equipment required for catheter placement, the use of maximal sterile-barrier precautions (i.e., use of cap, surgical masks, sterile gown, sterile gloves, and large sterile drape) during catheter insertion, and trying to remove these catheters as quickly as possible [33–38].

A similar approach has been taken to the prevention of ventilator-associated pneumonia in the ICU with the use of targeted education programs [39–41]. These quality improvement education programs have in general followed CDC guidelines on measures to prevent healthcare-acquired pneumonia and have been directed at medical staff, ICU nursing staff, and respiratory therapists [42]. Key elements of the program include a focus on hand hygiene, maintaining the patient in a semirecumbent position with the head of the bed elevated to 30 degrees, standardizing the approach to changing ventilator circuitry, avoiding nasal intubations, avoiding gastric distension, removing nasogastric tubes, and weaning patients as rapidly as possible [39].

SELECTED HEALTHCARE-ACQUIRED PATHOGENS

Clostridium difficile–Associated Colitis

C. difficile is the most frequent etiology for healthcare-acquired diarrhea [43]. The organism may asymptomatically colonize the gut or cause illness extending from watery diarrhea through pseudomembranous colitis, toxic megacolon, perforation, and even death [43,44]. Transmission in the healthcare setting appears to occur through transient hand carriage of healthcare workers, close contact to other colonized or infected patients, or exposure to spores present on contaminated environmental surfaces [44,45]. Exposure to antibiotics increases the risk for developing disease. Practically all antibiotics have been implicated in the development of Clostridium difficile Associated-Diarrhea (CDAD), but disease is especially common with clindamycin, penicillins, and cephalosporins. Current strains of *C. difficile* are more resistant to the fluoroquinolones than previous historical strains [46], and the widespread use of fluoroquinolones for the treatment of a variety of infections (e.g., UTI, community-acquired pneumonia) may in part be contributing to an increasing incidence of CDAD. In addition, there is also evidence that current *C. difficile* strains are both less responsive to treatment with metronidazole and associated with increased virulence [43,46,47].

Approaches to the prevention of CDAD are directed toward preventing horizontal transmission of the pathogen, as well as reducing the individual patient's risks of disease if they acquire the organism through the judicious use of antibiotic therapy. Barrier methods such as private rooms or cohorting patients remain fundamental to prevent the spread of CDAD. Alcohol hand hygiene preparations are not active against bacterial spores including those of *C. difficile*, and in a study where the introduction of alcohol hand hygiene reduced the incidence of other nosocomial pathogens, the incidence of *C. difficile* was unchanged [48]. The use of soap and water for enhanced mechanical clearance during hand hygiene should be considered in the setting of increased transmission of *C. difficile* [20,21].

In addition, healthcare workers should wear gloves when caring for patients with CDAD, and the use of gowns is also recommended when soiling of the patient's cloth is likely [21,49].

Methicillin-Resistant *Staphylococcus aureus*

The prevalence of MRSA in ICUs in the United States has risen markedly in the last 10 years, from an incidence of 30% to 40% in the middle of the 1990s to more than 60% in 2004 [5,46]. This increasing prevalence of MRSA in hospitals has also augmented the use of vancomycin therapy, leading to problems with both VRE and the rare (to date) emergence of vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant *S. aureus* (VRSA) [5,50–54]. Risk factors associated with acquisition of healthcare-acquired strains of MRSA include recent hospitalization, recent surgery, and residence in a long-term facility or injection drug use [55]. In addition, in the last 7 years, community-associated MRSA (CA-MRSA) strains have appeared in patients lacking these previous risk factors [55]. The CA-MRSA strains are distinct from traditional MRSA in several ways. First, they carry a unique gene cassette leading to methicillin resistance, type IV *mecA*. Second, they are significantly more likely to carry a gene for the Panton–Valentine leukocidin (PVL) toxin which has been associated with the development of necrotizing pneumonia and necrotic abscesses [31,55]. During the last 7 years, the prevalence of CA-MRSA has increased dramatically throughout the United States [56,57].

Current CDC guidelines recommend the use of "contact precautions" for patients known or suspected to be colonized with either healthcare-acquired MRSA or the CA-MRSA strains [20]. In the settings of outbreaks of MRSA, institutions may also consider instituting patient/staff cohorting, attempting to decolonize patients with topical nasal mupirocin and total body chlorhexidine baths/showers, and rarely screening healthcare workers for MRSA colonization [58,59]. Enhanced infection control policies with stringent contact precautions have been recommended for patients with VRSA [60].

Vancomycin-Resistant Enterococci

VRE was first recognized in Europe in 1988 and in the United States soon thereafter. By 1993, there had 20-fold increase in VRE prevalence in ICUs in the United States [61], and by 2003, VRE represented approximately 28% of enterococcal isolates in ICUs participating in the NNIS system [5]. Although not as virulent a pathogen as MRSA, VRE can cause infections in the debilitated ICU patient. Also, as the gene inducing vancomycin resistance in VRE, *vanA*, can be transferred to *S. aureus*, the presence of VRE in ICU patients increases the potential for the emergence of VRSA strains.

Infection control policies for contact precautions have been recommended for patients colonized or infected with VRE, and as with MRSA, the use of screening policies for patients at high risk for VRE can be considered. If treatment of VRE infection is necessary, the best therapeutic options at this time appear to be linezolid, daptomycin, and quinupristin/dalfopristin [62–64].

Multidrug-Resistant Gram-Negative Bacilli

The CDC NNIS database reported that in 2003, 20% of *P. aeruginosa* isolates recovered from ICU patients were resistant to carbapenems and approximately 30% were resistant to third-generation cephalosporins and fluoroquinolones [5]. *K. pneumoniae* isolates from ICU that were nonsusceptible to third-generation cephalosporin had increased to almost 50%, with many of these strains expressing ESBLs [5]. The emergence of *K. pneumoniae* species producing a carbapenemase enzyme (KPC) has appeared globally, and is a major threat due to limited options for treatment, and the KPC enzyme has now been seen in other related *Enterobacteriaceae* species [65–67]. The emergence of these strains appears related to independent risk factors including (i) severe illness, (ii) prior fluoroquinolones use, and (iii) prior extended-spectrum cephalosporin use [67]. Detection of KPC-producing strains based on routine antimicrobial susceptibility assays may be unreliable; therefore, methods are still being formalized the identification of these organisms to promptly treat and implement efficient infection control measures to contain the spread of these bacteria. Tigecycline and colistin appears among the remaining therapeutic options with the caveat of unknown clinical efficacious and toxicities.

A. baumannii has also emerged as a major ICU pathogen [65]. Overall, it is the fifth most common Gram-negative pathogen seen in NHSN ICUs [13]. Among them, 29% were resistant to carbapenems and only susceptible to colistin, an old and toxic agent. Unfortunately, this organism survives well in the environment and has been associated with significant ICU outbreaks. Infections due to this organism are associated with poor outcome, including higher rate of morbidity, mortality, and medical expenses. Control measures involve both the use of "contact precautions" and enhanced environmental cleaning efforts [20,68].

Given this rapidly increasing incidence of resistant Gram-negative strains, it is important for institutions to track rates of antibiotic resistance in their ICUs independent of overall institutional antibiotic resistance rates. Empiric antibiotic coverage for Gram-negative pathogens in given ICUs should be targeted at the known Gram-negative pathogens present in the environment. Enhanced infection control contact precautions should be used for patients who are colonized or infected with ESBL- or KPC-positive Gram-negative pathogens or multidrug-resistant *P. aeruginosa* or *A. baumannii*. Infection control measures effective in the ICU setting that are supported by well-designed clinical trials are summarized in Table 78.2

TABLE 78.2

EVIDENCE-BASED MEDICINE SUPPORTING INFECTION CONTROL MEASURES TO DECREASE HEALTHCARE-ACQUIRED INFECTIONS IN THE ICU

1. Use of a central venous catheter bundle intervention produced a large and sustained reduction in central venous catheter-related bloodstream infections in the ICU setting [32].
2. Daily patient bathing with chlorhexidine containing solution reduced the incidence of MRSA and VRE acquisition and the incidence of VRE bacteremia in the ICU setting [24].

ICU, intensive care unit; VRE, vancomycin-resistant enterococci.

CHAPTER 79 ■ CENTRAL NERVOUS SYSTEM INFECTIONS

HEIDI L. SMITH AND ALAN L. ROTHMAN

The central nervous system (CNS) infections of major interest in the intensive care unit (ICU) are bacterial meningitis, encephalitis, brain abscess, and other parameningeal foci of infection. The clinical presentations of these diseases may overlap. *Meningitis* means inflammation of the leptomeninges; its hallmark is stiff neck. *Encephalitis* is a syndrome consisting of disturbance of cerebral function and cerebrospinal fluid (CSF) pleocytosis. Many cases of bacterial meningitis also fit this definition of encephalitis due to the occurrence of mental status changes, seizures, or coma. Focal infections, such as brain abscesses, may present more as space-occupying lesions than with classical infectious signs or symptoms.

CSF examination is the major tool used in diagnosis of CNS infections. The terms *purulent* and *aseptic* describe contrasting CSF formulas, though overlap exists. The typical purulent CSF has a white blood cell count of more than 1,000 cells per mm^3 (most of which are neutrophils), a depressed glucose concentration (<40 mg per dL), and an elevated protein level (>100 mg per dL); it is most commonly seen in bacterial meningitis. In contrast, an "aseptic" formula has a lower total leukocyte count with a predominance of mononuclear cells, a glucose concentration greater than 40% to 50% of the blood level, and less marked elevation of protein; this picture characterizes most other CNS infections. An intermediate CSF formula, in which a moderate lymphocytic pleocytosis is accompanied by depressed glucose and elevated protein, suggests granulomatous disease.

GENERAL CLINICAL APPROACH

Initial evaluation of the patient with suspected CNS infection should focus on defining the nature of the symptoms (meningitic vs. encephalitic) and the presence and pattern of neurologic involvement (focal vs. diffuse).

If bacterial meningitis is suspected, expeditious analysis of CSF is critical. This must be balanced with the need to administer antibiotics promptly, because delays as short as 3 hours have been shown to lead to unfavorable outcomes [1,2]. If lumbar puncture (LP) is delayed for any reason, antibiotics (and dexamethasone; see later) should be started as soon as blood cultures have been obtained while efforts to obtain CSF proceed [3].

LP is not without risk. In patients with bleeding disorders, it should be delayed until the defect(s) can be corrected [4]. LP may be hazardous in the settings of intracranial mass lesion with edema and lumbar spinal epidural abscess. Concern for cerebral herniation as a consequence of the procedure has led to the common practice of routinely performing computed tomography (CT) scanning prior to LP. This practice is not well founded, however [5,6]. A prospective study has confirmed that CT scans rarely discover abnormalities that would represent a contraindication to LP except in patients who have a prior history of CNS disease, an immunosuppressive disorder, seizures, moderate-to-severe impairment of consciousness, papilledema, or focal neurological findings [7].

BACTERIAL MENINGITIS

Bacterial meningitis is perhaps the most clear-cut emergency in the field of infectious diseases. Delayed or inadequate treatment increases the risk of death or significant neurologic impairment [1].

Etiology

The predominant organisms vary based on the age and underlying condition of the host. Historically, bacterial meningitis in the United States has been primarily caused by five organisms: *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Listeria monocytogenes*, *Haemophilus influenzae*, and group B streptococcus. However, immunization of young children against *H. influenzae* and *S. pneumoniae* has had a marked impact on meningitis in the United States, raising the average age of meningitis due to these five pathogens from 15 months old to 25 years old [8].

S. pneumoniae accounts for almost half of the cases of community-acquired bacterial meningitis in the United States in all age groups beyond the neonatal period [8]. It is associated with a sixfold higher risk of unfavorable outcome (death, neurologic sequelae) than other pathogens [9]. Pneumococcal meningitis is more common in the setting of a CSF leak, hypogammaglobulinemia, asplenia, alcoholism, head trauma, or cochlear implant [10,11]. Routine infant immunization against *S. pneumoniae* has also reduced the incidence of pneumococcal meningitis in older children and adults due to a reduction in *S. pneumoniae* carriage in the younger population [12,13].

N. meningitidis accounts for approximately one fourth of cases of meningitis in the United States [8]. Nasal carriage of *N. meningitidis* gradually increases from infancy and peaks in the teenage years [14]; it is the most common cause of meningitis in older children and young adults. It is the one form of bacterial meningitis associated with epidemic spread. A polysaccharide-protein conjugate vaccine is available in the United States but does not provide protection against serogroup B strains. The vaccine is currently recommended for preadolescents, freshman entering college, and military recruits [15].

L. monocytogenes is a common cause of meningitis in the neonatal period or in the setting of malignancy, immunosuppression, or alcoholism. Approximately 30% of patients have no apparent immunocompromising condition; most of these individuals are older than 50 years [8,16,17].

H. influenzae type B was formerly the most common cause of bacterial meningitis in young children. Vaccination of children has reduced the incidence of invasive *H. influenzae* type B

disease by more than 80% [8,18]. Sporadic cases have recently been reported in unimmunized and partially immunized children, however [19]. *H. influenzae* in adults is uncommon and is usually associated with predisposing factors, such as anatomic defects (head trauma, CSF leaks) or defects in humoral immunity [20].

Gram-negative bacillary meningitis occurs in the neonatal period or after neurosurgery or trauma [21]. Community-acquired Gram-negative bacillary meningitis is rare in adults [21]. When it occurs, it is usually a complication of bacteremia from a distant site, often the urinary tract.

Staphylococcus aureus meningitis is associated with neurosurgery or trauma. Community-acquired cases occur in the presence of a focus of infection outside the CNS, such as endocarditis or soft tissue infections, and have a worse prognosis [22]. Meningitis in patients with CSF shunts is most commonly caused by skin flora (*S. aureus*, *Staphylococcus epidermidis*, *Propionibacterium acnes*) and Gram-negative bacilli [23]. These infections can have an indolent presentation and milder CSF abnormalities [3,23]. Use of shunt catheters impregnated with antibiotics has shown some promise in reducing the incidence of infection [24].

Several additional species of streptococci can cause meningitis. Group B streptococcus, *Streptococcus agalactiae*, is the most common cause of neonatal meningitis [8]. Rates of group B streptococcal invasive disease in adults are increasing, particularly in diabetic patients, but only a small proportion present as meningitis [25]. *Streptococcus suis* is an increasingly common cause of meningitis in Asia and should be considered in travelers, particularly those who may have ingested raw pork or had contact with pigs [26,27]. LP associated with the use of catheters for anesthesia and imaging procedures has been associated with the introduction of α-hemolytic streptococci in rare cases [28]. Anaerobic bacteria and other streptococci are otherwise uncommon causes of meningitis that are usually related to spread from brain abscess or parameningeal foci [29].

Pathogenesis

Bacterial seeding of the meninges usually arises from hematogenous spread. Spread from contiguous foci of infection is more often a cause of intracranial abscess. Bacteremia can arise from simple colonization of the nasopharynx, though colonization alone is obviously not sufficient, since 10% of the population is colonized with *N. meningitidis* at any given time [30]. The bacterial species most commonly associated with meningitis bind the laminin receptor on microvascular endothelial cells, potentially facilitating entry to the CNS [31]. Most meningitis pathogens also secrete immunoglobulin A proteases, facilitating immune evasion at mucosal sites [14]. Inadequate levels of antibody specific for the invading organism (such as occurs at the extremes of age or in acquired immunodeficiencies) and opsonophagocytic deficiencies (such as in asplenia, diabetes, or alcoholism) are the most commonly recognized risk factors for meningitis [32]. Individuals with terminal complement component deficiencies may experience recurrent episodes of meningococcal meningitis, though with lower mortality rates [33].

Once bacteria reach the CSF, both bacterial and host factors contribute to disease. Recognition of bacterial components, including cell wall molecules and bacterial DNA, leads to elaboration of inflammatory mediators such as tumor necrosis factor-α (TNF-α), interleukin-1, and interleukin-6 by leukocytes and endothelial cells. One of the major consequences is the disruption of the tight junctions of the blood–brain barrier. Additional inflammation, caused in part by increased migration and activation of neutrophils, triggers release of tissue factor (which aids thrombus formation and disrupts cerebral perfusion), nitric oxide (which disrupts autoregulation of blood flow and can have direct toxic effects on neurons), and matrix metalloproteinases (which can also disrupt endothelial junctions and impair neuronal function). Neuronal damage is further worsened by resulting increases in intracranial pressure [34,35].

Antibiotics that rapidly lyse bacteria generate a transient increase in inflammation as a response to the release of bacterial cell wall components [36]. Adjunctive steroid therapy acts to decrease inflammation associated with bacterial lysis [37]. The body also deploys endogenous immunomodulators such as TNF-related apoptosis-inducing ligand (TRAIL), which has been shown to reduce neuronal damage in animal models [38].

The clinical consequence of these pathologic processes is a generalized disturbance of cerebral function. An early phase of agitation or mania may be noted. Lethargy progresses to obtundation and sometimes coma. Seizures occur early in 20% to 30% of adults with meningitis [21]. Hyponatremia, caused by the syndrome of inappropriate antidiuretic hormone (SIADH) secretion, may contribute to obtundation and seizures. Focal neurologic deficits may be observed; sensorineural deafness is particularly common. Neurologic impairment persists in approximately 30% of survivors of meningitis in adulthood [6].

Diagnosis

History

Patients with meningitis may be unable to give a coherent history. Patients found unresponsive should be evaluated with a high level of suspicion for meningitis. Patients with fever and derangement of cerebral function, even if there is another cause for the latter, must have meningitis excluded. Persons with coexistent alcoholism, general debility, head trauma, or neurosurgery are at higher risk for meningitis.

Classic meningeal symptoms are headache (often with photophobia), neck pain, fever, and mental status changes; in a recent case series, 95% of patients with bacterial meningitis had at least two of these four symptoms [9]. Symptoms of other foci of infection, such as pneumonia, otitis, or sinusitis, may also be present [39]. Any history of head trauma (including remote events) or recent clear nasal or ear discharges should be obtained. Recent antibiotics, which could interfere with culture results, should be noted. A history of exposure to a patient with known meningococcal disease is usually forthcoming if present. In children, immunization history and history of school or daycare exposures should be elicited. Travel history may aid the identification of regionally endemic pathogens.

Physical Examination

Nuchal rigidity suggests meningitis when present. Limitation of motion caused by degenerative cervical arthritis may be a confounding variable in the elderly. Kernig's and Brudzinski's signs have low sensitivity but high specificity [40]. The initial neurologic examination should evaluate the mental status and the presence of focal deficits. Papilledema is rarely observed in meningitis [21,41] but alters the approach to LP when present. Serial examinations document any functional progression or improvement.

The systemic examination may give clues to the cause of meningitis. A thorough ear, nose, and throat examination can reveal possible foci leading to contiguous extension to the meninges. Petechiae or purpuric lesions strongly suggest meningococcal disease, though they may also be seen in *S. pneumoniae* and *H. influenzae* meningitis [39]. Petechiae may also be seen in aseptic meningitis caused by enteroviruses or Rocky Mountain spotted fever. Needle aspiration or punch biopsy of skin lesions should be used to obtain material

for Gram stain and culture. In one series of patients with *N. meningitidis* infection, bacteria were detected on either culture or stain in more than 60% of skin specimens. In addition, the Gram stain was positive in samples obtained as late as 45 hours after initiation of antibiotics [42].

Laboratory Tests

Evaluation of the CSF is essential for the diagnosis of meningitis. The typical features of purulent CSF have been noted earlier. Neutrophils constitute more than 50% of the cells in nearly all bacterial meningitis cases and more than 80% in the majority [21]. In rare cases, the CSF shows many organisms on Gram stain but few cells, implying rapidly progressive disease [9]. Elevated protein is also almost always present [21]. Severe depression of the CSF glucose (<20 mg per dL) is strong evidence for a pyogenic process, but CSF glucose is normal in up to 50% of patients with bacterial meningitis [21]. Patients with *L. monocytogenes* meningitis may have milder CSF abnormalities with relatively modest changes in glucose and protein and white blood cell counts of less than 2,000 cells per mm^3 [16,17]. Treatment with antibiotics prior to LP may alter CSF chemistries, resulting in higher glucose levels and lower protein levels, though cell counts are usually unaffected [43].

Cultures remain the mainstays of diagnosis. Blood cultures can be useful in identifying the causative agent of meningitis in cases where CSF cultures are unrevealing [44,45]. Ultimately, 60% to 90% of patients with community-acquired meningitis and purulent CSF have an organism isolated in culture [21,39]. Antibiotic administration is more likely to render cultures negative [43,46]. Bacterial antigen detection tests offer little additional information [47]. Newer techniques such as polymerase chain reaction (PCR) detection of bacterial DNA may provide more rapid and sensitive diagnosis, particularly in the setting of antibiotic pretreatment; however, these assays are not yet widely available [48].

Imaging studies are of secondary importance in the diagnosis of meningitis. Imaging of the chest and paranasal sinuses may identify other foci of infection. CT and magnetic resonance imaging (MRI) of the brain are most useful for evaluating complications of meningitis. Rapid deterioration should lead to consideration of subdural empyema, a collection between the dura and the arachnoid membrane, best visualized on MRI [6,49]. A new focal neurologic abnormality, decreased level of consciousness, or cerebrovascular accident with a nonarterial distribution should prompt imaging for venous thrombophlebitis, also best seen on MRI [6,49].

Differential Diagnosis

Several pathogens other than pyogenic bacteria can cause clinical presentations and/or spinal fluid formulas that overlap with bacterial meningitis.

Viral meningitis can have initial clinical presentations similar to bacterial meningitis. It can be caused by a wide range of pathogens including enteroviruses, arboviruses such as West Nile virus (WNV) [50], herpes viruses such as herpes simplex virus (HSV) [51], and acute HIV infection [52]. Mumps and lymphocytic choriomeningitis are the viruses most often associated with low CSF glucose levels. Very high CSF white blood cell counts and a high proportion of neutrophils occur in a few cases of enteroviral meningitis and eastern equine encephalitis. PCR assays for detection of enteroviruses can provide timely clarification [53]. Recurrent culture-negative meningitis, sometimes referred to as Mollaret's meningitis, can have an early neutrophil predominance; most cases have a positive HSV PCR in the CSF [51]. Other types of viral meningitis may also display an early neutrophil predominance, with a shift to lymphocytes taking place with time [3].

Tuberculous meningitis most commonly presents with a mononuclear predominance in the CSF along with low glucose and high protein. However, some cases have a total leukocyte count in the range of purulent meningitis with a polymorphonuclear predominance [54]. A history of tuberculosis, risk factors for exposure, or the presence of an immunocompromising condition should raise suspicion. If an initial diagnosis of bacterial meningitis is not confirmed by culture and the patient's condition does not improve, repeat LP with studies for acid-fast bacilli should be performed. A switch to lymphocytic predominance, additional decrease in CSF glucose and increase in protein, positive chest radiograph, or well-founded clinical suspicion mandates institution of antituberculous therapy [54,55]. The reported yield of acid-fast stains of CSF ranges from 15% to 60% but improves with repeat sampling [56,57]. Nucleic acid amplification tests may facilitate earlier diagnosis, but there is a wide variability in their availability and sensitivity [58]. MRI is more likely than CT to visualize tuberculomas [59].

Parasitic infections can cause purulent meningitis. Primary amebic meningitis with *Naegleria fowleri* is acquired through freshwater swimming and presents similarly to acute bacterial meningitis. Diagnosis is made on wet mount of CSF [60]. The nematode *Strongyloides stercoralis* is capable of establishing a cycle of autoinfection in immunosuppressed hosts, including those on oral corticosteroids. Migration of larvae from the gut can result in the deposition of enteric bacteria in the CNS, causing Gram-negative or polymicrobial meningitis [61].

Fungal meningitis may present with hypoglycorrhachia. An indolent course and lymphocytic CSF pleocytosis usually distinguish these from pyogenic infections, but *Coccidioides immitis*, an endemic fungus of the southwest United States, can have neutrophil predominance [62]. *Cryptococcus neoformans* is a major cause of meningitis in patients with immunosuppressive conditions, though it can occur in normal hosts. Cryptococcal antigen assay of the CSF provides a sensitive means of diagnosis [63].

Parameningeal foci of infection, including epidural abscess, can present a purulent picture, usually with elevated protein and a normal glucose concentration [64]. Brain abscess that has ruptured into the ventricles may duplicate the clinical picture of bacterial meningitis. Localizing neurologic findings or isolation of an anaerobe or multiple organisms from the CSF should suggest one of these diagnoses.

Noninfectious conditions can cause meningeal signs and CSF findings that overlap with those of bacterial meningitis. Hypoglycorrhachia may be seen in carcinomatous meningitis. Drug-induced meningitis may have a CSF formula indistinguishable from pyogenic infection; the most commonly implicated agents are nonsteroidal anti-inflammatories, antibiotics, and intravenous immunoglobulin [65]. Postneurosurgical chemical meningitis, believed to be an inflammatory reaction to surgical manipulation, blood, or bone dust, can present with a CSF profile similar to bacterial meningitis. Although symptoms, CSF leukocytosis, and hypoglycorrhachia are usually less severe, no single parameter has been proven to distinguish between the two conditions. Given the risk of postsurgical bacterial meningitis in this population, antibiotics are often administered until CSF culture results are finalized [66–68].

Therapy

The appropriate management of patients with bacterial meningitis involves prompt initiation of antimicrobial and anti-inflammatory therapy, aggressive control of the potential complications, and prevention of spread of disease [3]. Overall mortality from bacterial meningitis is in the range of 20% to 30% [9,21,69]. However, mortality rates are significantly influenced by both the pathogen, with *S. pneumoniae* among the most deadly, and the host, with elderly patients among the most

susceptible [9,21]. Consequently, most patients should be treated in an intensive care setting.

Antimicrobial Therapy

The principal consideration in choosing an antibiotic regimen for bacterial meningitis is that the agent(s) reach the CSF in concentrations that are bactericidal for the likely pathogens. Table 79.1 lists recommendations for therapy of bacterial meningitis in a variety of clinical settings. Initial therapy is usually selected empirically based on the age and underlying condition of the patient. Once the result of Gram stain of CSF is available, antimicrobial therapy can be targeted appropriately.

The third-generation cephalosporins (ceftriaxone or cefotaxime) are the mainstays of therapy for community-acquired meningitis. These agents are active against most strains of *S. pneumoniae* and provide excellent coverage against *N. meningitidis* and Gram-negative bacilli (except *Pseudomonas aeruginosa*). *S. pneumoniae* with reduced susceptibility to the cephalosporins has increased in frequency; this organism remains universally susceptible to vancomycin [70]. If the CSF Gram stain suggests pneumococci or is unrevealing, vancomycin should be given in addition to the cephalosporin until culture and sensitivity results are available [3]. Meropenem also demonstrates activity against many, but not all, cephalosporin-resistant strains of *S. pneumoniae* and has demonstrated clinical effectiveness for treatment of meningitis [70,71].

Ampicillin (or penicillin) should be included in the regimen for empiric therapy in neonates (<1 month old), individuals older than 50 years, patients with alcoholism, or those who are debilitated or immunosuppressed, for coverage of *L. monocytogenes* [16,72]. Initial therapy for postneurosurgical bacterial meningitis should include vancomycin plus either ceftazidime or cefepime to provide adequate coverage for methicillin-resistant staphylococci and *P. aeruginosa*. Resistance to antimicrobials, either at the outset or developing during treatment, can complicate therapy for Gram-negative organisms [73]. An increasing number of cases due to multidrug-resistant hospital-acquired organisms such as *Acinetobacter* sp have been reported [74].

Few good treatment regimens exist for the cephalosporin-intolerant patient. Consequently, a trial of the third-generation cephalosporins (or meropenem) should be strongly considered unless there is a documented, serious intolerance. Vancomycin is the preferred alternative for treatment of pneumococcal meningitis. The fluoroquinolone moxifloxacin has activity against pneumococci, meningococci, and *H. influenzae* and has shown promise in animal models of meningitis, but clinical experience is limited [3]. Trimethoprim–sulfamethoxazole is effective for the treatment of meningitis caused by *L. monocytogenes* and many Gram-negative bacilli other than *P. aeruginosa* [75].

If *S. pneumoniae* is isolated, adjustment of therapy should be based on the results of drug susceptibility testing. Fully susceptible organisms can be treated with third-generation cephalosporin alone. For resistant organisms, vancomycin and cephalosporin should be continued and the addition of rifampin considered [76]. Repeated examination of the CSF after 24 to 36 hours of therapy is warranted to monitor sterilization of the CSF in these cases [77]. Regardless of the causative organism, continued clinical instability after 48 hours of appropriate antibiotic therapy is also an indication for repeat LP [3]. Repeat CSF samples should have a negative Gram stain and culture after at least 24 hours of effective antibiotic therapy [6].

The recommended duration of antimicrobial therapy for meningitis depends on the etiology and the clinical response. For infection with *H. influenzae* or meningococci, 7 to 10 days of therapy is adequate. *S. pneumoniae* is usually treated for 10 to 14 days, but longer durations may be needed for drug-resistant organisms. Gram-negative bacillary meningitis is typically treated for 3 weeks and staphylococcal disease, when accompanied by bacteremia, for 4 to 6 weeks [3].

TABLE 79.1

ANTIMICROBIAL AGENTS RECOMMENDED FOR THERAPY OF BACTERIAL MENINGITIS

Clinical situation	Recommended therapy[a]
Initial cerebrospinal fluid (CSF) Gram stain negative or delayed	
Age <3 mo	Ampicillin plus ceftriaxone[b]
Age 3 mo to 50 y	Ceftriaxone[b] plus vancomycin[c]
Age >50 y	Ampicillin plus ceftriaxone[b] plus vancomycin[c]
After neurosurgery or penetrating cranial trauma	Vancomycin[c] plus ceftazidime[d]
Immunosuppression, alcoholism, debilitation	Ampicillin plus ceftriaxone[b] plus vancomycin[c]
Initial CSF Gram stain positive (community-acquired bacterial meningitis)	
Gram-positive cocci	Vancomycin[c] plus ceftriaxone[b]
Gram-negative cocci	Ceftriaxone[b]
Gram-positive bacilli	Ampicillin ± gentamicin[e]
Gram-negative bacilli	Ceftazidime[d] ± aminoglycoside[f]
Organism known, susceptibility not yet known	
Streptococcus pneumoniae	Vancomycin[c] plus ceftriaxone[b]
Streptococcus, group A or B	Penicillin G ± gentamicin[e]
Enterococcus	Penicillin G ± gentamicin[e]
Staphylococcus aureus	Vancomycin[c] (and/or nafcillin[g])
Listeria monocytogenes	Ampicillin ± gentamicin[e]
Neisseria meningitidis	Penicillin G
Haemophilus influenzae	Ceftriaxone[b]
Pseudomonas aeruginosa	Ceftazidime[d] plus tobramycin[f]
Other Gram-negative bacilli (e.g., *Escherichia coli, Klebsiella, Proteus*)	Ceftriaxone[b] plus gentamicin[f]

[a] Usual daily doses (schedules) for adults are as follows: ampicillin, 12 g/d (q4h); ceftriaxone, 4 g/d (q12h); ceftazidime, 6 g/d (q8h); nafcillin, 12 g/d (q4h); penicillin G, 24 million U/d (q2–4h).
[b] Cefotaxime, 8 to 12 g/d, given q4–6h, is equally effective.
[c] Usual daily dose of vancomycin for adults is 2–3g/d, given q8–12h, with body weight guiding dose and creatinine clearance guiding frequency of dosing. Troughs should be monitored with a goal of 15–20 mg/dL.
[d] Cefepime, 6 g/d given q8h, may be used as an alternative.
[e] Although CSF penetration of aminoglycosides is poor, some specialists recommend their use in these settings.
[f] Consideration should be given to initial intrathecal administration in addition to intravenous administration.
[g] In most areas, where methicillin resistance is common among isolates of *S. aureus*, vancomycin should be used and addition of nafcillin can be considered. In areas where methicillin resistance among *S. aureus* is still rare, nafcillin is the preferred agent.

TABLE 79.2

CHEMOPROPHYLAXIS FOR *NEISSERIA MENINGITIDIS* AND *HAEMOPHILUS INFLUENZAE*

Pathogen	Antibiotic	Dose and duration
N. meningitidis	Ceftriaxone[a]	125 mg for children or 250 mg for adults as a single intramuscular injection
	Ciprofloxacin[b]	500 mg as a single dose in adults
	Rifampin	10 mg per kg (maximum dose, 600 mg) by mouth twice a day for 2 d
H. influenzae	Rifampin	20 mg per kg (maximum dose, 600 mg) by mouth once a day for 4 d

[a]Preferred agent in pregnant women.
[b]In geographic areas where ciprofloxacin-resistant *N. meningitidis* has been reported, azithromycin 10 mg per kg for children or 500 mg for adults as a single dose can be used as an alternative.

Anti-inflammatory Therapy

The role of endogenous mediators of inflammation in the pathogenesis of meningitis has provided a rationale for the use of anti-inflammatory agents. Dexamethasone, 0.15 mg per kg every 6 hours for 4 days, has been shown to be of benefit in both childhood and adult meningitis [69,78]. Dexamethasone accelerated the normalization of CSF glucose, improved cerebral perfusion pressure, and reduced the incidence of hearing loss and other neurologic abnormalities in children, particularly those with *H. influenzae* meningitis [78], though there is renewed debate about the routine use of steroids in children given the decline in incidence of *H. influenzae* [79]. In adults, dexamethasone has been shown to reduce both mortality and neurologic sequelae [37,69]. The greatest benefits have been obtained when dexamethasone therapy was initiated before or simultaneously with the first antimicrobial dose [69]; the time period beyond the first antibiotic dose where steroids are effective is probably short but has not been well defined [37]. The recommended duration of steroid therapy is 4 days, but some studies in children suggest that 2 days may be adequate [37,80].

Adjunctive steroid therapy is not indicated in immunosuppressed individuals or postneurosurgical meningitis, as few of these patients were included in the clinical trials of dexamethasone and they are often infected with organisms not sufficiently evaluated in steroid trials [81]. In experimental animals infected with penicillin-resistant pneumococci, dexamethasone therapy reduced the penetration of vancomycin into the CSF, resulting in delayed sterilization of CSF [82]. However, given the demonstrated benefit of steroids and the lack of evidence for a similar effect in humans, steroids are still recommended in pneumococcal meningitis [3].

The benefits of steroid therapy seen in studies performed in industrialized countries have not been observed in the developing world [83,84]; therefore, adjunctive dexamethasone is not routinely recommended in these settings. Oral glycerol therapy is being explored as an alternative therapy to decrease cerebral pressure without immunosuppression, but is still in investigational stages [85,86].

Supportive Therapy

Treatment of meningitis also requires management of seizures and increased intracranial pressure. Seizures should be controlled by anticonvulsants as necessary (see Chapter 172), and aspiration and hypoxia must be prevented. Severe cerebral edema with evidence of uncal or cerebellar herniation can be managed with mannitol and steroids; several small case series have suggested that wider application of strategies for aggressive management of intracranial pressure is appropriate [87]. Fluid management should be directed at maintenance of euvolemia [88].

Bacterial meningitis in the setting of CSF shunts presents additional considerations. The highest rates of cure (88%) are obtained with initiation of antibiotics, removal of the entire shunt, temporary external drainage, and replacement of the shunt if follow-up cultures are negative upon repeat sampling of CSF. One stage removal with immediate replacement of the device followed by antibiotics is associated with a 64% rate of cure. Antibiotics alone, usually only considered for less virulent organisms such as *P. acnes* and non-aureus staphylococci, are successful 34% of the time [3,89].

Infection Control

Patients with *N. meningitidis* or *H. influenzae* type B meningitis should be managed with droplet precautions until 24 hours after initiation of antibiotics. Chemoprophylaxis is recommended in the situations described below. Dosing and duration are detailed in Table 79.2.

For *N. meningitidis*, household and day care contacts as well as hospital personnel who have performed unprotected cardiopulmonary resuscitation, intubation, or suctioning should receive chemoprophylaxis. Rifampin, ciprofloxacin, or ceftriaxone are the recommended agents. A small number of ciprofloxacin-resistant *N. meningitidis* isolates have been recently reported in North Dakota and Minnesota [90]. Primary rifampin resistance is similarly rare but may develop secondarily in individuals who receive rifampin for prophylaxis [91]. Quadrivalent (serogroups A, C, Y, and W-135) meningococcal vaccine can be used as an adjunct to chemoprophylaxis to prevent late secondary cases in contacts or to control outbreaks of disease [15,92].

For *H. influenzae* type B disease, chemoprophylaxis is recommended for household contacts only if there is at least one child younger than 4 years who is not fully vaccinated or if there is an immunocompromised child in the household [93]. In addition, if two or more cases have occurred in the same day care group within 60 days, chemoprophylaxis is recommended. Rifampin is the recommended agent.

ENCEPHALITIS

Encephalitis is a more rare infection than meningitis and a far less uniform one. Although a specific diagnosis provides important prognostic and epidemiologic information, there are only a handful of treatable causes of encephalitis.

Efforts should focus on identifying and addressing these causes. Infections of the brain that do not present as acute encephalitis but rather as subacute to chronic processes are not discussed further in this chapter.

Etiology

The causes of encephalitis endemic to the United States are predominantly viruses, although many other pathogens, including

TABLE 79.3

PROGNOSTIC CATEGORIZATION OF ENCEPHALITIDES INDIGENOUS TO THE UNITED STATES

Agent	Comments
Group 1: Causes of encephalitis that tend to resolve spontaneously and rarely leave neurologic residua	
Epstein-Barr virus	
Human herpes virus type 6	
Enteroviruses	
Mumps	
Lymphocytic choriomeningitis virus	
California encephalitis	Arbovirus
St. Louis encephalitis	Arbovirus
Colorado tick fever	Arbovirus
Herpes zoster	
Bartonellosis (cat scratch disease)	Especially acute cerebellar ataxia
Mycoplasma pneumonia	Especially acute cerebellar ataxia
Rocky Mountain spotted fever	Contingent on recovery from the systemic illness
Leptospirosis	Contingent on recovery from the systemic illness
Group 2: Causes of encephalitis that carry a small but definite risk of death and a sizable risk of sequelae	
Measles	
Powassan virus	Arbovirus
Western equine encephalitis	Arbovirus
West Nile virus	Arbovirus
Venezuelan equine encephalitis	Arbovirus
Smallpox vaccine	Vaccine is no longer in routine use
Group 3: Causes of encephalitis with a large risk of death; most survivors have significant residua	
Herpes simplex	
Cytomegalovirus	Immunosuppressed hosts
Eastern equine encephalitis	Arbovirus
Rabies	Six reported survivors

rickettsiae, *Mycoplasma pneumoniae*, *Bartonella* sp, *Treponema pallidum*, *Borrelia burgdorferi*, amoebae, *L. monocytogenes*, and *Toxoplasma gondii*, have all been associated with the syndrome [94,95]. *T. gondii* and cytomegalovirus (CMV) cause encephalitis only in patients with immunodeficiencies (see Chapters 84 and 85). In contrast, most of the acute viral encephalitides exhibit no particular predilection for the immunosuppressed host. In recent years, pressure to diagnose herpes simplex because of the potential for therapy has led to its documentation more frequently than any other form [95,96]. However, most cases of encephalitis elude diagnosis. Table 79.3 lists the causes of encephalitis that are indigenous to the United States in general prognostic categories. Despite the favorable prognosis, encephalitis caused by organisms listed in group 1 may be extremely severe, with prolonged unresponsiveness followed by gradual clearing.

Pathogenesis

Although HSV is the most common organism identified in encephalitis cases, the pathogenesis of herpes simplex encephalitis (HSE) is not entirely clear. The characteristic feature of HSE is its focal nature. It is an acute hemorrhagic necrotizing process with a predilection for the temporal lobe [97]. The virus is known to persist in the trigeminal ganglia and is thought to travel up to the trigeminal or olfactory nerves at the time of reactivation [97]. Recent studies of children with HSE have revealed defects in innate immunity [98,99].

Arboviruses are transmitted by the bite of their insect vector [100]. Blood transfusions and organ transplantation have also been a mechanism for transmission of WNV [101,102]. The mosquito-borne infections have seasonal prevalence in late summer and early fall. Prevalence in a given year can depend on weather trends affecting vectors. With the exception of the California group viruses, birds are a reservoir. Surveillance of bird populations is used to track the localities at risk for human disease [103,104]. The various arboviruses differ in their likelihood of producing overt disease, nonspecific febrile illness, or encephalitis, but they all affect young children and the elderly more severely. Eastern equine encephalitis is the most virulent, causing death or severe neurologic sequelae in more than 60% of cases [105,106]. The insect vector inoculates the arboviruses, producing viremia as an early event. The organisms replicate in reticuloendothelial tissues, where a secondary viremia arises and infects the CNS. By the time encephalitic symptoms develop, the virus has usually been cleared from the circulation and specific antibody is present, facilitating diagnosis [100].

Rabies virus reaches the brain by spreading up neural pathways from its site of inoculation, a process that may take weeks to years. Saliva contains the virus, which is usually introduced by a bite or salivary contamination of an open wound [107]. In the past 30 years, the majority of cases in North America have been caused by bat rabies [108]. Human-to-human transmission has occurred through organ transplantation from donors with undiagnosed rabies [109]. Although it has never been documented, human-to-human transmission through saliva is theoretically possible; therefore, patients should be placed in strict isolation. Prophylaxis for rabies exposure consists of a combination of passive immunization with rabies immunoglobulin plus active immunization with rabies vaccine [110].

There are numerous noninfectious processes that can produce a clinical picture overlapping with infection-related encephalitis. Anti-N-methyl-D-aspartate (anti-NMDA) receptor antibodies cause a severe form of encephalitis, sometimes associated with undiagnosed ovarian teratomas in young women [111]. Other autoantibodies, such as anti-Yo and anti-Hu, are associated with paraneoplastic syndromes, but their role in pathogenesis is less clear [112]. CNS vasculitis or sarcoidosis may manifest as acute or subacute encephalitis. Although the underlying etiologies are diverse, they share the common feature of vessel wall inflammation leading to ischemia and infarction [113].

Diagnosis

The diagnostic process is directed principally at identifying treatable causes of encephalitis, especially HSE or nonviral pathogens [96,97,114].

History

The epidemiologic features reviewed earlier (see Pathogenesis) are major contributors to diagnosis. In some cases of rabies, no apparent source can be determined. A history of foreign travel may widen the differential diagnosis beyond the considerations reviewed here. Establishing the host's immune status, and potential for occult HIV infection, will also help guide the diagnostic workup [115].

Fever is nearly universal in encephalitis. Headache is also common. A neurologic presentation may occur, with seizures,

mania, personality change, or another neuropsychiatric disorder as the principal signs [115]. Focal neurologic findings, including aphasia, suggest a diagnosis of HSE [114]. Aversion to water, refusal to swallow, and delirious behavior are classic features of "furious" rabies but are absent in about 20% of cases which present with flaccid paralysis, known as "dumb" rabies [107]. Flaccid paralysis mimicking poliomyelitis has also been observed in WNV encephalitis and with certain enteroviruses [50,116].

Physical Examination

The critical component of the physical examination is to determine whether an anatomic focus of abnormality is present, increasing the likelihood of HSE. Typical skin findings may suggest alternative diagnoses, such as Rocky Mountain spotted fever, measles, or herpes zoster.

Laboratory Tests

Analysis of CSF is the most important diagnostic procedure. The CSF in encephalitis usually fits the aseptic picture described earlier. It may be normal at the outset in 10% to 20% of patients subsequently proven to have HSE [114]. The presence of red blood cells suggests a hemorrhagic type of encephalitis, such as HSE, but is not diagnostic [97]. Eosinophils suggest infection with helminths, treponemes, rickettsiae, coccidiomycosis, toxoplasmosis, or *M. pneumoniae* [96].

Given its prevalence and the availability of specific therapy, PCR for HSV should be performed on CSF in all cases [96]. PCR can be positive even after several days of antiviral therapy. False-negative results can occur early in the disease, particularly in children [117]. A repeat HSV PCR in 3 to 7 days is recommended if the clinical scenario remains consistent with HSV and no alternative diagnosis has emerged [96,115].

Advancements have been made in molecular diagnostics for other forms of encephalitis. Reliable CSF PCR assays are available for VZV, CMV, and enteroviruses. PCR of serum can aid the diagnosis of ehrlichiosis, whereas PCR of lymph node tissue can detect *B. henselae* [96].

Diagnosis of most other causes of encephalitis relies on serologic testing. In arboviral infection, antibody is usually present at the onset of neurologic signs and is sufficiently rare in the general population to permit presumptive diagnosis [96]. The presence of antibody to *T. pallidum*, *B. burgdorferi*, rickettsia, or ehrlichia may reflect prior infection but is sufficient evidence to warrant treatment. Detection of pathogen-specific antibody in the CSF can provide more convincing evidence of the etiology of encephalitis, with a serum to CSF antibody ratio of less than 20 suggesting intrathecal production of antibody. Testing CSF for antibody to *T. pallidum* or *B. burgdorferi* is warranted when encephalitis secondary to syphilis or Lyme disease is suspected [96,115,118]. For most other causes of encephalitis listed in Table 79.3, the demonstration of a significant increase in antibody titer is required for diagnosis. The preferred approach is the comparison of a stored sample from the acute phase of infection to a sample obtained 2 to 4 weeks later [96].

Premortem noninvasive diagnosis of rabies is difficult. The reference standard is detection of viral nucleocapsid by fluorescent antibody staining of brain tissue, but this is often only obtained postmortem. Premortem diagnostic techniques exploit the fact that rabies virus nucleocapsids are concentrated in the nerve endings surrounding the base of hair follicles; nuchal skin biopsy followed by fluorescent staining or RT-PCR for virus has the highest sensitivity [119].

Although they share no distinct profile, patients with encephalitis due to noninfectious causes generally have lower CSF white blood cell counts and protein levels [120]. Recurrent encephalitis, patients with cerebellar dysfunction, and presentations with psychotic features are somewhat more likely to be secondary to noninfectious etiologies [120]. These characteristics would prompt additional imaging of the cerebral vasculature, assay of CSF for known paraneoplastic antibodies, or serum studies for markers of autoimmune disease.

CT and MRI are recommended for the evaluation of all patients with suspected encephalitis [96]. The findings in viral encephalitis are most often nonspecific, but the identification of mass lesions or infarcts will redirect the diagnostic workup toward brain abscess, vasculitis, or endocarditis. The finding of focal encephalitis, particularly involving the temporal lobes, is suggestive of HSE. MRI is more sensitive than CT in demonstrating temporal lobe involvement [49]. Characteristic abnormalities may not be seen initially, however [117]. If the clinical suspicion is high, imaging studies should also be repeated after several days.

Electroencephalography (EEG) may provide early clues to a diagnosis before CT changes are apparent, but the abnormalities seen are less specific. In patients with HSE, 80% have a temporal focus, although serial studies are often required to detect these changes [115].

With the advent of new molecular approaches and improved serologic diagnostics, brain biopsy is less commonly performed. However, it should be considered in select situations, such as when a patient continues to deteriorate on acyclovir. In the largest series reported, 9% of all patients with suspected HSE had another treatable disorder [121]. Neuroimaging should be used to guide sampling of abnormal tissue. Yield is likely to be higher earlier in disease. Specimens should be sent directly for culture, PCR, and immunofluorescence as well as fixed for routine histology with staining for pathogen detection [96].

Therapy

Empiric therapy with acyclovir (10 mg per kg every 8 hours in adults) should be initiated in all patients with encephalitis pending results of the diagnostic workup for HSE [96]. Subsequent management depends on the clinical response and the results of PCR testing. Total duration of therapy in confirmed HSE is at least 14 to 21 days. Repeat HSV PCR is recommended prior to stopping therapy in HSE patients who continue to exhibit encephalitic features, with continuation of acyclovir if the repeat PCR is positive [96].

Empiric doxycycline therapy (100 mg twice a day) should be considered for patients presenting with clinical suspicion of rickettsial or ehrlichial diseases in the summer months [96]. Early institution of tetracyclines reduces mortality in Rocky Mountain spotted fever. Therapy should be given in confirmed cases until the patient has been afebrile for 2 to 3 days [122].

Specific therapy is available for most nonviral microbial causes of encephalitis. Neurosyphilis should be treated with 10 to 14 days of high-dose penicillin G [123]. Meningoencephalitis caused by the Lyme disease spirochete is treated with ceftriaxone (2 g IV once daily) for 14 days [124]. Treatment for toxoplasmic encephalitis consists of pyrimethamine plus either sulfadiazine or clindamycin [125].

Antiviral therapy may be efficacious in some non-HSE forms of viral encephalitis. Although herpes zoster–associated encephalitis is usually self-limited, acyclovir therapy is recommended based on limited evidence of improved outcomes in small case series. CMV encephalitis can be treated with a combination of ganciclovir and foscarnet. Ribavirin can be considered in cases of encephalitis secondary to rabies or measles viruses, but there is little published experience. In influenza-related encephalitis with a susceptible strain, oseltamivir is recommended [96].

Treatment for most cases of encephalitis is supportive, with particular attention to the management of cerebral edema,

SIADH, and seizures. Status epilepticus (see Chapter 172) may produce additional neurologic damage. Intubation may frequently be necessary to prevent aspiration and to provide ventilatory assistance. The risks of nosocomial infection, particularly pneumonia, are very high for patients with prolonged periods of unconsciousness.

BRAIN ABSCESS

Etiology and Pathogenesis

Brain abscesses most commonly arise from chronic infections of the paranasal sinuses, middle ear, or mastoid [29,126]. Streptococci and anaerobes are the major organisms; *S. aureus* is involved less frequently. Enteric Gram-negative bacilli are commonly found in otogenic brain abscesses. Following penetrating trauma or surgery, staphylococci and Gram-negative bacilli are important pathogens [29]. Most brain abscesses are likely polymicrobial. Recent 16S ribosomal RNA gene sequencing of brain abscess aspirates has revealed a more diverse array of organisms than had previously been isolated in culture [127].

Hematogenous seeding of brain abscesses occurs in patients with cyanotic congenital heart disease and anaerobic pleuropulmonary infections as well as some normal hosts. Microaerophilic streptococci and anaerobes are the most common organisms. *S. aureus* endocarditis can also cause hematogenous brain abscess [29]. Brain abscesses caused by fungi, mycobacteria, or atypical organisms can be seen in immunosuppressed patients. In patients infected with HIV, mass lesions are most often caused by *T. gondii* [128]. Nocardia brain abscesses are commonly associated with defects in cell-mediated immunity, but at least half of cases occur in immunocompetent patients. They may occur as isolated lesions or in conjunction with pulmonary or cutaneous disease [29].

In the development of brain abscesses, initial infection of brain tissue leads to a focus of inflammation known as early cerebritis. This area appears hypodense on CT scan and will enhance with contrast administration. The area of cerebritis expands and develops a central area of necrosis in the late cerebritis stage. A ring-enhancing wall of well-vascularized tissue then separates the necrotic, infected area from healthy surrounding tissue in the capsule stage [29,49].

Diagnosis

Brain abscess usually presents more as a focal mass lesion—with headache, seizures, or neurological deficit—than as an infectious disease [126]. Low-grade fever is present in approximately half of patients. Blood cultures are helpful to assess for a hematogenous source. Cranial CT or MRI aids localization of abscesses, staging the disease, and evaluation of the underlying cause [49].

Therapy

Brain abscess is best treated with a combination of antibiotics and surgery. Initial antimicrobial therapy should be based on the pathogens predicted by the probable underlying source. Ceftriaxone plus metronidazole has been a successful approach and provides appropriate coverage for aerobic Gram-positive cocci, anaerobes, and aerobic Gram-negative bacilli [129]. Antistaphylococcal therapy may also be required. Duration of therapy is not well defined. Most cases require a prolonged 6- to 8-week course of intravenous antibiotics with serial cranial imaging to assess response to therapy. Some clinicians add an additional 2 to 3 months of oral antibiotic therapy and follow the collection to full resolution [29].

Prolonged antimicrobial therapy alone is curative in some patients, especially when the lesions are small (<2.5 cm) and do not have a well-defined capsule by CT criteria. However, in the absence of a contraindication, most specialists recommend prompt aspiration of the abscess contents using CT-guided stereotactic techniques. This provides confirmation of the diagnosis, material for culture, and possible adequate drainage of the focus of infection. In patients with multiple abscesses, the largest lesions are usually aspirated. The hospital stay and need for second surgical procedures are reduced by excision, but deep or multiple abscesses, abscesses in the early cerebritis stage, or abscesses in vital regions are poor candidates for this approach [130].

PARAMENINGEAL FOCI

Subdural Empyema

Subdural empyema usually arises from the same foci as brain abscess or as a complication of meningitis [6,131]. The infection spreads through venous drainage into intracranial vessels, which course through the subdural space. The clinical features of subdural empyema relate to local inflammation and cerebral edema, leading to increased intracranial pressure and herniation. Patients demonstrate depression of consciousness, hemiplegia, focal seizures, papilledema, and meningitic signs [131]. MRI is the most sensitive diagnostic modality [49]. Surgical decompression and drainage are urgent adjuncts to antibiotic therapy [131].

Dural Sinus Thrombophlebitis

Major dural sinus thrombophlebitis may occur in pyogenic meningitis but more often arises from contiguous spread of sinusitis, mastoiditis, otitis, or cranial skin and soft tissue infection. The microbiology reflects that of acute infection at these sites: *S. aureus*, *S. pneumoniae* or other streptococci, and anaerobes. Clinical signs and symptoms vary with the thrombus location. For instance, sagittal sinus thrombophlebitis may cause seizures and hemiplegia, whereas cavernous sinus thrombophlebitis presents with proptosis, marked chemosis, and ophthalmoplegia. Sigmoid sinus thrombophlebitis may give no neurologic signs but produce persistent fever in a case of chronic otitis media and mastoiditis. CT and MRI often can demonstrate thrombosis in the dural sinuses. Antibiotics and drainage or excision of the focus from which the problem originates are the mainstays of therapy. The merits of anticoagulation are controversial due to the propensity of venous infarcts to become hemorrhagic [132].

Spinal Epidural Abscess

Spinal epidural abscess is an infection that may be seeded during bacteremia or occur as a complication of vertebral osteomyelitis or surgery. More than half of cases are caused by *S. aureus*. *Pseudomonas* spp are also a common pathogen in injection drug users [64,133].

The classic triad of symptoms is back pain, fever, and neurologic deficit, though many patients do not demonstrate all three [64]. Percussion tenderness over the vertebral spinous processes should raise the suspicion of spinal epidural abscess. Meningismus may develop in some patients before neurologic deficits [133]. Most patients have elevated C-reactive protein

TABLE 79.4

SUMMARY RECOMMENDATIONS FOR MANAGEMENT OF CENTRAL NERVOUS SYSTEM INFECTIONS BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

- Dexamethasone treatment begun just prior to the institution of antibiotic therapy reduces the incidence of hearing loss in children with acute bacterial meningitis [78].
- Outcome of 2 vs. 4 days of therapy with dexamethasone was equivalent in childhood bacterial meningitis [80].
- Dexamethasone treatment begun just prior to the institution of antibiotic therapy reduces mortality and the incidence of neurologic sequelae in adults with acute bacterial meningitis [69].
- Acyclovir treatment reduces the mortality and the incidence of neurologic sequelae in herpes simplex virus encephalitis [135].

or erythrocyte sedimentation rate, two thirds have leukocytosis, and approximately 60% have positive blood cultures [64]. Early recognition of epidural abscess is critical because neurologic progression may be rapid and irreversible. MRI should be performed quickly to distinguish the extent of spinal involvement and to evaluate adjacent structures; contrast enhancement aids sensitivity [133].

Immediate neurosurgical consultation is mandatory. The goals of prompt surgical intervention are to prevent or relieve paraplegia and to obtain material for microbiological diagnosis. A nonoperative approach has been used with increasing frequency, particularly in patients with poor medical condition or if the neurologic condition is stable and a microbial etiology is identified quickly from cultures of blood or aspirated material [134]. However, the neurologic condition may deteriorate rapidly even after several weeks of antimicrobial therapy. MRI scanning and neurosurgical consultation should be available on an urgent basis for patients who are managed nonoperatively.

Blood cultures and image-guided abscess aspirate cultures should be obtained prior to initiation of antibiotic therapy in the neurologically stable patient [133]. Antistaphylococcal antibiotics should be started after cultures are obtained; Gram-negative coverage should be considered in intravenous drug abusers or patients with a documented Gram-negative focus elsewhere, such as the urinary tract. Therapy is adjusted based on the results of Gram stains and cultures. There are no controlled studies to support a specific duration of antibiotic therapy. Six to 8 weeks of therapy with close clinical monitoring, serial measurement of inflammatory markers, and repeat imaging is the most common approach [133,134].

Advances in CNS infections, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 79.4.

CHAPTER 80 ■ INFECTIVE ENDOCARDITIS AND INFECTIONS OF INTRACARDIAC PROSTHETIC DEVICES

KAREN C. CARROLL, SARAH H. CHEESEMAN AND SARA E. COSGROVE

Infective endocarditis (IE) is an infection of the endothelial lining of the heart, characterized on pathologic study by vegetations. The infected site is usually a valve, but endocarditis may be situated on mural thrombi (rare) or the endothelial surface on which the jet stream from a stenotic lesion (patent ductus, ventricular septal defect, or stenotic valve) impinges. The term encompasses infection of the endothelial surface of any blood vessel, which most frequently occurs on hemodynamically or structurally abnormal ones such as abdominal aortic aneurysms, arteriovenous fistulas, and prosthetic grafts. The peculiarities of these infections are beyond the scope of this chapter, and the general principles of diagnosis and treatment are the same.

Significant changes in the epidemiology and character of IE have been noted over the past three decades [1–9]. Shifting demographics, an expanding pool of elderly, chronically ill and

immunocompromised patients, and rising rates of nosocomial bacteremia have been observed [1–9]. Unanticipated increases in societal behaviors that predispose to bacteremia, such as injection drug use, body art (including piercing and tattooing [10]), and acupuncture [11], have also contributed to the steady incidence of IE. All of the above have contributed to changes in the microbiology of IE [1–9]. Simultaneously, advances in diagnostic criteria and methods and improvements in cardiothoracic surgery have occurred. Taken together, there has not been a noticeable decline in either the incidence or mortality of IE [1–9].

Since 1990, among published series of more than 100 patients, reported mortality ranged from 10% to 37% [1–4,9], with the lowest mortality rates attributed to earlier and higher rates of surgery, short delay before treatment, and high doses of bactericidal drugs. Decline in mortality has occurred predominantly among young patients. Mortality remains high in the elderly [2,3,12], diabetics [13], patients with other predisposing diseases such as chronic renal failure requiring hemodialysis and immunosuppression [1,2,9,14–17], patients with discernible valvular vegetations [15], patients with healthcare-associated infections [16], and those infected with staphylococci, particularly methicillin-resistant *Staphylococcus aureus* (MRSA) [2,8,15,18].

Traditionally two clinical forms of endocarditis have been delineated: acute and subacute. Subacute disease denotes insidious onset, with slow development of the characteristic lesions and absence of marked toxicity for a long period. A high proportion of these cases occur on previously damaged valves and many are caused by organisms of relatively low virulence, such as α-hemolytic streptococci (viridans streptococci). In contrast, acute bacterial endocarditis presents as a fulminant infection, with abrupt onset, high fever, more frequent leukocytosis, and rapid downhill course with respect to both valve destruction and systemic toxicity. This is most frequently secondary to *S. aureus* and may occur on previously normal valves. Among patients who require intensive care, the acute form of infection will be the more frequent problem.

A classification that more accurately characterizes current trends in IE has been proposed [6]. Dividing IE into four major categories as follows may provide better delineation of clinical conditions and microbial pathogens [6]. These categories are (a) native valve endocarditis; (b) prosthetic valve endocarditis (PVE)—early (<12 months following surgery) and late (>12 months following surgery); (c) IE in the injection drug user; and (d) nosocomial IE.

All observers of IE have noted a decrease in the frequency of rheumatic heart disease as a predisposing lesion and an increase in degenerative disease [3,6,7,9] and other previously unrecognized conditions such as mitral valve prolapse and idiopathic hypertrophic subaortic stenosis [14,15]. Taking these trends together, the universal observation of an increasing proportion of cases in older age groups is not surprising. Incidence of IE is higher among men compared with women in patients younger than 65 years and has remained relatively stable over the last several decades. In contrast, the incidence among women has significantly increased since 2000 especially among the elderly (>65 years) [8,9,12].

Populations particularly at risk for endocarditis are injection drug users and patients with prosthetic valves. Since the 1990s, other populations at risk have increased: transplant recipients [19,20], burn patients [21], patients with medical devices that put them at risk for bacteremia [9,16,22,23], and, most notably, persons on chronic hemodialysis [16,17,24,25].

Problems in endocarditis particularly relevant to patients in cardiac or intensive care units include the following:

1. Acute bacterial endocarditis,
2. Prosthetic valve endocarditis,
3. Endocarditis in patients with intravascular foreign bodies, such as pacemakers and indwelling vascular catheters,
4. Indications for surgery in endocarditis.

ETIOLOGY

The term *infective endocarditis* properly includes the whole world of microorganisms that can cause the disease. Fungi, rickettsiae (*Coxiella burnetii*, which causes Q fever), *Chlamydia* sp, and perhaps even viruses have been implicated in endocarditis, although bacteria are still the predominant cause. Substantial advances in the isolation of microorganisms and improvements in serologic testing and molecular detection have widened the spectrum of causative organisms. Uncommon species of streptococci, emerging pathogens such as *Bartonella* sp and *Tropheryma whipplei*, the increase in fungal pathogens among nosocomial cases and immunocompromised patients, and increasing resistance among "typical" endocarditis pathogens such as enterococci present unique diagnostic or therapeutic challenges [5,6,16,19–22,25].

Table 80.1 summarizes the most common pathogens from large series of endocarditis cases occurring since 1985 [1–4, 6–9,14,26–29]. Those series with a large number of injection drug users [1,6,14,18,27], patients on chronic hemodialysis [1,2,17,22], transplant recipients [19,20], and those series reporting healthcare-associated IE [1,6,7,16,22,23,25] tend to report more cases caused by *S. aureus*. Viridans streptococci occur more frequently but no longer predominate among non-injection drug user populations and the elderly [9]. Identification to species level among the viridans streptococci may have important therapeutic and prognostic implications. The *Streptococcus anginosus* (*milleri*) groups (*S. anginosus*, *S. constellatus*, and *S. intermedius*) are frequently associated with abscess formation and tend to cause severe disease but cause endocarditis less often than other viridans streptococci [30,31].

TABLE 80.1

ETIOLOGY OF ENDOCARDITIS FROM REPORTED LARGE SERIES SINCE 1985

Etiologic agents	Attributable range[a,b] (%)
Staphylococcus aureus	18–57
Viridans streptococci	11–53
Coagulase-negative staphylococci	1–15
Enterococci	4–10
Streptococcus bovis	1–13
β-Hemolytic streptococci	3–9
Streptococcus pneumoniae	1–3
Other streptococci	3–7
HACEK[c]	1–6
Enterobacteriaceae	1–4
Yeast	1–2
Molds	<1
Polymicrobial	1–6
Other bacteria[d]	2–11
Culture negative	2–39

[a] All figures are the percentage ranges of episodes reported.
[b] Rounded to nearest whole percentage.
[c] *HACEK*, *Haemophilus* sp, *Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, Kingella kingae.*
[d] Includes a variety of single isolates of species not represented by above genera, including *Neisseria sp, Pseudomonas, Legionella, Lactobacilli.*
Compiled from references [1–4,8,9,14,26–30].

S. anginosus is the least likely among the three species to cause abscesses and the most likely to be associated with endocarditis [31,32]. The nutritionally deficient streptococci include the following genus and species: *Abiotrophia defectiva*, *Granulicatella adiacens*, *Granulicatella para-adiacens*, *Granulicatella balaenopterae*, and *Granulicatella elegans* [33,34]. Together these organisms constitute 3% to 5% of cases of endocarditis caused by viridans streptococci [34]. These organisms require pyridoxal, the active form of vitamin B_6, for growth. Unlike other species of viridans streptococci, these organisms are tolerant to penicillin, and at least one series [33] has found decreased susceptibility to penicillin, extended spectrum cephalosporins, and macrolide antibiotics. High relapse rates are described especially when patients are treated with penicillin alone [34]. Most cases of viridans streptococcal endocarditis (80%) are caused by *Streptococcus sanguis*, *Streptococcus mitis*, or *Streptococcus mutans* [14,18,29,30]. There do not appear to be any statistically significant differences in the symptoms, demographics, or complications among patients with infections caused by this group of organisms. Newer species of viridans streptococci continue to be described.

Enterococci rank third in frequency of isolation in most series, including healthcare-associated cases and those among patients on hemodialysis. Among the non–viridans streptococci, pneumococci are still relatively uncommon causes of endocarditis (1% to 3% of all cases). The proportion of cases caused by β-hemolytic streptococci has not increased since 1980; infections with group B and group G are seen most frequently [32,35,36]. Patients with these infections usually have underlying valvular disease, numerous predisposing factors, most notably diabetes mellitus, and acute onset of their infection [32,35,36]. *Streptococcus bovis* deserves mention for several reasons. First, this organism group has undergone extensive reclassification based upon DNA–DNA reassociation studies, a description of which is beyond the scope of this chapter [37]. Second, some of the newly described species and subspecies (*S. gallolyticus* spp *gallolyticus*) are more frequently associated with endocarditis and with benign and malignant disorders of the gastrointestinal tract, while others are more frequently associated with meningitis (*S. gallolyticus* spp *pasteurianus*). In some series, this organism group has been increasing in frequency in Europe and South America [9], particularly among the elderly and among patients with chronic liver disease [4,37–39]. When this organism is isolated, the patient should be carefully evaluated for gastrointestinal tract malignancy, although it may occur months to years after the bacteremic episode [38]. Since these species and subspecies are difficult to differentiate using traditional microbiological methods, most clinical laboratories will likely continue to call them *S. bovis* or nonenterococcal Group D streptococci.

S. aureus has increased in frequency and accounts for more than 50% of cases in more recent series [1,2,6,9,16,17,19,25,27]. In several recent prospective studies, including data from the International Collaboration on Endocarditis-Prospective Cohort Study (ICE-PCS), patients with *S. aureus* endocarditis were more likely than patients with IE due to other pathogens to have a shorter duration of symptoms before diagnosis, to be hemodialysis dependent, and to have other serious comorbidities such as diabetes mellitus or other chronic illnesses [9,40–43]. Patients with *S. aureus* IE were also more likely to have severe sepsis with persistent bacteremia, major neurologic events, systemic embolization, and death than patients with IE caused by other bacteria [41–43]. In these studies, patients with *S. aureus* IE frequently had healthcare-associated or nosocomial acquisition and were more likely to have MRSA infection than patients with community-acquired *S. aureus*. In the ICE-PCS series [38], a multivariate model identified the following patient characteristics associated with MRSA IE: persistent bacteremia, chronic immunosuppressive therapy, intravascular devices as sources, and diabetes mellitus. Overall, MRSA now accounts for 25% to 50% of the cases attributable to *S. aureus* [2,25,40–43]. Persistent bacteremia correlated with infection caused by MRSA, and risk of embolic phenomena was negatively associated with oxacillin resistance [40–43].

Coagulase-negative staphylococci (CoNS) are recognized pathogens on prosthetic valves and close to 8% of cases on native valves are now caused by these organisms [44]. The majority of the CoNS species recovered are *Staphylococcus epidermidis* [44]. *Staphylococcus lugdunensis* has emerged as a particularly aggressive pathogen that causes a destructive native valve endocarditis, frequently following vasectomy or other procedures involving breaks in the skin in the perineal area [45]. In spite of universal susceptibility to β-lactams and other agents, mortality attributable to this pathogen is high, possibly related to the large vegetations frequently seen with this organism, leading to valvular dehiscence, abscess formation, and systemic embolization [45].

Before 1980, endocarditis caused by Gram-negative organisms comprised less than 3% of cases. Recent series report that Gram-negative organisms now account for 4% to 10% of all native valve endocarditis [3,6,15,46], but these rates vary by geographic location, whether the infection is community or healthcare associated and the type of Gram-negative pathogen involved. Within this subset is the HACEK group (*Haemophilus* sp, *Aggregatibacter* [previously *Actinobacillus*] *actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*), which accounts for 2% to 5% of cases [8,9,26,46]. *A. actinomycetemcomitans* is the HACEK species most frequently involved in IE [46]. HACEK organisms are fastidious, nonmotile, slow-growing coccobacilli that require a mean of 3.3 days of incubation in automated blood culture systems for growth [46]. The HACEK organisms rarely cause endocarditis in patients without preexisting valvular disease or in the absence of predisposing factors [46]. Non-HACEK Gram-negative endocarditis (*Enterobacteriaceae* and others) remains relatively rare and is seen primarily among debilitated patients with healthcare-associated infections related to medical devices or surgery [21,47,48].

Among the emerging pathogens of the 1990s are *Bartonella* sp. This genus continues to expand [49,50]. Seven species and subspecies, namely *B. quintana*, *B. henselae* (the agent of cat scratch disease), *B. elizabethae*, *B. vinsonii* spp *berkhoffii*, *B. vinsonii* spp *arupensis*, *B. koehlerae*, and *B. alsatica* have been implicated in cases of endocarditis [49,50]. *B. quintana*, the agent of trench fever, has been reported to infect middle aged, homeless male alcoholics without known underlying valvular disease. Contact with animals is a frequent association, and ectoparasites such as scabies, lice, and fleas are proposed as possible vectors of disease [49–51]. The majority of patients with *B. henselae* endocarditis have a previous history of underlying valvular disease and report contact with cats [49–51]. Characteristically, patients with *Bartonella* endocarditis present with a subacute course and large vegetations [49–51]. Because of the fastidious nature of the organism and serologic cross-reactivity between antibodies to *B. quintana* and *Chlamydia* sp, it is likely that cases of *Bartonella* endocarditis constitute a proportion of cases previously diagnosed as culture negative or due to *Chlamydia* sp [49–51]. Currently, approximately 3% of cases of endocarditis are secondary to *Bartonella* sp [51].

In spite of improvements in blood culture and serological techniques, negative blood cultures can occur in up to 31% of cases [1,2,3,7,52]. There are several reasons cited for negative blood cultures in IE: (a) prior antibiotic administration; (b) infection with fastidious, slow-growing organisms (e.g., *Bartonella* sp, fungi, *Chlamydia* and *Coxiella* spp); (c) infection with nonbacterial organisms such as fungi; and (d) endocarditis in patients with an indwelling cardiac device such as a

pacemaker [52,53]. Two recent surveys [52,53] of culture-negative cases in France over two decades used serological studies and molecular methods to augment blood cultures in determining the etiology for more than 348 [52] and 740 [53] patients, respectively. In the initial study of definite cases of IE, in the 79% of patients in whom an etiologic agent was determined, *C. burnetii* and *Bartonella* sp predominated, accounting for 76% of the total [52]. Other rare bacteria included *T. whipplei*, *Mycoplasma hominis*, various streptococci, and *Legionella pneumophila* [52]. Twenty-one percent did not have an etiology determined of whom 79% had received prior administration of antibiotics [52]. In the more recent prospective series, both definitive and possible cases were included and an etiologic diagnosis was determined in 64.6%. The same group of organisms predominated [53].

IE among injection drug-users has increased in the new millennium and *S. aureus* is by far the most common cause [54,55]. Enterococci, enteric Gram-negative bacilli, *Pseudomonas*, *Candida*, and other yeasts are also important [6,9,54]. Polymicrobial endocarditis is more common among injection drug users than in noninjection drug users [6,9,18].

The common causes of early-onset PVE are CoNS (mostly *S. epidermidis*), *S. aureus*, enterococci, diphtheroids, Gram-negative bacilli, and fungi. Among the fungi, *Candida* sp are most common and have emerged as causes of both early- and late-onset disease especially among patients with healthcare-associated infection [56]. However, late-onset disease is still caused mainly by organisms such as CoNS and streptococci, although *S. aureus* accounts for about 11% of cases [9,18,57,58]. This difference is thought to be explained by intraoperative or early postoperative contamination of the prosthesis with resistant hospital flora in early PVE. Late cases represent either smoldering infection with relatively avirulent organisms seeded at the original surgery or subsequent transient bacteremias, such as those that induce endocarditis on native valves [58].

PATHOPHYSIOLOGY

The laboratory model of endocarditis is a rabbit in which a catheter passed through a valve produces mild trauma with the elaboration of a fibrin–platelet thrombus. Subsequent injection of bacteria either through the catheter or at a distant vascular site leads to infection of the traumatized valve [59]. It appears that the fibrin–platelet thrombus allows for avid binding of the bacteria [6]. Adherent bacteria induce blood monocytes to produce cytokines that contribute to further enlargement of the vegetation [60]. As the vegetation matures, the bacteria become fully enveloped, which allows for persistence by avoiding host defenses.

This model conforms to the propensity of damaged human valves toward endocarditis. Transient bacteremia with mouth flora, predominantly viridans streptococci, during chewing, tooth brushing, and the like explains the pattern observed in subacute bacterial endocarditis [6]. More virulent organisms such as *S. aureus* seem to be able to invade even normal hearts. There are several factors expressed by this pathogen that make it more virulent. In addition to surface fibronectin-binding proteins that facilitate adherence, *S. aureus* produces exoenzymes and exotoxins that are controlled by global regulators, such as accessory gene regulator (*agr*) and staphylococcal accessory regulator (*sar*), the expression of which permit tissue invasion and destruction [6]. Intravenous drug users combine the injection of contaminated materials with particulate and often irritant matter, probably accounting for the frequency of endocarditis in this setting and the propensity for right-heart involvement [54,61,62]. The use of intravascular central lines reaching near the tricuspid valve or even crossing tricuspid and pulmonic valves reproduces the rabbit model of endocarditis in humans. The introduction of bacteria through these lines causes the specter of iatrogenic endocarditis.

Once the fibrin–platelet thrombus has become infected, the pathologic process is the enlargement of this mass into a vegetation and invasion of tissue by the infection with eventual disruption. In addition to the mass of the vegetation, there are perforations or total erosions of valve cusps, rupture of chordae tendineae, fistulas from the sinus of Valsalva to atrium or pericardium, and burrowing myocardial abscesses.

Depending on the valve involved, the physiologic consequences may be predicted. Rarely, a vegetation will be so large as to function as an occlusive or stenotic lesion [62]. More often, the tissue destruction process predominates and valvular incompetence results. New regurgitant murmurs of mitral, tricuspid, or aortic origin may acutely stress the heart with resultant congestive failure. Aortic valve disease carries the worst prognosis [62] for several reasons: (a) the heart tolerates acute aortic insufficiency least well; (b) pericardial tamponade or massive left-to-right shunt may develop if a sinus of Valsalva aneurysm erodes into the pericardium or right atrium, respectively; (c) heart block may occur if a myocardial abscess invades the conducting system; and (d) aortic valve ring vegetations are most likely to be flipped into the coronary arteries, infarcting already overworked muscle. These catastrophes are all even more likely in the presence of a prosthetic aortic valve, in which case the infection has its seat at the annulus. Tricuspid valve endocarditis is the most benign. Even total tricuspid insufficiency can be tolerated for a time, and acute right-side heart failure is not as life threatening as is the pulmonary edema of left-sided failure.

The vegetations themselves may break off in whole or part as emboli to the brain, viscera (spleen and kidney are particularly common targets), coronary arteries, and notably in fungal endocarditis, large arteries of the extremities. Septic emboli to the lungs can result in pulmonary infiltrates, often nodular and sometimes cavitating. Emboli to other organs produce infarction, which is usually bland, although splenic abscess, brain abscess, and even purulent meningitis may occur in staphylococcal endocarditis. The most common cerebral lesion, however, is embolic infarct with the clinical appearance of a stroke [62,63]. The smaller vascular lesions of endocarditis may be of an immunologic, vasculitic nature or truly embolic and suppurative in character. Emboli to the vasa vasorum or vasculitis of the arteries lead to mycotic aneurysms of both cerebral and peripheral vessels. The cerebral aneurysms are generally asymptomatic until they rupture and present as subarachnoid or intracerebral hemorrhage. Peripheral mycotic aneurysms may come to attention because of their obvious enlargement and frequent overlying inflammation. Other phenomena that fall into this category are the cutaneous stigmata of endocarditis—Osler's nodes, Janeway lesions, splinter hemorrhages, and petechiae—as well as the frequent renal involvement. Kidney pathology may take several forms: localized renal infarcts, vasculitic glomerulonephritis, acute diffuse glomerulonephritis thought to represent immune complex disease, renal cortical necrosis, and interstitial nephritis likely related to antibiotic administration [62].

DIAGNOSIS

Endocarditis is diagnosed on the basis of signs and symptoms that reflect the pathology: fever, embolic phenomena, and evidence of valvular dysfunction. A continuous bacteremia is characteristic and, indeed, highly suggestive of endovascular infection, although the entity of culture-negative endocarditis also exists. The frequency of various findings in IE is shown in Table 80.2 [1,3,4,9,14,18,27].

TABLE 80.2

CLINICAL FEATURES OF ENDOCARDITIS

Feature	Frequency range (%)
History	
Fever	81–98
Malaise/weakness	49–96
Weight loss	6–30
Musculoskeletal complaints	9–25
Mental status change/neurologic event	11–32
Previous heart disease	25–55
Physical examination	
Fever	54–95
Murmur	76–95
Change in murmur	10–67
Splenomegaly	1–29
Petechiae	12–16
Osler's nodes	3–16
Janeway lesions	3–5
Splinters	3–35
Fundoscopic abnormalities	0–3
Clubbing	6–20
Lab tests	
Hematuria	26–53
↑ ESR	22–89
Rheumatoid factor	5–51
Anemia	66–68
Echocardiographic vegetations[a]	60–86

[a]Combined transthoracic and transesophageal results.
↑ ESR, elevated erythrocyte sedimentation rate.
Data compiled from references [1,3,4,14,18,27].

Criteria

Proof of the diagnosis, in terms of histopathologic confirmation of vegetation with infecting organisms on the affected valve, may be obtained only in cases requiring cardiac surgery or, in the event of death, with autopsy. Clinical criteria for the diagnosis sufficiently stringent to allow for analysis of case characteristics, epidemiology, and the outcome of therapy have been devised and revised over the years with the latest version known as the Duke criteria [26]. The Duke criteria incorporate echocardiographic findings in addition to giving heavy weight to clinical circumstances such as the type of organisms recovered from blood and injection drug use as a predisposing factor. Major and minor criteria analogous to the Jones criteria for diagnosis of rheumatic fever are summarized in Table 80.3. A definite diagnosis requires the presence of two major criteria, one major and three minor criteria, or five minor criteria. The diagnosis is rejected if a firm alternate diagnosis adequately explains the clinical findings, they resolve with less than 4 days of antibiotic therapy, or histopathologic evidence is lacking at autopsy or surgery performed after no more than 4 days of antibiotic therapy. All other clinically suspect cases meriting more than 4 days of antibiotic treatment are classified as possible [26].

Several studies have demonstrated very good sensitivity and excellent specificity (92% to 99%) for the Duke criteria [64–66]. Moreover, these criteria have been evaluated for the diagnosis of IE in children [67] and the elderly [68], as well as in patients with PVE [69]. Several criticisms and proposed modifications have followed these rigorous studies. The inability of the Duke criteria to reject cases that receive more than 4 days of

TABLE 80.3

DUKE CRITERIA AND PROPOSED MODIFIED DUKE CRITERIA FOR DEFINITIVE CLINICAL DIAGNOSIS OF ENDOCARDITIS

Major criteria

1. Positive blood culture for infective endocarditis
   - Typical microorganisms for infective endocarditis from two separate blood cultures
   - Viridans streptococci, *Streptococcus bovis*, HACEK group, or *Staphylococcus aureus* or community-acquired enterococci in the absence of a primary focus, or
   - Persistently positive blood culture, defined as recovery of a microorganism consistent with infective endocarditis from
     - A. Blood cultures drawn more than 12 hours apart, or
     - B. All of three or a majority of four or more separate blood cultures, with first and last drawn at least 1 hour apart
     - C. Single positive blood culture for *Coxiella burnetii* or antiphase IgG antibody titer >1:800
2. Evidence of endocardial involvement
   - Positive echocardiogram for IE (TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE [paravalvular abscess]; TTE as first test in other patients), defined as:
     - A. Oscillating intracardiac mass on valve or supporting structures, or in the path of regurgitant jets, or on implanted material, in the absence of an alternative anatomic explanation, or
     - B. Abscess, or
     - C. New partial dehiscence of prosthetic valve, or new valvular regurgitation (increase or change in preexisting murmur not sufficient)

Minor criteria

1. Predisposition: predisposing heart condition or intravenous drug use
2. Fever: ≥38.0°C (100.4°F)
3. Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
4. Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth spots, rheumatoid factor
5. Microbiologic evidence; positive blood culture but not meeting major criterion as noted previously or serologic evidence of active infection with organism[a] consistent with infective endocarditis
6. Echocardiogram: consistent with infective endocarditis but not meeting major criterion as noted previously. Echocardiographic minor criteria eliminated (Proposed modifications, [72])

[a]Excluding single positive blood cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.
HACEK, *Haemophilus* sp, *Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, Kingella kingae*; IE, infective endocarditis; TEE, transesophageal echocardiography.
Modified from Durack DT, Lukes AS, Bright DK, et al: New criteria for the diagnosis of infective endocarditis: utilization of specific echocardiographic findings. *Am J Med* 96:200–209, 1994; and Li JS, Sexton DJ, Mick N, et al: Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis* 30:633–638, 2000, with permission.
Note: A definite diagnosis requires the presence of two major criteria, one major and three minor criteria, or five minor criteria.

antibiotic therapy may lead to occasional overdiagnosis of endocarditis [70]. Sensitivity may possibly be enhanced in those patients with suspected late PVE by the addition of heart failure and atrioventricular conduction disturbances to the minor criteria [69]. Likewise, others have suggested inclusion of positive serologic studies for Q fever as a major criterion, especially in endemic regions [71,72], and other physical findings, such as splenomegaly, and laboratory results, such as a high C-reactive protein, to the minor criteria [73]. Proposed modifications to the definitions have not been evaluated in large prospective studies [72]. Modifications to the major and minor criteria are listed in Table 80.3.

History

The most frequent symptoms reported by patients with endocarditis are fever and malaise, but some present with acute musculoskeletal symptoms, most frequently lower back pain or polyarthralgia [74], and others, because of an embolus, without complaining of or even noticing fever [71]. A common feature of endocarditis is loss of appetite, and its return may be the first clinical sign of response to treatment. Any febrile illness in a patient with known valvular heart disease must bring to mind the question of endocarditis. Similarly, a history of recent dental cleaning or extraction or genitourinary manipulation may indicate an opportunity for bacteremia and seeding of the valve and should be sought, as should suggestions of injection drug abuse. The history of appropriate antibiotic prophylaxis for these procedures is not sufficient to exclude the possibility of endocarditis because failures occasionally occur with currently recommended regimens.

It is important to establish the duration and tempo of the illness by history. Abrupt onset of symptoms, shaking chills, and body temperature greater than 38.9°C (102°F) strongly suggest acute endocarditis. Subacute bacterial endocarditis, in contrast, is characterized by a vague illness occurring over a period of several weeks or months.

Physical Examination

In contrast to the vagueness of the symptoms of endocarditis, many findings on physical examination are characteristic. Most pertinent to the diagnosis are cardiac murmurs and mucocutaneous embolic phenomena. Any heart murmur is compatible with a diagnosis of endocarditis because it is evidence of the turbulent flow that provides the proper nidus for infection. The fact that a murmur has been documented for a long time in no way excludes the possibility of active endocarditis. Changing murmurs, particularly new regurgitant murmurs, are much less commonly observed but are highly significant with respect to both certainty of the diagnosis and functional consequences. Thus, patients must be examined both supine and sitting up leaning forward so that an aortic regurgitant murmur is not missed. Careful listening on both sides of the sternum during inspiration is important to detect tricuspid insufficiency. Signs of congestive heart failure are not early findings in endocarditis but must be watched for because the onset of failure signals a need to consider cardiac surgical intervention.

The most commonly observed mucocutaneous lesions of endocarditis are petechiae. They most often appear on the plantar surface of the toes and fingertips, as well as the conjunctival and buccal mucosa (see Fig. 80.1B). They may be larger and more irregular in outline than conventional petechiae and sometimes have a white or even pustular center. Conjunctival petechiae commonly occur in patients on cardiopulmonary bypass [75], so it is necessary to record their presence or absence on first encounter with a patient after cardiac surgery and to interpret only those that develop under observation. The same necessity applies to subungual splinter hemorrhages, which are so commonly a result of trauma that many patients will have one or two on admission; only those which appear subsequently, while the patient is at rest in the hospital, have diagnostic usefulness [76].

Osler's nodes and Janeway lesions favor the plantar and palmar surfaces but are uncommon in recent series of endocarditis. Osler's node is a painful, tender, bluish-purple nodular lesion located on the pads of the fingers or toes. The Janeway lesion is a painless, pink, nontender macular lesion that is located commonly on the palms or soles [76,77].

Fundoscopic examination may also show evidence of endocarditis. Showering of emboli often occurs, as in the patient whose findings are illustrated in Figure 80.1. The fingertip, subungual, conjunctival, and retinal lesions all developed the day after admission for acute staphylococcal endocarditis. Splenomegaly is found in nearly half of patients with subacute bacterial endocarditis and in very few of those with acute disease.

Laboratory Tests

The key to the diagnosis of endocarditis is blood cultures. Two or three separate blood cultures within a 24-hour interval are recommended based on early studies that showed that 99.3% of all septic episodes will be detected by the first two blood cultures [78]. Strict aseptic technique and optimal skin preparation should be used when collecting blood cultures and the blood cultures should be obtained prior to administration of antibiotics [78]. In adults, 20 to 30 mL of blood per culture is optimal [78]. In cases that appear to be culture negative [52,53,78], the advice of a clinical microbiologist should be sought regarding the need for special media, such as those adequate for the propagation of *Brucella* sp, *Bartonella* organisms, or other nonculture-based tests such as serology and molecular methods (see later). Prolonging the incubation of standard blood culture bottles beyond 7 days has not been demonstrated to be necessary for successful recovery of HACEK organisms, nor does it significantly improve diagnostic yield of other fastidious pathogens [78–80].

Diphtheroids and CoNS should not be disregarded as skin contaminants if isolated repeatedly; they are well reported as causes of endocarditis. A particularly troublesome problem is the recovery of CoNS of different colony types or susceptibility patterns from different blood cultures. This is not necessarily evidence for multiple contaminated cultures because the pattern can be observed in true coagulase-negative staphylococcal endocarditis.

Fungal endocarditis has increased in frequency. Fungi most commonly isolated include *Candida albicans*, non-albicans species of *Candida*, *Aspergillus* sp, and *Histoplasma* sp [56,81]. In a recent review, emerging fungi accounted for 25% of cases [81]. In patients with fungal endocarditis, the overall frequency of positive blood cultures is 54% [81]. In cases of endocarditis caused by *Candida* sp, the percentage of positive blood cultures may be as high as 83% to 95% if appropriate methods are used [78].

Current commercially available routine manual and automated blood culture systems are usually able to recover yeasts within 5 to 7 days of incubation. The best chances for recovery of filamentous fungi such as *Aspergillus* or *Histoplasma* require the use of the lysis centrifugation method (Isolator, Wampole Laboratories, Cranbury, NJ) [78]. Premortem microbiologic diagnosis may often be made by culture and special histologic stains of large arterial emboli or cardiac vegetations [53,81].

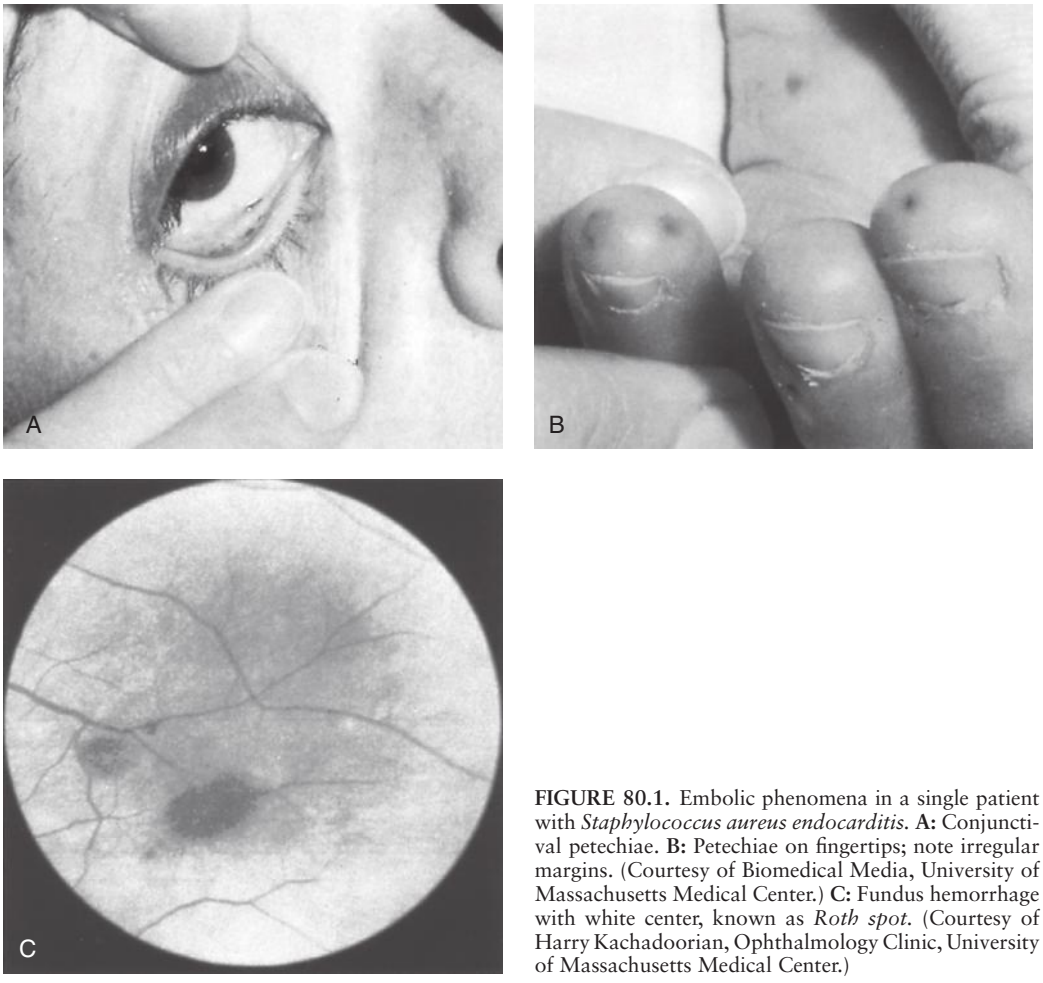

FIGURE 80.1. Embolic phenomena in a single patient with *Staphylococcus aureus endocarditis.* **A:** Conjunctival petechiae. **B:** Petechiae on fingertips; note irregular margins. (Courtesy of Biomedical Media, University of Massachusetts Medical Center.) **C:** Fundus hemorrhage with white center, known as *Roth spot.* (Courtesy of Harry Kachadoorian, Ophthalmology Clinic, University of Massachusetts Medical Center.)

Noncultivatable or difficult to cultivate organisms may be detected by serologic or molecular studies. Such organisms include *C. burnetii*, the agent of Q-fever endocarditis, *Chlamydia* sp, *Bartonella* sp, and some fungi [49–53,81,82]. Timely inclusion of serologic studies, particularly in environments where Q fever, *Brucella*, and *Bartonella* sp are prevalent, can enhance the definitive diagnosis of cases of endocarditis as demonstrated in the studies by Raoult et al. [53,83].

Molecular techniques such as polymerase chain reaction and sequence analysis of the amplified DNA have been applied both to blood cultures and to valvular tissue removed at the time of surgery [53,84,85]. Several studies have demonstrated the utility of these methods in assessing patients with high pretest probability of endocarditis but who have negative blood cultures by standard methods. Many of these studies are well summarized in the review by Syed et al. [84]. Advantages include high sensitivity, rapid results, and accurate identification. Limitations include potential for contamination and lack of an organism to test for antimicrobial susceptibility [53,84,85].

Other Diagnostic Tests

The electrocardiogram (ECG) is the simplest test for evaluation of perivalvular extension of infection in endocarditis [86]. Persistent (2 to 3 days) prolongation of the PR interval in the absence of digitalis toxicity, new persistent bundle-branch block, or complete heart block is quite specific for predicting extension into myocardial or aortic root tissue and the subsequent need for surgery [86]. However, the absence of PR prolongation does not rule out perivalvular extension.

Echocardiography plays an essential role in the diagnosis and management of IE and should be performed in all cases of suspected endocarditis [87]. Current roles for echocardiography include (a) diagnosis of IE by demonstration of vegetations, (b) characterization of underlying valvular disease, (c) clarification of the destructive nature of endocarditis, (d) assessment of the persistently febrile patient for evidence of perivalvular extension of infection, and (e) assessment of valvular function in PVE.

Studies performed in the period between 1988 and 1998 demonstrated that transthoracic two-dimensional (2D) echocardiography (TTE) has an overall sensitivity of vegetation detection of 50%, with a range of 14% to 78% in published series [88–90]. Sensitivity is affected by vegetation size, with 25% of vegetations less than 5 mm and 70% between 6 and 10 mm detected [91]. Obesity, chronic lung disease, and thoracic deformity may preclude obtaining the high-quality images needed to detect vegetations in as many as 30% of patients [91,92]. Equivocal results due to thickening or myxomatous degeneration of native valves and artifact from prosthetic valves are problems with TTE [89,92]. Diagnostic yield is also influenced by experience and skill of the person performing the procedure and the pretest probability of endocarditis. TTE has very limited ability to detect valve perforations and abscess extension, especially on prosthetic heart valves. Recent technological

advances such as harmonic imaging and digital processing and storage have improved TTE image quality [84,93]. At least one report describes improved sensitivity to more than 80% using contemporary TTE [93]. Likewise studies are beginning to emerge on the improved performance of TTE using live/real time three-dimensional (3D) probes and ultrasound systems, but these have yet to be evaluated in large series [84,94].

Transesophageal echocardiography (TEE) is a significant advance in the evaluation of the patient with IE [84,89,95]. Unlike TTE, TEE has a high negative predictive value in patients with suspect native valve endocarditis (86% to 97%) [84,89,95]. Despite the somewhat invasive nature of TEE, the procedure is quite safe when performed by a skilled physician, with interruption of the procedure or complications occurring less than 1% of the time [96]. Relative contraindications include esophageal diseases, severe atlantoaxial joint disease, prior irradiation to the chest, and perforated viscus [97].

Image quality of the TEE benefits from the high-resolution transducer and unobstructed view of cardiac structures [86,89–92]. The TEE is much more sensitive than TTE for the detection of valvular vegetations; sensitivity with current biplane TEE is 90%, with vegetations as small as 1 mm being seen [96,98–100]. Early studies on 3D TEE demonstrate the potential of this technology to enhance localization of vegetations [101]. Like the situation with 3D TTE, however, large series demonstrating superiority are lacking.

TEE is also superior to TTE for detection of perivalvular abscess, with approximately 87% sensitivity [88,98]. TEE appears to be the optimal tool to detect vegetations on prosthetic valves and to assess valve dysfunction. Likewise, TEE is superior to TTE in detecting infections of pacemaker leads [92,100–103]. TEE also appears superior to TTE in the intraoperative assessment of cardiac structure and hemodynamics [100,102]. The American Heart Association Guidelines [87] do not recommend TEE for all patients with suspected endocarditis, but do suggest that TEE should be considered when the diagnostic quality of TTE is inadequate or inconclusive or in the situations described earlier where TEE is clearly superior [87]. Other applications of TEE are summarized in several recent reviews [87,103,104–106].

The European Society of Cardiology practice guidelines recommend the use of echocardiography in the evaluation of patients suspected on clinical grounds as follows [107]. Patients with native valves should be screened initially by TTE. If the study images are deemed of good quality and clinical suspicion is low, then in the presence of a negative TTE, other diagnoses should be considered. If the suspicion is high, TEE should be performed when TTE is negative.

In suspected PVE and when the TTE is positive and/or when complications are suspected (e.g., the patient has a highly virulent organism in blood cultures), TEE should be performed. If TEE is negative and suspicion remains, the TEE should be repeated in 7 days. Repeatedly negative studies exclude the diagnosis of IE [107]. Some investigators advocate that if the pretest probability is high (ranging from 4% to 60%), it is more cost-effective to proceed directly to TEE as the first and only study [108].

Some investigators have attempted to determine cost-effective uses of echocardiography for patients with suspected endocarditis [108,109]. In determination of duration of therapy for catheter-associated *S. aureus* bacteremia (SAB), TEE is probably most cost-effective when used to stratify patients to short (2 weeks) or long (4 weeks) course therapy, when long-course therapy would have otherwise been chosen for an at-risk, native valve population without immunocompromise [109].

The prognostic implications of vegetations identified by echocardiographic studies remain controversial. Some recent studies have indicated an increased risk of embolization in patients with vegetations greater than or equal to 10 mm in size, particularly in patients with mitral valve disease [105,106]. Still others have found that the predictive value of size for embolization depended on the organism and the mobility of the vegetation [105,106,110]. Most investigators agree that the presence of a vegetation alone is not an independent indication for valve replacement [105,106]. However, echocardiography may be useful for stratifying patients to high-risk subgroups where early surgery should be considered [105,106,110].

DIFFERENTIAL DIAGNOSIS

By far, the most common difficulty confronting the present-day practitioner is deciding which episodes of bacteremia represent endocarditis. The question becomes particularly acute in patients with intravascular foreign bodies, such as pacemakers, valves, and patches, and when the organism is *S. aureus*. The approach to this problem must take into account the propensity for the foreign body to become infected, the propensity of the organism to cause endocarditis, and the duration of bacteremia. Because sustained bacteremia characterizes infection of endovascular sites, the longer the bacteremia lasts, the greater the concern for an endothelial origin. In addition, even if the origin is distant and known, the longer the organisms circulate, the greater is the risk that they have settled out and seeded the intravascular foreign body secondarily.

Prosthetic valves, both mechanical and of biologic origin, have a very high risk of becoming infected, whereas permanent pacemakers (PPMs), once endothelialized, appear to carry a relatively low risk. Infection usually occurs at the skin-catheter junction and thus is most likely to invade the circulation when the vessel is in close proximity to the skin wound. However, in patients with a PPM, sustained bacteremia without an obvious focus implies infection of the pacemaker electrode, the tricuspid valve, or fibrotic endocardial regions in contact with the electrode tip [111].

Enteric Gram-negative bacilli are among the most common blood culture isolates at most hospitals but are less common as a cause of endocarditis (see Table 80.1). Notable exceptions to this characterization of enteric Gram-negative bacilli are salmonellae, particularly *S. typhimurium* and *S. choleraesuis*, which seem to have an affinity for damaged vascular endothelium and have infected aortic aneurysms as well as cardiac devices [112]. AIDS patients older than 50 years who develop salmonella bacteremia in the setting of predisposing valvular disease appear to be at particular risk for endocarditis [48,113].

Nosocomial bacteremia with Gram-negative bacilli has been shown to constitute a risk for development of PVE. Fang et al. [114] found that 26% of new cases of PVE occurred in patients who developed nosocomial Gram-negative bacteremia, in most cases from an identifiable portal of entry. Thus, patients with Gram-negative bacteremia in the setting of a prosthetic valve should receive antibiotic therapy adequate for possible endocarditis.

SAB always raises the question of whether treatment as endocarditis is warranted. A classic study reported that 64% of all bacteremias with *S. aureus* from 1940 to 1954 represented endocarditis, proved by autopsy in 38% of cases [115]. A subsequent report from the same center defined 16% of 134 patients with SAB from 1975 to 1977 as having definite or probable endocarditis [116]. These and other studies have amply demonstrated the ability of *S. aureus* to produce endocarditis on a valve previously presumed normal and have shown that established endocarditis may be found at postmortem examination in patients in whom no murmur was ever heard during their lifetime [43,115]. The changing demographics of staphylococcal endocarditis have been discussed in detail in the "Etiology" section of this chapter.

The absence of a primary focus appears to be a powerful predictor of endocarditis in community-acquired staphylococcal bacteremia [43,117]. Injection drug users are also at high risk for endocarditis and metastatic abscesses, and SAB should be treated in a fashion appropriate to endocarditis whenever it occurs in this group.

TEE has been valuable in identifying which patients have endocarditis in the setting of staphylococcal bacteremia [40,109,118]. IE has been shown to be clinically occult in a high proportion of patients with staphylococcal bacteremia [119]. Several studies support the use of a 2-week course of antibiotic therapy for catheter-associated SAB in patients at low risk for endocarditis. This would include patients without valvular heart disease (or prosthetic valves) and in whom the catheter has been removed promptly, subsequent blood cultures are negative, defervescence occurred within 72 hours, and TEE is normal [109,118,120]. Failures may still occur in patients assessed as low risk using these criteria in up to 16% of cases [120], with a range of 5% to 24% of patients with catheter-associated bacteremia presenting with recurrences, usually within 10 weeks of discontinuing therapy [121,122]. Clearly, patients who have prolonged fever or bacteremia after catheter removal should receive the longer course of antibiotic therapy because of the high mortality with catheter-associated *S. aureus* endocarditis [41,121,122]. All patients with SAB whether treated with short or longer courses of therapy should be followed closely for at least 3 months following treatment, preferably by an infectious diseases specialist [123].

The overall mortality rate for staphylococcal endocarditis in one multicenter study ranged from 16.7% to 23.7% [41]. Overall mortality rates of 36% to 48% have been reported in the last decade [124]. In contrast, human immunodeficiency virus (HIV)–seronegative parenteral drug users with this disease have a 2% to 4% mortality rate, although considerable morbidity, including congestive heart failure, occurs in 23% [124]. The more favorable outcome of addicts is generally attributed to their younger age and absence of underlying systemic illness, as well as the location of their valve involvement (right-sided valvular disease). In the HIV-seropositive injection drug user, mortality is related to the degree of immunosuppression [125]. In one study, in patients with CD4 counts of 200 or more, there was no difference in mortality between HIV-positive and HIV-negative individuals and mortality was directly related to the valve involved [124].

The epidemiology of enterococcal bacteremia has also changed [126]. Enterococci have emerged as major causes of healthcare-associated infections and in so doing have become increasingly resistant to antimicrobial agents, most importantly the penicillins, aminoglycosides, and glycopeptides [16,126–128]. Frequently, the enterococcus occurs in polymicrobial bacteremic infections along with enteric Gram-negative bacilli [128]. Mortality attributed to bacteremia is high, ranging from 13% to 42%, and seems to correlate directly with the severity of underlying illness as well as with antimicrobial resistance [128,129]. Higher mortality rates are seen among patients infected with strains that have high-level aminoglycoside resistance and resistance to vancomycin [128–130].

Two case series of patients with enterococcal bacteremia examined the risk factors for development of endocarditis [126,127]. These studies refute previous reports that nosocomial bacteremia and polymicrobial infections with enterococci are rarely associated with endocarditis. In both studies, *E. faecalis* was the predominant enterococcal species. Approximately 60% of the patients had nosocomial infections and polymicrobial bacteremia varied from 17% to 37%. Factors that were significantly associated with endocarditis included three or more positive blood cultures, the presence of a prosthetic valve, underlying valvular disease, and infection with *E. faecalis* [126,127].

INFECTIONS OF CARDIOVASCULAR IMPLANTABLE ELECTRONIC DEVICES: PACEMAKERS, AUTOMATIC IMPLANTABLE CARDIOVERTER DEFIBRILLATORS, AND VENTRICULAR-ASSIST DEVICES

Cardiovascular implantable electronic devices (CIEDs) are essential in the management of cardiac disease, and their use has increased significantly in the United States [131]. A recent population-based survey on the use of CIEDs reported that 70% of device recipients are elderly and many of these patients have multiple coexisting illnesses placing them at risk for CIED infections [132]. Despite improvements in the technology and greater ease of implantation, CIED infections appear to be increasing with the probability of infection being higher among patients with implantable cardioverter defibrillators (ICDs) than with PPMs [131,133].

Several recent studies have identified risk factors for PPM infection including long-term corticosteroid use, the presence of more than 2 pacing leads versus 2 leads, fever within 24 hours of implantation, early reinterventions, and the use of temporary pacing before the implantation [134,135]. Other patients at risk include those individuals with diabetes mellitus, renal dysfunction, heart failure, and oral anticoagulant use [131]. All of the above studies show a lowered risk of infection when patients are given perioperative antimicrobial prophylaxis [131,134,135].

Infections of pacemakers can be divided into the following distinct syndromes:

1. Generator pocket infections, which tend to occur within 2 months of surgery and are usually caused by *S. aureus*.
2. Infections associated with the lead wire and electrode, which generally present months later and more typically are caused by CoNS.
3. Endocarditis, which usually follows contiguous spread of infection along the pacer system.

Local erythema, erosion over the generator site, or drainage characterizes pocket infections, whereas electrode infections and endocarditis present more typically with sepsis and sustained bacteremia. In cases of pacemaker endocarditis, TEE is a useful diagnostic tool for defining the pacemaker as the source of bacteremia by visualizing vegetations on the leads or the tricuspid valve [103,136].

Infections that involve pacemaker wires and electrodes are almost never cured with antibiotics alone, and the entire system should be removed [131,136]. This usually can be accomplished in a one-stage procedure in which the old system is removed and the new system placed at a site remote from the infection (usually the contralateral side), followed by a course of antibiotics [131]. However, new lead placement should probably be delayed until blood cultures have been negative for 72 hours in cases of bacteremia [131]. The optimal duration of antimicrobial therapy depends upon the extent of infection and whether bacteremia is present. Short-course therapy following extraction is possible with infections confined to the pacer pocket and in the absence of bacteremia, whereas much longer duration of treatment is essential in patients with bacteremia. Patients with SAB and no obvious source should have all hardware removed. Guidelines for management are discussed in detail in reference [131].

Removal of the old system may not always be easy to accomplish. Sometimes defective or infected electrodes become firmly enclosed by fibrous tissue and are adherent to the vessel

endothelium, precluding easy extraction through the venous system. Removal of a retained wire using traction devices has been successful in some instances, but serious complications such as avulsion of the tricuspid valve and creation of atrioventricular fistulae have been reported [136].

Specialized tools have been developed to remove leads from fibrotic tissue. The newest technologies are laser sheath devices. These consist of a hollow core that slides over the lead. An optical device at the proximal end of the core inserted into a laser generates pulses of ultraviolet light at various calibrated intensities. An outer sheath is loaded onto the laser sheath core prior to the procedure [137]. A multicenter study reviewed the experience with laser sheath extraction in the United States where 1,684 patients (2,561 leads) were treated with a laser sheath [137]. Complete success, defined as removal of all lead material from the vasculature, was seen in 90% of the patients. There was complete failure of lead extraction in 7% of the procedures attempted. Major complications such as tamponade and hemothorax were seen in 1.9% of patients with death occurring in 10 cases, and 1.4% of patients experienced a "minor" complication such as perforation or myocardial avulsion. The most predictive factor in failure to remove a lead by this procedure was lead implant duration of more than 10 years. Cardiopulmonary bypass surgery with dissection of the electrode is recommended for patients who can tolerate surgery when the measures discussed earlier are not successful [136].

Infection is one of the most serious complications of automatic implantable cardioverter defibrillators (AICDs). Infection rates of older AICDs, in which one of the electrodes is a surgically implanted epicardial patch, range from 1% to 7% [138]. Early infections typically involve the generator pocket and are caused by *S. aureus* [138]. Late infections tend to involve the patch with resultant purulent pericarditis, usually caused by CoNS and corynebacteria [139]. There is now agreement that these infections, whether early or late, require removal of the entire system [131,139]. Radical debridement of the pericardium is necessary if infection extends beyond the electrode patch capsule [139]. Prolonged antibiotic therapy (i.e., 6 weeks) follows these procedures. Reimplantation of the generator following disinfection and appropriate gas sterilization using new electrodes and wires after the patient has been on antibiotic therapy for 2 weeks has been successful [138] but is not recommended [131].

More recent AICDs use intracardiac defibrillating electrodes placed transvenously; management of infections involving these systems is similar to that of PPMs [131].

Ventricular-assist devices have revolutionized the management of patients with end-stage cardiac pump failure. They may be used temporarily in patients who are expected to have recovery of natural heart function, as a "bridge" in the group who are awaiting cardiac transplantation and more recently for destination therapy in patients ineligible for transplantation [140]. A ventricular-assist device consists of an encased pumping chamber usually placed in a preperitoneal or intra-abdominal position, a driveline tunneled to an exit point in the lower quadrant, and inflow and outflow conduits with unidirectional valves attached with a Dacron graft to the left ventricular apex and the ascending aorta, respectively [140].

Incidence of infection following left ventricular assist device (LVAD) implantation ranges from 18% to 59% and most infections occur between 2 weeks and 2 months of implantation [140]. Infections range in severity from local driveline exit site infection to pocket infection and bacteremia. The most serious of these infections is LVAD endocarditis, defined as infection of the LVAD surface or valves associated with persistent bacteremia or fungemia [140]. Clinical features include persistent fever, cachexia, septic cerebral embolization, and device failure [140,141]. Pathogens are typical nosocomial organisms such as *S. epidermidis*, *S. aureus*, enterococci, *Candida* sp, *Pseudomonas aeruginosa*, and other Gram-negative bacilli [140]. Mortality with LVAD endocarditis is high, approaching 50% in one series [141]. Treatment requires explantation of the device, prolonged antibiotics, and, often, emergent transplantation. Data indicate that patients with LVAD-related infections may be successfully transplanted, but reports are conflicting regarding posttransplantation survival [140]. Operative cultures and pathological examination of the LVAD at the time of transplantation can be used to guide therapy postoperatively [140].

TREATMENT

Treatment of IE encompasses antimicrobial therapy, close clinical monitoring, and the decision as to whether and when surgical intervention should be undertaken. In a consecutive series of patients admitted to medical intensive care units at a single hospital in France between 1993 and 2000, the in-hospital mortality rate was 45% (102 of 228) [142]. In an international collaborative study on native valve endocarditis managed between 2000 and 2005 at 61 centers in 28 countries, the in-hospital mortality was 143 of 1,065 (13%) in patients with community-associated disease and 138 of 557 (25%) in patients with healthcare-associated infection [16]. Mortality in prosthetic-valve endocarditis is higher and ranges from 13% to 45% [143]. In the years since 2000, antimicrobial resistance has increased among the usual causative organisms, particularly staphylococci and enterococci, increasing the challenge of treating these infections.

Antimicrobial Therapy

Antimicrobials used to treat IE must provide bactericidal activity in the bloodstream, bathing the infected vegetation and heart valve, since neither possesses an intrinsic vascular supply, and bacteria within the vegetation may be shielded by the surrounding fibrin–platelet thrombus. Certain organisms also produce a slime around indwelling devices that provides a further barrier to antimicrobial penetration and alters killing conditions. In vitro and animal model systems can suggest potential approaches to therapy, but clinical outcomes are the final arbiter of whether a particular drug or combination of drugs works in endocarditis. There have been very few controlled clinical trials [144–147]. Rather, regimens have been evaluated by comparing cure rates to those expected. In the clearest case, "Bacteriologic cure rates $\geq$98% may be anticipated in patients who complete 4 weeks of therapy with parenteral penicillin or ceftriaxone for endocarditis caused by highly penicillin-susceptible viridans group streptococci or *S. bovis* group" [87]. For other etiologies of IE, the expectation of success in therapy is less uniform. Extensive reviews of published data and the clinical wisdom of experts in the field provide the basis for therapeutic recommendations in various guidelines ([87], United States; [107], Europe; [148], United Kingdom).

In the following discussion, we review the major US recommendations [87], but urge that the reader consult the most up-to-date version of them at the time of need and take care to note the specifics of the organism, valve type, and dosing recommendations (see reference [87] for Web site address). As an example, for the highly penicillin-susceptible viridans group streptococci or *S. bovis* mentioned above (penicillin MIC $\leq$0.12 μg per mL), the dose of aqueous crystalline penicillin G is 12 to 18 million units IV divided into four to six daily doses, or ceftriaxone 2 g IV may be given as a single daily dose. A randomized controlled trial has shown that the addition of

gentamicin, 3 mg per kg IV once daily, given in close temporal proximity to the dose of the cell-wall active agent (penicillin or ceftriaxone), can reduce the duration of treatment to 2 weeks in patients without cardiac complications or extracardiac sites of infection [144]. For prosthetic valve infection, 6-week therapy with the cell-wall active agent is recommended, and gentamicin is optional. For strains with MIC greater than 0.12 but less than or equal to 0.5 μg per mL, the penicillin dose is higher (18 to 24 million units per day), short-course therapy is not an option, and gentamicin is recommended for the first 2 weeks in native valve endocarditis and for the entire 6-week course in prosthetic valve disease. Ampicillin, 2 g IV every 4 hours, may be used in place of penicillin in all of the above. Vancomycin is recommended for patients with endocarditis due to these organisms only if they are unable to tolerate penicillin or ceftriaxone, in which case gentamicin is not given. The vancomycin dose is 15 mg per kg IV every 12 hours, adjusted to yield peak levels of 30 to 45 μg per mL and trough levels of 10 to 15 μg per mL (and is the same for all other organisms causing endocarditis). Desensitization to a β-lactam antibiotic, rather than use of vancomycin, should be strongly considered in patients with anaphylactic β-lactam allergies.

Most centers must now use vancomycin as the initial therapy for suspected *S. aureus* infection, despite slower killing and inferior clinical response, due to the frequency of oxacillin resistance both in healthcare-associated and community-acquired strains. Empiric vancomycin should be changed to nafcillin or oxacillin, 2 g IV every 4 hours (or cefazolin, 2 g IV every 8 hours, for patients with nonanaphylactoid type of β-lactam hypersensitivity) when *S. aureus* is determined to be susceptible to oxacillin; desensitization to oxacillin or nafcillin should be strongly considered in patients with anaphylactic β-lactam allergies. Controlled trials have shown that the addition of gentamicin does not improve outcome in native valve *S. aureus* endocarditis [145–147]. Recent data also suggest that even short courses of low doses of gentamicin are associated with nephrotoxicity in patients with SAB and endocarditis, particularly in patients with any degree of baseline renal dysfunction, advanced age, or diabetes [149]. If gentamicin is used at all, it should be given only for the first 3 to 5 days, in two or three equally divided doses totaling 3 mg per kg per 24 hours [87]. However, gentamicin is recommended for the first 2 weeks of therapy of PVE caused by gentamicin-susceptible staphylococci. If the organism is gentamicin resistant but susceptible to a fluoroquinolone, then a fluoroquinolone should be used for PVE. Rifampin has a special role in PVE because of its ability to sterilize devices (probably due to activity within the slime) and 300 mg by mouth (preferred) or IV every 8 hours should be given for the entirety of the course, if the isolate is susceptible. The usual duration of therapy for *S. aureus* endocarditis is 4 weeks for uncomplicated cases, 6 weeks for complicated cases, and 6 or more weeks for PVE, although a 2-week course of nafcillin or oxacillin can be used in selected cases of native valve *S. aureus* endocarditis limited to the right side of the heart [87].

For MRSA endocarditis, vancomycin is still the current first-line recommendation. Daptomycin is an alternative therapy based on a recent trial that found that daptomycin was not inferior to standard therapy (as described earlier) for SAB and right-sided endocarditis [150]. The dose studied was 6 mg per kg daily, although some experts recommend consideration of high doses of 8 to 12 mg per kg daily for endocarditis because of the finding that 5% of patients in the daptomycin arm had emergence of reduced susceptibility to daptomycin during treatment [150,151,151A]. However, it is unknown whether higher doses of daptomycin prevent emergence of resistance or improve outcomes. The addition of synergistic gentamicin is not thought to be more useful in this situation than for oxacillin-susceptible disease, and coadministration with vancomycin may increase toxicity. Addition of rifampin to vancomycin therapy is not recommended due to a lack of benefit on either survival or duration of bacteremia [152]. Although the optimal approach is unknown, for patients who do not respond to standard therapies, a variety of salvage approaches have been attempted including addition of or switches to agents such as trimethoprim/sulfamethoxazole, linezolid, and quinupristin/dalfopristin. CoNS, best known for causing prosthetic valve and other device infections, should be assumed to be oxacillin resistant until proven otherwise by rigorous testing (not available in all laboratories). The same antimicrobial regimens are recommended as for MRSA, although there are occasional reports of successful therapy with linezolid [153,154].

Enterococcal endocarditis is one instance where combination of penicillin, ampicillin, or vancomycin with either streptomycin or gentamicin is required for clinical efficacy [155]. With the exception of piperacillin, other cell-wall active agents (oxacillin, nafcillin, ticarcillin, aztreonam, cephalosporins, cephamycins, and meropenem) cannot be used for this purpose, nor can the other aminoglycosides. The penicillin dose is 18 to 30 million units per day administered either as a continuous infusion or as 3 to 5 million units IV every 4 hours. The ampicillin dose is 2 g IV every 4 hours. Either of these agents should be used in preference to vancomycin unless the organism is resistant or the patient cannot tolerate the β-lactam. Gentamicin is administered in three equally divided doses at 1 mg per kg or as required to achieve peak serum concentrations of 3 to 4 μg per mL and trough concentration of less than 1 μg per mL. For enterococci with high-level resistance (MIC $\geq$500 μg per mL) to gentamicin but not to streptomycin, streptomycin is given at a dose of 15 mg per kg IV or intramuscular every 12 hours. When combination therapy with a β-lactam and gentamicin or streptomycin is used for native valve endocarditis of less than 3 months' duration, the recommended duration for both components of therapy is 4 weeks. For disease of longer duration, prosthetic-valve involvement, or vancomycin-based therapy, treatment is prolonged to 6 weeks with both drugs. A report from Sweden describes success with aminoglycoside therapy given for a median of 15 days [156]; although the guidelines do not yet recommend that approach, they do point out that the information may help in deciding whether to continue an aminoglycoside in the face of nephro- or ototoxicity [87].

Enterococci with high-level resistance to streptomycin and gentamicin, as well as strains resistant to penicillin and/or vancomycin, pose additional challenges for treatment. Resistance to ampicillin and penicillin mediated by β-lactamases may be overcome by the use of ampicillin–sulbactam, 3 g IV every 6 hours for 6 weeks. Testing at high inocula may be necessary to detect inducible β-lactamases; these organisms are frequently high-level resistant to streptomycin and gentamicin as well, in which case the duration of ampicillin–sulbactam therapy should be extended beyond 6 weeks. Double β-lactam combinations (ampicillin plus either ceftriaxone or imipenem) may provide synergistic activity in some cases of high-level aminoglycoside resistance but should be supported by in vitro studies using the patient's isolate [87,157]. Enterococci with intrinsic penicillin resistance are treated with vancomycin plus gentamicin for 6 weeks.

Endocarditis due to vancomycin-resistant enterococci (VRE) warrants infectious disease consultation and may require specialized laboratory investigation [87,107,148]. A recent review identified 19 reported cases, 14 of whom survived [158]. Three patients had organisms susceptible to ampicillin and with high-level susceptibility to gentamicin; all of these responded to combination therapy with those two drugs (one

patient also had valve replacement). The others received a variety of regimens directed by the susceptibility of their organisms; four had surgery. The surprisingly high survival in this series may reflect a bias toward reporting successful outcomes, but there was also considerable use of newer agents. Daptomycin has in vitro activity against VRE, and time–kill curves demonstrated synergy with gentamicin and rifampin in a case where that combination was used [158]. Quinupristin–dalfopristin is active only against *E. faecium*, and in this series was never the sole component of successful therapy [158]. The guidelines note that quinupristin–dalfopristin was effective in 4 out of 9 patients with endocarditis [87], but the compassionate-plea program reported clinical and bacteriologic response in only 2 out of 10 (0 of 1 evaluable) patients [159]. Linezolid 600 mg IV or orally every 12 hours proved successful in 10 (77%) of 13 evaluable cases of VRE endocarditis (9 courses of therapy were not evaluable) [160].

First-choice therapy for HACEK endocarditis is ceftriaxone 2 g IV every 24 hours (or other third- or fourth-generation cephalosporin) for 4 weeks in native valve disease and 6 weeks with prosthetic valves. Ampicillin–sulbactam may be used, but the combination of ampicillin and gentamicin is no longer recommended. Therapeutic failures with this combination in *A. actinomycetemcomitans* endocarditis include a nearly 30% mortality in one series [161,162]. Ciprofloxacin at 500 mg orally every 12 hours or 400 mg IV every 8 hours is the suggested alternative for patients who cannot tolerate ceftriaxone or ampicillin–sulbactam.

The choice of empiric therapy while awaiting results of blood cultures should reflect the clinical presentation and epidemiologic risks of the patient. Patients who present with acute native valve endocarditis should receive treatment appropriate for *S. aureus* and possibly enterococcus, whereas those with subacute presentation should be treated for viridans group streptococci and HACEK organisms, as well as the possibility of *S. aureus*. The European guidelines provide the clearest guidance for this situation and specify vancomycin plus gentamicin for native valve endocarditis requiring urgent therapy, or when cultures remain negative, and vancomycin, rifampin, and gentamicin for PVE [107]. However, as previously mentioned, the use of gentamicin must be weighed against the potential for increased nephrotoxicity [149]. The U.S. guidelines recommend addition of cefepime (2 g every 8 hours IV) in culture-negative PVE with onset within 2 months of surgery, directed at nosocomially acquired Gram-negative bacilli [87], and that possibility should also be considered in the choice of empiric therapy. For late-onset disease on prosthetic valves, many would concur with a recommendation for therapy appropriate for MRSA (vancomycin, rifampin, and gentamicin) with the possible addition of ceftriaxone [87].

When culture-negative endocarditis more likely represents infection with a fastidious or noncultivable organism than antibiotic interference with blood cultures, treatment directed against *Bartonella* (gentamicin plus doxycycline) should be added to ceftriaxone (for native valve disease) [87]. In the United Kingdom and Europe, Q fever (*C. burnetii*) causes a larger proportion of cases of endocarditis than in the United States, usually culture negative but proved by serology. Therapy for this pathogen is doxycycline plus ciprofloxacin or rifampin [107]. Duration of treatment is at least 3 years [148], perhaps lifelong after valve replacement [107]. *Candida* endocarditis has generally been regarded as an indication for valve replacement surgery, but often the patients who get this infection have been too ill for surgery. Factors associated with survival of some of these high-risk patients in the absence of cardiac surgery include receiving initial combination antifungal therapy (most often amphotericin B plus 5-flucytosine) followed by long-term suppressive therapy with fluconazole [163,164]. There are also case reports of good outcome in patients treated with caspofungin, including four who did not have valve replacement [165–167].

Supportive Care and Monitoring

Careful clinical monitoring of the patient on therapy for endocarditis includes surveillance for fever, evidence of congestive heart failure or other cardiac complication, metastatic infection, adverse effects of antimicrobial drugs (and levels, when appropriate), change in renal function, and superinfection. Repeat blood cultures should be obtained every 48 hours until they are repeatedly sterile. The duration of antimicrobial therapy is counted from the first day of sustained blood culture negativity [87]. In aortic and mitral valve endocarditis, serial ECGs should be obtained to look for prolongation of the PR interval or other conduction abnormality that would signal invasion of the interventricular septum by the infection. Echocardiographic imaging, should be repeated at 7 to 10 days into therapy, to look for enlarging vegetations or other complications and to better define disease in patients whose initial echocardiography was unrevealing. This study should also be repeated at the end of therapy as the patient's new baseline [87,107].

Recrudescence of fever after initial resolution most often indicates a new problem outside the heart, such as catheter-associated sepsis, drug fever, or antibiotic-associated *Clostridium difficile* colitis, but superinfection of the endocarditic valve may occur. Unless there is another immediately obvious cause, persistent or recurrent fever should prompt repeat echocardiography.

The possible need for cardiac surgery mandates discontinuation of warfarin and substitution of heparin when the diagnosis of endocarditis is made in patients on anticoagulant therapy for prosthetic valves or other indications [87,107]. Anticoagulation in endocarditis carries the risk of converting bland emboli (infarcts) to hemorrhagic ones, and thus should be carefully monitored and continued with caution. When emboli with hemorrhage occur, anticoagulant therapy should be withheld for a period of time. The risk of central nervous system (CNS) hemorrhage in *S. aureus* PVE is so high that some recommend discontinuation of all anticoagulation during the acute phase of this illness [168].

Role of Cardiac Surgery

At times, failure of antibiotics to sterilize the blood necessitates surgical debridement and removal of the infected focus—the valve. Even if bacteriologic cure is achieved, some patients have sufficient valvular damage that they will die of hemodynamic compromise unless a valve is replaced. The surprisingly favorable outcomes of a number of patients operated on in these desperate circumstances have led to consideration of cardiac surgery much earlier in the course of endocarditis [169–172]. The two indications for surgery already mentioned—microbiologic failure and congestive heart failure—are now well accepted. The challenge is to identify patients who would eventually meet these criteria before their clinical condition deteriorates.

Harbingers of microbiologic failure include difficult-to-treat and aggressive organisms, such as *S. lugdunensis*, *S. aureus*, *P. aeruginosa* or other Gram-negative bacilli involving the aortic or mitral valve, and fungi, particularly molds. *C. burnetii*, *Bartonella*, *Brucella*, and other unusual organisms associated with true culture-negative endocarditis are also difficult to eradicate with antimicrobial therapy alone. The risk of

microbiologic failure or relapse is elevated in the presence of prosthetic material, resulting in the recommendation for valve replacement in most cases of early PVE and the necessity of removing infected intracardiac devices such as pacemakers and other CIEDs. Conventional blood cultures should become sterile within 7 days after the institution of appropriate antibiotic therapy [78,87,167,172]. The median time for clearance of *S. aureus* varies in different studies but may be as long as 9 days [146], placing this organism among those for which cardiac surgery should be considered. Patients should defervesce within 9 to 10 days. Persistent fever may indicate continued active infection, myocardial abscess, or embolic complication.

Many patients with endocarditis have preexisting congestive failure as a result of their underlying valvular disease, but new-onset or worsening heart failure carries an ominous prognosis—a mortality of 56% in one series [171]. Urgent surgery is indicated for these patients, and a number of authors have noted that medical stabilization may be impossible once severe progressive failure begins [171]. Acute aortic and mitral regurgitation, due to perforation, valve rupture, or paravalvular leak (in the case of PVE), are frequent mechanisms of congestive failure [172]. Valvular obstruction is less common but does occur on prosthetic valves and is an equally urgent indication for surgery. Rupture of sinus of Valsalva aneurysm into the right heart or pericardium also mandates surgery [173]. It cannot be overemphasized that once surgery is clearly indicated it should not be delayed, because of the unpredictability of the clinical course and the increasing risk of the operation as failure progresses [171,172,174].

Echocardiography may be very helpful in defining the presence of complications that do require surgery, including destruction of the valve or extension of infection beyond the valve ring as a myocardial abscess. Myocardial abscess may be the reason for prolonged fever [172,175], lead to conduction defects [86,172], or cavitate into the pericardium with resultant purulent pericarditis [172]. Myocardial abscess is generally an indication for surgery to extirpate all infected tissue as well as correct the accompanying hemodynamic abnormalities [87,107,172,173]. Occasionally, abscesses that are less than 1 cm, that do not progress on therapy, and that are not complicated by disruption of other structures may be followed with serial TEE and do not require surgery [87,172].

The risk of embolization is often viewed as an indication for surgery, but this risk diminishes greatly over the first 2 weeks of antimicrobial therapy [87,107,172,173]. In one recent large study, 56% of embolic events in 629 patients with IE occurred before hospital admission or on the day antibiotic treatment started [176], and in another, only 7.3% of 384 patients had new embolic events after the initiation of therapy [177]. The difficulty is in defining when there is sufficient risk of clinically significant systemic or cerebral embolization to justify cardiac surgery not required for any other reason but before serious target organ damage has already occurred. There have been many attempts to establish echocardiographic predictors of embolization; vegetation length more than 10 mm by TEE was associated with a ninefold increase in risk of systemic or cerebral embolization on therapy and "severe mobility," defined as "prolapsing vegetation that crosses the coaptation plane of the leaflets during the cardiac cycle," with a 2.4-fold increase [177]. The U.S. guidelines deem one or more embolic events during the first 2 weeks of therapy a class I indication for surgery (condition for which there is evidence, general agreement, or both that a given procedure or treatment is useful and effective) [87]. Anterior mitral valve leaflet vegetations, especially those greater than 10 mm, and the presence of persistent vegetations after systemic embolization are class IIa indications (the weight of evidence/opinion is in favor of usefulness/efficacy), but increase in size of vegetation despite therapy is less well established as an indication for surgery [87]. European guidelines advise consideration of surgery for recurrent emboli despite adequate antibiotic therapy or mobile vegetation greater than 10 mm before or during the first week of antibiotic therapy [107]. U.S. experts recommend delaying valve surgery for a minimum of 2 weeks after a CNS embolic event [87,172] and at least a month after CNS hemorrhage [172], but European guidelines suggest that surgery can be performed within the first 72 hours of CNS embolism if a computed tomographic scan of the brain performed immediately preoperatively shows no hemorrhage [107].

Right-sided endocarditis requires surgical intervention much less frequently than left-sided disease. Persistent fever for longer than 3 weeks is an indication for surgery, but pulmonary emboli are not [107,172]. In patients with isolated right-sided lesions, most often addicts, tricuspid vegetectomy, valve repair, or valvulectomy may permit cure of endocarditis due to resistant organisms without the risk of subsequent PVE. In the absence of pulmonary hypertension, tricuspid regurgitation may be tolerated without valve replacement [107,172].

The surgical approach for endocarditis is changing, with increasing interest in vegetectomy and valve repair rather than replacement. Repair is most often performed on the mitral valve and offers improved outcome over replacement [178,179]. Complete debridement of all infected tissue is mandatory. The European guidelines advocate consideration of early surgery for "kissing mitral vegetation," defined as secondary infection of the mitral valve by contact with a large aortic vegetation prolapsing during diastole, to preserve the structure and function of the native mitral valve, implying that the surgical procedure would be vegetectomy or valve repair, not replacement [107]. The reconstructive techniques developed for valve repair may also facilitate the surgical approach in cases with extensive perivalvular infection, where homografts and pericardial patches may be used to construct an annulus to which to attach a prosthetic valve when large amounts of normal tissue have been lost. The current view is that the risk of recurrent endocarditis on bioprosthetic and mechanical valve replacements is

TABLE 80.4

INDICATIONS FOR CONSIDERATION OF SURGERY IN PATIENTS WITH INFECTIVE ENDOCARDITIS

Indications	Evidence Grade
Congestive heart failure	I B
Fungal or highly resistant organisms	I B
Echocardiographic evidence of valve dehiscence, perforation, rupture, fistula, or large perivalvular abscess	I B
Mobile vegetation >10 mm (particularly on the anterior leaflet of the MV) or persistent vegetation after systemic embolization	IIa B
Increase in vegetation size on appropriate therapy	IIb C

I, evidence or general agreement that cardiac surgery is useful and effective; IIa, inconclusive or conflicting evidence or a divergence of opinion about the usefulness/efficacy of cardiac surgery, but weight of evidence/opinion of the majority is in favor; IIb, inconclusive or conflicting evidence or a divergence of opinion; lack of clear consensus on the basis of evidence/opinion of the majority; Level of evidence B, data derived from a single randomized trial or nonrandomized studies; Level of evidence C, consensus of opinion of experts; MV, mitral valve. Adapted from reference 87.

TABLE 80.5

SUMMARY RECOMMENDATIONS FOR MANAGEMENT OF ENDOCARDITIS BASED ON RANDOMIZED CLINICAL TRIALS

- Native valve endocarditis caused by highly penicillin-susceptible viridans streptococci or *Streptococcus bovis* is effectively treated with a 2-week regimen of ceftriaxone 2 g every 24 h IV with gentamicin 3 mg/kg/24 h IV given in a single dose [144]
- Addition of 2 weeks of gentamicin to 4 weeks of oxacillin or nafcillin therapy for methicillin-susceptible *Staphylococcus aureus* endocarditis does not improve outcome [145,146]
- Uncomplicated tricuspid valve endocarditis caused by methicillin-susceptible *Staphylococcus aureus* is effectively treated with a 2-week regimen of either nafcillin or oxacillin 12 g/24 h IV in 4 to 6 equally divided doses ([87], based on a trial comparing cloxacillin 2 g IV q4h with and without gentamicin 1 mg/kg IV q8h in injection drug users [147])

comparable, about 2% to 3% [87,107]. If valve cultures from surgery are negative, the duration of the antibiotic course originally planned should be completed, as long as it extends at least 7 to 15 days postoperatively. If intraoperative cultures are positive, the full recommended duration of antibiotics for the infecting organism should be administered counting from the day of surgery [87].

There is little difference in the clinical indications for surgery in native and PVE, but the proportion of patients requiring surgery is higher among those with prosthetic valves, approximately 50% [143,172,178,180–184]. Staphylococcal etiology and CNS embolization are uniformly identified as poor prognostic features. Early surgical intervention reduces the overall mortality of PVE [172,182,184]. More recent studies have identified patients with PVE in whom medical therapy has equivalent outcomes to surgery as those with late-onset streptococcal disease who have no significant heart failure, no new valvular regurgitation or other intracardiac complication, and no CNS or systemic embolization [144,180,181]. Most important is that cardiac surgical treatment reduces the mortality rate among patients with poor prognostic factors to the level experienced by the patients with more favorable disease characteristics [143].

Table 80.4 lists indications for surgery in patients with endocarditis by the strength of evidence supporting each indication [172,173,184]. Individual patient situations may modify the readiness to resort to surgery. For instance, in a patient with another condition that makes the risk of general anesthesia prohibitive, such as severe restrictive lung disease, one might elect to operate only in the event of congestive heart failure. The guidelines for surgical intervention are not absolute predictors of failure of medical management but overall can predict a low success rate.

Overall, therapy for endocarditis requires skillful manipulation of antibiotics and careful day-to-day judgment of the relative risks of expectant versus surgical management. It should be stressed that in cases with any adverse prognostic features, including all patients with staphylococcal or PVE, it is wise to make provisions for possible urgent surgery early in the course. This includes discussions of surgery with the patient and family and consultation with the cardiac surgical team. Table 80.5 provides a summary of recommendations for management of endocarditis supported by randomized controlled clinical trials.

CHAPTER 81 ■ INFECTIONS ASSOCIATED WITH VASCULAR CATHETERS

SUZANNE F. BRADLEY AND CAROL A. KAUFFMAN

Medical technology has led to the creation of a variety of indwelling vascular catheters that have greatly improved our ability to deliver care to critically ill patients, but also have led to increased risks of infection. It is estimated that more than 200 million intravascular devices will be inserted every year in the United States [1]. Approximately 250,000 to 500,000 episodes of healthcare-associated bloodstream infections occur per year in the United States, and are commonly associated with the use of central venous catheters. It is estimated that 12% to 25% of these device-related infections will result in death [1,2]. As a consequence of catheter-associated bloodstream infections, hospital length of stay is prolonged by 10 to 40 days, and mean attributable costs are increased by $18,432 ($3,592 to $34,410) per episode [1–3].

Guidelines for the prevention and treatment of catheter-associated infections have been published in the past few years [4–6]. Recommendations in this chapter are based on these published guidelines. The reader is referred to these publications for a more in-depth review of the topics of prevention and treatment of catheter-associated infections.

PATHOGENESIS

Foreign bodies that penetrate the cutaneous barriers of the host induce a chronic inflammatory response and are coated with host proteins, including fibronectin, fibrin, laminin, and others [7]. The coated catheter can then provide a niche for microorganisms that adhere by fimbriae and adhesins, which bind to surface receptors present on some of the coating proteins, or by electromagnetic interactions leading to the formation of biofilms within days of insertion [7,8].

Microorganisms gain entry to the catheter primarily at the insertion site. Particularly in catheters used for short term, there is a correlation between organisms isolated from the catheter and those obtained from the insertion site. Contamination of the catheter hub and ultimately the internal lumen of the catheter plays a larger role in the development of infections in catheters remaining in place for more than 1 month [7,8]. Less common are catheter-associated infections occurring as a result of hematogenous seeding from a distant focus of infection or from contaminated infusates [8].

DIAGNOSIS

Diagnostic Methods

The diagnosis of catheter-associated infection still relies primarily on the recognition of clinical signs and symptoms in a patient who has an intravascular device in place, absence of an alternative cause for those clinical findings, and microbiological evidence for infection [2]. The clinical signs noted in some, but not all, patients with a catheter-associated infection are development of warmth, erythema, and pain at the site of current or recent venous or arterial catheter placement. Patients with catheter-associated bloodstream infection generally have fever, with or without hypotension, and other signs of sepsis. Finding microorganisms on culture of a catheter in an asymptomatic patient is not indicative of infection, and conversely, impressive local findings may reflect only phlebitis or reaction to the infusate. Thus, differentiating catheter-associated infection from colonization of the catheter can be difficult, and no perfect diagnostic method has been established.

Blood Culture with Catheter Retention

Positive blood cultures in a patient who has an indwelling vascular catheter and who has no other source of infection raise the possibility of catheter-associated infection. A variety of approaches have been devised to help differentiate whether a positive blood culture represents catheter-associated infection or has arisen from another source. Quantitative cultures of blood taken simultaneously from the catheter and from peripheral blood that demonstrate a difference of more than threefold microorganisms from the catheter are probably the most accurate method to determine if catheter-associated infection is present without removing the catheter [1,2]. However, few, if any, clinical laboratories routinely perform quantitative blood cultures.

Differential time to positivity of blood cultures taken from a central line compared with those taken from a peripheral vein is another diagnostic method. Blood cultures obtained from an infected central catheter may turn positive a least 2 hours sooner than blood drawn simultaneously from a peripheral vein [2].

Another method that does not require the removal of the catheter involves culture of peripheral blood as well as the insertion site and hub. Growth of more than 15 colonies of the same organism from all three sites suggests short-term catheter-related infection [4,9].

It is important to minimize the possibility of contamination when obtaining blood for culture by having specifically trained personnel obtain the samples. Disinfection of the skin and hub using alcohol, tincture of iodine, or alcoholic chlorhexidine, but not povidone-iodine, is recommended. Blood samples taken from a peripheral vein are preferred as they are less likely to be contaminated than blood samples obtained from catheter hubs. However, all of the techniques listed above require sampling from the catheter as well as from a peripheral vein.

Catheter Culture Following Catheter Removal

Although very helpful in the diagnosis of catheter-associated infection, culture of the catheter necessitates removal of the catheter before the diagnosis can be made. For optimum culture, the catheter tip, or the introducer tip for pulmonary artery catheters, should be cultured. Quantitative cultures obtained

by vortexing or sonicating the catheter tip most accurately determine the numbers of microorganisms present on both the internal and external surfaces of the catheter. However, this method is not practical in the clinical setting [2].

Rolling the distal segment of the catheter on an agar plate yields semiquantitative results that compare favorably with quantitative methods and has gained the greatest acceptance. The presence of ≥15 bacterial colonies on an agar plate correlates significantly with the presence of local inflammation and signs and symptoms of bloodstream infection. No similar cutoff has been established when yeasts are grown from the catheter tip. Some patients with catheter-associated infection will have fewer colonies, and catheter tips from asymptomatic patients will sometimes yield ≥15 colonies. A drawback of this technique is that only the external portion of the catheter is cultured, not the lumen, which may be the primary site of infection in long-term catheters. The roll-plate technique is the recommended method for diagnosis of presumed infection in short-term catheters after they have been removed [2,4].

Definitions

Adherence to standardized definitions of catheter-related infection is critical to make informed comparisons among the myriad studies that have been performed in this area. Although definitions may vary slightly from investigator to investigator, consensus has been reached in recent years [2,4,5].

Catheter colonization: The patient has no signs and symptoms of infection but a quantitative or semiquantitative culture of the catheter tip or catheter hub yields significant growth of a microorganism.

Catheter-associated bloodstream infection: Bacteremia/fungemia in a patient who has an intravascular catheter in place and who has at least one positive blood culture taken from a peripheral vein, clinical manifestations of infection (fever, chills, and/or hypotension), and no apparent source except the catheter. Additionally, there should be evidence linking the catheter to the infection using one of the semiquantitative or quantitative techniques described earlier.

Exit site infection: These infections manifest erythema, induration, and/or tenderness within 2 cm of the catheter exit site, and exudate at the exit site yields a microorganism. There may or may not be concomitant bloodstream infection.

Tunnel infection: Tenderness, erythema, and/or induration are present more than 2 cm from the exit site along the subcutaneous tract of a tunneled catheter with or without concomitant bloodstream infection.

PREVENTION OF CATHETER-RELATED INFECTIONS

Catheter Insertion

Local Skin Flora

Regardless of the type of catheter inserted, the major risk factor for the development of catheter-associated infection is the breach of a major host defense against infection—the skin. Catheter-associated infections are usually due to normal skin flora, particularly Gram-positive cocci, such as coagulase-negative staphylococci and *Staphylococcus aureus*. However, the distribution of microorganisms on the skin varies. For example, Gram-negative bacilli, *Candida* species, and anaerobes are increased in the groin area and on the lower extremities [10].

The ecology of normal human flora is further altered by illness, hospitalization, and the presence of foreign bodies. The use of antimicrobial agents inhibits the growth of normal flora and contributes to the emergence of resistant Gram-negative bacilli, *S. aureus*, vancomycin-resistant enterococci, and yeasts. Patients who have a productive cough or a tracheostomy can easily contaminate their skin with organisms from their respiratory tract. The hands of healthcare personnel may facilitate the transfer of potential pathogens from patient to patient [6].

Choice of Insertion Site

The site of catheter insertion influences the risk of infection. Central venous catheters inserted in the internal jugular vein become infected more often than those in the subclavian vein, perhaps because of difficulties in dressing the area and contamination with respiratory secretions [5,11]. Catheter insertion in the lower extremities should be avoided in adults because of increased risk of phlebitis and infection in this area of poor blood flow [5,6]. Placement of femoral lines should be a last resort in emergent situations or when no other vascular access is available, and these lines should be removed as soon as possible [5].

Insertion Techniques

Catheter-associated phlebitis and infection are more likely to occur when catheters are inserted by inexperienced personnel rather than personnel who are trained in these techniques. Prospective, randomized trials have shown that strict adherence to sterile technique (i.e., mask, cap, and large sterile drape, gloves, and gown) is beneficial in preventing central venous catheter infections, and also highly cost effective [5,6]. The importance of sterile techniques using maximal barrier precautions for short-term central catheters cannot be overemphasized and should become a part of house staff training [5,6]. Use of a catheter checklist to ensure and document adherence to infection prevention practices at the time of insertion is recommended [6,12].

Ultrasound guidance for the insertion of central vascular catheters, especially internal jugular catheters, has been shown in a meta-analysis to decrease the risk of mechanical complications associated with placement [5]. A biodegradable collagen cuff impregnated with silver ions is commercially available to attach to short-term central venous catheters before insertion. Two initial randomized controlled trials showed protection against catheter-associated colonization and bacteremia, but subsequent trials have failed to show a decrease in infection rates [5,8]. Currently, it is recommended that these cuffs not be used [5].

Cutaneous Antisepsis

Several different antiseptics, 70% alcohol, chlorhexidine, and iodine-based solutions, have been found to reduce microbial contamination at the insertion site of the catheter [4,5]. Several studies and a meta-analysis have found that chlorhexidine-based aqueous or alcoholic solutions are superior to povidone-iodine solutions in reducing colonization at the catheter insertion site and catheter-associated bacteremia [5,13,14]. Current recommendations are to use 2% chlorhexidine gluconate for antisepsis of the insertion site, allowing it to dry before catheter insertion [5,6]. Chlorhexidine products have not been approved for children less than 2 months of age.

Antimicrobial ointments have been shown to increase the risk of infection with *Candida* and antibiotic-resistant bacteria and may affect the integrity of some catheters. With the exception of povidone-iodine ointment for some hemodialysis

catheters, routine use of ointments at the catheter insertion site is discouraged [5,6,15].

A chlorhexidine-impregnated patch (BIOPATCH, Ethicon, Somerville, NJ) has proved efficacious in reducing colonization at the catheter site, and in reducing bloodstream infections [8,16,17]. There currently are no firm recommendations as to whether this device should be routinely used with short-term central venous catheters [5]. However, a recent guideline suggests considering use of this patch when the rates of catheter-associated infection remain above target rates despite consistent use of evidence-based prevention bundles [6]. Use of these patches also should be considered in patients who have limited access and a history of recurrent catheter-associated infections and in those who have a heightened risk of severe sequelae if infection should occur, such as patients with recently implanted intravascular devices [6]. The use of systemic antibiotics as prophylaxis before the placement of central venous devices is strongly discouraged because selection for antibiotic-resistant microorganisms is highly likely [5,6].

Type of Catheter

Nontunneled Central Venous Catheters

These catheters are inserted into the subclavian vein, the internal jugular vein, and rarely the femoral vein. They can be single or multilumen, depending on the specific needs of each patient. Some studies, but not all, have shown that multilumen catheters are associated with a higher rate of colonization and infection than single-lumen catheters, particularly when used for an extended period of time [18–22].

Increased risk for infection, especially with multilumen catheters, occurs with the frequent manipulations that are required in the care of critically ill patients. In one study, only one of three lumens was used in most of the multilumen catheters that were inserted [21]. Therefore, it is recommended that a central venous catheter be chosen with the minimum number of ports or lumens required for the care of the patient [5]. It is recommended that the care of these multilumen lines be limited to a few well-trained personnel and that the catheter be changed to a single-lumen catheter if all the ports are no longer needed [5]. These catheters should be used predominantly in patients in the intensive care setting.

Antimicrobial Impregnated or Coated Central Venous Catheters

Numerous antimicrobial agents (tetracyclines, rifamycins, glycopeptides, β-lactams, micafungin), antiseptics (benzalkonium chloride, chlorhexidine, tridodecylmethylammonium chloride, iodine, gentian violet, and silver molecules), and antithrombotic agents (heparin, ethylenediaminetetraacetate [EDTA]) alone or in various combinations have been bound to polymer material or used to coat the surfaces of catheters in the hope of reducing colonization, thrombosis, and subsequent infection [2,8,23,24]. Heparin-coated catheters should not be used because of concerns for developing heparin-induced thrombocytopenia.

Minocycline/rifampin-coated catheters (Cook Medical, Bloomington, IN), chlorhexidine/silver sulfadiazine-coated catheters (Arrow International, Reading, PA), and a silver-platinum-carbon–impregnated catheter (Vantex CVC with Oligon, Edwards Life Sciences, Irvine, CA) are currently available. All of these catheters have been shown to reduce catheter-associated colonization [2,5,8,23,25]. In some controlled trials, the rates of catheter-associated bacteremia were sufficient to demonstrate significant reductions in infection rates when antimicrobial catheters were compared with standard catheters [2,5,8,26]. One study showed that a minocycline/rifampin-containing device was more effective at reducing both catheter colonization and catheter-associated bloodstream infections than a chlorhexidine/silver sulfadiazine-coated catheter [27]. However, that study was performed using the first-generation chlorhexidine/silver sulfadiazine catheter (ArrowGard) that was coated only on the external surface. Subsequent studies assessing the second-generation catheter that is coated on both external and internal surfaces (ArrowGard Plus) against the minocycline/rifampin catheter have not been performed.

Several meta-analyses have noted both reduced infection rates and costs when coated catheters are used for 5 to 14 days [2,23]. The recommendations are to strongly consider the use of antimicrobial-coated catheters for those adult patients who will likely require a central catheter for 5 to 14 days if the rates of catheter-associated bloodstream infections are unacceptably high in spite of adherence to other measures, such as maximal sterile barriers and use of chlorhexidine antisepsis [5]. Use of these catheters also should be considered for patients who have limited venous access and a history of catheter-associated bloodstream infection and for those with heightened risk for severe sequelae if they develop systemic infections, such as patients with recently implanted devices [6]. Each hospital must decide, based on their rates of catheter-associated bloodstream infection, whether the higher costs of purchasing antimicrobial-coated catheters are justified.

Peripherally Inserted Central Venous Catheters

Peripherally inserted central venous catheters (PICC) have become increasingly popular and appear to have lower rates of infectious complications when compared with other central venous catheters [2,4,5,8]. Initial insertion costs are lower than those for tunneled central venous catheters, but rates of mechanical complications and phlebitis are higher. These catheters must be inserted by specially trained healthcare workers or interventional radiologists. A PICC can be left in place for weeks to months as long as there is no malfunction, evidence of phlebitis, or infection.

Semipermanent Tunneled Catheters (Long-Term Central Venous Catheter)

In the 1970s, Broviac introduced a cuffed, silicone rubber central venous catheter for the purpose of hyperalimentation, and Hickman devised a similar catheter of larger gauge that allowed the administration and withdrawal of blood. The double-lumen catheter resulted when both Hickman and Broviac catheters were combined for the purpose of infusing parenteral nutrition solutions as well as other drugs. The risk of infection with semipermanent tunneled catheters appears to be low [2,4,28]. They are especially useful for administration of chemotherapy and other agents in cancer patients and in those requiring long-term parenteral nutrition. Routine use in the intensive care setting is not practical.

Pulmonary Artery Catheters

The risk of infection of percutaneously inserted heparin-bonded benzalkonium-impregnated pulmonary artery catheters appears to be low in those patients in whom the catheter requires little manipulation and is left in place for less than 7 days. The use of plastic sleeves to cover the pulmonary artery catheter is recommended to reduce the risk of contamination and prevent bloodstream infection [5]. Autopsy evidence of right-sided endocardial damage has been noted in most patients with pulmonary artery catheters, but endocarditis is relatively rare [29].

Peripheral Arterial Catheters

Indwelling arterial catheters appear to have rates of complications similar to those for venous catheters [5,8]. It has been estimated that thrombosis complicates as many as 19% to 38% of arterial catheterizations, and infection may occur in as many as 4% to 23% of patients with arterial catheters in place [30]. Signs and symptoms of infection in arterial catheters are similar to those for venous catheters; however, the absence of local signs of inflammation does not preclude infection. Distal embolic lesions and hemorrhage are highly predictive of arterial catheter-associated bloodstream infection. Late complications such as pseudoaneurysm formation and rupture of the artery may occur [31]. The rate of bloodstream infection increases the longer the catheter remains in place, with one study noting increasing risk of infection after day 4 of catheterization [30].

Midline Catheters

Midline catheters are midsized (3 to 8 in.) peripheral catheters that are inserted into the antecubital fossa or upper arm veins and extend no further than the distal portion of the subclavian vein. They can remain in place for 4 weeks, are convenient to insert, are associated with fewer infections than central venous catheters, and cause less phlebitis than peripheral catheters [4,5].

Care of the Catheter and Insertion Site

Insertion Site Dressings

Either traditional gauze and tape bandages or transparent semipermeable dressings can be used for peripheral and central catheters. Transparent dressings are changed every 5 to 7 days and gauze dressings every 2 days or more frequently if the dressing is soiled, loose, or damp [6]. Site care should be performed with a chlorhexidine-based antiseptic with each dressing change [6]. In some centers, chlorhexidine patches are placed on catheters during routine dressing changes.

Catheter Hub Disinfection

Local disinfection of the hubs of central venous catheters must be performed using either a chlorhexidine-based preparation or 70% alcohol before attempting access [5,6]. With either preparation, it is very important to allow the antiseptic to dry to ensure antimicrobial activity before accessing the catheter.

Catheter Replacement

Peripheral Catheters

Phlebitis of a peripheral vein is a well-recognized harbinger of infection and may be quite uncomfortable for the patient. A catheter causing phlebitis should be removed promptly and the tip cultured. Complications of peripheral venous catheter insertion, including phlebitis and catheter-associated infection, increase after 72 hours of insertion. Recommendations to remove and change these catheters to another site every 72 hours are aimed at decreasing the risk for infection and the discomfort associated with phlebitis [5]. The longer midline catheters and PICC lines should not be removed and changed routinely unless phlebitis or signs of infection develop [5].

Central Catheters

The risk of infection increases during the time that a central catheter is in place, but several studies have shown that routine replacement of these catheters does not reduce rates of catheter-associated bloodstream infections [5]. Routine rotation of a central catheter to a different site is associated with increased risk for pneumothorax, laceration of a vessel with hemothorax, and arrhythmias and, thus, is not recommended [5].

The use of routine catheter change over a guidewire has also been tried as a means to decrease catheter-related infections. However, a meta-analysis of studies employing this technique failed to show an effect on decreasing infections, and routine catheter changes over a guidewire are not recommended [5,32].

Thrombosis requires removal of an indwelling catheter [33]. An exception is made for the patient who has poor access and is dependent on a surgically implanted semipermanent central catheter. Under these circumstances, an attempt to salvage the catheter is reasonable [4].

Infusion-Related Issues

Local Effects

Intravenous solutions and drugs that are acidic, hypertonic, or directly irritating to vascular endothelium (KCl, certain antibiotics, chemotherapeutic agents) may lead to a local inflammatory response, thrombosis, and phlebitis, with an increased risk of infection, particularly in small-caliber peripheral veins. When such infusions are necessary, a central catheter should be used.

Infusion Tubing

Most infusion tubing should be used no longer than 96 hours [6]. However, tubing used to administer blood products or lipid emulsions should be changed every 24 hours [5].

In-Line Devices and Filters

In-line devices can be a significant source of catheter-associated infection. Pressure transducers have been implicated in outbreaks of catheter-associated bloodstream infection, particularly those due to water-associated Gram-negative bacilli, including *Pseudomonas, Serratia, Enterobacter, Citrobacter*, and *Acinetobacter* spp [34]. Stopcocks are easily contaminated through manipulation by personnel or by injection with contaminated syringes and may be an important source of infection; use of a closed system rather than stopcocks has been shown to lead to less contamination of the line [5,6]. Some studies suggest that needleless mechanical valve devices may pose a greater risk of infection than split septum devices [35,36]. Disposable transducer domes, stopcocks, needleless components, and other in-line devices should be changed with the rest of the infusion set. In-line filters do not decrease the rate of infection, and their use is not recommended [5]. All catheter hubs, needleless connectors, and injection ports should be disinfected with a chlorhexidine preparation before accessing the device [6].

Contamination of Infusates

Although contamination with microorganisms during manufacture now occurs rarely, breaks in sterile technique by hospital personnel continue to be important in causing sporadic outbreaks of infusion-related bloodstream infection. Several Gram-negative bacilli, including *Enterobacter, Klebsiella, Serratia, Citrobacter*, and *Erwinia* spp, are particularly adept at proliferating in the acidic environment of intravenous fluids containing minimal nutrients [37]. Other organisms, such as *Candida* species, have a propensity to grow in total parenteral nutrition (TPN) solutions [38,39]. The addition of albumin directly to TPN solutions increases the growth of bacteria and fungi, and the addition of fat emulsions has been associated

TABLE 81.1

SUMMARY OF RECOMMENDATIONS FOR PREVENTION OF CENTRAL VENOUS CATHETER-ASSOCIATED INFECTIONS BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS [4–6]

- Use maximal sterile barriers (sterile full-sized drape, sterile gown, sterile gloves, face mask, head cap) during insertion.
- Perform insertion site antisepsis with chlorhexidine.
- Consider the use of a chlorhexidine-impregnated patch at the insertion site.
- Cover the insertion site with either a transparent or gauze dressing.
- Do not routinely change central intravascular catheters.
- Consider use of central intravascular catheters coated with antimicrobial agents (minocycline-rifampin) or chlorhexidine-silver sulfadiazine when infection rates are high.

with the growth of corynebacteria and the yeast *Malassezia furfur* [38,40].

Multifaceted Approach to Infection Prevention

An optimum approach to prevent catheter-associated infection likely involves the use of several infection control strategies. In Michigan, 108 intensive care units assessed the impact of five-evidence–based procedures recommended by the Centers for Disease Control and Prevention to prevent catheter-associated bloodstream infection [12]. This bundle, consisting of full-barrier precautions for catheter insertion, hand washing, insertion site cleansing with chlorhexidine, avoidance of femoral insertion site, and removal of unnecessary catheters, was implemented in conjunction with clinician education, use of a designated central-line cart, a checklist to ensure adherence, and empowerment of the assistant to stop the procedure if the practices in the bundle were not being followed. This intervention led to a sustained 66% reduction in catheter-associated bloodstream infections over 18 months. This "bundle" approach has become standard of care and has been incorporated into practice recommendations endorsed by the infection control community, the Joint Commission, and the American Hospital Association to prevent catheter-associated infections [6].

Advances in prevention of infections associated with vascular catheters, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 81.1.

CATHETER-ASSOCIATED INFECTIONS

Microbiology

Coagulase-negative staphylococci (*S. epidermidis* and other species) are most commonly implicated in catheter-associated infections, followed by *S. aureus,* a variety of Gram-negative bacilli, other Gram-positive cocci and bacilli, and *Candida* and other yeasts [4,41–44]. The most common pathogens, coagulase-negative staphylococci, are associated with less severe disease than most other organisms. *S. aureus* bloodstream infection is most likely to cause complications, and *Candida* species have a propensity to seed to other structures, especially the eye [4,45,46].

Complications

Major complications of catheter-associated infection include septic shock, suppurative phlebitis, metastatic infection, endocarditis, and arteritis [4]. Complicated catheter-associated infection often requires aggressive management combining appropriate antimicrobial therapy as well as surgical intervention. Complications of bloodstream infection should be suspected, especially if the catheter has been removed, when a patient has persistence or relapse of the same organism in blood cultures after 72 hours of appropriate medical therapy and no alternative explanation is found.

Suppurative Phlebitis

Suppurative phlebitis associated with vascular catheters is manifested by fever and positive blood cultures; signs of phlebitis may or may not be obvious. For peripheral catheters, old healed insertion sites may require exploration by needle aspiration or incision; purulent material may occasionally be expressed if the vein is "milked." Suppurative phlebitis of central veins, particularly of the subclavian veins and superior vena cava, should be confirmed by detection of a thrombus by computerized tomography, magnetic resonance imaging, venography, or ultrasound [47,48]. Surgical or interventional radiological procedures to remove the thrombus are technically difficult. Most patients will respond to 3 to 4 weeks of treatment with systemic antimicrobial therapy. Surgical resection should be considered if bloodstream infection persists despite conservative management or if purulence extends beyond the vessel wall [4].

Endocarditis

Endocarditis can occur after the use of peripheral or central catheters [4,49]. The aortic and mitral valves are involved most often; presumed normal valves as well as those damaged from congenital, rheumatic, and degenerative diseases may be infected. Right atrial catheters that cross the tricuspid valve can cause endothelial damage and turbulence, predisposing the patient to the development of right-sided endocarditis if transient bacteremia or fungemia occurs. Persistent or intermittent bacteremia or fungemia despite catheter removal, or evidence of pulmonary, cutaneous, central nervous system, or other emboli by physical or laboratory examination, suggests the diagnosis of endocarditis [4]. Transesophageal echocardiography (TEE) is extremely useful in determining the presence and size of vegetations, the valves involved and their function, and the presence of myocardial abscesses [4,50]. Even if endocarditis is not present, metastatic foci to bone and visceral organs often occur as a consequence of catheter-associated *S. aureus* bacteremia [45].

Initial Treatment

In the febrile patient in whom catheter-associated bloodstream infection is suspected, empiric treatment should include antimicrobial agents that cover both Gram-positive cocci and Gram-negative bacilli [4]. Vancomycin is chosen most frequently because it is consistently active against methicillin-resistant strains of *S. aureus* (MRSA) and coagulase-negative staphylococci. An alternative agent, such as daptomycin, should be considered in settings in which MRSA isolates commonly have vancomycin minimum inhibitory concentrations (MIC) ≥ 2 μg/mL. For Gram-negative bacilli, the choice of a β-lactam/β-lactamase inhibitor combination, an antipseudomonal cephalosporin, or a carbapenem, with or without an aminoglycoside, should be based on local antimicrobial susceptibility data. Use of an antifungal agent should be considered

TABLE 81.2

SYSTEMIC TREATMENT OF INTRAVASCULAR CATHETER-ASSOCIATED BLOODSTREAM INFECTION

Pathogen	First-line agent	Alternative agents	Comments
Coagulase (−) staphylococci			
Methicillin-susceptible	Nafcillin, oxacillin	Cefazolin, vancomycin	
Methicillin-resistant	Vancomycin	Daptomycin, linezolid	
Staphylococcus aureus			
Methicillin-susceptible	Nafcillin, oxacillin	Cephazolin, vancomycin	
Methicillin-resistant	Vancomycin	Daptomycin, linezolid	Use an alternative agent if the vancomycin MIC ≥2 mg/mL
Gram-negative bacilli			
Enterobacteriaceae			
ESBL (−)	Ceftriaxone, ceftazidime Ampicillin + sulbactam Piperacillin + tazobactam	Ciprofloxacin, aztreonam, cefepime	
ESBL (+)	Carbapenem	Ciprofloxacin, cefepime	
Pseudomonas	Cefepime, carbapenem Penicillin + tazobactam	Ciprofloxacin, aztreonam	Consider addition of an aminoglycoside
Candida species	Echinocandin fluconazole	Lipid amphotericin formulations	Use an echinocandin for severely ill patients when *Candida glabrata* is likely and fluconazole in patients without prior exposure

ESBL, extended spectrum beta-lactamase; MIC, minimum inhibitory concentration.

in a patient who is clinically septic and who has a femoral catheter, parenteral nutrition, broad-spectrum antibiotic therapy, a hematological malignancy, prior transplant, and with a history of colonization with *Candida* species at multiple sites [4]. Once the organism has been identified, then appropriate systemic antibiotic therapy can be chosen based on antimicrobial susceptibilities and expert recommendations (Table 81.2).

Should the Catheter Be Removed?

It is recommended that peripheral catheters with pain, erythema, induration, or exudate be removed. Also catheters associated with a tunnel infection should be removed. For exit site infections without gross purulence, systemic signs of infection, or associated positive blood cultures, treatment with topical agents as well as systemic agents can be tried based on culture data from a sample taken at the exit site. If treatment fails, then the catheter should be removed.

In the febrile patient who is clinically stable and without localizing signs of infection along the catheter insertion site, short-term central catheters need not be removed until a microbiological assessment that includes samples of blood with or without culture of insertion sites and hubs is performed. Cultures that are positive from a single blood sample for organisms that are part of the normal skin flora, such as coagulase negative staphylococci, diphtheroids, or propionibacteria, should be repeated to establish whether a true bloodstream infection is present [2,4]. Once true bacteremia has been established and in the absence of an alternative source, short-term catheters should be removed because they serve as a persistent nidus of infection [4]. If a catheter has been changed over a guidewire, and there is significant growth of organisms from the tip of the removed catheter, the newly placed catheter is almost certainly infected and should be removed [5].

Catheter Salvage

In the case of long-term, tunneled, semipermanent catheters or ports that cannot be easily removed or in patients who have limited vascular access, treatment of catheter-associated infection with antibiotics without catheter removal has been accomplished. Catheter salvage is not recommended in patients with complications of catheter infection, such as suppurative phlebitis, endocarditis, tunnel infection, or in patients who have severe sepsis or have an implanted intravascular device, such as a prosthetic cardiac valve [4].

If salvage is a consideration, most success has occurred with coagulase-negative staphylococcal infections; in one series 80% of infections were cured without removal of the central catheter [2]. Candidates for salvage therapy should have resolution of fever and bloodstream infection within 72 hours of initiation of appropriate treatment. For bloodstream infections due to *S. aureus* and *Candida* species, catheter salvage should be reserved for extenuating circumstances, that is, when there is no alternative access. These infections and those due to Gram-negative bacilli almost always require catheter removal [4]. Thrombolytics are not recommended as an adjunct to the treatment of catheter-associated bloodstream infection [33].

Antibiotic lock therapy, as an adjunct to systemic antimicrobial therapy, has been suggested for salvage of long-term catheters [4]. In general, lock therapy involves the instillation of 2 to 5 mL of an antibiotic, often with an anticoagulant, into the catheter, allowing it to dwell until the catheter is reaccessed. Ethanol and ethylenediaminetetraacetic acid (EDTA) have also been used for lock therapy. Short-term catheters are less likely to have an intraluminal source of infection and are less likely to benefit from antibiotic lock therapy. The lock therapy antimicrobial agents and systemic antibiotics should be used concomitantly; the duration of both treatments varies widely depending on the organism and the investigator [2,4]. In general, the duration of lock and systemic therapy ranges from 7 to 14 days (Table 81.3). If antibiotic lock therapy cannot be given, then systemic treatment should be administered directly through the infected catheter. If patients with no alternative access do not respond to antibiotic treatment, exchange over a guidewire can be attempted; in this situation, exchange with an antimicrobial-impregnated catheter has been suggested [4,51].

For treatment of infections due to common Gram-positive cocci, an antibiotic lock solution containing a combination of

TABLE 81.3

APPROACH TO THE PATIENT WITH A CENTRAL VASCULAR CATHETER-ASSOCIATED BLOODSTREAM INFECTION

Initial decision	CNS	*Staphylococcus aureus*	Gram-negative bacilli	Candida species
Short-term (nontunneled) catheters				
Removed	SysRx 5–7 d[a]	SysRx >14 d[a] if no metastatic infection, & echo (−)	SysRx 7–14 d[a]	SysRx 14 d[a] after 1st (−) culture
Retained	SysRx 10–14 d[a] LT 10–14 d	Not recommended	Not recommended	Not recommended
Long-term (tunneled/implanted) catheters				
Removed	SysRx 5–7 d[a]	SysRx 4–6 wk echo (+), septic phlebitis (+), or deep infection (+); otherwise ≥ 14 d	SysRx 10–14 d[a]	IV 14 d after 1st (−) culture
Retained	SysRx 7–14 d[a] LT 10–14 d[a]	SysRx ≥14 d[a] LT ≥14 d[a] echo (−)	SysRx 14 d[a] LT 14 d[a] No other access Not recommended	Not recommended

[a]Recommended duration assumes that the bloodstream infection is uncomplicated, fever has resolved in <72 h, and the patient has no implanted intravascular devices or evidence of endocarditis or suppurative phlebitis. For *S. aureus*, no immunosuppression or active malignancy should be present. CNS, coagulase-negative *Staphylococcus*; LT, antibiotic lock therapy; SysRx, systemic antibiotics.
Adapted from references [2] and [4].

vancomycin plus heparin or saline is used most often; the vancomycin instilled should be 1,000-fold higher than the MIC for the bacteria involved [2]. Anecdotal use of lock therapy using gentamicin, amikacin, ciprofloxacin, ampicillin, cefazolin, ceftazidime, and also minocycline/EDTA has been reported [4,52]. Compatibility issues are important; some antibiotics precipitate in heparin at higher concentrations, and some solutions may influence the integrity of the catheter structure [4]. There are insufficient data to recommend the use of ethanol alone as a lock solution at this time [4].

Staphylococcus aureus Infections

It is very difficult for physicians to distinguish uncomplicated from complicated infection due to catheter-associated *S. aureus* bloodstream infection; this has resulted in considerable debate concerning the appropriate length of therapy for these infections. Several studies suggest that physicians cannot predict which patients have endocarditis or other complications by clinical history and physical examination alone [45,50,53]. Echocardiography should be done if the results will change duration of antibiotics or the need for surgery. If transthoracic echocardiography (TTE) is equivocal, then TEE should be performed for *S. aureus* bloodstream infection without a known source [54]. If the catheter is promptly removed and a TEE examination is negative for vegetations, *S. aureus* bacteremia can be treated with a minimum of 2 weeks of a penicillinase-resistant β-lactam antibiotic or a first-generation cephalosporin. Vancomycin should be used if the patient is allergic to β-lactam antibiotics or if the organism is methicillin resistant [4]. However, even those patients who appear to be appropriate candidates for short-course therapy may later present with metastatic foci or endocarditis, so it is essential to reassess "uncomplicated" cases if the patient develops relapse of fever, bacteremia, or embolic phenomena [4,55].

Candida Species Infections

Current recommendations are to treat all patients with catheter-associated fungemia with antifungal therapy [46]. The possibility that the organism has seeded to distant sites, especially the eye, is high, and the consequences of infection may be catastrophic. All candidemic patients should have a dilated retinal examination, preferably by an ophthalmologist [46]. Most studies show that outcome is improved if the catheter is promptly removed [46], but the point has been argued that many patients with neutropenia have the gut as the source, and the catheter does not have to be removed. In the nonneutropenic patient, the recommendations remain to remove all central catheters in patients with candidemia. Treatment with an echinocandin (anidulafungin, caspofungin, micafungin) or fluconazole is recommended [46]. Treatment should continue for 2 weeks after the first negative blood culture is obtained; however, if a metastatic focus of infection is noted, prolonged therapy will be required.

CHAPTER 82 ■ URINARY TRACT INFECTIONS

STEVEN M. OPAL

Urinary tract infection (UTI) remains a common nosocomially acquired infection, accounting for approximately 25% to 40% of all infectious complications in hospitalized patients [1–5]. In a nation-wide surveillance study of nearly one-half million intensive care unit (ICU) patients in the United States, UTI accounted for 23% of all infections and was associated with urinary catheters in 97% of patients [2]. Similar findings have recently been reported from surveys from Spain [3], Germany [4], and Brazil [5] with an overall incidence of urinary catheter-associated UTI of about 1 to 10 episodes per 1,000 catheter days. Furthermore, the urinary tract is the most frequently recognized source of Gram-negative bacteremia, which constitutes a major cause of infectious morbidity and mortality in the critically ill patient [1,6–8]. Approximately 100,000 annual admissions to acute care hospitals in the United States have been attributed to severe infections of the urinary tract [9]. Complicated UTI, progressive antimicrobial resistance, and the prevention of UTI with the widespread use of indwelling urinary catheters remain major challenges in critical care practice.

THE PATHOPHYSIOLOGY OF URINARY TRACT INFECTIONS

UTIs are primarily caused by Gram-negative bacilli (71%), with Gram-positive pathogens and fungi accounting for the remainder of microorganisms [6]. *Escherichia coli* is by far the most common cause of community-acquired and nosocomially acquired UTI. Most UTIs arise from ascending infection by enteric organisms that colonize the perineum and distal urethra. Specific clones of *E. coli* have evolved that readily colonize the uroepithelium and cause UTI. These clones possess the requisite set of virulence genes needed to successfully attach, survive, and invade the urinary tract in nonimmunocompromised patients with anatomically normal genitourinary (GU) tracts [10].

An essential characteristic of uropathogenic *E. coli* is its ability to adhere to uroepithelial membranes. Urinary isolates of *E. coli* possess an array of adhesions including type I (common pili), S pili, FIC pili, and P pili. These bacterial surface structures facilitate attachment to epithelial surfaces. Type I pili bind to mannose-containing polysaccharides on the cell surface of epithelial membranes. This allows the organism to attach and persist within the urinary tract and avoid elimination during micturition [11].

Another important adhesin of uropathogenic *E. coli* is the expression of P pili on the bacteria's outer membrane [12]. P pili bind to α-D-galactose 1 $\rightarrow$ 4 β-D-galactose (Gal-Gal) containing disaccharides of the globoseries of glycolipids. These glycolipids are found primarily on the epithelial surfaces of the upper urinary tract, enterocytes, and erythrocytes. The ability of *E. coli* to express P pili is particularly important in the establishment of upper UTIs where Gal-Gal disaccharide-containing glycolipids are found in large concentration. Recent genetic analysis reveals that bacterial pathogens cluster their virulence factors in discreet loci along the chromosome known as pathogenicity-associated islands (PAIs). These genetic elements contain a large number of genes associated with virulence and distinguish uropathogenic strains from nonpathogenic colonizing strains [13].

Other genera of the Enterobacteriaceae, including *Citrobacter, Klebsiella, Enterobacter, Serratia, Proteus, Morganella,* and *Providencia* spp, become more common causes of UTI when patients receive antibiotics or have anatomic or functional abnormalities in urine flow [14]. The microbiology of UTI after short-term urinary catheterization is similar to that observed in the noncatheterized patient. However, long-term (>30 days) catheterization generates an environment that supports a complex and often polymicrobial microflora. An extensive extracellular array of microbial-derived polysaccharides surrounds bacterial microcolonies within the lumen of the long-term urinary catheter. This biofilm structure protects bacterial populations for immune, phagocytic, or antibacterial clearance [15]. Bacteria found in the urine in chronically catheterized patients differ from noncatheterized patients. *Proteus, Providencia, Morganella,* and *Pseudomonas* species become more common, whereas *E. coli* and *Klebsiella* species become less common (Fig. 82.1). *Proteus* species, some other Gram-negative enteric organisms, and *Staphylococcus saprophyticus* synthesize the enzyme urease, a known bacterial virulence factor in the urinary tract. The generation of ammonia from the breakdown of urea increases regional pH, favoring the generation of the "triple-phosphate crystals" struvite and apatite in urine. Struvite crystals can block urinary catheter flow and promote the formation of urinary calculi [16].

Gram-positive bacteria occasionally cause UTIs in critically ill patients. The isolation of *S. aureus* in the urine is significant as it often accompanies staphylococcal bacteremia. *S. aureus* isolation in urine cultures, particularly in noncatheterized patients, should prompt a search for extrarenal sources of staphylococcal infection. *S. aureus* may also colonize chronically catheterized patients. This is particularly true for methicillin-resistant *S. aureus* strains, which may thrive in hospital settings with many elderly, catheterized patients [8].

Enterococci are prevalent in the GU tract of elderly populations and in patients with long-term urinary catheters. The remarkable ability of this organism to resist antimicrobial agents, including β-lactam antibiotics, aminoglycosides, quinolones, and recently vancomycin, makes this organism a frequent urinary pathogen in hospitalized patients [6–8]. *Candida* species and other fungal organisms may colonize or infect the GU tract. Candiduria may be associated with hematogenous dissemination ("descending UTI") or ascending UTIs from perineal surfaces. The unique problems associated with the isolation of *Candida* species of the urinary tract are considered in the final section of this chapter.

HOST DEFENSE MECHANISMS AGAINST URINARY TRACT INFECTION

The human GU tract is remarkably resistant to UTI by mechanical, mucosal, and immunologic mechanisms. The flushing action of urinary flow itself is an important defense against UTI.

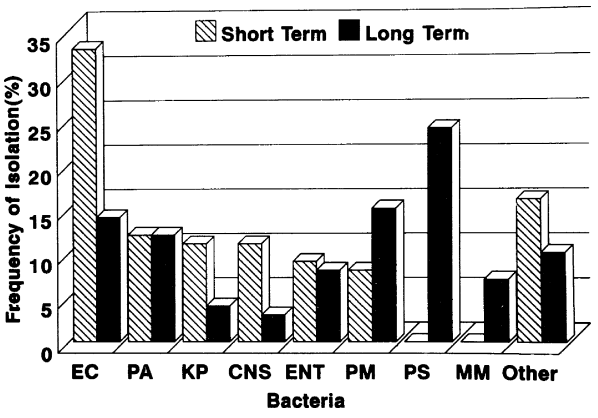

FIGURE 82.1. Distribution of bacterial isolation associated with catheter-related UTI. CNS, coagulase-negative staphylococci; EC, *Escherichia coli*; ENT, Enterococci; KP, *Klebsiella pneumoniae*; MM, *Morganella morganii*; PA, *Pseudomonas aeruginosa*; PM, *Proteus mirabilis*; PS, *Providencia stuartii.*

The frequent occurrence of UTI after obstruction or incomplete bladder emptying attests to the importance of micturition in clearing potential pathogens. Patients with neurogenic bladder or vesicoureteral reflux are highly susceptible to UTI and renal scarring. While urinary pathogens must possess a full complement of virulence factors to cause infection in the anatomically normal urinary tract, UTI in the obstructed urinary tract occurs with bacterial species devoid of special urinary virulence factors [10].

Urinary osmolarity, urea concentration, pH, and oxygen concentration limit the growth potential of many bacterial pathogens in the urinary tract. Continuous sloughing of uroepithelial cells, urinary mucosal glycocalyx (slime), and secretion of the Tamm–Horsfall protein assist in the mechanical removal of adherent bacteria that have entered the urinary tract [17].

The ability of bacteria to adhere to the mucosal surface of uroepitheilial cells is dependent on the mucopolysaccharide content of this surface and its chemical composition. Patients with high concentrations of Gal-Gal disaccharides on the cell surfaces in the urinary tract are predisposed to UTI from P-piliated *E. coli* [10]. Patients who are nonsecretors of blood group antigens have an increased risk of UTI [18]. Blood group antigens coat uroepithelial cells when secreted onto the mucosal surface. These antigens prevent attachment of bacteria to adhesin-receptor oligosaccharides on the surface of epithelial cells. Individuals who fail to secrete blood group antigens are rendered infection prone to UTI.

Although secretory immunoglobulin, neutrophils, and cell-mediated immunity contribute to the host defense against UTI, their roles are secondary to mechanical and physical barriers to infection. Uroepithelial cells produce the chemokine interleukin-8 (IL-8) in response to *E. coli* infection. IL-8 promotes neutrophil migration to the urinary tract which reduces the risk of disseminated infection. Patients differ in their level of expression of the IL-8 receptor CXCR1. Decreased CXCR1 expression in the urinary tract might contribute to increased susceptibility to pyelonephritis in some patients [19].

Adult women are much more likely to develop UTI than men. Women are more likely to develop pyelonephritis if they are sexually active, use spermicidal agents, experience urinary incontinence, have diabetes mellitus, or a family history of UTI [16]. The increased anatomic distance from the urethral orifice to the urinary bladder, the infrequent presence of Gram-negative bacteria around the male urethra, and the production of inhibitory prostatic secretions protect men from UTI until they become elderly [20]. Bladder neck obstruction from age-related benign prostatic hypertrophy causes urinary obstruction and UTI in elderly men.

SEVERE URINARY TRACT INFECTION

Acute Pyelonephritis

Acute pyelonephritis can precipitate in severe sepsis/septic shock when complicated by urinary obstruction, papillary necrosis, or other local suppurative complications. Failure of the patient to respond clinically within 72 hours to seemingly appropriate antimicrobial therapy should prompt a search for complications of UTI. Functional or mechanical obstruction to urinary flow is the principal underlying cause of treatment failure in UTI. Obstruction may arise from extrarenal causes such as retroperitoneal or pelvic masses or abnormalities intrinsic to the GU tract such as renal calculi or ureteral obstruction. Alleviation of obstruction facilitates antimicrobial treatment and is often essential to successfully eradicate infections in the upper urinary tract system [21].

Suppurative Complications of Urinary Tract Infection

Abscess formation within the GU tract may take several forms and pose a diagnostic and therapeutic challenge. It is important to distinguish between these entities because the clinical implications and medical-surgical management of each process differ substantially (see Table 82.1). Radiographic findings in a typical case of emphysematous pyelonephritis (usually caused by enteric bacteria, not *Clostridium* spp or other anaerobes) are seen in Figure 82.2A, B. Suppurative complications of UTI necessitate urgent urologic intervention with percutaneous or surgical drainage [21].

Diagnostic Methods in Urinary Tract Infection

The clinical diagnosis of acute UTI of the upper urinary tract in the noncatheterized patient is usually straightforward, with a history of urinary frequency and dysuria accompanied with costovertebral angle (CVA) tenderness and signs of systemic toxicity. The urinalysis often shows positive "dipstick" results for leukocyte esterase and nitrite, markers for leukocytes, and enteric bacteria. The presence of excess numbers of urinary leukocytes and bacteria in the urinary sediment, in the absence of contamination by epithelial cells, is indicative of a UTI in symptomatic patients. Pyuria alone without bacteriuria is indicative of GU inflammation (e.g., allergic interstitial nephritis, prostatitis, urethritis) or infection by difficult-to-culture pathogens (*Mycobacterium, Chlamydia, Mycoplasma* spp, etc.) and warrants further investigation to determine its etiology.

The urinary Gram stain of unspun urine is helpful in determining the most likely agent causing the UTI. Gram-negative rods in the urine are readily identifiable and this confirms the presence of significant bacteriuria. The finding of more than one organism per high-powered field in unspun urine equates with $>10^5$ colony-forming units (CFU) per mL [22,23]. Urinary Gram stain can also detect Gram-positive microorganisms, such as enterococci and staphylococci, and fungal elements. Polymicrobial bacteriuria is often apparent by urinary Gram stain and may be seen in UTI from long-standing urinary catheterization, enterovesical fistula, or complicated UTI associated with obstruction or foreign bodies.

Patients with severe UTIs requiring critical care management should have quantitative urinary culture performed,

TABLE 82.1

SUPPURATIVE COMPLICATIONS OF URINARY TRACT INFECTION

Disease process	Pathogenesis	Predisposing factors	Common pathogens	Radiographic features	Standard treatment
Papillary necrosis	Ischemia, necrosis, infection	Analgesics, diabetes, obstruction	Gram-negative enterics	Sloughed papilla in calyx	Antibiotics alone
Pyonephritis	Infection with hydronephrosis	Ureteral obstruction, calculi	Gram-negative enterics	Hydronephrosis with gas, debris in collecting system	Nephrostomy tube, antibiotics
Focal bacterial nephritis	Ascending UTI with focal renal inflammation	UTI with upper tract involvement	Gram-negative enterics	Focal defect on contrast-enhanced CT scan	Antibiotics alone
Corticomedullary abscess	Ascending UTI with focal renal liquefaction	UTI with obstruction, diabetes	Gram-negative enterics	Focal fluid-filled defect on CT or ultrasound	Antibiotics alone or percutaneous drainage
Xanthogranulomatous pyelonephritis	Enlarging granulomatous process with cholesterol-laden macrophages	Chronic obstruction with infection	*Proteus* spp, *Klebsiella* spp	Large heterogenous mass	Partial or complete nephrectomy
Emphysematous pyelonephritis	Ischemic necrosis with infection from gas-forming organisms	Elderly diabetic	Gram-negative enterics, rarely anaerobes	Gas on plain film, CT	Closed or open drainage or nephrectomy, antibiotics
Cortical abscess (renal carbuncle)	Hematogenous seeding of kidney	Extrarenal infection with *Staphylococcus aureus*	*S. aureus*	Semisolid intrarenal mass with caliceal distortion	Antibiotics alone or with percutaneous drainage
Perinephritic abscess	Rupture of intrarenal abscess	Obstruction, diabetes, renal transplants	*Escherichia coli, Proteus* spp, *S. aureus*, others	Displaced renal tissue, perinephric mass	Closed or open surgical drainage, antibiotics

CT, computed tomography; UTI, urinary tract infection.

preferably before the initiation of antimicrobial therapy. The urine culture confirms the diagnosis and defines the most appropriate antimicrobial agent for treatment. The progressive increase in antimicrobial resistance makes it imperative to carefully select antimicrobial agents based on susceptibility patterns of the infecting microorganism. Greater than 10^5 CFU per mL in clean catch, midstream urine is generally diagnostic. The quantitative level of bacteriuria diagnostic for acute UTI varies depending on the clinical situation.

In clinical surveys of symptomatic women with UTI, repeated isolation of as few as $>10^2$ pathogenic microorganisms per mL is diagnostic [21]. Catheterized patients may also have UTI with $<10^5$ CFU per mL. The presence of an indwelling urinary catheter may not allow ongoing replication of microorganisms in the urinary tract to achieve levels greater than 10^5 CFU per mL. Moreover, urinary cultures from noninstrumented men are significant with as little as 10^3 CFU per mL [24].

The absence of pyuria and significant bacteriuria does not exclude the possibility of a potentially serious UTI. Patients with severe neutropenia may not have significant levels of pyuria. Urine cultures may be negative in more than 40% of patients with perinephric abscess, and most patients with renal cortical abscesses have urinalyses without significant bacteriuria [25]. Complete unilateral urinary obstruction associated with pyonephrosis can fail to show the primary pathogen within voided urine. Urinary stent placement increases the risk of UTI. In a recent survey, voided urine specimens taken at the time of stent removal were negative in the presence of microbial colonization in 40% of the patients [26].

Blood cultures should be obtained on all patients who are septic as a result of a UTI. Urine cultures should also be performed from nephrostomy tube drainage in patients with prior urinary diversion procedures. It is generally unnecessary to change a urinary catheter before the acquisition of urine cultures in patients with acute UTI.

RADIOGRAPHIC PROCEDURES FOR THE DIAGNOSIS OF URINARY TRACT INFECTION

Complicated UTIs often require radiologic methods to establish the correct diagnosis. Routine abdominal radiographs may assist in the diagnosis of complicated forms of UTI. The presence of radiopaque renal calculi can be readily detected on abdominal radiography. Emphysematous pyelonephritis appears as an abnormal collection of gas within the renal parenchyma. Gas is detectable in the urinary collecting system in many patients with pyonephrosis. Abnormal renal shadows and loss of psoas margins may suggest the presence of a perinephric abscess. Renal ultrasonography and computed tomography (CT) have replaced the intravenous pyelogram (or excretory urogram) as the principal radiographic technique in the detection of complicated UTI. The anatomic definition of the kidney and

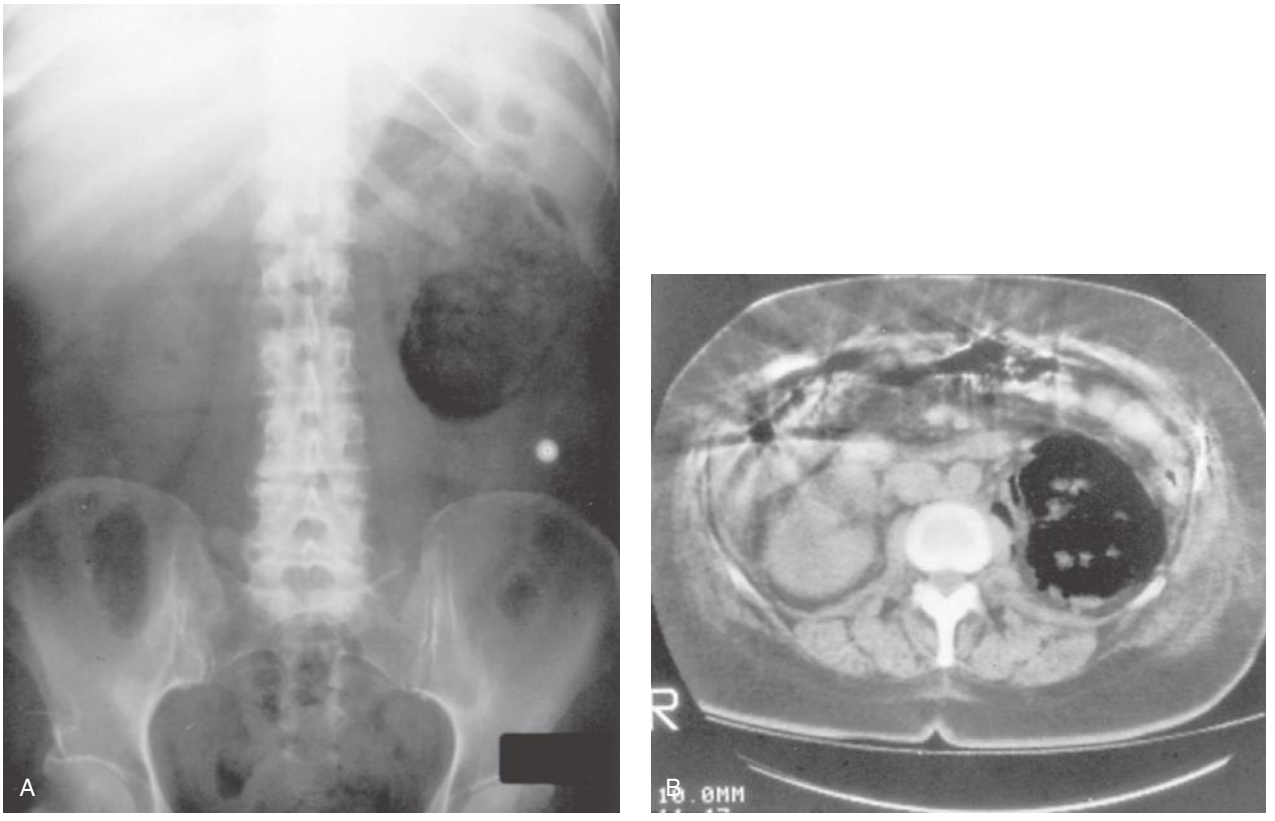

FIGURE 82.2. Radiographic findings in a diabetic woman with emphysematous pyelonephritis caused by *Escherichia coli*. **A:** Plain abdominal radiograph with evidence for gas in the left renal fossa. **B:** Computed tomography scan confirming gas in the left kidney. This patient recovered following emergency nephrectomy and antimicrobial therapy.

perirenal tissues is superior with a contrast-enhanced abdominal CT scan and is generally the preferred imaging method for complicated UTI (see Table 82.1). Renal ultrasound provides another rapid method of detecting hydronephrosis and anatomic detail of the renal parenchyma. Ultrasonography can also determine the solid or cystic nature of a renal mass detected on abdominal CT. Ultrasound can study the kidney on any plane and may be performed urgently in the absence of intravenous contrast media. The CT scan or renal ultrasound is indispensable in the localization of inflammatory processes during diagnostic aspiration or percutaneous drainage procedures. Magnetic resonance imaging (MRI) provides detailed information about the renal structures and retroperitoneal space, but the CT has sufficient resolving power in most forms of renal inflammatory disease.

The gallium-67–scan or indium-111–labeled leukocyte studies can occasionally be useful in the diagnosis of complicated UTI. These nuclear medicine studies assist in the differentiation between a renal neoplasm and a focal inflammatory process of the kidney. These studies are useful in the evaluation of patients with fever of unknown origin secondary to perinephric abscess or renal cortical abscess [27].

Intravenous pyelography (IVP) provides refined details of the calyces and ureters and remains an excellent diagnostic method for the diagnosis of papillary necrosis or small, radiolucent urinary calculi. The need for intravenous contrast media carries attendant risks of hypersensitivity reactions and radiocontrast-induced renal failure. The potential toxicity and limited resolution outside the urinary collecting system has relegated the IVP to an infrequently performed procedure in the workup of UTI in ICU patients [28].

MEDICAL MANAGEMENT OF URINARY TRACT INFECTION

Patients admitted to the ICU for management of UTI usually suffer from severe infections complicated by a systemic inflammatory response (sepsis) or suppurative complications of the GU tract. Medical management initially consists of stabilization of the patient's hemodynamic parameters and supportive measures in the management of septic shock. After the completion of appropriate diagnostic studies, empiric antimicrobial therapy should be directed toward the most likely infecting urinary pathogen(s). A urinary Gram stain usually provides evidence of either a Gram-negative or Gram-positive bacterial pathogen. If this is unavailable or nondiagnostic, then broad-spectrum, empiric antimicrobial therapy is indicated.

In the septic patient with UTI, the initial use of a β-lactam antibiotic (assuming there is no history of allergic reactions to β-lactams) in combination with an aminoglycoside has been the traditional therapeutic regimen in hospitalized patients. The β-lactam/aminoglycoside combination supplies optimal therapy for systemic infections with enteric Gram-negative bacilli, enterococci, and nonfermentative, multiresistant, Gram-negative bacterial pathogens. Severely ill septic patients who are immunocompromised also warrant combination antimicrobial therapy [21]. Increasingly, the therapeutic trend in empiric therapy is away from aminoglycosides to monotherapy with β-lactams alone, β-lactam/β-lactamase inhibitors, and/or fluoroquinolones [29].

Community-acquired UTIs in nonimmunocompromised patients who have not received antimicrobial agents infrequently

harbor multiresistant Gram-negative bacilli or *Pseudomonas* sp. Should the urinary Gram stain exclude enterococci as a potential pathogen, then single therapy with a third-generation cephalosporin, extended-spectrum penicillin, carbapenem (e.g., imipenem or meropenem), β-lactam/β-lactamase inhibitor (e.g., piperacillin-tazobactam) trimethoprim-sulfamethoxazole, or a fluoroquinolone is acceptable therapy while awaiting culture results. Local susceptibility patterns of urinary pathogens should guide the selection of antimicrobial therapy until specific susceptibility data are available. There is no evidence that combination antimicrobial therapy is necessary for UTIs caused by Gram-negative bacilli unless *Pseudomonas aeruginosa* infection with neutropenia is present. A single antimicrobial agent known to be active against the infecting uropathogen should be employed once the causative organism is known. Parenteral therapy is generally administered until the patient has been rendered nontoxic and afebrile for 24 to 48 hours. Therapy may then be administered orally and should be given for a total of approximately 2 weeks [21,24]. Patients with obstructive lesions and complicated UTIs not amenable to corrective surgery may require prolonged courses of antimicrobial therapy, as indicated by their underlying urologic disorder. Common antimicrobial agents useful in the treatment of severe UTIs are listed in Table 82.2.

Standard therapy for severe enterococcal UTIs has been ampicillin and an aminoglycoside. Although this regimen remains active against most enterococcal isolates, progressive antimicrobial resistance to aminoglycosides, ampicillin, and other β-lactams and vancomycin has complicated the antimicrobial therapy for enterococcal infections [30]. Rare strains of β-lactamase–producing enterococci are susceptible to β-lactam inhibitors such as ampicillin/sulbactam or piperacillin/tazobactam. High-level aminoglycoside-resistant strains of enterococci are problematic, as the addition of an aminoglycoside no longer contributes to synergistic clearance of these infections. Aminoglycosides should not be used in this situation.

Glycopeptide-resistant strains of enterococci pose a serious threat to the antimicrobial management of enterococcal infections. Some of these isolates remain susceptible to β-lactam agents. Newer fluoroquinolones occasionally have activity against enterococci and may be useful in the treatment of glycopeptide- and β-lactam–resistant strains of enterococci. Tetracyclines and nitrofurantoin are useful alternatives for uncomplicated, enterococcal UTI if susceptibility testing indicates activity. Quinupristin/dalfopristin is a streptogramin antibiotic useful in the treatment of vancomycin-resistant *Enterococcus faecium* (but not *Enterococcus faecalis*) infections [30]. Linezolid, an oxazolidinone that inhibits the initiation of translation at the 30S ribosome of bacteria, has activity against vancomycin-resistant enterococci [31]. Multidrug-resistant enterococci are an infection control hazard in the ICU and contact precautions are recommended.

Antistaphylococcal penicillins such as nafcillin or oxacillin are indicated in the empiric therapy of renal cortical abscesses (renal carbuncle). Vancomycin should be instituted if there is a suspicion of the presence of methicillin-resistant staphylococcal isolates in a patient with a cortical abscess or perinephric abscess.

Urgent percutaneous nephrotomy tube placement for urinary drainage and abscess management is indicated in severely

TABLE 82.2

COMMON ANTIMICROBIAL AGENTS FOR SEVERE URINARY TRACT INFECTION

Agent	Dose and frequency[a]	Principal indications	Comments
Ampicillin–sulbactam	3.0 g IV q6–8 h	Gram-negative enterics	Other β-lactam/inhibitor combinations also effective
Aztreonam	1 g IV q8 h[b]	Gram-negative enterics *Pseudomonas* spp	Useful in penicillin-allergic patients
Cefazolin	1.0 g IV q8 h		
Cefotaxime	1–2 g IV q8 h	Gram-negative enterics	Other second- and third-generation cephalosporins also effective
Ciprofloxacin	400 mg IV q12 h	Gram-negative enterics *Pseudomonas* spp	Other fluoroquinolones may not be effective; moxifloxacin and gemifloxacin do not achieve high levels in urine
Fluconazole	200 mg loading 100 mg q24 h	*Candida* spp UTI	If non-*albicans Candida* spp, check susceptibility or use Amphotericin B
Gentamicin[c]	1.5 mg/kg IV q12 h or 5 mg/kg/d	Gram-negative enterics *Pseudomonas* spp enterococci	Dosing interval dependent on renal function
Piperacillin/tazobactam	3.375 g IV q8 h[d]	Gram-negative enterics *Pseudomonas* spp	Other extended-spectrum penicillins also effective
Trimethoprim/sulfamethoxazole	160/800 mg IV q12 h	Gram-negative enterics	Watch for sulfa allergies
Vancomycin	500 mg IV q12 h	MRSA	Watch renal function carefully
Linezolid	600 mg IV or PO q12 h	MRSA, VRE	Monitor complete blood counts

[a] Adult dosing in patients with normal renal function; follow susceptibility test results and treat parenterally until systemic toxicity resolves.
[b] Aztreonam dose can be increased to 2 g q8 h for *P. aeruginosa* infection.
[c] Gentamicin or other aminoglycosides often given with a β-lactam agent in Gram-negative septic shock or severe enterococcal infections.
[d] Piperacillin/tazobactam dose can be increased to 4.5 g q8 h for *P. aeruginosa* infection.
MRSA, methicillin-resistant *S. aureus*; UTI, urinary tract infection; VRE, vancomycin-resistant enterococci.

septic patients with obstructed urinary collecting systems. Percutaneous catheter drainage of perinephric abscesses, renal carbuncles, and infected urinary cysts is often necessary in combination with antimicrobial therapy to manage these complicated UTIs. Open surgical drainage is reserved for patients who fail to respond to attempted percutaneous drainage.

PREVENTIVE MEASURES AGAINST URINARY TRACT INFECTION IN THE INTENSIVE CARE UNIT SETTING

The most efficacious method of preventing UTIs in critically ill patients is not using urinary catheters at all or limiting their duration of use as much as possible [32]. Asymptomatic bacteriuria should generally not be treated whether an indwelling urinary catheter is present or not. Asymptomatic bacteriuria in pregnant women and immunocompromised patients should be treated with specific antimicrobial agents as the risk of ascending UTI is considerable and may be avoided by early medical intervention [21,33].

The Management of Catheter-Related Urinary Tract Infection

The ubiquitous presence of the indwelling urinary catheter in hospitalized patients provides microbial pathogens ready access to the urinary tract with subsequent development of UTI. It is estimated that 10% of all hospitalized patients in the United States will have a urinary catheter inserted during their hospitalization, resulting in over 1 million UTIs per year [6,21,22,24]. The overall incidence of catheter-acquired UTI in patients within critical care units varies from 0.5 to 10 UTI per 1,000 catheter days [3–5,22]. The risk factors for acquisition of catheter-related UTI include duration of catheter placement, increasing patient age, female gender, severity of underlying illness, and perhaps obesity [22,23]. The estimated risk of bacteriuria after urinary tract catheterization is approximately 5% for each day of catheterization. Chronically catheterized (more than 30 days) patients almost invariably have bacteriuria, and their admission to the ICU poses a threat of cross-contamination of urinary pathogens to other ICU patients. Despite continued infection control efforts to decrease the frequency of contamination, UTI remains the major complication of urinary catheters. The average, calculated, incremental cost associated with the hospital care of a patient with a catheter-related UTI is $589.00 [32,34].

Pathogenesis

The catheter itself interferes with physiologic host defense mechanisms against UTI. Trauma produced by an indwelling catheter may damage the bladder mucosa and the mucous layer that coats uroepithelial cells [35]. This exposes the cell surface of epithelial cells to bacterial adhesions and increases the risk of UTI. Indwelling catheters prevent complete bladder emptying. Residual urine serves as a culture medium for bacteria in an inadequately drained urinary bladder. Additionally, temporary obstruction of urine flow caused by kinking or clamping of the urinary catheter can lead to bladder distension, vesicoureteral reflux, and infection.

Bacteria gain access to the urinary tract in catheterized patients by one of three mechanisms: (a) during insertion, (b) along the external surface after insertion, or (c) via the inner lumen of the urinary catheter. Implantation of bacteria into the bladder during catheter placement occurs at a frequency of approximately 0.5% to 8% [35]. This risk varies with the experience of the healthcare worker placing the catheter and with the level of periurethral colonization by potential uropathogens. Ascending infection from within the lumen accounts for approximately 20% of catheter-related UTIs [21]. The use of sterile, closed urinary collecting devices with a sterile vent to avoid a standing column of urine from the bladder to the collecting bag has decreased the frequency of UTI. Optimal catheter design includes a sterile sampling port that obviates the need to open the system to collect urine samples. The collecting bag should have a large reservoir with a device to measure urine output with minimal manipulation of the catheter system.

Most catheter-related UTIs are derived from microorganisms that enter the urinary bladder along the external surface of the catheter [35,36]. The periurethral space becomes colonized with enteric organisms, which then migrate along the periurethral mucous sheath that surrounds the surface of the catheter. Continued movement of the catheter in and out of the urinary bladder occurs upon repositioning of the patient or catheter manipulations. This process provides ample opportunity for organisms coating the catheter surface to gain access to the urinary bladder and cause infection.

Numerous enteric organisms avidly adhere to the mucosal surface of the urinary bladder. Some organisms, such as *Providencia stuartii* and *P. aeruginosa*, also possess surface adhesins that bind directly to the urinary catheter itself. The urinary catheter becomes an ecologic niche for these organisms, resulting in prolonged infections that may persist for months in the catheterized patient [37]. More than 90% of *P. stuartii* bacteremias occur as the result of urinary catheter-induced UTIs [38]. The urease produced by *Proteus* species affects the local pH surrounding the catheter, which facilitates the deposition of struvite microcrystals on the surface of the catheter. These encrustations serve as a nidus for persistent colonization with urinary pathogens. Adherent bacteria establish microcolonies coated with extracellular polysaccharides. The continued buildup of this biofilm within the lumen of the urinary catheter eventually leads to obstruction of urinary flow [15,39]. The presence of a foreign body within the urinary bladder interferes with the penetration and antimicrobial action of antibiotics. Bactericidal agents inhibit, but often fail to kill, microorganisms that adhere to catheter materials. Furthermore, the catheter serves as a foreign body inducing early degranulation and loss of bactericidal activity of neutrophils. These factors contribute to the difficulties eradicating urinary pathogens in the catheterized patient.

Diagnosis

The presence of bacteriuria in the catheterized patient documents colonization of the urinary tract but does not necessarily confirm the presence of an actual UTI. A UTI develops when a host response occurs to the presence of microbial pathogens in the urine. As many as 70% of patients who develop catheter-related bacteriuria remain symptom free and resolve spontaneously with the catheter removal [40]. It is generally acknowledged that the treatment of asymptomatic bacteriuria in the catheterized patient is not warranted, except in some specific circumstances [41]. The severely neutropenic patient with asymptomatic bacteriuria should be treated because of the risk of systemic infection in this patient population. In addition, treating asymptomatic bacteriuria in catheterized patients might be warranted in an outbreak setting of

nosocomially acquired infection to prevent further spread of specific urinary pathogens [42].

It is often difficult to recognize that a symptomatic UTI is present in the catheterized patient. Altered levels of consciousness may interfere with the patient's awareness of the UTI. Furthermore, the presence of a urinary catheter removes the symptoms of urinary frequency and the perception of dysuria. Hematuria and pyuria may be found in the catheterized patient in the absence of urinary colonization with bacteria. Isolated pyuria in patients with asymptomatic bacteriuria is not an indication for antimicrobial treatment [41]. This is presumably related to sterile inflammation and trauma induced by the catheter itself. High-grade pyuria (>50 white blood cells per high power field) with fever supports the diagnosis of a UTI in the catheterized patient [43].

The presence of lower numbers of bacteria than the traditional $>10^5$ CFU per mL can indicate infection in catheterized patients [44]. Quantitative counts as low as 10^2 CFU per mL may be significant in the catheterized patient. Low colony counts in catheterized urine can progress to high-grade bacteriuria in catheterized patients. Clinical laboratories should isolate and characterize urinary isolates from catheterized patients with low-grade bacteriuria. A recent consensus review recommended the cutoff of $>10^3$ CFU per mL for significant bacteriuria in catheterized patients [43]. The high flow rate of catheterized urine, presence of inhibitors to bacterial growth, and significance of slow-growing organisms such as enterococci and *Candida* make it incumbent on the laboratory to characterize even low numbers of uropathogens in these patients. Moreover, polymicrobial bacteriuria occurs in more than 15% of patients with catheter-related UTI [44]. Multiple organisms must be isolated, characterized, and subjected to susceptibility testing to ensure adequate treatment of catheter-related UTIs.

Most patients with catheter-associated UTIs have lower urinary tract involvement. Upper tract involvement occurs in up to one-third of catheter-related UTIs and may have serious consequences [45]. The clinical and laboratory recognition of upper urinary tract involvement in persons with UTI (with or without a catheter) remains imprecise and unsatisfactory. ICU patients with UTIs may have altered levels of consciousness and may not be able to relate the symptoms of upper tract involvement. Antibody-coated bacteria have not proved to be sufficiently reproducible to distinguish upper from lower UTI [21]. Bladder washout techniques are effective [46] but are cumbersome and infrequently used in the ICU setting. Upper tract involvement can be detected in ICU patients by ultrasound or CT imaging demonstrating kidney enlargement and focal nephritis. Evidence of systemic toxicity from a UTI is highly indicative of upper tract disease and should be treated accordingly. Bacteria confined to the urinary bladder, in contrast, readily clear with removal of the catheter and a short course of antimicrobial therapy, if necessary.

Treatment

The most important therapeutic modality in catheter-related UTIs is the removal of the urinary catheter itself. Up to two thirds of patients with bacteriuria associated with urinary catheterization spontaneously resolve within 1 week after catheter removal [37]. If persistent bacteriuria is present after short course therapy, upper tract involvement should be assumed and the patient treated with a 14-day course of an active antimicrobial agent. If patients have persistent bacteriuria after short-course therapy, upper tract infection is assumed to be present and a 14-day course of an active antimicrobial agent is indicated [41,43].

If a patient becomes systemically ill from a UTI, treatment is warranted even if the catheter must remain in place. It is possible to successfully treat UTIs in patients with indwelling catheters, although treatment failures and reinfection occur at a greater frequency than in noncatheterized patients [21]. Antimicrobial agents useful in the treatment of catheter-related UTI are described in Table 82.2.

Routine replacement of indwelling urinary catheters complicated by UTI is generally unnecessary. Nonetheless, some organisms such as *Proteus, Providencia, Morganella,* and *Pseudomonas* species and enterococci may colonize the urinary catheter in greater quantities than the bladder itself. Despite the fact that the microbiology of urine samples from indwelling catheters and replacement catheters does not differ markedly in the presence of a UTI [47], catheters should be replaced if they malfunction, leak, or have been in place for prolonged periods (longer than 2 weeks). Leaking urinary catheters generally indicate luminal obstruction and require replacement.

Long-term urinary catheterization may be associated with other local suppurative complications, particularly in adult men. These include prostatitis, prostatic abscess, epididymitis, scrotal abscess, and other urethral complications [48]. These local complications require urologic management and necessitate the removal of the urethral catheter.

Prevention

Alternatives to Urethral Catheterization

The high frequency of catheter-related UTIs has led to concerted efforts to find alternative methods to manage the incontinent patient and patients with urinary outflow obstruction. Bladder training, meticulous nursing care, special linens, and adult diapers may assist some incontinent patients and avoid long-term catheterization.

Condom catheterization has been used for men with urinary incontinence and consists of the application of an external collector about the penis with a collection tube and drainage bag. Condom catheterization may be a reasonable alternative in highly motivated, cooperative, selected patients. However, leakage of the catheter, kinking and disruption of the collecting system, and maceration and ulceration of the epithelium of the penis are frequent complications of condom drainage. The overall incidence of UTIs with condom drainage does not differ significantly from indwelling catheter drainage [49].

Catheter Design, Maintenance, and Care

Because most catheter-related infections are derived from endogenous perineal organisms adherent to the exterior surface of the catheter itself, daily application of antimicrobial materials at the urethral orifice would seem to be a logical preventive measure. However, randomized controlled clinical trials with meatal care and application of povidone-iodine solution or topical poly-antimicrobial applications have failed to convincingly demonstrate a reduction in catheter-related infections [36]. This procedure cannot be recommended as a means of prevention of catheter-associated UTI.

Considerable effort is under way to develop a urinary catheter that prevents binding with bacteria, inhibits biofilm formation, or possesses antibacterial properties. The value of siliconized catheters [50], antibacterial-coated catheters, and other catheter innovations designed to decrease the risk of UTI is an active research priority [51,52]. A recent evidence-based systematic review of the existing literature indicates that antibiotic-coated catheters reduce the incidence of bacteriuria following short-term catheterization; however, there is no clear evidence of reduced symptomatic UTI or major complications such as bacteremia [53]. Such catheters may be considered in selected patients at great risk of complications for UTI such

TABLE 82.3

EVIDENCE-BASED RECOMMENDATIONS FOR URINARY TRACT INFECTION

Summary of recommendations for the prevention and management of bacteriuria and urinary tract infections in catheterized patients

- Screening for asymptomatic bacteriuria in a patient with an indwelling urinary catheter is not recommended [41].
- Treatment of asymptomatic bacteriuria is not recommended in the chronically catheterized patient [41,43].
- The use of antimicrobial-coated urinary catheters to prevent catheter-associated urinary tract infections is effective in preventing bacteriuria in patients with short-term urinary catheterizations; however, the cost implications and impact of these catheters on other urinary catheter-associated infectious complications such as bacteremia is unclear [50–53].
- There are insufficient data to support the use of chemical disinfection of the urinary drainage systems as a means of preventing catheter-associated urinary tract infections [54,55].
- Daily meatal care to prevent contamination of the external surface of the urinary catheter is not recommended as a means of preventing catheter-associated urinary tract infections [36].
- Persistent bacteriuria >48 h after removal of a urinary catheter should be treated with antimicrobial agents [41].

Summary of recommendations in the management of candiduria in the ICU patient

- Quantitative cultures with $>10^3$ CFU/mL of *Candida* spp in a catheterized patient or $>10^4$ CFU/mL of *Candida* spp in a noncatheterized patient is considered clinically significant [43,60,61,63].
- The finding of a fungus ball within the urinary collecting system, papillary necrosis, fungal casts in the urine, or renal abscess in the presence of candiduria is considered clinically significant [43,64,66].
- In medically stable patients without major immunocompromised states, simple removal of an indwelling urinary catheter without specific antifungal therapy may be an acceptable treatment option [43,57,66].
- Because of high levels of urinary excretion, fluconazole is preferred over caspofungin, other β-glucan inhibitors, and other triazoles (such as voriconazole, itraconazole, or posaconazole) in the treatment of genitourinary candidiasis [43,66].
- Bladder irrigation with a short course of amphotericin B (2 d) remains a viable treatment option in catheterized patients with candiduria in the absence of evidence of disseminated candidiasis [70].
- A short course of fluconazole (5–7 d) is usually sufficient to treat urinary tract infections due to *Candida* spp [73].

as a patient with severe neutropenia, but such patients are uncommon in most critical care units.

Exogenous contamination of urine within the collection bag remains a potential problem associated with indwelling urethral catheters. The instillation of antiseptic agents within the drainage bag as a means of prevention of catheter-related UTIs has met with conflicting results [54,55]. The procedure may decrease the risk of colonization but increase the acquisition of multiple drug-resistant Gram-negative bacilli. Urinary irrigation with antimicrobial agents or the instillation of antiseptic in the urinary drainage bag to prevent UTI is not recommended based upon current clinical evidence. The urinary collection bag should not be allowed to be elevated above the urinary bladder. This results in reflux of voided urine back into the bladder with its attendant risk of inducing UTI. Collecting bags with antireflux valves should be used to avoid this complication of urinary catheterization.

Short-term systemic antimicrobial prophylaxis against catheter-related UTI might be useful in special circumstances such as renal transplantation or foreign body implant surgery. A summary of evidence to support prevention and treatment recommendations for urinary catheter-associated UTI is listed in Table 82.3.

THE PROBLEM OF CANDIDURIA

The clinical interpretation of the isolation of *Candida* species from the urine is problematic in that candiduria may occur in a spectrum of illnesses ranging from simple urinary contamination to life-threatening systemic candidiasis. *Candida* species are normal inhabitants of the vaginal tract of women and may contaminate inadequately collected urine specimens. This is particularly true in older women, diabetics, and patients receiving antibacterial therapy. Additionally, *Candida* species frequently colonize the urinary tract in catheterized patients. These organisms are of marginal clinical significance and frequently disappear on removal of the urinary catheter without any specific antifungal therapy [56]. In a recent survey of 861 patients with funguria by the national mycoses study group, no treatment was given in 155 patients and funguria resolved spontaneously in 76% of these patients [57].

However, tissue invasive infection of the urinary bladder has been documented cystoscopically in patients with GU candidiasis. *Candida cystitis* may produce a friable white pseudomembrane on the bladder mucosa similar to the findings of oral thrush. Furthermore, ascending urinary infection of the kidney and renal pelvis may follow GU candidiasis. Papillary necrosis, fungus ball formation, urinary obstruction, bladder rupture, and perinephric abscess have all been described from ascending infection with *Candida* species [58,59]. *Candida* infection of the upper urinary tract may arise from hematogenous dissemination of *Candida* organisms from extrarenal sites. Microabscesses of the renal parenchyma with subsequent candiduria are a frequent finding in disseminated candidiasis. A positive urine culture for *Candida* species may be the first indication of disseminated candidiasis in the critically ill patient. Therefore, the clinical significance of *Candida* in the urine remains a diagnostic dilemma.

Quantitative culture of the urine has been used in an attempt to determine the clinical ramifications of candiduria. Unfortunately, the quantitative colony counts of *Candida* species in the urine do not have the same diagnostic and prognostic implications as quantitative bacteriology of the urine [43,60]. Large studies and review of this topic [43,60,61] indicate that quantitative values for candiduria of clinical significance are seen at more than 10^3 CFU per mL (catheterized patients) or more than 10^4 CFU per mL (noncatheterized patients). The finding of urinary casts made up of *Candida* elements is of diagnostic significance and indicates invasive upper tract candidiasis. Candiduria associated with a fungus ball in the urinary collecting system dictates the need for antifungal therapy,

as does papillary necrosis or abscess formation within the renal parenchyma. Recurrent isolation of *Candida* species in urine cultures in immunocompromised patients, or patients with unexplained fever and pyuria, suggests UTI with *Candida* species. Evidence of concomitant infection with *Candida* organisms in other organ systems increases the likelihood of the significance of *Candida* isolates in the urine. Disseminated candidiasis should be considered in patients with repeated and unexplained *Candida* isolates in the urinary tract [62–64].

THE TREATMENT OF GENITOURINARY CANDIDIASIS

There are several management options available for candiduria, depending on the clinical circumstances in each patient. The discontinuation of antibacterial agents, removal of immunosuppression, or removal of urinary catheters may be sufficient to spontaneously clear candiduria in medically stable patients [65].

Published treatment guidelines for GU candidiasis recommend fluconazole in place of amphotericin B as the preferred treatment in the ICU setting [66]. This triazole compound is water soluble, available as oral or intravenous formulations, and is excreted as the active compound in the urine. Posaconazole, itraconazole, caspofungin, and voriconazole are not as useful in GU candidiasis as they are hepatically excreted and do not uniformly achieve fungicidal levels in the urine. Fluconazole also provides systemic antifungal activity if unrecognized disseminated candidiasis is present.

It is now recommended that antifungal susceptibility testing be performed for serious *Candida* infections for fluconazole, itraconazole, and flucytosine [67]. Resistance among *Candida albicans* isolates is increasingly recognized and these findings emphasize the necessity of antifungal susceptibility testing [68]. *Candida krusei* is intrinsically resistant to fluconazole; *Candida lusitaniae* is resistant to amphotericin B; and *Candida glabrata* is variably sensitive to antifungal agents. *Candida parapsilosis* appears to be less susceptible to the echinocandins [66]. Amphotericin B in vitro susceptibility testing is technically difficult and the methodology has not yet been standardized for routine clinical laboratory testing [67]. High doses of amphotericin B instilled into the bladder may be potentially toxic to uroepithelial cells [69]. However, a 2-day infusion of 50 mg of amphotericin B in 1,000 cc of sterile water per day is effective [70]; a single systemic dose of amphotericin B can also clear candiduria [71]. Systemic fluconazole or amphotericin B is indicated in candiduria patients with suspected systemic candidiasis, renal abscess formation, and fungus balls within the urinary collecting system [72]. *Candida* UTI may be readily treated with oral or intravenous fluconazole. A short course of fluconazole at 200 mg orally followed by 100 mg daily for 5 to 7 days is generally sufficient for the treatment of *Candida* [73] cystitis while upper urinary tract disease is generally treated with 200 to 400 mg fluconazole for 2 weeks [66]. Clinical evidence in support of the current management strategies for GU candidiasis is provided in Table 82.3.

CHAPTER 83 ■ LIFE-THREATENING COMMUNITY-ACQUIRED INFECTIONS: TOXIC SHOCK SYNDROME, OVERWHELMING POSTSPLENECTOMY INFECTION, MENINGOCOCCEMIA, MALARIA, ROCKY MOUNTAIN SPOTTED FEVER, AND OTHERS

MARY T. BESSESEN

This chapter covers several infections of low incidence and high mortality, a combination of factors that challenges the physician to recognize a life-threatening disease he or she may never have seen before and institute appropriate therapy promptly. To assist in this challenge, as these diseases are discussed, key historical points and clinical clues will be emphasized.

The critically ill febrile patient should undergo a thorough history and physical examination. Family members may need to be interviewed if the patient is too ill to participate fully in the history. Key points of the exposure history include travel, employment, hobbies, and exposure to pets, wildlife, and livestock. This portion of the interview will yield better results if it is carried out in a slow-paced conversational fashion, allowing the patient or family member to chat a bit. It is less focused than a standard social history and review of symptoms due to the heterogeneous nature of the exposures being sought. A complete physical examination should be performed. In assessing vital signs, one must evaluate hypothermia (temperature less than 36°C) in the same light as fever (temperature higher than 38°C). Laboratory studies should include a complete blood count with platelet and differential counts; prothrombin and partial thromboplastin times; electrolytes, including calcium and magnesium; blood glucose; renal and liver functions; two sets of blood cultures, urine for culture and urinalysis; and a chest radiograph. If a serious infection is under diagnostic consideration, the hematology laboratory should supplement the automated differential leukocyte count with a manual differential count by microscopic examination of the peripheral blood film. This may require a specific request from the physician, especially if the total leukocyte count falls within the normal range.

TOXIC SHOCK SYNDROMES

There are two toxic shock syndromes commonly recognized, one caused by *Staphylococcus aureus* (*S. aureus*), and the other caused by *Streptococcus pyogenes* (*S. pyogenes*) (group A streptococcus). To further complicate this picture, it has recently been reported that group C and group G streptococci may occasionally cause toxic shock syndrome [1]. In addition, *Clostridium sordellii* has been reported to cause a similar, but clinically distinct, toxic shock syndrome in obstetric patients, injection drug users, and recipients of musculoskeletal tissue allografts. Each of these three syndromes is discussed in the following sections.

Staphylococcal Toxic Shock Syndrome

Staphylococcal toxic shock syndrome (TSS) was first described in 1978 [2], and gained notoriety in the early 1980s when menstrual-associated cases struck large numbers of young women [3]. It is a multisystem disease characterized by acute onset of high fever, hypotension, diffuse macular rash, severe myalgia, vomiting, diarrhea, headache, and nonfocal neurologic abnormalities. The primary focus of staphylococcal infection may be mucosal, typically vaginal, associated with tampon or diaphragm use, or a wound. Currently there are four well-recognized forms of staphylococcal TSS: menstrual [3], postsurgical [4], influenza associated [5], and recalcitrant erythematous desquamating syndrome in acquired immunodeficiency syndrome (AIDS) [6].

Etiology

Staphylococcal toxic shock syndrome is a toxin-mediated illness caused by *S. aureus* strains that produce superantigens (SAgs). Menstrual-associated TSS is almost always caused by a strain that carries the SAg TSS toxin-1 (TSST-1), which is able to cross-intact mucous membranes. Nonmenstrual TSS may be caused by any of 15 described SAgs, but is most commonly associated with TSST-1, staphylococcal enterotoxin B (SEB), or staphylococcal enterotoxin C (SEC) [7]. Staphylococcal enterotoxins B and C are not absorbed across mucous membranes, but can cause TSS in cases of staphylococcal infection of wounds. There are rare case reports of staphylococcal TSS associated with nosocomial strains of methicillin-resistant *S. aureus* (MRSA) [8]. TSS has not been a feature of the epidemic of the community-associated MRSA strain, USA300, nor was TSS identified in a large collection of USA300 isolates [9].

Pathogenesis

In TSS, bacterial toxins function as superantigens. Conventional antigens presented in the context of major histocompatibility molecules on antigen-presenting cells (APC) must be processed by the APC and recognized by multiple elements of the T-cell receptor (TCR). In contrast, superantigens do not require processing by an antigen-presenting cell but instead

bind directly to the TCR to activate T-cells. Expansion of T-cell populations expressing particular TCR Vβ chains results in massive release of proinflammatory cytokines such as gamma-interferon (IF-γ), tumor necrosis factor-α (TNF-α), interleukin 1-β (IL-1β), and interleukin-2 (IL-2), leading to a capillary leak syndrome [7]. The absence of preexisting antibody to the pertinent bacterial toxin is a critical host factor in TSS. Among cases of menstruation-associated TSS, 90% do not have preexisting antibody to TSST-1. In contrast, more than 90% of healthy persons over the age of 25 years have antibody to TSST-1.

Diagnosis

Clinical Features. The classic case profile is a young (15 to 25 years old), menstruating female. However, any staphylococcal infection can predispose to TSS, including surgical wound infections, furuncles, and abscesses. Postpartum cases can occur after vaginal or cesarean delivery. Nasal reconstructive surgery carries an especially high risk of TSS. Cases may also occur after nasal packing for epistaxis.

The typical presentation is one of high fever, rash, and confusion. There may be a prodromal period of 2 to 3 days, consisting of malaise, myalgia, and chills. Patients are listless, but focal neurologic findings are not seen. Examination of patients with menstruation-associated TSS reveals vaginal hyperemia and exudate that yields *S. aureus* on culture. In nonmenstrual cases, a careful examination usually reveals a focus of staphylococcal infection. It is important to note that this focus may be subtle, with only serous drainage [4]. This is a toxin-mediated disease, and the local appearance is not one of intense purulence. Drainage of local infections is essential to a favorable outcome.

Laboratory Findings. Leukocytosis with marked left shift, thrombocytopenia, azotemia, sterile pyuria, and elevated transaminases are common, although nonspecific findings. Cultures of blood and cerebrospinal fluid (CSF) are usually sterile. Cultures of the local site of infection are usually, but not invariably, positive for *S. aureus*.

Differential Diagnosis. Streptococcal scarlet fever, measles, leptospirosis, Rocky Mountain spotted fever, Stevens–Johnson syndrome, and Kawasaki's disease can mimic TSS. Multiorgan involvement is usually absent in streptococcal scarlet fever, and the primary focus yields *S. pyogenes*. Exclusion of measles, leptospirosis, ehrlichiosis, and Rocky Mountain spotted fever requires a careful history for potential exposures and serologic testing. Stevens–Johnson syndrome is characterized by target lesions and is commonly associated with exposure to medications. Kawasaki's disease is characterized by fever and rash without multisystem involvement, is most commonly seen in children under the age of 6 years, and is associated with thrombocytosis rather than thrombocytopenia.

Treatment

The primary intervention consists of fluid resuscitation and supportive care. Any focus of staphylococcal infection must be drained. In women, a vaginal examination must be performed as soon as the patient is stabilized, and any foreign bodies (such as tampon or diaphragm) removed. After cultures of the local site and the blood are obtained, antistaphylococcal therapy should be administered intravenously.

Empiric antibacterial therapy for the critically ill patient should include an agent which is active against 100% of suspected pathogens, if feasible. At this time, the antibiotic that is most likely to cover all *S. aureus* isolates is vancomycin. There is in vitro evidence that clindamycin [10] and linezolid [11] inhibit staphylococcal toxin production, whereas β-lactam agents increase TSST-1 in culture supernatants, probably due to cell lysis releasing toxin [12]. The initial treatment of choice for menstrual TSS is nafcillin or oxacillin combined with clindamycin. After 48 hours, clindamycin can be discontinued. First-generation cephalosporins (cefazolin) may be substituted for an antistaphylococcal penicillin in patients with a history of non–life-threatening allergy to penicillins. If a healthcare-associated source of *S. aureus* infection is suspected, vancomycin should be used in place of the β-lactam agent until susceptibility tests are completed.

Intravenous immune globulin (IVIG) may be a useful adjunctive therapy. Higher doses of IVIG may be required for staphylococcal TSS than for streptococcal TSS [13].

Outcomes

The mortality of menstrual staphylococcal TSS is 3%, and 2 to 3 times higher in nonmenstrual-associated cases. Poor outcomes are associated with prolonged and refractory hypovolemic shock, acute respiratory distress syndrome, acute renal failure, electrolyte and acid-base imbalances, cardiac dysrhythmia, and disseminated intravascular coagulation (DIC) with thrombocytopenia.

Staphylococcal TSS may recur in patients with menstrual or nonmenstrual disease [14,15]. Recurrence is associated with continued use of tampons and absence of antistaphylococcal therapy for the initial episode.

Streptococcal Toxic Shock Syndrome

The clinical presentation and pathophysiology of streptococcal TSS are similar to staphylococcal TSS with a few notable differences: bacteremia is commonly seen, rash is less common, and mortality is markedly higher (30% to 70%) [7].

Like staphylococcal TSS, streptococcal TSS is a toxin-mediated disease. Streptococcal toxins that function as superantigens are streptococcal pyrogenic exotoxins A (SPE A) and B (SPE B). In addition, M-protein, a classic streptococcal virulence factor, may be released from the cell surface, bind to fibrinogen, and form large aggregates that activate intravascular polymorphonuclear leukocytes, leading to a vascular leak syndrome [16]. Blood cultures are usually positive in streptococcal TSS. Underlying infections are varied and include cellulitis, necrotizing fasciitis, postpartum myometritis, surgical wound infection, and occasionally pharyngitis [17]. Diagnosis is made by Gram stain and culture of blood and other bodily fluids.

Treatment is similar to that for staphylococcal TSS in that supportive care, including fluids, vasopressors, and ventilatory assistance, should be administered as needed, and surgical drainage of pyogenic sites is imperative. For confirmed streptococcal TSS, the antibiotic of choice is intravenous penicillin. For those who are intolerant to penicillin, other suitable agents are cephalosporins and vancomycin. Until the bacteriologic diagnosis is confirmed by culture, staphylococcal coverage should be included in the antibiotic regimen. Clindamycin is also very active against *S. pyogenes*. In an animal model of streptococcal myositis, clindamycin was more effective than penicillin [18]. This may be due to greater activity against high burdens of organisms (inoculum effect). An alternative explanation is that inhibition of protein synthesis blocks toxin production by the pathogen and reduces TNF production by the host [19]. A case control study has shown improved outcomes among children with invasive *S. pyogenes* infections whose therapy included clindamycin or erythromycin in the first 24 hours [20]. The usual adult dose of clindamycin in this setting is 600 mg per kg every 8 hours. Adjunctive therapy of streptococcal TSS with IVIG is recommended by many experts, based on retrospective studies employing doses ranging from 400 mg per kg to

2 g per kg for variable durations [21,22]. A randomized controlled trial was attempted but halted prior to completion, and it showed a trend toward improved survival in the treatment group [23]. In that trial, the dose of IVIG was 1 g per kg on day 1 and 0.5 g per kg on days 2 and 3.

Clostridium Sordellii Toxic Shock Syndrome

Clostridium sordellii is an anaerobic, Gram-positive spore-forming bacillus that has been an occasional cause of obstetric infections for many years [24]. Recently there have been reports of a TSS due to this pathogen in association with surgical and medical abortion [24,25], subcutaneous injection of black-tar heroin [26], and musculoskeletal tissue allografts [27]. The distinctive features of this syndrome are hypothermia and profound hemoconcentration. Management consists of supportive care including aggressive volume resuscitation, drainage of purulent foci, and broad-spectrum antibacterial therapy to include anaerobic organisms. Antitoxin therapy is of theoretical interest but clinically unproven.

OVERWHELMING POSTSPLENECTOMY INFECTION

Overwhelming postsplenectomy sepsis is a catastrophic illness with high morbidity and mortality in patients who have undergone splenectomy or who have severe splenic dysfunction. The spleen provides three major functions in protection from infection. It acts as a mechanical filter for infected or senescent erythrocytes; it participates in the production of soluble immune factors, including immunoglobulins and tuftsin; and it provides a site for components of the cellular immune system to act in proximity to one another [28].

Splenic function may be lost due to surgical removal, irradiation, several disease processes, and therapies [29], including sickle cell anemia, systemic lupus erythematosus, celiac disease, liver disease, acute alcoholism, high-dose corticosteroid therapy, splenic irradiation [30], and bone marrow transplantation. Normal aging has also been associated with a decrease in splenic function [31].

Splenectomy was the accepted procedure for splenic trauma for centuries, due to the belief that it served no important physiologic function, repair of trauma was difficult due to the friable nature of the organ, and expected high mortality of attempted conservative management. This prevailing wisdom was challenged in the 1970s, and currently splenic salvage is reported in 90% of cases of splenic rupture [32]. Splenic salvage in the trauma setting is associated with marked reductions in the risk of infection during the acute hospitalization, including surgical site infections and pneumonia [33]. Implantation of splenic fragments into the peritoneum has been performed in an attempt to maintain splenic function. Immune protection by these splenic fragments is incomplete at best, due to the loss of the normal splenic circulation. The presence of Howell–Jolly bodies on the peripheral blood smear indicates decreased splenic function, placing the patient at risk for overwhelming postsplenectomy infection (OPSI) [34]. Although Howell–Jolly bodies may be detected by autoanalyzers, a manual blood film should be reviewed if there is a clinical question of hyposplenism.

Epidemiology

The incidence of OPSI is impacted by many factors, including underlying disease, patient age, age at the time of splenectomy, time elapsed since splenectomy, pneumococcal vaccination, and antibiotic prophylaxis. Reported incidence rates are highest among patients with underlying thalassemia; intermediate in patients with sickle cell anemia, malignancy, or hematologic disorders; and lowest among patients who undergo splenectomy for trauma.

Encapsulated bacteria are the most common organisms causing OPSI. *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae* are the organisms of greatest concern. *S. pneumoniae* is the most frequently isolated pathogen, representing over 50% of cases of OPSI. Other bacterial pathogens include *Salmonella* spp [28], *Capnocytophaga canimorsus* [35], which is associated with dog bites, and *Campylobacter* spp [36].

Asplenic individuals are also at risk for severe infection with the intraerythrocytic pathogens *Babesia microti* and *Babesia bovis*. Both organisms are transmitted by tick bites; *B. microti* is endemic on islands off the northeastern coast of the United States (Long Island, Nantucket Island, Martha's Vineyard), whereas *B. bovis* is found in Europe. The acute phase of malaria may be more severe in splenectomized individuals, but splenectomy may be protective in the chronic phase. Atypically severe cases of *Plasmodium vivax* and *Plasmodium ovale* have been reported in splenectomized individuals, and relapse of malaria following splenectomy has occurred [28].

Diagnosis

Clinical Presentation

OPSI should be considered in any febrile patient with a history or abdominal scar consistent with splenectomy or disease process associated with hyposplenism. The initial symptoms of OPSI are fever, headache abdominal pain, vomiting, and diarrhea. There may be a nonspecific prodrome characterized by low-grade fever and myalgias. If untreated, the disease evolves into fulminant septic shock and death over 2 to 5 days [37]. In advanced cases, acute tubular necrosis, adrenal cortical necrosis, and disseminated intravascular coagulation may occur. A petechial or purpuric rash may be seen. Meningitis or pneumonia occurs in approximately one-half of cases; in the remaining cases septicemia occurs, which is presumed to arise from colonization of the pharynx.

Laboratory Features

Blood cultures yield the causative organism in most cases of OPSI. Infections of lesser severity also occur and may not be associated with detectable bacteremia. Hematologic findings of DIC (thrombocytopenia, elevated prothrombin time, D-dimer, and fibrin split products), elevated serum creatinine, and blood urea nitrogen are frequently seen. Howell–Jolly bodies are found on a peripheral blood film. In the immediate postsplenectomy period, mild elevation in the platelet and leukocyte numbers are physiologic, but a leukocyte count higher than 15,000 cells per μL after the fourth postoperative day suggests infection is likely the cause [38].

Differential Diagnosis

OPSI may be mistaken for uncomplicated sepsis if the history of asplenia or hyposplenism is not appreciated. Thrombotic thrombocytopenic purpura may also have a similar presentation, with fever, thrombocytopenia, and acute renal failure.

Management

In addition to supportive care, antimicrobial therapy should be initiated promptly. Third-generation cephalosporins are active

against *S. pneumoniae, N. meningitidis,* and *H. influenzae* in most locales. Cefotaxime 2 g intravenously every 8 hours or ceftriaxone 1 to 2 g intravenously once daily [39] may be used for uncomplicated cases. If meningitis is suspected, the dose of cefotaxime should be increased to 2 g every 4 to 6 hours; ceftriaxone should be given in a dose of 2 g twice daily. If pneumococci with high-grade resistance to penicillin and cephalosporins are prevalent in the region, vancomycin should be added until culture and susceptibility data become available. Patients with a severe allergy to penicillins and cephalosporins may be treated with vancomycin given with chloramphenicol or a fluoroquinolone [29]. Expert consultation should be sought in such cases.

Prevention

Guidelines for management of the postsplenectomy patient were published [40] prior to the advent of the quadrivalent conjugate meningococcal vaccine. Recommendations include timely vaccination with the 23-valent pneumococcal vaccine, preferably 2 weeks or longer prior to splenectomy. If that is impractical, it is recommended that patients be immunized as soon as possible postoperatively. Recent observations that antibody levels are improved if vaccination is delayed until 14 days postoperatively [41] must be weighed against the risk that vaccination may be overlooked if it is not carried out prior to hospital discharge. A reasonable compromise may be to immunize the patient at hospital discharge. Pneumococcal vaccine boosters should be administered every 5 years. Meningococcal conjugate vaccine (MCV4) should be administered to patients who are asplenic or who have splenic dysfunction. Due to the ongoing risk for meningococcal disease in asplenic persons, MCV4 vaccination should be repeated at 3- to 5-year intervals [42,43]. The conjugate *H. influenzae* vaccine should be administered to asplenic patients according to the standard schedule for all children [40].

Lifelong antibiotic prophylaxis is recommended by some authors [40], whereas others question this approach [28]. The data supporting prophylaxis are stronger in the pediatric population than in adults [29]. In the first 2 years following splenectomy in a child, or a patient with thalassemia or immune deficiency, antibiotic prophylaxis is recommended by most experts. Penicillin remains the drug of choice despite the emergence of resistance among some isolates. Ideally it should be dosed twice daily, but if adherence is an issue, it may be given once daily. Erythromycin may be substituted for patients who are allergic to penicillin. "Standby" antibiotics, to be taken early in the course of a febrile illness, is a strategy favored by all [28,40]. Amoxicillin-clavulanate is a good choice for this indication. Patients must be counseled to seek medical care if they are ill, and not rely on standby antibiotics alone.

MENINGOCOCCEMIA

The Centers for Disease Control (CDC) estimates that each year 1,400 to 2,800 cases of invasive meningococcal disease occur in the United States [42,44]. This section will cover *Neisseria meningitidis* bacteremia. Meningitis is covered in Chapter 79. Although infants are at highest risk for meningococcal disease, case rates also rise in the early teenage years, and 32% of cases occur among persons aged 30 years or older [44]. There are five serogroups, A, B, C, Y, and W-135. In the United States, serogroups B, C, and Y cause 93% of cases, with each representing about one third of cases. Serogroup B disease is more common among infants. Disease rates vary seasonally, with the lowest rates in the summer and early autumn months [42].

Pathophysiology

Neisseria meningitidis colonizes the nasopharynx in normal individuals by adherence to epithelial cells via pili and other adhesion factors. In the majority of individuals, it never causes disease. Invasive disease has been associated with a variety of factors, including antecedent viral infection, exposure to passive smoking, and inhalation of dry, dusty air [45]. Specific antibody and the complement system are key protective components of the host immune system. Deficiency of components of the complement system due to genetic defects or underlying disease predisposes to invasive meningococcal disease [46]. When bacteria invade the bloodstream, endotoxin activates the host immune system and proinflammatory cytokines cause a vascular leak syndrome. The endothelial thrombomodulin-endothelial protein C receptor pathway is downregulated, leading to thrombosis and purpura fulminans [47]. Profound vasoconstriction leads to peripheral ischemia and gangrene [45], and depression of myocardial contractility by cytokines contributes to shock.

Diagnosis

Clinical Manifestations

Few disease states are as impressive as full-blown meningococcal sepsis. The challenge is early recognition and intervention before irreversible damage occurs. Early in the course of meningococcal sepsis, nonspecific symptoms and signs are the only manifestations. Fever, malaise, myalgias, vomiting, tachypnea, and tachycardia are typical. The rash begins as an erythema, progressing to the characteristic petechiae and purpura only later in the course of disease. As the disease progresses it evolves to septic shock, with hypotension, poor peripheral perfusion, impaired mentation, and anuria or oliguria. Other manifestations include hemorrhage, cardiac failure, acute renal failure, and thrombocytopenia with or without DIC [48]. Other, less common complications of meningococcal sepsis include adrenal hemorrhage and failure (Waterhouse–Friedrichson syndrome), chronic renal failure necessitating hemodialysis, cutaneous necrosis with sloughing requiring skin grafting, extremity gangrene requiring subsequent amputation, and often several surgical revisions, septic arthritis, endophthalmitis, and pericarditis. Mortality remains high, despite antibiotics and intensive care; 20% to 50% of children who develop shock from meningococcal sepsis die. Transfer to a specialist unit is associated with a marked reduction in mortality [49].

Laboratory Findings

Leukocytosis or leukopenia, with a shift to immature forms, and thrombocytopenia are typical. There may be laboratory evidence of DIC. Chemistries may demonstrate acidemia, hypoglycemia, decreased cortisol levels, and elevated blood urea nitrogen and creatinine. Diagnosis is confirmed by isolation of *N. meningitidis* from cultures of blood or other normally sterile body fluids. If the diagnosis of meningococcal sepsis is clinically apparent, some experts caution against performing a lumbar puncture for cerebrospinal fluid culture due to concerns for brain herniation or clinical deterioration related to positioning the patient for the procedure. Latex agglutination and polymerase chain reaction assays provide increased sensitivity [50].

Differential Diagnosis

Purpura fulminans is characteristic of meningococcemia, but may also be caused by *S. pneumoniae* or *H. influenzae* type B.

Other infections that may mimic meningococcemia are fulminant *S. aureus* sepsis, *S. pyogenes* bacteremia, Gram-negative sepsis, Rocky Mountain spotted fever, vasculitis, thrombotic thrombocytopenic purpura, Henoch–Schonlein purpura, and any febrile illness in a patient with thrombocytopenia.

Therapy

Third-generation cephalosporins are the treatment of choice for meningococcemia due to reports of penicillin resistance [51]. Ceftriaxone, 4 g intravenously daily in one or two divided doses or cefotaxime 8 to 12 g intravenously daily in four to six divided doses should be administered to adults with suspected meningococcal disease. There is limited clinical experience with alternative antibacterial agents for patients with a history of cephalosporin allergy. Based on in vitro susceptibility data, options include meropenem and chloramphenicol [51,52]. Fluoroquinolones may be useful in postpubertal persons, but rare cases of fluoroquinolone resistance have been reported [53].

Patients should be admitted to an intensive care unit and placed in respiratory isolation until 24 hours of appropriate antibiotic therapy has been administered. Supportive care is critical to a favorable outcome. Surgical intervention may be indicated for necrotic skin lesions and gangrenous limbs. Early fasciotomy appears to limit the extent of amputation that is ultimately required [54]. Adrenal insufficiency may occur; in hypotensive patients corticosteroids should be administered pending return of results of cosyntropin stimulation test. Use of plasmapheresis has been reported in uncontrolled series [55,56].

Drotrecogin-α has been approved for severe sepsis syndrome in adults, based on randomized controlled trials that included patients with meningococcal sepsis [57], and the pathophysiology of purpura fulminans suggests that activated protein C may be beneficial. However, the most significant toxicity of drotrecogin-α is spontaneous bleeding events, and risk of bleeding would be predicted to increase in patients with meningococcal sepsis due to the thrombocytopenia and hypoprothrombinemia that are commonly observed. Retrospective analysis of patients with purpura fulminans, meningitis, or meningococcal disease treated with drotrecogin in several trials showed no overall increased risk of bleeding as compared to patients with sepsis of other etiologies, but the risk of intracranial hemorrhage was increased [58]. Most of the intracranial hemorrhages that were observed were in patients with meningitis. Systemic arterial hypertension, thrombocytopenia, and age greater than 65 years were also commonly observed in patients with intracranial hemorrhage. Drotrecogin-α, given as an intravenous infusion of 24 μg per kg per hour for 96 hours, may be used for adult patients with meningococcemia who otherwise meet criteria for APC therapy. Caution is advisable in patients with concomitant meningitis, thrombocytopenia, or a history of hypertension.

Prophylaxis

The CDC recommends chemoprophylaxis after exposure to people with *N. meningitidis* infection for household, day care, and other close contacts; for people in close contact with infected respiratory secretions, such as those performing mouth-to-mouth resuscitation; and for travelers in contact with respiratory secretions of, or seated next to, an index case for 8 hours or more [42]. The agents recommended for chemoprophylaxis are rifampin (600 mg orally for adults, 10 mg per kg orally for children) given every 12 hours for four doses; or ceftriaxone, 125 mg intramuscularly in children younger than 15 years or 250 mg intramuscularly in people aged 15 years or older [42]. Resistance to ciprofloxacin, which has been widely used for prophylaxis, has recently been reported in several cases of meningococcal infection in North Dakota and Minnesota, leading to a recommendation to use alternative agents for prophylaxis in those areas [59]. Routine chemoprophylaxis is recommended for medical staff only if they have had prolonged close contact before the institution of antibiotic therapy.

Immunization with the tetravalent (serogroups A, C, W135, and Y) MCV4 is indicated for the following populations: children at their 11- to 12-year-old preadolescent healthcare visit, college freshmen living in dormitories, travelers to areas where *N. meningitidis* is epidemic or hyperendemic, microbiologists with frequent exposure to *N. meningitidis,* military recruits, those at risk during an outbreak (such as school or dormitory mates), and those with increased susceptibility (e.g., persons with complement deficiencies or asplenia) [42].

MALARIA

In developed countries malaria is primarily seen in travelers, immigrants, and military personnel, but in the developing world it is a major cause of morbidity and mortality. Worldwide there are between 300 and 660 million cases that occur annually, resulting in 700,000 to 2.7 million deaths each year [60]. Imported cases have increased throughout the world; in the United States, approximately 1,300 cases have been reported annually to the National Malaria Surveillance System, a passive reporting system administered by the CDC, over the past decade [61]. In 2003, *Plasmodium falciparum* was identified as the causative species in 53% of cases; 70% of the cases were acquired in Africa. Virtually all of the fatal cases of malaria in the United States are caused by *P. falciparum.* Although the great majority of cases occurred among persons who did not follow a CDC-recommended prophylaxis regimen, it must be noted that approximately 20% of patients with malaria reported taking appropriate chemoprophylaxis. Failure to take a recommended regimen resulted in fatal malaria in seven reported cases since 1992 [62]. There have been small clusters of mosquito-borne malaria transmission within the United States as well as occasional congenital cases and transmission via blood transfusion [63]. This discussion will focus on severe malaria and its management in critical care settings.

Etiology

Plasmodium is an intracellular parasite that sequentially infects hepatocytes and then erythrocytes, resulting in clinical malaria. Four species cause disease in humans: *P. falciparum, P. malariae, P. ovale,* and *P. vivax*. *Plasmodium* is transmitted to human hosts by its vector, the female *Anopheles* mosquito.

Pathophysiology

Severe malaria is almost always due to *P. falciparum*, which, because of its ability to infect erythrocytes of all ages, can produce very high levels of parasitemia. Cerebral malaria is the most common clinical presentation of severe malaria. Many factors can contribute to diminished brain function in severe malaria, including obstruction of microvascular flow, elevated intracranial pressure, cerebral edema, disruption of the blood–brain barrier, hypoglycemia, hypovolemia, and seizure activity.

Obstruction of microvascular flow is caused by sequestration of erythrocytes in brain capillaries, autoagglutination, and decreased erythrocyte deformability due to intracellular parasites. Cytoadherence, a process in which *P. falciparum* derived

proteins on infected erythrocytes attach to the CD36 receptor on vascular endothelial cells, appears to mediate sequestration [64].

In endemic areas, malaria is largely a disease of children. By the time they reach adulthood, residents of endemic areas develop partial immunity to *Plasmodium* infections, limiting the severity of disease. Travelers, conversely, are generally not immune; nonimmune adults who become infected are almost always symptomatic, and severe disease may develop.

Diagnosis

Clinical Features

Although imported malaria may occur at any time after leaving an endemic area, there are epidemiologic clues to help guide the evaluation. Among returning travelers presenting with fever, the most common specific diagnosis is malaria, occurring in 9% of cases [65]. Among cases diagnosed in New York, 80% of patients had symptom onset within 1 month of leaving the endemic area. Most of the cases presenting later than 1 month post-departure had *P. vivax*, which rarely causes life-threatening disease.

Patients with malaria present with a history of fever and chills, but fever may not be present at the time of the initial examination. The classic descriptions of tertian and quartan fever are rarely seen; their absence is not evidence against the diagnosis of malaria. Chills, headache, fatigue, and myalgias are common complaints. Signs include hypotension, jaundice, and hepatosplenomegaly, but these are seen in a minority of patients [66]. If hypotension is present, Gram-negative bacteremia must be excluded and treated empirically until cultures return. Cough, dyspnea, and tachypnea may dominate the clinical picture in children, causing confusion with pneumonia in areas of the developing world where chest radiography is not readily available [67].

Malaria in pregnancy presents with similar, although more severe, manifestations. Hypoglycemia and lactic acidosis are more frequently seen in maternal malaria, and the mortality of cerebral malaria is increased [68]. The partial immunity of residents of endemic areas is blunted in pregnancy [69]. Other complications include preterm delivery, intrauterine growth retardation, anemia, postpartum hemorrhage, and eclampsia [68]. Human immunodeficiency virus (HIV)–infected gravida are both at increased risk of infection with *Plasmodium* species, and have a more severe course of malaria. Additionally, malaria is associated with an increased maternal HIV viral load, and may increase HIV transmission to the fetus [70]. Placental malaria may be present even if peripheral blood films are negative for parasites [71].

Complications

The most common complications of malaria are cerebral malaria, severe anemia, metabolic acidosis, and noncardiogenic pulmonary edema. Gram-negative sepsis and metabolic acidosis are less common, but potentially grave complications of severe malaria.

Variability in host susceptibility and in the definition of cerebral malaria may account for the wide range of reported incidence. The World Health Organization defines cerebral malaria as coma that cannot be explained by hypoglycemia, postictal state, or other nonmalarial causes, such as sedative drugs, in a patient with parasitemia. Common findings are decerebrate or decorticate posturing, flaccid tone, seizures, and retinal hemorrhages. A recent study on imported severe *falciparum* malaria reported cerebral malaria in 37% of cases [61]. Overall mortality of severe malaria in that series of cases treated in a highly experienced intensive care unit setting was 11%. Cerebral malaria was present in 90% of nonsurvivors.

Laboratory Features

Common laboratory findings are anemia, thrombocytopenia, and hyperbilirubinemia. Hypoglycemia, elevated creatinine, and hypothrombinemia may also be present [61].

Microscopic examination for parasites on thick and thin films of peripheral blood remains the standard for diagnosis of malaria. Sensitivity is increased when blood for malaria smears is obtained from a capillary-rich area, such as the fingertip or earlobe, rather than by venipuncture. A thick smear examined by an experienced microscopist can detect 50 parasites per μL of blood, which is equivalent to 0.001% of erythrocytes infected [71]. Sensitivity is approximately 10-fold lower in routine clinical laboratories. In addition, patients with *falciparum* malaria may have parasites sequestered in deep capillaries in the spleen, liver, bone marrow, or placenta, with a false negative peripheral smear. Because the sensitivity of the smear is imperfect, empiric therapy for malaria should be administered when clinical suspicion is high. The thin blood film is used to identify the species and to quantitatively follow the parasitemia on serial samples. Real-time polymerase chain reaction (PCR) is more sensitive than microscopy, especially at low levels of parasitemia, and although it is not FDA-approved, the assay is readily available from reference laboratories.

Differential Diagnosis

Cerebral malaria may mimic meningoencephalitis due to viral, bacterial, fungal, or other parasitic causes. Dengue, typhoid, rickettsial infection, or mononucleosis may present with an undifferentiated fever in a returned traveler. The differential diagnosis of jaundice in this population includes leptospirosis, yellow fever, viral hepatitis, sepsis, and relapsing fevers [67]. Bacterial sepsis must also be considered as a separate or a complicating diagnosis.

Treatment

Management in an intensive care unit is indicated for patients with severe malaria. Careful management of fluids and electrolytes is critical, as well as monitoring for hypoglycemia. Renal, cardiac, and neurologic function should also be carefully monitored.

Intravenous quinidine has been used in the United States for treatment of severe malaria since 1991, when the CDC stopped providing intravenous quinine [72]. At that time, quinidine was readily available on most hospital formularies, and therapy could be initiated rapidly. The declining use of intravenous quinidine for cardiac dysrhythmias has reduced the ready availability of quinidine, but a replacement strategy has not yet been developed [73] and it remains the drug of choice. It should be initiated for severe malaria, defined as a positive blood smear with any one of the following criteria: impaired consciousness/coma, severe normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, disseminated intravascular coagulation, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, repeated generalized convulsions, or parasitemia greater than 5%.

Hypoglycemia, QT interval prolongation, cardiac dysrhythmias, and hypotension may complicate quinidine infusion. Intensive care unit monitoring and consultation with an infectious disease specialist and a cardiologist are recommended. Cardiac complications may require slowing or stopping the

infusion. When dosage is calculated, it is important to distinguish the salt from the base to ensure accuracy. The usual dose is 6.25 mg base per kg (10 mg salt per kg) loading dose intravenously over 1 to 2 hours, then 0.0125 mg base per kg per minute (0.02 mg salt per kg per minute) continuous infusion for at least 24 hours. If the patient has received mefloquine or more than 40 mg per kg of quinine in the 12 hours prior to beginning quinidine infusion, the loading dose should be omitted. Dosage adjustment for renal failure is not necessary in the first 48 hours of therapy [74]. Thin smears to assess the degree of parasitemia should be performed every 12 to 24 hours. Oral quinine 542 mg base (650 mg salt) three times daily for 3 to 7 days should be substituted when the patient is able to swallow, parasitemia is less than 1%, and mental status is normal. For infections acquired in Southeast Asia, the CDC recommends that therapy continue for 7 days; for disease acquired in Africa therapy should be stopped after 3 days.

Patients with malaria normally show improvement in 1 to 3 days [75]. If the course is more prolonged, drug resistance or inadequate serum drug levels should be suspected. In addition to quinine, the patient should be treated with one of the following: doxycycline 100 mg orally twice daily for 7 days, tetracycline 250 mg four times daily for 7 days, or clindamycin 20 mg base per kg per day orally in three divided doses for 7 days.

Artesunate, a new agent that was developed in China, has been shown in a randomized controlled trial to be superior to quinine for therapy of severe malaria [76]. Although it is not FDA approved for use in the United States, it may be available by making a treatment investigational new drug (IND) request from the CDC for cases of severe malaria. Physicians who encounter a case of *falciparum* malaria should contact the CDC malaria hotline 770-488-7788 for updated information on treatment recommendations, including changes in the availability of artesunate.

Treatment of a pregnant woman with malaria requires additional considerations [68]. High doses of quinine are reported to be abortifacient. Nevertheless, treatment with quinine has not been associated with an increased risk of congenital abnormalities, low birth weight, or stillbirth, and it is considered to be safe in the first trimester [77]. Chloroquine is safe for use in pregnant women for the treatment of non-*falciparum* or chloroquine-sensitive *falciparum* malaria. As discussed earlier, quinidine is substituted for quinine in the United States. Quinidine is listed as category C and is considered safe for breastfeeding women. Clindamycin may be used as a second agent, after completion of quinidine or oral quinine treatment. Artesunate-atovaquone-proguanil has been shown to be superior to quinine during the second and third trimesters, with no differences in birth weight, duration of gestation, or congenital abnormality rates in newborns [78]. As discussed later, exchange transfusion has also been used for severe *falciparum* malaria during pregnancy [79]. If fetal distress is observed on monitoring, emergency cesarean delivery may be necessary [67,79].

Exchange transfusion is controversial due to the lack of randomized trial data, but its use is recommended by the World Health Organization for patients with parasitemia greater than 30%, and for patients with parasitemia greater than 10% and severe disease, failure to respond to chemotherapy within 12 to 24 hours, or baseline poor prognostic factors such as advanced age or schizonts on peripheral blood film [67].

A randomized controlled trial has shown that corticosteroids were of no benefit and potentially harmful in the treatment of cerebral malaria [80]. Other adjunctive therapies that should not be used include heparin, sodium bicarbonate, mannitol, immunoglobulins, and iron chelators [67,80].

Advances in cerebral malaria, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 83.1.

TABLE 83.1

SUMMARY RECOMMENDATIONS FOR MANAGEMENT OF CEREBRAL MALARIA BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

- Corticosteroids are harmful and should not be used.[a]
- Artesunate is the antimalarial of choice for cerebral malaria. When it becomes available in the United States, it should replace quinidine for this indication. Physicians who encounter a case of cerebral malaria should contact the CDC for an update on availability of artesunate.[b]

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (RMSF) is a potentially fatal zoonosis caused by the agent *Rickettsia rickettsii*, which is transmitted by ticks. Although the classic constellation of findings is fever, rash, and tick bite occurring in the summer months, it is important to consider the disease even when some of these features are lacking. A history of tick bite is reported in only 60% of documented cases [81], and rash may be absent in 20%. Recognition of RMSF is critical, as outcome is much improved with timely, appropriate therapy [82].

RMSF is transmitted by the hard ticks *Dermacentor andersoni, Dermacentor variabilis, Amblyomma cajennense,* and *Rhipicephalus sanguineus*. The latter tick, previously a recognized vector for RMSF in Mexico, was implicated in a recent outbreak of RMSF in Arizona, an area that had previously been spared this disease [83]. The incidence of reported RMSF has increased threefold in the 2002–2006 period compared to 1996–2001 [84]. Although the peak incidence is in the summer months, cases occur throughout the year. Classically it has been taught that children and males are at highest risk, but recent CDC data show that females and adults have only a slightly lower incidence. Native Americans have a higher incidence than other ethnic groups. RMSF was first described in Montana, thus its name, but is more frequently seen in the southeastern United States, especially the Carolinas, Oklahoma, Arkansas, and Missouri.

Pathophysiology

Rickettsia rickettsii parasitize endothelial cells of many organs and vascular smooth muscle. The organisms cause a direct cytopathic effect, leading to vascular injury, clotting activation, and a vascular leak syndrome. In severe cases, this manifests as multiorgan failure. Renal failure, respiratory failure, and coma may ensue.

Diagnosis

The presentation of RMSF is protean due to the multisystem nature of the disease. Symptoms include fever, malaise, headache, rash, myalgia, nausea, vomiting, abdominal pain, and diarrhea. Two thirds of cases have a temperature above 102°F at presentation; 90% have temperature above 102°F

within 48 hours of presentation. Rash generally appears by the second or third day of illness and classically starts at the wrists and ankles, but is frequently generalized. It may involve the palms and soles; the face is spared. Rash may be missed in persons with dark skin. Gastrointestinal symptoms may be prominent, despite the systemic nature of the disease. Headache is typically present and is often severe. The key to the diagnosis is to consider it in any febrile patient who has been spending time outdoors in an endemic area.

Laboratory findings include a white blood cell count that is typically in the normal range, although a manual differential count reveals a shift to immature neutrophils. Platelets are usually decreased. Other nonspecific findings reflect the multisystem nature of the process and include hyponatremia, elevated creatine phosphokinase, hepatic transaminases, and creatinine and clotting indices (prothrombin time, partial thromboplastin time, and fibrin degradation products). CSF examination commonly demonstrates a mononuclear pleocytosis and occasionally an elevated CSF protein and low CSF glucose levels [82]. Diagnosis may be confirmed by biopsy of skin involved with rash and processed with immunofluorescence or immunoperoxidase staining, or by serologic testing.

Differential Diagnosis

RMSF is frequently misdiagnosed as pharyngitis or scarlet fever, despite the low incidence of sore throat [85]. Gastroenteritis is also a common initial diagnosis due to prominent gastrointestinal symptoms. RMSF must also be distinguished from rheumatic fever, encephalitis, meningitis, pneumonia, measles, meningococcemia, leptospirosis, acute abdominal illness, idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, drug reaction, ehrlichiosis, and vasculitis [82,85,86].

Therapy

Specific therapy should not be delayed while awaiting confirmation of the diagnosis. Most broad-spectrum antibacterial agents such as cephalosporins, penicillins, and sulfa drugs are inactive against *R. rickettsii*. The treatment of choice for nonpregnant adults and children weighing more than 45 kg is doxycycline [87], 100 mg twice daily for 7 to 10 days. Children who weigh less than 45 kg should be given 2.2 mg per kg twice daily [81,88]. The risk of dental staining by tetracyclines in children is small for short courses of therapy; this consideration should not delay treatment [89]. Therapy of pregnant women is problematic because tetracyclines are associated with maternal hepatotoxicity and fluorescent yellow discoloration of fetal deciduous teeth. Calcification of permanent teeth does not begin until after birth; discoloration of permanent teeth would not be expected. The U.S. Food and Drug Administration and the Australian Drug Evaluation Committee have assigned pregnancy category D to doxycycline. Chloramphenicol is considered pregnancy category A by the Australian Drug Evaluation Committee [90]. Although teratogenicity has not been proven with chloramphenicol, maternal aplastic anemia or reversible bone marrow suppression may occur. Gray baby syndrome has occurred in neonates treated with chloramphenicol, and may occur in infants born to women treated with chloramphenicol near term. Doxycycline may be used for women presenting with RMSF near term [91]. Most authorities recommend therapy of pregnant women in the first or second trimester with chloramphenicol, 50 to 75 mg per kg per day in divided doses. Corticosteroid therapy has not been studied in a controlled fashion, although older literature has recommended it for patients with widespread vasculitis and encephalitis [92].

Prognosis

Outcome is directly related to timely, appropriate therapy. Mortality rates are as high as 20% for untreated cases, and 5% with proper therapy [93,94]. Risk factors for mortality include central nervous system involvement, renal dysfunction at presentation, a delay in the institution of therapy, therapy with an agent other than a tetracycline [87], and increased age.

MISCELLANEOUS INFECTIOUS DISEASES

There are many unusual infectious diseases that occasionally lead to intensive care unit admission. Several of these diseases are discussed briefly below and others such as serious epidemic viral pneumonias (Chapter 90) and biologic agents of mass destruction (Chapter 213).

Ehrlichiosis and *anaplasmosis* are tick-borne rickettsial diseases that present as a fever with few localizing symptoms or signs. Headache, myalgias, malaise, and rigors are seen in nearly all cases; gastrointestinal or respiratory symptoms may occur in a minority of cases [95]. Human monocytic ehrlichiosis (HME), caused by *Ehrlichia chaffeensis,* is most commonly seen in the southeastern United States. HME may present with meningoencephalitis, acute respiratory distress syndrome (ARDS), and a toxic shock–like illness [96]. Human granulocytic anaplasmosis (HGA), caused by *Anaplasma phagocytophilum*, is most commonly seen in the upper midwestern states and the northeastern United States [86]. HGA is typically a less severe disease than HME. It is found in the same geographic areas as babesiosis and Lyme disease and transmitted by *Ixodes scapularis* and by *Ixodes pacificus,* the same ticks that transmit *Borrelia burgdorferi* and *Babesia* species. Coinfection with *A. phagocytophilum, Babesia* spp, and *B. burgdorferi* has been reported [86,97]. *Ehrlichia ewingii* infection has been reported to cause a granulocytic ehrlichiosis in the southeastern United States, primarily in immunocompromised hosts [86]. In contrast to most tick-borne illnesses, ehrlichiosis and anaplasmosis are more frequently seen in middle-aged and older individuals [96,97]. Cases most often present in spring and summer, but have been reported in every month of the year [96]. HME may follow a fulminant course in HIV-infected individuals [98]. Leukocyte counts are generally low or normal with a shift to immature forms, elevated transaminases, and thrombocytopenia typically found if patients are followed carefully [95,97]. The diagnosis may be confirmed by the observation of clumps of organisms within leukocytes, termed morulae, but the sensitivity of microscopy in the first week of illness is only 60%, even in very experienced hands [97]. Sensitivity is even lower later in the course. The diagnosis may be confirmed serologically or by a polymerase chain reaction assay at a reference laboratory [86], but therapy may need to be initiated while awaiting results if suspicion is high. The treatment of choice is doxycycline; rifampin has been used if doxycycline is contraindicated [97]. Due to the overlap in clinical syndromes and the uncertainty of diagnosis early in the course, it is important to be certain that RMSF has been ruled out if an alternative agent to doxycycline is selected.

Capnocytophaga spp are fastidious Gram-negative rods that cause soft tissue infections, fever of unknown origin, bacteremia, and meningitis [99,100]. *C. canimorsus* is normal oral flora in dogs, and infection is often associated with a dog bite. Cases have been reported in association with cat bites and with nontraumatic exposure to the oral secretions of dogs. Several other species of the *Capnocytophaga* genus are normal oral flora of humans, and may cause bacteremia in the setting of cancer chemotherapy [101,102]. Compromised hosts may

follow a severe course of illness, especially if bacteremia is complicated by disseminated intravascular coagulation. *Capnocytophaga* spp are resistant to many antibacterial agents that are commonly used to treat skin and soft tissue infections, including oxacillin and cefazolin. Ampicillin-sulbactam is a good empiric choice for serious soft tissue infection when there is a history of a dog bite. Clindamycin can be used for culture-proven cases of monomicrobial infection with *Capnocytophaga* in the case of penicillin allergy [101], but it is not active against *Pasteurella multocida,* which is a common pathogen in cases of dog or cat bites. Imipenem-cilastin is another alternative active against *Capnocytophaga* and *P. multocida* as well as other common pathogens of skin and soft tissue except MRSA.

CHAPTER 84 ■ ACUTE INFECTION IN THE IMMUNOCOMPROMISED HOST

JENNIFER S. DALY AND ROBERT W. FINBERG

Advances in the management of neoplastic diseases, transplant immunology, and the therapy of autoimmune diseases have resulted in marked improvements in life expectancy and the quality of patients' lives. However, patients with autoimmune diseases, neoplasia, or transplants become highly susceptible to infection by virtue of their associated therapies or by the nature of their underlying illness. Infection has been and remains a leading cause of death in patients with leukemia and lymphoma and a major cause of morbidity and mortality in patients with solid tumors or transplants [1–4]. Rapid progression of fungal, bacterial, and mycobacterial infections occurs in patients given monoclonal antibodies to treat Crohn's disease and autoimmune diseases such as rheumatoid arthritis [5–8]. The epidemic of human immunodeficiency virus (HIV)-1 infection has added to the numbers of immunocompromised hosts by virtue of the central event of the virus's pathogenesis—a progressive, irreversible weakening of cell-mediated immunity unless the patient responds to antiretroviral agents. See Chapter 85.

Traditionally, infection has accounted for up to 75% of deaths in patients with acute leukemia or Hodgkin's disease [1,9] or in transplant recipients [4,10], but with advances in prophylaxis and management, deaths due to infections have decreased to about 50% while deaths due to graft versus host disease, relapse of malignancy, and multiorgan failure have increased [3,11–13]. Once patients require the care of an intensive care unit (ICU), the mortality increases, and the 1-year survival of cancer patients that require mechanical ventilation in the ICU is below 11% in some centers [14] with acute mortality between 44% and 74% [15–17]. While intensive efforts are clearly beneficial in stem cell transplant patients requiring ICU care in the pre-engraftment period, patients with graft versus host disease following engraftment have the worst prognosis [14]. Early ICU admission has been advocated based on one small study demonstrating that among patients initially thought to be too sick to benefit from ICU care, many were subsequently admitted to the ICU, and did well [18].

Although a great variety of microorganisms have been noted to cause severe, life-threatening infections in immunocompromised hosts, the clinician can formulate a diagnostic plan and decide on empiric therapy by giving careful consideration to the nature, duration, and severity of the immunosuppression that is causing the patient's predisposition to infection. Infection can arise as a consequence of derangements in host defenses that result from the primary disease, the medical and surgical treatment of the condition, or a combination of these factors. Additionally, immunocompromised patients are likely to manifest their infections in ways that are characteristically different from those of patients with intact immune responses.

IMMUNE DEFECTS AND ASSOCIATED ORGANISMS AND INFECTIONS

Underlying disease or treatments affect different aspects of the immune system and, depending on the type of defect, are associated with predisposition to infection with specific classes of organisms or disease syndromes. A level of suspicion of infection with certain organisms depends on the specific immune defect, the duration of immunosuppression, surgical and medical interventions, colonization with nosocomial pathogens, and previous latent or asymptomatic infections that may reactivate after immunosuppression. In general, the most common sites of serious, definable infection in the immunocompromised host are the bloodstream [including infection related to intravenous (IV) access devices], lung, and mucocutaneous surfaces (including oral, gastrointestinal, skin, and perirectal areas). The diverse organisms frequently or uniquely associated with infections in the compromised host are listed in Table 84.1. As a general rule, patients whose underlying disease or treatment leads to a lack of T cells or any abnormality in T cell-macrophage activation will be subject to infections with organisms that live intracellularly such as viruses, fungi, and intracellular bacteria (e.g., *Listeria*, *Legionella*, mycobacteria). Patients with profound neutropenia will be subject to infection with aerobic Gram-positive and Gram-negative bacteria that live on the skin and within the gut. Patients lacking antibodies or a spleen will be unusually susceptible to infection with encapsulated bacteria (*Streptococcus pneumoniae, Haemophilus influenzae,* and *Neisseria meningitidis*). As for any patient in the ICU, the immunocompromised patient is susceptible to infection with bacteria that are found in ventilators or spread in the ICU. The most common organisms found in patients with bloodstream infections vary by center and whether or not patients are on prophylactic antimicrobials [19]. *Escherichia coli* and *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), continue to be common, followed by coagulase-negative staphylococci, enterococci including vancomycin-resistant enterococci, *Pseudomonas aeruginosa*, *Klebsiella* spp, *Enterobacter* spp, and various streptococci [20–23]. In patients with neutropenia and documented bacteremia, Gram-positive organisms predominate over Gram-negative bacilli in patients in most centers, and the presence of an intravascular device is associated with having a positive blood culture [24]. Fungal infections increase in frequency with increasing duration of the immunocompromised state and therapy with broad-spectrum antibiotics.

Anatomic Barriers

The skin and mucosal surfaces serve a primary role in the defense of the host against invasion by endogenous and exogenous microorganisms. Mucous membrane ulceration in the mouth and gastrointestinal tract can occur spontaneously in patients with acute leukemia, although this complication more commonly arises after chemotherapy. In patients with solid tumors, disruption of mucocutaneous barriers can result from invasion, obstruction, or perforation by the malignancy. Iatrogenic disruption of the normal skin and mucosal barriers results from medical and surgical support interventions common to the ICU, including intravascular and urinary catheters [25]

TABLE 84.1

ORGANISMS COMMONLY OR UNIQUELY ASSOCIATED WITH ACUTE INFECTION IN THE IMMUNOCOMPROMISED HOST

Organism	Type of immune deficiency most likely to predispose to this organism
Bacteria	
Enteric Gram-negative bacilli (*Escherichia coli, Klebsiella*, *Enterobacter*, or *Proteus* spp	All immunocompromised patients, especially those with neutropenia and those on mechanical ventilation or medications that suppress gastric acid
Staphylococcus aureus	All immunocompromised patients, especially those with skin infections or intravascular catheters
Pseudomonas aeruginosa	Especially common in neutropenic patients and those on mechanical ventilation
Listeria monocytogenes	Patients with T cell or macrophage deficiencies, HIV/AIDS patients
Legionella pneumophila and related organisms	Patients with T cell or macrophage deficiencies and anyone exposed to water sources contaminated with Legionella
Skin/mucous membrane saprophytes	All immunocompromised patients
Corynebacterium jeikeium	Neutropenic patients, especially those with indwelling catheters; splenectomized patients
Capnocytophaga spp	Splenectomized patients
Coagulase-negative staphylococci	Patients with indwelling vascular catheters or prosthetic material
Nocardia spp	Patients with T cell or macrophage abnormalities
Streptococcus pneumoniae	Patients with immunoglobulin deficiencies or hyposplenism
Haemophilus influenzae	Patients with immunoglobulin deficiencies or hyposplenism
Neisseria meningitidis	Patients with immunoglobulin deficiencies or hyposplenism
Mycobacteria	Patients with a history of high risk exposure for tuberculosis (lived in an endemic area or history of a positive tuberculin skin test) or long-standing immune defects and/or chronic lung disease
Fungi	
Candida albicans and other *Candida* spp	Patients with vascular catheters after abdominal surgery, including liver transplantation; patients with prolonged neutropenia; and those receiving intravenous hyperalimentation
Torulopsis glabrata	Same as Candidiasis, increased in patients with diabetes and urinary tract colonization
Aspergillus spp	Patients with prolonged neutropenia, after transplantation, or on medications such as steroids and cytotoxic agents
Zygomycetes spp	Patients with neutropenia, after transplantation, with diabetes, or on medications such as steroids and cytotoxic agents
Trichosporon spp	Patients with neutropenia, after transplantation, or on medications such as steroids and cytotoxic agents, with vascular catheters and those receiving intravenous hyperalimentation
Fusarium spp	Patients with neutropenia, after transplantation, or on medications such as steroids and cytotoxic agents, with vascular catheters and those receiving intravenous hyperalimentation
Pneumocystis jiroveci	Patients with T cell or macrophage deficiencies, especially those receiving steroids, antirejection agents, or with lymphocytic leukemia or HIV/AIDS
Endemic fungi and yeasts	
Cryptococcus neoformans	Patients with HIV/AIDS, after transplantation, or receiving steroids
Histoplasma capsulatum	Patients from an endemic area
Coccidioides immitis	Patients from an endemic area
Protozoa	
Toxoplasma gondii	Patients with HIV/AIDS, after transplantation, or on medications such as steroids and cytotoxic agents
Parasites	
Strongyloides stercoralis	Patients from an endemic area and after transplantation, or on medications such as steroids and cytotoxic agents
Viruses	
Cytomegalovirus	Patients after bone marrow or solid organ transplantation
Varicella-zoster virus	Patients with T cell or macrophage abnormalities, especially those not receiving antiviral prophylaxis with cancer, or after bone marrow or solid organ transplantation
Herpes simplex virus	Patients with T cell or macrophage abnormalities and ICU patients, especially those not receiving antiviral prophylaxis with cancer, or after bone marrow or solid organ transplantation

(see Chapter 81 on catheter infections). Organisms that most frequently cause infection of intravascular catheters include coagulase-negative staphylococci, *S. aureus*, enterococci, *Corynebacterium* spp (including *C. jeikeium*), and *Candida* spp [1,25,26]. Percutaneously inserted central catheters (PICC) are associated with an increased risk of both infection and thrombosis [27]. The risk of these infections can be reduced, although not eliminated, through the use of permanent, subcutaneously tunneled catheters (e.g., Hickman, Broviac, Groshong, or Portacath systems) [28]. Genitourinary tract infections are associated with disruption of the urinary tract integrity, as occurs with urinary catheter drainage, pelvic tumors, or radiation with resultant ureteral obstruction, or after renal transplant.

The gastrointestinal tract is a source of occult bacteremia or fungemia, as chemotherapy and neutropenia cause breakdown in normal mucosal defenses of the gut, facilitating entry of bacteria or yeast into the bloodstream. Clinically apparent intestinal problems seen in neutropenic patients include typhlitis, anorectal cellulitis/fasciitis/abscess, necrotizing colitis, and *Clostridium difficile*-associated colitis caused by chemotherapy or antibiotics [29]. Typhlitis, an inflammatory disease of the cecum, may lead to toxic megacolon and perforation and requires a high index of suspicion and prompt diagnosis. Unusually severe and prolonged viral gastroenteritis caused by cytomegalovirus (CMV), adenovirus, rotavirus, and Coxsackie virus has been observed in marrow transplant recipients [30–32]. Herpes simplex virus (HSV) should be suspected as a possible cause for any lesion of mucous membranes in an immunocompromised host, and may also cause fatal hepatitis [33]. Adenovirus may cause hepatitis, pneumonitis, or hemorrhagic cystitis [32], and BK and JC viruses may cause persistent fever and renal insufficiency [34,35]. Necrotizing gingivostomatitis caused by oral anaerobes as well as severe periodontal infection may also complicate neutropenia.

Defective Phagocytosis

Neutrophils and macrophages provide defense against infection by bacteria and many fungi. Patients with leukemia, particularly an acute type of leukemia, commonly have a reduction in their absolute number of circulating neutrophils; qualitative defects of neutrophil function have also been described in these patients. Aplastic anemia, as well as extensive bone marrow involvement caused by lymphoma or metastatic solid tumors, may result in neutropenia. By far the most common cause of neutropenia, however, is cytotoxic chemotherapy. Patients whose neutrophils are reduced in number by malignancy or chemotherapy are at risk for development of spontaneous bacteremia. The risk becomes significant at absolute neutrophil counts that are persistently below 500 per mm^3 (or below 1,000 per mm^3 and falling) and increases dramatically at counts below 100 per mm^3 [32,36].

Invasive and disseminated fungal infections also may be a consequence of neutropenia and become more common after the neutropenic patient has received broad-spectrum antibiotic therapy [32,37]. *Candida* and *Aspergillus* spp are the most common fungal pathogens observed in neutropenic hosts, but unusual genera such as *Fusarium, Trichosporon, Scedosporium* (*Pseudallescheria),* and *Cunninghamella* have been described with increasing frequency [38,39]

Altered Humoral Immunity

B-cell lymphocytic function and antibody production may be impaired in untreated patients with chronic lymphocytic leukemia, multiple myeloma, and lymphoma. Acquired deficits in antibody production may also be encountered in otherwise healthy patients (e.g., immunoglobulin A deficiency, common variable immunodeficiency). Hypogammaglobulinemia or impaired antibody response predisposes patients to infections attributable to encapsulated bacteria such as *S. pneumoniae, H. influenzae,* and *N. meningitidis*; moreover, these infections are likely to be sudden, severe, and associated with fulminant bacteremia [32]. Infections caused by enteric Gram-negative bacilli and *P. aeruginosa* also may be seen in previously untreated patients with defective humoral immunity secondary to B-cell malignancies.

Impaired Cell-Mediated Immunity

T cell-mediated immunity includes cytotoxic (killer) T cells, activated macrophages, and antibody-dependent cellular cytotoxicity. These critical components of immunity are impaired in patients with Hodgkin's disease [40] and other lymphomas and in those taking antirejection drugs (e.g., cyclosporine, mycophenolate mofetil, tacrolimus, sirolimus, and antilymphocyte antibodies), antibodies against tumor necrosis factor-α, or corticosteroids [4,6,8,41]. Patients infected with HIV-1 experience a progressive and devastating loss of T cell-mediated immunity. This virus selectively infects and lyses $CD4^+$ lymphocytes that play a central role in governing humeral and cellular immune responses. Defects in cell-mediated immunity are commonly associated with primary or reactivation of infection by herpes viruses (varicella-zoster virus, CMV, HSV), protozoa (*Toxoplasma gondii* and *Cryptosporidium* spp), fungi (*Pneumocystis jiroveci*, *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Candida* spp), helminths (*Strongyloides stercoralis*), mycobacteria (*M. tuberculosis, M. avium-intracellulare, M. kansasii, M. chelonae*), and other intracellular bacteria (*Listeria monocytogenes*, *Salmonella*, and *Legionella* spp) [4,40,42].

Immunosuppressive Medications

Cytotoxic chemotherapy, corticosteroids, anticytokine antibodies, and other immunosuppressive therapeutic regimens can alter host defenses in several ways. Immunosuppressive effects depend on the class of drug, dose and duration of therapy, and timing relative to other therapeutic modalities (e.g., radiation, which may contribute to neutropenia). Several new inhibitors of cytokines and cytokine activation (including anti-TNF and anti-IL-1 antibodies) used to treat autoimmune disorders have resulted in the reactivation of latent tuberculosis and histoplasmosis as well as invasive aspergillosis [6,43,44]. Physicians need to be aware of the fact that patients on such agents have a risk of reactivation of intracellular organisms.

Antimicrobial Therapy

Antibiotic therapy is highly effective in the management of documented infections and febrile episodes in the compromised host. These agents are double-edged swords, however, and promote a shift toward increasing frequency of infections caused by progressively more resistant organisms, including *P. aeruginosa, Enterobacter* spp, expanded spectrum β-lactamase producing *Klebsiella* spp, multiply resistant enterococci, methicillin-resistant *S. aureus*, and fluconazole-resistant *Candida* spp. Unusual, intrinsically resistant bacteria (e.g., *Capnocytophaga* and *Corynebacterium* spp) and fungi (e.g., *Scedosporium* and *Fusarium* spp) are being seen with increasing frequency in oncology centers.

Splenectomy

Splenectomy, which results in the loss of the reticuloendothelial capacity to clear organisms from the bloodstream, predisposes patients to fulminant, overwhelming bacteremia caused by encapsulated bacteria (*S. pneumoniae, H. influenzae,* and *N. meningitidis*) as well as *S. aureus*. Although the syndrome of overwhelming postsplenectomy infection is most common in patients whose splenectomy was for malignancy or reticuloendothelial disease, overwhelming postsplenectomy infection can occur in any splenectomized patient regardless of underlying disease or interval since surgery (see Chapter 3). Accordingly, fever higher than 38°C in the splenectomized patient warrants immediate investigation and empiric therapy for possible bacteremia or focal bacterial infection. Consideration of ICU admission and presumptive antibiotic therapy is appropriate if the patient appears systemically toxic. A third-generation cephalosporin (e.g., ceftriaxone or cefotaxime) is reasonable empiric therapy, although if skin or skin structure infection is present, vancomycin should be added because of the increasing likelihood of community-acquired methicillin-resistant *S. aureus*.

DIAGNOSTIC APPROACH TO FEVER

In the evaluation of acutely ill, immunocompromised patients with fever in the ICU, a meticulous and thorough history and physical examination must be performed initially and repeated daily. Particular attention should be directed to sites of high risk, such as the oropharynx, anorectal region, lungs, skin, optic fundi, and vascular catheter sites [32,45]. Patients with focal abnormalities such as solid tumors, organ transplants, or recent surgery need to have these specific sites investigated with special care. Patients with neutropenia and infection exhibit fewer and less striking physical findings of infection (e.g., local warmth, swelling, adenopathy, exudate, or fluctuance) than are ordinarily encountered in immunocompetent individuals (see Chapter 76).

Initial laboratory studies that should be performed in the evaluation of the acutely ill, febrile, compromised host include (a) cultures of blood; (b) cultures of urine if symptoms or abnormal urinalysis; (c) routine sputum culture if the patient has symptoms or signs of pulmonary disease; (d) swab, aspiration, or biopsy of suspect skin, mucous membrane, or other lesions for smears, cultures, and pathologic examination; (e) semiquantitative culture of IV catheters in place when fever develops, if possible (if the cannula is a critical lifeline or a subcutaneously tunneled device that shows no local signs of infection, removal can be deferred pending results of routine blood cultures); (f) chest radiography; and (g) serum chemistries (i.e., electrolytes, liver chemistries, creatinine), in part to detect possible visceral involvement or multiorgan failure caused by disseminated infection and also to serve as baselines for monitoring possible adverse reactions to subsequent antimicrobial therapy.

Patients with defects in cell-mediated immunity (e.g., HIV-1 infection, lymphoma, transplant recipients) often harbor organisms that are best diagnosed by histological examination (e.g., *Pneumocystis jiroveci, T. gondii*) or special culture techniques (e.g., mycobacteria, viruses). In instances in which such organisms are high in the differential diagnosis, initial evaluation often entails immediate biopsy of the pathologic process. Localizing symptoms and signs may indicate the need for other studies, such as computed tomography (CT), magnetic resonance imaging (MRI), or nuclear medicine scans [e.g., gallium-67 scan to detect *P. jiroveci* pneumonia (PCP)]. Tachypnea warrants arterial blood gas studies because progressive hypoxemia in the absence of radiographic findings can be an early indicator of pulmonary infection, especially PCP, and may indicate a need for bronchoscopy. Depending on the nature of the abnormality and the state of immunosuppression, consider lung biopsy and/or quantitative culture of washings or protected brushings obtained through the bronchoscope if patient presents with pulmonary symptoms and a new finding on chest X-ray [46,47].

APPROACH TO SPECIFIC INFECTIOUS DISEASE PRESENTATIONS

Acute Fever without Obvious Source: Neutropenia

In patients with fever and neutropenia, shock may be an early complication of bacteremia. Consequently, even though the wide use of antibiotic prophylaxis during episodes of neutropenia has decreased the incidence of documented infection in febrile neutropenic patients to only 20% to 30% [48,49], multiple randomized trials and consensus guidelines support the initiation of empiric broad-spectrum antibiotic therapy for all patients with fever greater than 38°C and absolute neutrophil counts less than 500 per μL (or less than 1,000 per μL and falling) [36,37,45,50]. The immediate institution of such therapy in these patients (even in the absence of documentation of bacterial infection) dramatically reduces morbidity and mortality. The most rapidly fatal infectious agents that are documented to cause acute fever in the critically ill neutropenic cancer patient are enteric Gram-negative bacilli (e.g., *E. coli*, *Klebsiella* spp, *Proteus* spp), *P. aeruginosa*, and *S. aureus* [36,37]. In the patient without an obvious site of infection, initial empiric antibiotic therapy should be directed against these pathogens (Table 84.2). Such therapy should take into consideration idiosyncrasies of the antimicrobial susceptibility patterns of organisms in the institutions where the patient has resided in the months before infection and recent antibiotic use in a particular patient.

Despite the testing of hundreds of antibacterial regimens for use in patients with fever and neutropenia, there is no consensus on one best regimen. For patients who have not received prior antibiotic prophylaxis or therapy, a single antipseudomonal third-generation cephalosporin (e.g., ceftazidime or cefepime), piperacillin/tazobactam, or a carbapenem (imipenem or meropenem) constitutes an appropriate regimen [51,52]. Although the use of cefepime or piperacillin/tazobactam alone is somewhat controversial, none of the β-lactam agents discussed earlier are clearly preferred, except as dictated by local resistance patterns or cost [45,51,52]. Current data indicate that the empiric use of aminoglycosides with broad-spectrum β-lactam agents is not needed [53].

In a patient in septic shock who is admitted to the ICU or in institutions with endemic-resistant Gram-negative bacteria, a multidrug regimen may be indicated. For patients with immediate hypersensitivity reactions to cephalosporins and penicillins, aztreonam has activity against Gram-negative bacilli and can be used with an antimicrobial agent with activity against a broad spectrum of Gram-positive organisms (e.g., vancomycin typically is added to this regimen because aztreonam has no Gram-positive activity). Because of the increased prevalence of methicillin-resistant staphylococci, recent guidelines have recommended routine initial inclusion of vancomycin in empiric regimens for patients in shock, particularly in patients on antimicrobial prophylaxis and those with evidence for skin or

TABLE 84.2

EMPIRIC REGIMENS FOR INITIAL THERAPY OF CRITICALLY ILL, FEBRILE, ADULT ICU PATIENTS WITH NEUTROPENIA AND CANCER (DOSAGES PROVIDED FOR PATIENTS WITH NORMAL RENAL FUNCTION)

Choice of β-lactam or monobactam[a] Piperacillin/tazobactam 3.375 g IV q 4 or 4.5 g IV q6h OR Ceftazidime 2 g IV q8h OR Imipenem/cilastatin 500–750 mg IV q6h OR meropenem 1 g IV q8h For penicillin and cephalosporin allergic patients: aztreonam, 2 g IV q6–8h, plus vancomycin, 2 g/d divided q6–12h	Plus or minus additional antimicrobial to treat skin/soft tissue infections if present (must use for patients given aztreonam) or patient suspected of having staphylococcal infection[a] Vancomycin 1–1.5 g IV q12 (weight based—15 mg/kg q12h) (alternatives for allergic patients include linezolid, daptomycin, quinupristin/dalfopristin, or clindamycin)

[a]The choice of regimen should be based on local resistance patterns and the individual patient's most recent prior antimicrobial therapy.

skin structure infections or with inflammation at the site of or dysfunction of indwelling plastic venous access catheters [45]. Randomized controlled trials have demonstrated no benefit to continuing vancomycin after 72 hours unless patients demonstrated a Gram-positive infection [45,54].

Most standard regimens are designed for patients who have not previously received antibiotics. The development of fever with systemic symptoms such as shock or respiratory distress in a patient on antibiotic therapy requires a change in therapy to include organisms that are known to be resistant to classes of antibacterials the patient has received. For example, in a patient who recently has received cephalosporins, the choice of piperacillin, piperacillin/tazobactam, or imipenem may be preferable to ceftazidime especially if expanded spectrum β-lactamase–producing organisms are established flora in the local ICU.

After initial evaluation of the patient and initiation of empiric antibiotic therapy, subsequent management is based on (a) identification of a focus of infection, (b) isolation of an etiologic agent, (c) defervescence versus continued fever, and (d) duration of neutropenia. In the patient for whom an infection has been documented clinically or by culture, antibiotics should be continued as appropriate for the site of infection, susceptibility profile of pathogens, and the patient's clinical response. Even when a specific pathogen is identified by culture, in patients who are neutropenic a broad-spectrum regimen usually is maintained for the duration of neutropenia [37,45,55]. In patients likely to have permanent or extremely prolonged granulocytopenia, attempts to stop therapy are reasonable but should be made with continuing close clinical observation [45,56].

If fever has not been eliminated or the patient continues to have evidence of ongoing sepsis, the search should continue for potential sites of focal infection (skin, optic fundi, oropharynx, chest, abdomen, and perirectal area). The serial, empiric addition of one antibiotic after another without culture data is not efficacious in most settings and may lead to confusion in the event that an adverse reaction occurs [45]. Cephalosporins and vancomycin can cause bone marrow suppression and lead to colonization with resistant organisms. The addition or sequential substitution of multiple cephalosporins may induce β-lactamase production by some organisms.

Persistent or Recurrent Fever without Obvious Source: Neutropenia

Should fevers persist for 4 to 7 days of neutropenia, randomized controlled trials have found that empiric antifungal therapy with an amphotericin B preparation, voriconazole, or caspofungin [57–59] is appropriate. The rationale for such therapy is that it is difficult to culture fungi before they cause disseminated disease, and that the mortality from disseminated fungal disease in neutropenic hosts is high. *Candida* and *Aspergillus* spp are common pathogens, and *Fusarium, Trichosporon*, and *Bipolaris* spp are seen occasionally but are becoming more common [60–63]. The use of the serum assay for galactomannan as a marker for *Aspergillus* infection is controversial as sensitivity is low, and there may be false-positive results in patients receiving piperacillin [64,65]. Another serum assay that tests for 1,3-β-D-glucan antigenemia shows promise but serial monitoring is needed and predictive value for invasive fungal infections varies in different centers [66,67]. More research is needed on both these assays.

Patients at particularly high risk of disseminated fungal disease include those with (a) prolonged granulocytopenia, (b) parenteral nutrition, (c) *Candida* colonization in oropharynx or urine, (d) corticosteroid therapy, and (e) advancing multiple organ dysfunction (renal, hepatic, pulmonary). Moreover, multiorgan failure often is a reflection of disseminated candidiasis [68]. The use of antifungal prophylaxis with the imidazoles (fluconazole) has caused a shift in the species of *Candida* causing infection from *C. albicans* and *C. tropicalis* to the more imidazole-resistant *C. krusei* and *C. glabrata* [69], and with the use of posaconazole or voriconazole a shift has started to occur to more infections due to *Zygomycetes* [70]. Hepatosplenic (also called *chronic disseminated*) candidiasis presents with fevers and elevation of serum alkaline phosphatase that continue through the return of neutrophils to greater than 1,000 cells per mm^3 [71]. Multiple embolic lesions are present in liver and spleen, and prolonged therapy with amphotericin B, itraconazole, fluconazole, or caspofungin, depending on the sensitivity of the organism, is beneficial [72].

Based on the findings from a randomized clinical trial of primary therapy and randomized studies of salvage therapy, voriconazole is the drug of choice for infections caused by *Aspergillus* [73,74]. However, an amphotericin preparation continues to be the drug of choice when a fungal infection is suspected in patients already receiving an azole antifungal [70]. Amphotericin has activity against *Aspergillus*, the *Zygomycetes*, and many other filamentous fungi. According to data from randomized clinical trials, the newer preparations of amphotericin B appear to decrease renal toxicity while maintaining efficacy; therefore, amphotericin B complexed with cholesteryl sulfate, with liposomal vesicles, or with a bilayered lipid membrane have become standard for use in patients on other nephrotoxic drugs or those with impaired renal function, despite their higher cost [75] (see Chapter 77). Prognosis

remains poor, however, for patients treated for documented invasive fungal infection in the setting of persistent neutropenia [60,76]. Most ICU patients who remain febrile and neutropenic after 4 to 7 days of broad-spectrum antibacterials should be treated with either voriconazole, an amphotericin B preparation, or echinocandin, although in selected low-risk patients (where the risk of *Aspergillus* or *Zygomycetes* is low), itraconazole or fluconazole is equally efficacious, as shown in open randomized clinical trails and endorsed in expert reviews of these studies [59,77–80].

Pneumonia in the Compromised Host

The lung is one of the most common identifiable sites of infection in immunocompromised patients [2,46,81]. Pulmonary disease can be caused by a wide variety of agents, including bacteria, protozoa, helminths, viruses, fungi, and mycobacteria (Table 84.3) (see Chapter 68). The differential diagnosis is made even more difficult by the various noninfectious pulmonary complications that can present abruptly with acute respiratory symptoms and fever. These include underlying malignancy or vasculitis, drug toxicity, interstitial fibrosis, diffuse alveolar hemorrhage, radiation pneumonitis, cardiogenic pulmonary edema, bronchiolitis obliterans organizing pneumonia (BOOP), diffuse alveolar damage syndrome, acute fibrinous organizing pneumonia (AFOP), pulmonary alveolar proteinosis, and pulmonary embolism [46,81].

Pneumonia in the immunocompromised patient often presents without the symptoms and signs seen in normal hosts. Regardless of cause, fever and progressive shortness of breath (and concomitant tachypnea and arterial hypoxemia) tend to be common symptoms; in the neutropenic patient, cough, sputum production, and physical examination (as well as radiographic) findings are likely to be unimpressive or absent. Chest radiographs should be obtained promptly in the compromised patient with fever or dyspnea. High-resolution CT or MRIs will often reveal infiltrates or masses that cannot be appreciated on conventional X-rays and thus are recommended in cases in which there is question about the diagnosis [82].

Differential Diagnosis

Developing an appropriate differential diagnosis for the causative agents of pneumonia in the immunocompromised host rests first on an appreciation of the nature, severity, and duration of the immune suppression. In addition to being susceptible to conventional respiratory tract pathogens (*S. pneumonia*e, *H. influenza*e), hospitalized immunocompromised hosts are prone to Gram-negative bacillary pneumonia; those with prolonged (greater than 7 days) or profound (less than 100 neutrophils per mm^3) neutropenia may become infected with *Aspergillus* or *Zygomycetes* spp [2]. T cell-deficient hosts (e.g., patients with HIV infection, transplant, or lymphoma) are more likely to acquire PCP [83] or infection with CMV, HSV [84–86], endemic fungi (*Cryptococcus, Histoplasma*) [44,87,88], *Nocardia* spp, or intracellular bacteria (mycobacteria, *Legionella* spp) [89–91]. Patients who have resided in tropical countries may reactivate latent infection by *Strongyloides stercoralis* in the setting of altered cell-mediated immunity. Pulmonary infiltrates, polymicrobial bacteremia, and bacterial meningitis are the hallmarks of this syndrome [92]. Patients with deficient neutrophil and T cell function (e.g., bone marrow transplant recipients) may be at risk for all of these pathogens.

Chest radiographs may provide useful clues; focal or multifocal infiltrates tend to suggest infections by bacteria or fungi, but are unlikely to provide a definitive diagnosis. Computerized tomographic scanning often provides more information, including the detection of lesions not seen on routine chest radiograph [46]. Diffuse disease is more characteristic of viral causes (HSV, CMV), PCP, or noninfectious processes (drug toxicity, lymphangitic carcinomatosis, and radiation pneumonitis). Cavitary disease can be seen with certain of the necrotizing Gram-negative bacilli such as *P. aeruginosa* as well as *S. aureus* and anaerobes (e.g., postaspiration or postobstructive). Cavities also can be a late finding with pneumonia due to *Aspergillus, Zygomycetes*, and *Nocardia* spp. It is impossible, however, to make firm rules with regard to radiographic patterns. Gram-negative bacilli or *Legionella* may progress to diffuse disease or incite the acute respiratory distress syndrome. Patients with severe defects in cell-mediated immunity may manifest a miliary pattern caused by disseminated tuberculosis or histoplasmosis. Conversely, radiation pneumonitis may present as focal, sharply demarcated infiltrates confined to the irradiated portion of the lung.

TABLE 84.3

COMMON CAUSES OF ACUTE PULMONARY DISEASE IN IMMUNOCOMPROMISED PATIENTS

Infectious causes

Bacteria
- *Streptococcus pneumoniae*
- *Haemophilus influenzae*
- *Pseudomonas aeruginosa*
- Enteric Gram-negative bacilli
- *Staphylococcus aureus*
- *Legionella* spp
- *Nocardia* spp
- Mycobacteria

Fungi
- *Aspergillus* spp
- *Pneumocystis jiroveci*
- *Candida* spp
- *Zygomycetes* spp
- *Cryptococcus neoformans*

Viruses
- Cytomegalovirus
- Herpes simplex virus

Protozoa
- *Toxoplasma gondii*

Parasite
- *Strongyloides stercoralis*

Noninfectious causes

Primary disease (malignancy, autoimmune, or other illnesses that led to immunocompromising condition)

Malignancy
- Primary
- Metastatic

Vasculitis

Alveolar damage, fibrosis, and organizing pneumonia
- Bronchiolitis obliterans and organizing pneumonia (BOOP)
- Acute fibrinous organizing pneumonia (AFOP)
- Diffuse alveolar damage syndrome

Drug toxicity
- Bleomycin
- Busulfan
- Cyclophosphamide

Hemorrhage

Congestive heart failure

Radiation

Diagnostic Approach and Empiric Therapy

The diagnostic approach to pulmonary disease in the immunocompromised host also depends on the nature of the immune deficit. As a general rule, all accessible sites (blood, urine, and sputum) should be cultured, although sputum of high quality is obtained rarely in these circumstances. In neutropenic hosts, empiric antibacterial therapy is begun at the outset regardless of radiographic pattern, using one of the regimens discussed previously for fever and neutropenia [36,37]. In the case of ventilated inpatients, treatment of pneumonia must include antibiotic(s) that are effective against organisms that are likely to be present in the ICU (some of these organisms are typically resistant to antibiotics typically used in treating febrile, neutropenic patients). These regimens typically contain more than one antibiotic and they should be adjusted based on the cumulative susceptibility report of the hospital or unit. While logical, the use of "protected specimen brushes" has not been shown to be of clear clinical value and should not be a reason to perform an invasive procedure in an immunocompromised patient [93].

If a clinical response occurs in a neutropenic patient, therapy is continued until neutropenia resolves. In the setting of persistent neutropenia, a clinical picture of progressive pulmonary disease despite antibiotic therapy suggests invasive disease caused by fungi found in the environment (a variety of "saprophytic" fungi are a major concern, especially *Aspergillus,* but also *Rhizopus, Fusarium,* and *Trichosporon* spp) [38,62,63]. Expectorated sputum, bronchial brush specimen cultures, or bronchial lavage fluid may provide presumptive evidence of these pathogens, but prompt definitive diagnosis often requires open or thoracoscopically guided lung biopsy. Transbronchial biopsy is often nondiagnostic. Typically, pneumonia caused by *Aspergillus* or *Zygomycetes* spp causes areas of lung infarction that may be missed by transbronchial biopsy [94,95]. Computed tomographic scans may show the classic "crescent" sign in patients with aspergillosis but this is a sign of late disease, and although it may be helpful diagnostically in patients who are recovering, early diagnosis is important to prevent mortality in persistently neutropenic patients. Unlike bacteria, which are usually easy to culture, fungi are often not isolated in cases where histopathology eventually demonstrates their presence. While PCR (polymerase chain reaction)-based techniques have yet to be of demonstrated clinical usefulness in these clinical situations, measurements of polysaccharide antigen in serum or other body fluids has been of demonstrated utility in the diagnosis of both *Cryptococcus*- and *Histoplasma*-associated pneumonia.

The standard approach to therapy of confirmed pulmonary disease caused by *Aspergillus* is to treat with voriconazole as this agent has been shown to be superior to treatment with amphotericin B preparations [74,96]. While the use of combinations of antifungal agents (including echinocandins and azoles as well as echinocandins and amphotericin) has rationale, support from animal data, and anecdotal human experience, large trials have yet to be performed, making it difficult to recommend this approach at this time unless single agents have failed. There is no established therapy for some emerging fungal pathogens such as *Trichosporon* or *Fusarium* spp, although encouraging results have been reported in a few cases using posaconazole and voriconazole [96].

In patients with compromised T cell immunity, the list of diagnostic possibilities is longer and more diverse, making a single formula for empiric therapy a virtual impossibility. Clinicians caring for these patients should be guided both by the type of the underlying immunodeficiency as well as the patent's previous experiences with both pathogens and antimicrobial agents. Expectorated or induced sputum may demonstrate the organism by special stains in a minority of cases (*P. jiroveci, M. tuberculosis, Nocardia asteroides*), but flexible bronchoscopy with lavage or transbronchial biopsy and open or thoracoscopically assisted lung biopsy may be required in order to make a diagnosis for these patients [46,97,98] (see Chapters 9 and 69). Bronchoscopy is particularly helpful for diffuse or interstitial disease, in which it not only provides lavage fluid with reasonable diagnostic accuracy for infectious agents such as *P. jiroveci* and bacteria but also pathologic specimens that may allow diagnosis of CMV infection, drug pneumonitis, hemorrhage, or lymphangitic carcinomatosis. In patients with focal or nodular disease, thoracoscopically assisted biopsy is likely to yield the best results.

In the immunocompromised host (non-HIV infected), the diagnosis of PCP often requires bronchoscopy with bronchoalveolar lavage with or without biopsy. A variety of other infections also require biopsy for diagnosis. It is reasonable to treat (empirically) with trimethoprim-sulfamethoxazole (15 per kg of the trimethoprim component IV daily divided every 6 or 8 hours) while arrangements are made for diagnostic procedures, as the organisms persist for the first few days of treatment. It is usually an error to postpone performing bronchoscopy (with biopsy) or thoracoscopically guided lung biopsy in severely ill immunocompromised patients with pulmonary infiltrates in the hope that they will improve, because clinical deterioration may make the procedure (and the diagnosis) impossible. If PCP is confirmed and the patient has severe renal insufficiency, serum drug concentration monitoring, if available, should be used to adjust therapy to obtain a peak serum sulfamethoxazole level of 100 μg per mL or trimethoprim levels of 5 to 8 mg per μL [99]. An alternative diagnosis, established by histologic or microbiologic diagnosis, allows

TABLE 84.4

ADVANCES IN MANAGEMENT BASED UPON RANDOMIZED CONTROLLED CLINICAL TRIALS AND META-ANALYSES OF THESE TRIALS

Acute fever without obvious source: neutropenia

- Broad-spectrum antibiotic therapy should be started for all immunocompromised patients with fever greater than 38°C and absolute neutrophil counts less than 500/mm^3 (or less than 1,000/mm^3 and falling) [36,37,50–52].
- There is no benefit to continuing vancomycin after 72 h unless a Gram-positive infection is documented [51,54].
- There is no benefit to adding an aminoglycoside to a β-lactam agent in patients with fever and neutropenia [52,53].

Persistent fever or recurrent fever with obvious source: neutropenia

- Empiric antifungal with an amphotericin B preparation, voriconazole, or an echinocandin should be started for the immunocompromised patient with neutropenia and fever of 4–7 d duration [57–59,77,78].

Treatment of aspergillosis

- Voriconazole is the drug of choice for documented infections due to *Aspergillus* [73].

Prophylaxis of fungal infections

- In patients undergoing chemotherapy for acute myelogenous leukemia or the myelodysplastic syndrome, posaconazole prevented invasive fungal infections more effectively than did either fluconazole or itraconazole and improved overall survival. There were more serious adverse events possibly or probably related to treatment in the posaconazole group [103,104].
- Both fluconazole and itraconazole have shown benefit for prophylaxis in patients after allogeneic stem cell transplant [108].

institution of specific therapy, such as acyclovir for HSV pneumonia, ganciclovir for CMV pneumonia, trimethoprim-sulfamethoxazole for nocardiosis, or corticosteroids for radiation pneumonitis, BOOP, AFOP, or drug-induced disease [46,97,100,101].

PREVENTION OF INFECTION

Increasing emphasis is being placed on the prevention of opportunistic infections in immunocompromised hosts. These strategies have taken many different forms. Early efforts were directed at modifications of the environment of neutropenic patients through laminar airflow, nonabsorbable antibiotics, and elaborate efforts at disinfecting the inanimate environment. These approaches have proven expensive and laborious and since they did not affect either disease remission or mortality, they have been abandoned by most centers.

Oral fluoroquinolone (and trimethoprim-sulfamethoxazole) administration has been studied in patients with prolonged neutropenia. These agents reduce levels of aerobic Gram-negative bacilli in the gut lumen, the major reservoir for dissemination of infection in the neutropenic host, and studies document the efficacy of levofloxacin in preventing infections and hospitalizations in patients with chemotherapy-induced neutropenia [102].

Antifungal prophylaxis with oral fluconazole (400 mg orally daily or 200 mg IV every 12 hours) has proved effective in reducing infection by *Candida* spp in bone marrow transplant recipients [81]. See Chapter 188. Recent studies suggest that posaconazole, which has a much broader spectrum than fluconazole (including *Aspergillus*), is efficacious in preventing fungal infections in severely neutropenic patients, hematopoietic stem cell transplant patients, and those with graft versus host disease [103,104].

Antiviral prophylaxis with acyclovir has been shown to reduce mucositis and mucocutaneous infections by HSV in transplant recipients and in patients with leukemia [105,106]. Although prophylactic administration of ganciclovir has been demonstrated to decrease CMV disease in solid organ transplant recipients, the administration of this agent to bone marrow transplant patients results in neutropenia. Consequently, most centers are now using "preemptive" treatment with ganciclovir (beginning treatment only when DNA levels are increased in the serum of patients at risk). See Chapter 188.

Administration of granulocyte-colony–stimulating factors hasten bone marrow recovery and shorten the duration of neutropenia in some patients receiving chemotherapy. Consensus guidelines suggest that they should be used to support dose-intense chemotherapy and have little impact on mortality in patients with existing neutropenia and fever and should not be used as a routine adjunct to antimicrobials [107].

Advances in infection in the immunocompromised host, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 84.4.

CHAPTER 85 ■ INTENSIVE CARE OF PATIENTS WITH HIV INFECTION

SARAH H. CHEESEMAN AND MARK J. ROSEN

At the start of the pandemic in the 1980s, AIDS was considered to be rapidly fatal in almost all cases, and the benefits of aggressive interventions, including treatment in the intensive care unit (ICU), were questioned for patients with advanced disease. Respiratory failure due to *Pneumocystis jiroveci* pneumonia (PCP) was by far the most common disorder that prompted ICU admission, outcomes were uniformly dismal, and intensive care admission was often discouraged by clinicians and declined by patients. HIV-infected persons who now have access to effective combination antiretroviral therapy (ART) for HIV infection enjoy much better outcomes. Since the use of these drugs became the standard of care in 1996, U.S. mortality rates due to AIDS declined from an annual high of around 45,000 per year to the current plateau of around 14,000 by 2007 [1]. Until recently, the hopeful prognosis in the United States and developed nations stood in sharp contrast to the global epidemic, where an estimated 2.7 million people acquired HIV infection in 2008 and 2 million died [2], but dramatically scaled-up access to combination ART is now reducing HIV-related mortality in sub-Saharan Africa [1].

With the use of ART, the spectrum of critical illness in HIV infection is changing along with the short- and long-term prognosis following these illnesses. In addition, the use of antiretrovirals entails risk of drug interactions and toxicity, requiring vigilance in the multidrug complexity of ICU care.

REASONS FOR INTENSIVE CARE UNIT ADMISSION

The literature on the frequency and reasons for ICU admission in patients with HIV infection must be interpreted with the understanding that with rare exception, each study reviews the experience of a single center and reflects local ICU admission criteria and practice patterns. Care of patients with HIV infection and with critical illness in general may vary widely, so the conclusions of these reports cannot be generalized [3]. The decision on whether to admit HIV-infected patients to the ICU or withhold such treatment varies by hospital characteristics (county/state, Veterans Affairs Medical Centers, church affiliated, voluntary, and for profit) and geographic location, and these differences are maintained after controlling for severity of illness and patient demographic and socioeconomic characteristics. Thus, data on diseases and outcomes from one center cannot be applied reliably to others. Endemic fungi and other pathogens influence ICU admission rates for different diseases; this may be important in the United States, where the epidemic has shifted from the east and west coasts to the southern states [1].

There is emerging evidence that the reasons for ICU admission have changed over the last three decades of the AIDS

epidemic, largely due to reduced incidence of opportunistic infections owing to ART. In the era before ART, an estimated 5% to 10% of hospitalizations of patients with HIV infection involved an ICU admission; most patients were admitted for respiratory failure, and PCP was the most common diagnosis [4–6]. Although PCP has always been the most common cause of respiratory failure in patients with HIV infection, it appears that ICU admissions for PCP, and for respiratory failure in general, continue to decline [7,8]. The few studies of intensive care in the era of ART suggest that overall ICU utilization by HIV-infected persons has not declined; respiratory failure is still the most common reason for admission, but its relative frequency is declining as other organ failures are increasing [8]. Patients are also less likely to be admitted for PCP and other HIV-associated opportunistic infections, and are now more likely to have life-threatening bacterial pneumonia, sepsis, neurologic disorders, and complications of end-stage liver disease [7–11]. Patients may also become critically ill from the toxic effects of antiretroviral medications and from an accelerated inflammatory response related to immune reconstitution resulting from the use of ART.

PULMONARY DISORDERS

Pneumocystis Pneumonia

Pneumonia caused by *Pneumocystis jiroveci* (formerly classified as *Pneumocystis carinii*) has always been a major cause of illness and death in patients with HIV infection. Once thought to be a parasite, genomic analysis revealed that *P. jiroveci* is in fact a fungus that infects only humans, while *P. carinii* is pathogenic only in immunodeficient rats [12]. Although the taxonomy of this pathogen changed, the term PCP is still acceptable shorthand for *Pneumocystis* pneumonia.

Despite immune restoration from ART and effective specific chemoprophylaxis for PCP, this infection still occurs for several reasons: many patients do not know that they have HIV infection until they develop an opportunistic infection; others know that they have HIV but are not receiving medical care; and some are in care but are either not prescribed or choose not to take prophylaxis or ART [13]. Adherence to complex regimens with difficult-to-tolerate side effects is often problematic, and suboptimal adherence leads to selection of HIV mutations that confer drug resistance. Some patients take prophylaxis for PCP, but are still so profoundly immunocompromised that it is ineffective [14]. Nevertheless, the incidence of PCP has declined in the era of ART.

PCP should be suspected in a patient with known or suspected HIV infection, fever, and progressive cough and dyspnea. Radiographically, the diagnosis is strongly suggested by perihilar or diffuse ground glass opacities, but this pattern is not specific for PCP. Other presentations include pneumatoceles, pneumothorax, nodules, lobar consolidation, and normal images [15]. The diagnosis can be confirmed only by identifying the organism in specimens obtained from the respiratory tract, either in sputum induced by inhalation of hypertonic saline or by bronchoscopy. Although establishing a diagnosis is not difficult, many clinicians treat patients with suspected PCP empirically, reserving bronchoscopy for patients who do not respond to treatment. A decision-analysis model and a retrospective study comparing these two strategies suggest that the outcomes are similar, but no clinical trial has ever evaluated whether initial empiric therapy or a more aggressive diagnostic strategy that includes bronchoscopy is preferable [16,17]. In intubated patients, the diagnosis may be established easily with bronchoalveolar lavage.

The treatment of PCP is outlined in Table 85.1 [18]. Trimethoprim-sulfamethoxazole (TMP-SMX) is the preferred treatment for PCP in patients who have not had an adverse reaction to this drug [18]. Many physicians are willing to use TMP-SMX despite a history of a prior adverse reaction in patients receiving adjunctive corticosteroid therapy and ICU support, because it is not clear whether any of the alternatives is as effective for moderate-to-severe disease. Patients with severe PCP who do not respond or who are intolerant of this medication are usually given pentamidine, but this drug is associated with adverse reactions that are more serious than those associated with TMP-SMX. Clindamycin with primaquine is effective for moderate-to-severe PCP, but primaquine cannot be administered parenterally, potentially limiting its use.

When treatment of PCP is delayed or ineffective, patients may develop hypoxemic respiratory failure. The clinical and radiographic features of severe PCP resemble the acute respiratory distress syndrome (ARDS), with hypoxemia, intrapulmonary shunting, reduced pulmonary compliance, and diffuse radiographic opacities [19]. As the disease progresses and pulmonary compliance diminishes, pneumothorax is common and is associated with a particularly poor prognosis [20,21]

TABLE 85.1

TREATMENT OF MODERATE-TO-SEVERE *PNEUMOCYSTIS* PNEUMONIA

Drug	Dose	Comments
Trimethoprim-sulfamethoxazole	15–20 mg/kg/d TMP plus 75–100 mg/kg/d SMX *IV* or *PO* in 3 or 4 divided doses	Drug of choice, but toxicity (rash, fever, nausea, leukopenia) is frequent
Pentamidine isethionate	3–4 mg/kg IV daily	Toxicity: dysglycemia, renal failure, QT interval prolongation, arrhythmias, pancreatitis, hypotension; 50% dextrose must be available
Clindamycin plus primaquine	Clindamycin 600–900 mg q6–8 h *IV* or *PO* plus 30 mg primaquine base *qd* (15 mg primaquine base = 26.3 mg primaquine phosphate)	Screen for glucose-6-phosphate dehydrogenase deficiency
Prednisone	40 mg PO *bid* days 1–5, 20 mg PO *bid* or 40 mg PO daily, days 6–10 20 mg PO daily, days 11–21	Recommended as adjunctive therapy for severe disease [PaO_2 ≤70 mm Hg, or $P(A\text{-}a)O_2$ >35 mm Hg breathing room air] within 72 h of PCP therapy

IV, intravenous; PO, by mouth; SMX, sulfamethoxazole; TMP, trimethoprim.

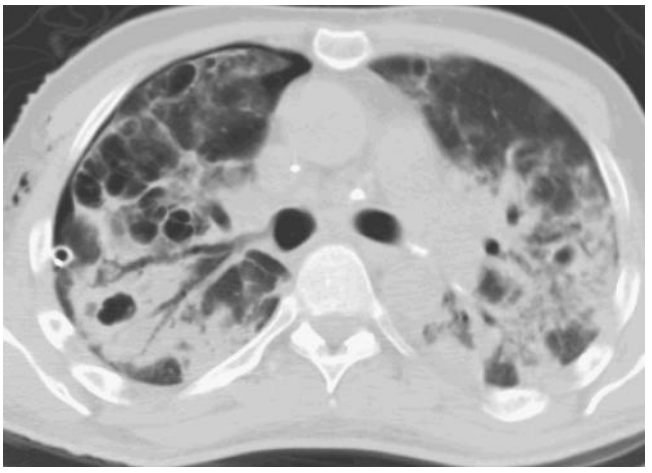

FIGURE 85.1. Selected computerized tomographic image of a patient with severe *Pneumocystis* pneumonia. This patient has significant cystic changes, as well as areas of dense pulmonary consolidation. Note the pneumothorax and chest tube in the right lung.

(Fig. 85.1). Just as severe PCP resembles ARDS clinically, the supportive treatment is similar, including intubation, mechanical ventilation, application of positive end-expiratory pressure, and lung-protective ventilation strategies [22].

Animal models of PCP indicate that the clinical severity of infection correlates more closely with markers of inflammation than with the organism burden, suggesting that the immune response and its attendant inflammation account for the clinical manifestations of pneumonia [23]. Respiratory compromise is believed to be mediated by activated CD8+ cells and neutrophils in the lung in response to killed organisms, and patients with PCP typically have deterioration of gas exchange during the first few days of treatment with anti-*Pneumocystis* agents alone [24]. When corticosteroids are administered to patients with moderate-to-severe PCP (defined as a PaO_2 less than 70 mm Hg while breathing room air or an arterial-alveolar oxygen difference greater than 35 mm Hg) at the start of anti-*Pneumocystis* treatment, there is a reduced likelihood of respiratory failure, deterioration of oxygenation, and death [25,26]. Corticosteroids may attenuate lung injury caused by the inflammatory response to killed organisms, allowing the patient to survive to receive more antimicrobial therapy. Corticosteroids offer no benefit in patients with less severe abnormalities in gas exchange at the start of therapy, or in whom they are administered more than 72 hours after anti-*Pneumocystis* treatment has begun.

Other Pulmonary Disorders

A wide variety of infectious and noninfectious HIV-associated pulmonary disorders may lead to respiratory failure. Bacterial pneumonias, most commonly caused by *Streptococcus pneumoniae,* have probably surpassed PCP as the cause of respiratory failure in the era of ART [27]. In patients with severe immune compromise, pulmonary infection or disseminated disease with *Pseudomonas aeruginosa*, *Mycobacterium tuberculosis*, cytomegalovirus, endemic fungi, and *Aspergillus* spp may also lead to respiratory failure [28].

COINFECTION WITH HIV AND HEPATITIS VIRUSES

With improved treatment of HIV with antiretroviral agents, complications of hepatitis B (HBV) and C viruses (HCV) have emerged as a major cause of mortality in HIV-infected persons [29–31]. An estimated 15% to 30% of patients with HIV are coinfected with HCV, an eightfold increase in HCV infection compared with the general population [32]. Patients coinfected with HCV and HIV are more likely to develop cirrhosis than those with HCV alone. Thus, many patients with HIV infection are admitted to ICUs with end-stage liver disease and associated encephalopathy and gastrointestinal hemorrhage. Although a number of antiretroviral agents are also active against HBV, permitting construction of regimens effective against both pathogens for HIV-HBV coinfected patients, management of coinfection with HIV and HCV entails separate combination drug regimens with interactions and overlapping toxicities, administered for at least 6 months and often more than 12 months. Such therapy requires close supervision by experienced personnel and may exacerbate liver dysfunction in cases of decompensated cirrhosis.

IMMUNE RECONSTITUTION DISORDERS

Initiation of antiretroviral therapy may be followed by paradoxic worsening of known opportunistic infections after an initial response to therapy, characterized by an unusual degree of inflammatory reaction. Alternatively, patients with an infection not yet manifested clinically may develop an inflammatory reaction at the infected site (so-called unmasking). These reactions are not typical of the usual clinical presentation of the infectious agent, and are now termed "immune reconstitution inflammatory syndrome" (IRIS) or "immune restoration disease" (IRD) [33,34]. For instance, *Mycobacterium avium* complex, which usually produces disseminated disease with no histologic evidence of host response in persons with advanced HIV infection and CD4+ lymphocyte counts <50 per μL, may present with fever and pain due to focal necrotizing lymphadenitis. A meta-analysis of 64 reports comprising 13,103 persons initiating antiretroviral therapy found that 13% developed IRIS; some series report much higher rates, particularly in patients with cytomegalovirus retinitis [35]. The time to onset of IRIS is reported to vary from 3 to 658 days after starting ART with a median of 29 to 49 days [34,36,37]. The risk is higher for patients with lower CD4+ counts before initiation of ART, but the occurrence of IRIS seems to correlate better with rapid decline in viral load than with increase in CD4+ lymphocyte count [36,37], and the meta-analysis found a case-fatality rate of 6.7% [35]. IRIS-related respiratory compromise is reported in association with mycobacterial infection and PCP [38,39]. Corticosteroids may be used to suppress the aberrant inflammatory reaction, but there are no guidelines as to when to use them or the optimal dose and duration. Corticosteroids are usually reserved for patients with severe inflammatory disease.

OTHER CRITICAL ILLNESSES

HIV-infected persons are not spared any of the diseases that can bring non-HIV-infected persons with otherwise similar characteristics to the ICU, including severe bacterial infections, gastrointestinal hemorrhage, trauma, drug overdose, violence, and cardiovascular disease. Injection drug users are obviously at increased risk of developing infective endocarditis.

Patients with HIV infection have accelerated atherosclerosis and increased risk of coronary artery disease; this was previously attributed to therapy, particularly protease inhibitors which are known to increase plasma lipid levels [40,41]. However, the risk of major cardiovascular disease outcomes increased in patients randomized to interrupt ART when CD4+ lymphocyte count rose above 400 compared to those who

continued therapy and who had more drug exposure [42]. Subsequent analyses have correlated cardiovascular disease risk to higher levels of viremia [43] and abnormalities of endothelial function that improve with ART [44].

Laboratory abnormalities, including pancytopenia, eosinophilia, and transaminase elevations, may either represent the patient's baseline or indicate significant disease or drug toxicity. Among laboratory abnormalities that may safely be ignored are macrocytosis as a normal accompaniment of zidovudine, stavudine, or tenofovir therapy (provided there are no hypersegmented polymorphonuclear leukocytes), mild indirect hyperbilirubinemia in patients on atazanavir or indinavir, and hyperuricemia in patients taking didanosine. Elevations of creatine phosphokinase in patients taking zidovudine or tenofovir may also be asymptomatic and benign, but some reflect clinical myositis caused by these drugs. Hyponatremia seems to be relatively common and well tolerated in advanced HIV infection, but frank adrenal insufficiency or isolated hypoaldosteronism may require specific diagnosis and management.

TOXIC EFFECTS OF ANTIRETROVIRAL THERAPY

The drugs used in antiretroviral therapy are associated with several life-threatening toxicities that prompt admission to the ICU. Nucleoside analog reverse transcriptase inhibitors (NRTIs), especially didanosine and stavudine (and zalcitabine, which is no longer available in the United States), can cause pancreatitis, which may be severe. In a retrospective study of 73 HIV-infected patients with pancreatitis, 46% of cases were attributed to drug toxicity, with didanosine and pentamidine (used to treat PCP) the most common offending agents [45]. Didanosine may cause portal hypertension without cirrhosis [46]. Patients who received this drug even many years before may present with life-threatening hemorrhage from esophageal varices.

Nucleoside reverse transcriptase inhibitors can cause lactic acidosis by inhibiting DNA polymerase-γ, disrupting mitochondrial DNA. This may also cause hepatic steatosis or mitochondrial myopathy [47]. Lactic acidosis is the consequence of increased anaerobic glycolysis by damaged mitochondria, coupled with decreased lactate clearance by the fatty liver. Mild hyperlactatemia occurs commonly in patients receiving NRTIs and is not clinically important, but severe lactic acidosis occurs at a rate of 1.3 to 3.2 cases per 1,000 person-years of nucleoside exposure and may be life threatening [48,49]. The appearance of nausea, vomiting, abdominal pain, dyspnea, or weakness in persons on long-term therapy with these agents may herald the onset of this life-threatening illness and should prompt measurement of serum lactate. This entity should be considered in the differential diagnosis of apparent sepsis, hepatic failure, and pancreatitis requiring ICU admission of patients on antiretroviral therapy. Since patients may also develop severe lactic acidosis due to sepsis, empiric antibiotics should be administered pending the results of microbiologic evaluation. If severe hyperlactatemia or lactic acidosis is found, all antiretroviral therapy must be stopped immediately since continuation of a partial regimen may lead to viral resistance. In addition to standard care, case reports suggest that this disorder may improve with use of riboflavin, thiamine, L-carnitine, and coenzyme Q [50–52]. The same drugs and mechanism underlie a syndrome of severe neuromuscular weakness and respiratory failure that may mimic Guillain–Barré syndrome or botulism, and the same therapies have been proposed [53]. The newer NRTIs (tenofovir, emtricitabine, lamivudine, and abacavir) produce less inhibition of DNA polymerase-γ and largely replace the agents most commonly implicated (stavudine, didanosine, and zidovudine); this seems to have reduced the incidence of syndromes related to mitochondrial toxicity.

Abacavir hypersensitivity is a protean syndrome that may include fever, chills, nausea, diarrhea, rash, myalgia, aseptic meningitis, hepatitis, cough, or influenza-like illness within a few weeks of starting treatment. Discontinuation of the drug leads to resolution of symptoms, but rechallenge can produce an anaphylactic reaction with cardiovascular collapse and high fever [54,55]. This syndrome should be virtually eliminated by the introduction of screening for the HLA-B*5701 allele and avoidance of abacavir in persons who carry it [56,57].

Severe rash, including Stevens–Johnson syndrome, is most notably associated with nevirapine, but can occur with other nonnucleoside reverse transcriptase inhibitors (NNRTIs) and rarely with protease inhibitors and NRTIs.

MANAGEMENT OF PROPHYLAXIS AND ANTIRETROVIRAL AGENTS

Even when critically ill, patients who received prophylaxis against opportunistic infections like PCP before the ICU admission should generally continue to receive it, and initiation of appropriate measures should be considered in those who have not. However, even a single dose of glucocorticoids can reduce the CD4+ lymphocyte count dramatically, so decisions should be based on recent values before receiving corticosteroids if they are available. In patients who stopped taking ART for more than a month, it is usually best to assume that the risk of a patient developing opportunistic infections corresponds to that before starting ART.

The use of ART in critically ill patients requires expertise in selection of drugs and consideration of their doses, toxicity, and interactions with other treatments. The critical care clinician is well-advised to manage these patients in close collaboration with an expert in antiretroviral treatment. Patients receiving ART should continue to receive these drugs whenever possible, as discontinuing therapy is associated with viral replication, emergence of resistance, and clinical progression of HIV infection. In patients coinfected with HBV, discontinuation of lamivudine (and presumably emtricitabine and tenofovir, the other antivirals active against HBV) may result in exacerbations of hepatitis B that may be fatal [58,59].

The feasibility of continuing antiretroviral therapy depends on that of enteral administration. When the gastrointestinal tract is significantly dysfunctional, all of the drugs in a patient's regimen will inevitably be stopped at the same time, and no harm is likely if they can be resumed in a few days. Still, the NNRTIs (efavirenz, nevirapine, and etravirine) are eliminated very slowly, and stopping all agents at the same time may lead to a prolonged period of inadvertent NNRTI monotherapy and the selection of drug-resistance mutations. When ART therapy must be interrupted for more than a few days, consultation with an expert is in order.

Continuing antiretroviral therapy entails potentially complex interactions with other drugs prescribed, including effects on absorption and metabolism that result in either suboptimal or toxic levels of both the antiretrovirals and other drugs. For example, administration of proton-pump inhibitors causes significant reductions in the protease inhibitor atazanavir; an H_2 blocker can be given safely 12 hours before or after atazanavir. Protease inhibitors significantly reduce the metabolism and increase the activity of midazolam. Lorazepam and temazepam may be safer alternatives for sedation, but dose titration with close monitoring of effect in the ICU setting may suffice to overcome the potential risks of midazolam administration. Given the frequency of cardiovascular disease as a cause of ICU admission among HIV-infected persons, HMG-CoA reductase

inhibitors may be prescribed, but protease inhibitors have significant and varying interactions with most of these drugs; simvastatin and lovastatin are contraindicated with all of the protease inhibitors because of massive increases in their plasma levels.

The presence of acute kidney injury necessitates dose adjustments of all the nucleoside analogs except abacavir, and the components of fixed-dose combinations require individual adjustments. If renal function varies or is impaired for several days, the best way to assure consistently adequate and nontoxic levels of antiretrovirals is to change the regimen to drugs that do not require adjustment for renal insufficiency, when possible.

In considering whether to start antiretroviral therapy in a critically ill patient who did not receive it before, a few questions may guide the decision. First, is the enteral route expected to remain available to permit consistent and continuous drug administration? If not, antiretroviral therapy must wait. Second, does the patient have an infection for which there is no effective therapy other than the potential offered by improved immunologic status (e.g. cryptosporidiosis or progressive multifocal leukoencephalopathy)? In this situation, all other care is futile unless antiretroviral therapy is begun, and it should be. Third, did the patient not receive ART because the diagnosis of HIV infection was never established, by choosing not to take ART because of personal reasons, or because of repeatedly opting to stop ART? The latter two do not lend themselves to easy answers, and it may be well to wait at least until the patient is no longer critically ill and able to make an informed choice. Patients with advanced neurocognitive disease may have marked improvement on antiretroviral therapy and may regain functional independence; for them, treatment is as imperative as for those with otherwise untreatable infections. When therapy is started in patients who are deemed to be at high risk of abandoning it, the regimen should have minimal adverse consequences if discontinued abruptly (e.g., NNRTIs should be avoided).

The risk of IRIS has been a deterrent to starting antiretroviral therapy early in patients with opportunistic infection, but more recent studies have clarified this issue considerably. A randomized trial of early versus deferred ART in patients with acute opportunistic infections excluding tuberculosis found that fewer patients who received early therapy had progression of AIDS or death, with no difference in the rate of IRIS [60]. Other studies support a survival advantage for patients who started on ART in the ICU [61,62]. In patients with tuberculosis, IRIS occurred in 12.4% of patients randomized to early ART (started at a mean of 70 days after the initiation of antituberculous therapy) and only 3.8% of those whose ART was delayed until completion of treatment for tuberculosis (mean of 260 days), but mortality was significantly higher in the delayed-ART group (12.1% versus 5.4%), and no deaths were attributed to IRIS [63]. However, in patients with cryptococcal meningitis treated with a suboptimal fluconazole regimen that is the only one commonly available in Africa, early initiation of ART (within 72 hours of diagnosis) resulted in nearly threefold increased mortality compared to initiation after 10 weeks, with median survivals of 28 and 637 days, respectively [64]. Although firm conclusions are not yet available about the timing of ART in patients with serious opportunistic infections, it seems that the opportunistic infection should be under good control before initiating ART and that the clinician must anticipate the potential emergence of serious effects from IRIS [65].

PREDICTORS OF OUTCOME

Overall, it seems that critically ill patients with HIV infection have similar short-term outcomes as other patients with a comparable severity of illness, and survival rates seem to be improving [7,8,10,66,67]. Most studies in patients with HIV infection are limited by selection bias, as they are usually retrospective analyses where the admitting physician's knowledge of the patient's serostatus may have affected the decision to admit to ICU or vigor of care. In a study conducted in a South African surgical ICU, HIV testing was performed but results not divulged and there were no differences in ICU or hospital mortality or duration of stay when outcome was adjusted for age, despite a higher incidence of sepsis and organ failure in the HIV-infected patients [68]. Thus, evidence from a variety of settings supports the concept that HIV-infected and uninfected persons have similar outcomes of intensive care, and that decisions regarding the appropriateness of ICU interventions should not use HIV status alone as a criterion.

Studies examining the value of laboratory tests and scoring systems in predicting ICU outcomes for HIV-infected patients, including lactate dehydrogenase (LDH), serum albumin, CD4+ lymphocyte count, APACHE II score, and multisystem organ failure scores yield conflicting data on their reliability. It now seems clear that patients with HIV/AIDS have similar short-term outcomes to those of other patients with a similar severity of illness. Long-term survival is related to the severity of the HIV disease, other comorbid illness, and whether the patient has been treated with ART. In addition to the patient's illness, the experience of the hospital and healthcare providers in treating HIV infection and its complications also influences mortality. In one large study, adjusted mortality for patients with AIDS was 30% lower among hospitals with the most experience treating these patients [69].

Since the outcome of intensive care does not depend directly on the patient's HIV status, determination of whether or not a patient has HIV infection or determination of CD4+ lymphocyte counts should not be overriding considerations in deciding whether to offer or withhold intensive care. Rather, these decisions should be made using the same criteria as for all patients, namely, the likelihood of benefit and the patient's wishes.

RISK TO HEALTHCARE WORKERS AND POSTEXPOSURE PROPHYLAXIS

The risk of acquiring HIV-1 infection by mucous membrane exposure is approximately 0.09% (just under 1 in 10,000) and by percutaneous (e.g., needlestick) exposure, approximately 0.3%, or 1 in 300 instances [70,71]. Virtually all documented infections have involved accidents with hollow-bore needles. The risk is higher when inflicted by a device that came directly from the HIV-infected patient's artery or vein, had visible blood on it, produced deep injury, or came from a source patient with terminal illness (defined as death due to AIDS within 60 days of the healthcare worker's exposure). Each of these features increases the risk of infection independently. In a case-control study where healthcare workers infected by needlestick exposures were compared with healthcare workers who sustained exposures from HIV-infected patients but did not become infected, the only factor that was shown to reduce the risk of infection was postexposure use of zidovudine by the healthcare worker [72]. Zidovudine prophylaxis appeared to reduce the risk of infection by 81%. This study led to much stronger recommendations for antiretroviral therapy in healthcare workers with percutaneous or mucous membrane exposure to HIV-1.

Current recommendations reflect the failure rate of single-agent postexposure prophylaxis, the prevalence of zidovudine-resistant virus, the proven antiviral efficacy of three-drug regimens in infected individuals, and the importance of tolerability of the regimen to ensure completion of a full 4-week

course [73]. Most percutaneous exposures from a known HIV-positive source warrant three or more drugs, with the exception of superficial injury from a solid needle used for a patient with asymptomatic HIV infection or known low viral load of less than 1,500 HIV RNA copies per mL, for which two-drug therapy is recommended. Three or more drugs are also recommended for large-volume splashes to mucous membranes or nonintact skin from patients with symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. Two-drug regimens are recommended for small-volume exposures to mucous membranes or nonintact skin. The National Institutes of Health AIDS Information Web site provides the most current drug recommendations [73]; expert consultation is advised, especially for cases involving drug-resistant virus and pregnant or breastfeeding personnel. Recommendations for postexposure prophylaxis emphasize initiating treatment within an hour or two of exposure, and data from infants of HIV-positive mothers not treated during pregnancy and delivery suggest little benefit to therapy delayed beyond 48 to 72 hours [74]. However, the time after which therapy will not be successful has not been defined.

The list of potential side effects of antiretroviral drugs is daunting, and most healthcare workers will experience some of them, along with justifiable anxiety. They should be reassured that most HIV-infected people tolerate these regimens with the help of adequate psychosocial support and proper medical follow-up.

SUMMARY

In summary, the evolution of the AIDS epidemic and the introduction of effective antiretroviral therapy have changed the spectrum of critical illnesses in patients with HIV infection.

TABLE 85.2

SUMMARY RECOMMENDATION FOR MANAGEMENT OF PULMONARY COMPLICATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

- Early adjunctive treatment with corticosteroids reduces the risks of respiratory failure and death in patients with acquired immunodeficiency syndrome (AIDS) and moderate-to-severe *Pneumocystis* pneumonia [18,25,26].
- Early versus deferred ART in patients with acute opportunistic infections excluding tuberculosis decreases progression to AIDS or death, with no difference in the rate of IRIS [60].
- Early versus deferred ART in patients with tuberculosis decreases mortality, but increases risk of IRIS [63].

ART, antiretroviral therapy; IRIS, immune reconstitution inflammatory syndrome.

The use of ART led to reduced risk of AIDS-associated illness and improved survival, but raises new and complex questions about how best to use these treatments in patients with critical illness. Clearly, large-scale multidisciplinary studies of critical care of patients with HIV infection would yield valuable insights, but until the important clinical questions are answered, critical care clinicians must work closely not only with the ICU multidisciplinary team, but also with colleagues with backgrounds in infectious diseases, pharmacology, and palliative care. Advances in HIV infection, based on randomized controlled trials or meta-analyses of such trials, are summarized in [18] and Table 85.2.

CHAPTER 86 ■ INFECTIOUS COMPLICATIONS OF DRUG ABUSE

AFROZA LITON AND WILLIAM L. MARSHALL

Drug abuse, the deliberate taking of an unprescribed drug dose or illicit substance, is a pervasive problem in our society [1]. A variety of drugs are abused, including opiates, depressants, stimulants, and hallucinogens. This chapter will focus on infections that occur as a consequence of drugs that are either explicitly illegal or those which are legal but are used by the patient for purposes other than for which they were prescribed. Abused drugs can be administered by a variety of means, including "snorting" through the nasal mucosa, via inhalation through smoking, and orally by parenteral routes, including injection into the soft tissues, called "skin popping," or directly into the vascular system.

Drug abuse is attended by an increased risk in a number of infections, some of which may lead patients to be admitted to the intensive care unit (ICU) [2]. Infections associated with parenteral drug abuse include skin and soft tissue infection, endocarditis, bone and joint infections, pneumonia, ophthalmologic infections, and hepatitis [2–4]. Illicit drugs are often "cut" or mixed with adulterants, which may be contaminated with bacteria or may suppress the immune response—as is the case with agranulocytosis caused by levamisole-containing cocaine leading to bacterial or fungal infection [5]. Illicit drug injection occurs under unsanitary conditions, using drugs that are not sterile and injection equipment that has often been used more than once. Such practices provide a mechanism for passage of a variety of infectious agents. Although in some instances, particularly for the hepatitis viruses and human immunodeficiency virus (HIV), the infectious agent is passed directly from blood-contaminated drug paraphernalia to the patient, the mode of spread is less clear for other agents. Prevention of infectious complications of drug use is directed at treating addiction, or failing that, mitigating infectious complications via needle exchange programs [6]. Finally, many patients with substance abuse problems are homeless, have poor nutrition, and live under crowded conditions, placing them at increased risk for tuberculosis.

FEVER

Fever is one of the most common complaints of parenteral drug users presenting to the hospital. Self-limited illnesses are the most common causes of fever in this population. More significant etiologies include pneumonia, cellulitis, and soft tissue abscesses. Endocarditis accounts for fewer than 15% of all cases of fever [7].

All febrile parenteral drug users should undergo a thorough history, physical examination, and have routine blood laboratories and chest radiographs taken. Particular attention should be paid to abnormalities of the skin and soft tissues, cardiac valvular abnormalities, bony tenderness, and pulmonary abnormalities. However, clinical evaluation alone often does not differentiate major disease from trivial illness in these patients. Parenteral drug users who are febrile should be admitted to the hospital for further observation.

Weisse et al. have developed an algorithm for febrile parenteral drug abusers with no apparent source of infection [7]. In this approach, blood cultures are obtained on all patients and empiric antibiotic therapy is started. If blood cultures are positive or if the patient has clinical stigmata indicative of endocarditis, an echocardiogram is performed. If valvular vegetations are seen, the diagnosis of endocarditis is considered established. On the other hand, if blood cultures are negative and the patient is clinically well, antibiotic therapy may be stopped. However, parenteral drug users commonly self-administer antibiotics and this practice may substantially reduce the likelihood of positive blood cultures, as can prophylactic antibiotics in HIV+ patients [8,9]. Hence, careful clinical evaluation is advised when making antibiotic decisions in these patients.

BACTEREMIA

Bacteremia is a frequent occurrence in the febrile parenteral drug user [10,11]. Approximately 60% of bacteremias in parenteral drug abusers are due to causes other than endocarditis [12]. Of these, the majority are due to either skin or soft tissue infections or to mycotic aneurysms of peripheral arteries. A smaller number of bacteremias are due to miscellaneous causes, such as septic arthritis, septic thrombophlebitis, or pneumonia. In about 3% of cases, the source of the bacteremia is undiscovered.

Although the organisms associated with bacteremias in the parenteral drug user may vary based on geographic location and the type of drug abused, some generalizations can be made [12,13]. Drug users have an increased incidence of staphylococcal carriage of the skin, nose, and throat [14]. Bacterial infection derives principally from the user's own flora, so that *Staphylococcus aureus* constitutes the majority of bacteremias in these patients. In this regard, methicillin-resistant *S. aureus* (MRSA) infections are now being encountered with increasing frequency in parenteral drug users and in the community [14,15].

Streptococci and Gram-negative aerobic bacilli are the next most frequently isolated organisms. Polymicrobial bacteremias occur in about 10% of cases, and in about two-thirds of these cases at least one of the organisms isolated is a *Staphylococcus* spp [12]. Bacteremia and other infections due to the facultative anaerobe *Eikenella corrodens* are particularly associated with injecting drug users who contaminate the injection needle or the injection site with saliva [16].

The approach toward the bacteremic parenteral drug user should be to search for an underlying etiology and to begin empiric antibiotic treatment. The isolation of a group A β-hemolytic streptococci from the blood should prompt a search for a cutaneous or soft tissue focus of infection [17]. Empiric antibiotic therapy may be based on local experience but should generally include agents directed against staphylococci and streptococci as well as aerobic Gram-negative bacilli. If

MRSA infections have previously occurred in parenteral drug users in the community, vancomycin should be considered.

SOFT TISSUE INFECTIONS

Skin and soft tissue infections occur commonly in the parenteral drug user and are increasing in frequency [18,19]. Such infections are often polymicrobial and appear to derive from either the skin or oral cavity [18,20,21]. The most common pathogens are *S. aureus,* streptococci, oral anaerobes, and aerobic Gram-negative bacilli [16–21]. Cutaneous infection in the intravenous drug user generally occurs in the antecubital fossa, forearm, and hand since these are the sites of the most accessible veins. However, intravenous drug users may also avail themselves of other, less available sites with infection occurring in the feet, legs, anterior neck, groin, and axilla [22,23].

The most common skin infections in the injecting drug user (IDU) are simple cellulitis and localized skin abscess. These occur more frequently among those who "skin pop" compared to those who inject intravenously [24]. Simple cellulitis usually requires only antibiotic therapy directed against staphylococci and streptococci. Since the incidence of MRSA infections is rising, and the IDU is particularly at risk for MRSA infections of the skin and soft tissues [14], patients requiring intravenous therapy should receive vancomycin. Localized soft tissue abscesses that do not penetrate into the deep subcutaneous tissue should be drained. Given the risk of occult bacteremia in this population, antibiotic therapy should be given as directed by Gram stain of the drained material. In all patients with a history of injection drug use, blood cultures should be obtained in the workup of skin and soft tissue infections.

The presence of vesicles or bullae, an area of central necrosis within a larger area of erythema, and the presence of subcutaneous crepitation in a patient with systemic toxicity is suggestive of necrotizing fasciitis [25]. Gas seen in the soft tissues on radiographs is also indicative of deep infection [26]. However, extensive necrosis may be present even in the absence of these signs, and surgical exploration should be considered in any case that manifests local erythema, fluctuance, and induration [27]. Suspicion for needles or other foreign bodies should similarly prompt surgical exploration. Any abnormal material from this exploration should be immediately examined using Gram stain to provide the basis for empiric antimicrobial therapy. Examination of a sample of tissue using frozen-section biopsy may also be useful [28]. Magnetic resonance imaging (MRI) typically reveals increased T2 signal along fascial planes and gadolinium enhancement, whereas contrast-enhanced computed tomography (CT) scanning is a less sensitive diagnostic tool for necrotizing fasciitis [26].

Necrotizing fasciitis, pyomyositis, or gangrene requires immediate, aggressive debridement in the operating room in association with parenteral antibiotics [27]. Gram stain and culture are imperative to guide antimicrobial therapy. Empiric therapy should be directed against staphylococci, streptococci, anaerobes, and aerobic Gram-negative bacilli. Surgical debridement may be required on multiple occasions before infection is controlled [29]. There have been multiple outbreaks of soft tissue infection with or without systemic symptoms associated with *Clostridium* spp discussed later in this chapter.

PERIPHERAL VASCULAR INFECTIONS

Because parenteral drug use often involves vascular injection of material under non-sterile conditions, it is not surprising that a wide range of vascular complications may result from these practices [30]. The most frequent manifestations of such infections are fever associated with pain, redness, and swelling over the involved area. When the injecting site is into the deep tissues of the groin or neck, it may be difficult to distinguish involvement of vascular structures from simple cellulitis, soft tissue abscess, or fasciitis. If there is any question, angiography should be performed to determine if vascular tissue is involved. Septic thrombophlebitis usually presents as fever, bacteremia, and swelling over the involved vein. This can often be treated with antibiotics alone, although incision, drainage, and removal of the vein are sometimes necessary. Anticoagulation is generally not required [12].

Mycotic aneurysms result when the user injects directly into the artery [12,30]. Aneurysms most frequently occur in the femoral arteries. Carotid aneurysms and brachial artery aneurysms occasionally occur [30]. The classic presentation of this syndrome is a febrile patient with a tender, pulsatile mass, usually in the groin or the neck. Sometimes, there is a small amount of bleeding at the site. If there is any question of an aneurysm, a vascular surgical consultation should be obtained prior to any exploration of the lesion. Angiography will confirm the site and extent of the aneurysm. The most frequent microbiological agents isolated are *S. aureus* and streptococci, with aerobic Gram-negative bacilli occasionally being identified [12]. Empiric antibiotic therapy should be directed against these organisms. Ligation and excision of the involved arterial segment is usually successful [31].

ENDOCARDITIS

Endocarditis in the parenteral drug abuser differs in several respects from endocarditis in the nonaddict. It is more likely to occur in persons without underlying valvular heart disease, to involve the tricuspid valve, to be due to *S. aureus*, and to have a more benign outcome [3,32]. Certain types of intravenous drug abuse may predispose to the development of endocarditis. Heroin use has long been associated with this complication [33].

Tricuspid-valve endocarditis is the prototypical presentation of endocarditis in the parenteral drug user [33]. The patient complains of fever, usually for less than 1 week. There may be a history of chills and pleuritic chest pain and occasionally hemoptysis. On physical examination, fever is a nearly universal finding. A systolic murmur may or may not be present on admission, but often develops during the course of therapy. Signs of peripheral embolization, such as petechiae, splinter hemorrhages, Janeway lesions, or Roth spots, are uncommon. Osler's nodes are frequently absent. On chest radiograph, multiple patchy infiltrates indicative of pulmonary emboli are strongly suggestive of the diagnosis of tricuspid endocarditis. Blood cultures are usually positive and in the majority of instances, *S. aureus* is isolated. When blood cultures are negative in the face of the appropriate clinical syndrome, one should suspect that the patient has recently taken antibiotics.

Endocarditis involving the valves of the left side of the heart may also occur in the parenteral drug user. Compared to patients with tricuspid-valve endocarditis alone, there is more likely to be a history of underlying heart disease [12]. On examination, a heart murmur is usually evident on presentation, and peripheral emboli are frequent. Streptococci are more likely to be isolated from the blood, but *S. aureus* is still frequently isolated [3,12,33].

In addition to staphylococci and streptococci, a variety of other organisms have been associated with endocarditis in the parenteral drug user, including aerobic Gram-negative bacilli, particularly *P. aeruginosa*, and fungi, notably *Candida* spp [3]. Moreover, polymicrobial bacteremia is a well-recognized complication of endocarditis in this population and is usually

indistinguishable on clinical grounds from that due to a single organism [34].

Bacteremia and pulmonary emboli on chest radiograph are highly predictive of tricuspid-valve endocarditis in the parenteral drug user [3,12]. However, all individuals with clinically suspected endocarditis should have echocardiography performed. Transesophageal echocardiography is more sensitive than transthoracic echocardiography in identifying valvular vegetations [35]. When echocardiographic findings are combined with clinical manifestations, the diagnosis of endocarditis can usually be established with high sensitivity and specificity using the Duke criteria or modifications of the Duke criteria [36], even in IDUs with HIV infection [37].

Empiric therapy for endocarditis in the parenteral drug user should be directed against staphylococci, streptococci, and aerobic Gram-negative bacilli. Nafcillin, oxacillin, and cefazolin are reasonable choices only if methicillin resistance among staphylococci has not been encountered. Vancomycin is the current alternative for the treatment of MRSA infections and for the β-lactam-allergic patient. Until cultures return, a broad-spectrum antibiotic, such as ceftazidime, should also be added for initial empiric therapy of aerobic Gram-negative bacilli because of the frequency of this type of endocarditis in addicts [38].

The prognosis for tricuspid-valve staphylococcal endocarditis in the parenteral drug user is good, with a mortality of less than 10% employing a choice of several therapies [3,12,37]. There was no difference in outcome between treatments with a β-lactam antibiotic alone and in combination with an aminoglycoside for 4 weeks [39]. Although a combination of a penicillinase-resistant penicillin with an aminoglycoside has been advocated for 2-week therapy for right-sided endocarditis [40], one study found that results for combination therapy were no different from those when a penicillinase-resistant penicillin was used alone [41].

Nonstaphylococcal endocarditis, particularly that involving the aortic and mitral valves, has a significantly worse prognosis. Left-sided endocarditis secondary to *P. aeruginosa* has a particularly poor outcome, with a mortality rate of nearly 70% [12]. To achieve cure, a 6-week course of intravenous therapy with an antipseudomonal β-lactam antibiotic plus an aminoglycoside, both at high doses, combined with early surgical removal of the involved valve is usually required [38]. *Candida* endocarditis also has an extremely high mortality rate even with prompt valve replacement and systemic antifungal therapy [42].

The role of surgery in endocarditis in the parenteral drug user is no different from endocarditis in the general population. Hemodynamic decompensation, persistently positive blood cultures in the face of appropriate antimicrobial therapy, multiple embolic episodes after therapy is initiated, fungal endocarditis, and evidence of extravalvular extension of infection constitute major criteria for valve replacement [43]. Tricuspid valvulotomy is successful in the majority of patients with isolated tricuspid-valve involvement and intractable infection. Only about 10% of patients require a subsequent prosthetic valve to control congestive right-heart failure [44].

SKELETAL INFECTIONS

Infections of the bones and joints represent a distinct clinical syndrome in the drug abuser. Most cases have been reported among intravenous heroin users, and many cases occur in association with endocarditis [45]. Bacterial osteomyelitis of the vertebral column is the most frequent skeletal infection reported. The lumbar, cervical, and thoracic spine are involved, in that order. Patients generally present with weeks to months of pain in the involved area. High fevers are unusual, and many patients are afebrile. There is usually tenderness over the involved vertebral bodies and radiographic evidence of osteomyelitis. Laboratory values are generally normal, although the peripheral white blood cell count may be modestly elevated. The erythrocyte sedimentation rate and/or C-reactive protein are almost always elevated and may serve as useful markers of a response to therapy [46]. Because of the chronicity of symptoms and the general lack of toxicity of these patients, it is not unusual for the diagnosis to be missed for weeks or even months. The complaint of low back or neck pain in an intravenous drug user should always suggest the diagnosis of vertebral osteomyelitis. Septic arthritis often involves the sacroiliac and sternoarticular joints and the symphysis pubis. There is usually weeks to months of pain at the site and tenderness to palpation at the site of involvement. Radiographs are usually normal at presentation. MRI is preferable to contrast-enhanced CT of the spine to make the diagnosis of vertebral osteomyelitis [47].

The bacteriology of skeletal infections among drug users is quite different from that seen in other patients. Gram-positive cocci, such as staphylococci and streptococci, as well as aerobic Gram-negative bacilli, particularly *P. aeruginosa*, are frequently isolated [45]. Skeletal infections due to *Candida* spp may also occur, either alone or as part of a dissemination syndrome [48]. Because of this, it is imperative that a bacteriologic diagnosis be established in such patients. In most cases, this can be achieved by needle aspirate of the involved bone or joint. For sternoarticular infections, open surgical exploration is often required. Therapy involves long-term antibiotic therapy and in some cases surgical debridement [49].

SYSTEMIC SYNDROMES WITH SPORE-FORMING BACTERIA

Anaerobic spore-forming bacilli of the genus *Clostridium* are ubiquitous in the environment; exospores can remain viable indefinitely. If illicit substances become contaminated with these spores, subsequent injection of the substances may result in severe illness or death. The first reports of infections in people addicted to morphine injection were of tetanus in 1876. By the 1950s in New York, drug addiction accounted for the majority of cases of tetanus. Wound botulism caused by *Clostridium botulinum* was first observed in IDUs in the United States in 1982. Cases increased during the 1990s with the use of black-tar heroin, and a similar outbreak was seen in Germany in 2005. These patients presented with abscesses associated with symmetrical descending paralysis, some requiring mechanical ventilation. Treatment included antitoxin, antimicrobials, and surgical drainage of abscesses [50]. In the last decade, there have been outbreaks of serious illness and death among IDUs in the United Kingdom due to *Clostridium novyi* and *Clostridium histolyticum* [51]. Skin poppers using subcutaneous and intramuscular injection appear to be particularly at risk [52].

Similar to infections with *Clostridium* spp, since 2009 there have been cases of anthrax confirmed in heroin users in Scotland [53]. All injection routes have been implicated, but smoking or snorting may also pose a significant risk. Most had severe soft tissue infections with significant soft-tissue edema but differed from classic necrotizing fasciitis or classic cutaneous anthrax. Patients had vague prodromal symptoms, appeared very ill, but their symptoms had nonspecific systemic features. Some developed septic shock leading to multiorgan failure.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Injecting drug use represents the third most common risk behavior for infection with HIV in the United States and is

associated with 75% of HIV cases among heterosexual men. Black and Hispanic ethnic groups are disproportionately represented among IDUs with HIV infection [54]. In some metropolitan regions, notably Atlanta, Detroit, and San Francisco, the rate of HIV infection among IDUs is approximately 10%. There is great geographic variability in the prevalence of HIV infection among IDUs. The highest rates are in the northeastern United States and Puerto Rico.

Certain practices increase the risk for a drug user to acquire HIV infection. These include frequent intravenous drug injections, injection in "shooting galleries," places where users rent the injecting paraphernalia and return it after use, injection with used needles, or sharing needles. Additional factors associated with an increased risk include use of cocaine or other drugs that prompts HIV risk behaviors and having sex partners who use intravenous drugs. The latter is significantly associated with HIV infection in women [55]. Finally, the use of methamphetamine, "crystal meth," has been linked to an increase in the sexual transmission of HIV, including highly antiretroviral-resistant strains [56]. In vitro studies show that opiates, methamphetamine, and cocaine can potentiate HIV replication and can enhance neurotoxicity [57].

HIV-positive IDUs are more likely to develop infections that are not AIDS-defining illnesses. Disease patterns in this group may differ from the other HIV-infected groups [58]. In particular, they have a high risk of developing bacterial pneumonia and bacterial sepsis, especially due to encapsulated organisms such as *Streptococcus pneumoniae* or *Haemophilus influenzae*. This observation highlights the importance of pneumococcal and *H. influenzae* type B vaccines in this group [58]. Progressive decline of CD4 lymphocyte counts to less than 200 per μL, and smoking illicit drugs significantly increase the risk of bacterial pneumonia [59]. In one study, *Pneumocystis* pneumonia, community-acquired bacterial pneumonia, and tuberculosis were the three most frequent pulmonary diseases seen among a group of illicit drug users in Washington, DC [60].

Any intravenous drug user should be considered at risk for HIV infection, and such patients should be offered testing for infection [54]. In areas of high prevalence, the clinician should be aware that HIV-related immunodeficiency might be complicating the clinical course in an IDU. In the United States, IDUs are also the highest risk group for human T-cell lymphotropic virus type I or II (HTLV-I or HTLV-II) infection [4]. The impact of this on HIV-related mortality is unclear, but coinfection with HIV and HTLV-I has been associated with myelopathy [61].

VIRAL HEPATITIS

Acute and chronic hepatitis have long been recognized as common reasons for hospital admission among drug users [4]. Of the infectious causes, hepatitis B virus (HBV) remains a principal pathogen. It is estimated that from 60% to 80% of parenteral drug users in the United States are infected with hepatitis B, and that nearly 10% are chronic carriers [62]. Moreover, coinfection with the hepatitis delta virus, a hepatotropic agent that requires hepatitis B for replication, has been reported in 8% to 40% of IDUs infected with hepatitis B and is associated with a more fulminant course [63]. Hepatitis A has also been documented as a cause of acute hepatitis among intravenous drug users [64].

After HIV infection, infection with hepatitis C virus (HCV) is the next emerging infectious disease epidemic in the United States. The vast majority of cases of HCV infection are associated with injecting drug use. Acute infection, which occurs relatively soon after injection drug practices begin, is rarely symptomatic, but chronic infection occurs in 85% of all cases. Patients may develop chronic liver disease and cirrhosis. In one survey, HCV infection was identified in 80% of intravenous drug users [65], but more recent studies report a decrease in HCV seroprevalence among IDUs from 65% to 35% [66]. Psychiatric comorbidities in drug users complicate the treatment of HCV with interferon.

Parenteral drug abusers may suffer multiple attacks of acute hepatitis and are also likely to have significant structural and functional abnormalities of their liver, even if they are asymptomatic. Noninfectious factors, particularly the use of alcohol and other drugs, may act synergistically with the hepatitis viruses to lead to a poorer outcome [62].

In addition, coinfection with HIV, although decreasing [6] may also cause increased activity of these viruses, particularly HCV, promotes liver damage and lower response to the treatment [67]. Finally, concomitant HCV and either HBV or hepatitis A virus (HAV) can lead to severe hepatitis or death, underlining the importance of vaccinating eligible parenteral drug users for HAV and HBV [68]. Special attention is required to choose therapies in patients with HIV and HBV coinfection. Antiretroviral medications like lamivudine or tenofovir are only partially active as monotherapy against both viruses, requiring thoughtful combination therapy to be effective against both viruses. There is an increase in the incidence of hepatocellular carcinoma and hepatotoxic effects associated with antiretroviral drugs in patients with HIV and HCV/HBV coinfection [69].

Sexually Transmitted Diseases

Sexually transmitted infections such as Chlamydia and gonorrhea are closely associated with substance abuse, both due to frequent exchange of sex for money or drugs and because of the sexual disinhibition that result from the use of psychoactive substances, especially alcohol and cocaine. Crack use has also been linked to an increased risk of syphilis and other ulcerative genital infections [70]. The high false-positive rate of nontreponemal tests for syphilis (rapid plasma reagin test and the Venereal Disease Research Laboratory test) in IDUs requires use of specific treponemal tests (e.g., the fluorescent treponemal antibody absorption test). Standard therapy for syphilis appears to be effective in both HIV-seropositive and HIV-seronegative IDUs. HIV-infected women have higher risk of cervical dysplasia and cancer associated with concurrent human papillomavirus infection that warrants at least yearly Papanicolaou smears in this group [58].

PULMONARY DISEASE AND TUBERCULOSIS

As noted earlier, community-acquired pneumonia, tuberculosis (TB), HIV-associated *Pneumocystis* pneumonia, and septic pulmonary emboli due to right-sided endocarditis are the major pulmonary complications of illicit drug use [12,60]. In addition, pulmonary edema may acutely attend drug injection. This is not associated with infection and usually clears in 1 to 2 days.

A unilateral infiltrate on chest radiograph in a drug abuser should suggest a bacterial pneumonia. Antibiotic therapy should be directed against community-acquired pathogens, such as *S. pneumoniae*, *S. aureus,* and nonpseudomonal Gram-negative bacilli, such as *H. influenzae* and *Klebsiella pneumoniae*. If there is a recent history of unconsciousness suggesting aspiration of oropharyngeal contents, antimicrobial therapy directed against anaerobes should be considered.

Nearly 1 out of 3 U.S.-born persons older than 15 years of age who has TB is substance abuser. In addition to poor socioeconomic condition, substance abuse often takes place in enclosed spaces with poor ventilation and high volumes of human traffic, and increases the likelihood of TB transmission

[71]. The risk of developing active tuberculosis among IDUs is significant, particularly if they are coinfected with HIV. Many drug users with HIV infection and TB may not demonstrate cutaneous tuberculin reactivity probably because of anergy. These patients have a high risk for developing active TB that is more likely to be extrapulmonary [72]. Data indicate the effectiveness of preventive isoniazid therapy for all drug users who are HIV infected and live in areas of high prevalence of TB [73]. Some experts advocate treatment of latent TB regardless of tuberculin skin test reaction but the spread of multidrug-resistant TB in HIV+, drug-using populations suggests that this approach may not always be successful [74].

The clinician should maintain a high index of suspicion of TB in any drug user with pulmonary disease, particularly if the patient is infected with HIV. If there is any possibility of pulmonary TB, patients should be placed in respiratory isolation. Acid-fast smears should be performed on at least three respiratory specimens before active pulmonary TB is ruled out. If smears are positive, antituberculous therapy should be initiated [75] (see Chapter 87). Clinicians must address barrier to treatment adherence to reduce the risk of treatment failure that will lead to developing drug resistance [58].

DISSEMINATED CANDIDIASIS

A distinctive form of disseminated candidiasis has been described in injecting drug abusers who use brown heroin. *Candida albicans* has been specifically implicated in these cases. The source of infection is unclear but appears to be derived from the drug user's own flora [76]. The syndrome is characterized by fever within hours after injection, followed days to weeks later by skin, eye, and osteoarticular lesions. The skin lesions consist of deep subcutaneous nodules confined to the scalp or other hairy areas, and painful pustules on an erythematous base found in all areas of the body. Direct examination of expressed material from these pustules will demonstrate budding yeast. Costochondral tumors are a unique part of the syndrome, presenting as pain and swelling over the involved ribs. Biopsy of such lesions is often diagnostic, demonstrating both pseudohyphae and yeast. Optimal therapy is not established. Azole antifungals have been used successfully in many cases of skin involvement alone, but amphotericin B and surgery have been required with ocular or osteoarticular involvement [76].

OCULAR INFECTIONS

IDUs have an increased risk of eye infections, usually secondary to hematogenous spread from another site. Most cases are secondary to *Candida* spp, either as part of the disseminated candidiasis syndrome described earlier or with eye involvement alone. *Aspergillus* and *Fusarium* spp have also been associated with endophthalmitis in the parenteral drug user. Usually only one eye is involved, and there are no other sites of infection [77]. Treatment generally requires vitrectomy combined with systemic antifungal therapy such as voriconazole or amphotericin B.

Endophthalmitis due to bacteria is far less common than that due to fungi. Unlike fungal endophthalmitis, which often presents indolently, the onset of bacterial endophthalmitis is usually explosive with acute pain, redness, and decreased visual acuity. It may be mistaken initially for conjunctivitis. Progressive destruction of the eye may occur rapidly and immediate ophthalmologic consultation is requisite. Unusual organisms have been frequently isolated in this disease, such as *Bacillus* spp and *Staphylococcus epidermidis* [77].

CENTRAL NERVOUS SYSTEM INFECTIONS

Epidural abscess is the most frequent central nervous system infection in the IDUs [2,78]. A common presentation is indolent radicular pain associated with an underlying vertebral osteomyelitis. Imaging studies, such as myelography, CT scan, or MRI, are useful in defining the extent of the infectious process. Needle aspiration under radiographic visualization can establish the microbiologic etiology. Staphylococci are the most frequent cause, although other pathogens, including *P. aeruginosa* and *M. tuberculosis*, have also been recognized. Neurosurgical consultation should be obtained at the time the diagnosis is first suspected [2,78].

Brain abscesses may occur, usually as a result of embolization from either endocarditis or a mycotic aneurysm. They are usually multiple and generally due to *S. aureus*. Antibiotic therapy alone has led to cure in some cases [79]. Cerebral mucormycosis is another complication of intravenous drug use and is suggested by the finding of lesions in the basal ganglia [80].

CHAPTER 87 ■ TUBERCULOSIS

ROBERT W. BELKNAP AND RANDALL R. REVES

EPIDEMIOLOGY

Tuberculosis (TB) continues to cause significant morbidity and mortality worldwide. In 2007, there were an estimated 9.27 million new cases, 13.7 million prevalent cases, and 1.75 million deaths due to TB [1]. Globally, the total number of TB cases is increasing but because of population growth, the overall incidence rate per 100,000 persons has declined minimally. In the United States, incident TB cases have been declining since 1992 and reached a historic low in 2009 at 11,545 [2]. The challenge for TB controllers is continuing to progress toward the goal of TB elimination. Concurrent with the decline, TB in the United States has increasingly become a disease of foreign-born, minority, and other underserved populations.

A threat to TB control efforts worldwide has been the rise of multidrug-resistant (MDR) and extensively drug-resistant (XDR) forms of TB. Both forms have been present in relatively low numbers for decades but an outbreak of XDR TB in rural South Africa associated with a high and rapid mortality brought this issue to international attention [3]. The World Health Organization's 4th report on drug-resistant TB estimated that 0.5 million MDR-TB cases occur annually and approximately 7% of these are XDR TB [4]. The accuracy of these estimates is limited by the absence of culture and susceptibility testing in many high-burden countries. Nevertheless, the overall trend appears to be increasing and may have important implications for choosing empiric treatment in hospitalized patients and for infection control.

The proportion of newly diagnosed TB patients who require hospitalization each year is poorly characterized. One large urban hospital reported that TB accounted for 1% of medical intensive care unit (ICU) admissions over a 15-year period [5]. Epidemiological studies show that between 3% and 24% of hospitalized TB patients require treatment in an ICU and between 2% and 13% require mechanical ventilation [5,6]. While overall mortality from TB in the United States has been around 5% for the past decade [2], mortality remains particularly high (50% to 60%) among patients with TB-associated respiratory failure requiring mechanical ventilation [6–8]. Factors associated with mortality include multiorgan failure, malnutrition, renal failure, immunosuppression, and delayed diagnosis [6–10].

PATHOGENESIS

The pathogenesis of TB is a two-stage process, which can be divided into TB infection and progression to disease [11,12]. These stages are reflective of the risk factors that should be considered when determining the likelihood that a patient has TB (Table 87.1). TB infection, with rare exceptions, results from the airborne transmission of tubercle bacilli. In a susceptible host upon reaching the alveoli, the tubercle bacilli multiply to produce a localized pneumonia, spread to involve the hilar lymph nodes, then enter the bloodstream through the thoracic duct, and disseminate throughout the body. This primary infection is usually clinically unapparent. Most patients develop cell-mediated immunity to *Mycobacterium tuberculosis*, which brings the infection under control over a period of weeks. Despite initial immunologic control of TB infection, viable tubercle bacilli remain in scattered foci as latent TB infection that if untreated may persist for life [13].

The second stage is the development of active TB, which occurs at a variable rate dependent on the person's age at infection and other medical conditions [12]. Progression from latent to active TB, termed reactivation, is much more frequent in people with certain conditions, particularly HIV infection (Table 87.1) [12,14]. Patients with advanced HIV have a 10

TABLE 87.1

FACTORS THAT SHOULD PROMPT CONSIDERATION OF TUBERCULOSIS IN THE DIFFERENTIAL DIAGNOSIS

Risks for tuberculosis infection

1. History of active tuberculosis, particularly if never or inadequately treated
2. History of a positive tuberculin skin test
3. Other risk factors for infection (tuberculin status unknown)
   - Contact with known or suspected tuberculosis
   - Presence of fibrotic lung lesions compatible with inactive tuberculosis
   - Immigration from countries with high risk for tuberculosis
   - Advanced age
   - Medically underserved populations
   - Alcohol or other drug use
   - Institutional exposure
   - Homeless shelters
   - Correctional facilities
   - Nursing homes
   - Some hospitals and mental institutions

Risks for progression to active tuberculosis (tuberculin status positive or unknown)

1. Known or suspected HIV infection
2. Other immunosuppressive conditions
   - Lymphatic and reticuloendothelial disorders
   - High-dose corticosteroids, tumor necrosis factor-α inhibitors, and other immunosuppressive therapy
3. Recent tuberculosis infection
4. Presence of upper lobe scars compatible with inactive tuberculosis
5. Certain medical conditions
   - Silicosis
   - Chronic renal failure
   - Diabetes mellitus
   - Intravenous drug use
   - Gastrectomy or other conditions associated with weight loss

times greater risk while those on effective antiretroviral therapy (ART) still have twice the risk of an uninfected person [12]. In most cases, reactivation of TB causes pulmonary disease, but reactivation can occur at any site where a latent focus was established during the initial infection [11]. Disseminated disease may also occur and is believed to result from the erosion of a tuberculous focus directly into a blood vessel [15]. In a critically ill patient, the presence of any risk factor for infection or progression should prompt consideration of TB in the differential diagnosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Physicians in intensive care settings face the challenge of maintaining an appropriate index of suspicion for TB when it is a relatively rare cause of critical illness. Prompt recognition of TB and early institution of effective multiple-drug therapy are required to achieve the dual goals of successfully treating patients and preventing nosocomial TB transmission. Delays in diagnosis are unfortunately common and have been noted in more than half of patients admitted to community hospitals [16]. Concomitant nontuberculous infections occur in up to a third of patients and can lead to delays in diagnosis [8]. Fluoroquinolones are quite active against *M. tuberculosis,* and patients with unrecognized pulmonary TB are increasingly being treated initially with these agents for presumed community-acquired pneumonia. An initial clinical response to fluoroquinolones has been documented as a cause for delays in diagnosing TB [17].

TB may present as the primary cause of a life-threatening illness, but it may also be a coincidental illness in patients being treated for another condition [8] (Fig. 87.1). The symptoms and signs of TB are variable and depend on the site and extent of disease [6–8]. The history of a chronic, progressive illness with fever, night sweats, and weight loss, with or without a chronic cough, is most suggestive of TB. However, obtaining an accurate history can be difficult and TB patients often report the acute onset of symptoms [7,18,19]. A variety of laboratory abnormalities have been associated with TB, including anemia, hypoalbuminemia, elevated alkaline phosphatase, and hyponatremia, but are nonspecific [11,20].

FIGURE 87.1. Chest radiograph of a 41-year-old homeless patient who was hospitalized with multiple fractures, including the right clavicle, after being hit by a car. The patient denied all respiratory symptoms despite having extensive bilateral upper lobe fibronodular and cavitary disease. Sputum samples were smear positive and grew *Mycobacterium tuberculosis*.

Pulmonary Tuberculosis

Pulmonary TB is the most common form of disease accounting for 80% of cases in the United States [2]. Extrapulmonary TB is more common among patients who are female, born outside the United States, and with HIV infection [21]. Acute respiratory failure, which occurs in 2% to 13% of hospitalized TB cases, is the most common reason for admission to an ICU [5,6,10,19]. While chronic cough and fevers are usually present, other symptoms suggestive of pulmonary TB include weight loss, dyspnea, and hemoptysis [11]. Of note, dyspnea may be minimal despite fairly extensive lung destruction. Hemoptysis occurs in about 20% of patients and occasionally can be massive [22]. Pulmonary TB may also be asymptomatic, occurring in patients with primarily extrapulmonary disease, or may be a coincidental finding (Fig. 87.1).

Definitively diagnosing pulmonary TB relies on the collection of respiratory samples for smear and culture. Sputum samples should be considered in symptomatic patients at risk for TB even when the chest radiograph appears normal. Positive sputum cultures in the absence of radiographic abnormalities were relatively rare in the pre-AIDS era [23] but appear more commonly among TB cases associated with AIDS [24]. The proportion of hospitalized TB patients who have a positive sputum smear ranges between 35% and 65% [7,9]. A minimum of three sputa or other lower respiratory tract specimens should be collected when pulmonary, pleural, or disseminated TB is suspected. The samples should be collected 8 to 24 hours apart preferably with at least one early morning specimen [25].

Patients who are unable to spontaneously produce sputum should have samples induced using nebulized hypertonic saline [11]. Bronchoscopic specimens are not more sensitive, and should not be considered a replacement for three expectorated or induced sputa [26]. Bronchoscopy is generally helpful if alternative diagnoses are being sought or if a tissue biopsy is needed. For select patients, including young children, who either cannot tolerate the nebulizer or who still do not produce an adequate sputum sample, gastric aspirates should be obtained. When acid-fast bacilli (AFB) smears of respiratory secretions are negative, other specimens that may yield a diagnosis include pleural fluid, pleural biopsy, or transbronchial biopsy [11,27]. More invasive procedures such as transthoracic needle biopsy of the lung or mediastinal lymph nodes or open lung biopsy may be necessary in certain circumstances.

Pleural Tuberculosis

Pleural TB presents in two forms, commonly as tuberculous pleuritis and rarely as tuberculous empyema [11,28]. Tuberculous pleuritis occurs in 6% of HIV-negative and 11% of HIV-positive patients [29], and the incidence increases with declining CD4 cell counts [30]. It results from the rupture of a granuloma into the pleural space and may occur alone or in conjunction with pulmonary disease [28]. Often patients are asymptomatic but some present with acute symptoms of fever and chest pain, suggesting a viral or bacterial cause. The pathogenesis is primarily an immunologic reaction with very few tubercle bacilli actually present in the pleural space. Radiographically, a unilateral effusion covering less than half the hemithorax is typical. Untreated, tuberculous pleuritis often resolves but these patients are at high risk for recurrent pulmonary disease. Tuberculous empyema is much less common and results from the entry of large numbers of bacilli into the pleural space due to the rupture of an adjacent cavity or development of a bronchopleural fistula [31].

Pleural fluid and tissue biopsy are typically needed to definitively diagnose tuberculous pleuritis. Sputum specimens should

also be collected to evaluate for concurrent pulmonary disease. The pleural fluid most often shows a serous exudate with elevated protein and lactate dehydrogenase levels, low-to-normal glucose levels, and a pH range between 7.05 and 7.45 [29,32]. Early in the process, the fluid has a predominance of polymorphonuclear leukocytes that are replaced by lymphocytes within days. Adenosine deaminase (ADA) and other biochemical markers have been studied extensively, alone and in combination, as markers for diagnosing tuberculous pleuritis. Recent studies have supported measuring ADA levels, especially isoenzyme 2, showing additive diagnostic sensitivity and specificity when combined with other tests [33]. Interferon-gamma release assays (IGRA) are also undergoing investigation as diagnostic tools for pleural TB [34]. Both ADA and IGRA tests may be useful in settings that lack the capacity to do cultures, but should not replace a pleural biopsy which provides tissue for culture and pathology review.

AFB smears of pleural fluid and pleural biopsies are rarely positive (10% to 20%). The earliest presumptive diagnosis is provided by pathologic findings of granulomas with or without caseation, which are seen histologically in 60% of specimens [28]. Pleural fluid cultures are positive in only 20% to 30%. The yield increases slightly with multiple samples but usually delays the initiation of TB treatment [35]. Pleural biopsies are culture positive in 55% to 85% of specimens and should be sought whenever TB is considered a likely diagnosis.

Disseminated Tuberculosis

Disseminated TB refers to multiorgan involvement and may occur during progressive primary infection or as a complication of chronic TB [27,36]. The term *miliary tuberculosis*, which refers to the histologic appearance of diffuse nodular lesions resembling millet seeds, has historically been used interchangeably with disseminated disease. Now the term miliary is generally reserved to describe a diffuse micronodular infiltrate on the chest radiograph (Fig. 87.2). Young children and immunocompromised patients are at greatest risk for disseminated TB. However, a chronic, cryptic form of disease, termed *late generalized tuberculosis*, can occur in the elderly or those with other underlying illnesses [15]. In this cryptic form of disseminated TB, miliary infiltrates are rare and a diagnosis is often made postmortem.

Clinical evidence of dissemination is seen in up to 10% of HIV-associated and 33% of solid-organ-transplant–associated TB cases [37,38]. The presentations range from generalized lymphadenopathy to fulminant respiratory failure [39]. The duration of symptoms before diagnosis may vary from 1 week to over a year. Fever and other constitutional symptoms are seen in over 90%, respiratory symptoms in 75%, abdominal symptoms in 25%, and central nervous system (CNS) symptoms in 20%. In some reports, the presentation of disseminated TB has been similar to that of Gram-negative sepsis [40]. Acute respiratory failure is uncommon but a well-characterized complication of disseminated or miliary TB [19,41]. Laboratory abnormalities in disseminated disease are nonspecific. Anemia is common, but leukocyte and platelet counts range from markedly elevated to severely depressed [36]. Alkaline phosphatase levels are frequently elevated, likely related to granulomatous hepatitis. Chest radiographic findings are variable and may demonstrate miliary nodules of 1 to 3 mm in diameter or larger nodules of 5 to 7 mm. In about 10% of disseminated cases, radiographs will be normal, particularly early in the illness.

Virtually any body fluid, tissue, or organ may yield a diagnosis, particularly with clinical or laboratory abnormalities that suggest an extrapulmonary site of disease. Because extrapulmonary TB usually involves a lower burden of organisms compared with pulmonary disease, histologic examination and culture of biopsy specimens often provides the greatest diagnostic yield. Sputum smears should be examined for AFB but are positive in less than a third of patients with miliary TB. Histology and cultures of transbronchial, thoracoscopic, or traditional open lung biopsy will usually confirm the diagnosis. However, a careful search for chronic skin lesions, scrotal involvement, or lymphadenopathy may disclose other more accessible sites for a diagnostic biopsy [42]. Urine and stool cultures are easily obtainable and also may provide the diagnosis. Lumbar puncture should be considered in patients with headache or other CNS symptoms since meningitis is found in nearly 20% of patients with disseminated TB. A mycobacterial blood culture is

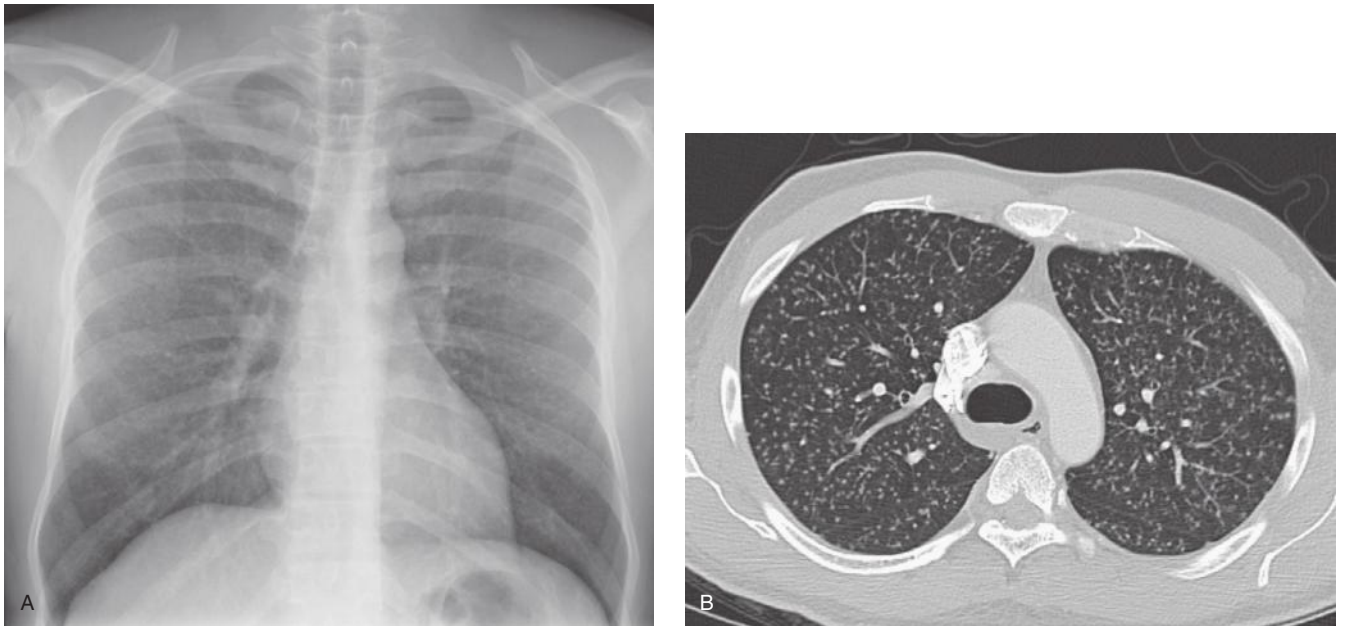

FIGURE 87.2. Chest radiograph (**A**) and CT scan (**B**) showing miliary disease in a 36-year-old patient who presented with several months of fever, weight loss, and abdominal pain.

positive in about 26% to 42% of HIV-infected individuals, and is the only culture-positive specimen in some [43]. Other potentially useful diagnostic tests include culture of gastric aspirates and biopsy specimens of liver or bone marrow. In disseminated TB, granulomas are seen in about 90% of liver biopsies; the yield is lower from bone marrow biopsy unless pancytopenia is present [44].

Central Nervous System Tuberculosis

TB involving the CNS may present as meningitis, as one or more parenchymal tuberculomas, or as a combination of both [45,46]. The clinical presentation varies from an indolent illness with headache and subtle changes in mental status to more acute presentations. Focal neurologic symptoms and signs may result from a tuberculoma causing a localized mass effect or from basilar meningitis affecting the cranial nerves directly or causing infarction of intracranial arteries [45]. Evidence of active or inactive TB at another site is noted in about three-fourths of cases, most often miliary infiltrates on chest radiographs. Tuberculomas of the CNS are readily detected by computed tomography (Fig. 87.3), but magnetic resonance imaging is often needed to detect basilar meningitis [46]. Tuberculous meningitis and tuberculomas are more common among HIV-infected individuals and present with signs, symptoms, and laboratory findings that are similar to those found in individuals who are HIV-negative [47].

Rapid diagnosis and treatment is critical to patient survival and neurological outcomes in tuberculous meningitis. A definitive diagnosis can be difficult though and antituberculous treatment should be initiated immediately in suspect cases since delays in therapy are correlated with outcomes. Evaluation of cerebral spinal fluid (CSF), although often nonspecific, is important for diagnosing CNS TB. The CSF findings classically described are a lymphocytic pleocytosis, low glucose, and an elevated protein. However, the absence of these findings does not exclude the diagnosis since the white cell count may range widely, a polymorphonuclear predominance occurs in up to 30%, and the protein and glucose may be normal [45,46]. AFB smears of CSF are positive in only 10% to 20% of cases and cultures are positive in <50%. Because disseminated disease is common with tuberculous meningitis, AFB cultures sent from other sources, including sputum, urine, and stool, may provide a diagnostic smear or culture. CNS tuberculomas may be diagnosed by a typical radiographic appearance and response to treatment, but definitive diagnosis usually requires biopsy or surgical excision.

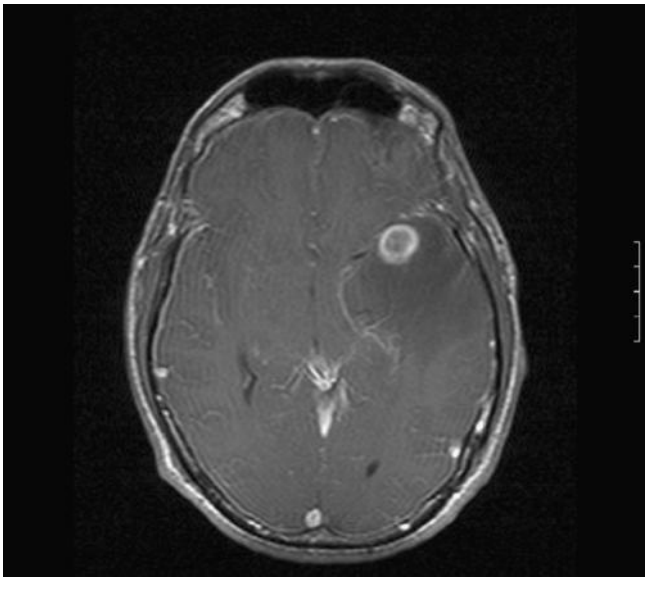

FIGURE 87.3. Computed tomographic scan of a 45-year-old patient with AIDS, known to be TST (+) but never completed latent treatment, who presented with a headache, expressive aphasia, and neologisms. The scan shows a tuberculoma with marked surrounding edema. Cerebral spinal fluid (CSF) showed a white blood cell count of 675 (100% lymphocytes), glucose 42 mg/dL, and protein 246 mg/dL. CSF cultures were negative but the diagnosis of isoniazid-resistant tuberculosis was confirmed by excisional biopsy.

Other Forms of Extrapulmonary Tuberculosis

Other forms of TB, such as lymphatic, pericardial, gastrointestinal, cutaneous, skeletal, and genitourinary, may be either coincidental findings or may provide clues to the diagnosis of disseminated disease in critically ill patients [11].

TB patients on therapy also may present to the ICU after developing an immune reconstitution syndrome or paradoxical reaction. This syndrome is characterized by a worsening of symptoms and/or radiographic studies despite effective chemotherapy with microbiologic improvement [48]. Typical manifestations are the recurrence or development of fever and other systemic manifestations, enlargement and suppuration of lymphatic tissue, worsening of pulmonary infiltrates, and life-threatening complications such as respiratory failure or enlargement of intracranial lesions. These reactions can occur in any TB patient but are most common in patients with TB and advanced AIDS who are started on antiretroviral therapy (ART) within the first few months of TB treatment [49].

Chest Radiography

Routine chest radiography is an invaluable screening and diagnostic tool for patients at risk for TB. Radiographs are able to detect most active pulmonary TB cases, particularly the most infectious cases with extensive parenchymal disease and cavitation. Radiographs can demonstrate fibrosis from previously active TB that identifies patients at higher risk for reactivation, and can provide clues to the diagnosis in patients with extrapulmonary disease. The classic radiographic appearance of active TB is a fibrotic, cavitary upper lobe opacity (Fig. 87.1), but pulmonary TB can present with a variety of findings on chest radiograph, including a normal film. The radiographic appearance of TB depends primarily on the duration of illness and the host's immune function. For example, primary TB typically presents as a lower lobe infiltrate often with ipsilateral hilar adenopathy. Primary TB occurs most often in young children but can be seen at any age including the elderly, as described among recently infected nursing home residents [50]. Other radiographic appearances, which can be seen alone or in combination, are alveolar opacities, mixed alveolar-interstitial infiltrates, miliary disease, and intrathoracic adenopathy (Figs. 87.2 and 87.4) [8]. These "atypical" presentations of pulmonary TB have been reported in up to 34% to 45% of HIV-negative individuals in some series [51,52]. In the presence of advanced immunodeficiency, there is greater variation in the radiographic patterns of TB with more frequently lower lobe involvement, diffuse infiltrates, hilar or mediastinal adenopathy, and pleural effusions [37,53].

Tuberculin Skin Testing and Interferon-Gamma Release Assays

The tuberculin skin test (TST) had been the only licensed test for detecting TB infection, but newer blood tests, IGRAs, are now commercially available [11,54]. IGRAs measure the

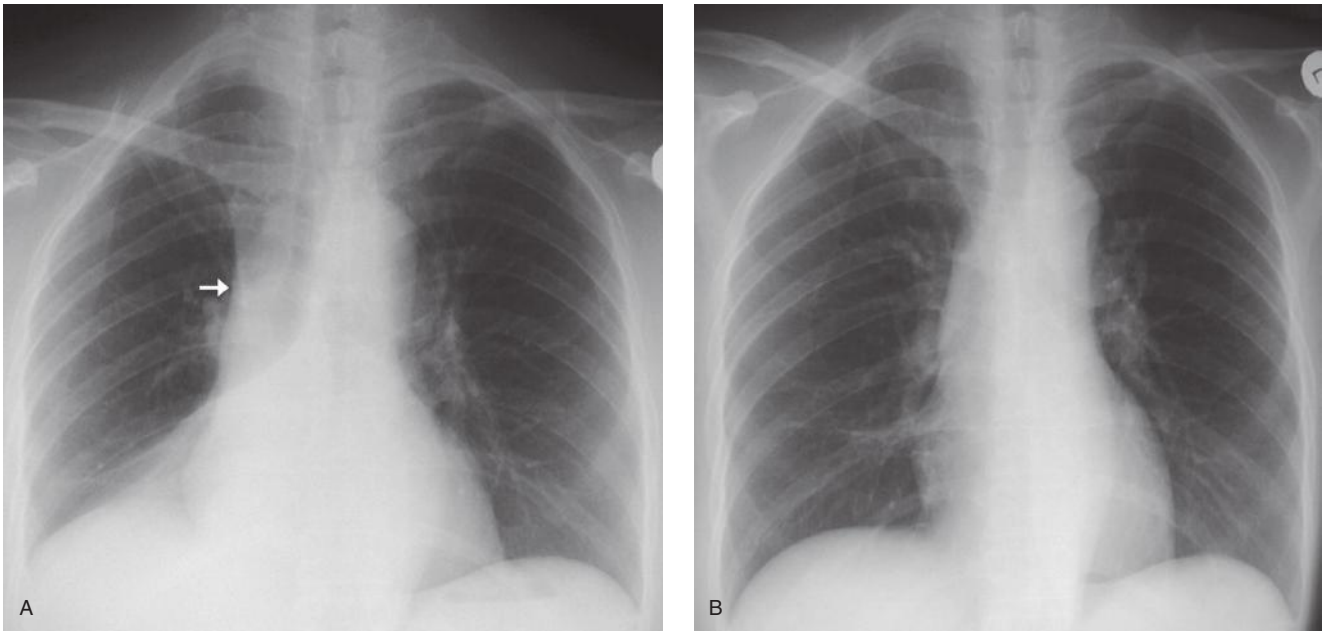

FIGURE 87.4. Chest radiographs of a 49-year-old patient who had undergone a liver transplant 6 months prior for hepatitis-B–associated liver disease. The initial radiograph (**A**) showed right paratracheal adenopathy (*arrow*) with partial right lung collapse that resolved by the end of treatment (**B**). The patient received standard tuberculosis therapy with the substitution of rifabutin for rifampin to minimize the drug interaction with tacrolimus.

interferon gamma produced by peripheral blood lymphocytes after stimulation with mycobacterial antigens. Both the TST and IGRAs are useful adjunctive tests but must be interpreted with caution. A positive result indicates the patient has been infected and may increase your clinical suspicion for active disease but is nondiagnostic. Similarly, a negative test does not rule out active TB since between 10% and 25% of patients with culture-confirmed disease will have a negative TST or IGRA [55,56]. Anergy testing is of no diagnostic value and is no longer recommended for any patient population [11].

Nucleic Acid Amplification Tests

Culture remains the gold standard for diagnosing all forms of TB but is not always rapid or highly sensitive. One approach to overcome these limitations has been the development of nucleic acid amplification (NAA) tests [57]. These tests offer several advantages including a rapid result, high specificity, and broad application to tissue samples, and in some cases even formalin fixed tissue [58]. The unfortunate limitation to NAA tests has been the somewhat disappointingly low sensitivity, particularly in paucibacillary disease. The approximate sensitivity of these tests in diagnosing smear negative pulmonary, pleural, and meningeal TB is 50%, and therefore should be interpreted in the context of clinical suspicion [46,59].

Culture and Drug Susceptibility Testing

The importance of using rapid diagnostic techniques in clinical mycobacteriology has been tragically illustrated in outbreaks of drug-resistant TB among immunocompromised hosts whose median survival with standard, ineffective therapy was 16 days [3]. Liquid culture systems containing radiometric or colorimetric material permit detection of mycobacterial growth in 2 to 6 days. The traditional use of biochemical testing for identification of isolates as *M. tuberculosis* has been largely replaced by the more accurate and rapid methods using commercial nucleic acid probes or high-performance liquid chromatography. Drug susceptibility testing can also be done more rapidly with the commercial liquid cultures systems. Rapid susceptibility testing is most important for identifying *M. tuberculosis* isolates with resistance to at least isoniazid and rifampin. These isolates are referred to as multidrug resistant because TB due to these strains can be expected to fail standard therapy [60]. Many hospital laboratories now lack the expertise and the number of specimens to conduct the full range of testing on a daily basis [11]. More timely results may be achieved by sending specimens, particularly those that are AFB smear positive to a full-service mycobacteriology laboratory. Molecular methods for rapidly detecting drug resistance have been developed and are proving highly sensitive and specific, particularly for isoniazid and rifampin [61]. Where available, these tests provide the earliest evidence for MDR TB.

TREATMENT

Principles of Therapy for Tuberculosis

Two characteristics of *M. tuberculosis* dictate the requirements for successful therapy—a high frequency of spontaneous mutations and a slow, intermittent growth cycle. Overcoming these characteristics requires multiple drugs to prevent the selection of drug-resistant mutants and an extended duration of therapy to kill the dormant mycobacteria [60]. Culture confirmation should always be pursued aggressively, but empiric therapy for TB based on clinical suspicion should be considered and may be important for the survival of critically ill patients.

Recommendations for Initial Therapy

The choice of initial TB therapy in the ICU should be made after considering the risk for MDR disease. The potential for drug-resistant TB can be estimated by knowing the patient's

country of birth and whether they have a history of prior TB treatment. In 2008, the percentage of patients with MDR TB among U.S.-born and foreign-born persons with no prior TB treatment was low, 0.6% and 1.2%, respectively. Among those with a history of prior treatment, these rates increased to 1.3% in U.S.-born and 6.0% in foreign-born persons [2]. Drug resistance should also be suspected in patients who fail while on treatment or who relapse after treatment has ended, particularly patients who did not get directly observed therapy [62,63].

For most patients, the four-drug, oral regimen of isoniazid, rifampin, pyrazinamide, and ethambutol will be appropriate [60]. The choice of therapy, when drug resistance is suspected, should be made in consultation with a physician experienced in treating MDR TB, and generally should include two or more agents likely to have activity. The agents usually chosen include an aminoglycoside (amikacin, kanamycin, or capreomycin), a quinolone (typically levofloxacin, moxifloxacin, or gatifloxacin), and one or two of the "second-line" agents such as ethionamide, cycloserine, or *p*-aminosalicylic acid (PAS) [60,64]. Of note, ethambutol, pyrazinamide, ethionamide, cycloserine, and PAS can only be given orally or enterally via a feeding tube [60,64]. Due to the relatively poor anti-TB activity of second-line drugs, some experts have recommended measuring serum drug levels to allow dose increases in order to achieve concentrations above the in vitro minimum inhibitory concentration [65]. Although not examined in a comparative trial, surgical resection may be a useful adjunct in the therapy of MDR TB after weeks or months of medical therapy [64].

More detailed information regarding TB treatment is available on the CDC Web site, http://www.cdc.gov/tb/publications/guidelines/Treatment.htm. Other complicating factors that may need consideration when starting TB therapy in a critically ill patient are shown in Table 87.2.

TABLE 87.2

SELECT THERAPEUTIC CHALLENGES IN TREATING CRITICALLY ILL TUBERCULOSIS PATIENTS (WHEN DRUG SUSCEPTIBLE DISEASE IS KNOWN OR EXPECTED)

1. Documented or anticipated malabsorption—medications which can be given parenterally:
   a. Rifampin
   b. Quinolone—levofloxacin, moxifloxacin, or gatifloxacin (ofloxacin or ciprofloxacin may be used if the others are not available)
   c. Aminoglycoside—amikacin (streptomycin can be used if drug susceptibility is known); second-line agents are kanamycin and capreomycin
   d. Isoniazid—when available but it may be difficult to obtain
2. Hepatic failure—acute or severe
   a. Empiric therapy: aminoglycoside, quinolone (levofloxacin may be preferred since moxifloxacin is hepatically cleared), ethambutol (consider including rifampin if not fulminant hepatic failure)
   b. Avoid: isoniazid and pyrazinamide
3. Renal failure
   a. Dose adjust: ethambutol, pyrazinamide, aminoglycosides, and levofloxacin
   b. No change in dosing: isoniazid, rifampin, and moxifloxacin
4. Pregnancy
   a. Empiric therapy: isoniazid, rifampin, ethambutol
   b. Avoid: pyrazinamide (may be safe but data lacking), aminoglycosides, and quinolones (both could be considered for critically ill patients when malabsorption is likely or drug resistance is a concern)

Adjunctive Corticosteroids

In certain circumstances, corticosteroids may be useful in TB treatment by reducing the intensity of the inflammatory response [60]. In a randomized, placebo-controlled trial, corticosteroids were shown to lower the mortality and morbidity of patients with tuberculous meningitis [66]. Corticosteroids also reduce the need for pericardiocentesis in patients being treated for tuberculous pericarditis [67], but there does not appear to be a long-term benefit in reducing the late complication of constrictive pericarditis. Corticosteroids also appear beneficial for treating severe pulmonary TB with more rapid defervescence, weight gain, and radiographic improvement [68]. The initial corticosteroid dose in most studies has been the equivalent of 40 to 80 mg of daily prednisone, tapering off over 1 to 3 months.

Management of Adverse Drug Effects

During the treatment of TB, serious mistakes can result from the failure to appropriately recognize and manage adverse drug effects [69]. Most mistakes fall into three categories: (a) failing to discontinue therapy in the face of a serious adverse effect; (b) abandoning important first-line drugs because of minor adverse effects; and (c) failing to recognize serious drug-drug interactions. Drug-induced hepatitis is probably the greatest concern for clinicians treating TB, particularly when patients have underlying liver disease. Fortunately, the risk of fulminant hepatitis is low and generally occurs when TB medications are continued despite evidence of toxicity.

While clinically significant or fulminant hepatitis is rare, increased transaminase levels are common with the combination of isoniazid, rifampin, and pyrazinamide. Clinicians should also remember that patients with severe or disseminated TB might have elevated liver function tests, particularly alkaline phosphatase, as a result of their disease. Patients with abnormal liver function tests and no known cause should have TB treatment held if transaminases are three times the upper limit of normal and the patient has symptoms of toxicity (i.e., nausea, vomiting, loss of appetite, or jaundice) or if transaminases are five times the upper limit in asymptomatic patients [70]. Patients with underlying liver disease and/or baseline liver function abnormalities should generally start standard TB treatment with close monitoring of symptoms and liver function tests.

The decision to stop or change therapy due to liver dysfunction must be made on a case-by-case basis. When therapy is held due to hepatotoxicity, the drugs are usually restarted cautiously, resuming one drug at a time. Pyrazinamide is the most frequent cause of liver injury in patients receiving the standard four-drug regimen, and may best be avoided if rifampin and isoniazid are reintroduced without difficulty. In critically ill patients for whom holding therapy may pose a significant risk, reasonable short-term therapy can be achieved with an aminoglycoside, fluoroquinolone, and ethambutol (Table 87.2). Patients who develop a rapid rise in transaminases to levels of 10 to 20 times normal should probably not be rechallenged with pyrazinamide or isoniazid. Other serious side effects that should result in the permanent discontinuation of the offending medication are severe rifampin-associated hypersensitivity reactions like acute renal failure, hemolysis, or thrombocytopenia.

When minor side effects occur, all attempts should be made to treat the symptoms and to determine if an alternative cause exists before discontinuing standard first-line TB medications. Minor side effects such as gastrointestinal upset can often be managed by adjusting the dosing schedule or by prescribing an antiemetic. Isolated bilirubin elevation caused by rifampin-associated cholestasis may occur but resolves despite continued therapy. Transient minor rashes or pruritus are often associated with pyrazinamide and may be managed using antihistamines without interrupting therapy.

Finally, recognizing potentially serious drug-drug interactions and adjusting therapy accordingly can avoid many drug-associated adverse events. Rifampin and to a lesser extent rifabutin are inducers of the hepatic cytochrome P450 enzyme system. Therefore, particular caution should be used when HIV-infected TB patients are taking or may be starting ART [71]. In general, few HIV-infected patients in the ICU will be able to take ART, but for those who can recent observational and randomized trials have shown a mortality benefit from early initiation of ART particularly for patients with CD4 counts below 200. Updated recommendations for the combined use of TB and HIV drugs can be found on the CDC Web site, http://www.cdc.gov/tb/publications/guidelines/TB_HIV_Drugs/default.htm. Other notable interactions with rifamycins include warfarin, most antiseizure medications, and many antirejection medications given for bone marrow and solid-organ transplants. The safest practice is to review all medications when treating someone with a rifamycin.

INFECTION CONTROL AND RESPIRATORY ISOLATION

Preventing Nosocomial Transmission

Early suspicion for TB is the most important step in preventing transmission because it allows the appropriate use of effective respiratory isolation, prompt diagnostic evaluation, and initiation of effective treatment. Screening for active TB is generally achieved through the collection of three successive morning sputa for AFB smear. However, nearly half of patients with pulmonary TB are smear negative, and smear-negative patients are able to transmit infection [72]. Therefore, hospitalized patients with negative sputum smears but a high risk for TB should be kept in respiratory isolation until an alternative diagnosis is made or empiric TB treatment has been initiated for several days. The infectiousness of TB begins to decrease within days after initiating effective therapy, probably by decreasing the cough as well as by reducing the number of tubercle bacilli. Decisions about discontinuing isolation once treatment is instituted should be carefully individualized, avoiding a decision based only on the number of days on therapy. The safest approach in a patient receiving treatment in the hospital is to continue isolation until three sputum smears are negative, particularly when drug susceptibilities are unknown. Other measures that may be of benefit in intubated patient include the use of a closed suctioning system to avoid generating infectious aerosols and the use of submicron filters for air exhausted from ventilators [25].

All healthcare workers who will be exposed to potentially infectious TB patients should use personal protective devices. Properly fitted masks capable of filtering at least 95% of particles 1 μm in size are recommended with fit-testing to ensure a face-seal leakage of less than 10%. Powered air-purifying respirators with a helmet or hood are a more effective and more expensive option. These could be considered in certain high-risk situations such as an unavoidable bronchoscopy of an infectious case of TB. Periodic tuberculin testing of hospital personnel should be continued as a means of monitoring the effectiveness of other measures and of evaluating tuberculin converters and providing treatment when appropriate [25].

TABLE 87.3

SUMMARY OF RECOMMENDATIONS FOR TUBERCULOSIS TREATMENT THAT ARE SUPPORTED BY RANDOMIZED CONTROLLED TRIALS

Treatment for known or suspected drug-susceptible tuberculosis, initial phase
1. INH, RIF, PZA, EMB 7 d/wk for 56 doses (8 wk) [60]

Adjunctive corticosteroids are recommended for:
1. Tuberculous meningitis—improved survival and fewer serious adverse events [66]
2. Tuberculous pericarditis—improved survival and decreased need for repeat pericardiocentesis but no decreased risk of constrictive pericarditis [67]

Early initiation of antiretroviral therapy is recommended for patients co-infected with TB and HIV
1. Start ART in the first 2 weeks of TB treatment for HIV-infected patients with a CD4 < 200 [71]

Public Health Aspects

Presumptive and confirmed cases of TB should be promptly reported to the local public health department as required by law in every state. The function of this reporting is to provide the opportunity to conduct timely contact investigations, which may be critical to prevent life-threatening complications of TB among small children or immunocompromised household members. In addition, many health departments can assist in ensuring completion of outpatient therapy and thus prevent a hospital readmission for treatment failure or relapse with drug-resistant TB.

Treatment recommendations for TB, based on randomized controlled trials, are summarized in Table 87.3.

CHAPTER 88 ■ BOTULISM

MARY DAWN T. CO AND RICHARD T. ELLISON, III

The name botulism is derived from the Latin term *botulus* for sausage. Justinus Kerner (1786–1862) first recognized the association between the mysterious "sausage poison" and paralytic illnesses in 1820. *Clostridium botulinum*, the etiologic agent of botulism, is an anaerobic, spore-forming organism that elaborates a neurotoxin that prevents the release of acetylcholine. Illness develops after toxin exposure, and patients present with a symmetric descending paralysis that characteristically begins with dysarthria, diplopia, dysphonia, or dysphagia. The most common botulism syndromes include food-borne, wound, and infant botulism. Botulism toxin is also now used therapeutically in neuromuscular and ophthalmologic disorders as well as a cosmetic enhancement tool, and cases of iatrogenic botulism have occurred. Although the majority of cases are due to infant botulism, food-borne botulism is considered a public health emergency as there is always a potential that a large number of individuals may have been exposed. Additionally, botulinum is a category A biological agent, and any case must initially be considered as potentially linked to a bioterrorist event (see Chapter 213).

PATHOGENESIS

C. botulinum is an anaerobic Gram-positive bacillus that produces heat-resistant spores that can survive boiling. Under conditions of an anaerobic environment, low acidity (pH greater than 4.6), and low temperature, the organism can germinate, grow, and produce a neurotoxin that itself is readily inactivated by heat (greater than 85°C for 5 minutes) [1].

Seven distinct antigenic neurotoxins (A through G) may be produced by *C. botulinum* but only four types—A, B, E, and F—are associated with human disease. Food-borne botulism occurs after the ingestion of preformed toxin in foods contaminated by spores. Wound botulism occurs when spores infect traumatized or contaminated skin. Infant botulism occurs in infants 3 to 26 weeks old after intestinal colonization by *C. botulinum* [2]. Botulism of undetermined etiology occurs in adults whose intestinal flora has been altered or whose gastric barrier has been compromised because of intestinal surgery, gastric achlorhydria, or antibiotic therapy [2,3].

All botulinum toxins have the same mechanism of action [2]. The toxin is carried via the bloodstream to the neuromuscular junction where it binds irreversibly and thereby produces paralysis. However, it does not affect the central nervous system or the adrenergic nervous system [1]. The toxin is a zinc-containing endopeptidase that cleaves to specific sites on three proteins (VAMP, SNAP25, syntaxin), interfering with the release of acetylcholine [4].

EPIDEMIOLOGY

There have been approximately 20 cases of food-borne botulism yearly in the United States, with the majority of cases caused by toxin type A (50%), followed by toxin type E (37%), and then toxin type B (10%) [5]. Food-borne botulism has traditionally been associated with home-processed foods. However, an increasing number of cases have been associated with commercially prepared foods that have inadvertently been processed in a manner that allowed the production of the toxin.

Wound botulism has primarily been seen in intravenous drug users who present with cranial nerve palsies in the setting of abscesses from heroin use [6]. California has accounted for over 75% of U.S. cases, with an epidemic noted in individuals injecting black tar heroin [7].

Iatrogenic botulism has rarely developed after botulinum toxin (Botox) has been injected for cosmetic or neurologic purposes [8,9]. Although the normal concentration of botulinum toxin A in the therapeutic preparation allows for a large margin of safety with minimal treatment side effects, therapeutic doses have been reported to cause generalized muscle weakness with widespread electromyogram (EMG) abnormalities typical of botulism [10]. In addition, four individuals have contracted botulism after receiving unlicensed preparations of botulinum toxin for cosmetic purposes [11].

Botulism toxin is the most poisonous substance known to man with 1 g of toxin able to potentially kill 1 million people [9]. Given its ease of production and transport, it is a major bioterrorism threat and is classified as a category A biological agent. Botulism toxin was used as a bioweapon in the 1930s by the Japanese military who fed cultures of *C. botulinum* to prisoners during that country's occupation of Manchuria [12]. Aerosols derived from botulism toxin were also dispersed in Japan on at least three different occasions by a Japanese cult, although for unclear reasons these terrorist attempts failed [12] (see Chapter 213).

CLINICAL MANIFESTATIONS

Clinical manifestations of all forms of botulism are similar. Cardinal features include (a) cranial nerve palsies, (b) descending paralysis, (c) symmetry in symptoms, (d) absence of fever, (e) clear sensorium, and (f) lack of sensory findings [1]. Food-borne botulism may be preceded by gastrointestinal symptoms such as cramps, nausea, vomiting, and diarrhea [2,12]. Infant botulism is usually characterized by a history of constipation and feeding difficulties [2,12].

Patients may complain of dry mouth secondary to parasympathetic blockade as well as neurologic symptoms such as dysphagia, dysphonia, diplopia, and dysarthria related to palsies of the bulbar musculature. Symptoms then progress to involve lower extremity weakness and loss of the protective gag reflex requiring respiratory support. Physical examination is significant for a lack of fever except in cases of wound botulism with secondarily infected wounds. Sensory findings are absent except for periorbital paresthesias secondary to hyperventilation. Deep tendon reflexes, although present initially, usually disappear. Ocular findings are common and include dilated, poorly reactive, or fixed pupils, ptosis, nystagmus, and sixth cranial nerve dysfunction. A clear sensorium is usually present because the toxin does not usually penetrate the central nervous system [2,12].

The incubation period of food-borne botulism is usually 12 to 36 hours after toxin ingestion but may be as short as 2 hours [2,12]. Severity of disease depends on the amount of toxin that is absorbed into the system. Mortality has improved with the advances in critical care, and eventual recovery is seen in 95% of cases in the United States [8]. The recovery period may be protracted and is dependent on the reinnervation of paralyzed muscle fibers [13,14].

DIAGNOSIS

Successful diagnosis of botulism requires a high index of suspicion for the disease, given that the symptoms and laboratory values are often nonspecific. If there is a suspected case of botulism, the local state health department should be notified [15]. The Centers for Disease Control (CDC) can also be contacted through its 24-hour botulism consultation service for additional information [8]. Prior to the administration of antitoxin, a serum sample (10 to 15 mL) should be collected and refrigerated. Anaerobic cultures and toxin assays of stool, serum, and gastric aspirates, suspected foodstuff, or wounds should be collected. Early cases are more likely to be diagnosed by toxin detection, while later cases are confirmed by culture [16]. The only acceptable method for the detection of the botulism neurotoxin is the mouse bioassay in which a patient's serum or supernatant from a culture of the patient specimens suspected to contain toxin is administered to pairs of mice with and without toxin, serving to confirm the diagnosis and define the circulating toxin. However, a recent study on clinical wound botulism revealed the sensitivity of the assay to be only 68% [17].

DIFFERENTIAL DIAGNOSIS

Diseases mistaken for botulism include brainstem infarction, polyradiculopathies such as the Guillain–Barre syndrome or its Miller Fisher variant, myasthenia gravis (MG), brainstem infarction, tick paralysis, polio, meningitis or encephalitis, and poisonings such as carbon monoxide, shellfish, or organophosphate poisoning [1,7]. An improvement of strength after the edrophonium test is suggestive of MG but has also been reported in botulism [18]. The Guillain–Barre syndrome is characterized by an ascending paralysis and usually, but not always, an elevated cerebrospinal fluid protein level initially. Electrophysiologic studies may be helpful in distinguishing between causes of flaccid paralysis such as MG, the Guillain–Barre syndrome, and the Lambert–Eaton syndrome. Normal nerve conduction velocity, absence of sensory deficits, and a small increment of motor response seen on repetitive nerve stimulation at 20 Hz (as compared to the 4 Hz in MG) are characteristic of botulism. Tick paralysis is diagnosed by the presence of an embedded *Dermacentor* tick. Altered mental status is usually seen in encephalitis, organophosphate, and carbon monoxide poisonings rather than botulism. Shellfish poisoning presents with tremors and paresthesias that are usually absent in botulism [1].

TREATMENT

The mortality rate from botulism has decreased dramatically since the first decades of the 20th century to its current rate of 3% to 5% with the advent of intensive care units [19], and all patients suspected of botulism should initially be monitored in an intensive care setting.

Therapy consists of toxin removal, supportive care, including nutritional support and treatment of secondary infections, and passive immunization with equine antitoxin [2]. Patients should be assessed and monitored for the adequacy of cough, the control of oropharyngeal secretions, and ventilation. Readers can refer to the Chapter 50 on extrapulmonary causes of respiratory failure for guidelines on how to monitor for the adequacy of ventilation and when to consider endotracheal intubation (Chapters 1 and 58), and to the Chapter 59 on invasive mechanical ventilation for guidelines on how to ventilate patients with respiratory failure due to neuromuscular diseases. Studies in infants have suggested that a reverse Trendelenburg position (20 to 25 degrees) may be helpful in nonintubated patients by reducing the entry of oral secretions and also by improved respiratory mechanics [4].

For adults and older children, passive immunization with equine antitoxin should be administered as soon as botulism is diagnosed. Antitoxin will only neutralize toxin molecules that have not bound to nerve endings. Timely administration minimizes subsequent nerve damage and severity of disease but will not reverse existing paralytic damage [20]. There are several antitoxins available including an FDA (U.S. Food and Drug Administration)-approved bivalent antitoxin containing antibodies to toxins A and B, and a non–FDA approved BAT-E (Botulism antitoxin E); both of these are available through the CDC [12]. Additionally, there is a heptavalent (A–G) despeciated antitoxin available through the U.S. Army. Clinicians should contact their local state health departments or the CDC (770-488-7100) or U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) (888-872-7443) to obtain these antitoxins. Patients should be skin tested prior to antitoxin administration and desensitized using the protocol enclosed with the antitoxin if there is any evidence of a wheal and flare reaction.

Equine antitoxin is not recommended for treatment of infants suspected of botulism because of the potential serious side effects of serum sickness and anaphylaxis. However, a recent study found that the administration of human botulism immune globulin intravenous within 72 hours of hospitalization for suspected infant botulism decreased illness severity, shortened hospital stays, and reduced costs [21]. This preparation, human botulism immune globulin (Baby-BIG), is now FDA agent approved and available through the California Department of Public Health.

Patients with wound botulism also require aggressive wound debridement regardless of how well the wound appears as toxin is produced until the infection is eliminated. Antitoxin should be administered prior to surgery to neutralize toxin released by the procedure. Penicillin therapy, 10 to 20 million units per day, is appropriate [4,7]. Aminoglycosides and clindamycin should be avoided because of the potential for neuromuscular blockade [22,23].

Because botulinum toxin is not absorbed through intact skin, standard precautions should be undertaken when caring for patients suspected of botulism. There have been no cases of human-to-human transmission described [8].

Advances in botulism, based on randomized controlled trials, are summarized in Table 88.1.

TABLE 88.1

RECOMMENDATIONS FOR THE TREATMENT OF BOTULISM BASED ON RANDOMIZED CLINICAL TRIALS

■ Treatment with the drug, human botulism immune globulin, intravenously given within 3 d of hospital admission for infant botulism shortens length and cost of the hospital stay and the length of illness.[a]

CHAPTER 89 ■ TETANUS

MARY DAWN T. CO AND RICHARD T. ELLISON, III

Tetanus, caused by the neurotoxin tetanospasmin, is produced by the anaerobic spore forming Gram-positive bacterium *Clostridium tetani*. Clinically, tetanus presents with skeletal muscle rigidity and spasms that classically involve the muscles of the face (lockjaw). It is a relatively rare clinical entity in developed countries because of the broad use of tetanus toxoid immunization. However, tetanus still occurs frequently in the Third World, and in individuals who have never been or have been inadequately vaccinated in the setting of a wound infection or another portal of entry. Diagnosis is based on clinical suspicion and the exclusion of other entities because of a lack of timely confirmatory testing. Treatment relies mainly on respiratory support and symptomatic management of the muscular rigidity and spasms and the autonomic manifestations of the disease.

PATHOGENESIS

Clostridium tetani is an obligate anaerobic spore-forming bacillus. Mature organisms develop spores that are widely distributed in soil and dust as well as in the intestines and feces of animals. While the bacteria are sensitive to heat and aerobic conditions, the spores are resistant to ethanol, phenol, and formalin. However, they do not survive treatment with iodine, glutaraldehyde, hydrogen peroxide, or autoclaving at 121°C and 103 kPa (15 psi) for 15 minutes [1].

The vegetative form of *C. tetani* produces two types of zinc metalloproteinase toxins, tetanospasmin and tetanolysin, with tetanospasmin playing more of a prominent role in pathogenesis. Unlike the toxin produced by *Clostridium botulinum*, the *C. tetani* neurotoxin is of a single antigenic type and specifically targets the central nervous system (CNS), including the peripheral motor end plates, spinal cord, brain, and the sympathetic nervous system [1,2]. Although this toxin can exert an excitatory effect, it acts primarily by blocking the release of neurotransmitters such as glycine and γ-aminobutyric acid (GABA), which normally acts to inhibit the transmission of motor nerve impulses. Specifically, the toxin degrades synaptobrevin, a protein required for contact of inhibitory neurotransmitter vesicles with their release site on the presynaptic membrane [3].

Antitoxin is of therapeutic value only in protecting neurons that have not already bound the toxin. As the effect of the toxin on a synapse does not appear reversible, recovery from tetanus depends on the generation of new nerve terminals and new synapse formation.

EPIDEMIOLOGY

Tetanus is endemic in the developing world with neonatal tetanus accounting for the majority (>50%) of deaths due to tetanus [4]. Tetanus is a rare disease in the developed world with morbidity and mortality in the United States declining

steadily, due to the availability of tetanus vaccines, improved wound management, and the use of tetanus immunoglobulin for postexposure prophylaxis [5]. According to the 1998 to 2000 surveillance data, an average of 43 tetanus cases occurred yearly in the United States with the majority of cases related to acute injuries such as puncture wounds, lacerations, and abrasions [6]. The highest incidences were reported in individuals ≥60 years old, persons of Hispanic origin, older adults with diabetes, and intravenous drug users. No deaths were reported in those individuals who received adequate immunization.

CLINICAL MANIFESTATIONS

Tetanus usually occurs in the setting of necrotic or infected tissue in which anaerobic bacterial growth is facilitated. However, in up to 30% of cases, no acute injury is reported [6]. The incubation period for tetanus varies from 3 to 21 days, with the length of the incubation period dependent on how far the injury site is from the CNS [7]. The first nerves affected are the shortest, accounting for the early symptoms of facial distortion and neck stiffness. It has been found that the shorter the incubation period, the worse the prognosis [8].

Clinical tetanus can present in three forms—local, cephalic, and generalized—with 80% of cases being generalized. Local tetanus presents as a focal region of muscle contraction at a site of spore inoculation [1]. Symptoms may persist but usually resolve spontaneously. *Cephalic tetanus* develops after a traumatic head injury, but has been reported after otitis media when *C. tetanus* was present in the middle ear [9]. Typically, there is involvement of the cranial nerves, especially cranial nerve VII in the facial area.

Generalized tetanus typically presents with involvement of facial musculature, starting with masseter rigidity (lockjaw or trismus) and risus sardonicus (orbicularis oris), and then progresses in a descending fashion with difficulty swallowing and abdominal rigidity [1]. Spasms, which are often triggered by sensory stimuli, are common and may resemble seizures with flexion of the arms and the extension of legs (opisthotonus). The patient does not lose consciousness and severe pain usually accompanies the spasms. Laryngospasm and respiratory compromise may result from vocal cord or diaphragmatic spasms and upper airway obstruction. In addition, fractures of the spine or the long bones, dislocations, and rhabdomyolysis may occur as a result of spasms. The course of this illness occurs over 2 weeks, reflecting the time it takes for intraaxonal toxin to travel to the CNS. Spasms occur within the first 2 weeks of illness followed by autonomic disturbances such as extremes in blood pressure and cardiac arrhythmias including sinus tachycardia and cardiac arrest [10,11]. Individuals with tetanus are at high risk for nosocomial pneumonia with an incidence of approximately 35%. Autonomic dysfunction is an independent risk factor for pneumonia in patients with tetanus [12].

Neonatal tetanus, more often seen in developing countries, is a form of generalized tetanus that commonly arises when an unhealed umbilical stump becomes infected after an incision with an unsterile instrument and if the mother has not been adequately immunized [1,7].

DIAGNOSIS

No laboratory test is available that provides a definitive diagnosis of tetanus. Diagnosis is clinical and primarily based on the presence of trismus, dysphagia, muscular rigidity, and spasm, and confirmed by the detection of toxin in bodily fluids using mouse bioassays, microbiologic isolation from infected wounds, or by the use of real-time polymerase chain reaction (PCR) assays that detect a fragment of the neurotoxin gene of *C. tetani* [2]. The organism is isolated only 30% of the time in wound tetanus [7]. In addition, the presence of the bacteria does not necessarily indicate tetanus, since not all strains of *C. tetani* carry the toxin producing plasmid [2,13]. Antitetanus antibodies can be measured, although a minimally protective level of antibody concentration has not been established [14]. In individuals with tetanus, with the "spatula" test (sensitivity of 94% and specificity of 100%), insertion of a spatula into the patient's mouth induces a reflex spasm of the masseter instead of a gag reflex, leading to the patient biting the spatula [15].

Few other conditions present with muscular rigidity and sympathetic hyperreactivity except for strychnine poisoning. Strychnine blocks the inhibitory glycine receptor in the spinal cord and the brain. Unlike tetanus, however, the sudden contraction of all striated muscles is usually followed by complete relaxation of these muscles. Additional conditions that can mimic the spasms seen in tetanus include hypocalcemia and reactions to certain medications including neuroleptic drugs and central dopamine antagonists. Odontogenic infections can produce trismus but not the other manifestations of tetanus [1].

TREATMENT

The mortality rate in tetanus varies from 6% in mild to moderate tetanus up to 60% in the severest of cases [1,16]. Autonomic nervous system dysfunction has been shown to predict a poor outcome in mild to moderate cases of tetanus [17]. Illness is less severe among patients who have received a complete immunization series of tetanus toxoid compared with those who were never or inadequately vaccinated [18].

Individuals suspected of generalized tetanus should be observed in an intensive care setting with minimal stimuli. Initial management consists of airway stabilization and general intensive care support including mechanical ventilation, nutritional support, and deep venous thrombosis prophylaxis. Diagnostic evaluation should include blood samples for antitoxin levels, strychnine and dopamine antagonist assays, and electrolytes (including creatinine kinase), along with urine samples for toxicology and myoglobin levels [1]. Antihistamines such as benztropine or diphenhydramine should be administered to rule out a dystonic reaction to a dopamine-blocking agent.

Benzodiazepines such as midazolam, lorazepam, and diazepam have been the mainstay of treatment [1]. This class of agents acts as GABA agonists, thus indirectly opposing the effects of the toxin by competing for receptor sites [2]. Doses are initially titrated to produce sedation and limit reflex spasms. Propofol (alone or in combination with benzodiazepines) and intrathecal baclofen are alternative options that have been used [19,20]. Intravenous diazepam and lorazepam contain propylene glycol, which may increase the risk of lactic acidosis at the recommended doses of treatment [21]. If the muscle spasms cannot be controlled with these agents, a paralytic agent such as vecuronium can be added [1]. Once the symptoms have resolved, benzodiazepines should be tapered to prevent withdrawal.

If a portal of entry can be identified, the wound should be debrided and an antibiotic active against anaerobic organisms should be administered with metronidazole for 7 to 10 days now considered to be the first line of therapy. Treatment courses of 7 to 10 days using regimens of penicillin, either as a single-dose intramuscular benzathine dose or intravenous benzyl penicillin, are alternative regimens [1,22]. Passive immunization with human tetanus immunoglobulin (at a dose of

TABLE 89.1

RECOMMENDATIONS FOR THE TREATMENT OF *CLOSTRIDIUM TETANI* BASED ON RANDOMIZED CLINICAL TRIALS

- Treatment with metronidazole, benzyl penicillin, or intramuscular benzathine penicillin has a comparable impact on the need for tracheostomy; the use of neuromuscular blockade; the need for mechanical ventilation; and the incidences of dysautonomia, nosocomial pneumonia, and in hospital death [22].
- Treatment with intrathecal rather than intramuscular administration of antitetanus immunoglobulin showed better clinical progression including fewer respiratory complications and a significantly shorter duration of spasms [24].

500 units) may shorten the course and severity of tetanus by neutralizing toxin that has not reached the CNS [23]. A randomized clinical trial has found that patients treated with intrathecal rather than intramuscular administration of human antitetanus immunoglobulin showed better clinical progression including fewer respiratory complications and significantly shorter duration of spasms [24].

Autonomic dysfunction is usually related to excessive catecholamine release and can be treated by a combined alpha- and beta-blocker such as labetalol. Beta-blockade alone may result in severe hypertension due to an unopposed α effect [25].

Since the amount of toxin causing disease may be too small to induce a consistent immunological response, immunization with tetanus toxoid should be given at diagnosis, at 4 to 6 weeks and 1 year later to prevent future attacks [1,7].

Advances in tetanus, based on randomized controlled trials, are summarized in Table 89.1.

CHAPTER 90 ■ SERIOUS EPIDEMIC VIRAL PNEUMONIAS

DANIEL H. LIBRATY

There are a number of established, emerging, and reemerging viruses that can lead to severe respiratory illness in immunocompetent individuals. The etiologic agents of serious viral pneumonias can generally be divided into three groups:

1. *Human-adapted respiratory viruses*. The primary site of entry, replication, and disease for these viruses is the human respiratory tract. They are spread efficiently by person-to-person transmission. The most significant members of this group are the human influenza A and B viruses; others are respiratory syncytial virus (RSV) and adenovirus.
2. *Human-adapted viruses—respiratory disease after a viremic phase*. Viral entry and person-to-person spread of these viruses is via the respiratory tract. However, these viruses cause respiratory illness after a phase of systemic viral replication and dissemination. Members of this group include varicella zoster virus (chickenpox) and rubeola virus (measles).
3. *Zoonotic viruses*. Viruses in this group include the severe acute respiratory syndrome (SARS) coronavirus, New World hantaviruses producing the hantavirus cardiopulmonary syndrome (HCPS), and the H5N1 avian influenza A virus.

PATHOGENESIS

A virus must first gain access to the lower respiratory tract in order to produce severe pneumonia. The most common mode of entry is via droplet transmission. Airborne virus-containing droplets 5 to 10 μm in diameter are filtered and deposited in the upper respiratory tract. Virus reaches the lower respiratory tract after efficient replication and spread within squamous epithelial cells, often in the setting of impaired mucociliary clearance (due to extremes of age, antecedent or concurrent infections, and drugs). This is the usual mode of entry for many human-adapted respiratory viruses, such as influenza, RSV, adenovirus, and coronavirus. Person-to-person spread via droplets is limited to a distance of approximately 1 m. Other viruses such as varicella and rubeola are transmitted via aerosols (particles 1 to 5 μm in diameter) that can deposit directly in the lower respiratory tract. As such, they are highly infectious and can be transmitted over greater distances and time than agents transmitted by droplets. Although deposited directly in alveoli, viral dissemination in the lung typically occurs hematogenously after a viremic phase [1,2].

Once in the lower respiratory tract, there are a limited number of ways that the lung can respond to a viral infection and produce respiratory illness. Viral invasion and replication can directly produce a necrotizing bronchopneumonia with highly inflammatory, purulent, and exudative reactions. This is not common, but can be seen with influenza and adenovirus infections. Respiratory viral infections can impair host lung defenses in a way that leads to secondary bacterial pneumonias, particularly with *Streptococcus pneumoniae* or *Staphylococcus aureus*. The classic examples are postinfluenza or measles pneumonias. Finally, viral infection of the lower respiratory tract may produce severe disease by triggering a common tissue response to acute lung injuries termed *diffuse alveolar damage* or *acute respiratory distress syndrome*. The acute lung injury may progress from an early exudative phase, often with profound noncardiogenic pulmonary edema (especially in HCPS), to a proliferative or organizing phase that produces interstitial inflammation, and a late resolving phase [3].

CLINICAL MANIFESTATIONS

The limited host response patterns to virus-induced lung injury means that there is significant overlap in the clinical manifestations of viral pneumonias. The clues to a specific viral etiology are often found in assessing host risk factors and epidemiology on presentation. A summary of the common clinical manifestations for specific viral pneumonias is presented in Table 90.1. Many of the viral infections discussed in this chapter are characterized by a "flu-like illness" prodrome. Symptoms begin with the acute onset of headache, chills, and myalgias. Within a few days, a cough and sore throat develop along with upper respiratory tract infection. The presence or absence of upper respiratory symptoms at this stage may provide one clue to the specific viral etiology. The human-adapted respiratory viruses (human influenza, RSV, adenovirus, non-SARS coronavirus) generally all produce upper respiratory symptoms. Measles is characterized by coryza and conjunctivitis in the prodrome. The absence of upper respiratory symptoms has been reported to be characteristic of infections with several of the zoonotic viruses: SARS coronavirus, hantavirus, and the H5N1 avian influenza virus [4–6]. The lower respiratory tract signs and symptoms in viral pneumonias are generally nonspecific and progress to dyspnea, tachypnea, and inspiratory crackles. Sputum production is variable. If the clinical course is biphasic (dyspnea and productive cough after improvement of a flu-like illness), then a secondary bacterial pneumonia should be suspected.

Routine laboratory tests are generally of little help in distinguishing among the viruses that can produce severe respiratory illness. Total leukocyte counts are typically within the normal range or slightly elevated. One exception is measles virus infection, which can produce a marked leukopenia [7]. The most common hematologic finding in the viral pneumonias is a relative lymphopenia. The complete blood count may be useful for diagnosing HCPS. In HCPS caused by Sin Nombre virus (a New World hantavirus), the triad of thrombocytopenia (platelet count less than 150 K per mm^3), absolute neutrophilia, and the presence of immunoblasts was a sensitive and specific predictor of HCPS in one study [5]. Electrolyte abnormalities and hepatic transaminase elevation can occur among any of the severe viral pneumonias.

TABLE 90.1

PRESENTATION AND MANIFESTATIONS OF SPECIFIC VIRAL PNEUMONIAS

Virus	Transmission	Epidemiology/settings	Pulmonary manifestations	Extrapulmonary manifestations	Laboratory findings	Radiographic findings
Human influenza A and B viruses	Airborne droplet transmission (≥10 μm) Small aerosol (rare) Fomite contact	Yearly and seasonal (peak season November–April in temperate climates) Attack rates highest at extremes of age Predisposing risk factors for pulmonary complications: chronic heart, lung, renal disease; pregnancy Nosocomial transmission in hospitals and institutional settings	Flu-like illness prodrome (see text) with upper respiratory signs/symptoms Bronchitis Croup Unilateral and bilateral primary viral pneumonia Secondary bacterial pneumonias (*Streptococcus pneumoniae* and *Staphylococcus aureus*)	Secondary bacterial otitis media Myositis (early convalescence) Myocarditis/pericarditis Reye's syndrome (children)	(Nonspecific) Relative lymphopenia in adults Leukocytosis in children	(Nonspecific) Segmental and bilateral alveolar and/or interstitial infiltrates Consolidation suggests superimposed bacterial process Diffuse hemorrhagic alveolitis seen in primary influenza pneumonia
Respiratory syncytial virus	Airborne droplet transmission (≥10 μm)	Yearly and seasonal (overlaps with human influenza) Severe illness at extremes of age: <2 and >65 years old High-risk individuals: children with underlying cardiopulmonary disorders; adults with congestive heart failure or chronic pulmonary disease Outbreaks in long-term care facilities	Prodrome with upper respiratory signs/symptoms as with human influenza Bronchiolitis (common in infants) Pneumonia, unilateral and bilateral	Otitis media	(Nonspecific) Same as influenza	(Nonspecific) Segmental and multiple areas of interstitial and/or alveolar infiltrates In children, hyperaeration is reported as common finding
Adenovirus	Airborne droplet transmission (≥10 μm)	Endemic: mild respiratory disease year round Epidemic: outbreaks in military barracks, hospitals, and institutional settings	Flu-like illness prodrome with upper respiratory signs/symptoms Progression to severe pneumonia, can be necrotizing	The adenovirus serotypes that produce severe pneumonia are generally not the ones that produce extrapulmonary disease such as diarrhea, epidemic keratoconjunctivitis, or hemorrhagic cystitis	(Nonspecific) Relative lymphopenia	(Nonspecific) Segmental and multiple areas of interstitial and/or alveolar infiltrates Focal infiltrates reported as a common presentation
Varicella virus	Airborne: aerosol transmission	Year-round transmission with peaks in late winter and early spring in temperate climates Intimate contact with index case of primary varicella infection (chickenpox) Incubation period is 10–20 d after infection Risk factors for developing pneumonia: nonimmune adults; smoking; chronic obstructive pulmonary disease; >100 skin lesions; pregnancy, third trimester	Pneumonia presents 1–6 d after onset of typical rash (chickenpox) Fever, dyspnea, tachypnea in absence of upper respiratory symptoms	Cutaneous lesions (chickenpox) CNS involvement (uncommon): acute cerebellar ataxia, encephalitis, CNS vasculitis	(Nonspecific)	Nodular or interstitial pneumonitis common

Rubeola virus	Fomite and direct contact with respiratory droplets Airborne: aerosol transmission	Epidemic transmission, localized outbreaks in household and community settings Outbreaks in doctor's offices and emergency departments Infectivity greatest in the 3 d before onset of rash in index case (incubation period 10–14 d) Risk factors for severe illness: nonimmune adults and children <5 years old; crowding; pregnancy; HIV infection; malnourished children, developing countries; vitamin A deficiency	Prodrome: cough, coryza, conjunctivitis Unilateral and bilateral primary viral pneumonia Secondary bacterial pneumonias (*S. pneumoniae*, *S. aureus*, and others)	Typical morbilliform rash (see text) CNS involvement: acute or chronic encephalitis (typically after respiratory disease)	Leukopenia	(Nonspecific)
SARS coronavirus	Airborne droplet transmission (≥10 μm) Fomites	Epidemic/outbreak settings Originated in Asia Person-to-person transmission after contact with symptomatic, SARS CoV-infected person No transmission seen since 2003	Fever, myalgias, cough Upper respiratory signs/symptoms are uncommon Dyspnea, tachypnea, respiratory decompensation develop around second week of illness	Watery diarrhea in 25% of patients around second week of illness	Absolute lymphopenia common	Ground-glass opacifications Unilateral and bilateral focal infiltrates Pneumomediastinum without preceding intubation or positive pressure ventilation reported as characteristic sign
New World hantaviruses	Small-particle aerosols generated from rodent excreta	Sporadic, clustered cases in Americas Exposure to rodents, their droppings and urine, especially in closed spaces In general, no person-to-person transmission (except possibly with Andes virus)	Febrile/flu-like prodrome usually without any upper respiratory signs/symptoms Rapid progression to noncardiogenic pulmonary edema/ARDS with hypotension	Renal dysfunction with proteinuria and microscopic hematuria	Thrombocytopenia (early and nearly all cases) Absolute neutrophilia Relative lymphopenia with immunoblasts on peripheral smear Elevated hepatic transaminases (nearly all cases)	Bilateral noncardiogenic pulmonary edema/ARDS
Avian influenza A virus H5N1	Presumed droplet transmission and/or direct contact from bird to human	Sporadic cases in countries with animal influenza A H5N1 Close contact/exposure to live or dead domestic fowl or wild birds or domestic ducks Few reports of limited person-to-person transmission by intimate contact only	Flu-like prodrome often without upper respiratory signs/symptoms Early development of primary viral pneumonia	Watery diarrhea Multiorgan failure	(Nonspecific) Lymphopenia Mild-to-moderate thrombocytopenia Elevated hepatic transaminases	(Nonspecific) Unilateral and bilateral infiltrates Multifocal consolidations ARDS

ARDS, acute respiratory distress syndrome; CNS, central nervous system; HIV, human immunodeficiency virus; SARS, severe acute respiratory syndrome.

The radiographic findings in viral pneumonias are also broad and nonspecific. Radiographic infiltrates can have interstitial, alveolar, or combined patterns. The presence of only a diffuse alveolar pattern might suggest a primary influenza pneumonia with hemorrhagic alveolitis [8] or the capillary leak syndrome of acute respiratory distress syndrome, especially due to HCPS. Peribronchial nodular infiltrates is a pattern often reported with varicella pneumonia [9]. Computed tomography (CT) scans are better at detecting the presence, extent, and complications of respiratory infections than chest radiographs. However, they are no better at defining particular radiographic patterns of specific viral or bacterial causes [9].

DIAGNOSIS

The diagnostic modalities available for viral pneumonias rely on detection of a viral component (nucleic acid or protein), growth of the virus in vitro, or development of a virus-specific antibody response. Definitive serologic evidence of a viral infection requires a rise in virus-specific antibody titers between paired acute illness and convalescent sera. With a few exceptions, serologic assays are therefore not generally helpful for the clinician in the acute setting of a viral pneumonia. This section will focus on diagnostic tests that may assist the clinician faced with a critically ill patient and suspected viral pneumonia.

Human Influenza A and B

Rapid, direct, antigen-detection assays are commercially available for diagnosing human influenza A and B virus infections. These assays rely on detection of the influenza virus nucleoprotein in respiratory secretions, and results can be obtained within 1 hour. Because they are based on the viral nucleoprotein, none of the rapid antigen tests provide information about influenza A hemagglutinin subtypes (e.g., H1, H3). Details regarding the available rapid antigen tests for influenza are provided by the Centers for Disease Control (CDC) (http://www.cdc.gov/flu/professionals/diagnosis/rapidclin.htm). The test specificities for diagnosing an influenza virus infection are generally high (more than 90%), but reported sensitivities are lower (33% to 80%) and may vary for different human influenza A virus subtypes [10–12]. In clinical practice, the timing and method of sample collection can greatly affect test sensitivity. Influenza A virus shedding from the upper respiratory tract typically peaks 2 to 3 days after symptom onset [13,14]. The window available to reliably detect viral antigen from upper respiratory tract secretions may extend only 5 to 6 days after symptom onset. Influenza virus nucleoprotein is most abundant in the columnar respiratory epithelium. Posterior nasopharyngeal swabs or aspirates that collect columnar epithelial cells are usually the preferred samples for rapid antigen detection assays [10,15,16], even for mechanically ventilated patients in the intensive care unit (ICU).

Reverse transcriptase polymerase chain reaction (RT-PCR) assays and viral culture are the next most commonly used diagnostic tests for human influenza virus infections. Posterior nasopharyngeal swabs or washes, and samples of lower respiratory tract secretions such as endotracheal aspirates or bronchoalveolar lavages, are acceptable samples. Virus typing and influenza A subtyping can be accomplished with either method. Due to its high sensitivity, specificity, and throughput, RT-PCR assays have generally supplanted virus culture in many clinical microbiology laboratories. Unlike viral culture, the detection of influenza viral RNA by RT-PCR cannot assess the presence of live virus in respiratory secretions.

Respiratory Syncytial Virus

Rapid antigen-detection assays and direct immunofluorescent staining for RSV from respiratory secretions have been the primary diagnostic tests used in children. These tests have >80% sensitivity and >90% specificity [17]. RT-PCR assays and respiratory viral culture are the other common diagnostic approaches in pediatric populations. In adults, the RSV rapid antigen assays and viral culture are generally insensitive due to low virus shedding and preexisting anti-RSV antibody in respiratory secretions [18,19]. Direct fluorescent antibody staining in nasopharyngeal specimens was reported to be the only rapid assay at least equivalent to viral culture in adults [17]. A RT-PCR assay on respiratory secretions is the preferred acute illness diagnostic method for RSV infection in adults [20,21].

Adenovirus

PCR of adenovirus DNA or respiratory viral culture from a nasopharyngeal swab or aspirate, sputum, or lower respiratory tract secretions is the diagnostic test of choice for adenoviral pneumonia. Direct adenovirus antigen assays that cover most serotypes, such as immunofluorescent antibody staining, are not as sensitive as PCR assays or viral culture.

Varicella

Varicella pneumonia typically develops within 1 to 6 days after the characteristic rash of chickenpox has appeared [22]. If desired, a specific microbiological diagnosis can be obtained by PCR assay or viral culture from a swab or scraping at the base of an unroofed vesicle. Viral detection in respiratory secretions is generally not required.

Rubeola (Measles)

Pulmonary involvement with measles is generally diagnosed on the basis of history and physical findings. In outbreak settings, pneumonia should be suspected in patients who develop respiratory distress and persistent or recurrent fevers during the course of typical measles. Measles is characterized by malaise and fever, followed rapidly by coryza, conjunctivitis, and cough [23]. Early in illness, the presence of Koplik spots on the buccal mucosa is pathognomonic of measles. The classic morbilliform rash begins 3 to 4 days after onset of illness and starts to fade after another 3 days. Worsening respiratory symptoms as the rash is fading is suspicious for rubeola pneumonia. Laboratory confirmation may be useful, particularly in suspected sporadic cases within a highly immunized population. Viral isolation or rapid detection of measles antigen in nasopharyngeal secretions is difficult and not readily available. A presumptive serologic diagnosis can be made by detection of serum antimeasles virus immunoglobulin M (IgM) or immunoglobulin G (IgG) in unimmunized individuals. Serum antibodies appear 1 to 3 days after onset of the rash [24]. Definitive serologic diagnosis requires paired acute and convalescent sera. In immunocompromised patients with overwhelming pneumonia, the antibody response may be minimal. Viral antigen staining of cells or RT-PCR assays on nasal exudates or urinary sediment may be useful in this setting [23].

Severe Acute Respiratory Syndrome Coronavirus

The most practical diagnostic approach for SARS coronavirus is a RT-PCR assay on nasopharyngeal specimens within

2 weeks after symptom onset [25]. The other primary site where SARS coronavirus RNA can be detected is stool (week 2 onward). Lower respiratory tract secretions harbor a greater viral load than upper respiratory tract secretions early in illness. However, lower respiratory tract aspiration, lavage, or intubation pose serious nosocomial transmission risks and should not be pursued solely for diagnostic purposes. IgM seroconversion does not occur until after the first week of illness and therefore is also of limited diagnostic utility [4]. With resolution of SARS viral transmission in 2003, and the apparent subsequent mutation of the virus [26], any initial positive test for SARS coronavirus must be viewed as a potential false-positive finding.

Hantavirus

There are nearly a dozen New World hantaviruses that have been associated with HCPS. Sin Nombre virus (in the southwestern United States) and Andes virus (in South America) are the two best known HCPS-associated hantaviruses. The diagnosis of HCPS can be made by detection of antihantavirus IgM antibodies in acute illness serum. Nearly all patients with HCPS have detectable IgM in their sera at the onset of pulmonary edema. The currently available IgM capture enzyme-linked immunosorbent assay using a recombinant Sin Nombre virus antigen can be used to diagnose all New World hantavirus infections [27]. RT-PCR assay on blood or lung tissue is a research assay of limited utility and not widely available. Because of low yield and biosafety issues, attempted culture of hantaviruses in clinical microbiology laboratories is not recommended.

Avian Influenza Virus (H5N1)

If H5N1 influenza A virus infection is suspected on epidemiologic grounds, then all avenues for making a definitive diagnosis should be pursued. The diagnostic approach to H5N1 influenza is to collect nasopharyngeal and lower respiratory tract specimens for rapid antigen detection, RT-PCR assay, and viral culture. Aerosol-generating procedures for specimen collection should be performed with appropriate infection control precautions. Detection of viral RNA in respiratory specimens by RT-PCR is the most sensitive and rapid method for detecting influenza A/H5N1. A hallmark of H5N1 influenza has been a higher frequency of virus detection and viral loads in pharyngeal and lower respiratory tract samples than in nasal samples between 2 and 16 days after the onset of illness [6,28]. Viral RNA has also been detected in fecal samples. The CDC has provided guidance for the laboratory testing of suspected H5N1 cases (http://www.cdc.gov/flu/avian/professional/guidance-labtesting.htm). The clinical microbiology laboratory should be notified if H5N1 influenza A virus infection is suspected and specimens are collected for viral culture. This is to ensure that the specimens will be handled and processed with the appropriate biosafety containment level.

TREATMENT AND MANAGEMENT

Caring for a patient with a severe viral pneumonia can be complex; however, the approach to such a patient is often identical to that of other acute severe pneumonias. First, a clinical assessment of disease severity is made so that an appropriate level of care can be established. This process can be assisted by standardized scoring algorithms established for critically ill patients or community-acquired pneumonias [29,30]. Supportive care with maintenance of ventilation, oxygenation, and hemodynamic parameters is based on general principles previously outlined in Chapter 68. Next, diagnostic procedures to try to establish the cause of the severe pneumonia can be pursued. Finally, one needs to evaluate the role of specific antiviral and/or immunomodulatory therapies in the care of the patient. As with most infectious pneumonias, the decision to treat with these therapies is often made empirically or with limited diagnostic information. A summary of potential therapeutic options, dosages, and adverse effects is presented in Table 90.2.

Human Influenza A and B

There are two classes of antiviral drugs currently available for the treatment of human influenza virus infections: adamantanes (amantadine and rimantadine) and neuraminidase inhibitors (oseltamivir, zanamivir, peramivir). The adamantanes are older, established compounds, but they are not active against influenza B. In placebo-controlled trials, when amantadine or rimantadine therapy was initiated within 48 hours of symptom onset in influenza A virus infections, there was a 1 to 2 day reduction in duration of fever and overall illness symptom scores [31]. However, there are no controlled data on the utility of adamantanes in the treatment of severe influenza A lower respiratory tract infections, and several factors make them less than ideal for patients in the ICU. In several studies, rimantadine treatment produced small initial decreases in viral titers, but later in therapy, similar or higher frequencies of viral shedding compared to placebo [32]. The incidence of adamantane resistance among influenza A viruses worldwide has increased in recent years [33]. Resistance emerges at a high frequency during treatment with adamantanes, and resistant virus can be transmitted to the close contacts of patients in community and nosocomial settings [32,34].

The neuraminidase inhibitors have activity against influenza A and B. As with the adamantanes, oseltamivir and zanamivir decrease the duration and severity of generalized symptoms by approximately 1 day when started within 48 hours after onset of illness [35]. Some lines of evidence make the neuraminidase inhibitors attractive for treatment of patients with severe influenza virus pneumonias. They markedly reduce viral load during the first 48 hours of treatment, can decrease viral shedding, and may lower the incidence of influenza-related lower respiratory tract complications [36–38]. However, the latter benefit has been questioned by a recent meta-analysis [39]. Development of resistance to oseltamivir or zanamivir has been uncommon in immunocompetent adults, but appears to be higher in children and immunocompromised individuals [40,41]. Importantly, person-to-person transmission of resistant virus has not been documented. Zanamivir may be active against some oseltamivir-resistant strains.

Despite the lack of randomized controlled trials in the ICU setting, most practitioners would initiate treatment with a neuraminidase inhibitor in patients with suspected or confirmed severe influenza pneumonia. Some clinicians advocate the use of oseltamivir at twice the recommended dose for patients with severe influenza pneumonia or a combination of oseltamivir and rimantadine. There are no randomized clinical trial data to support these approaches at the present time, but they are being actively investigated. Zanamivir should not be nebulized for patients on mechanical ventilation due to possible obstruction of the ventilation circuit (http://www.fda.gov/safety/medwatch/safetyinformation/safetyalertsforhumanmedicalproducts/ucm186081.htm). Peramivir is an intravenous neuraminidase inhibitor that received emergency use authorization by the U.S. Food and Drug Administration in the setting of the 2009 novel H1N1 influenza A pandemic. Pregnant women,

TABLE 90.2

SUMMARY OF ANTIVIRAL AGENTS AND THERAPEUTIC OPTIONS FOR SPECIFIC VIRAL PNEUMONIAS

Virus	Drug	Adult dosage (duration)	Dosage adjustments[a]	Potential adverse effects	Comments
Human influenza viruses	Oseltamivir	75 mg PO b.i.d (5 d)	Decrease to 75 mg PO qd in patients with CrCl between 10 and 30 mL/min	Nausea, vomiting, headache	Neuraminidase inhibitors effective against human influenza A and B viruses Some consider increase to 150 mg PO b.i.d × 7–10 d—no randomized trial
	Zanamivir	2 × 5 mg oral inhalations bid (5 d)	None	Cough, nasal and throat discomfort, bronchospasm, decreased lung function	Use with caution in patients with asthma or COPD
	Amantadine	100 mg PO b.i.d or 200 mg PO qd (3–5 d)	Decrease to 100 mg/d for patients >65 y old or CrCl <50 mL/min	Anticholinergic effects: CNS effects can include insomnia, delirium, hallucinations, and seizures	Adamantanes not effective against human influenza B viruses
	Rimantadine	100 mg PO b.i.d or 200 mg PO qd (3–5 d)	Decrease to 100 mg/d for patients >65 y old, CrCl <10 mL/min, or with severe hepatic dysfunction	Same as amantadine, except CNS adverse effects less common	
Adenovirus	Cidofovir	5 mg/kg IV × 1	Contraindicated in patients with CrCl ≤55 mL/min	Renal toxicity: acute renal failure, proteinuria Neutropenia Metabolic acidosis Uveitis	Cidofovir given with probenecid (2 g PO 3 h before cidofovir infusion, and 1 g PO 2 and 8 h after the infusion) Also, prehydrate with 1 L IV NS
Varicella	Acyclovir	10 mg/kg IV q8 h × 7–10 d	Decrease to 10 mg/kg IV q12 h for CrCl 10–50 mL/min 10 mg/kg IV q24 h for CrCl <10 mL/min	Occasional mild nausea, vomiting, diarrhea Crystal formation and renal tubular obstruction Dizziness, delirium, obtundation (rare)	IV hydration to avoid renal toxicity CNS toxicity seen with high drug levels
Rubeola (measles)	Vitamin A	200,000 IU PO qd × 1–2 d (100,000 IU PO qd if ≤1 y old)	None		
	Ribavirin?	20–35 mg/kg/d IV × 7 d	None	Dose-related hemolytic anemia (common) Cough, dyspnea, nausea, headache, fatigue Hypocalcemia with IV ribavirin	Data from small case series; no randomized trial
New World hantaviruses	Ribavirin?	33 mg/kg IV load, then 16 mg/kg IV q6 h × 4 d, 8 mg/kg IV q8 h × 3 d	None	Same as previously noted	No suggestion of benefit if ribavirin started in cardiopulmonary phase of HCPS; unknown if there would be benefit if initiated earlier during prodromal phase
Avian influenza A H5N1 virus	Oseltamivir	75 mg PO b.i.d × 5 d or consider increase to 150 mg PO b.i.d × 7–10 d	Same as previously noted	Same as previously noted	Most experience to date in treating H5N1 infections has been with oseltamivir, but no randomized trials
	Zanamivir	2 × 5 mg oral inhalations b.i.d (5 d)	None	Same as previously noted	Same cautions as previously noted

[a]Consult appropriate references for potential drug–drug interactions.
Note: Zanamavir may be useful for oseltamivir-resistant H5N1 strains, but no experience as either single agent or in combination with other antivirals.
b.i.d, twice daily; CrCl, creatinine clearance; COPD, chronic obstructive pulmonary disease; CNS, central nervous system; HCPS, hantavirus cardiopulmonary syndrome; IV, intravenous; PO, orally; NS, normal saline.

infants and children younger than 2 years, individuals with chronic cardiopulmonary or renal disease, and those immunosuppressed were at higher risk of developing severe illness during the 2009 H1N1 influenza pandemic (same as in all human influenza outbreaks). The 2009 novel H1N1 virus has now become the dominant circulating influenza A H1N1 strain worldwide. There are no data to support the use of corticosteroids in the treatment of influenza pneumonia, and inhaled ribavirin is not beneficial [42]. An important addition to the treatment of influenza pneumonia is antibacterial therapy. There is a high incidence of secondary bacterial infections complicating influenza pneumonia, particularly with *S. pneumoniae* or *S. aureus* [43]. In this setting, antibiotic therapy directed against *S. aureus* should be added to the antibiotic regimen used for community-acquired pneumonia bacterial pathogens. In areas where there is a high prevalence of community-acquired methicillin-resistant *S. aureus*, vancomycin should be used as the initial antistaphylococcal antibiotic.

Respiratory Syncytial Virus

Because RSV is a frequent cause of serious lower respiratory tract infections in infants and young children, data on potential therapies come from pediatric studies. There have been no trials of anti-RSV therapies in adults to date. Current treatment strategies for RSV lower respiratory tract infections are essentially supportive. Aerosolized ribavirin therapy of infants with RSV lower respiratory tract infections had no significant effects on clinical outcome in two randomized trials [44,45]. Palivizumab, a humanized anti-RSV neutralizing monoclonal antibody, has been successful in reducing hospitalizations of high-risk children for RSV lower respiratory tract infections when given prophylactically [46]. However, the utility of palivizumab or anti-RSV immune globulin as a potential treatment of serious RSV infections is unknown. Clinical observations and a mouse model of RSV infection have demonstrated airway hyperresponsiveness and other asthmatic changes in RSV-infected lungs [47], and prompted trials of anti-inflammatory therapies. Unfortunately, two randomized trials failed to demonstrate any overall beneficial effect of intravenous dexamethasone in RSV lower respiratory tract infections [48,49]. On subgroup analysis in one study, dexamethasone treatment was beneficial in mechanically ventilated patients with bronchiolitis and mild gas exchange abnormalities (PaO_2/FIO_2 more than 200 mm Hg or mean airway pressure $\leq$10 cm H_2O) [48]. These findings have yet to be confirmed in a prospective fashion.

Adenovirus

Adenoviral pneumonia occurs in isolated outbreaks among immunocompetent adults or sporadically in immunocompromised individuals. As such, there are no prospective randomized trials of antiviral medications. Cidofovir is an antiviral drug with potent in vitro activity against adenovirus. Cidofovir has been reported to be successful in treating adenoviral pneumonia in small case series [50–52], and is currently considered the antiviral agent of choice. Because severe adenovirus disease is associated with defects in cellular or humoral immunity, donor lymphocyte infusions and intravenous immunoglobulin have been used as adjunctive therapy [50]. Their efficacy in the treatment of adenoviral pneumonia is unknown.

Varicella

Intravenous acyclovir is considered standard therapy for the treatment of varicella pneumonia. There have been no randomized controlled trials of acyclovir for varicella pneumonia. Its efficacy in reducing the severity of pox lesions [53,54] and apparent benefit in numerous case series of varicella pneumonia support its use. A compilation of 46 case reports and 227 patients with varicella pneumonia suggested that mortality was 3.6-fold higher in untreated compared to acyclovir-treated patients [22]. In a small uncontrolled retrospective study, patients who received adjunctive corticosteroids had shorter ICU and hospital stays than those who did not receive corticosteroids [55]. There are no prospective controlled studies supporting the use of adjunctive corticosteroid therapy in varicella pneumonia.

Rubeola (Measles)

Pneumonia is the most common severe complication of measles and accounts for most measles-associated deaths [56]. There is no specific antiviral therapy for measles. In developing countries, treatment with vitamin A has been associated with a 50% reduction in the mortality of severe measles. Hospitalized children with measles in the United States often have a measurable deficiency in Vitamin A, and they are more likely to have pneumonia or diarrhea. The World Health Organization recommends vitamin A therapy for all children with measles, and the American Academy of Pediatrics recommends vitamin A therapy for hospitalized children older than 2 years with measles in the United States [56]. Data in older children and adults are lacking, but vitamin A treatment should probably be extended to all individuals with severe measles [57,58]. Intravenous ribavirin was reported to have beneficial effects in a small case series of measles pneumonia in adults [59], but there are no data from prospective randomized studies. Another important point in the treatment of measles pneumonia is antibacterial therapy. Secondary bacterial pneumonia and laryngotracheobronchitis are frequent complications of measles. As with influenza, *S. aureus* and *S. pneumoniae* are the most commonly isolated bacterial pathogens. Less frequent bacterial causes of pneumonia following measles include *Neisseria meningitidis, Klebsiella pneumoniae, Escherichia coli, Haemophilus influenzae*, and *Pseudomonas* spp [56]. Broad-spectrum antibiotic therapy, including coverage for *S. aureus* and *S. pneumoniae*, should be instituted.

Severe Acute Respiratory Syndrome Coronavirus

The SARS epidemic of 2003 was marked by the empiric use of several antiviral and immunomodulatory strategies because controlled trials were not possible. Ribavirin was the most commonly used antiviral agent, but its poor in vitro activity against the SARS coronavirus and its apparent limited ability to reduce early viral shedding in patients makes its usefulness questionable [60]. Corticosteroids were used extensively during the SARS outbreak of 2003 at varying doses and durations. Retrospective analyses on the effects of corticosteroids in SARS suggest that they did not provide any significant benefits and may have been associated with some adverse outcomes [60,61].

Hantavirus

There has been one placebo-controlled, double-blind trial of intravenous ribavirin for treatment of HCPS due to Sin Nombre virus [62]. The accrual of study subjects was low and inadequate to clearly assess the efficacy of ribavirin. There were no trends to support the use of ribavirin in patients presenting in

the cardiopulmonary phase of HCPS. Whether ribavirin may have a beneficial effect if initiated during the prodromal phase is unknown. Intravenous ribavirin was beneficial when given early to patients with another hantavirus disease, hemorrhagic fever with renal syndrome caused by Hantaan virus [63]. There is no evidence that pharmacologic doses of corticosteroids provide any benefit in HCPS.

At the present time, clinical management of HCPS involves supportive care with several caveats. Excessive fluid resuscitation will exacerbate the pulmonary edema of HCPS without commensurate improvement in cardiac output. Recommendations are to fluid resuscitate with 1 to 2 L of isotonic crystalloid and then maintain as low a wedge pressure (8 to 12 mm Hg) as is compatible with satisfactory cardiac output (cardiac index more than 2.2 L per minute per m^2). The use of loop diuretics is discouraged. Inotropic agents (e.g., dobutamine, dopamine, norepinephrine) should be initiated earlier in resuscitation than in other conditions, instead of continued fluid boluses [5].

Avian Influenza Virus (H5N1)

The H5N1 influenza A viruses are susceptible in vitro to the neuraminidase inhibitors, and neuraminidase inhibitors have been protective in animal models of influenza A H5N1 infection [64–66]. Although prospective clinical trials have not been performed, the current recommendation is that patients with suspected influenza A H5N1 infection promptly receive a neuraminidase inhibitor, preferably within 48 hours of infection [6,67]. Doubling the standard doses of oseltamivir and increasing the duration of treatment for 7 to 10 days are considerations for severe H5N1 infections [6]. Emergence of resistance to oseltamivir has been documented in a few patients with H5N1 infections treated with oseltamivir [68]. These strains remain susceptible to zanamivir. Whether combination therapy with zanamivir or other antivirals is beneficial and would reduce the emergence of oseltamivir resistance is unknown. The influenza A H5N1 isolates from Asia are highly resistant to the adamantanes, and therefore these drugs do not play a therapeutic role [6]. Corticosteroids have been used in the treatment of sporadic influenza A H5N1 infections, but their routine use cannot be recommended. In a randomized trial in Vietnam, all four patients given dexamethasone died [69].

INFECTION CONTROL ISSUES FOR THE INTENSIVE CARE UNIT

Most of the viruses presented in this chapter can be transmitted in the nosocomial setting via direct contact with an infected patient and through inhalation of droplets or aerosols. Efforts to reduce transmission to healthcare workers and other patients are often guided by the transmission efficiency of the specific viral agents. Human influenza, RSV, adenovirus, varicella, and measles are efficiently transmitted person to person. SARS coronavirus and avian influenza A H5N1 virus are transmitted less efficiently, but nosocomial transmission may be promoted by aerosol-generating procedures. The New World hantaviruses are generally not transmitted person to person, except possibly the Andes virus.

Strategies to prevent nosocomial transmission include isolation precautions for patients, chemoprophylaxis and immunization of healthcare workers if possible, and surveillance and rapid identification of healthcare workers' exposures. In general, patients with suspected epidemic viral pneumonias should be housed with a combination of standard, contact, droplet, and airborne isolation precautions. When feasible, limit the number of healthcare workers with direct access to the patient and limit their contact with other patients. Restrict visitors to a minimum and provide them appropriate personal protective equipment. High-efficiency N-95 masks or powered air-purifying respirators are preferred for healthcare workers. If high-efficiency masks are limited or unavailable, surgical masks may be considered if the primary mode of agent transmission is via droplets and no aerosol-generating procedures are performed. Detailed guidelines can be found on the CDC Web site (http://www.cdc.gov/ncidod/dhqp/guidelines.html).

Advances in antiviral or immunomodulatory therapy of viral pneumonias based on randomized controlled trials or meta-analyses of such trials is summarized in Table 90.3.

TABLE 90.3

SUMMARY RECOMMENDATIONS FOR ANTIVIRAL OR IMMUNOMODULATORY THERAPY OF VIRAL PNEUMONIAS BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

Human influenza
- Neuraminidase inhibitors given within 48 h of flu symptom onset decrease the duration of symptoms, viral load, and viral shedding; controversy as to whether they lower the incidence of influenza-related lower respiratory tract complications [35,39]; no randomized controlled trials for treatment of severe pneumonia.
- Aerosolized ribavirin does not provide any clinical benefit [42].

Respiratory syncytial virus (RSV)
- Aerosolized ribavirin has no significant effect on outcome in infants with RSV lower respiratory tract infections [44,45].
- Intravenous dexamethasone does not provide any overall beneficial effect in RSV lower respiratory tract infections [48,49].
- On post hoc analysis, dexamethasone (0.6 mg/kg IV q6 h × 48 h) may be beneficial in mechanically ventilated patients with bronchiolitis and mild gas exchange abnormalities (PaO_2/FIO_2 >200 mm Hg or mean airway pressure ≤10 cm H_2O) [48].

Adenovirus
- No randomized controlled trials of cidofovir for adenovirus pneumonia.

Varicella
- No randomized controlled trials of IV acyclovir for varicella pneumonia. A meta-analysis of published case series suggests that IV acyclovir decreases mortality [22].

Rubeola (measles)
- Oral vitamin A therapy decreases mortality and improves recovery from pneumonia in children [56,57].

SARS coronavirus
- No randomized controlled trials for antivirals or corticosteroids.

Hantavirus cardiopulmonary syndrome (HCPS)
- No trends to support the use of ribavirin in patients presenting in the cardiopulmonary phase of HCPS [62].

Avian influenza A virus (H5N1)
- Neuraminidase inhibitors have been protective in animal models of influenza A H5N1 infection. There are no patient-based randomized controlled trials.
- No trends to support the use of dexamethasone from a small, unpublished, randomized trial [69].

IV, intravenous; SARS, severe acute respiratory syndrome.

CHAPTER 91 ■ UPPER AND LOWER GASTROINTESTINAL BLEEDING

RYAN F. PORTER, GARY R. ZUCKERMAN AND CHANDRA PRAKASH GYAWALI

Acute gastrointestinal (GI) bleeding is a common emergency that often necessitates admission to the intensive care unit (ICU). There are compelling differences in incidence, clinical presentation, severity, and mortality between lower and upper GI hemorrhage. The annual incidence rate of lower intestinal bleeding is estimated at 20.5 to 33 cases per 100,000 adult populations [1,2], while that of upper GI bleeding is estimated between 60 and 125 cases per 100,000 [3,4]. The incidence of upper GI bleeding has declined in those younger than age 70 years to as low as 47 per 100,000 over the past decade [2,5]. *Helicobacter pylori* eradication efforts and widespread use of proton pump inhibitor (PPI) therapy may account for this decline. The incidence in older populations, however, remains stable possibly from more frequent use of aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) [4,6]. The majority of upper GI bleeds are nonvariceal (80% to 90%), of which 28% to 59% are attributable to peptic ulcer bleeding [3,4]. Patients with lower GI bleeding are half as likely to present with hemodynamic compromise or require blood transfusion, and have significantly higher hemoglobin concentrations at presentation compared to upper GI bleeding [7]. The mortality rate from upper GI bleeding has remained stable at 5% to 12%, while mortality rates for lower intestinal bleeding remain below 5% [4,7]. Newer surgical, endoscopic, and medical therapies, as well as improved ICU care, will hopefully improve survival rates for both upper and lower GI bleeding in the coming years.

INITIAL EVALUATION AND RESUSCITATION

Resuscitating the actively bleeding patient takes priority over localizing the bleeding source. The immediate goals are to replete intravascular volume and prevent irreversible shock. However, even in situations of exsanguinating hemorrhage, limited attempts to localize bleeding while resuscitation continues may be required to help direct a surgical or angiographic approach.

An initial brief history and physical examination that includes serial measurement of vital signs and evaluation of the volume and character of bleeding helps determine the urgency and degree of resuscitation necessary. Tachycardia (pulse >100 beat per minute), hypotension (systolic blood pressure <100 mm Hg), or orthostatic hypotension (an increase in the pulse of ≥20 beats per minute or a drop in systolic blood pressure of ≥20 mm Hg on standing) indicates significant intravascular volume depletion [4]. Insight into volume status can also be gained from evaluation of mucous membranes and neck veins, and measurement of urine output [4]. Bleeding patients will need large bore intravenous-access catheters (e.g., peripheral catheters 16 or 18 guage or central venous access), supplemental oxygen, correction of coagulopathies and prompt packed red blood cell transfusion for tachycardia, hypotension or hemoglobin less than 10 g/dL [4]. Clinical parameters and evidence of gross bleeding will dictate the approach, but preparedness should be for the potential of massive bleeding.

Older patients with hemodynamic compromise or shock have a poor outcome (Table 91.1) and need urgent resuscitation and close monitoring. In situations of massive hematemesis, endotracheal intubation provides airway protection and facilitates endoscopic evaluation and therapy. Chest pain may imply a superimposed myocardial infarction or dissecting aneurysm, whereas a history of abdominal vascular surgery adds aortoenteric fistula to the differential diagnoses. GI bleeding is generally not associated with significant abdominal pain, and its presence could signify hematobilia, intestinal infarction, or intestinal perforation.

FURTHER EVALUATION AND MANAGEMENT

Resuscitation may need to continue even after the initial volume deficit has been corrected if there is evidence of ongoing or renewed bleeding. Because of the laxative properties of fresh blood in the GI tract, repeated passage of liquid blood per rectum implies ongoing or recurrent bleeding. As bleeding stops, the stool becomes formed and converts from red or maroon blood to darker stool and eventually to brown stool that contains occult blood, which may persist for as long as 2 weeks after GI bleeding has ceased.

TABLE 91.1

CLINICAL RISK FACTORS FOR MORTALITY IN ACUTE UPPER GASTROINTESTINAL BLEEDING

Clinical feature	Mortality (%)
Age ≥60 y	11
Age <60 y	1
Shock on admission	23
No shock	4
Rebleeding in 72 h	30
No rebleeding	3
Failure to clear red nasogastric aspirate	50
Red-to-clear nasogastric return	8

Data derived from Branicki FJ, Boey J, Fok PJ, et al: Bleeding duodenal ulcer: a prospective evaluation of risk factors for rebleeding and death. *Ann Surg* 211:411, 1989; Hunt PS: Bleeding gastroduodenal ulcers: selection of patients for surgery. *World J Surg* 11:289, 1987; and MacLeod IA, Mills PR: Factors predicting the probability of further hemorrhage after upper gastrointestinal hemorrhage. *Br J Surg* 69:256, 1982, with permission.

TABLE 91.2

COMPLETE ROCKALL SCORE FOR RISK STRATIFICATION OF ACUTE UPPER GASTROINTESTINAL BLEEDING

Variable	Points
Clinical Rockall score	
Age	
<60 y	0
60–79 y	1
≥80 y	2
Shock	
Heart rate >100 beats/min	1
Systolic blood pressure <100 mm Hg	2
Coexisting illness	
Coronary artery disease, congestive heart failure, other major illness	2
Renal failure, hepatic failure, metastatic cancer	3
Endoscopic diagnosis	
No finding, Mallory–Weiss tear	0
Peptic ulcer, erosive disease, esophagitis	1
Cancer of the upper GI tract	2
Endoscopic stigmata of recent bleeding	
Clean based ulcer, flat pigmented spot	0
Blood in upper GI tract, active bleeding visible vessel, clot	2

Note: Patients with a clinical Rockall score of 0 or a complete Rockall score of <2 are considered to be at low risk for rebleeding or mortality. Higher scores indicate higher risks.
Adapted from Gralnek IM, Barkum AN, Bardou M: Management of acute bleeding from a peptic ulcer. *N Engl J Med* 359:928–937, 2008.

In patients without hematemesis, a nasogastric (NG) tube aspirate of red blood may be a poor prognostic sign [3,4], but the lack of red blood or coffee ground material does not exclude an upper GI bleeding source [4]. Clinical variables at presentation in combination with endoscopic findings have been used to triage and risk-stratify patients, assess risk of poor outcomes, and aid in guiding management [3,4]. The Glasgow-Blatchford Score is a validated tool based solely on clinical variables scored from 0 to 23, with higher values predictive of higher risk. Scores of 0 are at low risk of rebleeding and mortality and can be considered for outpatient management [4,8]. The Rockall Score can be calculated prior to and after endoscopy (Table 91.2), with higher scores predictive of higher risk of a poor outcome [4,9]. While their exact role in clinical management continues to be evaluated, these scores will likely continue to have an increasing role in patient care.

DIAGNOSTIC EVALUATION

Bedside Diagnosis

While hematemesis is clearly a symptom of upper GI bleeding, black tarry melenic stool predicts an upper GI bleeding source, and brighter colors of red in the stool are more often associated with a distal colonic bleeding source. However, color of bloody stool may not always be helpful in predicting the level of GI bleeding and is subject to interpretation variability of both patients and physicians. A pocket-sized color card is helpful in confirming the stool color, as described by the patient, and suggesting the level of bleeding in the GI tract [10]. When bright blood in the stool (implying a lower GI bleed) is associated with hemodynamic compromise, as many as 11% of patients may have an upper GI bleeding source, even if the NG aspirate is negative [3,4]. In this setting, an upper endoscopy may be the first endoscopic evaluation even though the presenting symptom is hematochezia.

Upper Endoscopy

When bleeding is suspected to originate proximal to the jejunum, esophagogastroduodenoscopy (upper endoscopy) is the diagnostic procedure of choice. This identifies the bleeding source in 80% to 90% of cases with a high degree of accuracy, provides therapeutic options, and carries low morbidity [3,4]. Endoscopy has the added advantage of detecting prognostic signs (Table 91.2) and classifies bleeding stigmata as high or low risk for rebleeding based on the Forrest grade (Table 91.3) [11].

Even when an exact diagnosis cannot be made, localizing the bleeding to a specific region within the upper GI tract can be helpful to the surgeon (if resection is indicated) or interventional radiologist (if embolization of the bleeding vessel is recommended). Erythromycin or metoclopramide can be administered intravenously to induce gastric emptying and clear the stomach of blood and clots prior to endoscopy [12,13]; repeated lavage with saline through a wide-bore orogastric tube also may be used for this purpose. However, routine gastric lavage may not be necessary and is not endorsed by the authors. Complications related to endoscopy are higher when the procedure is performed on an emergency basis.

The timing of endoscopy in upper GI bleeding continues to be evaluated. Endoscopy within 12 hours of presentation increased the use of endoscopic therapy but did not reduce rebleeding rates or improve survival rates [14]. However, endoscopy within 24 hours did demonstrate a reduction in the length of hospital stay and need for surgical intervention [15,16]. Patients with bloody NG aspirate did benefit from

TABLE 91.3

RISK FACTORS FOR CONTINUED BLEEDING OR REBLEEDING FROM PEPTIC ULCER

Endoscopic finding	Forrest grade	Proportion that continues to bleed or rebleed (%)
Arterial bleeding	IA	90
Nonbleeding visible vessel	IIA	40–50
Adherent clot	IIB	10–25
Oozing	IB	<20
Flat pigmented spot	IIC	<10
Clean ulcer base	III	<5
Ulcer of posterior-inferior duodenal bulb (gastroduodenal artery)		[a]
Ulcer of lesser-curve gastric body (left gastric artery)		[a]

[a] Percent unknown but frequent finding at surgery for ongoing bleeding.
Note: Forrest grades IIC and III are considered low risk for rebleeding.
Data from NIH Consensus Conference: Therapeutic endoscopy and bleeding ulcers. *JAMA* 262:1369, 1989; Swain CP: Pathology of bleeding lesions, in Sugawa C, Schuman B, Lucas C (eds): *Gastrointestinal Bleeding*. New York, Igaku-Shoin, 1992, p 26; Lane L: Rolling review: upper gastrointestinal bleeding. *Aliment Pharmacol Ther* 7:207, 1993; Forrest JA, Finlayson ND, Shearman DJ: Endoscopy in gastrointestinal bleeding. *Lancet* 2:394–397, 1974.

endoscopy within 12 hours to reduce the blood transfusion requirements and length of hospital stay [14]. Therefore, endoscopy offered within 24 hours of upper GI bleeding presentation appears appropriate, with consideration for early endoscopy within 12 hours for patients with bloody NG aspirate or clinical suspicion for high-risk lesions [17]. The benefit of a repeat "second-look" endoscopy is an area of investigation, especially in the presence of factors associated with an increased risk of rebleeding (history of peptic ulcer disease, previous ulcer bleeding, presence of shock at presentation, ulcers >2 cm, large underlying bleeding vessel ≥2 mm diameter, and ulcers located in lesser curve of stomach or posterior/superior duodenal bulb) [18,19]. A meta-analysis in 2003 concluded that second-look endoscopy was associated with a decreased risk of recurrent bleeding but did not alter subsequent surgery rates or mortality [20]. Scheduled repeat endoscopy therefore is not routinely recommended, but can be considered on an individual case basis if clinical signs of recurrent bleeding are present or if there are questions about adequate hemostasis [21,22].

Enteroscopy

If a small bowel lesion is suspected after a negative upper endoscopy, a longer endoscope can be used to evaluate the proximal small bowel (push enteroscopy), which allows visual inspection and endoscopic hemostasis of bleeding lesions as far distal as the proximal jejunum [23]. Further evaluation of small bowel bleeding lesions can be provided by capsule endoscopy. Disadvantages of capsule endoscopy in acute bleeding include the lack of accurate localization of visualized lesions, and the fact that the test is not performed in real time [23]. Bleeding lesions beyond the reach of a push enteroscope can potentially be approached using single- and double-balloon enteroscopy, techniques that allow for visualization of most of the small bowel. Balloons at the endoscope tip and an overtube can be consecutively inflated and deflated while inserting and pulling out the endoscope to allow bowel to pleat over the overtube, thus allowing deep endoscope insertion into the small bowel, either through the mouth or the anus [23].

Sigmoidoscopy/Colonoscopy

When a distal lower GI bleeding source is suspected, early sigmoidoscopy may be helpful if the bleeding is not of a magnitude that would prevent adequate visualization. For most situations, however, colonoscopy replaces sigmoidoscopy in the diagnostic approach. Early colonoscopy provides a higher yield of the bleeding source compared to radiologic studies, especially when performed within 24 hours of presentation [24,25]. In patients with severe hematochezia and diverticulosis, urgent colonoscopy (within 6 to 12 hours of hospitalization or diagnosis of hematochezia) after rapid bowel purge can provide endoscopic treatment of diverticular hemorrhage and may prevent recurrent bleeding and decrease the need for surgery [26]. Only 20% of patients with lower GI bleeding, however, have a lesion amenable to endoscopic intervention [27]. Even when the exact cause of bleeding cannot be determined, colonoscopy may localize fresh blood to a segment of colon and direct further therapies such as angiotherapy or surgery. Patients with subacute bleeding or hemorrhage that has ceased can undergo adequate bowel preparation followed by semiurgent colonoscopy [28].

Radionuclide Bleeding Scan

The technetium-99m–labeled red blood cell scan performed at the bedside offers a noninvasive diagnostic approach to patients suspected of having GI bleeding originating beyond the reach of an endoscope, especially in unstable patients where bowel preparation or endoscopy cannot be safely performed. Although bleeding rates as low as 0.1 mL per minute can be detected by this method, the patient should have evidence of ongoing bleeding during the study [7]. If the test localizes bleeding, angiography or endoscopy (push enteroscopy, colonoscopy, double-balloon enteroscopy, capsule endoscopy) is needed to confirm the site, to further define the cause, and to offer therapy for ongoing bleeding [7]. If the test is negative, colonoscopy followed by capsule endoscopy is usually performed to evaluate potential colonic and small bowel bleeding sources [23].

Mesenteric Arteriography

Because a more rapid bleeding rate is necessary for a positive arteriogram (0.5 mL per minute), this procedure typically is performed after active bleeding is documented on a radionuclide bleeding scan [7]. However, because of the intermittent nature of bleeding and the variable timing of mesenteric arteriography, a positive red blood cell scan does not always result in a diagnostic arteriogram [7]. Arteriography is also useful for upper GI bleeding sources not visualized on upper endoscopy because of rapid bleeding or a blood-filled stomach.

THERAPEUTIC PROCEDURES FOR HEMOSTASIS

Evidence-based recommendations for the therapy of GI bleeding are summarized in Table 91.4.

Endoscopic Therapy (Endotherapy)

Endotherapy offers a convenient and expedient method for treatment of GI bleeding. Although endotherapy was primarily used for the treatment of upper GI and peptic ulcer bleeding, these modalities can also be applied to patients with lower GI bleeding [4,29–31]. Endotherapy is indicated for all patients with high-risk lesions because of the significant risk of persistent or recurrent bleeding (22% to 55%) and even death

TABLE 91.4

SUMMARY OF EVIDENCE-BASED FINDINGS FOR THERAPY OF GASTROINTESTINAL (GI) BLEEDING

- Octreotide infusion is an effective adjunct to endoscopic therapy for variceal bleeding [51,57,58].
- Endoscopic variceal band ligation is the therapy of choice for esophageal variceal bleeding [71].
- Identification of patients at high risk for rebleeding and mortality, and early diagnostic endoscopy with hemostatic therapy in patients with high-risk stigmata of rebleeding improve outcome in acute nonvariceal upper GI bleeding [8,9,11,101].
- Intravenous proton pump inhibitors, especially when administered as an infusion after a bolus dose, are superior to intravenous histamine-2 receptor antagonists in the reduction of rebleeding after successful endoscopic therapy in acute nonvariceal upper GI bleeding [105,106,108].
- Early colonoscopy for acute lower GI bleeding may identify a bleeding source more often compared to radiologic studies, but the choice of diagnostic test may not affect patient outcome [25].

if left untreated [3,4,32]. Randomized trials demonstrate that endotherapy for upper GI bleeding decreases further bleeding, shortens hospital stay, decreases transfusions, decreases emergency surgery, decreases mortality, and lowers costs [17]. Optimal therapy for adherent clots remains controversial; a recent meta-analysis demonstrated reduced rebleeding rates (RR 0.35, 95% CI 0.14–0.82) with endoscopic removal of clot and treating of the uncovered lesion, but no change in length of hospitalization, need for surgery, transfusion requirements, and mortality compared to only medical therapy [33–35].

The most common modalities used are thermal therapy (heater probe, bipolar probe, argon laser coagulation), injection therapy (epinephrine, hypertonic saline, sclerosing solutions), and mechanical therapy (hemoclips, endoloops, and band ligation). The treatment modalities are generally comparable with respect to efficacy and safety even when used in combination [3,36]. In a Cochrane database systemic review, addition of an alternative modality of endotherapy to epinephrine injection alone reduced further bleeding from 18.8% to 10.4% (OR 0.51), need for emergency surgery from 10.8% to 7.1% (OR 0.63), and mortality from 5% to 2.5% (OR 0.50) in high-risk ulcers [37]. These findings are similar to prior meta-analysis and mirrors published guidelines [38]. However, despite successful endotherapy, rebleeding can occur in up to 30% of patients (Table 91.3). The Baylor bleeding score, using patient age, number of illnesses, illness severity, site of bleeding, and stigmata of bleeding, has been proposed to predict the likelihood of rebleeding [39].

Angiotherapy

Intra-arterial vasopressin and/or embolization are used for angiographic control of various bleeding lesions [7]. A recent randomized study comparing urgent colonoscopy to radionuclide scanning followed by angiography demonstrated no differences in hospital stay and transfusion requirements, despite the fact that colonoscopy identified a definitive bleeding source more often. However, this study used only vasopressin infusion and did not use embolization as a mode of angiotherapy [24]. Vasopressin has potential to cause cardiovascular complications. Gelfoam and metal coil used for embolic therapy after superselective cannulation of the bleeding artery are effective because they can be delivered close to the terminal bleeding vessel and result in localized thrombosis with vessel occlusion. Embolization successfully controls bleeding in 52% to 94% of patients, with approximately 10% of these patients requiring repeat embolization for recurrent bleeding [40]. Angiotherapy may be a first-line treatment for uncontrolled lower GI bleeding from lesions such as diverticula and angiodysplasia, but its use in the upper gut is reserved for peptic ulcer bleeding that is not localized or controlled by endotherapy in the presence of a prohibitive surgical risk. Angiotherapy can be comparable to surgical intervention when endoscopic therapy fails for bleeding peptic ulcers. A retrospective analysis demonstrated no difference between embolization and surgery in recurrent bleeding (29.0% and 23.1%), additional surgery required (16.1% and 30.8%), and mortality (25.8% and 20.5%) despite an older population and higher prevalence of heart disease within embolization group [41]. The timing for the use of angiography and angiotherapy must be individualized and usually is a consensus decision by the involved physicians.

Surgical Therapy

The appropriate timing of when a surgeon should be involved in the care of a bleeding patient is physician and institution dependent, and ranges from an early team approach at presentation to involvement once the risk of significant morbidity and mortality are established after a poor response to medical and endoscopic therapy. Surgical intervention is an effective and safe alternative for patients with uncontrollable bleeding or those unable to tolerate additional bleeding [42]. Prior to surgical intervention, a repeat endoscopy for a patient with persistent or recurrent bleeding can be considered due to lower risks of side effects from endoscopy compared to surgery [43,44]. A possible exception may be ulcers >2 cm in hypotensive patients where the risk of rebleeding is extremely high with repeat endoscopic therapy [44,45].

Patients with massive hemorrhage that overwhelms the resuscitation effort may need to proceed directly to the surgical suite during ongoing resuscitation. If these patients are high-risk surgical candidates, angiotherapy for variceal bleeding or a percutaneously or surgically placed portal-hepatic shunt for variceal bleeding may be alternatives.

SPECIFIC BLEEDING LESIONS

Variceal Upper Gastrointestinal Bleeding

Portal hypertension, most frequently a consequence of cirrhosis, leads to portosystemic collateral circulations at the squamocolumnar junctions in the gut (i.e., gastroesophageal, anal, and peristomal), which progressively enlarge to form varices. Bleeding from gastroesophageal varices characteristically is brisk and typically presents as hematemesis, melena, or hematochezia in association with hemodynamic instability. The presentation may be less dramatic, as acute blood loss can be self-limited in 50% to 60% of cases [46]. One-half to two-thirds of patients with cirrhosis and acute upper GI bleeding have nonvariceal sources of hemorrhage documented by endoscopy [47,48]. Upper GI variceal bleeding occurs in at least 20% of all patients with cirrhosis who develop varices, with bleeding episodes carrying a mortality rate of at least 20% at 6 weeks [49,50]. Once active bleeding stops, the likelihood of recurrent variceal hemorrhage is 40% within 72 hours and 60% within 10 days if no definitive treatment is pursued [33]. Risk factors associated with variceal rupture include a portal pressure gradient greater than 12 mm Hg, large variceal size (greater than 5 mm), and progressive hepatic dysfunction [51]. Endoscopic findings that implicate esophageal or gastric varices as the bleeding source include the red sign, where one varix is brighter red than the others from microtelangiectasia (red-sign variants include red-wale marks, cherry-red spots, hematocystic spots, and diffuse redness of varix), and the white-nipple sign, in which a fresh fibrin clot may be seen protruding from a varix [51–53]. Endotracheal intubation protects the airway from aspiration of blood in obtunded patients, especially in the setting of massive bleeding [54]. Additional complications that must be addressed include alcohol withdrawal, aspiration, infection, and electrolyte imbalances.

Octreotide is a somatostatin analog that decreases splanchnic blood flow and portal pressure, controlling variceal bleeding in as many as 85% of patients [55–57] with an efficacy approaching that of endoscopic therapy (Table 91.4) and providing improved visibility during subsequent endoscopy [57–61]. Octreotide typically is administered intravenously as a bolus dose of 50 to 100 μg followed by continuous infusion of 25 to 50 μg per hour continued 3 to 5 days after diagnosis, but tachyphylaxis may limit efficacy of repeated bolus administrations [51,58–60,62–64]. Aside from transient nausea and abdominal pain with bolus doses, significant adverse effects from octreotide are rare [65]. Vasopressin, once widely used in this setting, has a significant cardiovascular side-effect profile and for this reason has been replaced by octreotide.

Infection (specifically spontaneous bacterial peritonitis) occurs in patients with cirrhosis and GI bleeding of any type in 25% to 50% of cases, leading to increased bleeding and mortality [66–68]. Antibiotic prophylaxis with a fluoroquinolone (norfloxacin or ciprofloxacin) in all cirrhotics with GI hemorrhage reduces the rate of bacterial infections and improves survival [69,70]. Intravenous ceftriaxone is an alternative for patients with advanced cirrhosis or when quinolone-resistant organisms are suspected [51].

Endoscopic band ligation has gained acceptance as the preferred endoscopic treatment for patients with bleeding esophageal varices, with rapid obliteration of varices, and low rates of complications and rebleeding (Table 91.4) [51,71]. Endoscopic variceal sclerotherapy (injecting a sclerosing solution into the variceal lumen or into the adjacent submucosa), although successful in controlling variceal bleeding, is associated with a 20% to 40% incidence of complications, and has largely been relegated to a second-line therapeutic modality [51,72]. Complications of band ligation include recurrent bleeding from treatment-induced esophageal ulcers, stricture formation, esophageal perforation, and acceleration of portal hypertensive gastropathy [72,73]. Repeat variceal band ligation is performed at 2- to 3-month intervals until varices are obliterated, as this approach reduces the incidence of rebleeding [51].

Gastric varices are detected in approximately 20% of patients with portal hypertension, but can also occur from splenic vein thrombosis. Gastric varices bleed less often, but blood loss can be more substantial compared to esophageal varices [74]. When available, endoscopic injection of a tissue adhesive such as butyl cyanoacrylate is effective, with hemostasis rates approaching that of TIPS with fewer recurrences [51,75,76]. Complications include a propensity for embolic phenomenon posttreatment, including massive pulmonary embolism [77]. Gastric variceal hemorrhage dictates earlier consideration of nonendoscopic therapeutic approaches such as transjugular intrahepatic portosystemic shunt (TIPS) placement. Embolization of the short gastric veins and varices is a potential management option for isolated gastric varices. In the setting of splenic vein thrombosis, splenectomy may be an appropriate therapy.

A TIPS (an iatrogenic fistula between the hepatic vein and portal vein) decreases portal pressure gradient to less than the 10 mm Hg necessary for the formation of esophagogastric varices [78,79]. TIPS commonly is recommended if esophageal variceal bleeding recurs after two or more endoscopic attempts at therapy [80], if active bleeding is not responsive to variceal ligation or sclerotherapy, or as first-line treatment for gastric variceal bleeding [51]. Complications include transient deterioration of liver function, new or worsened hepatic encephalopathy (25%), and shunt insufficiency from thrombosis or stenosis [79]. When placed in an emergency setting to control active bleeding, a 10% in-hospital mortality and 40% 30-day mortality have been reported [79,81–83].

Surgically created shunts reliably control acute bleeding (>90%) and prevent rebleeding (<10%) [84–87] but are limited by high operative mortality and postprocedure encephalopathy. Therefore, surgical shunts are only considered in well-compensated cirrhotic patients with good long-term prognoses [87].

Esophageal or gastric balloon devices may be used for direct tamponade of the bleeding source when definitive therapy is not immediately available. There are two basic types of balloon tubes: those with gastric and esophageal balloons (Sengstaken–Blakemore and Minnesota tubes), and those with a large gastric balloon alone (Linton–Nachlas). The incidence of rebleeding is expectedly high. Other complications (aspiration, balloon migration, airway occlusion, perforation, pressure necrosis) occur in 15% to 30% of patients, including death in 6% [88,89]. Instructions for correctly placing and maintaining a specific balloon device are included as a product insert and should be reviewed before balloon use.

Peptic Ulcer Bleeding

The most important etiologic factors for peptic ulcer disease are *H. pylori* infection and NSAID use. Although the role of *H. pylori* infection in ulcer formation is established, its exact role in precipitating ulcer bleeding is controversial [90–92]. With long-term NSAID use, there is a greater risk of gastric ulceration compared to duodenal ulceration. Bleeding risk varies depending on NSAID dose and agent used. Other cofactors, including older age, a history of past peptic ulcers (especially with ulcer bleeding), and a history of coronary disease, may be independent risk factors for ulcer bleeding [93,94]. Population-based studies have suggested that ulcer formation and bleeding occur even with COX-2 inhibitors, albeit at a lower rate [95]. Both COX-2 inhibitors and their nonselective analogs are associated with increased risk of ulcer bleeding when taken in conjunction with anticoagulants such as warfarin [96]. This risk with nonselective NSAIDs and anticoagulation taken together may be as high as 13 times that of patients taking neither NSAIDs nor anticoagulants [97]. Less than 1% of peptic ulcers result from hypersecretory states such as Zollinger–Ellison syndrome. In a proportion of patients, the disorder remains idiopathic, either because of inability to demonstrate *H. pylori* or lack of a history of obvious NSAID use.

Although 80% or more patients with acute GI bleeding eventually stop bleeding [98], it is important to recognize factors associated with higher risk for morbidity and mortality, including older age, large ulcer size (more than 2 cm), large-volume bleeding, and onset of bleeding while hospitalized (Table 91.1). Other prognostic information can be obtained from endoscopy findings, which should detail whether stigmata of recent bleeding (active bleeding, nonbleeding visible vessel, adherent clot, flat pigment spots) or no stigmata (clean ulcer base) were found in association with the ulcer (Table 91.3). These criteria can be used to predict rebleeding and the need for therapeutic intervention [32,98–100]. Patient age, hemodynamic parameters, comorbidities, and endoscopic findings have been compiled into scoring system by Rockall et al. [101] and Blatchford [4]. The Rockall score (Table 91.2) has been validated as a predictor of short-term mortality, but not recurrent bleeding [9].

In vitro data suggest that gastric acid plays an important role in impairing platelet aggregation, clot lysis, and increased fibrinolytic activity that is reversible at pH values above 6 to 6.5 [102–104]. Proton pump inhibitors (PPIs) can effectively raise gastric pH >4.0 but their ability to elevate pH to >6.0 is unclear [102]. However, these differences in gastric pH may not translate into clinical benefit. In contrast to histamine-2 receptor antagonists, PPIs have been established as beneficial in acute nonvariceal upper GI bleeding (Table 90.4), with a rapid increase in gastric pH, especially with IV PPI, when a mean pH of 6 is reached approximately 1 hour sooner than oral PPI [105]. A recent Cochrane meta-analysis reaffirmed the established understanding that IV PPI therapy in the setting of peptic ulcer disease decreased rebleeding rates (OR 0.40, 95% CI 0.24–0.67), need for urgent surgery (OR 0.50, 95% CI 0.33–0.76), and risk of death (OR 0.53, 95% CI 0.31–0.91) [106]. Intravenous PPI therapy upon presentation (when compared to IV PPI therapy initiated after endoscopic therapy) decreases the need for endoscopic therapy but not rebleeding rates, blood transfusion requirements, or mortality, a result supported by meta-analysis [107,108]. This approach has been demonstrated to be cost effective, reducing need for endoscopic therapy by 7.4% [109].

Therefore, the current clinical practice is to administer intravenous PPI therapy at presentation of acute upper GI bleeding. Intravenous PPI dosing regimens continue to be debated. A pooled randomized controlled trial suggested that IV bolus followed by continuous infusion decreased rebleeding rates and need for surgery compared to bolus dosing alone [110], leading recent reviews in the topic to suggest a regimen of IV PPI (80 mg bolus dose plus continuous infusion at 8 mg per hour) for 72 hours after endoscopic therapy of nonvariceal upper GI bleeding for any patient with a high-risk Forrest grade bleeding lesion [4]. Oral administration can be substituted after the initial intravenous period once oral intake is resumed.

Mallory–Weiss Tear

A Mallory–Weiss tear represents bleeding from a mucosal disruption at the area of the esophagogastric junction and is found in approximately 5% to 15% of cases of upper GI bleeding. The classic history is a patient with vomiting of nonbloody gastric contents followed by hematemesis, although this presentation is variable (29% to 86%) [111]. Blood with the initial emesis does not exclude the diagnosis. The great majority of patients (80% to 90%) bleeding from a Mallory–Weiss tear stop bleeding without therapeutic intervention, and rebleeding rates are low (less than 5%). Endoscopy offers diagnosis and the option for endotherapy; rarely nonendoscopic measures such as angiography and embolic therapy are required.

Angiodysplasia

Angiodysplasia lesions are small (3 to 15 mm) vascular mucosal abnormalities that can cause GI bleeding from the stomach, small bowel, or colon. Bleeding upper GI lesions frequently occur in patients with chronic renal failure [112,113], whereas vascular heart disease is associated with colonic lesions [114]. The character of the bleeding usually is subacute and recurrent rather than massive. Angiodysplasia typically is diagnosed at endoscopy; bleeding colonic angiodysplasia lesions can also be detected with angiography. Angiodysplasia lesions are the most frequent finding in the small bowel on wireless capsule endoscopy performed for evaluation of obscure GI bleeding. Endoscopic thermal therapy typically is successful in obliterating the lesions [115]. When large lesions are encountered, the periphery is cauterized first to obliterate the feeder vessels, and the center of the lesion is treated last [116]. Angiotherapy and surgery can be used to treat bleeding vascular lesions.

Dieulafoy's Lesion

Dieulafoy's lesion, an unusual cause of massive bleeding, represents a mucosal defect, not an ulcer, that exposes an end artery of the same caliber as its feeding submucosal artery [117]. The lesions are typically located in the gastric cardia/proximal stomach but are rarely found in the duodenum and other parts of the GI tract including the colon and rectum [118]. Bleeding often is massive and recurrent yet difficult to diagnose. The site is minute, innocent-looking, and frequently not appreciated at endoscopy once bleeding has stopped. Upper endoscopy can offer diagnosis and treat a lesion that was previously considered amenable only to surgical resection [119]. Endoscopic band ligation is one method that has been successful for hemostasis [120].

Colonic Diverticular Bleeding

Bleeding colonic diverticula are the most frequent cause of lower GI bleeding, but a definitive diagnosis (e.g., finding stigmata of recent bleeding) is established in only 20% of patients with hematochezia and colonic diverticula [121]. Diverticular bleeding demonstrated by angiography usually is localized to the right colon, whereas the left colon is the more common location when colonoscopy is performed as the diagnostic study (descending colon, 21%; rectosigmoid, 35%) [122,123]. The character of diverticular bleeding invariably is bright red or maroon blood per rectum, sometimes associated with orthostasis or hypotension. The majority of patients stop bleeding spontaneously, but approximately 20% to 30% rebleed.

Urgent colonoscopy after a rapid colonic purge (more than 4 to 6 hours) is recommended as an option in patients with ongoing bleeding, once the patient is resuscitated and hemodynamically stable [29,31]. However, a recent randomized controlled study failed to demonstrate an outcome benefit between urgent colonoscopy and radiologic studies for localization of bleeding, despite a higher likelihood of finding the bleeding source in the urgent colonoscopy group (Table 90.3) [24]. When a bleeding diverticulum is identified by the finding of a visible vessel or a pigmented protuberance [123], epinephrine injection, thermal contact therapy, or hemoclip application can be considered [30,31,124]. One study demonstrated that visualized diverticular bleeding treated with endoscopic therapy had no recurrent bleeding during a 30-month follow-up compared to 53% of patients with medical therapy alone [31]. Surgical intervention, either segmental or subtotal colectomy, is required in 18% to 25% of patients requiring blood transfusion [125]. Angiotherapy with vasopressin infusion or embolization after superselective cannulation of the bleeding vessel is an alternative approach in patients unstable for surgery.

There is limited evidence that endoscopic therapy may prevent recurrent bleeding and the need for surgery [31]. Alternatively, in patients who have stopped bleeding, elective colonoscopy can be performed during the same hospital stay, after adequate bowel preparation.

Aortoenteric Fistula

The key to recognizing an aortoenteric fistula is inclusion within the differential diagnosis of every patient with bleeding and a history of aortic graft surgery. Although fistulas can occur rarely between a native aortic aneurysm and the intestinal lumen, they more commonly occur in patients who have undergone abdominal aortic graft surgery (0.5% to 2.4%) [126]. This communication with resultant bleeding presents, on average, 4 years after the surgery. The point of intestinal breach can be anywhere from the esophagus to the colon, but occurs most often in the third duodenum (75%). A massive bleeding episode may be preceded by a small "herald bleed" that stops spontaneously. The interval between the first event and the exsanguinating hemorrhage can be hours, weeks, or months (average, 1 to 3 weeks). Making the diagnosis is difficult, but upper endoscopy is useful in excluding the diagnosis by identifying another lesion that is actively bleeding or has stigmata of recent bleeding. Endoscopic visualization of the graft eroding through the intestinal wall is diagnostic but uncommon. In some cases, computed tomography of the abdomen can identify graft abnormalities such as air–fluid levels that may indicate an enteric communication [127]. Angiography has not usually been helpful in the diagnosis unless bleeding is ongoing. If available, a vascular surgeon and an interventional radiologist should be part of the evaluating team. Graft repair surgery or an endovascular approach may be required for a confirmed diagnosis, and exploratory surgery likely is necessary for a presumed diagnosis of a fistulized or infected graft site.

CHAPTER 92 ■ STRESS ULCER SYNDROME

SONAL KUMAR, CHANDRA PRAKASH GYAWALI AND GARY R. ZUCKERMAN

Stress ulcer syndrome refers to the acute onset of upper gastrointestinal (GI) bleeding, usually from proximally located gastric ulcers and erosions, in patients admitted to an intensive care unit (ICU) for other illnesses. Gastric mucosal erosions have been found at protocol endoscopy within hours of ICU admission [1–4], typically without clinical bleeding at this early stage, and sometimes are referred to as *stress-related mucosal disease*. Descriptions of acute ulcerations of the intestines in the setting of acute burns date back more than 150 years [5]. The "stress" tag dates back to 1950 [6] and refers to extreme physiologic stress during critical illness that necessitates an ICU admission. Stress ulcer syndrome has been related temporally to a number of acute disorders including burns [3,7], cerebral lesions, stroke [4,8], various surgical procedures [1,9,10], and other acute medical illnesses found in an ICU [2]. The goal of management is prophylaxis, preventing the formation of the early acute gastric precursor lesions and/or preventing progression to clinically significant GI bleeding.

CLINICAL CHARACTERISTICS AND PRESENTATION

Stress ulcers frequently are asymptomatic and come to clinical attention only when they manifest bleeding. Progression to stress ulcer syndrome (SUS) (i.e., clinical bleeding or intestinal perforation) is uncommon. When it occurs, GI bleeding typically presents within 14 days of the onset of physiologic stress or ICU admission [11]. Hematemesis, gross blood from the nasogastric tube, and melena are the usual presentations of SUS [1–4,12,13]. The true incidence of overt GI bleeding resulting from stress ulceration is difficult to ascertain and varies depending on the definition of bleeding and the category of ICU patients. The finding at preemptive endoscopy of a small amount of blood adjacent to an ulcer without clinically evident overt bleeding has been noted in 22% to 36% of ICU admissions [2,3]. Significant stress ulcer bleeding occurs in 2% to 7% of critically ill patients [14,15]. Patients with thermal injury from burns or with acute intracranial disease including head trauma and coma appear to be at increased risk of developing stress ulcer–related bleeding [3,12]. Evidence is surfacing that the incidence of stress ulcer bleeding is decreasing, from as high as 22% in the 1970s to 1.6% to 6.0% of patients admitted to ICUs in more recent studies [3,16–19]. Our recent experience suggests that SUS now occurs in less than 1% of ICU admissions [20]. This may be related to the common use of prophylactic agents and improved care of critically ill patients in the present-day ICU setting.

Stress ulceration with clinically significant bleeding is associated with a mortality rate as high as 50% to 80% [16–19,21], although death often is a result of the underlying disease and not directly linked to GI bleeding [16]. Thus, stress ulcer bleeding may serve more as a marker for the severely ill patient having a cascade of complications rather than represent a unique clinical entity.

RISK FACTORS FOR STRESS ULCER SYNDROME

Clinical risk factors commonly associated with SUS include mechanical ventilation, coagulopathy, major surgery, hemorrhagic shock, hypotension, trauma, and sepsis [11]. A statistically significant predisposition to stress ulceration has been demonstrated in ICU patients with coagulopathy or a requirement for prolonged mechanical ventilation (over 48 hours) [16,17]. Hypotension and shock also are more frequent among patients with bleeding attributed to stress ulceration but do not reach statistical significance as independent risk factors [16]. Patients with thermal injury from burns (>35% body surface area) and patients with acute intracranial disease including head trauma and coma also are at increased risk of having stress ulcers (Curling's and Cushing's ulcers, respectively) [22,23]. Conditions that present a low risk for SUS include myocardial infarction, congestive heart failure, arrhythmias, chronic renal failure on dialysis, chronic obstructive pulmonary disease, and malignancy [11]. Recent studies emphasize that although the incidence of GI bleeding increases with up to two risk factors, additional risk factors do not further increase bleeding potential [24].

PATHOPHYSIOLOGY

Stress ulcer is a misnomer in that many of the lesions appear as shallow mucosal erosions without the depth of an ulcer (Table 92.1). The earliest mucosal changes have been described in the most proximal parts of the stomach [25], but the process can eventually involve the distal stomach and duodenum [17,20]. Early mucosal changes include pallor, mottling, and submucosal petechiae which coalesce to form superficial linear erosions and ulcers. This can progress to diffuse mucosal damage with bleeding and in rare cases, perforation. On endoscopy, mucosal erosions have been found as early as 5 hours after ICU admission, and most are evident within 72 hours. Within 24 hours of ICU admission, they have the appearance of small (1 to 2 mm), round, shallow erosions, and by 48 hours, the lesions can be larger (2 to 25 mm), deeper, and associated with a clot. When patients bleed, 10 or more gastric mucosal erosions usually are observed at endoscopy [25,26]. The result is a diffuse area of involvement that can result in a spectrum of manifestations ranging from oozing of blood to massive hemorrhage or perforation [11,16].

Although the precise etiology of stress ulceration is not known, a number of factors have been implicated and studied in animal models. Animal studies using endoscopic and pathologic analyses have demonstrated progressive gastric mucosal injury from the physiologic stress of induced shock [27], a process that has been observed in humans under similar stress [1,27,28]. Gastric acid, but not hypersecretion, appears to be an essential prerequisite for the development of stress ulceration [29,30]. The classic lesion has been associated with a

TABLE 92.1

CHARACTERISTICS OF STRESS ULCER SYNDROME

Endoscopic evidence of gastric erosions within 72 h of intensive care unit admission
Multiple ulcers located in the proximal stomach, in contrast to peptic ulcers, which typically are found in the distal stomach
Duodenal ulcers uncommon; when present, usually associated with proximal gastric ulcers
Onset of hemorrhage within 14 d of intensive care unit admission
Abdominal pain unusual except in the infrequent setting of gastroduodenal perforation

normal or even decreased intraluminal gastric acid secretion [31–33], suggesting that a breakdown in the mucosal defense mechanism must also be present for stress ulceration to occur. Mucosal ischemia is thought to be the inciting event in the pathogenesis [31,32]. In experimental models, stress causes a decrease in gastric mucosal blood flow, resulting in decreased delivery of oxygen and nutrients and leading to a deficit in aerobic metabolism and high-energy phosphate compounds [30,34,35]. Diminished intramucosal blood flow decreases the availability of systemic bicarbonate to buffer back-diffused hydrogen ions, thereby allowing a fall in the intramural gastric pH [30,31,36]. Mucosal ischemia and subsequent reperfusion result in the formation of toxic oxygen-derived free radicals and superoxides [33,37,38] while decreasing the synthesis of cytoprotective prostaglandins [38], thereby creating a favorable scenario for mucosal damage.

Factors such as elevated gastrin and pepsin levels, increased intraluminal bile and urea concentrations, and decreased gastric motility from enhanced vagal stimulation appear to be contributory to the development of a stress ulcer but are inadequate by themselves to induce the lesion [31,39]. The impact, if any, of *Helicobacter pylori* on the risk and development of stress ulcer is unknown. *H. pylori* seropositivity has been found to be lower in patients with stress ulcer bleeding when compared with controls [40]. In fact, it is possible that some of the *H. pylori*–positive cases diagnosed as stress ulcer actually represent *H. pylori*–associated peptic ulcer disease.

PROPHYLAXIS

The logic of prophylaxis lies in the assumption that the formation of stress ulcers can be prevented, or that, once formed, the progression from ulcer to bleeding or perforation can be halted. Several studies have suggested that the risk of bleeding from stress ulcer and the overall prognosis are related primarily to the severity of the underlying disease [2,12,41,42], and aggressive management of the underlying disease while attempting to maintain visceral perfusion should always take precedence. If those patients at risk can be identified sufficiently early in their ICU stays, the administration of any standard prophylactic agent shortly after ICU admission decreases the rate of stress ulcer bleeding. The international guidelines of early goal-directed therapy also include stress ulcer prophylaxis with histamine-2 receptor antagonists (H2RAs) or proton pump inhibitors (PPIs) as part of initial management in patients with severe sepsis or septic shock [43]. Decreasing or neutralizing gastric acid is the most common prophylactic approach, and antacids and H2RA initially fulfilled this role effectively. The ideal pH threshold and the duration of pH elevation required to prevent bleeding are not known. In fact, stress ulcer bleeding is not always pH dependent, as bleeding has been noted in patients with a mean gastric pH greater than 4.0 [44].

TABLE 92.2

RECOMMENDED AND PUTATIVE CATEGORIES OF ICU PATIENTS WHO COULD BENEFIT FROM STRESS ULCER PROPHYLAXIS

ICU patients with
Coagulopathy
Requirement for mechanical ventilation for >48 h
Head injury (with Glasgow Coma Score of ≤10)
Burns involving >35% of body surface area
Multiple trauma, including spinal cord injuries
Partial hepatectomy
Peri- or postoperative status, especially after hepatic or renal transplantation
Acute hepatic failure
Acute renal failure
History of gastric ulceration or bleeding during year before admission

ICU, intensive care unit.

More recently, PPIs have been shown to be comparable with H2RA [45], and an orally administered PPI has been approved by the Food and Drug Administration (FDA) for prophylaxis [14]. The difficulties of evaluating and comparing studies involving prophylaxis of stress ulcers include the variability in patient populations, severity of disease, definition of bleeding, and the type and method of drug delivery.

A national survey of clinicians demonstrated a lack of consensus in the use of stress ulcer prophylaxis, with many patients receiving prophylaxis for an extended period without clear-cut indications or documented benefit [46]. Development and implementation of institution-specific guidelines (taking into account drug cost and availability), with prophylaxis reserved for patients at highest risk for stress ulcer bleeding (Table 92.2), has been demonstrated to increase appropriateness of prophylaxis and decrease cost of care without increasing the incidence of stress ulcers or frequency of clinically significant GI bleeding [47–49].

Regimens for Prophylaxis

Histamine-2 Receptor Antagonists

H2RAs are commonly used agents for the prophylaxis of stress ulcers [46]. They have been found to be comparable or superior to antacids in preventing bleeding, and antacids and H2RAs are superior to no treatment or placebo [50–52]. Intravenous (IV) H2RA prophylaxis confers a significantly lower bleeding rate from stress ulceration in critically ill ventilated patients [53]. H2RAs are administered intravenously as a standard intermittent bolus or by continuous infusion, though continuous infusion more effectively maintains the desired gastric pH [54]. Nevertheless, studies using intermittent bolus IV doses of H2RA achieved the goal of prevention of bleeding as well as studies using continuous titrated dosing [21]. This would suggest that 24-hour pH control is not necessary for the prophylactic effect. Of note, patients with a creatinine clearance of less than 30 mL per minute should receive half the recommended dose, and caution should be exercised in patients with thrombocytopenia [54].

Proton Pump Inhibitors

PPIs block the final pathway for acid secretion by irreversibly inhibiting H+/K+-ATPase in gastric parietal cells. They can be administered enterally or intravenously at once-daily dosing, provide predictable and sustained pH control, and have been demonstrated to be safe and effective in stress ulcer prophylaxis [50–52,55]. Omeprazole administered orally as a suspension at a dose of 40 mg daily was effective in preventing clinically significant GI bleeding in trauma patients requiring mechanical ventilation and with at least one other risk factor for stress ulcer development [50]. IV PPIs may also be effective for stress ulcer prophylaxis, although studies of patients at risk for stress ulcer bleeding are lacking. A randomized, double-blind study utilizing immediate-release omeprazole suspension (40-mg dose followed in 6 to 8 hours with a second 40-mg loading dose and 40 mg daily thereafter via nasogastric or orogastric tube), compared with IV cimetidine (50-mg bolus and 50 mg per hour thereafter), showed that the immediate-release omeprazole suspension was as effective as cimetidine in preventing upper GI bleeding (a "noninferiority" analysis utilizing cimetidine as the benchmark). The omeprazole suspension was also more effective than IV cimetidine in maintaining gastric pH greater than 4 in these critically ill patients [14]. Another recent randomized, "noninferiority" study compared multiple doses of IV pantoprazole to continuous infusion cimetidine, finding effective control of gastric pH and no episodes of clinically significant upper GI bleeding, and demonstrated similar outcomes with either prophylactic approach [52]. Trends in recent years have been toward the use of some form of prophylaxis in patients at risk, more often PPIs than H2RAs [20,56].

Antacids

Antacids can be administered through a nasogastric tube every 1 to 2 hours to control gastric pH. Studies evaluating the efficacy of antacids in the prophylaxis of stress ulcer have emphasized maintaining gastric intraluminal pH above 3.5 to 4.0 to prevent bleeding [41,57]. This involves the time-consuming process of frequent monitoring of gastric pH by gastric fluid aspiration or using indwelling probes and titrating antacids to pH findings. In fact, the optimal gastric pH level is unknown, the practice of titrating gastric pH is not of proven necessity for adequate prophylaxis, and the need for continuous 24-hour pH control does not appear to be critical. Antacids may cause diarrhea, may be contraindicated in renal failure, and may affect bioavailability of oral medications. In spite of these disadvantages, antacids have demonstrated efficacy in the prevention of stress ulcer bleeding [41,57]. Various antacids have had previous FDA approval for stress ulcer prophylaxis, and the doses varied with the preparation.

Sucralfate

Sucralfate is the aluminum salt of sulfated sucrose and does not affect gastric acidity. Some studies report efficacy similar to H2RA in the prevention of stress ulcer bleeding [58,59]. The primary mechanism of action likely is related to its intestinal mucosal cytoprotection and the ability to preserve microvascular integrity while coating early mucosal erosions and protecting them from further acid and pepsin damage. Its use may be associated with a lower risk of nosocomial pneumonia at a lower cost to the patient [60–65], although more recent data suggest no increase in the incidence of pneumonia with H2RA [66]. Sucralfate usually is administered in the form of slurry through a nasogastric tube at a dose of 4 to 6 g per day. Sucralfate can be incorporated into liquid slurry by dissolving a 1-g tablet in 5 to 15 mL of water. Sucralfate suspension (Hoechst Marion Roussel, Kansas City, MO) currently is available at the strength of 1 g in 10 mL; however, equivalence of the suspension to similar doses of sucralfate tablets has not been demonstrated. Although generally safe for short-term use in critically ill patients [67], toxic plasma aluminum levels may result in patients with impaired renal function [68], and therefore sucralfate is not generally recommended for "first-line" prophylaxis.

TABLE 92.3

SUMMARY OF EVIDENCE-BASED FINDINGS FOR PREVENTION OF STRESS ULCER SYNDROME

- Intravenous histamine-2 receptor antagonists (cimetidine, ranitidine) significantly reduce the incidence of clinically important gastrointestinal bleeding in mechanically ventilated patients, without increasing the risk for ventilator-associated pneumonia [53]. Although cimetidine has been shown to be an effective prophylactic agent, its safety profile (various drug–drug interactions, thrombocytopenia) has decreased its clinical usage.
- Sucralfate administered by nasogastric tube also reduces the bleeding risk, but intravenous ranitidine may be superior [53,69].
- Omeprazole administered orally or through a nasogastric tube (particularly immediate-release formulation) may be as effective as intravenous cimetidine infusion in preventing stress ulcer bleeding [14,51].
- Pantoprazole IV effectively controls gastric pH and may prevent stress ulcer bleeding [49].
- The results of "noninferiority" studies of a few PPIs have been extrapolated to the usage of all PPIs in many ICUs.

ICU, intensive care unit; PPIs, proton pump inhibitors.

Other Measures

There is evidence that stress-related upper GI bleeding may be reduced by enteral feeding [51,53,69]. Prostaglandins; free-radical scavengers, such as dimethylsulfoxide and allopurinol; and the bioflavonoid meciadanol also have been used in stress ulcer prophylaxis with varying results [70–72]. The use of these novel therapies over conventional prophylactic agents currently is not recommended, although some show promise for stress ulcer prophylaxis in limited studies [47].

A summary of evidence-based findings for management of SUS is provided in Table 92.3.

Complications of Prophylaxis

Although therapeutic agents are superior to no prophylaxis in preventing stress ulcer bleeding, there is a growing concern about potential complications of prophylaxis, particularly nosocomial pneumonia. The incidence of nosocomial pneumonia is approximately 20-fold higher in mechanically ventilated patients, in whom the mortality rate from the pneumonia can be as high as 60% [73,74]. Gastric alkalinization and colonization with Gram-negative bacilli is thought to play a causal role [74,75], rendering pH-altering drugs potentially disadvantageous. Although a persistently alkaline gastric environment increases the likelihood of bacterial colonization, it is unclear if this is influenced by the pharmacologic agent used for stress ulcer prophylaxis, as several meta-analyses have provided conflicting results [76–78]. Studies show a higher incidence of nosocomial pneumonia in patients treated with antacids when compared with sucralfate, a drug that does not alter the gastric pH and appears to have bactericidal properties [79,80]. Other

studies and one meta-analysis have shown no statistically significant difference in the rate of pneumonia in sucralfate- and H2RA-treated, mechanically ventilated patients [58,59,65, 81–83]. Thus, the relationship of stress ulcer prophylaxis and nosocomial pneumonia needs further clarification before one prophylactic agent can be recommended over another.

Additional issues with stress ulcer prophylaxis include patients being inappropriately continued on acid-suppressive therapy after transfer out of the ICU. A recent study demonstrated that as many as 86% of patients remained on either PPI or H2RA after transfer from the surgical ICU, and 24% of patients were discharged from the hospital with continuation of the medications in the absence of risk factors for SUS-related GI bleeding [84]. There has been no evidence to suggest that noncritically ill patients are also at risk for developing stress ulcers, and continuation of prophylaxis is likely inappropriate [56,85]. In addition to potential side effects of taking medications, there is also a significant economic impact of overutilization of stress ulcer prophylaxis, both in the noncritically ill patient population and in patients on discharge from the hospital [86]. Therefore, it is essential to identify patients at risk for developing stress ulcers and utilize prophylaxis in only that setting.

THERAPY FOR ESTABLISHED BLEEDING

Once clinically significant bleeding commences, upper GI endoscopy should be performed as soon as possible to establish the diagnosis and to determine the need for endoscopic hemostasis. Although multiple stress ulcers or erosions have the potential to bleed at the same time, it is not unusual for only one or two ulcers to be actively bleeding and to respond to endoscopic therapy (authors' personal experience, Gary R. Zuckerman, C. Prakash Gyawali). If endoscopic measures fail, it may be necessary to resort to angiography with intra-arterial vasopressin or embolization, as used in peptic ulcer bleeding. Surgical therapy should be reserved for patients with continuing life-threatening hemorrhage that is unresponsive to endoscopic therapy. Surgical procedures that leave significant amounts of gastric mucosa intact are associated with a recurrent bleeding rate that approaches 50%, mainly because of the proximal gastric locations and multiplicity of the bleeding lesions [87]. The mortality associated with total gastrectomy in these critically ill patients approaches 100%, however. The addition of vagotomy may decrease the high rebleeding rate and has prompted the use of subtotal gastrectomy with vagotomy and oversewing of any ulcers in the residual stomach [88].

OUTCOME

The mortality rate for critically ill patients with or without stress ulcer bleeding varies in large part with the type and severity of the underlying disease [16]. Although mortality in ICU patients with stress ulcer bleeding can be as high as 80% [3,9,12,34], the relationship of stress ulcer bleeding and mortality is unclear. An earlier natural history study from a medical ICU that did not use prophylaxis found that the overall mortality rate for patients who bled was 90%, whereas it was only 13% for nonbleeders [16]. Meta-analyses of studies performed to evaluate stress ulcer prophylaxis have shown no effect on mortality with the use of antacids or H2RA [76,77]. One analysis found a reduced mortality rate with the use of sucralfate relative to antacids and a trend toward reduced mortality compared with H2RA [65], whereas another meta-analysis did not find any overall mortality advantage for sucralfate-treated patients [76].

The advantage, if any, of a specific prophylactic agent over any other or of a non–pH-altering drug over one that does affect gastric pH has not been clarified at this time. The choice of a prophylactic agent is influenced not only by one's interpretation of the scientific literature but also by the willingness of the ICU staff to adhere to a particular protocol for stress ulcer prophylaxis.

CHAPTER 93 ■ GASTROINTESTINAL MOTILITY IN THE CRITICALLY ILL PATIENT

FILIPPO CREMONINI, ANTHONY J. LEMBO, BRENNAN M.R. SPIEGEL AND INDER M. SINGH

The gastrointestinal tract is a series of coordinated organs that propels its contents through the precise regulation of neural, chemical, and endocrine signals. Although a detailed review of the physiology of motility is beyond the scope of this chapter, it is important for the critical care provider to understand that the closely coordinated movements of the gastrointestinal tract, from mouth to rectum, can frequently be disrupted and deranged in the setting of severe illness.

Unfortunately, the bowels are not a teleologic priority when systematic illness strikes. Rather, during severe illnesses, physiologic reserve shifts away from the gastrointestinal tract to critical organs such as the lungs, brain, and cardiovascular system, resulting in significant dysfunction of the gastrointestinal tract. This presents most often as delayed transit, or even bowel paralysis, which may occur at any level of the gastrointestinal tract causing gastroparesis or bowel ileus. These conditions can lead to a range of clinically significant consequences, including aspiration, erosive esophagitis, decreased oral intake, nosocomial pneumonia, abdominal pain and distention, obstipation, and even life-threatening bowel perforation.

Because alterations in bowel motility are extremely prevalent in the critically ill population, providers must be prepared to identify and treat these common, morbid, and sometimes fatal disorders. Although there has been surprisingly little research dedicated to understanding the pathophysiologic basis of motility abnormalities in the critically ill patient [1], there have nonetheless been several advances in the treatment of these disorders. This chapter will focus on the clinical presentations of the most common motility disorders in the critically ill patients, including gastroesophageal reflux disease (GERD), gastroparesis, ileus, and colonic pseudoobstruction and will review the current evidence supporting diagnostic and therapeutic approaches for these conditions.

GASTROESOPHAGEAL REFLUX DISEASE

Critically ill patients are especially prone to developing gastroesophageal reflux and related complications, particularly erosive esophagitis, which is one of the leading causes of inpatient upper gastrointestinal tract hemorrhage in mechanically ventilated patients, after stress-related mucosal disease [2,3]. GERD is particularly prevalent in the critically ill patient for several important reasons (Fig. 93.1). First, critically ill patients are often in the recumbent position, which promotes acid reflux [4–6] and reduces acid clearance from the esophagus. Second, many critically ill patients are intubated, sedated, or too ill to report symptoms of acid reflux. Significant reflux can thus go unrecognized until significant complications occur. This prolonged acid exposure is exacerbated in patients who are *nihil per os (nothing by mouth)*, in whom decreased swallowing leads to poor clearance of esophageal contents. Third, critically ill patients are more likely to have increased transient relaxation of the lower esophageal sphincter (LES), due to use of drugs (e.g., morphine, atropine, theophylline, barbiturates) and to the frequent use of indwelling nasogastric tubes [7–9]. Fourth, mechanically ventilated patients are prone to acid reflux and microaspiration, at least in part due to mechanical deformities of the upper esophageal sphincter created by the pressure of the endotracheal tube cuff [4]. Fifth, critically ill patients often develop concomitant gastroparesis (see following discussion) from a host of factors, which, in turn, favors retrograde flow of gastric contents toward the distal esophagus. Taken together, these multiple mechanisms concur to clinically significant acid reflux and to its related complications.

Several steps can be taken in the critical care setting to minimize complications of acid reflux in the critically ill patient. First, patients should be kept in the semirecumbent or upright position as often as possible. This maneuver can minimize acid stasis in the distal esophagus and improve emptying of stomach contents, thereby reducing complications of acid reflux [4,5]. The effectiveness of this maneuver in patients who are mechanically ventilated remains controversial [5,6]. Nevertheless, as positional changes are generally a low risk and easy to enact measure, it seems prudent to position patients in a semirecumbent or upright position when feasible and be wary when patients remain in the supine position for prolonged periods.

Another step is to minimize the use of nasogastric tubes. Data indicate that indwelling nasogastric tubes promote GERD and subsequent microaspiration of bacterially contaminated contents into the lower airways [7–9]. Thus, gastroesophageal reflux also can lead to nosocomial pneumonia [10,11]. Results from a small ($n = 17$) randomized trial suggests that the nasogastric tube size (i.e., 2.85 mm vs. 6.0 mm) does not appear to reduce GERD [9], although clearly this study was not powered to demonstrate statistically significant differences in clinically relevant outcomes (such as bleeding or pneumonia). Placement of a gastrostomy tube in mechanically ventilated patients may reduce GERD and potentially its complications, although such intervention is not without its own risks and side effects [12].

A final step is to minimize the use of medications known to relax the LES. Many of these agents (Table 93.1) are commonly used in the intensive care setting. It should be noted that while these agents are known to decrease LES resting pressure, the clinical significance on the development of complication of GERD including erosive esophagitis or upper gastrointestinal hemorrhage is unknown. Thus, the agents listed in Table 93.1 should not be avoided on the basis of theoretical concerns alone, assuming their use is otherwise medically justified.

Pharmacological therapy is often necessary especially in the intensive care unit (ICU) to reduce the potential complications of GERD. Treatment relies primarily on acid suppression. Traditionally, intravenous (IV) histamine-2 receptor antagonists (H2RAs) have served as the mainstay antisecretory therapy in the critical care setting. H2RAs are particularly useful for prophylaxis against stress-related mucosal disease [13] and are therefore primarily used for stress ulcer prophylaxis (as opposed to GERD prophylaxis) (see Chapter 92). However, IV

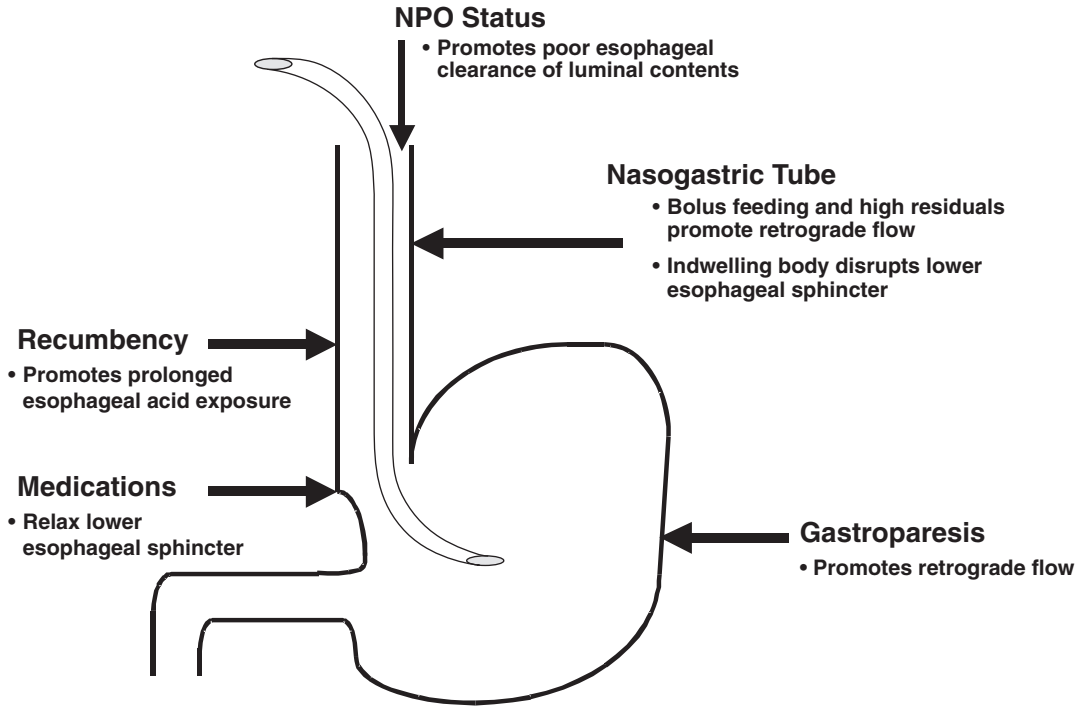

FIGURE 93.1. The combination of factors contributing to gastroesophageal reflux disease (GERD) in the critically ill patient. Patients in the intensive care unit setting are highly susceptible to each of these factors making GERD a prevalent problem. NPO, nothing by mouth.

proton pump inhibitors (PPIs) (pantoprazole, esomeprazole) have since replaced H2RAs as the antisecretory of choice in the hospital setting. IV PPIs have excellent effectiveness in reducing recurrent hemorrhage following endoscopic hemostasis for bleeding peptic ulcer [14]. Although there are limited data regarding their use for erosive esophagitis, experimental data have shown that IV PPIs produce potent and longer-lasting acid inhibition [15], making them the preferred antisecretory medication in patients at risk for GERD-related complications [16].

GASTROPARESIS

Gastroparesis, or delayed gastric emptying in the absence of mechanical obstruction, may lead to several complications in critically ill patients, including malnutrition, erosive esophagitis (as previously noted), and aspiration of gastric contents with resulting nosocomial pneumonia.

As with GERD, gastroparesis arises from a confluence of several common factors (Table 93.2) in the critically ill patient, including medications (especially narcotics and anticholinergic agents), autonomic dysfunction, postsurgical states, and endocrine abnormalities, among others.

Patients with gastroparesis typically present with nausea, vomiting, abdominal pain, early satiety, and postprandial bloating. In patients receiving tube feeding, high gastric residuals are a common early sign of delayed gastric emptying. Because the symptoms of gastroparesis are often nonspecific, the clinician should maintain a low threshold for considering the diagnosis. A combination of physical examination findings and imaging studies confirm gastroparesis and exclude competing diagnoses, including mechanical obstruction and mucosal diseases. On examination, patients with gastroparesis may demonstrate epigastric distention with tenderness but typically lack abdominal rigidity or guarding, signs of a potentially more ominous and acute diagnosis. The examiner should evaluate for a succussion splash by placing the stethoscope over the left upper quadrant while gently shaking the abdomen laterally by holding either side of the pelvis. A positive test occurs when a splash is heard over the stomach and favors the diagnosis of mechanical gastric outlet obstruction over gastroparesis. Of note, the maneuver is only valid if the patient has not ingested solids or liquids within the previous 3 hours.

Laboratory testing may help determine the underlying cause of the decreased motility. Serum electrolyte levels, serum glucose level, serum cortisol level, thyroid-stimulating hormone level, amylase, and white blood cell count (screen for infection) should be measured. A host of other tests can be used in the outpatient setting to investigate chronic gastroparesis (e.g., erythrocyte sedimentation rate [scleroderma, myopathies, lupus], urinary protein [amyloidosis], chest radiography [lung cancer with gastroparesis as a paraneoplastic syndrome], and antineuronal or anti-Hu antibodies [paraneoplastic gastroparesis]), but these are rarely useful in the critically ill patient.

Plain films of the abdomen should be obtained to evaluate for evidence of gastric distention and to screen for overt evidence of gastric obstruction. Upper endoscopy should be considered if there is suggestion of gastric outlet obstruction,

Median arcuate ligament syndrome

[a]This list is not comprehensive but is specifically relevant to the critically ill patient.

because significant amounts of retained food, feedings, and secretions can be found in the stomach even in the absence of an obstruction to the pyloric outlet. Additional imaging tests for the investigation of gastroparesis in the ICU setting are infrequently indicated. If the problem is suspected by the presentation, becomes a primary issue, and is not easily linked to other disorders in the ICU patient, then confirming the diagnosis by other methods may be merited once the patient leaves the ICU. The most accepted diagnostic test, usually performed in the outpatient setting, is a scintigraphic emptying study. Most centers use a 4-hour gastric emptying test, with a ^{99}Tc-labeled-egg meal. In health, gastric retention of more than 10% at 4 hours suggests delayed gastric emptying [17]. Alternative diagnostic tests include stable isotope-labeled breath tests, magnetic resonance imaging, catheter-based manometry, and newly developed wireless capsule-based manometry. Still, the simple finding of persistent high gastric tube residuals should be sufficient to formulate a presumptive diagnosis in the critically ill patient.

Once diagnosed, gastroparesis is treated by reversing known underlying causes of decreased motility, providing adequate nutritional support, and employing medical therapies to promote gastric motility and reduce gastric acid to prevent complications of GERD. Principles of nutritional support include using smaller volume, low-fat, and low-fiber meals or tube feeds [18]. Consultation with the nutrition or metabolic support services is often warranted to help select between available liquid caloric supplements. In general, parenteral nutrition should be avoided if possible. Rather, patients who need long-term nutrition support due to gastroparesis should be considered for a percutaneous endoscopically or radiologically placed jejunostomy tube [19], often placed in conjunction with a gastrostomy tube for venting of the stomach [20]. Surgical interventions should only be used as a last resort in patients with intractable nausea, vomiting, and malnutrition, and this has no place in the critically ill patient.

The currently available medications are unfortunately limited in both number and efficacy. With the removal of cisapride and tegaserod from the menu of available promotility agents, clinicians have limited options. Most authorities recommend metoclopramide, despite its neurologic side effects (e.g., akathisia) that impact up to 30% of users [21]. Reducing the rate of IV infusion may reduce frequency of neurological side effects. Metoclopramide has multiple actions, including coordination of antral, duodenal, and pyloric muscle function while simultaneously serving as a centrally acting antiemetic [22,23]. Metoclopramide can be administered orally, intravenously, rectally, and subcutaneously. In the critically ill patient, metoclopramide typically is dosed at 10 to 20 mg IV every 6 hours. The major disadvantage of IV bolus dosing is that plasma levels are often erratic, largely because levels peak rapidly and the half-life is short. Subcutaneous dosing (two to four times per day in 2-mL aliquots) has been promoted as an alternative route, as it is associated with more stable plasma levels [24]. Although the tardive dyskinesia side effects have been known for decades, the Food and Drug Administration (FDA) recently issued a "black box" warning in reference to metoclopramide, which indirectly has put some pressure on clinicians toward less use of this medication.

Erythromycin, an antibiotic with motilin-receptor agonist properties, also has promotility effects. Oral tablets generally have poor efficacy in gastroparesis [25], the preferred route of oral administration being liquid suspension at low doses of 125 to 250 mg twice daily. Erythromycin may be used in combination with metoclopramide for patients with an incomplete response to either agent alone. IV dosing of erythromycin (100 to 200 mg every 6 hours) improves gastric contractility by invoking high-amplitude gastric contractions [26]. It is particularly effective in diabetic patients and has also shown benefits in reducing high tube feed residuals [27]. Unfortunately, long-term use of erythromycin leads to tachyphylaxis from down-regulation of motilin receptors [25] and also is associated with antimicrobial resistance.

Nonpharmacologic therapies include gastric pacing and pyloric botulin toxin injection [28]. These options are currently available at limited centers but rarely used in critically ill patients.

ILEUS

Any disease state affecting neurohormonal mediators, vascular perfusion, electrolyte balance, and muscular contraction has the potential to affect the coordinated propulsive small and large intestinal motility, resulting in ileus. Virtually all causes of ileus can present in the critically ill patient. The postoperative state, inflammation, metabolic derangement, neurogenic impairment, and drug-induced aperistalsis are all common occurrences in the ICU. As a result of decreased impaired propulsive activity, patients develop obstipation and, eventually,

TABLE 93.3

DIFFERENTIATION OF ILEUS AND SMALL BOWEL OBSTRUCTION

Clinical feature	Ileus	Small bowel obstruction
Bowel sounds	Generally absent	High-pitched and active
Peritoneal signs	Less common	More common, although inconsistent
Involved bowel on radiograph	Small and large bowel dilated	Small bowel dilated
Rectal gas	Present	Absent
Air fluid levels	Absent	Present, although inconsistent
Luminal "cut point"	Absent	Present, although inconsistent

inability to tolerate enteral intake. Patients typically present with abdominal distention, nausea, vomiting, abdominal pain, and high tube feed residuals.

Distinguishing ileus from small bowel obstruction is critical, as prolonged mechanical obstruction can lead to bowel ischemia and peritonitis. Table 93.3 compares classical physical examination and radiographic findings of adynamic ileus and small bowel obstruction. These conditions share many clinical manifestations, including abdominal distention, obstipation, pain, vomiting, and decreased ability to tolerate oral intake. Peritoneal signs and auscultation of high-pitched bowel sounds favor the diagnosis of small bowel obstruction, whereas a silent bowel suggests ileus. Although the skilled clinician often can reliably distinguish small bowel obstruction from ileus on the basis of history and physical examination alone, plain abdominal radiographs may serve to confirm the clinical impression. Ileus typically is characterized by the presence of both small and large bowel dilatation, the presence of gas throughout the bowel and into the rectum, lack of a luminal "cut point" or caliber transition, and an elevated diaphragm. In contrast, small bowel obstruction typically presents with small bowel distention in the absence of colonic gas, a paucity of gas in the rectum, air fluid levels on upright positioning, and evidence of a luminal cut point. Despite the stereotypical features of small bowel obstruction and ileus, plain film imaging does not always provide a definitive diagnosis, as long-standing ileus or partial small bowel obstruction may appear similar on abdominal imaging. In addition, late-stage mechanical obstruction may lead to exhaustion of intestinal propulsive activity, resembling adynamic ileus without high-pitched bowel sounds and a similar air distribution pattern on plain abdominal X-rays. In cases in which the plain films are inadequate, contrast-enhanced computed tomography (CT) should be considered [29]. A CT scan may provide additional information to complement the clinical picture, such as the presence or absence of intra-abdominal inflammation (e.g., pancreatitis, abdominal abscess) or retroperitoneal pathology.

Once ileus has been diagnosed and small bowel obstruction excluded, the next step is to identify and treat reversible causes of hypomotility. Bearing in mind that common causes of ileus in the critically ill patient include electrolyte abnormalities, sepsis, inflammation, postoperative hypomotility, and medications (Table 93.4), initial laboratory studies should include serum potassium, magnesium, calcium, bicarbonate, lipase, blood urea nitrogen, creatinine, and white blood cell count. Electrolyte abnormalities can often be easily reversed, leading to improvement in small bowel motility. Medications should be carefully reviewed, and potentially causative agents discontinued or limited if otherwise warranted. There are no specific rules about how and when to discontinue medications in the setting of ileus, especially when necessary pain medications (e.g., narcotics) are implicated. Ultimately, the decision rests on a careful balance of clinical factors and meticulous attention to the progress and clinical sequelae of the ileus. In particular, if there is concomitant evidence of significant cecal or large bowel distention to suggest colonic pseudoobstruction and impending perforation, then all the medications contributing to aperistalsis must be discontinued.

In contrast, if there are no clinical signs of deterioration and no worsening on serial abdominal X-rays, the ileus is nonprogressive and stable, and a supportive, conservative treatment is preferred, the treatment plan should include adequate IV hydration, electrolytes replacement, and treatment of the underlying condition, with close clinical and radiological follow-up. There is little evidence [30–40] to support insertion of a nasogastric tube for decompression of prolonged ileus and worsening abdominal distention; however, when vomiting is present, this is routinely performed. One caveat to this widespread approach is the trend in favor of more atelectasis and pneumonia in patients receiving nasogastric decompression in randomized controlled trials [30–40]. Overall, individual trials' data and meta-analyses on tube decompression, mostly in postoperative ileus patients, do not support the need for this intervention [33,41].

Active treatments for ileus remain limited, and the usual promotility agents are generally ineffective.

Opioid-induced bowel dysfunction can occur after the initial dose of opioids and not resolve for some time after therapy is discontinued. The constipating effect of narcotics is not characterized by tolerance [42]. While stool softeners, stimulant, and osmotic laxative are traditionally used, a subset of critically ill patients will not respond to traditional measures and will go on to develop inability to tolerate enteral feedings and laxatives [43]. Opioid reversing agents, with limited systemic bioavailability, have been traditionally used, such as Naloxone, naltrexone, and nalmefene. However, early transit across the blood–brain barrier by these agents caused concomitant analgesia reversal and the onset of opioid withdrawal, without consistent restoration of peristalsis [44]. The newer naltrexone derivative methylnaltrexone is less lipid-soluble than

TABLE 93.4

COMMON CAUSES OF ILEUS IN INTENSIVE CARE UNIT PATIENTS

Electrolyte disorders
Medications
Peritoneal inflammation

Mesenteric ischemia
Sepsis
Retroperitoneal disease
Myocardial infarction

the previous agents and does not cross the blood–brain barrier. Methylnaltrexone is efficacious in treating opioid-induce bowel dysfunction both orally and intravenously, and in most patients, it is effective within 4 hours of the first dose [45].

Postoperative ileus, the interruption of colonic motor activity after surgery, has a multifactorial pathophysiology, with surgical stress hormones, activation of the endogenous opioid system, exogenous opioids given for pain, and inflammation compounding imbalances in fluid and electrolytes.

Traditional prokinetics have been used for reversal of postoperative ileus. Although metoclopramide has proven efficacy in the foregut, it provides little or no benefit for postoperative ileus [46–50]. There have been few studies of metoclopramide in postoperative ileus, so it is difficult to conclude whether its ineffectiveness in postoperative ileus extends to other forms of ileus. Similarly, randomized controlled trials of erythromycin in postoperative ileus demonstrated minimal, if any, benefit [51]. The somatostatin analog, octreotide, has been used empirically, although no good randomized controlled data exist for its use in humans with postoperative ileus, and there are potential detrimental effects on gastric emptying with octreotide that need to be considered before administering in severe whole gut dysmotility.

One trial of 65 postcolectomy patients demonstrated efficacy of methylnaltrexone (see earlier) 0.3 mg given intravenously every 6 hours to achieve a first bowel movement and to hasten discharge from the hospital [52]. These observations support a role for opioid reversal even in the absence of a previous effect of exogenous opioids on gut motor function. Larger trials on methylnaltrexone are needed.

Another opioid antagonist, the selective μ-opioid receptor antagonist, alvimopan, is approved by the FDA for the treatment of postoperative ileus [53,54]. Oral alvimopan is administered preoperatively and postoperatively. In one randomized, controlled, blinded clinical trial of postoperative ileus, alvimopan, 6 mg twice daily, led to a faster passage of flatus (by 21 hours), earlier initiation of bowel movements (by 41 hours), and faster time to discharge (by 23 hours) than placebo [53]. A subsequent larger trial in 510 patients demonstrated similar results [54]. These dramatic effects in postoperative ileus set the stage for the use of alvimopan in other forms of ileus. In a study of 522 patients with noncancer pain requiring an equivalent dose of narcotics more than 30 mg of oral morphine daily, alvimopan was superior to placebo in increasing bowel movement frequency and other endpoints correlated to severe opioid-induced constipation. Although this study was not in a critical care population, the data suggest that alvimopan could be administered after the bowel dysfunction ensues and could prove efficacious for opioids-induced ileus in the critically ill patient [55].

ACUTE COLONIC PSEUDOOBSTRUCTION (OGILVIE'S SYNDROME)

Acute colonic pseudoobstruction, or Ogilvie's syndrome, is characterized by marked dilatation of the cecum and ascending colon in the absence of mechanical obstruction (Fig. 93.2). Similar to ileus, colonic pseudoobstruction generally occurs in critically ill patients with sepsis, recent surgery, electrolyte abnormalities, and trauma, among other conditions. The diagnosis rests on radiographic evaluation of the cecum, where a diameter of more than 9 cm suggests evidence of pseudoobstruction in the absence of a mechanical obstruction. This threshold is somewhat arbitrary and is based on an early series from 1956 that linked this diameter with clinically significant sequelae, namely colonic perforation [56]. More recent case series suggest that a cecal diameter exceeding 12 cm correlates most highly with bowel perforation and should serve as a critical threshold to track in patients with suspected pseudoobstruction [57,58].

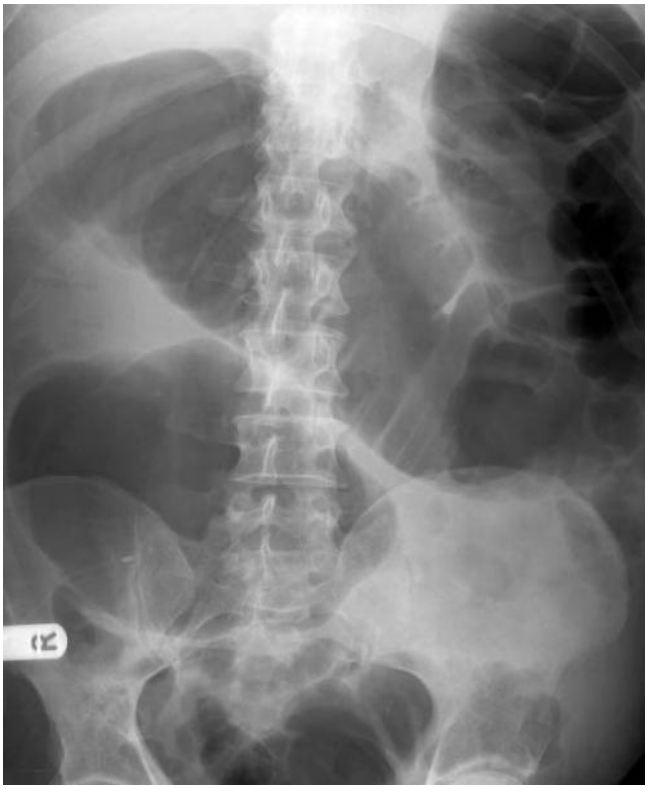

FIGURE 93.2. Marked dilatation of the cecum and other colonic regions in colonic pseudoobstruction. When the cecal diameter exceeds 12 cm, the risk for perforation rises substantially. [From the Scottish Radiological Society (SRS-X: www.radiology.com.uk/srs-x), with permission.]

The exact mechanism by which cecal dilatation occurs remains unclear. There are two competing theories [59]. The first theory, originally postulated by Ogilvie himself in 1948 [60], suggests that sympathetic drive to the enteric nervous system is interrupted, thereby promoting unopposed parasympathetic stimulation. This, in turn, could promote unabated distal colonic luminal contractions and a potential source of obstruction. The second theory, espoused by Hutchinson and Griffiths [61], contends that colonic pseudoobstruction arises from a combination of sympathetic overdrive and parasympathetic suppression, both described in the setting of physiologic stress, thereby leading to colonic hypomotility and eventual paralysis. The proven effectiveness of neostigmine in colonic pseudoobstruction (see following discussion) supports the validity of the latter theory. In contrast, there are few physiologic data to support Ogilvie's original concept of sympathetic interruption. It must be noted that the autonomic nervous system is not the sole player in colonic motility, as the regulators of the enteric nervous system are potentially innumerable, including, among the many, neurohormonal factors and gut peptides.

The clinical presentation of acute colonic pseudoobstruction is typical of obstructive colonic processes, with the patient demonstrating marked abdominal distention, nausea, vomiting, and abdominal pain. If left untreated, colonic pseudoobstruction can lead to ischemia, perforation (in approximately 3% of cases overall), peritonitis, and death [62–65]. Thus, the clinician must keep a high index of suspicion for colonic pseudoobstruction in patients with risk factors, as the consequences of late diagnosis can be grave.

Fortunately, conservative measures are sufficient in most cases, and the cecal dilatation resolves spontaneously. Conservative measures consist of ceasing oral intake, frequent repositioning of the patient, and treating potential underlying causes of dysmotility (as with ileus). Although nasogastric tubes are often employed in cases of colonic pseudoobstruction, there are no data from randomized controlled studies to support its effectiveness in reducing clinically significant endpoints. Because nasogastric decompression has limited, if any, role in ileus [40–49], there is little a priori reason to believe that the maneuver would be of benefit in colonic pseudoobstruction, a condition that is even more distal to the tip of a nasogastric tube than ileus. In contrast, case series do support the effectiveness of colonoscopic decompression, which reduces the cecal diameter in nearly 70% of patients [62,65]. Unfortunately, colonoscopic decompression alone is often short lived, and recurrent distention occurs in approximately half of patients [59,62]. Thus, colonoscopic decompression usually is accompanied by placement of a rectal tube or stent with its proximal tip in the ascending colon. Although colonoscopic decompression and tube placement is conceptually attractive, the procedure is challenging and often unsuccessful and it must be conducted in an unprepared bowel without the benefit of full air insufflation.

In patients failing to respond to conservative measures after 24 to 48 hours, including correction of electrolyte abnormalities, IV hydration, correction of underlying medical causes, and minimization of culprit medications, pharmacologic therapy is generally warranted. Moreover, if at any time the cecal diameter exceeds 12 cm, or if there is evidence of worsening clinical status, then aggressive treatment should be pursued immediately, because these findings constitute a gastroenterological emergency, which mandates early consultative involvement of a surgeon. In patients with markedly dilated large bowel, some specialists would defer even an initial attempt at colonoscopic decompression to a trial of medical therapy. The acetylcholinesterase inhibitor neostigmine increases the postsynaptic concentration of acetylcholine, thereby favoring a boost in the deranged colonic motor function. Neostigmine is effective in colonic pseudoobstruction, and its IV administration has been accepted as initial therapy. This recommendation is largely based on a pivotal controlled trial in which 10 of 11 patients randomized to receive neostigmine had prompt evacuation of their colonic contents and normalization of their cecal diameter, whereas none of 10 patients randomized to placebo had these outcomes [63]. Moreover, all of the patients in the placebo arm achieved a response when crossed over to neostigmine in an open-label fashion. The dosage used was 2 mg IV in one infusion followed by an additional 2 mg infusion 3 hours later if there was no initial response or adverse event. Being an anticholinesterase inhibitor, neostigmine has an array of well-defined cholinergic side effects, including bronchoconstriction, abdominal cramping, hypersalivation, diaphoresis, and bradycardia. Hemodynamically relevant side effects, including cardiac arrest and cardiovascular collapse, can occur, requiring neostigmine to be administered in a monitored setting. It is contraindicated in patients with bradycardia, active bronchospasm, and mechanical bowel obstruction. Existing electrolyte imbalances and use of antimotility agents were predictors of poor response to neostigmine. Patients with postoperative colonic ileus had the best response rate [64]. The combined administration of 2 mg neostigmine with glycopyrrolate, an anticholinergic agent that has limited activity on the muscarinic receptors of the colon and has the potential of reducing the incidence of cholinergic side effects of neostigmine, has been evaluated in a randomized, controlled study of 13 patients with neurogenic bowel using videofluorographic assessment of evacuation [65]. The neostigmine–glycopyrrolate combination resulted in bowel evacuation with significantly less bradycardia and increase in airways resistance than with neostigmine alone, suggesting that the coadministration would make treatment with neostigmine safer in clinical settings where cardiorespiratory function is compromised.

When severe colonic pseudoobstruction fails to respond to conservative measures, neostigmine, and colonic decompression, surgery must be considered. In these settings, surgery has a high morbidity and may lead to poor outcomes in patients who are already critically ill. Indeed, case series indicate that one quarter of patients with colonic pseudoobstruction die in the perioperative period, even in the absence of bowel perforation [60], although the presence of underlying critical illness is arguably the strongest predictor of such a guarded prognosis. Alternatively, endoscopic cecostomy with placement of a percutaneous tube using a modified Seldinger technique similar to percutaneous gastrostomy has been described [66].

SUMMARY

Gastrointestinal motility requires coordinated neural, chemical, and endocrine signals. Faced with serious systemic illness, the gastrointestinal tract often becomes dysfunctional, leading to syndromes such as GERD, gastroparesis, ileus, and colonic pseudoobstruction. Although there are no randomized trials to support IV PPI therapy versus IV H2RA therapy in the critically ill patient, there is a biological rationale to consider using IV PPI therapy.

In general, the critical care provider should aim to maintain the appropriate physiologic environment (e.g., normalize electrolytes imbalances, maximize blood flow) and limit known causes of dysmotility (e.g., narcotics, anticholinergics) to ensure at least some level of gastrointestinal motor function. When these measures fail, providers should employ therapies that are supported by the highest level of evidence, namely randomized controlled trials, when available (Table 93.5). Among the therapies described in this chapter, there is high level of

TABLE 93.5

SUMMARY OF EVIDENCE-BASED MANAGEMENT RECOMMENDATIONS

- Treatment and prevention of complications from gastroesophageal reflux should include encouraging the semirecumbent or upright position, avoidance of nasogastric tubes, and use of potent antisecretory therapy, such as intravenous proton pump inhibitors.
- Medical therapy for gastroparesis often is ineffective, although modest benefits are seen with metoclopramide (especially subcutaneous administration) and erythromycin.
- Evidence for placement of a nasogastric tube for decompression in postoperative ileus is weak, as indicated by meta-analyses.
- Data indicate that there is little or no benefit of metoclopramide or erythromycin in the setting of ileus.
- Methylnaltrexone is an opioid reversal agent that does not cross the blood–brain barrier and achieves sustained laxation in opioid-induced bowel dysfunction.
- Alvimopan, a highly selective opioid receptor antagonist, has demonstrated excellent results in postoperative ileus in randomized controlled trials.
- Neostigmine was shown in effective medical therapy for the treatment of acute colonic pseudoobstruction in the presence of colonic diameter >12 cm as determined by direct abdominal X-ray. Endoscopic bowel decompression with insertion of a decompression tube is an effective alternative management option.

evidence to support neostigmine in colonic pseudoobstruction, alvimopan in postoperative ileus, methylnaltrexone in opioid-induced bowel dysfunction, and good evidence supporting the use of metoclopramide in gastroparesis. Future research on critical care patients should study the effects of novel medications under development on endpoints of motor function, morbidity, and mortality, with fewer systemic side effects and an excellent risk profile.

CHAPTER 94 ■ FULMINANT COLITIS AND TOXIC MEGACOLON

STEPHEN B. HANAUER

Ulcerative colitis is characterized by a diffuse, continuous inflammatory process usually limited to the superficial mucosa of the colon. *Fulminant colitis* implies progression of mucosal inflammation into deeper (muscular) layers of the colon wall. It generally is associated with severe bloody diarrhea, fever, tachycardia, and abdominal tenderness. Systemic manifestations result from transmural colitis, which may also produce circular muscle paralysis precipitating dilatation. *Toxic megacolon* refers to acute dilatation of the colon, generally as a complication of ulcerative colitis, but it may occur with any severe inflammatory colitis. Toxic megacolon has been described with idiopathic and infectious colitis, including ulcerative colitis, Crohn's disease, amebic colitis, pseudomembranous colitis, and other infections [1]. Toxic megacolon has been reported to complicate from 1% to 13% of all ulcerative colitis cases [2] and from 2% to 3% of Crohn's colitis cases [1]. Although mortality in early series was as high as 25% (reaching 50% if colonic perforation occurred), early recognition and management of toxic megacolon has substantially lowered mortality to below 15% [3] and usually below 2% in experienced centers [4]. Factors associated with increased mortality include age older than 40 years, the presence of colonic perforation, and delay of surgery [3,4]. Colonic perforation, whether free or localized, is the greatest risk factor leading to increased morbidity or death.

PREDISPOSING FACTORS

The severity of disease activity is the most important predictor of toxic megacolon, which is more common in extensive colitis than in proctitis or proctosigmoiditis [5]. Limited right- or left-sided segmental colitis also has been associated with toxic megacolon. Concomitant *Clostridium difficile* infection often occurs in hospitalized patients with inflammatory bowel disease and can be associated with refractory disease [6,7]. Similarly, cytomegalovirus (CMV) infections frequently complicate colitis in the setting of immune suppression with corticosteroids or cyclosporine [8,9]. Treatment of CMV with ganciclovir usually is not necessary unless there are systemic manifestations such as fever or associated hepatitis.

Toxic megacolon typically occurs early in the course of ulcerative colitis, usually within the first 5 years of disease, and 25% to 40% of cases present with the initial attack [1]. The onset of toxic megacolon has been linked to patients who have recently undergone diagnostic examinations, such as barium enemas or colonoscopy, suggesting that manipulation of the inflamed bowel or vigorous laxative preparation may exacerbate the process, possibly through electrolyte imbalance (Table 94.1) [3,10].

Certain drug therapies have been implicated in the development of toxic megacolon. Diphenoxylate hydrochloride/atropine sulfate (Lomotil), loperamide, and other inhibitors of colonic motility such as opiates and narcotics may contribute to the development of toxic megacolon by inhibiting colon muscle function in severe transmural disease [11].

Electrolyte and pH disturbances are risk factors for toxic megacolon. Severe potassium depletion, secondary to severe diarrhea or corticosteroid therapy, or both, is known to inhibit colonic motility. Potassium requirements of patients with colitis

TABLE 94.1

POTENTIAL PRECIPITANTS OF TOXIC MEGACOLON

Concurrent pathogens (*Clostridium difficile*, CMV)
Narcotics
Anticholinergics
Antidiarrheal agents (diphenoxylate with atropine, loperamide, opiates)
Barium enema
Colonoscopy

CMV, cytomegalovirus.

may be massive, and restoration of serum potassium alone may not be adequate to replenish body stores [1,11].

Despite early speculations on the role of corticosteroids in inducing toxic megacolon, most experienced clinicians do not accept the implication that corticosteroids or adrenocorticotropic hormone are precipitating factors [1,11–13]. Concern remains, however, that corticosteroids may suppress signs of perforation, thereby delaying surgical therapy.

CLINICAL FEATURES

Toxic megacolon usually occurs on the background of chronic inflammatory bowel disease [1,3]. The presentation typically evolves with progressive diarrhea, bloody stool, and cramping abdominal pain. Occasionally, in patients treated for inflammatory bowel disease over long periods of time, a paradoxic decrease in stool frequency with passage of only bloody discharge or bloody membranes may be an ominous sign (Table 94.2). Thereafter, clinical signs of toxemia, including pyrexia (temperature >101.5°F), tachycardia, and leukocytosis (total white blood cell count >10,500 cells per μL), develop as abdominal pain and distention become progressive and bowel sounds diminish or cease. Signs of peritoneal irritation, including rebound tenderness and abdominal guarding, represent transmural inflammation to the serosa, even in the absence of free perforation. Conversely, peritoneal signs may be minimal or absent in elderly patients or those receiving high-dose or prolonged corticosteroid therapy. In such patients, loss of hepatic dullness may be the first clinical indication of colonic perforation. Mental status changes, including confusion, agitation, and apathy, occasionally are noted. Leukocytosis with a left shift generally is present. Anemia, hypokalemia, and hypoalbuminemia are common. The presence of anemia, requirement for transfusion hypoalbuminemia, and malnutrition are poor prognostic factors [14,15].

Plain films of the abdomen usually are sufficient radiographic studies, revealing loss of haustration with segmental or total colonic dilatation. Clinical studies have demonstrated a strong correlation between colonic dilatation and deep ulceration involving the muscle layers [16]. The magnitude of dilatation may not be severe, averaging 8 to 9 cm (normal is <5 to 6 cm), although colonic diameter may reach 15 cm before rupture. Maximal dilatation can occur in any part of the colon. Accompanying mucosal thumbprinting or pneumatosis cystoides coli reflect severe transmural disease. Free peritoneal air should serve as an immediate indication for surgery [3]. Infrequently, retroperitoneal tracking of air from a colonic perforation may produce subcutaneous emphysema and pneumomediastinum without pneumoperitoneum. In patients with severe colitis, small bowel ileus may herald toxic megacolon and is a bad prognostic sign for medical success. Discrepancies may exist between physical and radiographic findings. Abdominal distention by physical examination can be minimal despite massive colonic dilatation. Conversely, physical findings may dominate the presentation, and peritoneal signs in the absence of free air or dilatation should not be ignored.

A limited proctoscopic or flexible sigmoid examination generally shows extensive ulceration with friable, bleeding mucosa. In rare instances, however, such as with rectal enema therapy or Crohn's disease, the rectum may be normal [17]. An abdominal radiograph after cautious proctoscopic examination can assist in determining the extent and severity of colitis. Computed tomography scans can demonstrate thinning of the colonic wall or evidence of perforation or abscess [1]. More extensive endoscopic examinations, although controversial, generally are contraindicated. If performed, the presence of severe colitis (deep penetrating ulcers) in conjunction with clinical features of severe disease is a poor prognostic sign [16]. Similarly, the presence of extensive and deep ulcerations is a poor prognostic marker in Crohn's disease [17].

TABLE 94.2

CLINICAL FEATURES OF TOXIC MEGACOLON

Symptoms and signs
Increased diarrhea and bleeding
Fever >101.5°F
Abdominal distention
Decreased or absent bowel sounds
Peritoneal signs (potentially masked by corticosteroids)
Hemodynamic instability
Mental status changes
Radiographic findings
Progressive segmental or pancolonic dilatation (may not correlate with physical findings)
Pneumocystoides intestinalis
Laboratory test findings
White blood cell count >10,000/μL, with pronounced left shift
Anemia (may not be reflected in initial measurement if dehydrated)
Hypernatremia (if dehydrated)
Hypokalemia
Metabolic alkalosis (diarrhea)/acidosis (sepsis)
Hypomagnesemia
Hypophosphatemia
Hypoalbuminemia

MANAGEMENT

Few medical emergencies require as close cooperation between medical and surgical personnel as fulminant colitis and toxic megacolon [3,13,18]. A team approach with early management and continuous assessment is vital not only to determine whether surgery is indicated but also to support the critically ill patient preoperatively and postoperatively. Early recognition and institution of therapy by an experienced team can alter the outcome of this life-threatening illness (Table 94.3).

TABLE 94.3

MANAGEMENT OF TOXIC MEGACOLON

Team approach toward management, including medical and surgical personnel
Resuscitation and stabilization—electrolyte and fluid repletion, central venous pressure measurements, blood transfusions to maintain hematocrit greater than 30%, nasogastric suctioning, broad-spectrum antibiotics, administration of intravenous corticosteroids (e.g., methylprednisolone, 40 mg/d, and hydrocortisone, 400 mg/d)
Evaluate status—abdominal examination every 6 h, radiographs of abdomen every 12–24 h
Surgical intervention required for clinical deterioration at any time, failure of medical management to improve status within 48 h, evidence of perforation, shock, persistent hemorrhage
Consider cyclosporine A or infliximab for nontoxic patients without response to intravenous corticosteroids after 3–5 d

Medical Treatment

Despite the fact that "bowel rest" is ineffective as primary therapy for severe colitis, oral intake of fluids should be discontinued in fulminant colitis or once colonic dilatation is recognized [11,13,18]. A nasogastric tube is indicated for patients with associated small bowel ileus. Rolling the less toxic patient from front to back may redistribute colonic air and assist in decompression. Rarely, patients who have been made "nothing by mouth" with colonic dilatation *in the absence of toxic signs or symptoms* may benefit from resumption of oral feeding. Anticholinergic and narcotic agents should be discontinued [11]. Resuscitative measures, including vigorous fluid, electrolyte, and blood replacement, are paramount. Extracellular fluid loss may be severe and, when combined with a low oncotic pressure from hypoalbuminemia, the hemodynamic state often is unstable. The goal of fluid replacement should be to restore previous losses and continue replenishing ongoing losses from diarrhea, fever, and third spacing of fluids. Transfusion of packed red blood cells should be instituted to maintain the serum hematocrit above 30%. Although severe hypokalemia may not be present, total body potassium depletion is common, and resuscitative measures should include adequate potassium replacement. Phosphate, calcium, and magnesium depletion should be corrected parenterally.

Aminosalicylates, a mainstay of maintenance therapy and the treatment of mild-to-moderate disease, have no role in the treatment of fulminant colitis or toxic megacolon. Their activity, limited to superficial inflammation, is insufficient to abort or control the transmural disease, while the potential adverse effects (e.g., nausea, vomiting, or worsening colitis) may confuse the clinical picture [13]. They should be withheld until the patient has recovered and resumed a normal diet. Broad-spectrum antibiotics, with adequate Gram-negative and anaerobic coverage, are considered standard therapy and should be administered without delay once transmural inflammation or toxic megacolon is suspected [13,18]. Antibiotics should be continued until the patient stabilizes over several days to a week, or through the initial postoperative period. Unfortunately, the evidence base is weak regarding the role of antibiotics in fulminant colitis or toxic megacolon and, hence, the ultimate benefits (or risks) have not been adequately determined.

Corticosteroids have long been used in the management of ulcerative colitis as well as in Crohn's colitis [12]. In general, parenteral corticosteroids are essential to patients with toxic megacolon, and most patients are likely to be receiving the drugs before toxic megacolon develops [11]. Augmented doses of corticosteroids should be administered in view of the additional stress of the toxic state. There is no general agreement regarding which corticosteroid preparation or dose should be given. Prednisone, 20 mg intravenously every 6 hours, and prednisolone sodium phosphate have been used successfully. Hydrocortisone, 100 mg every 6 hours, and methylprednisolone, 6 to 15 mg every 6 hours, also are available for intravenous (IV) administration. A continuous infusion of corticosteroids may be beneficial to maintain steady plasma levels [11]. Patients who fail to respond with a reduction in bowel movements, cessation of transfusion requirements, and normalization of C-reactive protein within 5 to 7 days are unlikely to respond [11,18,19].

Cyclosporin A, 2 to 4 mg per kg per 24 hours administered as an IV continuous infusion, in severe ulcerative colitis has been effective for patients failing to improve after 7 to 10 days of intensive IV hydrocortisone therapy [11,13]. Most recently, cyclosporin A, without steroids, was also effective in a small pilot trial in patients with severe ulcerative colitis (not toxic) [20]. Most recently, a trial comparing 2 mg per kg with 4 mg per kg of cyclosporin A in conjunction with corticosteroids in severe colitis demonstrated that the lower dose was equally efficacious with less adverse effects [21]. In contrast, the role of cyclosporin A in toxic megacolon is controversial [22,23]. There are scant data regarding the long-term outlook after cyclosporin A therapy for fulminant or severe colitis, although patients who respond and are maintained on azathioprine have improved, long-term outcomes [11].

TABLE 94.4

EVIDENCE-BASED THERAPY OF FULMINANT COLITIS AND TOXIC MEGACOLON

Cyclosporin A at 4 mg/kg is effective either alone or with corticosteroids to treat severe fulminant ulcerative colitis (toxic megacolon excluded from trials) [11].
Cyclosporin A at 2 mg/kg is equally effective as 4 mg/kg in conjunction with corticosteroids in severe ulcerative colitis (toxic megacolon excluded) [21].
Infliximab is effective in moderate-to-severe, refractory ulcerative colitis in the outpatient setting [24]; the role in severe-to-fulminant colitis is less established [11].

Most recently, the biologic chimeric anti–tumor necrosis factor monoclonal antibody, infliximab, has been used to treat ulcerative colitis [11]. Formal studies have not been performed in the setting of fulminant colitis or toxic megacolon, although, in the setting of *severe* colitis in hospitalized patients, infliximab may have acute benefits [11]. Nevertheless, the long-term outcome has not been assessed for this group of patients. A summary of the evidence-based medical management approaches for fulminant colitis and toxic megacolon is provided in Table 94.4 and a recently proposed algorithm by Hart and Ng is presented in Figure 94.1 [11].

Resuscitative measures for fulminant infectious colitis resulting in toxic megacolon should be initiated in the same manner as for idiopathic ulcerative colitis. Broad-spectrum antibiotic coverage should be followed by pathogen-specific therapy after the causative organism has been identified. Vancomycin may be preferred over metronidazole in the setting of severe or fulminant colitis if *C. difficile* is considered likely because of prior antibiotic exposure or the presence of pseudomembranes [7]. The same criteria for surgical treatment should be used [3].

Surgical Intervention

When no improvement or deterioration occurs, despite 12 to 24 hours of intensive medical management, surgical intervention is required for toxic megacolon [3,11]. Failure to substantially improve within 5 to 7 days of intensive corticosteroid or cyclosporin A therapy is an indication for surgery [3,11,18,19]. Some physicians actually view early surgical management of toxic megacolon as the conservative approach, noting that delay of operative therapy may promote higher mortality [25,26].

Evidence of colonic perforation is an unequivocal indication for emergent surgery. If physical signs of perforation are absent, 12- to 24-hour radiographic surveillance is necessary. Perforation is associated with severe complications, including peritonitis, extreme fluid and electrolyte imbalance, and hemodynamic instability. Early recognition of perforation should lessen morbidity or mortality [3]. Other indications for emergent surgery precluding protracted medical management include signs of septic shock and imminent transverse colon rupture (diameter >12 cm). Hypoalbuminemia, persistently elevated C-reactive protein or erythrocyte sedimentation rate, small bowel ileus,

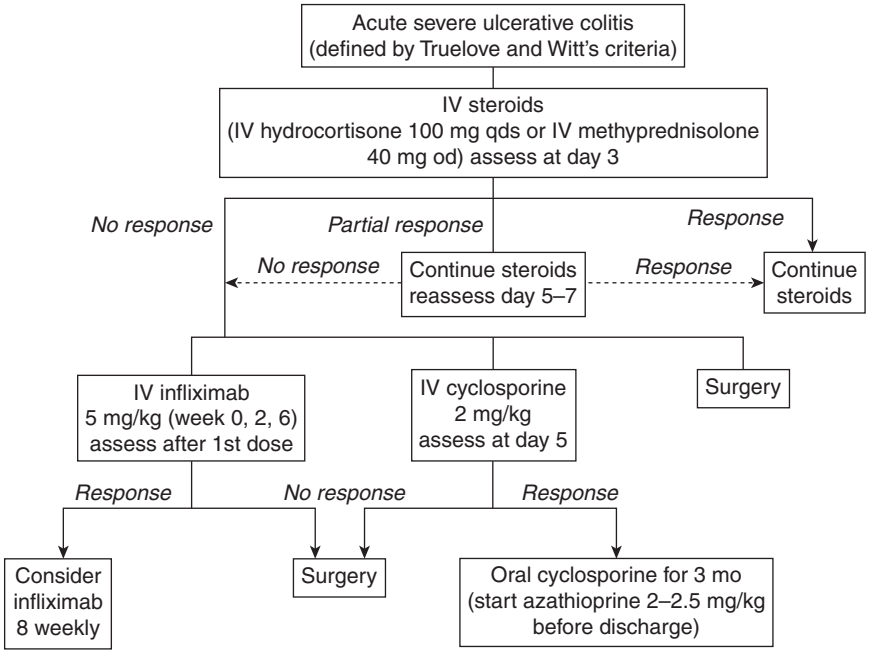

FIGURE 94.1. Proposed algorithm for the treatment of hospitalized patients with severe ulcerative colitis. [From Hart AL, Ng SC. Review article: the optimal medical management of acute severe ulcerative colitis. *Aliment Pharmacol Ther* 32(5):615–627, 2010.]

and deep colonic ulcers are poor prognostic factors for successful medical therapy [11].

Although the medical management of fulminant colitis is similar to that of toxic megacolon, the absence of acute colonic dilatation may permit delay of surgical intervention. The timing of surgical intervention in these less urgent cases requires experienced clinical judgment, however. Early intervention to reduce mortality must be balanced against the potential for intensive medical management to control the inflammatory process and complications; these efforts aimed at preventing the psychosocial and medical stigmata of a colectomy. In general, in the absence of colonic dilatation, medical management may be continued for 5 to 7 days in a further attempt to reverse transmural inflammation, as long as the patient is stable and improving. The option between cyclosporine and infliximab for patients with severe, nontoxic ulcerative colitis is controversial and has yet to be addressed in controlled, comparative effectiveness trials [11]. Patients who do not begin to respond to the intensive IV steroid regimen should be referred to centers experienced in biologic (infliximab) or cyclosporin therapy in severe colitis, or undergo colectomy [11,13,18].

The type of operation performed for treatment of fulminant colitis or toxic megacolon depends on the clinical status of the patient and the experience of the surgeon [3,4,14]. A one-stage procedure that cures ulcerative colitis without the need for a second operation is appropriate for older patients or those not desiring restorative ileal pouch-anal anastomosis. Most surgeons prefer a limited abdominal colectomy with ileostomy, leaving the rectosigmoid as a mucous fistula or the rectum alone, using a Hartmann procedure [3,11]. This approach has the advantages of limiting the lengthy pelvic dissection in acutely ill patients while allowing for the option of a subsequent restorative, sphincter-saving procedure (ileoanal anastomosis). In patients with indeterminate colitis or Crohn's disease, preservation of the rectum may provide the opportunity for an eventual ileorectal or ileoanal anastomosis to preserve anal continence after temporary diversion and pathologic review of the colectomy specimen.

The surgical management of toxic megacolon must be individualized for each patient. The type of operation selected depends on the clinical condition of the patient and the experience of the surgeon [3,27,28].

CHAPTER 95 ■ EVALUATION AND MANAGEMENT OF LIVER FAILURE

GOWRI KULARATNA AND MAURICIO LISKER-MELMAN

INTRODUCTION

Liver failure results from progressive deterioration of hepatic function in the setting of either acute or chronic liver disease. *Acute* or *fulminant hepatic failure* (FHF) is a devastating condition in which the liver fails within a short period of time, encompassing a range of clinical syndromes. FHF is an uncommon entity, estimated to affect approximately 2,000 patients annually in the United States. Prompt evaluation and aggressive management, including liver transplantation, play an integral part in successfully treating patients with FHF in the intensive care unit (ICU). In contrast, *chronic liver failure* is a more frequent medical condition that may evolve into end-stage liver disease, independent of its cause (e.g., viral, autoimmune, metabolic, toxic). It usually develops after years of hepatocyte insult. The definition, etiology, clinical features, complications, and management of fulminant and chronic liver failure are reviewed in this chapter. The role of liver transplantation and future therapies for fulminant and chronic liver disease are discussed briefly.

FULMINANT HEPATIC FAILURE

Definition

Fulminant hepatic failure (FHF) is a rare condition which includes evidence of coagulation abnormalities (international normalized ratio [INR] >1.5) and any degree of mental alteration (encephalopathy) in a patient without preexisting cirrhosis and with an illness of no more than 24-week duration. This definition can be further classified by length of illness: *hyperacute liver failure* (7 days), *acute liver failure* (8 to 28 days), *subacute liver failure* (29 to 60 days), *late-onset hepatic failure* (8 to 24 weeks), and *subfulminant hepatic failure* (jaundice to encephalopathy in 2 to 12 weeks). These terms, however, are not helpful, as they do not provide prognostic or practical information separate from etiology. Terms such as *late-onset hepatic failure* (8 to 24 weeks from the beginning of symptoms) and *subfulminant hepatic failure* (jaundice and encephalopathy in 2 to 12 weeks) are not commonly used. Patients with acute liver failure superimposed on a chronic liver disease do not fit the classic definition of FHF. There are classifications [1,2], however, that allow for the inclusion of these patients with previously asymptomatic chronic conditions as having FHF.

Etiology

Numerous causes of FHF are recognized, and their relative importance differs around the world. Some authors classify them into four major categories: infectious (e.g., viral hepatitis), drugs/chemicals/toxins (e.g., acetaminophen, isoniazid, *Amanita phalloides*), vascular (e.g., Budd–Chiari syndrome, ischemic hepatitis, tamponade), and metabolic (e.g., Wilson's disease, Reye's syndrome, acute fatty liver of pregnancy). In the United States, acetaminophen accounts for nearly 50% of cases followed by idiosyncratic drug reactions (12%). Acute viral hepatitis (hepatitis A and hepatitis B) is the etiologic factor in 12% of cases and has become an infrequent cause of FHF over the last few decades due to effective immunization programs. In contrast, in the developing world, viral hepatitis is the dominant etiology of fulminant hepatitis. Hepatitis C is a rare source of FHF [3].

The identification of the cause of FHF is important because it can provide important prognostic information as well as dictate treatments and antidotes. In the case of viral hepatitis, patient contacts must be identified and informed of the potential need for prophylaxis as indicated. Approximately 20% of adult cases with acute liver failure have indeterminate causes, with women affected more often than men [4,5]. Initial laboratory

TABLE 95.1

INITIAL LABORATORY TESTING FOR FHF

Initial laboratory testing for FHF	
■ Complete blood count ■ Basic metabolic panel ■ INR ■ Liver chemistry panel ■ Lactate ■ Blood gas ■ HIV (rapid antibody test) ■ Pregnancy testing ■ Blood and urine cultures ■ Imaging and other testing – CXR/ECG – RUQ US with Dopplers	■ Viral markers – Hepatitis A IgM antibody – Hepatitis B markers – Hepatitis C antibody ■ Autoimmune markers – Antinuclear antibody – Anti–smooth muscle antibody ■ Toxicology screen and drug panel – Urine and serum drug screen including acetaminophen, cocaine, alcohol

CXR, chest x-ray; ECG, electrocardiogram; INR, international normalized ratio; HIV, human immunodeficiency virus; RUQ US, right upper quadrant ultrasound.
Liver chemistry panel: aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, total and direct bilirubin, albumin, total protein.
Hepatitis B markers: hepatitis B surface antigen, hepatitis B surface antibody, hepatitis B core antibodies (IgG, IgM).

testing to delineate etiology and assess degree of injury is obligatory (Table 95.1).

Acetaminophen is the most common cause of FHF in the United States and the United Kingdom. This drug is a constituent in numerous over-the-counter preparations and is also commonly combined with prescription analgesics. Although the recommended doses of acetaminophen (up to 4 g per day) are safe in healthy individuals, dose-dependent hepatotoxicity can occur. Hepatotoxicity can occur through intentional (e.g., suicide attempt) or unintentional (e.g., combined with alcohol, barbiturates, or other inducers of the cytochrome P450 system) overdose. Approximately one third of cases can occur in association with efforts at pain relief; these "therapeutic misadventures" occur with lower cumulative doses of ingested acetaminophen [6]. These patients may seek late medical attention resulting in delayed physician recognition.

Acetaminophen is 95% eliminated by hepatic conjugation. Approximately 5% of acetaminophen is converted to *N*-acetyl-p-benzoquinone-imine (NAPQI), which is inactivated after reaction with cellular glutathione and excreted rapidly. If glutathione stores are depleted, NAPQI becomes highly toxic and produces massive liver necrosis. NAPQI accumulates at a higher rate in the setting of increased cytochrome P450–2E1 activity, as seen with chronic alcohol ingestion, and with medications that induce the P450 system. As a result, patients with chronic moderate alcohol intake can develop toxicity with ingestion of less than 10 g of acetaminophen. For more detail on this topic, please refer to chapter 120.

Patients with acetaminophen toxicity present in three phases. The first phase involves acute gastrointestinal (GI) symptoms of nausea, vomiting, and abdominal pain within the first few hours after ingestion. During the second phase (12 to 48 hours), asymptomatic liver test abnormalities occur, with marked elevation of liver enzymes and a high aspartate aminotransferase (AST)/alanine aminotransferase (ALT) ratio. The third phase presents with manifestations of hepatic failure, including jaundice and encephalopathy. The mortality of acetaminophen toxicity is higher when associated with severe acidosis, coagulopathy, renal failure, mental status changes, and cerebral edema (CE) [6] (Table 95.2).

The effective antidote, *N*-acetylcysteine (NAC), is potentially lifesaving when administered early, especially within 24 hours of acute ingestion. Thus, suspicion and early identification of acetaminophen toxicity are of vital importance in treating patients presenting with FHF. NAC replenishes glutathione stores, preventing depletion and subsequent tissue hypoxia and ischemic damage. Both, the oral and intravenous forms can be used with similar efficacy [7]. Oral NAC is given over 72 hours with a loading dose of 140 mg per kg and subsequent doses of 70 mg per kg every 4 hours for a total of 17 doses. Because of its sulfur moiety, NAC has a strong odor and taste, and it needs to be diluted (usually in cola) to be tolerated. It is not uncommon for oral NAC to induce nausea and vomiting. A nasogastric or nasoduodenal feeding tube

TABLE 95.2

INDICATORS OF POOR PROGNOSIS IN ACUTE LIVER FAILURE

Etiology	Parameter
Acetaminophen-induced liver failure	Arterial pH <7.30[a] PT >100 s INR >6.5 Creatinine >300 μmol/L (2.3 mg/dL) Encephalopathy grade 3–4
Nonacetaminophen liver failure	PT >100 s[b] INR >6.7[b] Age <10 or >40 Serum bilirubin >300 μmol/L (2.3 mg/dL) Seronegative hepatitis or drug reaction

[a]Highest sensitivity (49%), specificity (99%), and positive predictive value (81%).
[b]Highest specificity (100%) but lower sensitivity (34%) and positive predictive value (46%).

Modified from the Kings College Criteria indicating a poor prognosis in acute liver failure.

may be placed in this situation to reliably deliver the medication. If the patient develops significant nausea or vomiting, has a polysubstance overdose requiring gastric decontamination, GI bleeding, or intestinal obstruction, IV NAC is the preferable administration route. IV NAC is given as a 150 mg per kg loading dose, then 50 mg per kg over 4 hours, followed by 100 mg per kg over 16 hours. It has been our experience that dosing of both, oral and IV NAC, can be administered beyond the recommended doses until improvement in liver chemistry parameters is noted. Anaphylactoid reactions are seen in 5% to 14% of patients, typically occurring with the IV loading dose [8,9]. Because this reaction may be rate dependent, the loading dose has to be administered over 15 to 60 minutes.

The decision to administer NAC is dependent on serum levels of acetaminophen and time after ingestion (consult nomogram in acetaminophen chapter 120). Although the therapeutic benefit of NAC is best when given within 10 hours, its effects can still be of value within 36 hours of ingestion. When administered early, NAC leads to greater than 95% survival. The administration of NAC to patients with nonacetaminophen FHF has shown possible benefit [10]. However, combined analyses of these data do not demonstrate a mortality benefit in nonacetaminophen hepatotoxicity cases [11]. Larger controlled trials are needed to better assess the use of NAC in these patients.

Clinical Manifestations and Management

Despite timely intervention, multisystem organ failure can develop in patients with FHF. Hepatic encephalopathy (HE) and CE affect patients with FHF in varying degrees. Coagulopathy and jaundice are often present before severe encephalopathy occurs. Cardiorespiratory failure, renal failure, and infectious complications can develop and further complicate the management of these patients. Unfortunately, multisystem organ failure is a cause of ineligibility for transplantation in 20% of patients with FHF [12].

Hepatic Encephalopathy

HE is a syndrome of disordered consciousness and altered neuromuscular activity. HE is present in all patients with FHF, with symptoms ranging from subclinical confusion (grade 0) to coma (grade 4) (Table 95.3). The mechanism of HE is complex with interplay of many hypothesized factors including CE; toxins such as ammonia, glutamate, and endogenous benzodiazepines; and cytokine-like mediators such as interleukin (IL-1), IL-6, and tumor necrosis factor [13–15]. Alterations in cerebral blood flow due to loss of intracranial autoregulation may be a minor contributor to HE [16]. The diagnosis of mild HE is made through interviewing the patient for signs of impaired cognition. This may manifest itself through mild agitation, inability to concentrate, or more subtly, as an inability to perform counting tasks. HE may progress rapidly to grade 3 or 4, and frequent monitoring is essential. Arterial ammonia level more than 200 μg per dL is associated with cerebral herniation, although levels do not correlate with the degree of HE [17]. Mechanical intubation is indicated in the setting of significant acidosis or grade 4 HE, to protect patient's airway and decrease metabolic stress. Treatment is directed at the correction of precipitating factors such as sepsis, GI bleeding, medications, and fluid and electrolyte imbalance [18]. Standard therapy for HE in chronic liver disease, such as lactulose, neomycin, or rifaximin, have no proven benefits in FHF and can induce significant side effects such as bloating, abdominal pain, nausea, and electrolyte disturbances from diarrheal losses [19]. Flumazenil, a benzodiazepine antagonist, had limited success in one trial treating HE in children with FHF, and no definitive data are available for its use in adults [20].

TABLE 95.3

STAGES OF HEPATIC ENCEPHALOPATHY

- *Grade I*: sleep reversal pattern, mild confusion, irritability, tremor
- *Grade II*: lethargy, disorientation, inappropriate behavior, asterixis
- *Grade III*: somnolence, severe confusion, aggressive behavior, asterixis
- *Grade IV*: Coma

Cerebral Edema

CE is a devastating complication of FHF that accounts for about 25% of deaths. It is seen in up to 80% of patients with FHF and advanced encephalopathy [21]. The pathogenesis of CE is thought to be the result of progressive accumulation of water in the brain. Two main mechanisms have been proposed to explain CE. The first is water influx down an osmotic gradient into the gray matter, astrocytes in particular [22]. Osmotic and metabolic alterations in the astrocytes lead to cellular swelling and accumulation of glutamine. The second mechanism is reduced cerebral flow and loss of autoregulation, resulting in increased intracranial pressure (ICP) [23].

The early clinical manifestations of CE often overlap with advanced encephalopathy (grades 3 and 4) and include agitation, headache, nausea, or vomiting. The most feared complications are brain herniation and death. Frequent evaluation of mental status (avoiding sedation and neuromuscular blockade if possible), assessment for hyperreflexia, pupillary changes, and sudden systemic hypertension play an important role in monitoring these patients. The neurologic examination and computed tomography (CT) of the brain are often unreliable methods to follow CE or ICP [24]. However, head CT can be helpful if there is clinical suspicion for structural lesions or hemorrhage. Severe CE, cerebral herniation, or a large intracranial bleed from an underlying coagulopathy eliminate the possibility of transplantation.

ICP measurements obtained by placement of intraparenchymal, subdural or epidural pressure transducers, accurately determine ICP and help direct therapy. Monitoring of ICP has always provoked controversy. Some suggest that these patients can be monitored without the need of invasive placement of intracranial bolts, while others suggest that ICP monitors facilitate the care of patients with CE [25,26]. ICP monitoring should be considered in patients with progressive mental status impairment (HE grades 3 and 4) and under consideration for liver transplantation. Placement of ICP monitors may be complicated by intracranial bleeding (<5%) in the setting of severe coagulopathy [27,28] and volume overload from the use of blood products in an effort to correct coagulation abnormalities. Activated recombinant factor VII (see "Coagulopathy" section in the chapter) may help ameliorate these complications. Infections from monitor placement are also potential life-threatening complications. As a result, the efficacy and indication for ICP monitoring in patients with encephalopathy has been questioned [29]. Once the decision to place an ICP monitor is made, epidural pressure transducers are preferred because of a lower rate of bleeding complications (approximately 5%) compared with the intraparenchymal and subdural types (approximately 20%). Measurement of ICP with these monitors requires experience and familiarity with the equipment [30]. Monitoring mean arterial pressures (MAPs) and maintaining cerebral perfusion pressures (CPPs) (MAP minus ICP) are important. Ideally, ICP should be maintained around 15 mm Hg, with CPP greater than 40 to 50 mm Hg. Recovery of neurologic

function is optimized by maintaining CPPs at greater than 40 mm Hg.

Simple recognized strategies to stabilize or decrease the ICP include elevation of the head of the bed to 30 degrees to improve venous drainage and minimization of endotracheal suction and external stimuli [31], control of fever, correction of hyponatremia and hypoosmolality, and short-term hyperventilation to a P_{CO_2} of 30 to 35 mm Hg [32]. Intravenous administration of mannitol (100 mL of 20% solution given intravenously at 0.5 to 1.0 mg per kg) and intravenous hypertonic saline boluses (20 mL 30% saline) to obtain sodium levels of 145 to 155 mEq per L are considered first-line treatment strategy for CE. Mannitol draws water osmotically from brain tissue reducing the ICP and may be helpful to "bridge" patients to liver transplantation. It should be avoided in patients with renal failure. Hypertonic saline infusions have been used to decrease the incidence and severity of increased ICP in FHF [33]. Hyponatremia increases ammonia-induced CE and has been recognized as a cause of this complication in postoperative patients treated with excessive 5% glucose solutions [23].

No established role exists for the use of regular diuretics. Administration of corticosteroids such as dexamethasone has failed to show any benefit in treating elevated ICP [34]. Hypothermia (32°C to 34°C) reduces the production of inflammatory mediators, decreases arterial and cerebrospinal spinal fluid ammonia levels, and attenuates ICP pressure; however, no control studies are available, and its use as a therapeutic option remains uncertain [35–38]. Barbiturates have been investigated as a treatment option for CE in FHF; however, with the exception of patients with seizures and CE, barbiturates are not useful. Experimental use of NAC and prostaglandin I_2 infusions increases cerebral microcirculation and blood flow. The role of these agents remains to be determined in human studies.

Definitive treatment of CE in FHF is liver transplantation. Prolonged low CPPs and increased ICP are contraindications to liver transplantation given the high risk of brain death and significant neurologic sequelae. Despite the most appropriate care and stringent inclusion criteria, residual neurologic deficits may persist after transplantation [39].

Coagulopathy

Because of the loss of hepatocyte function in FHF, there is reduced synthesis of coagulation and anticoagulation factors that results in marked elevation of the INR, prolongation of the prothrombin, and activated partial thromboplastin times. These parameters should be followed to monitor hepatic function recovery (in the absence of fresh frozen plasma). Factor V has the shortest half-life and is a sensitive marker of defective synthesis of coagulation factors, but it is rarely measured. Along with clotting factor deficiencies and consumption, there may be platelet dysfunction, thrombocytopenia, and fibrinolysis resulting in a clinical picture similar to disseminated intravascular coagulation [40].

In the setting of coagulopathy due to clotting factor synthesis deficiency, overt bleeding does not frequently occur. However, when severe coagulopathy develops along with platelet dysfunction, GI and oropharyngeal bleeding can result. Protection of the gastric mucosa with proton pump inhibitors, H2 blockers, or sucralfate is important. The skin, lungs, and urogenital tract are also potential sites of significant blood loss. Fresh frozen plasma and platelets are indicated in patients with active bleeding or before invasive procedures. Packed cell replacement is required for significant blood loss. However, due to risk of worsening CE and fluid overload, blood products use must be judicious.

Factor VII is a central figure in the clotting cascade. Its activation is in response to tissue factor release after endothelial injury [41]. Recombinant activated factor VII (rFVIIa) has emerged as a potential treatment and prophylaxis option for bleeding in patients with liver disease. Prophylactic use of rFVIIa is not standard of care. In a group of children with FHF, prophylactic rFVIIa allowed for decreased transfusion requirements and better maintenance of fluid balance [42]. Data also supports rFVIIa use in patients who are undergoing placement of ICP monitors. In seven patients receiving rFVIIa, complete normalization of the prothrombin time (PT) allowed ICP monitor placement in comparison with three out of eight historical controls managed by conventional means. The patients receiving rFVIIa also had a significant decrease in mortality and anasarca due to fluid overload. The high cost of rFVIIa limits its more frequent use (approximately $2,000 for a 60 kg patient). However, the cost savings from decreased transfusion requirements and hemofiltration for fluid overload may offset the additional costs of rFVIIa [43].

Cardiac Complications

Elevated cardiac output (hyperdynamic circulation), decreased peripheral oxygen extraction (tissue hypoxia), and low systemic vascular resistance are present in patients with FHF [44]. These hemodynamic parameters, possibly due to the release of vasoactive mediators from dying hepatocytes, are similar to sepsis. Splanchnic and peripheral vasodilatation leading to systemic hypotension should be treated with volume replacement. Pulmonary artery catheter, central venous pressure, or esophageal Doppler monitoring can be crucial in assessing and correcting fluid status in these patients. MAP should be maintained above 50 mm Hg. Norepinephrine is generally used as the primary vasopressor due to its consistent effects on CPP. Conflicting data exist regarding vasopressin and terlipressin and their effects on ICP and systemic hemodynamics. A progressive rise in systolic blood pressure, within minutes or hours, can be indicative of ICP elevation and should be treated as discussed earlier.

Respiratory Complications

Respiratory complications occur frequently in patients with FHF. Hypoxemia can result from acute lung injury, cardiogenic or noncardiogenic pulmonary edema, pneumonia, intraalveolar hemorrhage, or intrapulmonary vascular shunting (hepatopulmonary syndrome). These patients should be treated with supplemental oxygen or intubation as clinically indicated. Intubation, however, is used more frequently for airway protection rather than for respiratory failure. Positive pressure ventilation should be used to optimize compliance with caution, as the resulting decreased vascular return can lead to increased ICP and cardiac output. The combination of rising ICP and metabolic acidosis in patients with FHF leads to a compensatory hyperventilation and hypocapnia.

Monitoring the development of CE becomes difficult in patients who are intubated, sedated, and paralyzed. As a result, intubation should be performed in those who are unresponsive in a grade 3 or 4 HE and require airway protection with ventilatory assistance.

Renal Failure

The development of renal failure in FHF is a poor prognostic indicator and is the result of a variety of factors. Up to 75% of patients with acetaminophen toxicity develop acute renal failure from direct renal toxicity of NAPQI. Renal failure also occurs in approximately 30% of patient with FHF from other causes [8]. The most frequent causes of renal failure are intravascular volume depletion (relative hypovolemia caused by vasodilatation), acute tubular necrosis, and hepatorenal syndrome (HRS). Type I HRS predominates in FHF. It is rapidly progressive and carries a dismal prognosis.

Oliguric renal failure in FHF is defined as urine output less than 300 mL per 24 hours [45] or serum creatinine 3.4 mg per dL (>300 mmol per L). Renal failure leads to a variety of metabolic disorders including hyperkalemia, hypercalcemia, hyperphosphatemia, hypophosphatemia, and hypermagnesemia that can further complicate patient management.

Diagnosis requires close monitoring of urine output, volume status (see "Cardiac Complications" section in the chapter), and measurement of urinary sodium and creatinine. Urinary sodium and creatinine can help identify the presence of acute tubular necrosis (high or normal urine sodium) but cannot differentiate between prerenal azotemia and HRS (low urine sodium). Nephrotoxic agents and mannitol should be avoided in renal failure, and careful renal dosing is vital. Some patients will require hemodialysis or hemofiltration to control the volume status, especially in the setting of CE, correct acidosis, improve electrolyte imbalance, and azotemia. Patients with tenuous hemodynamics who require hemodialysis or hemofiltration are best served with continuous modes of renal replacement [46].

Metabolic Disorders

Lactic acidosis is a severe metabolic complication of FHF. Serum lactate accumulates as a result of tissue hypoxia from hypotension as well as impaired hepatic uptake and metabolism of lactate. Renal dysfunction and other metabolic abnormalities can easily contribute to increase the underlying acidosis. Severe, refractory lactic acidosis requires intravenous bicarbonate infusion or dialysis.

Hypoglycemia also frequently complicates FHF given the primary metabolic role of the liver in glycogen storage and gluconeogenesis. Massive hepatic damage is required before serum glucose drops to levels that impair neurologic and cellular function. Nonetheless, frequent glucose monitoring and infusion of concentrated dextrose solutions may be required [47].

Sepsis

Patients with FHF are at high risk for septic complications. Abnormal neutrophil and Kupffer cell function, decreased bacterial opsonization, bacterial gut translocation, and altered cytokines contribute to immunologic impairment [48]. Up to 80% of patients with FHF will develop a bacterial infection. The urinary tract and pulmonary system are the most frequent sources of infection. Skin wounds, indwelling vascular access catheters, and ICP monitors are also potential sources of infection. The most common organisms identified are *Staphylococcus*, *Streptococcus*, Gram-negative organisms, and *Candida* species. Fungal infections occur late in the course of illness and are associated with high mortality.

Because the hemodynamic, metabolic, and hematologic parameters of FHF are often indistinguishable, hospital staff must maintain a high level of suspicion for infectious complications. In fact, one third of septic patients maintain a normal white cell count and remained afebrile. Since sepsis may be easily overlooked, early surveillance cultures should be obtained with a low threshold to start broad-spectrum antibiotics. If possible, aminoglycosides should be avoided owing to their nephrotoxicity. The use of prophylactic antibiotics is controversial. The addition of enteral decontamination regimens has not been shown to decrease the incidence of infection [49]. Sepsis can be catastrophic, since it compromises the opportunity to proceed with transplantation and contribute to multisystem organ failure.

The systemic inflammatory response syndrome (SIRS) presents clinically with manifestations compatible with sepsis: fever or hypothermia, tachycardia, leucocytosis or leucopenia, and tachypnea or hyperventilation, and it can be triggered by a variety of infectious and noninfectious conditions [50]. In FHF, SIRS can be associated with infection or by the release of inflammatory cytokines from the necrotic hepatocytes; as such, high level of suspicion and early identification of infectious sources are needed for adequate treatment and ICU support.

Prognosis

Prognostic factors in patients with FHF have been investigated to determine patient survival and identify those who would be best treated by transplantation. The Kings College criteria [51] produced the first prognosis model and have been used most often worldwide (Table 95.2) for this purpose. These criteria have a high positive predictive value and remain useful today [52]. Recent papers suggest that elevated lactate levels on admission improves the sensitivity of the model to predict mortality in acetaminophen-induced FHF [53]. On admission to the ICU, the Acute Physiology and Chronic Health Evaluation (APACHE) II system has been found comparable with the Kings College criteria in those with acetaminophen-induced liver failure [54]. However, more recent studies have shown that the absence of these criteria may not be as reliable in predicting survival [55].

Age does not appear to play an important prognostic role in the situation of transplantation for FHF. Although the grade of encephalopathy may influence posttransplant outcome, its reliability has been debated. The role of serial Doppler ultrasounds has been investigated in predicting outcome by measuring the mean hepatic artery resistive index. Results have indicated that as the mean hepatic arterial resistive index increases, there is an associated poorer prognosis in those patients who meet transplant criteria [56]. Assessing patients with CT has also been investigated. A prior study indicates that patients with liver volumes of less than 1,000 mL have a poorer prognosis [57].

Measurements of serum alpha-fetoprotein (AFP) and serum protein Gc-globulin (an actin-binding protein released during massive tissue injury) have been investigated with promising results [58]. Of these potential markers, AFP has been investigated the most. Early AFP elevation in FHF is suggestive of regeneration and thus has garnered interest as a marker of survival. In a recent study, a threshold level of AFP of 3.9 μg per L or above was highly sensitive in predicting survival. In this study, AFP was measured 1 day after ALT levels peaked [59]. Despite these results, no marker or clinical finding has proven to be reliably predictive of outcome.

CHRONIC LIVER DISEASE

Chronic liver disease is a result of continuous, long-term hepatic injury. Chronic viral hepatitis is arbitrarily defined as the presence of persistent liver inflammation, liver chemistry abnormalities, and positive serologic and molecular markers for more than 6 months. The persistent nature of the hepatic insult leads to a sequence of damage and repair processes that may ultimately progress to the development of fibrosis, cirrhosis, and hepatocellular carcinoma (HCC). Damage to the hepatic parenchyma, with or without fibrosis, is a common outcome in chronic liver disease. Regardless of whether the insult to the hepatocytes, the biliary ducts, or the hepatic vasculature is toxic, viral, metabolic, autoimmune, or ischemic, the reparative process often leads to similar results.

Cirrhosis is a chronic diffuse condition characterized by replacement of liver cells by fibrotic tissue, which creates a nodular-appearing distortion of the normal liver architecture. Chronic liver disease and cirrhosis affects nearly 5.5 million Americans. Cirrhosis is the 10th leading cause of death in the United States.

Etiology

Chronic hepatitis C and B infection, chronic alcohol use, and nonalcoholic fatty liver disease (NAFLD) are the most common causes of chronic liver disease in the United States.

Hepatitis C virus (HCV) is a global health problem with approximately 200 million carriers worldwide. The incidence of HCV has declined in the last 30 years. The prevalence in the U.S. population is 1.8%, making HCV infection the most common chronic blood-borne infection. In the United States, 4 million people have been infected with this virus and 2.7 million have chronic infection. HCV is the leading cause of death from chronic liver disease [60–62].

Two billion people worldwide have serological evidence of past or present infection with the hepatitis B virus; approximately 400 million people are chronic carriers. HBV is unevenly distributed throughout the world. In endemic areas (Asia and sub-Saharan Africa), infection is usually acquired in childhood. In contrast, in Western countries where HBV is relatively rare, the infection is acquired in adulthood [63]. HBV causes 60% to 80% of HCC worldwide. It is estimated that between 500,000 and 1,000,000 deaths per year occur worldwide due to this disease.

Alcoholic liver disease also is a significant medical and socioeconomic problem worldwide. Although alcohol exerts a direct toxic effect on the liver, significant liver damage develops in only 10% to 20% of those patients with chronic alcohol abuse. The spectrum of alcoholic liver disease is broad, and a single patient may be affected by more than one of the following conditions: fatty liver (90% of alcoholics), alcoholic hepatitis, or alcoholic cirrhosis (common cause of end-stage liver disease and HCC).

NALFD is a clinicopathologic syndrome that encompasses several clinical entities that range from simple steatosis, steatohepatitis, fibrosis, and end-stage liver disease in the absence of significant alcohol consumption [64]. NAFLD is a worldwide phenomenon with an estimated prevalence of about 30% in the general population. The prevalence of NASH ranges from 3% to 9% with substantial variation among ethnic groups. It affects both children and adults, and the incidence increases with age. NAFLD is associated with an increasing prevalence of type II diabetes and obesity in the U.S. population. The metabolic syndrome including abdominal obesity, dyslipidemia, hypertension, and insulin resistance is also associated with NAFLD. NALFD-induced cirrhosis may progress to HCC (13% of all cases of HCC) [65].

Other causes of chronic liver disease include autoimmune liver disease, primary sclerosing cholangitis, primary biliary cirrhosis, hemochromatosis, Wilson's disease, α_1-antitrypsin deficiency, and Budd–Chiari syndrome.

Clinical Manifestations and Diagnosis

Clinical manifestations of chronic liver disease vary according to the functional and histologic stage of the liver disease. Patients may be asymptomatic or have one or several manifestations of liver dysfunction. Physical findings described in patients with cirrhosis include temporal wasting, jaundice, telangiectasia, gynecomastia, ascites, splenomegaly, caput medusae, palmar erythema, and testicular atrophy. Some laboratory abnormalities are suggestive of cirrhosis. Serum albumin and prothrombin time/INR, which are good indicators of hepatic synthetic function, are frequently abnormal. These markers reflect degree and progression of chronic liver disease and play an important role in determining patient prognosis. Bilirubin levels rise with disease progression, resulting in jaundice and pruritus. Hypoglycemia, frequently seen in FHF, rarely occurs in the setting of chronic liver disease.

The severity of chronic liver disease is often scored by the Child-Turcotte-Pugh (CTP) classification, which considers variables such as serum albumin, serum bilirubin, prothrombin time, and the degree of ascites and encephalopathy (Table 95.4). The model for end-stage liver disease (MELD), calculated from the INR, total bilirubin, and creatinine, predicts survival in patients with chronic liver disease awaiting transplant. Initially envisioned as a tool to evaluate patients undergoing transjugular intrahepatic portosystemic shunt (TIPS), it is now primarily used to prioritize liver allocation for liver transplantation in patients with end-stage liver disease.

Noninvasive imaging techniques including ultrasonography, CT, and magnetic resonance imaging (MRI) can identify hepatic steatosis, cirrhosis, and HCC. Liver biopsy remains the gold standard to establish the severity of liver inflammation and fibrosis.

Complications and Management

Portal hypertension is the most frequent complication in patients with cirrhosis. Clinical manifestations of portal hypertension include esophageal and gastric varices, portal hypertensive

TABLE 95.4

CHILD-TURCOTTE-PUGH SCORING SYSTEM

	Points scored for increasing abnormality		
Clinical and biochemical measurements	**1**	**2**	**3**
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Bilirubin (mg/dL)	1–2	2–3	>3
For cholestatic disease: bilirubin (mg/dL)	<4	4–10	>10
PT	1–4	4–6	>6
or			
INR	<1.7	1.7–2.3	>2.3
Ascites	Absent	Slight	Moderate
Encephalopathy (grade)	None	1 and 2	3 and 4

Child A, 5–6 points; Child B, 7–9 points; Child C, 10–15 points.
Prothrombin time (PT) or international normalized ratio (INR) may be used for scoring.

gastropathy, colopathy, splenomegaly, hypersplenism, ascites, spontaneous bacterial peritonitis (SBP), and HRS. HE that ranges from subtle cerebral dysfunction to deep coma is also a frequent complication of end-stage liver disease. Complications of chronic liver disease may result in frequent admissions to the ICU.

Portal Hypertensive Bleeding

Portal hypertension is characterized by increased resistance to portal flow and increased portal venous inflow. Portal hypertension is defined by measuring the pressure difference between the hepatic vein and the portal vein (normal pressure gradient 3 mm Hg) through transjugular approach. Varices do not form at hepatic venous pressure gradient less than 12 mm Hg [66,67].

Portal hypertension induces hemodynamic changes in the hepatic and splanchnic blood flow, with development of portosystemic collateral circulation (esophagus, stomach, rectum, umbilicus, retroperitoneum) and splenomegaly. Bleeding from gastric and esophageal varices is a common indication for ICU admission in patients with cirrhosis. Variceal bleeding presents with hematemesis, melena, or hematochezia. The bleeding event is often dramatic and associated with severe hemodynamic instability and frequently followed by HE. Patients with portal hypertensive gastropathy or colopathy usually present with less severe bleeding and often with chronic anemia. Given advances in medical and endoscopic therapy, acute variceal bleeding mortality has decreased significantly [68,69]. Recent studies show an associated in-hospital, 6-week, and overall mortality rates of 14.2%, 17.5%, and 33.5%, respectively [70]. Rebleeding episodes remain frequent (29%). Comprehensive management of patients with GI bleeding related to portal hypertension must include the following considerations: primary prophylaxis (banding of esophageal varices or use of nonselective beta-blockers), treatment of the active hemorrhage (blood/volume resuscitation, banding of esophageal varices, octreotide infusion, antibiotic prophylaxis), and prevention of rebleeding (secondary prophylaxis with nonselective beta-blockers). The management of variceal hemorrhage is discussed in Chapter 92. In esophageal bleeding refractory to endoscopic treatment, consideration has to be given to salvage therapy with TIPS [71].

Thrombocytopenia is common in patients with splenomegaly secondary to cirrhosis and it is one of the features of hypersplenism. The importance of thrombocytopenia in bleeding from portal hypertension is unclear. In our experience, transfusion of platelets should be limited to those patients who are actively bleeding or undergoing an invasive procedure.

Ascites

Mechanisms responsible for the formation of ascites are complicated, multifactorial, and result in sodium and water retention. Circulatory dysfunction characterized by arterial vasodilation with hypotension, high cardiac output, and hypervolemia is frequently seen in patients with portal hypertension and ascites. Levels of nitric oxide, a potent vasodilator, are elevated in the splanchnic circulation of patients with ascites. The ensuing arterial vasodilation triggers activation of baroreceptor-mediated systems, the renin–angiotensin–aldosterone system, and the sympathetic nervous system, inducing sodium retention. Regulation of water balance is also disrupted in patients with cirrhosis. As a result of the reduced effective intravascular volume, arginine vasopressin levels are elevated. The major clinical consequence of this elevation is dilutional hyponatremia, which occurs despite a sodium avid state [72].

Patients with large volume ascites generally present with abdominal distension with a fluid wave or shifting dullness on examination. Respiratory compromise from associated pleural effusion (hepatic hydrothorax) or increase intra-abdominal pressure may result. Large volume ascites may also induce the development of ventral and umbilical hernias, with increase risk of intestinal strangulation or rupture. At times, ascites may only be a radiologic finding (e.g., ultrasound, CT, or MRI).

Analysis of the ascitic fluid is essential for the appropriate management of patients with decompensated liver disease. Small volume (60 mL) diagnostic paracentesis should be performed in patients hospitalized with ascites. Even in the presence of severe coagulopathy, it is safe to remove fluid [73]. Infection and bleeding are rare complications (<1%) [74]. The ascitic fluid should be sent for cell count and differential, culture, albumin, triglycerides (chylous ascites), amylase (pancreatic ascites), adenosine deaminase (peritoneal tuberculosis), and cytology (malignant ascites), as clinically indicated. A serum-to-ascites albumin gradient (SAAG) more than 1.1 g per dL indicates portal hypertension with 97% specificity. A SAAG less than 1.1 g per dL is found in nephrotic syndrome, peritoneal carcinomatosis, serositis, tuberculosis, and biliary and pancreatic ascites.

Restriction of sodium intake to 2,000 mg per day and minimizing IV sodium load (fluids, antibiotics, total parenteral nutrition, blood transfusions) play an important therapeutic role. Fluid restriction to 1,000 to 1,200 mL a day is helpful in patients with severe hyponatremia (serum sodium <125 mEq per L). In cirrhotics, hyponatremia develops in the setting of ascites in an environment of avid renal sodium retention and increased extracellular fluid volume (hypervolemic hyponatremia) or due to excessive losses of sodium and extracellular fluid (hypovolemic hyponatremia). New V2-receptor antagonists that block the action of arginine vasopressin in the distal tubule of the kidneys are promising pharmacologic agents to treat patients with cirrhosis, dilutional hyponatremia, and ascites [75].

Potassium-sparing diuretics acting at the distal tubule (spironolactone, amiloride, triamterene) and loop diuretics (furosemide, bumetanide) are frequently used in combination in patients with cirrhosis. Spironolactone inhibits sodium reabsorption in the distal tubule and collecting ducts by antagonizing aldosterone. Spironolactone is very effective in managing cirrhotic ascites, but its use is associated with hyperkalemia and painful gynecomastia. Loop diuretics also have a natriuretic effect and can be used in combination with distal tubule diuretics to achieve a more rapid extravascular fluid loss. Furosemide is not as effective as spironolactone as a single agent in the long-term management of ascites because of its lack of inhibition of distal sodium reabsorption. Intravenous furosemide should be avoided as it can result in intravascular volume depletion and precipitate renal failure. Renal function should be closely monitored to avoid prerenal azotemia. The use of aspirin and nonsteroidal anti-inflammatory agents should be avoided because the inhibition of prostaglandin affects renal hemodynamics and natriuresis [76].

Large-volume paracentesis (LVP) can safely remove 8 to 10 L as a therapeutic measure in patients with significant abdominal discomfort or respiratory compromise. The administration of albumin (6 to 8 g per L of ascites removed) during LVP has been associated with a lower incidence of hemodynamic disturbances without affecting survival [77,78]. Refractory ascites is a condition that develops in patients who do not respond adequately to maximum doses of diuretics [79]. Progressive intravascular volume depletion, renal failure, and electrolyte abnormalities may limit the use of high-dose diuretics. A reasonable alternative in patients with refractory ascites requiring frequent LVPs with preserved liver function is a TIPS [80]. Complications associated with TIPS include HE, cardiopulmonary compromise, transient pulmonary hypertension, infection, bleeding, ischemic hepatitis, and shunt occlusion.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) is an infectious complication resulting from bacterial translocation that occurs through altered gut permeability and bacterial overgrowth. It is the most common infection in patients with cirrhosis and primarily seen in hospitalized patients. SBP develops in the setting of reticuloendothelial system depression and leukocyte dysfunction along with decreased opsonic activity in the ascitic fluid [81,82]. Almost 30% of patients with ascites admitted to the hospital for any reason have SBP [82,83]. Patients may present with abdominal pain, fevers, or mental status change; however, the diagnosis is often overlooked because clinical manifestations may be subtle or nonspecific. SBP is associated with high in-hospital mortality (10% to 30%). Advanced age and ICU stay are associated with increased mortality [84,85]. Recurrent SBP is common, with a 43% chance of recurrence at 6 months and 69% at 1 year [82,86]. Renal insufficiency occurs in up to one third of patients with SBP [87]. The median long-term survival of patients who develop SBP is 9 months [86].

A polymorphonuclear count of more than 250 per mm^3, a leukocyte count of more than 500 per mm^3, or the presence of a positive bacterial culture in the ascitic fluid establishes the diagnosis of SBP [88]. Ascitic fluid or blood cultures will be positive in at least one half of patients with SBP [88]. Identification of more than one organism raises the possibility of secondary bacterial peritonitis usually related to another intra-abdominal process. The most common organisms responsible for SBP are the Gram-negative enteric bacteria, *Escherichia coli*, and *Klebsiella*, accounting for 46% and 10% of cases, respectively [89]. *Streptococcus* sp (19%), *Staphylococcus* (1%), and anaerobic bacteria (6%) are less frequently implicated. Since identification of organisms is not immediately available, treatment should be targeted at the most likely culprits. The ideal antibiotic should have both Gram-negative and enteric organism coverage without nephrotoxicity. A third- or fourth-generation cephalosporin (cefotaxime, ceftriaxone), ampicillin/sulbactam, or ciprofloxacin at a renal adjusted dose are preferred therapies. Repeat paracentesis should be performed in patients who are not responding to therapy after 48 hours. If a 50% decrease in polymorphonuclear leukocyte count is not seen after 72 hours of antibiotic use, coverage should be broadened.

Two studies have demonstrated that administration of intravenous albumin in addition to antibiotics in the setting of SBP results in a lower incidence of renal impairment, improving short-term survival [90,91]. Due to the high recurrence rate of infection (70%), prophylactic, oral long-term antibiotic therapy is recommended after recovery. Secondary prophylaxis can be achieved with norfloxacin 400 mg daily. Primary antibiotic prophylaxis for SBP is indicated in the setting of acute GI bleeding [92].

Hepatic Encephalopathy

HE is a syndrome of disordered consciousness and altered neuromuscular activity, found in up to one third of patients with chronic liver failure [75]. Pathogenesis of this disorder is complex and incompletely understood. Inflammatory cytokines, benzodiazepine-like compounds, defective clearance of ammonia, and increased neuronal inhibition through the γ-aminobutyric acid (GABA) receptor supramolecular complex play a role in the pathogenesis of HE [93].

Clinical features range in severity from subclinical encephalopathy, manifested by disturbances in psychometric testing, to coma [94]. Symptoms may wax and wane over the clinical course of decompensated liver disease. Grade 1 encephalopathy involves personality changes and alterations in sleep patterns. Loss of orientation and lethargy develop as the grade of encephalopathy progresses. Asterixis and abnormal reflexes are seen on physical examination and are important clinical indicators of encephalopathy. The development of coma with decerebrate posturing indicates grade 4 encephalopathy. Although electroencephalograms are rarely used for the diagnosis, triphasic waves are present in grades 1 to 3 encephalopathy. Delta waves are frequently encountered in patients with coma (grade 4). CE and elevated ICP seen in acute liver failure is not present in patients with HE and end-stage liver disease. Serum ammonia is a popular marker for encephalopathy in chronic liver disease. However, there is poor correlation between ammonia levels and clinical disease [95] and in many cases results are of uncertain [96]. No single test is available to accurately assess for the presence or degree of encephalopathy.

Encephalopathy is usually precipitated by an acute event such as increased nitrogen load (GI bleeding, excess dietary protein intake, azotemia, constipation), the use of certain medications (sedatives, narcotics, diuretics), infection (SBP, pneumonia, urinary tract infection), electrolyte abnormalities (hypokalemia, hyponatremia), TIPS, surgical shunting, or superimposed acute liver disease. Noncompliance with medication used in the treatment of encephalopathy also may trigger this entity. Progression of underlying liver disease can also account for worsening encephalopathy.

Evaluation of patients with encephalopathy should start with identification of the precipitating event. Metabolic abnormalities such as abnormal serum sodium, potassium, and glucose as well as hypoxemia should be corrected. Hyponatremia should be treated with special caution, as rapid correction can lead to central pontine myelinolysis and neurologic damage [97]. Hypovolemia can be corrected with fluid resuscitation. A source of infection or sepsis should be investigated, even in the absence of fever, with cultures obtained from urine, blood, sputum, and ascites. Given the coagulopathy associated with chronic liver disease, a lumbar puncture should be pursued only if clinically imperative and after correction of blood clotting abnormalities. The presence of GI bleeding should be investigated. Prior history of medications or toxic ingestions should be reviewed.

Medications that decrease endogenous nitrogen production and nitrogen delivery to the liver play an important role in treating encephalopathy. Lactulose is a nonabsorbable disaccharide that reduces the intestinal production and absorption of ammonia [98]. The dose of lactulose should be titrated to achieve three to five soft stools a day, starting at 30 mL every 2 to 4 hours orally or via nasogastric tube. Lactulose can also be given as an enema in patients with an ileus or in those at increased risk of aspiration (300 mL lactulose in 700 mL distilled water). Rifaximin is a nonabsorbable rifamycin antibiotic, with broad-spectrum activity against Gram-positive and Gram-negative aerobes and anaerobes [99] with minimal side effects and no reported drug interactions. A dose of 1,200 mg per day (400 mg tid) is used as monotherapy or in combination with lactulose in the treatment of acute or chronic HE [100–103]. It is a safe drug in patients with renal impairment. Neomycin is a minimally absorbed antibiotic (1% to 3%) that efficaciously controls HE. It is given orally (500 to 1,000 mg every 6 hours) or as a retention enema (1% solution in 100 to 200 mL isotonic saline), as monotherapy or in combination with lactulose. It alters the colonic bacterial flora by acting against urease-producing bacteria. Neomycin is nephrotoxic and should be avoided in patients with renal insufficiency. Ototoxicity can also be associated with long-term use of neomycin. Metronidazole (250 mg orally every 8 hours) is also used to treat encephalopathy; side effects include metallic taste and peripheral neuropathy [104].

Dietary intake of protein should be reduced but not to the degree of inducing or exacerbating the catabolic effects of

chronic liver disease. Patients with prolonged ICU admissions should receive 40 to 60 g per day of protein. Tube feeds with high-branched chain amino acid concentrations are expensive and have no clinical benefits over formulas [105].

Hepatorenal Syndrome

Hepatorenal syndrome (HRS), a feared consequence of end-stage liver disease, occurs in up to 10% of patients hospitalized with cirrhosis and ascites [106]. It is characterized by functional renal failure in the absence of obvious abnormalities in kidney structure. The primary mechanism in the generation of HRS involves intense renal vasoconstriction in response to activation of neurohumoral factors including the renin–angiotensin–aldosterone system and the sympathetic nervous system [107] leading to low renal perfusion and glomerular filtration rate.

HRS is divided into two clinically distinct types. Type I HRS progresses rapidly and has a close temporal association with a precipitating event that results in either a doubling of the initial serum creatinine to greater than 2.5 mg per dL or a 50% reduction in the initial 24-hour creatinine clearance to less than 20 mL per minute in less than 2 weeks [107]. Type II HRS progresses in a slower but relentless fashion as a form of expression of circulatory dysfunction, and clinically manifests as diuretic-resistant ascites. In contrast to patients with type II HRS that present with better-preserved liver function, patients with type I HRS have a very poor prognosis. They are usually severely ill with marked edema, ascites, sodium retention, hyponatremia, and hypotension. Precipitants of HRS include SBP, LVP without plasma expansion, and GI bleeding [107,108].

Although diagnostic criteria for HRS and oliguric renal failure have been established (Table 95.5), the distinction between type I HRS and prerenal azotemia may be extremely difficult. Patients with type I HRS can be supported by hemodialysis or hemofiltration, but prognosis is poor, with a median survival of approximately 2 weeks [109]. Ultimately, the treatment of choice is liver transplantation [110]. In the absence of prior renal disease, patients with HRS may show recovery of renal function after transplantation [111]. Patients with type II HRS show manifestations of liver failure with severe ascites that is refractory to treatment with sodium restriction. Median survival in type II HRS is 6 months.

Pharmacologic therapy with splanchnic vasoconstrictor drugs and volume expansion has shown promise as a bridge to transplantation. The rationale behind the use of splanchnic vasoconstrictors is the reduction in portal blood flow and pressure [112]. Splanchnic vasoconstrictors used in the treatment of HRS include vasopressin, ornipressin, terlipressin, and norepinephrine or in combination with the α-agonist midodrine [110]. The most promising results have been shown with terlipressin in combination with albumin. Terlipressin administered at progressive dosage (0.5 to 1 mg intravenously at 4- to 6-hour intervals) is associated with improvement in renal function and hemodynamic status [110]. Reported side effects have been minimal and reversible with dose reduction or discontinuation. Albumin should be given concomitantly at a loading dose of 1 g per kg followed by 20 to 40 g per day [113]. Patients with type I HRS treated with terlipressin and albumin pretransplant have similar posttransplant outcome as patients without HRS [106]. A combination of octreotide, midodrine, and albumin also has been beneficial in the treatment of HRS in smaller studies [110,112].

HRS may occasionally be prevented by timely administration of albumin and antibiotics in the treatment of SBP [90,106,112]. Preliminary reports of TIPS as a treatment of types I and II HRS have shown success, although more data are needed before promoting its widespread use for these entities [114–116].

TABLE 95.5

DIAGNOSTIC CRITERIA OF HEPATORENAL SYNDROME

Major criteria
Low glomerular filtration rate, as indicated by serum creatinine >1.5 mg/dL or 24-h creatinine clearance <40 mL/min
Absence of shock, ongoing bacterial infection, fluid losses, and current treatment with nephrotoxic drugs
No sustained improvement in renal function (decrease in serum creatinine to 1.5 mg/dL or increase in creatinine clearance to 40 mL/min) after diuretic withdrawal and expansion of plasma volume with 1.5 L of a plasma expander
Proteinuria <500 mg/d and no ultrasonographic evidence of obstructive uropathy or parenchymal renal disease
Additional criteria
Urine volume <500 mL/d
Urine sodium <10 mEq/L
Urine osmolality greater than plasma osmolality
Urine RBCs <50/high-power field
Serum sodium concentration <130 mEq/L

Note: All major criteria must be present for the diagnosis of hepatorenal syndrome. Additional criteria are not necessary for the diagnosis but provide supportive evidence.
From Arroyo V, Gines P, Gerbes AL, et al: Definition and diagnostic criteria of refractory ascites and hepatorenal syndrome in cirrhosis. International Ascites Club. *Hepatology* 23:164, 1996, with permission.

LIVER TRANSPLANTATION

Fulminant Hepatic Failure

For many patients with FHF, liver transplantation provides the only realistic opportunity to stay alive. Of all liver transplants, approximately 5% are for patients with FHF. It has been estimated that 40% of patients with FHF admitted to transplant centers ultimately undergo transplantation. With supportive ICU care alone, only 25% will survive, while the remaining 35% perish despite the best intensive care available [55] and highest priority (status 1) assigned to these patients for liver transplantation by the United Network for Organ Sharing. The rapidly progressive nature of FHF and difficulty in obtaining organs prevents many potential recipients from receiving a transplant in a timely fashion. Patients listed as status 1 have an unacceptably high mortality rate while on the waiting list.

There is a favorable 3-year survival (75%) in those patients who undergo liver transplantation for FHF [55], and the outcome and prognosis of these patients is dependent on the specific etiology that induced the acute failure. Patients with FHF from acute hepatitis A, hepatitis B, and acetaminophen toxicity have better survival rates. Conversely, patients with FHF from idiosyncratic drug reactions, halothane exposure, and acute Wilson's disease tend to fare worse [55]. Regardless of the cause, early referral and evaluation for liver transplantation is imperative. Although most living donor transplantations are performed in patients with chronic liver disease, its role has been investigated in FHF. Survival up to 90% at 5 years has been reported in pediatric patients undergoing living donor transplants [117].

TABLE 95.6

SUMMARY OF EVIDENCE-BASED MANAGEMENT APPROACHES IN THE MANAGEMENT OF FULMINANT HEPATIC FAILURE AND CHRONIC LIVER DISEASE

Fulminant hepatic failure	
Hepatic encephalopathy	
Cerebral edema	■ There is no proven effective therapy. ■ There are no controlled trials to prove efficacy of ICP monitoring, and experience is variable across centers. ■ Mannitol has been shown in a controlled trial to decrease ICP and to improve survival. ■ Uncontrolled investigations show a benefit of hypothermia, but there are no controlled trials. ■ A randomized controlled trial has demonstrated that hypertonic saline and maintenance of hypernatremia (145–155 mmol/L) resulted in decreased incidence and severity of intracranial hypertension.
Acetaminophen toxicity	■ Based on controlled trials, *N*-acetylcysteine administration in oral or intravenous form can be recommended in suspected acetaminophen overdose.
Chronic liver disease	
Bleeding from portal hypertension	■ See Chapter 92
Ascites	■ Randomized controlled trials have demonstrated that the combination of sodium restriction to <2 g/d and oral diuretics is effective in reduction of ascites (AASLD guidelines). ■ Controlled trials have demonstrated that serial therapeutic paracentesis are equally as effective in controlling ascites as the combination of sodium restriction and oral diuretics; concomitant administration of albumin has been shown in uncontrolled trials to have a significant effect on electrolyte and creatinine levels without effect on clinical morbidity and mortality. It use remains controversial (AASLD guidelines). ■ Randomized controlled trials have demonstrated that TIPS is effective for controlling refractory ascites (AASLD guidelines).
Spontaneous bacterial peritonitis	■ Patients with SBP should receive antibiotics. ■ One randomized controlled trial demonstrated that administration of albumin (1.5 g/kg initially, then 1 g/kg on day 3) with antibiotics in SBP resulted in decreased mortality.
Hepatic encephalopathy	■ Lactulose and neomycin are the most frequently used agents in the treatment of hepatic encephalopathy; rifaximin has been shown in controlled trials to be an effective alternative or adjuvant to lactulose and neomycin.
Hepatorenal syndrome	■ Several uncontrolled studies and one small randomized study have demonstrated the use of terlipressin in combination with albumin improves renal function in type I HRS. ■ Small uncontrolled studies have demonstrated an improvement in renal function with the use of octreotide, midodrine, and albumin.

AASLD, American Association for the Study of Liver Diseases; HRS, hepatorenal syndrome; ICP, intracranial pressure; SBP, spontaneous bacterial peritonitis; TIPS, transjugular intrahepatic portosystemic shunt.

End-Stage Liver Disease

Liver transplantation is frequently indicated in patients with end-stage liver disease. The timing of liver transplantation in these patients is a complex issue. Transplant evaluation should be initiated when there is a decline in hepatic synthetic function, ascites, HE, or other complications such as ascending cholangitis, SBP, HRS, and HCC. Liver allocation in the United States is currently based on the MELD score. MELD is an accurate predictor of short-term survival (3 months) in patients with cirrhosis awaiting liver transplantation [118–121]. Contraindications for liver transplantation include sepsis, advanced cardiac or pulmonary disease, extrahepatic malignancy, multiorgan failure, and unresolved alcoholism, drug addiction, as well as psychosocial and compliance issues.

The 1-year survival for liver transplantation in the setting of chronic liver disease is currently 85% to 90% [122,123]. With increasing numbers of patients listed for transplantation and the relatively static number of cadaveric organs available, death is not uncommon while awaiting organ donation [124]. Because of the worldwide shortage of cadaveric liver donors, interest has developed in the role of living donors [125]. Living donors may provide a valuable option for some patients. Despite promising results, a number of donor deaths have occurred, raising questions regarding the suitability of this mode of transplantation [126].

Alternative Therapies

The severe and rapidly progressive consequences of FHF have led to investigate and develop other supportive modalities that could allow time for liver recovery or serve as a "bridge" to liver transplantation.

Prostaglandin E_1 (PGE_1) has been investigated as a possible therapy for patients with FHF. Benefits of intravenous PGE_1, especially if administered 10 days after the onset of symptoms, have not been verified [97,127]. Hepatic arterial infusions of

PGE_1 seem to be superior to IV administration in postsurgical acute liver failure based on very limited data [97].

Substitution of hepatocyte function with liver assist devices has been studied extensively [128–130]. These devices can be divided into biological (using whole animal livers), hybrid bioartificial (using cultured immortalized hepatocytes with both excretory and synthetic function), combination of both and nonbiological extracorporeal liver assist devices. Promise has been shown by the bioartificial hybrid systems which implement both mechanical toxin removal and biologic function provided by sliced or granulated livers or hepatocytes from low-grade tumor cells or pigs housed within a "bioreactor" [131]. In extracorporeal devices, albumin is the molecular absorbent used to remove toxins such as ammonia, bilirubin, aromatic amino acids, which accumulate as a result of liver failure and lead to the development of HE and renal failure. The most well studied of these dialysis systems is the molecular adsorbent recirculation system (MARS). It improves biochemical markers in both FHF and acute-on-chronic liver failure [132,133]. However, conclusive mortality benefits have not been shown and further trials are needed.

Human hepatocyte transplantation has also been investigated as an emergent alternative. There have been more than 80 cases of human hepatocyte transplantations, mostly in patients with inborn errors of metabolism (Crigler Najjar syndrome, Glycogen storage disease 1a and 1b, etc.) with short-term benefits [134,135]. In FHF and chronic liver failure, there is a reduction in bilirubin and ammonia with improvement in HE. Again, larger randomized clinical trials are needed to evaluate their efficacy. There are many barriers to overcome before this method can have widespread clinical use [136,137].

Evidence-Based Therapies

FHF and chronic liver disease are managed depending on the presentation and the presence and type of complications, as described in the earlier sections. In many instances, clinicians are guided by management strategies that have proved successful in the clinical setting. Some of the evidence-based approaches used in the treatment of these forms of liver disease are outlined in Table 95.6.

CHAPTER 96 ■ DIARRHEA

COLIN T. SWALES, LAURA HARRELL, EUGENE CHANG AND JOHN K. ZAWACKI

Diarrhea frequently complicates the course of the critically ill patient, occurring in 40% to 50% of patients in the intensive care unit (ICU). Diarrhea is the most common nonhemorrhagic gastrointestinal (GI) complication in this patient population [1–3]. Despite its high prevalence in the ICU patient population, diarrhea is frequently overlooked by physicians and the ICU team, especially when more emergent cardiovascular, respiratory, and infectious issues are present. Inattention to excessive stool output, however, can often result in serious perturbations of fluid and electrolyte balance, promote skin breakdown and infection, and create difficulty in the administration of proper nutritional support. In these instances, proper and immediate evaluation and management are essential to prevent further complications in a critically ill patient. The evaluation of diarrhea is often limited by the patient's status and practical limitations in performing diagnostic studies in the ICU setting.

The term diarrhea often carries a different meaning for patients and healthcare providers. Increases in stool frequency or fluidity do not necessarily indicate the presence of diarrhea. In a general patient population, an increase in daily stool weight or volume (exceeding 200 g per day) has been used as an objective-defining criterion [4]. In the critically ill patient, however, accurate measurement of stool output may be difficult, if not impossible. Physicians, therefore, must use their best judgment to decide whether diarrhea is present and to determine whether it represents a clinical problem requiring attention. This chapter provides helpful insights for making these decisions, presents guidelines for rapid and directed evaluation, and suggests effective approaches for the management of diarrhea in this setting.

ETIOLOGY

The causative factors of diarrhea in the ICU patient differ considerably from those of diarrhea in the general population. Numerous causes of diarrhea in the ICU setting exist and can be broadly divided into three categories: (i) diarrhea secondary to iatrogenic causes, (ii) diarrhea secondary to underlying diseases, and (iii) diarrhea resulting as a primary manifestation of specific diseases. Careful review of clinical information will allow physicians to narrow the diagnostic possibilities and avoid overlooking simple and common causes of diarrhea (Table 96.1). In some patients, diarrhea is the result of a combination of factors. Thus, it is incumbent on the physician to carefully review available data to identify the cause or causes of diarrhea.

Iatrogenic Causes

Iatrogenic factors are the most common and the most frequently overlooked cause of diarrhea in the critically ill patient. Furthermore, rapid and successful treatment of iatrogenic diarrhea can often be achieved by eliminating the offending agent or process.

Medications

Medications are a frequent cause of iatrogenic diarrhea in the ICU setting. Many of the drugs commonly used in the ICU can cause diarrhea (Table 96.2). Therefore, any medication

TABLE 96.1

DIFFERENTIAL DIAGNOSIS OF DIARRHEA IN THE INTENSIVE CARE UNIT SETTING

Iatrogenic causes
Medications
Enteral feeding
Pseudomembranous colitis
Diarrhea secondarily related to underlying disease
Infections in immunosuppressed patients
Neoplastic disease in immunosuppressed patients
Gastrointestinal bleeding
Neutropenic enteropathy
Ischemic bowel disease
Postsurgical diarrhea (postcholecystectomy, following gastric surgery)
Surgically induced short bowel syndrome or pancreatic insufficiency
Fecal impaction
Opiate withdrawal
Diarrhea as a primary manifestation of disease
Diabetic diarrhea
Renal failure
Sepsis
Adrenal insufficiency
Graft-versus-host disease
Vasculitis
Diarrhea-causing pathogens
Inflammatory bowel disease
Celiac sprue

TABLE 96.2

MEDICATIONS ASSOCIATED WITH DIARRHEA[a]

Antibiotics (especially erythromycin, ampicillin, clindamycin, azithromycin, cephalosporins)
Antacids (magnesium containing)
Magnesium and phosphorus supplements
Proton pump inhibitors
Lactulose
Colchicine
Digitalis
Quinidine
Theophylline
Levothyroxine
Aspirin
Nonsteroidal anti-inflammatory agents
Cimetidine
Misoprostol
Diuretics
Beta-blocking agents
Chemotherapeutic agents
Immunosuppressants (tacrolimus, sirolimus, mycophenolate mofetil, cyclosporine, azathioprine)
HIV medications (especially protease inhibitors, e.g., nelfinavir)
Oral hypoglycemics, e.g., metformin

[a] Additives in the physical formulation of medications (e.g., sorbitol, lactose) may produce diarrhea independently of the primary medication.

or combination of medications should be suspected, and uncertainty on the part of the physician warrants consultation with a pharmaceutical reference. Antibiotic-associated diarrhea occurs in 3% to 29% of hospitalized patients [5]. The frequency of diarrhea varies considerably depending on the antibiotic administered. The rate of diarrhea associated with parenterally administered antibiotics is comparable to orally administered antibiotics, especially antibiotics excreted into the enterohepatic circulation. Antibiotics most commonly associated with diarrhea include ampicillin, tetracycline, clindamycin, azithromycin, clarithromycin, fluoroquinolones, and many of the cephalosporins [6]. Antibiotic agents often cause a nonspecific, noninflammatory diarrhea associated with nausea, abdominal cramping, and bloating. In these instances, diagnostic studies generally are negative. Fluid and electrolyte losses are minimal and symptoms often abate after withdrawal or change of the medication. Alterations in intestinal flora, breakdown of dietary carbohydrate products, and prokinetic effects (e.g., from erythromycin) are all postulated mechanisms of diarrhea [7].

Clostridium difficile infection (CDI) is the most common cause of infectious diarrhea in the ICU [8]. In fact, residence in the ICU has been identified as a risk factor for developing CDI [9], and some authors believe that *C. difficile* toxins are responsible for 50% of the cases of diarrhea in the ICU setting. CDI in the ICU is increasing in not only in incidence but also in severity [10]. It can present as a serious and sometimes life-threatening complication. CDI must always be considered in ICU patients with diarrhea who are commonly exposed to various mediations, particularly antibiotics that predispose to the development of CDI. Classically, clindamycin, penicillin, and broad-spectrum cephalosporins have been implicated. However, CDI may be caused by any antibiotic, including metronidazole and vancomycin, the agents typically used to treat CDI. The risk factors associated with CDI, besides antibiotic exposure and environmental factors, include age greater than 60, severe underlying disease, gastric acid suppression, and immunologic susceptibility [7].

C. difficile produces multiple toxins, two of which have been well characterized. Toxin-induced changes in colonocyte function, cytokine release, and alterations in intestinal motility result in the signs and symptoms characteristic of CDI [11]. One strain of *C. difficile*, NAP1 (North American pulsed-field electrophoresis type 1), has been associated with both an increased morbidity and mortality [12]. Prompt recognition and treatment of CDI are essential because severe cases of CDI can progress to fulminant colitis and toxic megacolon requiring urgent surgical intervention.

Agents that increase the osmotic load in the gut lumen are also frequent causes of diarrhea in the ICU patient. Magnesium-containing antacids (e.g., Maalox and Mylanta) are common examples of such agents. The gut lumen osmotic load can also be increased as a result of aggressive enteral repletion of nutrients such as magnesium and phosphorus. Lactulose, a useful agent in the treatment of hepatic encephalopathy, provides an osmotic gradient resulting in increased fluid secretion and stool output. Many medications contain inert additives, sorbitol or lactose, which may also cause an osmotic diarrhea. In one study including 29 tube-fed patients with diarrhea, 48% of the cases were attributed to sorbitol-containing elixirs [13].

Proton pump inhibitors (PPIs), another commonly used class of medication in the ICU setting, frequently cause diarrhea, particularly when administered in higher doses. In fact, in a large study of more than 40,000 patients treated with omeprazole, lansoprazole, or pantoprazole, the most common adverse event was diarrhea [14].

Immunosuppressants used in transplantation (e.g., tacrolimus, sirolimus, mycophenolate mofetil, cyclosporine, and

azathioprine) are associated with diarrhea. However, these agents may not be causative. As an example, an alternative explanation was found in 50% of kidney transplant patients who developed diarrhea while receiving mycophenolate [15]. In patients with HIV who are treated with highly active antiretroviral therapy (HAART), drug-induced diarrhea occurs in up to 75% of patients, and the protease inhibitors as well as integrase inhibitors are the most common drug-related cause of diarrhea in this population [16]. Symptoms are lessened by dose reduction or eliminated by discontinuation of therapy.

Withdrawal from medications (e.g., long-term sedatives, analgesics) may also be associated with diarrhea [17].

Other medications associated with diarrhea include colchicine, quinidine, digitalis, metoclopramide, theophylline, levothyroxine, aspirin, nonsteroidal anti-inflammatory drugs, misoprostol, cimetidine, diuretics, cholinergic agents (e.g., bethanechol), and beta-blockers.

Enteral Feedings

Enteral feedings are the most common cause of diarrhea in the ICU setting, occurring in up to 63% of ICU patients [1,18]. Numerous studies have investigated the role of enteral feedings in causing diarrhea in the critically ill patient. Certain aspects, such as concurrent administration of antibiotics, osmolality of solution, type of solution, and serum albumin, have been assessed to determine their contributing roles in the occurrence and severity of diarrhea in these patients [19]. In most instances, diarrhea in enterally fed patients is associated with concurrent antibiotic administration [18,20]. However, enteral feeds also cause changes in gut function that can result in diarrhea. The osmolarity of the enteral solution may play a role when elemental-type diets are used, and especially when feedings are rapidly administered directly into the small intestine. Bolus feeding may be more physiologic, especially with regard to glucose homeostasis; however, feedings administered in this manner distal to the pylorus introduce high-osmolar contents rapidly into the small bowel, resulting in a higher incidence of diarrhea [21]. The impact of enteral nutrition-related complications, including diarrhea, was illustrated in a prospective, multicenter cohort study of 400 patients [22]. In this study, 62.8% (251 of 400) patients suffered GI complication with 14.7% of the studied patients experiencing enteral nutrition-related diarrhea. These authors found that patients with GI complications had a reduction in their tube feed volumes, longer length of stay in the ICU, and higher mortality.

Enteral formulas high in lactose or fat content may also be a factor in susceptible patients. Starved or chronically parenterally fed patients who have developed small bowel villus atrophy and a decrease in mucosal disaccharidase enzyme activity may experience diarrhea when enteral feedings are initiated.

The relationship between hypoalbuminemia and diarrhea is controversial. Hwang et al. [2] compared ICU patients with and without diarrhea and found that the albumin level was statistically different between groups (1.90 g per dL vs. 3.40 g per dL in the groups with or without diarrhea, respectively). Hypoalbuminemia with resulting lowered oncotic pressure may cause diarrhea by inducing changes in the Starling forces sufficient to inhibit intestinal fluid absorption. Some authors claim that concurrent nutritional intake and correction of the albumin deficit with intravenous salt-poor albumin may result in normalization and maintenance of albumin levels with an improved tolerance to enteral feedings and resolution of diarrhea [23]. Conversely, patients with severe hypoalbuminemia secondary to cirrhosis or nephrotic syndrome do not uniformly have diarrhea. Until further studies show efficacy, routine use of intravenous albumin repletion cannot be recommended.

Studies investigating the role of the intestinal response to tube feedings have revealed that intraduodenal infusion resulted in a normal postprandial pattern of small intestinal motility and an increase in the volume of fluid entering the colon, but did not result in diarrhea [24]. Intragastric infusion, on the contrary, resulted in small intestinal motility and colonic flow similar to fasting, and the majority of subjects developed diarrhea [25]. This has led to the conclusion that enteral feeding–related diarrhea may be secondary to a disorder in colonic function. Further supporting this hypothesis are studies that have shown that the ascending colon, normally the site of maximal absorption of water and electrolytes, actually secretes water, sodium, and chloride during intragastric and intraduodenal infusion [26]. Up to 3.2 L per day was secreted by the ascending colon in these studies. Although this is well within the estimated 5.7 L per day maximal absorptive capacity of the colon, diarrhea still occurred, suggesting that this reversal of normal colonic physiology seriously impairs the absorptive capacity of the colon [27].

Diarrhea Secondarily Related to Underlying Disease

Diarrhea may result from various processes or pathogens associated with disease states commonly seen in the critically ill patient. Diarrhea may occur more frequently in patients who are immunosuppressed, have alterations in cardiac output and blood flow, or have various primary GI diseases.

In immunosuppressed patients, multiple infectious agents may be responsible for the development of diarrhea. Cytomegalovirus (CMV), herpes simplex virus, *Giardia*, *Salmonella*, *Shigella*, *Cryptosporidium*, *Isospora*, *Campylobacter*, and *Mycobacteria* are among the most common identifiable pathogens. Postchemotherapy patients can also experience diarrhea as a result of direct injury to the bowel, ranging from bowel edema to frank infarction. The cause of these changes is unclear; however, infections, direct toxic effects of chemotherapeutic agents, neutropenia, and primary intestinal injury have been postulated as initiating factors [28]. Strongyloides stercoralis should be remembered as a cause of diarrhea in patients who lived or traveled to endemic areas. Untreated immunosuppressed patients may develop hyperinfection with pulmonary infiltrates and infection of the CSF and blood with enteric Gram-negative bacilli [29].

In patients with acquired immunodeficiency syndrome (AIDS), diarrhea is perhaps the most commonly experienced symptom. Aside from iatrogenic causes, these patients can develop diarrhea from a single or multiple pathogens. CMV, *Mycobacterium* spp, *Cryptosporidium*, and *Microsporidium* are the most common agents. *Cryptosporidium* typically results in a severe large-volume secretory diarrhea (often in excess of 1 L per day) [30]. Other pathogens such as *Entamoeba histolytica*, *Isospora belli*, *Giardia lamblia*, *Microsporidium*, adenoviruses, and other species described above are capable of causing diarrhea in patients with AIDS [31]. Bacillary dysentery may become chronic and relapsing, posing challenges with treatment. The herpes simplex virus may cause perianal ulceration, urgency, and frequent mucopurulent discharge, which may be interpreted as diarrhea [32]. The CD4 count (cluster of differentiation 4 count) indicates the degree of immunocompromise in these patients, and a lower count broadens the differential diagnosis of the etiology of diarrhea. *Cryptosporidium parvum*, *Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*, *Mycobacterium avium* complex (MAC), and enteroaggregative *Escherichia coli* cause self-limited disease in normal and mildly immunosuppressed individuals, but may

cause persistent, severe diarrhea in patients with CD4 counts less than 200 cells per mm [3,33–37]. CMV rarely causes diarrhea in patients with CD4 counts greater than 50 cells per mm [3,38]. Patients with AIDS also may develop high-grade intestinal lymphomas predominantly of B-cell origin, which may present as diarrhea. Kaposi's sarcoma may cause GI bleeding but rarely causes diarrhea [39].

Intestinal ischemia, especially involving the colon, may result in abdominal pain and diarrhea in the ICU patient. Postsurgical patients, especially those who have undergone repair of an abdominal aortic aneurysm, may have as high as a 6% incidence of colonoscopically documented ischemia [40]. Patients who have undergone an abdominoperineal resection or therapeutic angiography are also at risk. Compromise of the inferior mesenteric artery with left-sided colonic involvement is the primary etiologic factor. Symptoms may occur within hours to a few days following the procedure and may even be delayed for weeks. Patients in shock with depressed cardiac output may be more likely to present with right-sided colonic involvement, which is associated with a worse prognosis [41]. Severity can range from mild, transient ischemic changes to mucosal ulceration or bowel necrosis. Sympathomimetic drugs, vasopressin, ergot preparations, migraine therapies, alosetron, bevacizumab, and digoxin may further place susceptible patients at risk [42]. Likewise, small intestinal ischemia, especially venous ischemia, may present with bloody or nonbloody diarrhea. Bleeding of either the upper or lower GI tract is a frequent cause of bloody diarrhea in the ICU setting. Blood acts as both an irritant and osmotic agent resulting in diarrhea. Common causes of upper GI bleeding include esophagitis, gastric and duodenal ulcer disease, and hemorrhagic gastropathy, whereas infectious colitis, diverticulosis, and ischemia may result in lower GI bleeding.

Fecal impaction in both medical and surgical patients may cause diarrhea and should be considered in the ICU patient with diarrhea. Drugs such as analgesics, sedatives, aluminum-containing antacids, and sucralfate may decrease intestinal motility and fecal fluidity, resulting in formation of a partially obstructing fecal mass and diarrhea. Diverticulitis also may present with an accompanying diarrhea.

Diarrhea as a Primary Manifestation of Disease

Several common diseases are occasionally characterized by diarrhea during their courses. For instance, patients with diabetes can experience severe bouts of diarrhea. Diabetic diarrhea is thought to result from an autonomic neuropathy and its subsequent effect on intestinal fluid absorption [43]. These patients invariably have other signs of autonomic neuropathy including orthostatic hypotension, gastroparesis, anhidrosis, abnormalities in RR wave variation on electrocardiogram, and neurogenic bladder [44]. Abnormalities in motility with intestinal stasis and bacterial overgrowth may also play a role in the development of diarrhea in diabetic patients.

Other endocrine disorders such as adrenal insufficiency and hyperthyroidism should also be considered in the critically ill patient with diarrhea. Adrenal insufficiency, either primary adrenal failure as a result of result of bilateral adrenal hemorrhage or infarction, or relative deficiency induced by stress in patients chronically exposed to corticosteroids, may present with secretory diarrhea. The symptoms and signs of an adrenal crisis include shock, nausea, vomiting, diarrhea, abdominal pain, fever, fatigue, and sometimes confusion or coma. Patients with hyperthyroidism have increased fecal output largely due to increased intestinal motility [45].

Graft-versus-host disease (GVHD) may complicate both the short- and long-term course of patients who have undergone transplant (most commonly following allogeneic hematopoietic stem cell transplantation) [46,47]. Acute GVHD, occurring less than 100 days after transplant, typically is characterized by dermatitis, hepatitis, and gastroenteritis usually manifesting with nausea, abdominal pain, and diarrhea. Chronic GVHD (occurring more than 100 days after transplantation) may mimic autoimmune diseases, such as systemic lupus erythematosus, systemic sclerosis, or Sjogren's syndrome [48] and often is characterized by a less severe form of diarrhea.

Vasculitic diseases such as systemic lupus erythematosus, dermatomyositis, polyarteritis, and Wegener's granulomatosis can involve medium- and small-sized vessels supplying the GI tract. Abdominal pain, fever, bleeding, and diarrhea are common resulting symptoms.

Finally, one must always consider causes of diarrheal disease that are not unique to the critically ill patient. Infectious causes of diarrhea in immunocompetent hospitalized patients are possible, but are unusual in clinical practice unless the onset of the diarrhea is within the first few days of hospitalization or a nosocomial outbreak of infection is present [49]. Infectious causes that should be considered include *Salmonella*, *Shigella*, *Campylobacter*, *Giardia*, or *E. histolytica*, although other pathogens have also been implicated [50]. Nonenteric infectious causes of diarrhea include toxic shock syndrome and Legionnaires' disease. Other causes to be considered include lactose intolerance, inflammatory bowel disease, and celiac sprue.

DIAGNOSIS

History and Physical Examination

The history is important in establishing the diagnosis and etiology of diarrhea in the ICU patient; however, depressed neurological function as the result of the disease state or iatrogenic sedation and intubation may make obtaining a history impossible. Attention to onset, duration, character, relation to enteral intake, and associated symptoms of diarrhea may be helpful etiologic clues. Information on prior episodes of diarrhea, the patient's underlying medical conditions (which may be associated with diarrhea), or prior use of antibiotics is also important to elucidate. Next, a careful review of the patient's current medications and their administration relative to the onset of diarrhea should be performed. Any suspected agent should be discontinued if at all possible or changed to an alternative medication. Every effort should be made at decreasing the number of medications and continuing only those that are absolutely necessary. The physician should also determine whether the initiation of enteral feedings has correlated with the onset of symptoms.

A history of abdominal pain may suggest ischemia, infection, or various inflammatory conditions such as vasculitis or GVHD. Bloody diarrhea may suggest primary GI bleeding, ischemia, or occasionally pseudomembranous colitis secondary to CDI. Passage of frequent small-volume stools with urgency and tenesmus suggests distal, left-sided colonic involvement, whereas passage of less frequent, large-volume stools suggests more proximal involvement (small intestine or right colon). These historical clues, however, are not mutually exclusive, and in disease states with extensive bowel involvement, the distinction may not be appreciable.

Physical examination may provide further clues to the etiology of diarrhea, but findings are usually nonspecific. More important, the physical examination is essential in assessing the clinical severity of diarrhea. Orthostasis suggests severe volume

loss, adrenal insufficiency, or autonomic neuropathy (e.g., from diabetes). Fever may occur in individuals with infection, vasculitis, adrenal insufficiency, or hyperthyroidism. Abdominal tenderness may suggest infectious, ischemic, or vasculitic causes. Skin rashes or mucosal ulcerations in appropriate patients may suggest inflammatory bowel disease, vasculitis, or GVHD. Clinical manifestations of AIDS may be apparent. Abdominal distention, palpable bowel loops, or abnormal rectal examination may suggest a partially obstructing fecal impaction.

Laboratory Studies

Serum electrolytes especially sodium, potassium, magnesium, and phosphorus should be obtained and carefully monitored in patients with diarrhea. Severe diarrhea may result in a hyperchloremic metabolic acidosis and prerenal azotemia. The serum sodium may be normal, elevated, or depressed depending on the severity of diarrhea, oral/parenteral water intake, type of intravenous fluid administered, and other disease states (e.g., hepatic or renal dysfunction). The serum potassium, magnesium, and phosphorus may be normal or depressed, whereas elevations (e.g., in potassium) may suggest adrenal insufficiency or uremia. Leukocytosis may suggest infection or ischemia, whereas neutropenia may suggest an immunosuppressed state or sepsis. Low serum protein levels may be a clue to the presence of a protein-losing gastroenteropathy.

Examination of the stool may be the single most important and most overlooked laboratory investigation in the ICU patient with diarrhea. The presence of fecal leukocytes should be determined, and when present may suggest infection, ischemia, or mucosal inflammation. Newer assays for fecal calprotectin and lactoferrin have been validated for use in dysentery and inflammatory bowel disease, but its usefulness in the ICU setting requires study [51]. An assay for *C. difficile* should always be obtained; most toxin assays are enzyme immunoassays and are typically very specific, although 100 to 1,000 pg of toxin A or B must be present to obtain a positive result. Because testing two or three samples for the toxins improves the diagnostic yield by only 5% to 10% [14], consideration should be given for obtaining polymerase chain reaction (PCR) testing rather than ordering serial toxin assays if the clinical suspicion remains high. Cytopathic effect on cultured fibroblasts is more sensitive than the toxin assay but is not offered in many laboratories.

Fresh stool specimens for culture and ova and parasite examination should be requested in patients where there is a clinical suspicion, for example, in dysenteric presentations or when either fecal leukocytes or an elevated fecal calprotectin is found. Indiscriminate ordering of stool culture and O&P is not warranted. Immunosuppressed patients, however, require more extensive examination of the stool. Often, opportunistic pathogens are not detected readily through stool studies, and endoscopic examination with biopsies is required. Some pathogens such as CMV or MAC isolated from stool do not necessarily represent infection and require evidence of tissue invasion on biopsy for diagnosis.

Qualitative examination of the stool for fat using a Sudan III stain is the best screening test if a malabsorptive state is suspected. Determination of the stool osmolar gap, which is $290 - [(\text{stool } [Na^+] + \text{stool } [K^+]) \times 2]$, helps to distinguish osmotic and secretory causes of watery diarrhea. A gap grater than 125 mOsm per L is conventional for an osmotic diarrhea. High-volume stool output that persists with fasting suggests a secretory etiology, whereas an elevated stool osmolar gap suggests osmotic causes. A low stool pH may suggest bacterial overgrowth or carbohydrate malabsorption [4].

Special Diagnostic Investigations

Plain abdominal radiographs are sometimes helpful and may show signs of ischemia, obstruction, perforation, or a megacolon associated with colitis. Contrast studies better define GI pathology that may result in diarrhea but often cannot be performed in a critically ill patient. Both the above study types have been in practice supplanted by computed tomography (CT); newer imaging modalities, such as CT enterography and magnetic resonance enterography, are quickly replacing the more cumbersome enteroclysis and may be useful in selected cases.

Flexible sigmoidoscopy, colonoscopy, and upper endoscopy can be extremely useful in diagnosing various causes of diarrhea. Colitides, including infectious, ischemic/vasculitic, and pseudomembranous colitis, will often have a characteristic endoscopic appearance. The classic findings in *C. difficile* colitis include distinct, adherent, raised plaques (pseudomembranes) 2 to 5 mm in size that may be confluent. More commonly, the mucosa is normal; a normal appearance should not exclude the diagnosis of CDI, as mucosal biopsies may reveal pseudomembranes histologically. CMV or herpes colitis are best diagnosed endoscopically. CMV colitis may manifest as discrete ulcerations or widespread mucosal edema, erythema, and erosion. The characteristic vesicles of herpes may or may not be present and can be replaced by extensive ulceration. MAC (aforementioned) usually is diagnosed histologically; small bowel or colonic biopsies reveal abundant acid-fast bacilli. *Cryptosporidium* and *Giardia* can be made by histologic evaluation of small bowel biopsies, whereas identification of *Microsporidium* is more difficult and requires the use of electron microscopy. GVHD is confirmed most commonly by histopathological findings seen in biopsies obtained during flexible sigmoidoscopy.

Video capsule endoscopy, where a 12 mm capsule is either swallowed or placed in the small bowel endoscopically, captures via telemetry images of the entire small bowel. The mucosal detail provided is excellent, and so small bowel ulcerations, villus abnormalities, strictures, and other mucosal lesions are now more readily detected. Small bowel ulcerations, villus abnormalities, strictures, and other mucosal lesions are now more readily detected. For example, capsule endoscopy allows for a more precise gauge of the extent of Crohn's disease and celiac disease, and eosinophilic gastroenteritis has a characteristic capsule endoscopic appearance [52]. Although this technology permits detection of occult small bowel pathology not previously appreciated, its possible role and value in the diagnosis of persisting diarrhea in the ICU patient is unknown.

MANAGEMENT

Initial Management

The first and most important step in management of patients with diarrhea regardless of the etiology is correction of fluid and electrolyte imbalances (Fig. 96.1). Careful monitoring of the patient's physical and laboratory parameters will help guide replacement therapy. Most often, free water, sodium, potassium, phosphorus, or magnesium repletion will be required. If fluid losses are particularly severe or the patient's circulatory status is tenuous or compromised, central venous access and monitoring are essential. Physicians and nursing staff should ensure that proper patient hygiene and skin care are maintained. Suspected infectious causes of diarrhea warrant patient isolation and enteric precautions until a diagnosis is made and proper treatment instituted.

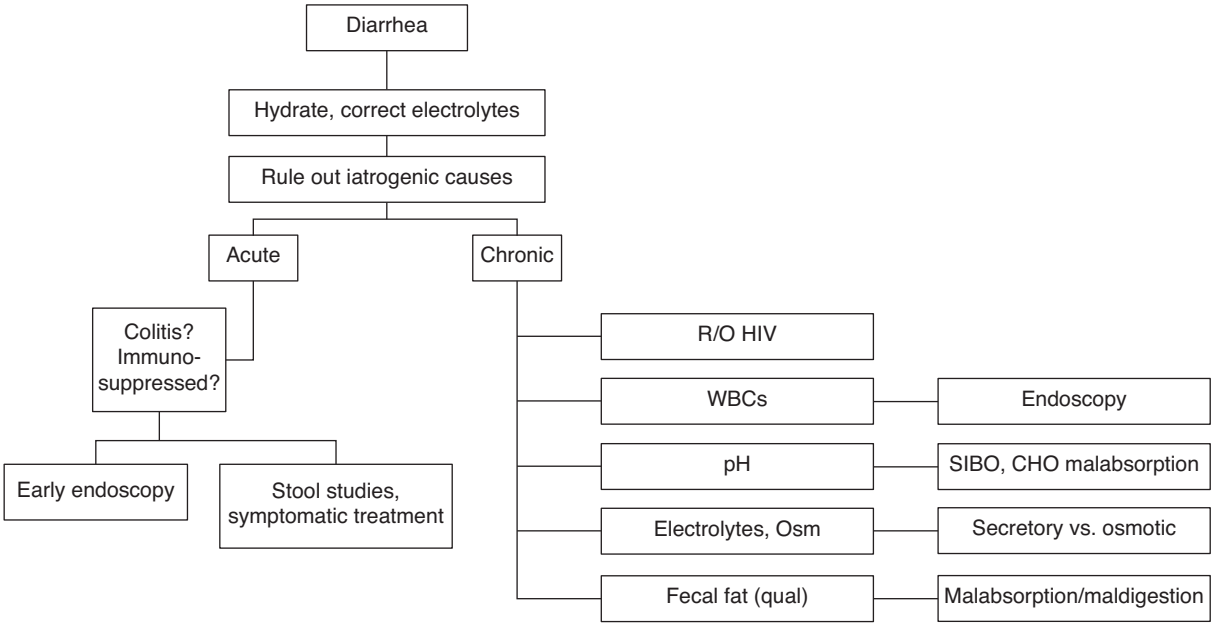

FIGURE 96.1. Algorithm for management of diarrhea in the intensive care unit.

Therapy of Iatrogenic Causes

Iatrogenic causes of diarrhea are among the most readily diagnosed and easily treated etiologies. Suspect medications, especially antibiotics, should be withdrawn or changed to those less likely to cause diarrhea.

If a diagnosis of *C. difficile* colitis is suspected or made, the offending antibiotic should be discontinued, or if necessary, replaced by agents less likely to cause CDI (Table 96.3). Vancomycin administered by the enteral route (0.5 to 2 g per day) has been a time-honored and highly efficacious therapy, resulting in improvement in more than 95% of patients [53]. Expense and concern over the selection of vancomycin-resistant bacteria, however, are major drawbacks. Several trials and a recent Cochrane meta-analysis show equal efficacy between metronidazole and vancomycin [54–56]. Thus, vancomycin should be reserved for those patients who cannot tolerate, do not respond to metronidazole, or suffer repeated relapses of infection. Metronidazole can be given 250 mg four times daily or 500 mg three times daily for 10 to 14 days. Patients will generally respond within 24 to 48 hours with improvement in diarrhea, pain, fever, and leukocytosis. Although there are limited data, two small studies have suggested that intravenous metronidazole is also useful for the treatment of CDI [55]. Intravenous vancomycin should not be used to treat CDI, as it is not excreted in the stool [57,58]. In severe cases of *C. difficile* colitis, high doses of oral vancomycin (500 mg four times daily) are preferred. If the patient has an ileus or toxic megacolon, intravenous metronidazole should be administered. One small series demonstrated benefit with the administration of vancomycin enemas in patients with severe pseudomembranous colitis [59]. Relapse rates may be high, occurring in as many as 24% of patients [60]. Case reports of successful salvage of toxic pseudomembranous colitis using intravenous immune globulin were not supported by a single-center, retrospective cohort [61]. Bile salt–binding resins such as cholestyramine or colestipol may be useful as adjunctive therapy in mild cases or in relapses but should not be used exclusively, especially in moderate to severe diarrhea. These agents can bind vancomycin, making this combination less desirable.

Small trials have suggested a benefit using probiotics for both primary and secondary prevention of antibiotic-associated diarrhea. A recent meta-analysis of these trials concluded that they may reduce the incidence of antibiotic-associated diarrhea (AAD) by about half, although there was significant heterogeneity in the trials [62]. Treatment studies for CDI have not demonstrated a significant benefit [63], and there have been several case reports of *Saccharomyces cerevisiae* fungemia in critically ill and immunocompromised patients who had been given probiotics containing *Saccharomyces boulardii*, which has identical DNA fingerprinting to *S. cerevisiae*. Given these case reports, probiotics cannot be recommended for the treatment of antibiotic-associated diarrhea in the critically ill patient [64].

Data are now emerging that exposure to PPIs is associated with increased odds of CDI in hospitalized patients. The postulate that acid suppression causes enteric infections seems reasonable but remains controversial. These data are observational and thus may be subject to uncontrolled confounding.

TABLE 96.3

TREATMENT OF *CLOSTRIDIUM DIFFICILE* COLITIS

General
Discontinue offending antibiotic if possible
Avoid antimotility agents
Isolation with enteric precautions
Antimicrobial
Metronidazole 250 mg PO q.i.d. or 500 mg t.i.d. for 10–14 d[a]
Vancomycin 125–500 mg PO q.i.d. for 7–14 d
Anion exchange resins (in combination with metronidazole in mild cases)
Cholestyramine 4 g PO t.i.d.
Colestipol 5 g PO t.i.d.

[a]If the patient has an ileus or toxic megacolon, metronidazole should be administered intravenously.

TABLE 96.4

A SUMMARY OF THE EVIDENCE-BASED MANAGEMENT APPROACHES FOR *CLOSTRIDIUM DIFFICILE*–RELATED DIARRHEA

- Vancomycin and metronidazole are equally effective in treating diarrhea from *C. difficile* colitis[a,b]
- Rates of recurrent *C. difficile*–associated disease following treatment with vancomycin or metronidazole are not significantly different[b]
- Tapered or pulsed dosing regimens of vancomycin are more effective than a 10- to 14-day course of vancomycin for the treatment of recurrent *C. difficile*–associated disease[c]

[a] Teasley DG, Gerding DN, Olson M, et al: Prospective randomised trial of metronidazole versus vancomycin for *Clostridium difficile*–associated diarrhea and colitis. *Lancet* 2:1043, 1983.
[b] Wenisch C, Parschalk B, Hasenhündl M, et al: Comparison of vancomycin, teicoplanin, metronidazole, and fusidic acid for the treatment of *Clostridium difficile*–associated diarrhea. *Clin Infect Dis* 22:813, 1996.
[c] McFarland LV, Elmer GW, Surawicz CM, et al: Breaking the cycle: treatment strategies for 163 cases of recurrent *Clostridium difficile* disease. *Am J Gastroenterol* 97:1769, 2002.

Nonetheless, it is prudent to review the indication for PPI prescription in all patients and restrict use of these drugs appropriately [65].

Antimotility agents should not be used in colitis, because they may lengthen the course of illness and may precipitate toxic megacolon [66]. If the patient with *C. difficile* colitis develops peritoneal signs, bacteremia unresponsive to antibiotics, progressive fever, rigors, or radiologic evidence of significant pericolonic inflammation with increasing bowel wall edema, surgical intervention is indicated [67]. The recommended procedure is subtotal colectomy with ileostomy, with possible ileorectal anastomosis after the inflammation has subsided. A summary of the evidence-based treatment approaches for *C. difficile*–related diarrhea is provided in Table 96.4.

There are several controlled trials now available which demonstrate the effectiveness of octreotide in chemotherapy and radiation-associated acute diarrhea. Doses range in these studies from 100 to 500 μg given subcutaneously twice or three times daily. Budesonide is not helpful in these settings [68].

Enteral feedings suspected of causing diarrhea should be reduced in volume, given by continuous infusion, or temporarily discontinued. Lactose-free feeds should be used, as the high incidence of stress-induced GI mucosal injury in the ICU population affects loss of disaccharidase activity. Fiber-containing formulas or fiber added to standard formulas may benefit ICU patients with tube feeding-associated diarrhea [69,70]. Elemental diet supplements may also be considered in patients with short bowel syndrome, pancreatic insufficiency, radiation enteritis, fistula, and inflammatory bowel disease. Their major disadvantages are high cost and increased osmolarity [71].

Treatment of Diarrhea Related to Disease

Efforts should always be made to treat the underlying disease causing diarrhea in the critically ill patient, although such efforts may or may not improve the diarrhea. Diarrhea secondary to sepsis will typically resolve, as the source of sepsis is treated, whereas diarrhea secondary to diabetes or uremia may not improve despite treatment of the primary disease.

Diarrhea-causing pathogens should, in general, be treated. The detection of *Blastocystis hominis* in parasite exams may indicate coinfection with other pathogens, and empiric nitazoxanide or metronidazole may be beneficial [72]. Infections in patients with AIDS and other immunocompromised settings are treatable with currently available therapy [73,74].

Patients with ischemic colitis without transmural necrosis may be managed with supportive care. Drugs that exacerbate ischemia should be discontinued if possible. Aggressive efforts at maintaining circulatory blood volume and maximizing oxygen delivery should be emphasized. Signs of infarction or perforation warrant operative management.

Fistulas should be managed by bowel rest or surgery depending on the clinical circumstances. Postcholecystectomy diarrhea may respond to bile acid sequestrants such as cholestyramine. Surgically induced cases of short bowel syndrome or malabsorption may be aided by enteral nutrition in the form of elemental diets or, if unsuccessful, parenteral nutrition. Fecal impactions should be removed by manual disimpaction followed by cleansing enemas consisting of tap water, sodium phosphate, or diatrizoate (water-soluble contrast) enemas. More proximal and firm impactions can be broken up using a sigmoidoscope and an irrigating device by directing a water jet into the fecal mass under direct vision. Prevention following treatment with appropriate laxatives or enemas is paramount.

Treatment of Diarrhea as a Primary Manifestation of Disease

Every effort should be made to treat the disease responsible for the diarrheal syndrome. General supportive measures previously discussed should also be employed in all patients. Diseases such as vasculitis should be managed with corticosteroid or immunosuppressive therapy. Adrenal insufficiency will respond promptly to the administration of corticosteroids. Hyperthyroid patients should receive appropriate therapies. GVHD should be managed with corticosteroids and immunosuppressive agents. The chronic form of the disease may be

TABLE 96.5

ANTIDIARRHEAL AGENTS AND DOSAGES

Loperamide (Imodium)
- Available forms: capsules (2 mg) and liquid (5 mL [1 tsp] = 1 mg)
- Dosage: 4 mg initially, followed by 2 mg after each diarrheal stool
- Maximum daily recommended dose: 16 mg per day

Diphenoxylate with atropine (Lomotil)
- Available forms: 1 tablet or 5 mL liquid = 2.5 mg diphenoxylate and 0.025 atropine
- Dosage: 2 tablets or 10 mL 4 times a day (20 mg of diphenoxylate) initially, then decrease and titrate to symptoms
- Maximum daily recommended dose: 20 mg/d (based on diphenoxylate)

Deodorized opium tincture
- Available form: 10 mg morphine per mL
- Dosage: 0.6 mL 4 times a day (range: 0.3–1 mL 4–6 times a day)
- Maximum daily recommended dose: 6 mL/d

Camphorated opium tincture (paregoric)
- Available form: 0.4 mg morphine per mL
- Dosage: 5–10 mL 1–4 times a day
- Maximum daily recommended dose: 40 mL/d

more effectively treated, whereas the acute variety may be less responsive, with a substantial mortality rate. Treatment of the inflammatory bowel diseases is address in another chapter, but generally includes aminosalicylates, corticosteroids, immunomodulating agents, biologics, and surgery. Celiac sprue will respond to supportive measures and a gluten-free diet.

Palliative Measures

The aforementioned diagnostic and therapeutic approaches will result in proper diagnosis and directed treatment in a majority of patients with diarrhea in the critical care setting. In a modest number of patients, however, a cause for diarrhea will not be found or a specific treatment will not be readily available. For this category of patients, palliative therapies are available with the goal to lessen fluid losses, patient discomfort, and morbidity (Table 96.5). Antimotility agents such as loperamide, diphenoxylate with atropine, and deodorized tincture of opium (DTO) may decrease frequency and severity of diarrhea in patients with diarrhea of unclear etiology or diarrhea due to enteral feeding or other noninfectious causes. Advantages of loperamide include the absence of central nervous system activity and resultant side effects, whereas DTO is administered in drop form, enhancing dosing flexibility. Octreotide can be used for palliation of diarrhea in patients with AIDS, GVHD, hormone-producing tumors, radiation- and chemotherapy-induced diarrhea, and other causes of secretory diarrhea [75].

CONCLUSION

Diarrhea is a frequently occurring complication in the ICU setting. It is a symptom that tends to be overshadowed by other processes in the ICU, but in and of itself may result in significant morbidity. In most instances, it can be managed following institution of proper diagnostic, therapeutic, or palliative measures.

CHAPTER 97 ■ SEVERE AND COMPLICATED BILIARY TRACT DISEASE

JOHN M. ISKANDER, SREENIVASA S. JONNALAGADDA AND RIAD AZAR

A wide spectrum of biliary tract diseases may be seen in the intensive care unit (ICU). Presentations vary from mildly abnormal blood chemistries to life-threatening septic shock. Unrecognized biliary disease can lead to significant morbidity. Awareness of the different biliary disorders commonly encountered in the ICU, in conjunction with a logical approach to noninvasive and invasive patient evaluation, allows the clinician to diagnose and treat these conditions appropriately.

The anatomy of the biliary tract is depicted in Figure 97.1. Approximately 500 mL of bile is secreted at the level of the canaliculus each day. Bile flows through progressively larger ductules until reaching the main bile ducts. The bile duct courses through or immediately adjacent to the head of the pancreas in more than 90% of patients. Hence, any pathology in the head of the pancreas can result in biliary obstruction. Bile flow into the duodenum is regulated by the sphincter of Oddi, which consists of muscle fibers that surround the distal bile duct in the wall of the duodenum at the major ampulla. Tonic contraction of the sphincter increases pressure in the common bile duct and allows the gallbladder to fill in a retrograde fashion through the cystic duct. A gallstone passing from the gallbladder to the duodenum typically would encounter resistance to passage in the region of the cystic duct and at the sphincter of Oddi. Biliary tree pathology can be diagnosed by transabdominal ultrasonography, computed tomography (CT), magnetic resonance cholangiopancreatography, endoscopic retrograde cholangiopancreatography (ERCP), or endoscopic ultrasonography (EUS). Access to the biliary tree for therapeutic purposes may be obtained via ERCP, percutaneously, or at open surgery.

DIAGNOSTIC EVALUATION

Physical Examination

Physical signs in patients with biliary tract disease may encompass a spectrum from the acute abdomen with localized right upper quadrant pain to nonspecific findings including ileus, fever, or sepsis with hemodynamic instability. When biliary tract disease is suspected, careful inspection and examination for findings of icterus, hepatomegaly, ascites, and focal tenderness over the liver or gallbladder should be undertaken.

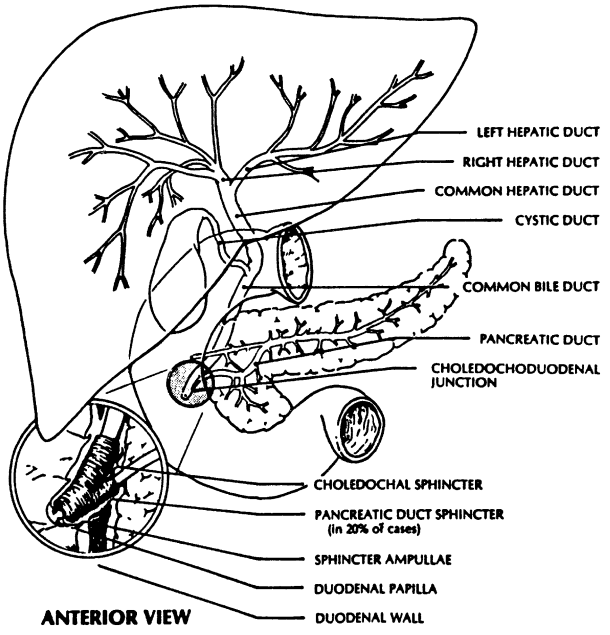

FIGURE 97.1. Normal anatomy of the biliary tract. [From Turner MA, Cho S-R, Messmer JM: Pitfalls in cholangiographic interpretation. *Radiographics* 7:1067, 1987, with permission.]

Laboratory Evaluation

In the obtunded or otherwise compromised ICU patient, abnormal laboratory values often are the first clue to biliary tract disease. All ICU patients should have appropriate laboratory testing on admission, including serum bilirubin, alkaline phosphatase, and transaminases (aspartate aminotransferase or alanine aminotransferase). Although elevations in bilirubin should result in an evaluation for an obstructive process, other processes such as sepsis, drug effects, hemolysis, or other nonbiliary etiologies should be considered in an acutely ill patient (see Chapters 99 and 150). Alkaline phosphatase elevation is often seen in patients with biliary tract disease, but it is not specific. The hepatobiliary origin of an elevated serum level of this enzyme can be confirmed by detection of concomitantly elevated 5′-nucleotidase or γ-glutamyltransferase. Serum transaminase elevations are the hallmark of hepatocellular injury. However, an elevation in transaminases can also be seen in patients with bile duct obstruction, and may precede elevation of bilirubin and alkaline phosphatase in the acute setting. Occasionally, a patient with significant biliary disease may present with a normal laboratory evaluation, as in cholecystitis without involvement of the common bile duct and without substantial pericholecystitic hepatitis.

Noninvasive Imaging Studies

Noninvasive radiologic imaging is essential in the evaluation of patients with suspected biliary tract disease.

Plain Abdominal Radiograph

The plain radiographic features of biliary tract disease usually are nonspecific [1]. The most common bowel gas finding seen in patients with acute biliary disease is a generalized ileus. Gallstones rarely are detected on plain radiographs, because only 20% of stones have a sufficient calcium concentration to make them radiopaque. Air in the biliary tree may result from a biliary-enteric fistula, prior sphincterotomy, or a biliary-enteric surgical anastomosis. Infections with gas-producing organisms rarely present with gas in the biliary tree or gallbladder wall.

Ultrasonography

Ultrasonography of the biliary tree is an extremely useful diagnostic test in the ICU setting and can be performed at bedside with good results [2]. It is a sensitive test for determining biliary ductal dilatation, and the accuracy of ultrasonography in detecting cholelithiasis exceeds 95%. However, its accuracy in detecting choledocholithiasis may be limited, as gas in the duodenum can obscure visualization of the distal bile duct. In the presence of cholelithiasis or gallbladder sludge, the findings of ductal dilatation, elevated liver enzymes, abdominal pain, and fever are strongly suggestive of cholangitis. Findings on ultrasonography that may indicate acute gallbladder disease include focal tenderness over the gallbladder, thickening of the gallbladder wall, and pericholecystitic fluid collections, but none is specific for cholecystitis. The technique also may detect other abnormalities, including liver lesions, pancreatic masses, abscesses, and ascites.

Hepatobiliary Scanning

Scanning the abdomen after an intravenous injection of technetium-99m iminodiacetic acid yields physiologic and structural information regarding the biliary tract. Filling the gallbladder with radionuclide confirms the patency of the cystic duct and virtually excludes the diagnosis of acute cholecystitis. False-positive examinations can be seen in patients with chronic cholecystitis, on long-term parenteral hyperalimentation, or after prolonged fasting. Delayed views and routine pretreatment with cholecystokinin increase the accuracy of technetium-99m iminodiacetic acid scanning for acute cholecystitis to greater than 93% [3]. Hepatobiliary scanning is also useful in identifying structural abnormalities of the biliary tree such as significant bile duct leaks, which can be identified in almost all patients with this problem. Scanning has a limited role in patients with poor hepatocellular function, complete biliary obstruction, and cholangitis because these defects often prevent adequate uptake or excretion of the radiopharmaceutical into the biliary tree.

Computed Tomography

CT is highly accurate for the detection of biliary tract disease [4]. The sensitivity for detecting choledocholithiasis is as high as 88% using helical CT. Unlike ultrasonography or radionuclide scanning, however, CT cannot be used portably in the ICU. Findings on CT for gallbladder disease include thickening of the gallbladder wall, pericholecystitic fluid, and adjacent abscesses. In addition, CT is highly accurate for the detection of biliary tract obstruction (i.e., the level and the cause). It also allows detailed visualization of the pancreas, vessels, and surrounding organs and can be used to assess the severity of pancreatitis including complications such as necrotizing pancreatitis or the formation of pseudocysts.

Magnetic Resonance Imaging

Advances in magnetic resonance imaging (MRI) technology have greatly improved the resolution of biliary imaging [5]. The use of magnetic resonance cholangiogram images can be manipulated to display highly accurate representations of the biliary tree. The sensitivity of this technique rivals that of direct cholangiography. In one study, the overall sensitivity and specificity of magnetic resonance cholangiograms for diagnosis of bile duct stones were 100% and 95.6%, respectively, with corresponding positive and negative predictive values of 92.6% and 100% [6]. This technique also permits visualization of any

mass contiguous to a bile duct stricture. In the intensive care setting, its use may be limited as patients must be transported to the scanner, and problems with magnetic compatibility of support equipment must be overcome. The noninvasive images of the biliary tree obtained, however, can be highly diagnostic and preclude other more invasive studies.

Summary

When evaluating the ICU patient with suspected biliary tract disease, ultrasonography should be the initial procedure of choice, followed by hepatobiliary scanning if cystic duct obstruction or bile leakage is suspected. Both are portable and noninvasive. Ultrasonography is highly accurate for the detection of gallstones and structural pathology. Hepatobiliary scanning, on the contrary, provides physiologic information, primarily regarding patency of the cystic duct. Such physiologic data are especially important for patients with suspected calculous or acalculous cholecystitis. CT or MRI should be reserved for those patients in whom sonographic or radionuclide findings are equivocal, if other intra-abdominal pathology needs to be excluded, or if ductal dilatation is seen on ultrasonography without a clearly defined etiology.

Invasive Diagnostic Tests

Endoscopic Retrograde Cholangiopancreatography

The technique of ERCP is used for both diagnostic and therapeutic purposes as described in Chapter 13. In brief, a side-viewing endoscope is passed through the mouth into the second duodenum, where the major ampulla is identified and cannulated. The biliary tree is then opacified with contrast injected through a catheter, allowing a retrograde cholangiogram to be obtained. Fluoroscopy and standard radiographs are used to examine the biliary tree and define such abnormalities as stones, strictures, leaks, and obstruction. Endoscopic therapy, including stone removal, biliary drainage, or stricture dilatation, can be accomplished in the same setting. ERCP can be used in the evaluation and therapy of the ICU patient, especially if the patient can be stabilized for endoscopy and transported to a fluoroscopy room. Rarely is it necessary to perform emergent biliary decompression at the bedside using portable fluoroscopy. Coagulopathies should be corrected before the procedure, especially if an endoscopic sphincterotomy (electrocautery incision of the sphincter of Oddi in the duodenal wall for stone removal or drainage) is anticipated. If coagulopathies cannot be satisfactorily corrected, a stent can be placed into the bile duct to ensure drainage without performing a sphincterotomy. Major morbidity from the diagnostic procedure includes pancreatitis, cholangitis, perforation, and hemorrhage. The complication rates of ERCP in a recent review noted reduced rates, compared with prior reporting, of pancreatitis at 3.5%, infection at 1.4%, and perforation at 0.6% under standard conditions [7]. The value of ERCP is largely operator dependent and can be highly successful in the delineation and treatment of biliary disease in the ICU patient [8].

Endoscopic Ultrasonography

EUS involves the transoral passage of an endoscope with an ultrasonic transducer at the tip. The limitations of transabdominal ultrasonography are overcome with this modality because all areas of the biliary tree, including the intrapancreatic portion of the bile duct as well as the pancreas, can be imaged without interference from gas in the intestines. EUS can reliably identify cholelithiasis and is more sensitive than transabdominal ultrasonography in detecting choledocholithiasis in patients with biliary pancreatitis. Although EUS is typically an elective procedure and uncommonly used in the ICU, the test may be useful in identifying those patients who would benefit from endoscopic stone extraction by ERCP [9].

Percutaneous Transhepatic Cholangiography

Percutaneous transhepatic cholangiography (PTC) also may be used in evaluating the ICU patient. The technique requires fluoroscopy to guide passage of a needle into the intrahepatic bile ducts. The biliary tree is then filled with contrast and images are taken. The use of PTC for the diagnosis of biliary tract pathology has been supplanted by ERCP and noninvasive examinations, such as ultrasonography, CT, and MRI. Currently, PTC is used primarily as an initial step in percutaneous transhepatic biliary drainage. Decompression of the biliary tree via a percutaneous catheter is a highly effective method for rapid nonoperative and nonendoscopic biliary decompression. This procedure is indicated when a patient requires emergent biliary drainage but is not stable enough to undergo ERCP under conscious sedation, if the major papilla cannot be reached endoscopically because of postsurgical anatomy or a technical failure in cannulating the bile duct. The technique involves an initial PTC to delineate the biliary anatomy, followed by selective cannulation of an appropriate intrahepatic bile duct with an 18-gauge needle. A guidewire is then passed into the biliary tree, the tract is dilated, and a drainage catheter placed. Successful drainage can be established in almost all patients. Percutaneous biliary drainage is an invasive procedure, and acute complications, including hemorrhage, sepsis, and bile leakage, occur in 1% to 5% of patients [10].

Percutaneous Liver Biopsy

Liver biopsy is an important technique in the evaluation of selected patients with hepatobiliary abnormalities who do not have obvious biliary ductal dilatation. Liver biopsy may lead to a rapid pathologic diagnosis in patients with intrinsic liver disease. In cases of infection, tissue can also be cultured. In patients with a coagulopathy, a liver biopsy may be obtained by way of the hepatic vein using a transjugular approach or percutaneously using a sheath, embolizing the tract after completion of the biopsy [11].

BILIARY TRACT DISORDERS ENCOUNTERED IN THE INTENSIVE CARE UNIT

Cholangitis

Acute cholangitis is a life-threatening illness. The presentation of patients with cholangitis may range from intermittent low-grade fevers to fulminant septic shock. This diagnosis must be considered and excluded in all patients who present to the ICU with shock and sepsis of unknown origin because of the high mortality if urgent biliary decompression is not accomplished. As partial or complete biliary obstruction is a prerequisite to the pathophysiology of cholangitis, it typically occurs in patients with biliary stasis secondary to stones, strictures, or recent manipulations of the biliary tree [12]. Bacteremia occurs when bacterial infection of the biliary tree is associated with an elevated intraductal pressure that allows reflux of bacteria into the portal venous circulation and bloodstream.

The clinical manifestations of cholangitis include fever or chills, abdominal pain, and jaundice. The classic triad of fever, right upper quadrant pain, and jaundice was described by Charcot [13] in 1877 and is seen in a small percentage of patients presenting with cholangitis [12]. Laboratory abnormalities are present in the overwhelming majority of patients, with more than 90% having elevation of bilirubin, alkaline phosphatase,

or transaminases. Blood cultures are positive in more than a third of patients [13,14], and solitary isolates of *Escherichia coli*, *Klebsiella pneumoniae*, or enterococcus are found most commonly. Polymicrobial infections, including anaerobes, are identified frequently if bile is cultured at operation [15,16]. Often it is difficult to prospectively diagnose cholangitis in the ICU population, and this entity should be considered in the differential diagnosis of all patients who present with sepsis.

Since most patients with cholangitis will demonstrate gallstones or a dilated biliary tree, an abdominal ultrasound is the best initial evaluation. This, in association with elevated liver enzymes, fever, or sepsis, is strongly indicative of this diagnosis and should prompt early consultation for therapeutics.

Treatment

Once cholangitis is suspected, the patient should be treated empirically with broad-spectrum antibiotics. Recent trials demonstrated the use of the extended-spectrum penicillins, cephalosporins, and ciprofloxacin in this setting [16,17]. Although most patients respond to antibiotic therapy alone, those with biliary obstruction may progress to a more fulminant state despite general resuscitative measures and broad-spectrum antibiotics. These patients must be identified rapidly and treated with emergent biliary decompression. This can be accomplished by endoscopic, percutaneous, or surgical means. Selection of a particular approach should be tailored to the patient's condition, local expertise, and the rapid availability of the procedure. Initial efforts in decompensated patients should concentrate on decompression of the biliary tree via ERCP or percutaneous drainage. Definitive therapy may be accomplished at a later time, even if this requires a second procedure. It must be recognized that even with modern support, biliary decompressive techniques, and broad-spectrum antibiotics, the mortality from acute fulminant cholangitis ranges from 10% to 50% [12,14].

Biliary Obstruction

Biliary obstruction may present in the ICU patient without cholangitis. The multiple causes of biliary obstruction are listed in Table 97.1, the most common being stone disease, benign stricture, and malignancy. The patient with physical findings and laboratory studies suggesting obstruction should initially be evaluated with noninvasive imaging to define the level of obstruction and determine the etiology. In the noninfected patient, an elective direct cholangiogram by ERCP or PTC should be obtained when the patient's condition allows. This provides anatomic details of the biliary tree and allows for definitive therapy planning. Care must be taken to ensure that the entire biliary tree is visualized at cholangiography and that adequate prophylactic antibiotics are administered. In addition, adequate biliary decompression after the procedure is essential to prevent the development of cholangitis.

Biliary obstruction without cholangitis is seen more often with malignancy than with stone disease or inflammatory strictures. The diagnosis can usually be made before laparotomy with ERCP or PTC. Definitive therapy for stone disease and benign strictures as well as palliative therapy for malignant strictures may also be accomplished during either procedure. Reviews of endoscopic or transhepatic stenting of malignancies demonstrate the use of these approaches when compared with surgical decompression for unresectable disease [18,19]. Surgical approaches are preferred in those patients who are good operative candidates and who may have resectable malignancy. Bile duct stenting often serves as a bridge to surgery in such patients.

TABLE 97.1

CAUSES OF BILIARY OBSTRUCTION

Intrinsic lesions
Stones
Cholangiocarcinoma
Benign stricture
Sclerosing cholangitis
Periarteritis nodosa
Ampullary stenosis
Parasites
Extrinsic lesions
Pancreatic carcinoma
Metastatic carcinoma
Pancreatitis
Pancreatic pseudocyst
Visceral artery aneurysm
Lymphadenopathy
Choledochal cyst
Hepatic cyst(s)
Duodenal diverticulum
Iatrogenic lesions
Postoperative stricture
Hepatic artery infusion chemotherapy

Bile Leaks

A bile leak may be seen after open or laparoscopic cholecystectomy, hepatic resection, liver transplantation, or trauma to the liver from penetrating abdominal injuries. In a postcholecystectomy setting, such a leak may occur from the cystic duct stump or branches of the right intrahepatic ductal system via the gallbladder fossa. The extravasated bile may accumulate focally to form a biloma or freely flow within the peritoneal cavity. The resultant bile peritonitis usually is associated with abdominal pain, ascites, leukocytosis, and fever. Occasionally, collections of bile become infected, resulting in an abscess if untreated. Seldom, patients may present solely with new-onset ascites and an elevated serum bilirubin level. Diagnosis of a biliary leak can usually be made with hepatobiliary scanning. Ultrasonography and CT may reveal a biloma or free fluid in the abdominal cavity. This can be followed by ERCP to determine the exact location of the leak and provide definitive therapy.

Patients with suspected bile leaks should be placed on broad-spectrum antibiotics, and the presence of a bile leak should be confirmed with hepatobiliary scanning followed by direct cholangiography. ERCP with therapeutic intent should be performed as soon as possible after diagnosis to limit the degree of bile leakage and patient symptoms. Postoperative leaks or premature removal of a T-tube often can be managed definitively with endoscopic decompression at the same setting as ERCP. This is accomplished by placing a biliary stent across the major papilla with or without concomitant biliary sphincterotomy. Rarely, if endoscopic therapy is unsuccessful in healing a bile leak, surgical repair may be required.

Acute Cholecystitis

Acute cholecystitis is a frequent and important event that occurs in the ICU. The signs and symptoms of acute cholecystitis often are not readily apparent in the compromised ICU patient. A high degree of suspicion and prompt use of noninvasive

testing, including ultrasonography and hepatobiliary scanning, are essential to arrive at a timely and correct diagnosis of this entity. Acalculous cholecystitis deserves special mention because it can result in significant morbidity and mortality in the ICU patient [20]. Although the signs and symptoms may be similar to those seen with calculous cholecystitis, the presentation in the postoperative or acutely ill ICU patient may be masked by the complicated underlying situation. In this setting, an aggressive diagnostic and therapeutic approach is essential because significant morbidity and even mortality continues to occur from complicated acalculous cholecystitis.

Supportive measures should be undertaken while the patient is being evaluated with noninvasive testing. Antibiotic therapy with broad-spectrum coverage should be initiated in patients with clinical evidence of sepsis, leukocytosis, or fever. Percutaneous cholecystostomy has become the therapy of choice for patients with acute calculous or acalculous cholecystitis who do not respond to conservative therapy and are too unstable for operative cholecystectomy. Percutaneous cholecystostomy is performed at the bedside using ultrasound guidance. A 22-gauge needle is inserted transhepatically into the gallbladder, and bile is aspirated. A guidewire is passed through this needle and the tract is dilated, allowing placement of a drainage catheter, with success rates exceeding 95%. Complications are few and include local wound infection, bleeding, and, rarely, bile peritonitis. The primary advantage of percutaneous cholecystostomy is that it can be done at the bedside without general anesthesia. Percutaneous cholecystostomy often is helpful in patients with suspected gallbladder disease, even if cholecystitis is not found, by excluding the diagnosis. Therefore, percutaneous cholecystostomy should be performed early if gallbladder disease is suspected. The cholecystostomy drainage catheter is left in place until acute symptoms resolve, at which time an elective surgical cholecystectomy or, in the setting of a patent cystic duct and functioning gallbladder, simple tube removal may be performed. In patients with acute calculous cholecystitis and severe underlying medical problems, the gallstones can be removed through the percutaneous tract using various techniques [21]. Such percutaneous gallstone removal is an effective alternate therapy to cholecystectomy for patients with other significant medical conditions.

Gallstone Pancreatitis

Acute pancreatitis often results from biliary stone disease. Although most cases are self-limited and respond to conservative management, fulminant pancreatitis may occur with mortality in excess of 10%. There are several theories regarding the pathogenesis of gallstone pancreatitis, the most accepted being that stone passage or impaction in the ampulla is responsible for this entity. Gallstone pancreatitis should be considered and excluded in the evaluation of all patients with acute pancreatitis because it is a recurrent and treatable cause of this presentation. Standard abdominal ultrasound in combination with laboratory screening for biliary obstruction can be used to exclude gallstones as the cause for the pancreatitis in most patients [22]. Patients with acute pancreatitis should be classified into risk groups based on one of the accepted prognostic scales [23]. These scales include the Ranson criteria, the Glasgow criteria, the Acute Physiology and Chronic Health Evaluation III scoring system, and CT criteria for grading severity of pancreatitis. Grading by CT is based on the degree of inflammation, the presence of fluid collections, and the area of pancreatic necrosis seen during bolus infusion of intravenous contrast while scanning. These prognostic scales allow physicians to identify patients who are at risk for developing severe pancreatitis and a complicated hospital course. Three or more of the following criteria defined by Ranson [23] at any time during the first 48 hours of hospitalization predict severe pancreatitis.

At admission or diagnosis:

1. Age older than 55 years
2. White blood cell count greater than 16,000 cells per mm^3
3. Blood glucose greater than 200 mg per dL
4. Serum lactate dehydrogenase greater than 350 IU per L
5. Serum aspartate aminotransferase greater than 250 Sigma-Frankel units per dL

During the initial 48 hours:

1. Hematocrit fall greater than 10%
2. Blood urea nitrogen rise greater than 5 mg per dL
3. Serum calcium level less than 8.0 mg per dL
4. Arterial oxygen partial pressure less than 60 mm Hg
5. Base deficit greater than 4 mEq per L
6. Estimated fluid sequestration greater than 6,000 mL

Patients with acute pancreatitis from biliary stone disease should be managed initially as detailed in Chapter 99. Although most patients improve with conservative therapy alone, patients with severe gallstone pancreatitis (three or more prognostic criteria) and high likelihood of having choledocholithiasis, cholangitis, or persisting biliary colic may benefit from early intervention with ERCP. Early ERCP [24,25] allows the removal of impacted or retained common bile duct stones, limiting further pancreatic inflammation and preventing cholangitis. Consultation with a skilled biliary endoscopist should be obtained early in the course of all patients with severe gallstone pancreatitis. It is generally accepted that patients with gallstone pancreatitis require definitive therapy to prevent recurrent bouts. This may be accomplished by cholecystectomy or endoscopic sphincterotomy with stone extraction in nonoperative candidates. Although debate continues regarding the timing of surgery, it is generally accepted that all patients who are operative candidates should undergo cholecystectomy during the initial hospital admission after the pancreatitis has subsided [26]. Early operative intervention in patients with active severe gallstone pancreatitis has been associated with unacceptably high morbidity [26].

Summary

The management of biliary tract disorders encountered in the ICU varies with the specific disorder. Several of the evidence-based treatment approaches are listed in Table 97.2.

TABLE 97.2

EVIDENCE-BASED MANAGEMENT APPROACHES FOR BILIARY TRACT DISORDERS ENCOUNTERED IN THE INTENSIVE CARE UNIT

- Early ERCP is beneficial in the management of biliary pancreatitis [25].
- ERCP is highly effective in the management of postoperative bile leaks [27].
- In patients with cholangitis, empiric antibiotic therapy should be directed against Gram-negative bacteria [28].
- Percutaneous cholecystostomy offers an important therapeutic alternative for critically ill patients with acute cholecystitis [29].

CHAPTER 98 ■ HEPATIC DYSFUNCTION

MAURICIO LISKER-MELMAN AND GOWRI KULARATNA

Liver function abnormalities are detected in about 50% of intensive care unit (ICU) patients, often leading to hepatology consultation [1]. The presentation of hepatic dysfunction range from simple abnormalities in biochemical tests with little impact on a patient's clinical course to complex manifestations of liver failure that require prompt intervention and have high morbidity and mortality. Etiologies of hepatic dysfunction are many and variable in this setting. Sometimes, a detailed clinical history is sufficient to establish the cause of the derangement; however, a combination of clinical experience and judicious use of supplemental testing is required to establish a specific diagnosis and suggest a therapeutic course of action. Understanding the anatomic interactions between the liver and other organs and the physiologic principles that determine hepatic function is essential for establishing a rational therapeutic approach for each disorder. In this chapter, we outline aspects of liver physiology that are altered in critically ill patients and review common disorders of hepatic dysfunction seen in this setting.

PHYSIOLOGIC CONSIDERATIONS

Blood Flow

In resting conditions, the liver receives 25% of the cardiac output and 10% to 15% of the total body blood volume. About 25% of the liver volume consists of blood (capacitance function). The human liver has dual blood supply. Approximately one third of the hepatic blood flow is supplied by the hepatic artery (low-flow, high-pressure system, well-oxygenated blood) and two thirds by the portal vein (high-flow, low-pressure system, poorly oxygenated blood). The hepatic artery supplies the capsule of the liver and bile ducts. The portal vein is formed by the splenic vein, superior mesenteric vein, and inferior mesenteric vein (it drains into the splenic vein). The left gastric vein branches from the portal vein and plays a fundamental role in the formation of esophageal varices in patients with portal hypertension. The portal vein provides venous drainage for

several abdominal organs: pancreas, stomach, intestine, and spleen. Once within the liver, arterial and venous bloods mix in the hepatic sinusoids [2]. The sinusoids are involved in the exchange between the blood, space of Disse, and the hepatocytes. The blood flowing through the sinusoids is collected in the central veins and then into the hepatic veins and inferior vena cava.

The sinusoids are composed of fenestrated endothelial cells, Kupffer cells, stellate cells, and natural killer (NK) cells. Endothelial cells represent 50% of the sinusoidal cells. They contain numerous fenestrae (not uniform in size or distribution) with dynamic structure and function. Endothelial cells have several functions including endocytosis, secretion (interleukins, interferon, eicosanoids, endothelin, and nitric oxide), and expression of adhesion molecules. Kupffer cells are phagocytic and remove infective, toxic, and foreign substances from the portal blood. They also release substances involved in the immune response by the liver. Stellate cells, also known as lipocytes, fat storing cells, or Ito cells, store fat vacuoles (major storage sites of retinoids). They have contractile activity regulating the blood flow through the sinusoids. The NK cells, also known as Pit cells are liver-associated lymphocytes with azurophilic granules with lysosomal activity [3,4].

Blood flow through the liver varies considerably under different physiologic conditions. In the normal state, the liver extracts less than half of its supplied oxygen (4.6 mg per minute per 100 g liver). Thus, in most conditions of increased oxygen demand, the liver can increase oxygen extraction without an alteration in blood flow [5]. Regulation of total hepatic blood flow occurs primarily at the level of the hepatic artery. If portal venous inflow decreases, compensation is accomplished through vasodilatation of the hepatic artery. However, reductions in mean arterial pressure below 50 mm Hg exceed the capacity of the autoregulatory mechanisms to maintain adequate liver perfusion [6].

Bilirubin Metabolism

The majority of bilirubin (80%) is generated from the breakdown of heme released by senescent red blood cells. Unconjugated bilirubin (indirect bilirubin) circulates bound to albumin before entering the hepatocyte through an active process mediated by transporter proteins. Once inside the hepatocyte, unconjugated bilirubin is transferred to the smooth endoplasmic reticulum, where it is conjugated with glucuronic acid (conjugated or direct bilirubin) and, in turn, secreted into the biliary canaliculi by a pump called multidrug resistance protein 2. Once in the gastrointestinal tract, bilirubin is deconjugated by gut bacteria enzymes and oxidized to stercobilin and eliminated in the stool. Stercobilin is also reabsorbed in the small intestine, passes the liver, and is reexcreted through the kidney (urobilirubin) in the so-called enterohepatic circulation [7].

Unconjugated hyperbilirubinemia results from increased bilirubin production (e.g., ineffective erythropoiesis, hemolytic disorders), impaired uptake (e.g., Gilbert's syndrome, use of certain drugs such as rifampin), or defective conjugation (e.g., Gilbert's syndrome, Crigler–Najjar syndrome types I and II). In the physiological jaundice of the newborn, the bilirubin metabolism is affected at various levels (increased disruption of hepatocytes, reduced hepatocyte uptake, intracellular transport and conjugation, and increased enterohepatic circulation) resulting in unconjugated hyperbilirubinemia. Breast milk jaundice is another form of unconjugated hyperbilirubinemia attributed to the ingestion of breast milk components that affect the enzyme that conjugates bilirubin [8]. Conjugated hyperbilirubinemia results from a wide spectrum of familial (Dubin Johnson syndrome and Rotor syndrome), hepatocyte, and biliary disorders that are associated with a benign course, acute or chronic liver cell damage, cholestatic injury, or biliary tree obstruction (intra- or extrahepatic) [9].

Drug Metabolism

The liver is positioned strategically between the digestive tract and the systemic circulation. Only those substances absorbed by the oral mucosa and the rectum bypass the liver, reaching the systemic circulation directly. Several diverse pathways participate in the metabolism of drugs and toxins by the liver. Three main enzymatic pathways participate in drug metabolism: oxidation, hydrolysis, and reduction, catalyzed by oxidoreductases, hydrolases, and transferases. The oxidoreductases and hydrolases catalyze phase I reactions that increase polarity (or water solubility) of substances and potentially generate toxic metabolites. The transferases catalyze phase II reactions through conjugation and produce less toxic and biologically less active products when compared with the parent compound. The most important drug-oxidation system is the P450 system (the electron-transport chain associated with the microsomal system). The central protein in this system is cytochrome P450, a hemoprotein [10]. The primary reactions, biochemical or physiologic changes, and toxic consequences to the liver of drug and toxin exposure may be variable and in part dependent on the interaction with the host [11,12].

Drug-induced liver injury (DILI) has a difficult to calculate incidence, ranging from asymptomatic liver chemistry abnormalities with a small potential impact to life or function to fulminant liver failure with high morbidity and mortality. A thorough medication history obtained from the patient, relatives, friends, caregivers, and pharmacy records is essential to identify and substantiate this challenging clinical problem. Factors to be considered when assessing patients with suspected DILI include clinical presentation and timeline of symptoms, timeline of drug ingestion, concurrent liver disease and other potential etiologies of liver injury, concomitant medications, herbal and substance abuse, biochemical pattern of liver injury, histologic findings, and response to rechallenge [13].

Hemostatic Function

The liver is the primary site of synthesis of most of the coagulation factors and the major inhibitors of the activated coagulation cascade. The synthesis of procoagulant factors II, VII, IX, and X and anticoagulant factor proteins C and S depends on the presence of vitamin K. The adequacy of hepatic synthetic function can be estimated by the prothrombin time or international normalized ratio (INR) [14]. In the presence of liver disease, there is reduced synthesis of clotting factors and inhibitors of coagulation. The synthesis of abnormal clotting proteins with anticoagulant activity leads to disseminated intravascular coagulation (DIC) and enhanced fibrinolytic activity [15,16]. In addition, thrombocytopenia, associated with portal hypertension and hypersplenism, and thrombocytopathy are usually identified in patients with end-stage liver disease. Consequently, most patients with liver disease have some measurable defect in hemostasis involving the coagulation system, fibrinolytic system, platelets, and reticuloendothelial system (Kupffer cells). The resultant clinical impact of this bleeding diathesis, however, is of variable importance. When and how the physician institutes therapeutic or prophylactic hemostatic interventions is debated and must be individually assessed for each patient.

CLINICAL DISORDERS

Ischemic Hepatitis

Liver ischemia is the consequence of hypoxic liver insult and presents in the setting of reduced liver blood flow, persistent hypotension, or severe hypoxemia. Common synonyms for ischemic hepatitis include acute hepatic infarction, shock liver, and hypoxic hepatitis [17,18]. The hepatic insult is diffuse, noninflammatory in nature, and results in variable degrees of central vein (zone 3) necrosis and collapse. The syndrome typically is recognized through detailed clinical history and biochemical evaluation, as the precipitating factor may not be apparent. Dehydration, heat stroke, hemorrhage, cardiogenic shock, acute decline in cardiac output in the absence of hypotension, traumatic shock, respiratory failure, aortic dissection, pulmonary embolus, and extensive burns have been associated with ischemic hepatitis [19–22]. In patients with congestive heart failure (left ventricular failure) and chronic passive liver congestion (right ventricular failure), even minor, additional insults may precipitate liver ischemia [23]. It is difficult to estimate the prevalence of ischemic hepatitis, but approximately 1% of patients in the ICU develop severe hypotension, cardiac failure, or respiratory failure and are susceptible to developing this condition [24].

The clinical presentation is highly variable. Biochemically, there is a characteristic rapid rise in serum aminotransferases, reaching 10 to 40 times the upper limits of normal. The lactate dehydrogenase also increases dramatically, whereas abnormalities in serum bilirubin, alkaline phosphatase, and prothrombin time are less striking. Peak elevations occur in the first 72 hours. In situations in which the triggering factor resolves, normalization of laboratory tests may occur over 7 to 10 days. Other chemistry abnormalities include renal failure with increased blood urea nitrogen and serum creatinine. Patients may present with hepatic encephalopathy, mild jaundice, weakness, or general malaise. More typically, the dominant clinical features are those of the disorder that triggered the ischemic insult [25]. The differential diagnosis includes other disorders associated with significant, rapid increases in liver enzymes, such as acute viral hepatitis, alcoholic hepatitis, and drug-induced hepatotoxicity. In only rare instances is a liver biopsy necessary for diagnosis [24].

Treatment of ischemic hepatitis is directed at correction of the underlying disease or factor that initiated the liver damage. The aim of treatment is to improve cardiac output, optimize liver and peripheral organ perfusion, and improve tissue oxygenation. The specific intervention depends on the precipitating factor and varies from case to case [26,27]. Ischemic hepatitis frequently is self-limiting, and recovery is associated with normalization of the hepatic architecture. From the liver standpoint, the prognosis depends on the presence of a normal or previously damaged liver and on the etiology of the underlying disorder [24,25,28].

Congestive Hepatopathy

Congestive hepatopathy and passive hepatic congestion are interchangeable terms used to refer to the outcome of increased hepatic vein pressure from a variety of causes. The increased pressure is transmitted through the hepatic veins and venules to the hepatocytes resulting in initial damage to cells in zone 3 [29]. Additional liver damage is thought to occur from decreased hepatic flow and decreased arterial oxygen saturation [30]. The most common causes are ischemic cardiomyopathy, heart failure, valvular heart disease, restrictive lung disease, and pericardial disease. Right-sided heart failure of any etiology (constrictive pericarditis, tricuspid regurgitation, mitral valve stenosis, or cardiomyopathy) increases the pressure of the inferior vena cava and the hepatic veins and ultimately produces liver congestion [31–33]. Although the clinical presentation of hepatic vein thrombosis (Budd–Chiari syndrome), primary thrombosis limited to hepatic venules, sinusoidal obstructive syndrome (formerly known as venoocclusive disease), and inferior vena cava thrombosis at its hepatic portion (obliterative hepatocavopathy) may be similar to congestive hepatopathy, accurate differential diagnosis is imperative. The workup of these conditions includes various imaging modalities, such as ultrasound with Doppler flow, fluoroscopic cavography, and magnetic resonance venography; at times, liver biopsy is needed for a definitive diagnosis. These medical conditions have different etiologic factors and treatment approaches [34–37].

The patient with liver congestion may present with signs and symptoms of right-sided heart failure and only subtle abnormalities in liver chemistries. The aminotransferases may be mildly elevated, reflecting limited degree of liver cell necrosis. Mild elevations of the alkaline phosphatase and total bilirubin are also common. In more severe presentations, the patient may be deeply jaundiced, suggesting extrahepatic biliary obstruction. Congestive hepatopathy can eventually lead to development of hepatocellular necrosis, broad fibrous septa deposition, regenerative nodule formation, architectural derangement, and frank cirrhosis, previously termed *cardiac cirrhosis*. Congestion produces tender hepatomegaly, and a pulsatile liver can occur with tricuspid regurgitation. Hepatojugular reflux may be elicited, and ascites is a frequent finding. In these patients, the ascitic fluid albumin is high (>2 g per dL); in contrast, in noncardiac cirrhosis, the ascitic fluid albumin is typically lower (<2 g per dL) [33,38]. The serum albumin to ascites albumin gradient (SAAG) is more than 1.1 g per dL in both conditions. Diagnosis rests on a combination of a high index of suspicion and studies that confirm the presence of cardiopulmonary disease. Pressure measurements through cardiac catheterization, transjugular hepatic venous pressure gradients, and cardiac imaging studies are diagnostic.

A transjugular liver biopsy, ideally obtained at the time of pressure measurements, can be helpful in difficult cases. Classic biopsy findings include centrilobular parenchymal atrophy, sinusoidal and terminal hepatic venular distention, and red blood cell congestion and extravasation into the space of Disse. In addition, perisinusoidal collagen deposition is seen in chronic congestion. Treatment is focused on management of the underlying pulmonary, cardiac, or pericardial disease. Ascites is managed with diuretics, low-salt diet, or large-volume paracentesis. Transjugular intrahepatic portosystemic shunts (TIPSs) are contraindicated in this condition, as the resulting marked increase in the right heart and pulmonary arterial pressures may precipitate severe heart failure [25].

Total Parenteral Nutrition

Total parenteral nutrition (TPN) remains a vital medical intervention, and its use has become routine to provide nutrition to those who are unable to eat or tolerate enteral nutrition (short gut syndrome, Crohn's disease, radiation enteritis, severe pancreatitis, post-op periods, etc.). Hepatobiliary dysfunction is recognized as a major adverse effect of short-term and long-term TPN use [39,40]. Variable degrees of liver dysfunction, ranging from subtle laboratory abnormalities to clinically apparent liver disease, develop in 40% to 60% of infants and 15% to 40% of adults who require long-term TPN [41–43]. The wide prevalence ranges reflect the difficulty in ascribing liver dysfunction to TPN, particularly in the ICU where the etiology of liver abnormalities may be multifactorial. The spectrum

of hepatobiliary complications attributable to TPN includes hepatic steatosis, intrahepatic cholestasis, biliary sludge, and cholelithiasis [44]. TPN-related complications are more commonly seen after prolonged periods of parenteral nutrition. Cholestasis predominates in infants (occurring in 40% to 60%), hepatic steatosis and steatohepatitis predominate in adults (occurring in up to 40% to 55%), while biliary sludge and cholelithiasis affect both groups [43]. Progression to cirrhosis and portal hypertension is rare and occurs more frequently in infants and neonates than in adults [43].

Most patients with hepatic steatosis are asymptomatic. Mild elevations of aminotransferases, alkaline phosphatase, and total bilirubin may be identified in up to 70% of patients [45]. Enzyme levels usually peak within 1 to 4 weeks of TPN initiation. The elevation is often transient and complete resolution may occur spontaneously despite continued use of TPN. Hepatic steatosis is most likely a direct consequence of a high carbohydrate load and defective secretion of triglycerides by the liver. Glucose or dextrose overfeeding (>50 kcal per kg per day) should be avoided [46]. With the development of currently accepted protocols for caloric intake (25 to 40 kcal per kg per day), including lipids as an alternative calorie source, the prevalence of liver steatosis has declined significantly [47,48]. In a prospective study, a 53% versus 17% reduction in hepatic steatosis was reported in patients who received only dextrose infusion when compared with mixed dextrose and lipid emulsion [49]. The use of fish oil–based lipid emulsions (instead of safflower or soybean oil) appears to be "hepatoprotective" in children receiving TPN, but this strategy has not been studied in adults [50].

Essential fatty acid and choline deficiency are less common causes of hepatic steatosis. Essential fatty acid deficiency may manifest with skin rash, neuropathy, hepatosplenomegaly, and thrombocytopenia. It can be avoided as long as patients receive 2% to 4% of their calories as linoleic acid [51,52]. Intravenous (IV) lipid emulsion preparations typically contain 50% linoleic acid [46]. Low plasma choline has also been observed in patients on TPN. Choline is necessary for the synthesis of very low-density lipoproteins (VLDL). Deficiency of VLDL promotes the accumulation of triglycerides (defective triglyceride transport) in the liver and steatosis. Restoration of normal plasma choline concentrations, in the form of lecithin, decreases hepatic steatosis [43,49,51,53,54].

Cholestasis is uncommon in adults on short-term TPN (<3 weeks) [45]. In contrast, in adults on long-term TPN, cholestasis has been reported in up to 65% [55]. In the same series of 90 patients, 41.5% developed serious liver disease–related complications including portal hypertension, ascites, gastrointestinal bleeding, coagulopathy, encephalopathy, and extensive fibrosis or cirrhosis [55]. The degree of laboratory abnormality does not necessarily correlate with the degree of injury [45]. Large doses of lipid emulsion (>1 g per kg per day), short bowel syndrome (small bowel remnant <50 cm), bacterial translocation, hypoxia, and sepsis have been associated with the development of chronic cholestasis [43,45,56]. Micronutrients found in TPN such as manganese, aluminum, and copper may play a toxic role. Administration of these additives is discontinued in patients who demonstrate signs of cholestasis [46,49,57,58]. Low levels of antioxidants such as vitamin A, vitamin E, and selenium are found in TPN solutions; however, supplementation does not always improve cholestasis [57,58]. In patients with transplanted allografts, the combination of cyclosporine and TPN may also induce cholestasis.

The major concern with cholestasis in those receiving long-term TPN is the risk of progression to chronic liver disease and liver failure [59]. In this setting, TPN may need to be discontinued. TPN-dependent individuals with intestinal failure, who have persistent liver enzyme abnormalities or evidence of impending liver failure, should be considered for isolated intestine transplantation. In the presence of end-stage liver disease, however, combined intestine and liver transplantation may become necessary [46]. Survival post-isolated intestine or combined intestine–liver transplantation is 50% at 5 years, making this a viable therapeutic option [46]. Ursodeoxycholic acid (10 to 30 mg per kg per day) has shown variable success in preterm infants and adults with TPN-induced cholestasis by improving bile flow and reducing gallbladder stasis [46,60].

Biliary sludge develops in 50% to 100% of individuals after more than 6 weeks on TPN [61]. Again, clinical manifestations vary significantly. Some patients may be asymptomatic, whereas others develop striking gallbladder distention, acalculous cholecystitis, or gallstone cholecystitis. Decreased release of cholecystokinin (biliary stasis), use of narcotics (increase in bile duct pressure), and increased bile lithogenicity are contributing factors. Early introduction of oral feeding decreases the incidence of biliary complications. Trials with cholecystokinin injections have mostly been conducted in the pediatric population. Overall, they have shown inconsistent results and its long-term effects in preventing sludge formation and cholelithiasis remain unknown [62–64]. Changes in the rate or composition of the TPN infusion to stimulate gallbladder contraction are impractical and not universally successful [65,66]. Acute acalculous cholecystitis is a serious condition that requires the use of broad-spectrum antibiotics, a percutaneous drainage procedure, or a surgical intervention (i.e., cholecystectomy).

Sepsis and Multiorgan System Failure

The liver often sustains injury and develops dysfunction in sepsis and in systemic inflammatory response syndrome. The injury that occurs in the first hours is most often a consequence of liver hypoperfusion, usually in the setting of shock. This can lead to alterations in liver function including DIC and bleeding complications. Progressive liver injury then accompanies systemic effects with release of bacterial and inflammatory mediators [67]. The liver also contributes to the host immune response through a variety of mechanisms. The portal circulation, which arises from the splanchnic vasculature, is susceptible to vasoconstriction and bacterial translocation during sepsis [68]. The liver is composed of several types of cells, including hepatocytes, Kupffer, endothelial sinusoidal, Stellate, NK cells, and others. All these cells contribute to the hepatic response in sepsis through a series of intercellular interactions as well as through circulating or secreted factors. Kupffer cells are responsible for production and clearance of inflammatory mediators, bacterial scavenging, and toxin inactivation [69]. The hepatocytes respond by altering their basic metabolic pathways toward gluconeogenesis and increased production of cytokines and coagulants. Lactate clearance and protein synthesis are reduced. Endothelial cells are responsible for production of cytokines in response to endotoxins. They further contribute to antimicrobial activity and host defense through production of nitric oxide. Activated neutrophils also are recruited to the liver and respond by release of oxygen-free radicals and destructive enzymes such as protease and elastase.

The acute-phase reactants produced in this setting promote a procoagulant state and induce activation of other cells involved in the immune response. However, the liver can be damaged by cytokines released by Kupffer cells as well as by factors released from activated neutrophils. The subsequent fibrin deposition and hepatocyte damage can adversely affect the microcirculation of the liver, thereby leading to progressive liver damage and systemic toxicity [70]. The role that the liver plays in the immune and metabolic responses to infection can lead to significant clinical sequelae. The majority of patients with bacteremia from either Gram-positive or Gram-negative bacteria have abnormal liver tests. Aminotransferase elevation

is characteristic in this setting and is reflective of cellular and mitochondrial injury. Abnormal liver enzymes and jaundice can occur in 2 to 3 days after the onset of bacteremia. It is not uncommon to see liver enzyme elevations reaching two to three times the upper limit of normal. The serum bilirubin level also may reach 5 to 10 times normal in the setting of sepsis [71].

Prompt treatment of sepsis with supportive care and antibiotic therapy can result in normalization of enzymes and reversal of the associated hepatic dysfunction. There is no evidence that antibodies directed toward endotoxins or cytokines play an important role in management [72]. The use of a stress dose of steroids has been found to favorably affect host defenses and reduce bacterial colonization of the liver during endotoxemia. Activated protein C (APC) in multicenter placebo-controlled trials has reduced mortality by 6% in severe clinical sepsis cases. Through its interactions with epithelial cells and macrophages, APC is thought to modulate inflammatory responses and increase microvascular perfusion. Effect of APC on hepatic microvasculature, however, has not been documented [73].

Multisystem organ failure is an ominous sign of progressive critical illness. Hepatic dysfunction in this setting is a poor prognostic indicator [74]. Sepsis, hemorrhage, severe trauma, or tissue injury such as pancreatitis can precipitate this clinical picture. Hepatic hypermetabolism leads to relative systemic hypoperfusion, and multiple organ injury develops as tissue perfusion is continually compromised. In these conditions, the liver reduces protein synthesis, increases protein catabolism, and decreases detoxification potential. Disproportionately high bilirubin levels compared with aminotransferase levels develop in patients with hepatic dysfunction. Patients with elevations in serum bilirubin greater than 8 mg per dL, without the presence of hemolysis or biliary obstruction, have a mortality rate greater than 90% [74]. Prompt reversal of hypotension can greatly reduce hepatic necrosis, bacterial translocation, and impaired Kupffer cell activity seen in patients with shock.

Drug-Induced Liver Injury

While DILI is suspected to be a common clinical problem in both out- and inpatients, its true incidence is unknown. Detection of DILI requires an elevated index of suspicion and probably its presence is frequently missed. In many instances, it is discovered unexpectedly and associated with only transient and asymptomatic abnormalities in liver chemistry. In contrast, patients with drug-induced cholestasis manifested with jaundice have an 11% probability of progressing to death or liver transplantation [75]. The incidence in DILI increases with age and is higher after the age of 40 [76]. As a result of an increasing number of available pharmacologic agents, the incidence of hepatotoxicity is rising [10]. A DILI network has been established as the first broad registry in the United States to understand and assess this problem [13]. According to the DILI network (apart from acetaminophen), antimicrobials and central nervous system drugs (45.5% and 15%, respectively) are the most common drug classes causing liver damage. The most common antibiotics found related with DILI were amoxicillin–clavulanate, trimethoprim–sulfamethoxazole, isoniazid, and nitrofurantoin.

DILI is a consequence of either a biochemical or an immune-mediated injury mechanism [77]. Biochemical injury develops from the direct effect of the drugs or their metabolites during hepatic detoxification process. Toxic by-products produced by the cytochrome P450 system or through conjugation can alter plasma cell membranes, cellular enzyme activity, or mitochondria. Drugs and their metabolites can also induce a host immune defense response with inflammatory cytokines, complement system activation, and nitric oxide, playing integral roles in the development of hepatocyte damage.

Mild or subclinical hepatic dysfunction occurs more frequently than overt dysfunction, and medications are responsible for up to 25% of cases of fulminant hepatic failure [78]. Drug hepatotoxicity can be intrinsic or idiosyncratic. Intrinsic hepatotoxicity is dose dependent, and, as seen with acetaminophen, the damage is predictable and uniform in presentation. Because the offending agent is directly toxic, close monitoring of drug levels may be preventative. In the case of idiosyncratic reactions, such as with isoniazid and phenytoin, the damage is dose independent and unpredictable. The drug or metabolite may either be directly hepatotoxic or induce a specific host immune response. Chronic liver disease can develop in the case of continuous or repeated exposure to an offending medication, inducing either type of reaction (such as amiodarone or methotrexate) [79].

Elevations in the serum aminotransferase levels from drug hepatotoxicity are typically mild and present in asymptomatic patients with mild dysfunction [80]. These elevations are observed within a few days to weeks after starting the offending agent and resolve without residual effect after its discontinuation. In more unusual cases, severe elevations of serum aminotransferases and submassive hepatic necrosis can develop and lead to fulminant hepatic failure. Histologic findings of autoimmune liver disease can be seen with some drugs that cause chronic active hepatitis [80].

Isolated serum enzyme abnormalities can be simply related to induction of cytochrome P450 enzymes and are not necessarily indicative of hepatotoxicity. Medications such as phenytoin and rifampicin induce the microsomal oxidase systems and can cause elevated gamma glutamyl transpeptidase (GGT) levels. These elevations are usually present in asymptomatic patients and do not represent cholestasis. Drug-induced cholestasis manifests as elevations in serum alkaline phosphatase, total bilirubin, and GGT. Cholestasis can occur with hepatocellular inflammation and necrosis, with associated systemic symptoms such as fever, myalgias, arthropathy, and rash. Toxicity from erythromycin, chlorpromazine, or oral hypoglycemic agents can present with this clinical picture. Cholestasis with minimal or no systemic symptoms can also occur and is the presentation typically associated with anabolic steroid or estrogen use [80]. Because the presentation of drug-induced cholestasis can resemble biliary obstruction, hepatobiliary imaging is often necessary to exclude biliary ductal dilation or a hepatic or pancreatic mass. Complete recovery after cessation of the offending agent may take several months.

The identification of specific markers of DILI to predict hepatotoxicity, pharmacogenomics, and pharmacovigilance, and the DILI network holds the promise of increasing our understanding of this challenging problem in this era of polypharmacy [81].

Sinusoidal Obstruction Syndrome

Sinusoidal obstruction syndrome (SOS), previously referred as hepatic venoocclusive disease, is a well-recognized complication of high-dose chemotherapy and total body irradiation in stem cell transplantation recipients [82]. SOS has also been reported in patients who ingested food contaminated with pyrrolizidine alkaloids (bush tea), following liver transplantation, after long-term use of azathioprine and other chemotherapeutic agents [83,84]. Although the incidence of SOS varies considerably, there is a perception of a declining occurrence due to newer nonmyeloablative conditioning regimens, avoidance of cyclophosphamide, and better patient selection.

Initially, the syndrome was thought to occur primarily as a result of injury directed toward the hepatic venules, with progressive venular obliteration, hepatocyte necrosis, and fibrosis. More recent studies indicate that venular involvement is not essential to pathogenesis, and that sinusoidal obstruction is

the primary mechanism behind disease development [82,85]. In SOS, damage to hepatocytes and sinusoidal endothelial cells is a central pathogenic event.

Classically, 3 to 4 weeks after the triggering event, the affected patient develops weight gain (fluid retention and ascites), right upper quadrant pain (tender hepatomegaly), and jaundice. Laboratory abnormalities begin with isolated hyperbilirubinemia (mostly conjugated or direct), followed by elevations in alkaline phosphatase and aminotransferases [36,86]. A high index of clinical suspicion must be maintained for a successful diagnosis, as several other conditions have similar presentations [82]. Clinical presentation may be similar to Budd–Chiari syndrome, congestive hepatopathy (i.e., right-sided heart failure, constrictive pericarditis, tricuspid regurgitation, pulmonary hypertension), graft-versus-host disease, or disseminated fungal infections [87,88].

The initial diagnosis of SOS is often made on clinical grounds, but the gold standard for diagnosis is liver histology. The major histological features are sinusoidal congestion and fibrosis, necrosis of pericentral hepatocytes, narrowing and eventually fibrosis, and obliteration of sublobular and central venules [89]. In early stages, the histological changes may be patchy and that may lead to erroneous interpretation. A transjugular approach to measure the hepatic venous pressure gradient (>10 mm Hg) may have differential diagnosis and prognostic implications, and in addition, it is useful to obtain a liver biopsy. Numerous biochemical markers including plasminogen activator inhibitor-1 (PAI-1) have been investigated as diagnostic markers in SOS. One study of 350 stem cell recipient patients showed that PAI-1 was elevated in all patients with SOS. Plasma levels not exceeding 120 ng per mL had a strong negative predictive value for SOS (100% sensitivity and 30.6% specificity) [90,91]. Imaging modalities such as ultrasonography, magnetic resonance imaging, and computed tomography are more useful in excluding other causes of liver dysfunction, such as biliary obstruction or malignancy, than in establishing the diagnosis of SOS [92].

Prognosis depends on the extent of hepatic injury and is classified into three stages: mild, moderate, and severe. The degree and rate of bilirubin elevation appear to be the best biochemical markers of prognosis [82]. Mild to moderate disease is characterized by eventual resolution of liver dysfunction, whereas severe disease is associated with multiorgan failure and a mortality rate approaching 100%. Death usually is a consequence of renal, pulmonary, or cardiac failure other than liver failure [82,92,93].

A variety of pharmacologic and preventive strategies for this form of circulatory obstruction are under investigation. Anticoagulants and thrombolytics have used in patients with SOS with variable success. Anticoagulants such as antithrombin III, and low dose and low-molecular-weight heparins, are awaiting randomized studies to confirm positive preliminary results. Potent thrombolytics such as tissue plasminogen activator (tPA) has been used with variable success for SOS. In a study of 16 patients with SOS diagnosed post–stem cell transplant treated with tPA, with and without heparin, 29% showed a response (defined as downward trend or stabilization in serum bilirubin). However, the probability of bleeding complications was high and the survival only 33% at day 100 [92,94].

Defibrotide, a single-stranded oligonucleotide with antithrombotic, thrombolytic, and anti-ischemic effects, is a promising agent for SOS. In several uncontrolled trials of patients with moderate to severe SOS, the IV administration of defibrotide was associated with resolution of symptoms (36% to 64% of patients) and with improve survival without noticing significant side effects [85,95]. The initial enthusiasm generated with defibrotide as a treatment agent for SOS has generated studies that explore its use as a prophylactic agent [95]; while results are optimistic, trials are small and retrospective.

Other therapeutic options for SOS such as TIPS, ursodeoxycholic acid, and pentoxifylline are under investigation [96]. Spontaneous resolution has been reported in 70% to 85% of patients in mild cases. Supportive care is paramount and includes minimizing sodium load, administration of diuretics, and therapeutic paracentesis [82,86,97].

CONCLUSION

Timely identification of contributors to hepatic dysfunction is the foundation of adequate management in critically ill patients. A history of alcohol use or risk factors for viral hepatitis may suggest the presence of acute or chronic liver disease, factors that may further complicate management of patients with liver chemistry abnormalities in the ICU. A complete medical history seeking explanations for liver dysfunction is at times difficult to obtain in ICU patients, and relevant medications may be overlooked by patients, family, or caregivers. No singular therapy is available for the patient in whom hepatic dysfunction develops in the ICU. Identification of the etiology and correction of the initial insult through applying a counteracting drug, volume resuscitation, cardiopulmonary support, treatment of infection, or withdrawal of an offending medication have an important management role. The few evidence-based management points related to this topic are summarized in Table 98.1. In patients with previously normal livers who survive, residual effects on hepatic function are infrequent.

TABLE 98.1

EVIDENCE FOR MANAGEMENT APPROACHES THAT ARE RELEVANT TO HEPATIC DYSFUNCTION IN THE ICU PATIENT

Clinical disorder	Management evidence
■ TPN-associated hepatic steatosis	■ Controlled trials have demonstrated that choline is a required nutrient in TPN preparation.
■ TPN-associated cholestasis	■ Uncontrolled trials indicate that ursodeoxycholic acid has variable success in preventing this complication of TPN; controlled studies are lacking.
■ Drug hepatotoxicity	■ Discontinue offending agent (see Acetaminophen toxicity chapter 120); specific controlled data are lacking.
■ Sinusoidal obstruction syndrome	■ Defibrotide has been shown to improve symptoms in uncontrolled investigations; controlled studies are in progress.

TPN, total parenteral nutrition.

CHAPTER 99 ■ ACUTE PANCREATITIS

MICHAEL L. STEER

DEFINITION, CLASSIFICATION, AND PATHOLOGY

Pancreatitis, an inflammatory disease of the pancreas, can be classified as *acute* or *chronic* on the basis of clinical, morphologic, or functional criteria. The classification of any particular patient's disease depends on the criteria being used. Clinically, acute pancreatitis is defined as a process that is of rapid onset and usually associated with pain and alterations in exocrine function. With successful treatment, complete resolution can be expected. Chronic pancreatitis, on the contrary, is usually associated with repeated episodes of pain or diminished exocrine function, or both, that recur even after successful treatment of an attack. The morphologic or functional classification of pancreatitis, which has been the subject of several international symposia [1–4], also distinguishes between an acute and a chronic form of the disease, but that distinction is based on the reversibility of morphologic or functional changes, or both, in the pancreas. According to this scheme, *acute pancreatitis* is defined as an inflammatory process that occurs in a gland that was morphologically and functionally normal before the attack and can return to that state after resolution of the attack. In contrast, *chronic pancreatitis* is defined as an inflammatory disease involving a pancreas that was morphologically or functionally abnormal, or both, before the onset of symptoms or that will remain abnormal even after the attack has resolved. For the most part, the term *acute pancreatitis* is used in this chapter in its clinical rather than its morphologic or functional context. For reasons of completeness, however, the pathologic, etiologic, and therapeutic issues that are of particular relevance to morphologically or functionally defined chronic pancreatitis also are discussed.

The pathologic changes associated with acute pancreatitis vary to a great extent with the severity of an attack [5]. Mild acute pancreatitis is associated with interstitial edema, a mild infiltration of inflammatory cells, and evidence of intrapancreatic or peripancreatic fat necrosis, or both. In contrast, severe attacks of acute pancreatitis usually are associated with acinar cell necrosis that may be either focal or diffusely distributed throughout the gland. In addition, thrombosis of intrapancreatic vessels, vascular disruption with intraparenchymal hemorrhage, and abscess formation may be noted. Because chronic pancreatitis involves inflammation in a previously diseased gland, areas of scarring with fibrosis along with atrophy of acinar tissue can be seen even in tissue taken during the early stages of an attack. Varying degrees of acute inflammation are usually observed to be superimposed on these more chronic changes.

ETIOLOGY

Pancreatitis is associated with a number of other disease states or conditions that collectively are referred to as the *etiologies* of pancreatitis [6–8]. In developed countries, 70% to 80% of patients with pancreatitis have the disorder in association with either ethanol abuse or biliary tract stone disease. Another 10% to 20% of patients have no identifiable cause for pancreatitis and are considered to have idiopathic pancreatitis. In the remaining 5% to 10% of patients, pancreatitis develops in association with one of the various etiologies listed in Table 99.1. In the less well-developed countries, particularly those in Africa and Asia, disease develops as a result of malnutrition or ingestion of potentially toxic agents, or both, in a significant fraction of patients with acute pancreatitis [9–12]. Their pancreatitis has been termed *nutritional* or *tropical* pancreatitis. This entity is particularly common in the Indian subcontinent, but its cause is unknown [12].

Biliary Tract Stone Disease

Biliary tract stones are the most frequent cause of morphologic and functionally defined acute pancreatitis and, along with ethanol abuse, account for 60% to 80% of patients with clinically acute pancreatitis in developed countries. The frequency of either biliary tract stones or ethanol abuse among any group of patients being evaluated with acute pancreatitis depends on the socioeconomic composition of that group; that is, in affluent suburban groups, biliary tract stones account for more attacks, whereas ethanol abuse is more commonly found to be associated with pancreatitis when inner-city and poorer patients are studied [6]. Biliary tract stone disease is a frequent cause of acute pancreatitis among American Indians of the desert Southwest, who are prone to development of stones, and among many Asian groups, who have a high incidence of stone formation as a consequence of chronic bactibilia.

Reports by Acosta and Ledesma [13] and Acosta et al. [14] indicated that the onset of pancreatitis associated with biliary tract stones is related to the passage of those stones through the terminal biliopancreatic duct and into the duodenum. The mechanism by which stone passage triggers this so-called gallstone pancreatitis has been the subject of considerable speculation and experimental investigation. Three theories have been proposed. The first was the "common channel" theory proposed by Opie [15] in 1901 after he noted gallstones impacted in the ampulla of Vater when patients dying of gallstone pancreatitis underwent autopsy examination. He suggested that such stones might create a common biliopancreatic channel proximal to the stone-induced obstruction and that, as a consequence, bile could reflux into the pancreatic ductal system. He reasoned that bile reflux would be injurious to the pancreas and trigger pancreatitis. Subsequent investigations by many groups, however, have challenged the validity of this theory pointing out that pancreatic duct pressure normally exceeds biliary duct pressure, and therefore pancreatic juice reflux into the biliary tract rather than bile reflux into the pancreas would be expected if an obstruction were to create a common channel [16]. Furthermore, many patients develop pancreatitis but lack a common channel that could permit reflux [17], and bile perfused into the pancreatic duct at normal pressure does not induce pancreatitis [18].

The second theory proposed to explain gallstone-induced pancreatitis suggested that the stone passing through the sphincter of Oddi could render that sphincter incompetent and, as a result, permit reflux of duodenal juice containing activated digestive enzymes into the pancreas [19]. This "duodenal reflux" would seem an unlikely explanation for the development of pancreatitis because it is now clear that neither endoscopic nor surgical procedures that make the sphincter of Oddi incompetent lead to subsequent attacks of acute pancreatitis.

The third theory suggests that either the stone or edema and inflammation resulting from stone passage cause pancreatic duct obstruction and that pancreatic duct obstruction is the event that triggers acute pancreatitis. Studies using a model of acute necrotizing biliary pancreatitis induced in opossums support this theory [20], but in virtually all other species (dog, cat, mouse, rat, rabbit, etc.), pancreatic duct obstruction leads to atrophy of the pancreas with little or no evidence of pancreatitis. This observation has cast considerable doubt on the duct obstruction theory.

Most students of acute pancreatitis favor the "common channel-bile reflux theory" but, clearly, uncertainty regarding mechanisms responsible for gallstone-induced pancreatitis persists. It is generally believed that acute pancreatitis results from an autodigestive injury to the pancreas by enzymes that it normally synthesizes and secretes. Normally, those digestive enzymes are synthesized, intracellularly transported, and secreted from acinar cells as inactive zymogens. Activation normally occurs within the duodenum where the brush border enzyme enterokinase activates trypsinogen and trypsin activates the other zymogens. During pancreatitis, however, zymogen activation appears to occur inside acinar cells, perhaps as a result of pathological changes in cytoplasmic calcium levels and co-localization of digestive zymogens with lysosomal hydrolases such as cathepsin B, and, subsequently, zymogen activation leads to the acinar cell injury/death which is the hallmark of severe pancreatitis [21–25].

Recent studies in our laboratory have revealed that the bile acid receptor Gpbar1 is expressed at the apical (luminal) pole of pancreatic acinar cells and that activation of Gpbar1 in acinar cells can cause pathological rises in cytoplasmic calcium levels, zymogen activation, and cell injury. These very recent findings

TABLE 99.1

MISCELLANEOUS ETIOLOGIES OF ACUTE PANCREATITIS

Trauma
Postoperative setting
Common duct exploration
Sphincteroplasty
Distal gastrectomy
Cardiopulmonary bypass
Cardiac or renal transplantation
Endoscopic retrograde cholangiopancreatography
Translumbar aortography
Metabolic disorders
Hyperparathyroidism
Hyperlipoproteinemias types I, IV, and V
Penetrating ulcer
Connective tissue disorders
Scorpion bite
Renal failure
Hereditary pancreatitis
Pancreatic duct obstruction from duodenal diverticulum, ampullary tumor, sphincter of Oddi dysfunction, duodenal Crohn's disease, pancreatic tumor
Drugs
Bacterial, viral, fungal infections, parasites
Pancreatic trauma
Ischemia or acidosis
Autoimmune

[24] suggest that indeed, biliary pancreatitis may be triggered by bile reflux into the pancreatic duct through a common biliopancreatic duct and that bile acids contained within that bile may trigger pancreatitis via events that are set in motion following activation of Gpbar1.

Ethanol Abuse

In most patients with ethanol-associated pancreatitis, their first clinical attack of pancreatitis develops after many years of ethanol abuse. The incidence of pancreatitis is related to the logarithm of alcohol consumption, but there is no threshold below which alcohol ingestion is not associated with an increased incidence of pancreatitis. The mean consumption of ethanol among patients with ethanol-associated pancreatitis is 150 to 175 g per day. The mean duration of consumption before the first attack is 18 ± 11 years for men and 11 ± 8 years for women [26]. Ethanol-associated pancreatitis, like ethanol abuse itself, is more common among men than among women. Epidemiologic studies suggested that ethanol-associated pancreatitis is most common among those ingesting a high-protein diet with either high or low fat content [26]. The mechanism by which chronic ethanol abuse leads to chronic pancreatic injury is not clear, although some studies suggest that injury may result from secretion of a juice that is high in proteolytic enzyme content, low in proteolytic enzyme inhibitors, and contains lysosomal hydrolases capable of activating trypsin either within acinar cells or in the pancreatic ductal space [26–28].

In some patients with ethanol-induced pancreatitis, the disease develops after only one or several exposures to ethanol. This observation, along with the finding that a substantial number of patients dying of ethanol-associated disease do not have pancreatic fibrosis at autopsy [29], suggested that ethanol might be a cause of morphologic and/or functional and clinical acute pancreatitis.

The mechanism by which ethanol might cause acute injury to the pancreas is not clear. Some suggested possibilities include a direct toxic drug-like effect on acinar cells or, alternatively, induction of ductal hypertension as a result of stimulating exocrine secretion and sphincteric contraction [30,31]. Recent reports have suggested that direct cellular injury may be mediated by ethanol metabolites [30–35], and that circulating levels of bacterial endotoxin, perhaps released by the intestinal effects of ethanol, may be important contributing events [34]. It is possible that the chronic pancreatitis associated with prolonged ethanol abuse represents the cumulative effect of repeated subclinical attacks of acute pancreatitis. Thus, mild episodes associated with minimal necrosis may progress to fibrosis (i.e., the necrosis–fibrosis concept) [36]. It is also possible that chronic exposure to ethanol interferes with the resolution of inflammation and fibrosis, which normally follow episodes of injury, and that, in this way, ethanol favors the persistence of pancreatic fibrosis/inflammation even after relatively mild episodes of injury [37].

Drugs

Exposure to certain drugs represents perhaps the third most common cause of acute pancreatitis [38–41] (Table 99.2). The relationship between drug exposure and the development of pancreatitis can be categorized as definite, probable, or equivocal on the strength of the data that indicate that the drug actually causes pancreatitis. The former category includes those drugs whose use is associated with an increased incidence of pancreatitis and that, on specific rechallenge, have been found to induce the disease. On the contrary, drugs in the equivocal category include those that are anecdotally associated with the disease but never demonstrated in prospective studies to be capable of inducing pancreatitis. Historically, diuretic agents such as the thiazides, ethacrynic acid, and furosemide were considered the most likely drugs to cause pancreatitis. More recently, however, drug-related pancreatitis has been reported to be the most common among individuals with acquired immunodeficiency syndrome or acquired immunodeficiency syndrome–related complex receiving dideoxyinosine [42], pentamidine, or related compounds and among transplant patients receiving immunosuppressant agents such as azathioprine. Although previously considered to cause pancreatitis, histamine-2 (H_2)–blockers and steroids are not currently believed to be capable of causing acute pancreatitis.

TABLE 99.2

DRUGS ASSOCIATED WITH ACUTE PANCREATITIS

Definite	
Thiazide diuretics	Valproic acid
Ethacrynic acid	Estrogens
Furosemide	Tetracycline
Azathioprine	Sulfonamides
Asparaginase	Mercaptopurine
Mesalamine	Pentamidine
Dideoxyinosine	
Probable	
Methyldopa	Iatrogenic hypercalcemia
Enalapril	Procainamide
Octreotide	Erythromycin
Chlorthalidone	Phenformin
Equivocal	
Isoniazid	Rifampin
Acetaminophen	Steroids
Histamine-2–blockers	Propoxyphene

Pancreatic Duct Obstruction

Obstruction of the pancreatic duct is considered by most investigators to be the mechanism by which biliary tract stones trigger acute pancreatitis. Other events or processes that cause pancreatic duct obstruction also can result in pancreatitis. Thus, pancreatitis may be caused by duodenal, ampullary, biliary duct, or pancreatic tumors that obstruct the duct or by inflammatory lesions (e.g., peptic ulcer, duodenal Crohn's disease, periampullary diverticulitis) that interfere with pancreatic duct drainage [6]. Pancreatic cysts and pseudocysts and periampullary diverticula filled with food and debris can interfere with duct drainage and as a consequence precipitate pancreatitis. Ductal strictures, frequently the result of traumatic duct injury or previous pancreatitis, can be a cause for obstructive pancreatitis. Finally, certain parasites, such as *Ascaris* and *Clonorchis*, can trigger pancreatitis by physically obstructing the pancreatic duct [6,43]. An association between pancreas divisum and pancreatitis has been claimed, presumably reflecting relative obstruction to pancreatic juice flow at the lesser papilla [44], but this is quite controversial [45,46].

Other Miscellaneous Causes of Acute Pancreatitis

Many of the remaining miscellaneous causes of pancreatitis are listed in Table 99.1. Traumatic pancreatitis usually follows blunt abdominal trauma, during which the body of the

pancreas is compressed against the vertebral column. As a result, the gland is "cracked," and the duct is either partially or completely transected [47]. Lesser degrees of blunt trauma may be associated with pancreatic contusion, whereas penetrating injury can affect any portion of the pancreas. Traumatic injury to the pancreas also can be associated with surgical procedures performed on or near the pancreas [48–50]. Postoperative pancreatitis is also frequently associated with procedures performed on or near the sphincter of Oddi (duct exploration, sphincteroplasty, distal gastrectomy), procedures associated with hypoperfusion or atheroembolism of the pancreatic circulation (cardiopulmonary bypass, cardiac transplantation, renal transplantation, translumbar aortography) [51,52], or procedures involving pancreatic duct injection (endoscopic retrograde cholangiopancreatography [ERCP]) [53].

Chronic pancreatitis can also be a familial disease transmitted by a mutation on chromosome 7 that is transmitted as an autosomal dominant with incomplete penetrance [54]. Reports indicate that the mutation results in synthesis of a cationic trypsinogen that is resistant to autoinactivation after activation has occurred [55]. Patients with classic cystic fibrosis mutations can present with pancreatitis even in the absence of pulmonary disease. Studies indicate that a substantial number of patients with so-called idiopathic pancreatitis may have nonclassic cystic fibrosis mutations or polymorphisms [56].

Pancreatitis can also develop on an autoimmune basis in association with other autoimmune processes such as primary sclerosing cholangitis, Sjogren's syndrome, and primary biliary cirrhosis. A number of recent reports, particularly from Japan, have drawn attention to a form of autoimmune pancreatitis characterized by extensive lymphoplasmacytic infiltration into the pancreas and sclerosis of the pancreatic and bile ducts. Patients with this form of pancreatitis frequently present with both bile and pancreatic duct obstruction and a mass in the head of the pancreas. They can easily be thought to have neoplastic disease of the pancreas but, if placed on steroid treatment, the changes of autoimmune pancreatitis rapidly resolve. Many, but not all, of these patients have elevated circulating levels of IgG4 and this may permit their identification [57].

Idiopathic Pancreatitis

Approximately 5% to 10% of patients with acute pancreatitis have the disease in the absence of biliary tract stones, ethanol abuse, or any other identifiable etiology. Reports suggest that many of these patients have biliary sludge, that their attacks can be prevented by cholecystectomy, and that they actually have biliary rather than idiopathic pancreatitis [58,59]. Approximately 40% of individuals with chronic pancreatitis neither abuse ethanol nor have malnutrition. As a result, they are considered to have idiopathic chronic pancreatitis [60]. Studies in Europe and the United States suggest that these individuals can be divided into a juvenile group, with an onset of disease at a median age of 18, and a senile group, whose disease begins at a mean age of 60. Disease in the former group is characterized by pain, whereas that in the senile group is most often painless and associated with calcifications, diabetes mellitus, or both [61].

CLINICAL PRESENTATION

Symptoms

The symptoms of acute pancreatitis include abdominal pain, nausea, and vomiting [6,7,43,62,63] (Table 99.3). The pain typically is localized to the epigastrium but frequently involves one or both upper quadrants. On occasion, it may be felt in the lower abdomen, one or both shoulders, or the lower chest. The pain is usually described as being of rapid onset, slowly increasing to a maximal severity, and then remaining constant. It usually lacks the waxing and waning character of intestinal or ureteral colic, but it may be diminished by assuming an upright position, leaning forward, or lying on the side with the knees drawn upward. The pain may have a pleuritic component and may be associated with rapid but shallow respirations. Frequently, the pain is described as being a boring or knifelike sensation that passes straight through to the midcentral back from the epigastrium.

TABLE 99.3

SIGNS AND SYMPTOMS OF ACUTE PANCREATITIS

Observation	Incidence (%)
Pain	95
Nausea/vomiting	80
Distention	75
Guarding	50
Pain radiating to back	50
Jaundice	20
Abdominal mass	15
Melena	4
Hematemesis	3

Nausea and vomiting commonly are noted in patients with acute pancreatitis. The vomiting typically persists even after the stomach has been emptied and may result in gastroesophageal tears with bleeding (i.e., Mallory–Weiss syndrome). The vomiting and retching may be relieved by passage of a nasogastric tube, but neither the vomiting nor gastric decompression results in reduction of the abdominal pain.

Physical Examination

Patients with acute pancreatitis typically appear anxious and ill. They may be diaphoretic and hyperthermic. Tachycardia, tachypnea, and hypotension are common. Patients often roll or move around in search of a more comfortable position. In this respect, they are quite unlike those with peritonitis caused by a perforated viscus, which remain motionless because movement exacerbates their pain. Most patients with acute pancreatitis have a clear sensorium, but some have mild or even severe alterations in their mental status as a result of drug or ethanol exposure, hypoxemia, hypotension, or release of circulating toxic agents from the inflamed pancreas. Jaundice is common, even in patients with nonbiliary pancreatitis, among whom the hyperbilirubinemia may reflect nonobstructive cholestasis.

The abdominal examination of patients with acute pancreatitis usually reveals abdominal tenderness and voluntary and involuntary guarding. These findings may be limited to the epigastrium or diffusely present throughout the abdomen. A mass, located in the epigastrium or left upper quadrant of the abdomen, or both, may be felt. Direct, percussion, and rebound tenderness usually can be elicited. Abdominal distention also can be seen. Hypovolemia and dehydration are commonly present and can be detected by the presence of hypotension, tachycardia, collapsed neck veins, dry skin, dry mucous membranes, and decreased subcutaneous elasticity. Bowel sounds are often diminished or absent. Flank ecchymoses (Grey Turner's sign) or other evidence of retroperitoneal bleeding (Cullen's sign) may be noted. Examination of the chest may reveal evidence of pleural effusion that may be on either or

both sides but is most commonly present on the left. Because of pleuritic and abdominal pain, deep breathing is difficult, and atelectasis, particularly at the bases, is common. Examination of the skin may reveal areas of tender subcutaneous induration and erythema that resemble erythema nodosum. These lesions are believed to result from fat digestion by circulating pancreatic lipases.

LABORATORY TESTS AND RADIOLOGIC EXAMINATIONS

Routine Blood Tests

Acute pancreatitis is associated with significant losses of intravascular fluid. A substantial amount of fluid is lost as a result of the anorexia, nausea, and vomiting that accompanies the disease. In addition to these fluid losses, large volumes of fluid can be sequestered in the retroperitoneum as a result of the pancreatic inflammatory process. In addition, a systemic "capillary leak" process may result in additional fluid sequestration. Taken together, these losses of fluid from the intravascular compartment can cause the hematocrit, hemoglobin, blood urea nitrogen, and serum creatinine to rise. Hypoalbuminemia is common, but the serum electrolytes may remain normal unless vomiting has been significant. Because of the pancreatic inflammatory process, the white blood cell count usually is elevated and the differential may show a shift to the left. Hyperglycemia, which commonly is noted, may result from the combined effects of elevated circulating catecholamines, decreased insulin release, and hyperglucagonemia [64,65]. A mild rise in serum bilirubin from nonobstructive cholestasis frequently is seen even in nonbiliary acute pancreatitis. When the disease is induced by the passage of gallstones, the hyperbilirubinemia is even more marked, and superimposed cholangitis with bacteremia and positive blood cultures can occur [66]. Markedly elevated circulating triglyceride levels always are seen in individuals whose pancreatitis is caused by hyperlipoproteinemia [67], but hypertriglyceridemia with lactescent serum also can be seen in alcohol-induced acute pancreatitis [68].

Hypocalcemia is relatively common among individuals with acute pancreatitis [69]. For the most part, the hypocalcemia is caused by hypoalbuminemia, and as a result, the ionized calcium level is actually normal. In some patients, however, hypocalcemia can develop that is out of proportion to the degree of hypoalbuminemia and that reflects a true decrease in circulating ionized calcium levels. Tetany and carpopedal spasm and other complications of their hypocalcemia may develop in some patients. Marked hypocalcemia has been considered to be a sign of a poor prognosis. In patients with severe pancreatitis, disseminated intravascular coagulation may develop [70], and as a result, they may have thrombocytopenia, elevated levels of fibrin degradation products, decreased fibrinogen levels, and prolongations of the partial thromboplastin and prothrombin times.

Amylase

The serum amylase concentration is usually, but not always, elevated during an attack of pancreatitis [7]. The magnitude of that rise does not depend on the severity of pancreatitis, and some reports indicate that as many as 10% of patients with normal or near-normal serum amylase levels may have lethal pancreatitis [71]. To a great extent, this may reflect the fact that amylase elevations during pancreatitis typically are transient, with an increase to 2 to 12 hours after the onset of an attack and a decline in serum amylase values to near-normal levels 3 to 6 days after the attack has begun. Thus, patients presenting long after the onset of an attack may have normal or only slightly increased serum amylase levels.

TABLE 99.4

CAUSES OF HYPERAMYLASEMIA

Pancreatic causes
Pancreatitis, pseudocyst, ascites
Pancreatic cancer

Lung tumors
Burns
Diabetic acidosis
Pneumonia

Serum amylase activity also may be increased in a number of diseases other than pancreatitis [7,63,72]. Amylase may be synthesized at extrapancreatic sites (e.g., salivary glands, fallopian tube, lung) or produced by nonpancreatic tumors (e.g., lung, prostate, ovary), and release of the nonpancreatic amylase into the circulation may result in hyperamylasemia (Table 99.4). Patients with these nonpancreatic extra-abdominal causes for hyperamylasemia rarely are confused with those who have pancreatitis, because the clinical features of pancreatitis usually are absent in the former group. On the contrary, some patients with disorders that might be clinically confused with acute pancreatitis also may have hyperamylasemia. This is particularly true for patients with acute cholecystitis, perforated gastric or duodenal ulcers, small bowel obstruction, intestinal ischemia, and intestinal infarction. It may also be true for some patients passing common bile duct stones into the duodenum who do not have pancreatitis.

The overall sensitivity and specificity of amylase determination in the diagnosis of pancreatitis depends on the value chosen as the cutoff level [73] and the presence or absence of clinical features of pancreatitis. Patients with hyperamylasemia but not pancreatitis usually have mild elevations of the circulating amylase level (approximately 200 IU per L) or lack clinical features of pancreatitis, or both, whereas those with pancreatitis usually manifest profound hyperamylasemia (>1,000 IU per L) in association with clinical features of the disease.

Approximately 0.5% of individuals have a condition referred to as *macroamylasemia* in which amylase is bound to an abnormal circulating protein and, as a result, the amylase is not cleared by the kidney [63,74,75]. Some of these individuals may develop abdominal pain and may be incorrectly suspected of having pancreatitis. In this setting, measurement of urinary amylase activity may be particularly helpful because, in macroamylasemia, urinary amylase levels usually are very low. Renal clearance of amylase also may be reduced as a result of renal failure, and this reduced clearance can lead to mild hyperamylasemia. On the contrary, enhanced renal clearance of amylase can occur in pancreatitis, and this phenomenon can

result in an increase in the clearance ratio for amylase compared with creatinine [75,76]. However, measurement of the so-called amylase to creatinine clearance ratio has not been helpful in the diagnosis of pancreatitis. Alterations of this ratio appear to represent a nonspecific response to an acute illness. Thus, the clearance ratio may be elevated in many patients who lack pancreatitis but may be normal in many who have pancreatitis [74–80].

Other Enzyme Assays and Blood Tests

The urine amylase level may remain elevated long after serum amylase levels have returned to normal [7,81]. As a result, measurement of urinary amylase activity may be particularly helpful in patients who are first seen several days after an attack of pancreatitis and who are found to have normal or near-normal serum amylase activity [63]. Hyperlipasemia also may persist after serum amylase levels have returned to normal, and in such patients, measurement of serum lipase activity may be useful [63,71]. Circulating levels of other pancreatic enzymes (trypsinogen, chymotrypsinogen, phospholipase, elastase) or urinary levels of the activation peptide released when trypsinogen is activated (i.e., trypsinogen activation peptide) can also be measured, but there is little or no evidence to suggest that these determinations are more helpful in the diagnosis of pancreatitis than the simpler measurement of serum amylase activity [71,82,83]. Acute pancreatitis also can be associated with methemalbuminemia [84] and with increased circulating levels of several cytokines (e.g., interleukin-1 [IL-1], IL-6, tumor necrosis factor-α) [85] and acute-phase reactants (e.g., C-reactive protein) [86,87]. The magnitude and duration of these changes may have some prognostic value in pancreatitis, but these changes are not specific to pancreatitis and are therefore of little diagnostic value.

Routine Radiography

Routine chest radiographs may reveal basal atelectasis as a result of splinted respiration, elevated diaphragms, or both. A pleural effusion, more common on the left than on the right, also can be seen. Abdominal films may reveal pancreatic calcifications in patients with chronic pancreatitis. These calcifications result from calcium precipitation in the proteinaceous intraductal plugs that develop in chronic pancreatitis. In general, plain abdominal films reveal evidence of a paralytic ileus, whereas contrast gastrointestinal studies may reveal displacement of peripancreatic organs by pancreatic masses. Retroperitoneal air may be seen when pancreatic abscess is caused by a gas-forming organism. In general, however, the value of routine radiographs when pancreatitis is suspected lies in the failure of those films to reveal evidence of nonpancreatic diseases that might mimic acute pancreatitis (e.g., pneumonia, perforated hollow viscus, and mechanical bowel obstruction).

Ultrasonography

Ultrasonography in patients with acute pancreatitis usually is limited by the presence of intestinal gas in the upper abdomen during the early stages of the disease. Even in this setting, ultrasonography may be helpful in detecting gallbladder stones, bile duct dilatation, or both. Later during the course of pancreatitis, ultrasonography may be very useful in detecting and monitoring pancreatic inflammatory masses and pseudocysts [88].

Computed Tomography

In acute pancreatitis, particularly during the early stages of the disease, computed tomography (CT) is the most useful imaging modality because it can define the gross features of the pancreas and peripancreatic organs without being limited by the presence of distended gas-filled loops of bowel in the upper abdomen [89]. The pancreas may be normal or slightly swollen in appearance on CT in mild cases of pancreatitis. Evidence of peripancreatic inflammation, including streaking in the retroperitoneal and transverse mesocolic fat, may also be seen. With more severe attacks, peripancreatic and intrapancreatic fluid collections can be detected. Dynamic CT, performed by rapidly imaging the pancreas during bolus injection of contrast material, can define areas of pancreatic necrosis because those areas do not enhance as a result of contrast administration [90–92]. Detection of these changes may be of prognostic value in acute pancreatitis [93] (see "Prognosis" section in the chapter), but their major value in the early stages of the disease lies in the fact that their presence confirms the diagnosis of acute pancreatitis. Conversely, the finding of a normal pancreas without signs of peripancreatic inflammation on the CT of a patient suspected of having severe pancreatitis, particularly if that patient's condition is deteriorating, should suggest that the patient does not have pancreatitis.

Magnetic resonance imaging (MRI) can also be of great value in the diagnosis of acute pancreatitis. It can reveal the presence of an inciting stone in the distal bile duct. In addition, MRI may be more accurate than CT in defining the extent of pancreatitis-associated necrosis [94].

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute pancreatitis includes other processes that may cause upper abdominal pain, nausea, vomiting, and abdominal tenderness. The serum amylase or lipase, or both, is usually elevated in acute pancreatitis and normal or near normal in many other processes that may cause similar symptoms. On the contrary, serum levels of pancreatic enzymes may be elevated in some states that can mimic acute pancreatitis (Table 99.5). For the most part, these states are associated with only one- to twofold elevations in circulating enzyme levels and with a normal appearance of the pancreas and peripancreatic tissues on CT examination. On occasion, however, the diagnosis may be uncertain, and operative intervention may be indicated to establish the diagnosis, particularly in patients whose conditions are deteriorating despite aggressive nonoperative therapy.

PROGNOSIS

Most patients with acute pancreatitis have a relatively mild self-limited attack that resolves with only supportive treatment. On the other hand, roughly 5% to 10% of patients in most series have a severe attack that is associated with considerable

Blood urea nitrogen rise >5 mg/dL
Serum Ca^{2+} <8 mg/dL
Partial pressure of oxygen <60 mm Hg
Base deficit >4 mEq/L
Fluid sequestration >6 L

morbidity and a mortality that can approach 40%. Certain clinical features have been identified that are associated with a poor prognosis. These include age older than 60 years, a "first attack" of pancreatitis, obesity, postoperative pancreatitis, hypocalcemia, methemalbuminemia, and the presence of either Grey Turner's or Cullen's sign [95]. Investigators in New York and Glasgow evaluated large groups of patients with pancreatitis and identified clinical and laboratory features that are available during the initial 48 hours of diagnosis that can be used to define the prognosis of an attack. These criteria, frequently referred to as the *Ranson* [96] and *Imrie* [97] *criteria*, are listed in Tables 99.6 and 99.7, respectively. The presence of fewer than three of the Ranson criteria is associated with mild pancreatitis, little morbidity, and a mortality of less than 1%. In contrast, many patients with three or more of these prognostic signs have severe pancreatitis, with a 34% incidence of septic complications and a mortality that, with seven to eight prognostic signs, may reach 90%. Using the Imrie criteria, severe pancreatitis has been found when three or more of the criteria are present, whereas mild pancreatitis is associated with fewer of the prognostic signs.

Although the criteria developed by the New York and Glasgow groups have proved to be of considerable value in allowing prospective trials in the evaluation of new therapies and interventions for acute pancreatitis, these prognostic criteria are not particularly helpful in the management of an individual patient and should never be used as criteria for the diagnosis of pancreatitis. It has been suggested that the Acute Physiology and Chronic Health Evaluation-2 (APACHE-2) system [98] might be a useful method for evaluating the severity of an attack, predicting its risk of morbidity and mortality, and comparing groups of patients with acute pancreatitis. It is likely that reports using this system will appear in the future, and that the APACHE-2 system will replace the Ranson and the Imrie systems for evaluating the prognosis of acute pancreatitis, because this system allows ongoing modifications in the grading of severity as the disease progresses.

TABLE 99.7

IMRIE'S PROGNOSTIC SIGNS

Age >55 y
White blood cell count >15,000/μL
Blood glucose >10 mmol/L
Serum urea >16 mmol/L
Partial pressure of oxygen <60 mm Hg
Serum Ca^{2+} <2.0 mmol/L
Lactic dehydrogenase >600 μg/L
Aspartate aminotransferase/alanine aminotransferase >100 μg/L
Serum albumin <32 g/L

The morbidity of an individual attack of pancreatitis is closely related to the presence of peripancreatic fluid collections demonstrable by CT. Ranson et al. [99], in a prospective study involving 83 patients with acute pancreatitis, noted that those with two or more peripancreatic fluid collections seen on CT had a 61% incidence of late pancreatic abscess, those with only one fluid collection or inflammation confined to the pancreas and peripancreatic fat had a 12% to 17% incidence of pancreatic abscess, and those with either no CT changes of pancreatitis or with only pancreatic enlargement on CT had a zero incidence of pancreatic abscess. The morbidity, incidence of abscess formation, and mortality of an attack of pancreatitis also have been shown to be related to the amount of pancreatic tissue that is not enhanced on CT after bolus administration of contrast material during dynamic CT. Beger et al. [91] suggested that patients might benefit from surgical intervention and necrosectomy of the pancreas when dynamic CT indicates that considerable portions of the pancreas are poorly perfused or nonperfused (i.e., necrotic).

In addition to these scoring systems, other factors characterizing acute pancreatitis may be helpful in predicting the severity and, thus, the outcome of an attack. Most notable in this regard are the presence or onset, shortly after presentation, of evidence suggesting organ failure and/or evidence of extravascular extravasation of normally intravascular fluid [7,100,101]. This fluid loss can result in renal failure, respiratory failure, or both as well as hemoconcentration, and each of these changes is predictive of a poor outcome. In contrast, the absence of hemoconcentration on admission usually suggests that pancreatic necrosis is unlikely [102,103]. Elevated circulating levels of other factors (e.g., C-reactive protein, certain cytokines, phospholipase A2, trypsinogen activation peptide, and trypsinogen-2) are also suggestive of a severe attack and predictive of a poor outcome [7].

TREATMENT OF ACUTE PANCREATITIS

Initial Management

During the early stages of an acute attack of pancreatitis, efforts should be made to confirm the diagnosis, control pain, and support fluid and electrolyte needs [104]. Establishing the diagnosis of acute pancreatitis may be difficult and, at times, impossible without exploratory laparotomy. Usually, the clinical picture combined with hyperamylasemia, a convincing CT, and favorable response to aggressive nonoperative therapy are sufficient, but when doubt persists, exploration may be warranted if the dire consequences of an overlooked bowel perforation, infarction, or obstruction are to be avoided [105]. On the contrary, reports have suggested that laparotomy may increase the incidence of septic complications in pancreatitis [106]; therefore, exploration should be avoided if possible.

Treatment of Pain

The pain of pancreatitis is often severe and difficult to control. Most patients require narcotic medications. Meperidine rather than morphine would appear to be the narcotic drug of choice for gallstone pancreatitis because it relaxes the sphincter of Oddi, whereas morphine causes sphincteric contraction [107].

Fluid and Electrolyte Replacement

The early stage of severe acute pancreatitis is characterized by major fluid and electrolyte losses. External losses, caused by repeated episodes of vomiting and exacerbated by nausea and diminished fluid intake, can lead to hypochloremic alkalosis. Internal losses caused by leakage of intravascular fluid into the inflamed retroperitoneum, pulmonary parenchyma, and soft tissues elsewhere in the body contribute to hypovolemia. The most sensitive indicator of the magnitude of fluid loss during this stage of pancreatitis is the hematocrit; serum electrolytes may remain normal, because electrolyte composition of the lost fluid is similar to that in plasma. On the contrary, the blood pH may fall as hypovolemia and poor tissue perfusion lead to metabolic acidosis. Hypoalbuminemia and hypomagnesemia, caused by preexisting malnutrition in chronic alcoholics, losses during the early stages of pancreatitis, or both, may warrant replacement therapy. Tetany, carpopedal spasm, or other manifestations of hypocalcemia are rare but when they occur should prompt aggressive calcium replacement.

The hemodynamic parameters during severe pancreatitis may resemble those of septic shock [108]. Thus, heart rate, cardiac output, and cardiac index rise and total peripheral resistance falls. The arterial-venous oxygen difference and intrapulmonary shunt rise, and marked hypoxemia may result. The basis for these changes is, most likely, multifactorial and includes hypovolemia, atelectasis, and the release of vasoactive agents and cytokines, including IL-1, IL-6, and tumor necrosis factor-α [85,109].

Treatment requires meticulous management of fluid and electrolyte needs. A fluid balance flow sheet may prove extremely useful in this regard. Endotracheal intubation and mechanical ventilatory support may be needed. For the most part, patients with severe pancreatitis should be in an ICU where facilities for close monitoring are available. Volume status can best be followed using a Swan-Ganz catheter to track filling pressures and an indwelling urethral catheter to monitor urine output. Arterial oxygenation can be followed using an indwelling arterial catheter and frequent blood gas determinations.

Aggressive and adequate fluid resuscitation, instituted during the early stages of acute pancreatitis, is essential. A growing body of evidence indicates that inadequate fluid resuscitation may promote progression of otherwise mild pancreatitis into severe pancreatitis, with its associated major morbidity and high mortality.

Other Treatments

The role of prophylactic antibiotics in the management of acute pancreatitis is not clear. Early randomized studies, performed primarily in patients with mild alcohol-induced pancreatitis, suggested that prophylactic antibiotics did not alter the incidence of septic complications or the mortality of pancreatitis [110,111]. More recently, however, studies evaluating this issue have focused on patients with severe gallstone-induced pancreatitis. Some have indicated that prophylactic treatment with broad-spectrum agents, such as imipenem, or a third-generation cephalosporin may be of benefit to these patients [112,113], whereas others have suggested that prophylactic antibiotics may be of little or no value in the management of patients with severe pancreatitis [114]. In some cases, the prophylactic use of broad-spectrum antibiotics may promote the emergence of resistant bacteria or fungi, or both. The latter problem may be reduced, to some extent, by the concomitant administration of an antifungal agent such as fluconazole [115].

The peritoneal exudate that develops during acute pancreatitis contains a number of potentially harmful vasoactive agents and enzymes. It is believed that these substances are absorbed from the peritoneal cavity into the circulation and contribute to the morbidity of pancreatitis by causing complications such as vasomotor collapse, myocardial depression, acute respiratory distress syndrome, and renal failure [116–119]. Peritoneal lavage has been used in an attempt to remove these substances, and early anecdotal reports suggested that peritoneal lavage was beneficial [106,120–123]. However, a large multi-institutional prospectively randomized and controlled trial in the United Kingdom indicated that short-term peritoneal lavage did not alter the morbidity or mortality of pancreatitis [124]. On the contrary, Ranson and Berman [125] reported the results of a study in which peritoneal lavage was performed for a prolonged period in a small group of severely ill patients with pancreatitis. They concluded that prolonged peritoneal lavage might indeed be of value in the management of such patients. Thus, at present, the actual value and the ideal method of performing peritoneal lavage in this setting remain unclear.

Peritoneal lavage

Many other methods of treating pancreatitis have been examined, but to date, no controlled trials have been reported that demonstrate a beneficial effect of these forms of therapy in pancreatitis (Table 99.8). Nasogastric suction has not been shown to alter the morbidity or mortality of pancreatitis, but many clinicians, including myself, believe that it improves patient comfort. Histamine-2 receptor antagonists, antacids, or both may diminish the risk of stress ulcers, but these drugs do not alter the severity or course of pancreatitis. Agents that reduce pancreatic function (atropine, glucagon, calcitonin, somatostatin), inhibit inflammation or cytotoxic responses (indomethacin, steroids, prostaglandins), inhibit digestive enzymes (procainamide, gabexate, aprotinin), or improve flow in the pancreatic microcirculation (isoproterenol, heparin, dextrans) have not been found to alter the course of pancreatitis in humans, although many of these approaches have been found to be of benefit if begun early in the course of experimental pancreatitis in laboratory animals [126,127]. A multicenter, prospective, controlled, randomized trial was reported, suggesting that the platelet-activating factor antagonist lexipafant

might favorably affect the course of acute pancreatitis [128]. Administration of lexipafant was found to reduce the mortality and incidence of organ failure in patients treated within 72 hours of the onset of acute severe pancreatitis. However, a more recent trial specifically focusing on the use of lexipafant during the initial 48 to 72 hours of pancreatitis found that it did not alter outcome [129]. Thus, at present, there is no evidence to support the use of this agent in pancreatitis.

By convention, most patients with severe pancreatitis are treated by a combination of bowel rest and either parenteral or enteral nutrition. The mortality rate for patients treated with enteral or parenteral nutrition has been found to remain unaltered, but those treatments have been reported to reduce the incidence of infections, complication, and the need for surgical intervention [130,131]. Furthermore, recent reports suggest that enteral nutrition can be successfully administered by either the nasogastric or the nasojejunal route and that the benefits of using either route are comparable [132,133].

Role of Surgery and Endoscopy in Gallstone Pancreatitis

Most patients with biliary tract stone–induced pancreatitis recover quickly and uneventfully, as the offending stone is either passed into the duodenum or disimpacts itself from the ampulla of Vater by moving proximally in the duct. The role of early interventions designed to remove obstructing stones in this disease has been extremely controversial. Acosta et al. [134] and Stone et al. [135] concluded that early surgical intervention could reduce the severity of pancreatitis and shorten the duration of hospitalization. In contrast, Kelly and Wagner [136] found that early surgical intervention was associated with greater morbidity and mortality than was delayed surgery. Three prospectively randomized controlled trials and a recent observational, prospective, multicenter trial have evaluated the benefit of early endoscopic sphincterotomy and stone extraction in the management of patients with gallstone pancreatitis [66,137–139]. Each study concluded that early intervention did not alter the course of mild pancreatitis, but three studies [66,137,139] suggested that the morbidity of severe pancreatitis, particularly if it was associated with cholestasis, was reduced by early stone removal. It appears that early stone removal by endoscopic sphincterotomy benefits these patients by reducing the incidence of associated cholangitis. On the basis of currently available data, it seems most appropriate that patients with mild pancreatitis do not undergo either early surgical or endoscopic intervention. On the contrary, early intervention seems warranted for patients with severe gallstone pancreatitis and intervention could either be surgical or endoscopic, depending on the local availability of expertise in these areas. It is possible that the benefit of early surgical or endoscopic intervention could also be achieved by the use of prophylactic antibiotics that are designed to prevent cholangitis, but a trial evaluating this approach has not been reported.

Recurrent attacks of gallstone pancreatitis may develop if stones either in the gallbladder or biliary ducts remain after resolution of the index attack. For that reason, most clinicians recommend that some form of treatment designed to prevent recurrent attacks should be administered before discharge of the patient from the hospital [130]. That might be accomplished by laparoscopic or open cholecystectomy combined with surgical or endoscopic duct clearance if choledocholithiasis is discovered by preoperative magnetic resonance cholangiopancreatography (MRCP). Alternatively, in patients whose only symptoms are those of duct disease and who lack symptoms of cholecystolithiasis, endoscopic sphincterotomy and duct clearance may be sufficient, particularly if those patients are poor surgical risks.

TABLE 99.9

COMPLICATIONS OF ACUTE PANCREATITIS

Systemic complications
- Cardiovascular collapse
- Respiratory failure
- Renal failure
- Metabolic encephalopathy
- Disseminated intravascular coagulation
- Gastrointestinal bleeding

Local complications
- Acute fluid collection
- Pancreatic necrosis ± infection
- Pancreatic pseudocyst
- Pancreatic abscess
- Pancreatic ascites
- Pancreatic-pleural fistula
- Duodenal obstruction
- Bile duct obstruction
- Splenic vein thrombosis
- Pseudoaneurysm + hemorrhage

Treatment of Systemic Complications

Systemic complications of acute pancreatitis include cardiovascular collapse, respiratory failure, renal failure, metabolic encephalopathy, disseminated intravascular coagulation, and gastrointestinal bleeding (Table 99.9). For the most part, the pathogenesis and management of these manifestations of acute pancreatitis are identical to those involved when these processes are superimposed on other diseases that result in severe peritonitis and hypovolemic shock. In other words, there may be nothing specific about these systemic complications of pancreatitis, although they may be worsened by circulating vasoactive agents, activated digestive enzymes, and protein breakdown fragments absorbed from the inflamed pancreas.

Treatment of the cardiovascular collapse of acute pancreatitis requires aggressive and meticulous fluid and electrolyte administration. Measurement of venous filling pressures, hematocrit, cardiac output, and urinary output may be extremely helpful in gauging fluid needs. The growing consensus is that aggressive fluid and electrolyte therapy may be the most effective method of preventing the appearance of pulmonary and renal failure in these patients. Theoretically, peritoneal dialysis, by removing the yet unabsorbed but potentially harmful agents released by the inflamed pancreas, and plasmapheresis, which could permit removal of circulating harmful agents, could also prevent or reduce the severity of these systemic complications of pancreatitis. Their value, however, has not been shown by definitive clinical studies.

Treatment of the atelectasis and acute respiratory distress syndrome associated with acute pancreatitis is similar to the treatment of these problems when they are associated with other causes of peritonitis. Thus, good pulmonary toilet combined with close monitoring of pulmonary function by measurement of mechanics and blood gases are indicated. With deterioration in function, intubation and respiratory support may be needed. Similarly, the management of the renal failure of pancreatitis is not different from that of acute renal failure caused by other diseases. The renal failure of pancreatitis is prerenal and, when it occurs, is associated with a poor prognosis.

Dialysis, usually in the form of hemodialysis, may be needed in the most severely affected.

Disseminated intravascular coagulation, manifested by decreased platelet counts and fibrinogen levels, prolonged prothrombin and partial thromboplastin times, and increased circulating levels of fibrin-split products, occurs in some patients with severe acute pancreatitis. Bleeding caused by disseminated intravascular coagulation, however, is rare. Thus, prophylactic anticoagulation with heparin in patients with biochemical evidence of disseminated intravascular coagulation is not indicated and may be associated with significant problems, including retroperitoneal hemorrhage.

The gastrointestinal bleeding that sometimes is seen in patients with pancreatitis usually results from stress-induced gastroduodenal lesions. Thus, prophylaxis with antacids, H_2-blockers, or proton pump inhibitors may be useful in preventing this problem. Rarely, massive bleeding may result from injury to gastrointestinal structures by the inflammatory process in the peripancreatic retroperitoneum. Thus, thrombosis of gastrointestinal vessels may lead to ischemic injury and bleeding from the stomach, intestine, or colon. In extreme cases, infarction and perforation of the viscus may occur. The inflammatory process may lead to erosion into retroperitoneal vessels near the pancreas. In these situations, treatment is dictated by the lesions present but usually involves resection of nonviable tissues.

LOCAL COMPLICATIONS OF PANCREATITIS

Definitions

Considerable confusion has surrounded the terminology used to describe the local complications of an acute attack of pancreatitis. At a symposium in Atlanta, an international group of clinicians and scientists attempted to resolve this confusion by proposing the use of the following definitions [140]:

1. *Acute pancreatic and peripancreatic fluid collections*: Fluid collections in or near the pancreas that occur early in the course of acute pancreatitis and that lack a wall of granulation or fibrous tissue.
2. *Pancreatic necrosis*: An area of nonviable pancreatic tissue that may be diffuse or focal and that typically is associated with peripancreatic fat necrosis. Pancreatic necrosis may be either *sterile* or *infected*.
3. *Pancreatic pseudocyst*: A collection of pancreatic juice that usually is rich in digestive enzymes and that is enclosed by a nonepithelialized wall of fibrous or granulation tissue (Figs. 99.1 and 99.2). It usually is round or ovoid in shape and not present until 4 to 6 weeks have elapsed from the onset of acute pancreatitis. Before this time, the fluid collection usually lacks a defined wall and may be either an *acute fluid collection* or a localized area of *pancreatic necrosis*. Bacteria may be present in a pseudocyst as a result of contamination, but in this setting, clinical signs of infection usually are absent. When pus is present, however, the lesion should be referred to as a *pancreatic abscess*. Leakage of pseudocysts into the peritoneal cavity or chest leads to the development of *pancreatic ascites* or *pancreatic-pleural fistula*, respectively.
4. *Pancreatic abscess*: A circumscribed intra-abdominal collection of pus, usually in proximity to the pancreas, which contains little or no pancreatic necrosis that arises as a consequence of either acute pancreatitis or pancreatic trauma (Fig. 99.3). The relative absence of necrosis distinguishes *pancreatic abscess* from *infected pancreatic necrosis*.

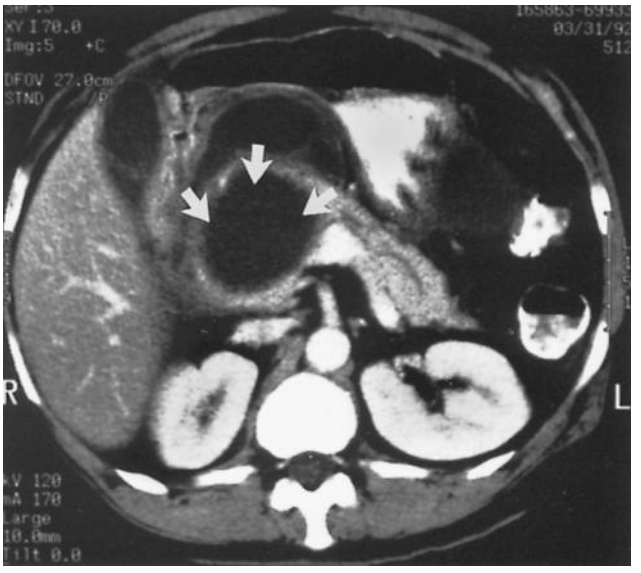

FIGURE 99.2. Computed tomography showing pseudocyst (*arrows*) in the head of the pancreas.

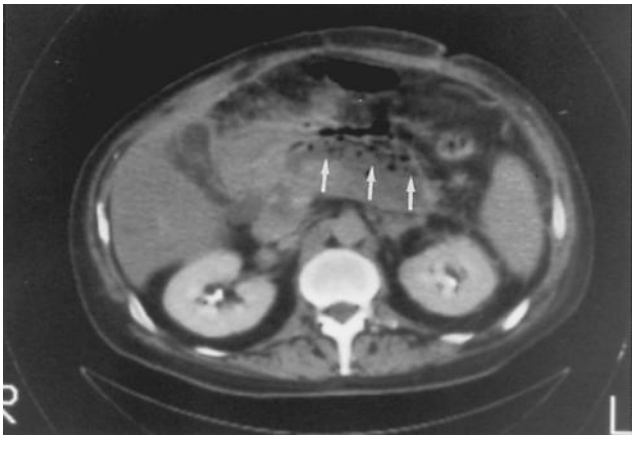

FIGURE 99.3. Computed tomography showing gas-filled pancreatic abscess (*arrows*).

Diagnosis

Patients with uncomplicated pancreatitis usually are judged by the various prognostication schemes to have mild pancreatitis at the time of diagnosis, and they generally recover uneventfully within the subsequent 1 to 2 weeks. In contrast, patients with severe pancreatitis, who remain ill for longer periods, frequently have one or more of the local complications of pancreatitis. In the past, these lesions were identified on the basis of physical examination, contrast radiography, and blood chemistry studies. For the most part, these relatively crude and inaccurate methods have been replaced by the techniques of ultrasonography (both transcutaneous and endoscopic), CT, and MRI. Ultrasonography and either CT or MRI can be used to diagnose and define the extent of acute fluid collections and pseudocysts accurately. These techniques can be used to follow the progression of these lesions and determine whether or not a wall, which distinguishes a pseudocyst from an acute fluid collection, is present.

Dynamic contrast-enhanced CT and MRI are the most accurate means of identifying and quantitating areas of pancreatic necrosis, whereas ERCP may be useful in determining whether or not fluid collections communicate with the main pancreatic duct. In addition, ERCP can be used to localize the point of duct rupture in patients with either pancreatic ascites or pancreatic-pleural fistulas. The presence of extraintestinal gas on either ultrasonography or CT is diagnostic of either infected necrosis or abscess, but this finding is only occasionally noted. More often, patients with either infected necrosis or abscess are found to have poorly enhanced areas on dynamic CT or fluid collections on ultrasonography, or both, in a clinical setting of suspected sepsis. When doubt about the presence or absence of infection persists, fine-needle aspiration of these areas, under either ultrasonographic or CT guidance, may yield material that, on Gram's stain, reveals the presence of bacteria [141,142].

Management

Acute Fluid Collections

Acute fluid collections generally require no specific treatment. They usually resolve spontaneously within several weeks of an attack. Attempts to drain these collections either by percutaneously placed catheters or by early surgical intervention should be discouraged.

Sterile Necrosis

In the past, sterile necrosis was treated during the early stages of pancreatitis by surgical necrosectomy combined with postoperative lavage of the peripancreatic area [143], particularly when large portions of the pancreas were devitalized. There has been considerable controversy, however, regarding this practice and, at present, the consensus view is that patients with sterile necrosis, even if extensive, should be managed nonoperatively during the initial few weeks of their illness [144]. Surgical intervention in such patients may be associated with considerable morbidity and may even result in secondary infection of the inflamed, but previously sterile, pancreas.

Although the consensus view is that patients with sterile necrosis do not need intervention during the early phases of their disease, the potential value of intervention at later times is not entirely clear. Some of these patients experience a very prolonged illness and full recovery may only be possible after the devitalized pancreatic and peripancreatic tissue has been removed. This can be accomplished surgically by exposing the involved area and removing the necrotic tissue—a procedure that may require repeated operations and can lead to considerable morbidity. Recently, alternatives to this approach have been proposed. They involve transpapillary or transcutaneous placement of irrigating catheters into the involved area followed by debridement achieved by continuous lavage [145–147]. In another approach, debridement is achieved using a percutaneously placed operating nephroscope or laparoscope [148,149]. The experience with these minimally invasive methods of debriding the inflamed pancreas is, to date, mostly anecdotal but suggests that debridement with little additional morbidity can be achieved.

Infected Necrosis

Infected necrosis usually is an indication for surgical intervention, whether it is detected by the presence of extraintestinal gas on CT examination or by fine-needle aspiration of an area of pancreatic necrosis. Organisms recovered in areas of infected pancreatic necrosis usually are those that are present in the gastrointestinal tract (*Klebsiella* spp, *Pseudomonas* spp, *Escherichia coli*, *Enterococcus*, *Proteus* spp) [150]. In addition, yeast such as *Candida albicans* may be encountered. It is believed that most of these organisms reach the inflamed pancreas via transmigration from adjacent segments of the intestine. Antibiotic therapy, although indicated, by itself usually represents an inadequate approach to the management of infected pancreatic necrosis. Similarly, because of the presence of large amounts of necrotic puttylike material, percutaneous drainage of these areas using indwelling catheters may prove unsuccessful and, for the most part, patients with infected necrosis require urgent, aggressive, and repeated surgical debridement and drainage. This is especially true for the unstable or septic patient who is doing poorly with nonoperative management. On the other hand, recent reports have suggested that stable patients with infected necrosis can be managed more electively and conservatively. For those stable patients, delay in performing surgical debridement may actually be beneficial, since it appears to improve survival, decrease surgical complications, and decrease the need for repeated operations when compared with early operation in this group [151]. Furthermore, although most of these patients will eventually need debridement, recent anecdotal reports have indicated that some may be definitively treated with either antibiotics alone or with antibiotics combined with percutaneous drainage [152].

Pseudocyst

Pseudocysts may cause symptoms either because they are themselves tender or because they result in obstruction of adjacent organs such as the stomach, duodenum, and bile duct. On occasion, pancreatic pseudocysts contribute to the progression of pancreatitis by causing pancreatic duct obstruction. On the other hand, many pseudocysts do not cause symptoms. Until relatively recently, the general consensus was that pseudocysts should be treated regardless of their size or whether they caused symptoms [153]. Several more recent reports, however, indicated that chronic pseudocysts, even those greater than 6 cm in diameter, can be safely observed and that treatment is only needed for those that become symptomatic [154,155].

Several methods of treating pseudocysts have been proposed, including either open or laparoscopic internal surgical drainage (cystogastrostomy, cystoduodenostomy, Roux-en-Y cystojejunostomy), endoscopic drainage (cystogastrostomy, cystoduodenostomy), and percutaneous drainage (aspiration, aspiration followed by administration of somatostatin, and catheter drainage, with or without administration of somatostatin) [156]. My experience with percutaneous drainage has, to a great extent, been disappointing because of a considerable incidence of either recurrence after aspiration or infection after catheter drainage. On the other hand, endoscopic drainage, via

endoscopic cystoduodenostomy or cystgastrostomy, is a highly effective way of managing cysts located in the pancreatic head or body, particularly if they are pressing inward on the duodenum or stomach and there is little in the way of tissue or blood vessels interposed between the cyst and the duodenal or gastric lumen [157]. Surgical internal drainage (i.e., cystojejunostomy, cystogastrostomy) would seem most appropriate for management of cysts in the pancreatic tail or the head/body cysts that cannot be safely accessed endoscopically.

Pancreatic Ascites, Fistulas, and Abscesses

Patients with pancreatic ascites or pancreatic-pleural fistulas may respond to nonoperative therapy with bowel rest, parenteral nutrition, and administration of somatostatin or other agents designed to inhibit pancreatic secretion [158–165]. Most, however, fail this method of treatment, and some form of intervention is needed. An ERCP should be performed to identify the site of duct disruption [166–168] that, if in the pancreatic tail, can be treated easily by distal pancreatectomy. Alternatively, anastomosis of a Roux-en-Y loop of jejunum to the site of rupture, particularly if it is in the head or neck of the gland, may be preferable. Endoscopically placed stents also can be used to prevent leakage of juice from the duct, and this nonoperative approach can be useful in the management of these complications [169].

Pancreatic abscess, like infected pancreatic necrosis, always requires some form of intervention, but, because pancreatic abscesses contain liquid pus rather than the paste-like material in pancreatic necrosis, percutaneous drainage of pancreatic abscesses might be considered. Alternatively, surgical or endoscopic intervention and placement of drainage catheters in the abscess may be appropriate. I have, for the most part, treated such patients with surgical drainage, but recent advances in endoscopy and in the field of invasive radiology may permit successful nonoperative management of such individuals.

TABLE 99.10

SUMMARY OF ADVANCES IN THE MANAGEMENT OF ACUTE PANCREATITIS

- Early, aggressive fluid resuscitation is beneficial in cases of severe acute pancreatitis associated with shock [170].
- In contrast to morphine, meperidine relaxes the sphincter of Oddi and is thus a favored analgesic in cases of pancreatitis [107,171].
- Use of enteral nutrition has shown benefit over parenteral nutrition in terms of duration of hospital stay, infectious morbidity, and need for surgery in meta-analysis [172–174]. Enteral nutrition, because it is associated with fewer complications, may be the better of these two treatment modalities.
- Antibiotic use remains controversial; meta-analyses have shown utility in preventing infection of pancreatic necrosis [175,176], although a large, randomized, controlled trial failed to demonstrate benefit [114].
- In cases of severe necrotizing pancreatitis, conservative management in an intensive care setting trends toward a survival benefit when compared with early surgical intervention [177].
- Early endoscopic sphincterotomy and stone extraction are beneficial in preventing sepsis in cases of severe gallstone pancreatitis in patients with jaundice [66,137,178].

Most aspects of the management of acute pancreatitis and its complications are based on information derived from clinical experience, case series, and retrospective comparisons. A summary of recent advances in the management of acute pancreatitis is provided in Table 99.10.

CHAPTER 100 ■ MANAGEMENT OF HYPERGLYCEMIA IN CRITICALLY ILL PATIENTS

MICHAEL J. THOMPSON, DAVID M. HARLAN, SAMIR MALKANI AND JOHN P. MORDES

INTRODUCTION

Hyperglycemia is a common problem that complicates the delivery of intensive care. About 7.8% of the U.S. population was reportedly diabetic in 2007 [1]. National Health Interview Survey and census projections suggest that between 2000 and 2050, the number of persons with diabetes will rise from 12 million to 48.3 million persons of all ages and that the prevalence will increase to 12% [2]. Perhaps, as many as one in three people born in the United States in 2000 will develop diabetes at some time [3]. In addition, the growing worldwide prevalence of obesity is increasing the prevalence of diabetes in many nations [4]. The world prevalence of diabetes among adults is predicted to be 7.7%, or 439 million adults, by 2030 [5].

Epidemiology alone would make diabetes a common problem in the intensive care unit (ICU), but poorly controlled diabetes also predisposes to cardiovascular [6,7], renal [8–10], and infectious [11–16] complications that often require intensive surgical and medical care. In addition, hyperglycemia frequently occurs in severely ill ICU patients who have no prior history of diabetes [17].

Whatever the primary problem, hyperglycemia amplifies the challenges of intensive care. Often, pre-existing diabetes itself is the primary problem, as in ketoacidosis and hyperosmolar coma. These conditions are discussed in Chapter 101.

ETIOLOGY AND PATHOPHYSIOLOGY

Metabolic Homeostasis

Individuals with normal glucose tolerance maintain their blood glucose concentration between 60 and 120 mg per dL. Maintenance of glucose within this narrow range is controlled by the degree of tissue insulinization (Fig. 100.1) [18]. This is a function of the amount of insulin available and the responsiveness of target tissues. After eating, blood glucose concentration rises but remains within the normal range as a result of increased insulin secretion. Insulin first promotes the transport of glucose into cells and the repletion of glycogen and protein stores. It then mediates the storage of excess glucose as triglyceride. When absorption of nutrients is complete, the concentrations of all metabolites and hormones return to basal levels.

In the fasting state, two mechanisms keep blood glucose concentration in the normal range, glycogenolysis and gluconeogenesis. Initially, hepatic glycogen is mobilized. If fasting persists longer than 12 to 18 hours, peripheral tissues begin to use free fatty acids for fuel, thereby sparing glucose. A low level of circulating insulin is permissive to the lipolytic release of these fatty acids. At the same time, gluconeogenesis supplies glucose for obligate glycolytic tissues, most notably the central nervous system.

If starvation continues for more than 72 hours, the brain begins to use ketone bodies as an alternative fuel, further sparing glucose utilization [18]. At this stage, a progressive decrease in hepatic gluconeogenesis occurs as a consequence of decreased amino acid release in the periphery. As starvation continues, lactate, pyruvate, and glycerol become the main gluconeogenic precursors in place of amino acids. At all times, a low level of circulating insulin regulates the rate of lipolysis, glucose transport, and gluconeogenesis. Healthy humans are always insulinized to an appropriate degree.

Metabolic Stress

Major surgery and critical illness are physiologically stressful events that provoke complex metabolic responses. Tissue hypoxia and hypoxemia adversely affect normal oxidative phosphorylation, and counterregulatory hormones are secreted. These hormones include epinephrine, norepinephrine, cortisol, growth hormone, glucagon, and various cytokines (e.g., tumor necrosis factor-α). They raise blood glucose concentration, mobilize alternative fuels, and increase peripheral resistance to the effects of insulin. In the ICU, their effects may be further amplified by the concurrent administration of exogenous vasopressors, glucocorticoids, and other drugs that can affect intermediary metabolism.

Stress and the Diabetic State

Stress-induced changes in metabolism normally lead to increased insulin release. This in turn enhances peripheral glucose utilization and inhibits alternative fuel mobilization. In this way, the body resists stress without losing control of the biochemical machinery. In patients with decreased insulin reserves (i.e., diabetes mellitus), failure of this feedback loop produces hyperglycemia and related metabolic complications. To preclude these complications, careful management of insulin, fluid, and electrolytes is necessary.

Classification of Diabetes

Diabetes is not one disease but rather a family of syndromes that have in common hyperglycemia resulting from inadequate insulinization. These syndromes vary with respect to

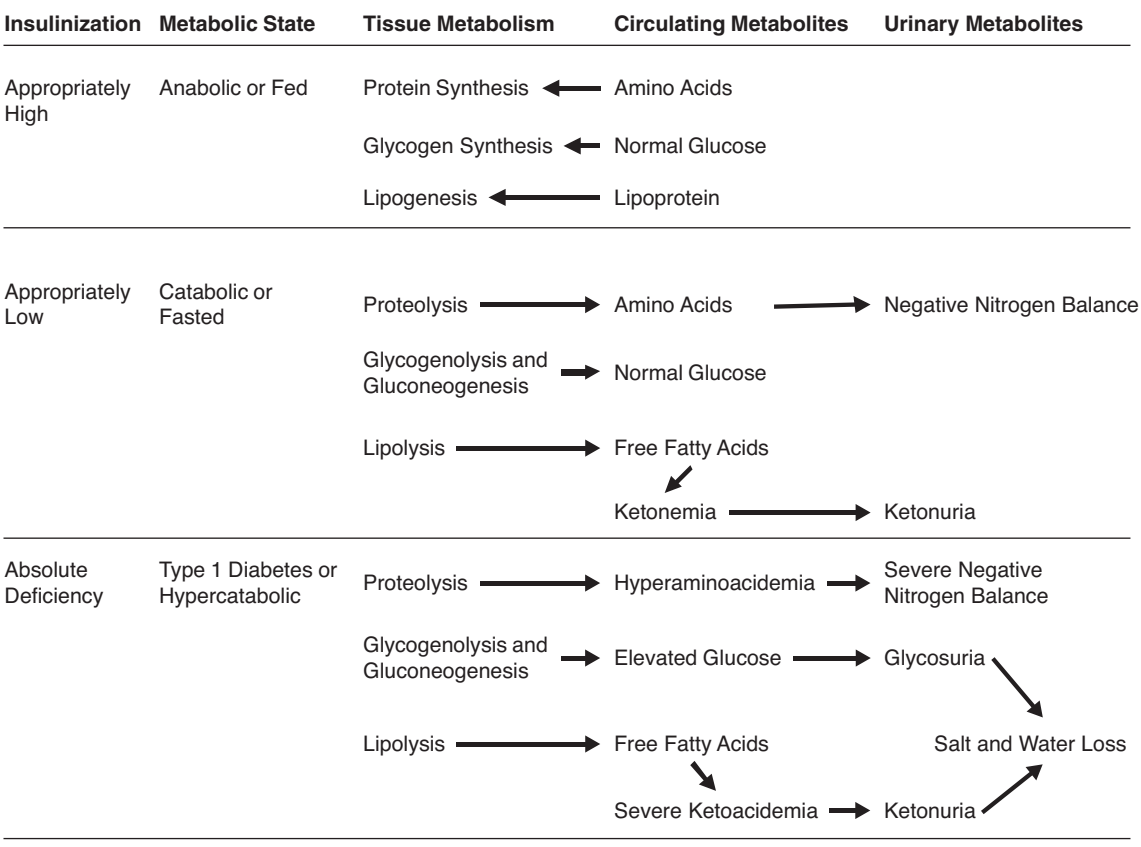

FIGURE 100.1. Metabolic effects of insulin in normal and diabetic states. *Upper* entries illustrate the anabolic, storage-promoting effects of insulin that occur with eating. *Middle* entries illustrate the controlled catabolic effects that occur during fasting. *Bottom* entries illustrate the *uncontrolled catabolism that ensues from absolute deficiency of insulin in type 1 diabetes*.

genetics, pathophysiology, and appropriate treatment modalities [19]. Table 100.1 outlines the American Diabetes Association's (ADA's) classification system.

Type 1 Diabetes

In type 1 diabetes, the insulin-producing β cells in the pancreatic islets are destroyed, resulting in near total deficiency of insulin [18,20]. Hyperglycemia develops rapidly, most commonly during childhood and adolescence. Most cases of type 1 diabetes are autoimmune in origin [20]. About 10% of persons with diabetes have this form of the disorder.

Patients with type 1 diabetes require exogenous insulin for survival (Fig. 100.1). The insulin can be given either as a continuous insulin infusion or as conventional subcutaneous injections. The key ICU issue is continuity of treatment. Inappropriate discontinuation of insulin treatment, even for relatively brief intervals, can lead to serious metabolic complications.

Patients with type 1 diabetes who are not given insulin can neither store nor use glucose, and unregulated gluconeogenesis and lipolysis occur (Fig. 100.1). In this hypercatabolic state, accelerating amino acid and fat mobilization produce hyperglycemia, hyperlipidemia, and ketosis. The excess glucose produced by uncontrolled gluconeogenesis remains in the circulation because there is no insulin to stimulate transport into cells. The osmotic diuresis of glucose and the buffering of ketoacids produce secondary fluid and electrolyte shifts. Ultimately, diabetic ketoacidosis occurs. This disorder is discussed in Chapter 101.

TABLE 100.1

CLASSIFICATION OF DIABETIC SYNDROMES [19]

Type 1 diabetes (β-cell destruction) autoimmune (Type 1 A) and idiopathic (Type 1B)
Type 2 diabetes (insulin resistance with variable insulin secretory defect)
Other specific types
Genetic defects of β-cell function (e.g., MODY, mitochondrial DNA)
Genetic defects in insulin action (e.g., lipoatrophic diabetes)
Diseases of the exocrine pancreas (see Table 100.2)
Endocrinopathies (see Table 100.2)
Drug or chemical induced (see Table 100.2)
Infections (e.g., congenital rubella)
Uncommon forms of immune-mediated diabetes (e.g., stiff-man syndrome)
Other genetic syndromes associated with diabetes
Gestational diabetes mellitus

MODY, maturity-onset diabetes of the young.

Type 2 Diabetes

Type 2 diabetes is characterized by relative, rather than absolute, deficiency of insulin. It involves defects in both insulin action and insulin secretion. Impaired response to insulin in peripheral tissues is often the dominant feature [21–23]. It develops insidiously, most commonly in obese individuals older than 40 years. It may go undetected for years, only to be discovered serendipitously or during the stress of surgery or other illness. Patients with type 2 diabetes account for more than 80% of the diabetic population.

TABLE 100.2

SOME CAUSES OF "SECONDARY" DIABETES [19,76]

Type	Examples	Type	Examples
Drug induced	Thiazide diuretics Loop diuretics (e.g., furosemide, ethacrynic acid, metolazone) Antihypertensive agents (e.g., β-adrenergic blockers, calcium channel blockers, clonidine, diazoxide) HIV protease inhibitors Hormones (e.g., glucocorticoids, oral contraceptives, α-adrenergic agents, glucagon, growth hormone) Interferon-α Sympathomimetic drugs Antineoplastic agents (e.g., asparaginase, mithramycin, streptozocin) Phenytoin (Dilantin™) Theophylline Niacin Cyclosporin Phenothiazines Lithium Isoniazid Pentamidine Olanzapine (Zyprexa™) Gatifloxacin	Other endocrine disorders	Cushing's syndrome Pheochromocytoma Acromegaly Primary hyperaldosteronism Hyperthyroidism Polyendocrine autoimmune syndromes POEMS syndrome (e.g., polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin changes) Somatostatinoma Glucagonoma
Pancreatic diseases	Hemochromatosis Pancreatic cancer Pancreatitis Cystic fibrosis Fibrocalculous pancreatopathy Abdominal trauma	Other genetic syndromes	Down syndrome Klinefelter syndrome Turner syndrome Wolfram syndrome Friedreich ataxia Huntington disease Lawrence–Moon–Bardet–Biedl syndrome Myotonic dystrophy Prader–Willi–Labhart syndrome Porphyria

Many patients with type 2 diabetes can be treated with diet, exercise, and oral hypoglycemic agents. Some patients, especially those who are not obese, need insulin to control their hyperglycemia. This is done to prevent symptoms (e.g., polyuria) and long-term complications. Even when type 2 diabetes is untreated, there is usually enough insulin present to control lipid mobilization and prevent ketoacidosis when the patient is otherwise well.

In the ICU, patients with type 2 diabetes whose diabetes is uncontrolled should be treated with insulin. Keys to management include attention to both blood glucose concentration and acid–base balance. Infection, metabolic stress, and many medications commonly used in the ICU can exacerbate type 2 diabetes and lead to ketoacidosis [24], hyperosmolar coma, or lactic acidosis. These disorders are discussed in Chapter 101.

Other Types of Diabetes

Additional forms of diabetes involve specific genetic defects or are secondary to intercurrent diseases, infections, medications, or a combination of these [19]. The broad categories into which these other specific types of diabetes fall are given in Table 100.1. A partial listing of the other types of diabetes and precipitants of secondary diabetes is given in Table 100.2.

ICU patients with any form of uncontrolled hyperglycemia require insulin to control hyperglycemia and prevent short-term metabolic complications. Patients who have undergone total pancreatectomy have absolute insulin deficiency, are ketosis prone, and are insulin dependent. Patients with other diseases of the exocrine pancreas (e.g., pancreatitis) can develop variable degrees of insulin deficiency and, in the ICU, should be considered potentially at risk for ketoacidosis. Gestational diabetes in an ICU setting should also be treated with insulin.

DIAGNOSIS OF HYPERGLYCEMIA IN THE INTENSIVE CARE UNIT

Diagnostic Criteria

All acutely ill patients should have their blood glucose level measured at entry into the ICU and at regular intervals throughout their stay. In the outpatient setting, diabetes is diagnosed by a fasting blood glucose level greater than 126 mg per dL or a glucose level greater than or equal to 200 mg per dL measured 2 hours after a 75-g oral-glucose tolerance test. It is required that this be a persistent condition confirmed by repeating the test on another day. A formal diagnosis of new onset diabetes should be made tentatively during the stress of an ICU admission as hyperglycemia may subsequently resolve. Hyperglycemic ICU patients with no prior history of diabetes should be evaluated for persistence of impaired glucose tolerance after recovery.

The majority of seriously ill patients with hyperglycemia do not have a preexisting diagnosis of diabetes. In one study of 1,200 subjects treated in a medical ICU, 70% of individuals at some time experienced a plasma glucose concentration of more than 215 mg per dL, and only about 17% of these patients had a prior history of diabetes [25].

Assessment of Severity

Whenever the glucose concentration in any patient is greater than about 250 mg per dL, actual or impending ketoacidosis and hyperosmolality must be excluded. Ketoacidosis can be diagnosed on the basis of history, physical findings, and the presence of an anion gap acidosis and ketonemia. Osmolarity can be measured by the laboratory or calculated from the serum concentrations of glucose, blood urea nitrogen, sodium, and potassium (Table 100.1; Chapter 101). Hyperosmolar states in the setting of diabetes are usually associated with severe dehydration, obtundation, and extreme hyperglycemia. Diabetic ketoacidosis and hyperosmolar coma require urgent treatment (see Chapter 101). In this chapter, we describe the goals, methods, and pitfalls of treating intercurrent diabetes mellitus in the ICU when neither ketoacidosis nor hyperosmolar coma is the primary disease process.

TREATMENT OF CRITICALLY ILL PATIENTS WITH PREEXISTING DIABETES

Initial Evaluation

Physicians caring for patients with diabetes in an ICU should attempt to determine the type of diabetes, its duration, the presence of diabetic complications, and the degree of previous glycemic control. Patients with type 1 diabetes require insulin treatment at all times; those with type 2 diabetes may or may not require insulin. Patients with diabetes that is secondary to some other disorder (Table 100.2) require diagnosis and treatment of the precipitating factors.

Long-standing diabetes is associated with complications that tend to be worse in patients with either type 1 [26] or type 2 [27] disease that is poorly controlled. These sequelae of diabetes complicate the management of critical illness. Diabetes is a leading cause of cardiovascular and peripheral vascular disease. Assessments of both cardiac function and peripheral circulation are advisable for all patients with diabetes. Diabetic neuropathy can affect the autonomic nervous system, with implications for management of blood pressure, heart rate, and voiding. Autonomic neuropathy should be suspected in patients with an abnormal pupillary response to light or absence of heart rate response (R-R interval change in the electrocardiogram) during Valsalva maneuver. Assessment of kidney function should include a urinalysis for protein; albuminuria precedes abnormalities in blood urea nitrogen and creatinine levels. Diabetic eye disease is not a contraindication to anticoagulation, but its severity should be documented before instituting therapy.

A history of poor control should alert the clinician to other potential problems. Poorly controlled diabetes may imply poor nutrition. This has important implications for resistance to infection and wound healing; nutritional assessment and vitamin repletion may be required. Thiamine in particular is a critical cofactor in carbohydrate metabolism, and patients with uncontrolled diabetes may be thiamine deficient. Occult infections to which individuals with diabetes are particularly susceptible include osteomyelitis, cellulitis, tuberculosis, cholecystitis, gingivitis, sinusitis, cystitis, and pyelonephritis [11,12,28,29]. Patients with type 2 diabetes are frequently hyperlipidemic and may develop pancreatitis when poorly controlled [30].

Systems are now available for accurately measuring a patient's blood glucose levels at the point of care and with near-immediate results using hospital-grade bedside machines, and should be on hand in all emergency departments, ICUs, operating suites, and recovery rooms [31,32]. It should be noted that glucose meter measurements can be influenced by hematocrit, creatinine concentration, plasma protein concentration, and PO_2, all of which can be very abnormal in ICU patients [33–35]. Test strips based on glucose dehydrogenase-pyrroloquinoline quinone (GDH-PQQ) methodology can falsely elevate blood glucose readings in patients receiving maltose or icodextrin by more than 100 mg per dL [36]. Maltose is used in a number of biological preparations and peritoneal dialysis solutions may contain icodextrin. Extremely elevated blood glucose concentrations may be outside the range accurately measured by the bedside monitor and should be verified with a serum sample sent to the laboratory [37]. In general, however, therapy should not be delayed by waiting for confirmatory results of laboratory glucose concentration.

Why Control Hyperglycemia in the Intensive Care Unit?

Hyperglycemia in the Intensive Care Unit Predicts Adverse Outcome

It is intuitively plausible to assume that glucose concentration should always be in the normal range, and studies show that hyperglycemia in the ICU is associated with adverse outcome. Even minimal hyperglycemia, plasma glucose concentration more than 110 mg per dL, has been shown to predict increased in-hospital mortality and the risk of congestive heart failure in patients with acute myocardial infarction [38]. Hyperglycemic patients also have an increased risk of wound infection as well as overall mortality following cardiac surgery [39,40]. Hyperglycemia is also associated with poor outcome in patients with stroke [41]. Patients in whom diabetes is diagnosed for the first time during an ICU admission reportedly have an 18-fold increase in their risk of in-hospital mortality [42].

How Does Hyperglycemia Adversely Affect Outcome?

Hyperglycemia predisposes to disturbances in sodium, potassium, and phosphate concentrations. Because uncontrolled hyperglycemia also provokes an osmotic diuresis, symptomatic hyponatremia can result. Hypokalemia predisposes to arrhythmia, and hypophosphatemia may interfere with platelet function and white cell motility. Control of glycemia prevents these problems and the need for compensatory correction. The susceptibility of patients with diabetes to infection is well recognized [11,12,28]. Uncontrolled glycemia appears to impair innate immunity (cytokine responses), granulocyte function (chemotaxis, phagocytosis, and killing), and, possibly, lymphocyte function and antibody formation [43–46]. Some microorganisms become more virulent in a high-glucose environment [43]. Endothelial function may also be impaired by hyperglycemia [47]. In general, better regulation of blood glucose leads to improvement in these parameters.

What is the Evidence that Control of Blood Glucose Concentration Alters Clinical Outcome in Intensive Care Unit Patients?

Recognizing that hyperglycemia is bad is not the same as saying that control of hyperglycemia in the ICU is beneficial. Attempting to normalize blood glucose concentration in the ICU is not without risk. The available evidence does not yet establish that intensive management of hyperglycemia within the normal is unequivocally beneficial [48].

The best evidence for benefit attributable to intensive management derives from studies performed in a surgical ICU

setting. Intensive insulin treatment reportedly improves myocardial performance and results in faster recovery after coronary artery bypass grafting [49]. Continuous intravenous insulin infusion also reduces the risk of sternal wound infection in diabetic patients after cardiac surgical procedures [39]. The studies reporting benefit, however, did not seek to reduce plasma glucose concentration all the way to the "normal" range. In 2001, an influential study of surgical ICU patients by Van den Berghe et al. [50] reported that intensive insulin therapy with a target plasma glucose concentration less than 110 mg per dL reduced in-hospital mortality by 34%, septicemia by 46%, acute renal failure by 41%, and critical-illness polyneuropathy by 44%. This study, together with the results of retrospective studies [40,51,52], generated widespread acceptance of the concept that intensive glycemic control is important in critically ill patients. This then led to implementation of intensive glycemic control protocols in a majority of academic ICU programs.

A question raised after the release of the results of the 2001 study by Van den Berghe et al. was whether intensive management would show similar benefit in the medical ICU. To some extent, this was a reflection of several atypical features in the original study, which involved only a single center and was not blinded [50]. In addition, the mortality among the cardiac surgery patients in the control group (5.1%) was several times higher than expected. Finally, all study subjects received 200 to 300 g of glucose daily, that is, 2 to 3 L of 10% dextrose and early enteral or parenteral feeding. These characteristics are not the norm for cardiothoracic surgery patients worldwide. A subsequent report from the Van den Berghe group [25] reported that intensive insulin therapy of patients in a medical ICU, while improving several indices of morbidity, did not reduce in-hospital mortality. Disturbingly, hypoglycemia (<40 mg per dL) occurred in 18% of subjects in the intensively treated group versus 3% of those in the conventionally treated group, and hypoglycemia was identified as an independent risk factor for death. The data concerning hypoglycemia were surprising, as this problem had not been encountered in several other studies designed to evaluate the safety and practicality of implementing intensive insulin protocols in ICU settings [52–54].

The lack of a consistent, evidence-based dataset led to several multicenter randomized controlled trials of blood glucose management in heterogeneous ICU populations. The GLUControl trial randomized 3,000 medical and surgical ICU patients in several centers in Europe to two regimens of insulin therapy targeted to achieve a plasma glucose concentration of either 80 to 110 mg per dL or 140 to 180 mg per dL [55]. The trial was stopped early due to an increased frequency of hypoglycemia together with lack of clinical benefit in the intensive insulin therapy cohort.

The NICE-SUGAR (Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation) trial randomized 5,000 medical and surgical ICU patients at multiple centers in Australia, New Zealand, and Canada to intensive (81 to 108 mg per dL) or conventional (≤180 mg per dL) management [56]. The investigators reported that intensive glucose control increased mortality and the rate of hypoglycemia compared with the conventional target cohort. It should be noted, however, that two features of this study are atypical. First, the protocol required measurement of glucose in the ICU only every 4 hours. Second, a substantial fraction of mortality occurred late, after discharge from the ICU, for reasons that are not clear.

A possible adverse effect of increased incidence of hypoglycemia resulting from intensive glycemic control efforts was also suggested by the results of the COIITSS (Corticosteroid Treatment and Intensive Insulin Therapy for Septic Shock in Adults) trial [57]. In this trial, critically ill patients with sepsis who were treated both with intensive insulin therapy and with glucocorticoids. The investigators reported a higher frequency of hypoglycemia (16.4%) in the intensive insulin cohort than in the conventional treatment group (7.8%) with no reduction in mortality.

Finally, the VISEP (Volume Substitution and Insulin Therapy in Severe Sepsis) planned to randomize 600 patients to receive either intensive insulin therapy to maintain euglycemia or conventional insulin therapy and either 10% pentastarch or modified Ringer's lactate for fluid resuscitation [58]. The trial was stopped early because at 28 days, there was no significant difference between the two groups in mortality, but the rate of severe hypoglycemia and other serious adverse events was higher in the intensive therapy group.

In critically ill patients, an association exists between even mild or moderate hypoglycemia and mortality [59,60]. Tight glycemic control has also been specifically associated with a high incidence of hypoglycemia and an increased risk of death in patients not receiving parenteral nutrition [61].

Recommended Glycemic Targets

The American Association of Clinical Endocrinologists (AACE) and the ADA have jointly recommended a glycemic target of 140 to 180 mg per dL in the ICU setting, noting that greater benefit may be realized at the lower end of this range [48]. Most experts have abandoned the target of less than 110 mg per dL suggested by the original Van den Berge study [50]. Glucose concentrations less than 80 mg per dL should be stringently avoided because they pose the hazard of hypoglycemia and might contribute to mortality [50,59,60]. An intensive insulin treatment program to achieve the AACE/ADA targets requires a strong institutional commitment. It is a team effort requiring participation of physicians, nursing, and pharmacy staff.

Treatment of Hyperglycemia in the Critically Ill

The majority of ICU patients will require treatment for hyperglycemia and we recommend that they be treated with a continuous intravenous infusion of regular insulin. This applies to all patients, irrespective of prior history of diabetes or previous treatment modalities. Patients known to have type 1 diabetes are absolutely insulin dependent, and they must be treated with exogenous insulin at all times. Oral hypoglycemic agents (see Chapter 106) should not be used in the ICU for many reasons. Their absorption, metabolism, and excretion cannot be predicted in the critically ill patient. Sulfonylureas can cause severe hypoglycemia [62] (see Chapter 106). Metformin should be discontinued because it can cause lactic acidosis in the setting of renal failure [63].

Our recommendations for the management of patients with ketoacidosis or hyperosmolar syndrome are given elsewhere (see Chapter 106). For patients whose primary ICU diagnosis is not diabetic ketoacidosis or hyperosmolar hyperglycemic syndrome, we recommend the treatment program advocated by the AACE and ADA [48].

Insulin Therapy

Although optimal glycemic targets are now agreed to, insulin infusion algorithms to achieve those targets necessarily will vary from ICU to ICU and need to be individualized by a multidisciplinary team. Every protocol will require development of guidelines for adjustment of the insulin infusion rate in response to *both* the absolute value *and* the rate of change of

the glucose concentration. Glucose concentration should be checked hourly until it is in the target range of 140 to 180 mg per dL, and every 2 hours thereafter. During the initial period, adjustments to the insulin infusion rate will depend on the patient's sensitivity to insulin (see later) and the observed response to therapy, which cannot be exactly predicted. Concurrent glucose infusions or parenteral or enteral feeding will also affect the dose required.

Diluted insulin solutions prepared for continuous insulin infusions have a limited storage life, since insulin adheres to the plastic infusion bag. There is no advantage to the use of rapid-acting semisynthetic insulin for this purpose, but it can be used when regular insulin is unavailable. It should be stressed that it is entirely appropriate to infuse insulin at low rates (e.g., 0.5 U per hour). A low rate of insulin infusion is often all that is needed to prevent ketoacidosis in a patient with type 1 diabetes.

Adjustment of the Insulin Infusion Rate

The amount of insulin required by a given ICU patient will depend in large part on the degree of insulin resistance induced by the primary illness, the agents used in its treatment, and the patient's body mass index. It will also depend on the type and amount of nutritional support being given. An escalating insulin infusion requirement is a sensitive indicator of increasing insulin resistance and requires careful reevaluation of the patient's overall metabolic status. Stressors that increase insulin resistance include sepsis, occult infections, heart disease, tissue ischemia, hypoxemia, and various medications. The most common offending medications are glucocorticoids and pressors.

In otherwise stable patients, instituting or increasing enteral or parenteral nutrition typically increases insulin requirements. Insulin-mediated glucose disposal is impaired in stressed patients with hyperglycemia, and even extremely high insulin infusion rates cannot prevent hyperglycemia due to unmanageable carbohydrate loads. To control hyperglycemia in the ICU, a choice must sometimes be made between increasing insulin infusion rates and reducing carbohydrate feeding. We recommend that insulin infusion rates should not be increased beyond 20 units per hour (480 units per day) without first decreasing any exogenous carbohydrate loads, especially in patients who are obese. This suggestion is based on the fact that maximal insulin effects are achieved when only some of the available insulin receptors are occupied [64,65]. High concentrations of insulin, such as those achieved during continuous intravenous infusions at high rates, desensitize target tissues at both the receptor and postreceptor levels, paradoxically enhancing insulin resistance [66].

Factors that increase insulin sensitivity in the ICU include improvement in intercurrent illnesses, changes in medication, and reductions in enteral or parenteral feeding. Occasionally, hepatic failure, renal failure, or adrenal insufficiency leads to a decreased insulin requirement.

When plasma glucose concentrations are lower than 140 mg per dL, a common response is to discontinue insulin completely. For patients with type 1 diabetes, this is always inappropriate because it can precipitate hyperglycemia and ketosis within hours. The proper response is to reduce the insulin infusion rate to 1 or even 0.5 units per hour and, if necessary, to give glucose in the form of 5% dextrose in water. We recommend the same strategy for most other hyperglycemic ICU patients as well. Unless their primary disease state has improved dramatically, they frequently experience recurrent hyperglycemia. Patients with hyperglycemia in the ICU should receive continuous intravenous insulin until they demonstrate clear improvement in overall clinical status and stability of glycemic control that extends over several blood glucose determinations.

Transition to Other Forms of Therapy

When the condition of an ICU patient with hyperglycemia has improved to such an extent that continuous insulin infusion is no longer needed, subsequent therapy will depend on the cause of the hyperglycemia. Patients with "secondary diabetes" (e.g., catecholamine or steroid induced) may need no further treatment for glucose control after the offending drug is stopped. In contrast, all patients with type 1 and most with type 2 diabetes will continue to require insulin. This should include intermediate or long-acting insulin, for example, neutral protamine hagedorn (NPH), glargine, or detemir (see Table 106.1 in hypoglycemia chapter for details).

It is not uncommon for glycemic control to deteriorate during the transition from intravenous insulin therapy to subcutaneous insulin therapy. It is essential that the intravenous infusion of regular insulin be continued for 2 to 3 hours after the first subcutaneous injection of insulin is given. The initial dose of subcutaneous insulin should be estimated from a review of the preceding intravenous insulin requirements. Presumably, the individual ready to transition to subcutaneous therapy will have had reasonably stable insulin requirements. We recommend basing this dose on the average hourly insulin requirement during the 6 hours prior to discontinuation of the insulin drip using the following procedure:

Calculating the starting intermediate (NPH) or long-acting (Glargine or Detemir) insulin dose

1. The average hourly insulin drip rate for the last 6 hours is ___ units per hour.
2. Multiply by 24 to give a daily usage rate: ___ units per day.
3. Multiply by 70% to estimate the first day's total insulin dose: ___ units.
4. All can be administered in divided doses twice daily; glargine can be given once daily. Dose adjustment may be necessary after first dose given. Review daily thereafter.

When patients are able to eat, a rapid-acting insulin (e.g., lispro, aspart, or glulisine) should be given before each meal. Some stable patients with type 2 diabetes can be managed with oral hypoglycemic agents (Chapter 106; Table 106.2) or diet alone, but that therapeutic decision is best made after discharge from the ICU on a regimen of subcutaneous insulin.

SURGERY IN THE CRITICALLY ILL PATIENT WITH DIABETES

Critically ill patients frequently require invasive procedures, surgery, and intensive postoperative care. In such situations, the treatment of intercurrent diabetes is obviously of importance. The possibility of diabetes must be considered in all surgical emergencies, and both glucose and electrolytes must be measured immediately. A critically ill patient with diabetes, even if previously undiagnosed, can rapidly develop metabolic derangements.

It is generally accepted that good perioperative control of glucose is desirable, but the target levels of glucose and the ideal method of insulin delivery during surgery need to be individualized [67]. Perioperative control of blood pressure and vascular responses may be as important as glucose control for prevention of adverse perioperative events.

Abdominal pain accompanied by guarding and rebound tenderness is a common symptom of diabetic ketoacidosis. The diagnosis of diabetic ketoacidosis has on occasion been made at laparotomy, and this disorder must be excluded in every patient being evaluated for an abdominal surgery. The patient with trauma being prepared for surgery should also be evaluated for diabetes, regardless of mental status. The stress of major

trauma and shock is less likely to be survived if ketoacidosis or hyperosmolarity is present or allowed to develop. Severe trauma causes the release of counterregulatory hormones, cytokines, and other unidentified factors that can rapidly induce a state of severe insulin resistance.

Transfers from the Intensive Care Unit to the Operating Room

The ICU patient with diabetes who requires surgery should be sent to the operating room or procedure suite with infusions of both insulin and 5% dextrose in half-normal saline.

Management During Emergency Surgery

Treatment of hyperglycemia in diabetic patients being prepared for urgent major surgery is also best achieved with an intravenous insulin infusion. Frequent monitoring of blood glucose is essential. Proper fluid and electrolyte balance must accompany the proper degree of insulinization; the amount and the type of fluid administered must be assessed on an individual basis.

In general, premedication in patients with diabetes should be kept to a minimum. With respect to the type and the route of anesthesia, the regional and local are preferred if possible. Inhalant and parenteral anesthetics affect carbohydrate metabolism either directly through impairment of insulin secretion or indirectly through interference with the peripheral action of insulin on glucose utilization [67,68]. Halothane can inhibit insulin release, and nitrous oxide, trichloroethylene, and cyclopropane promote sympathetic stimulation and catecholamine release. Barbiturates share some of these effects and also block the removal of glucose and perhaps free fatty acids from the circulation. Some anesthetic agents, including halothane, have also been associated with hypoglycemia (see Chapter 106; Table 106.3).

Management After Emergency Procedures

Patients managed with an insulin infusion must either be maintained on the infusion or switched to subcutaneous intermediate-acting insulin. Those kept on the infusion must have frequent blood glucose testing. Patients no longer critically ill who are able to resume oral feedings can generally resume their usual insulin regimen. The most important point is that insulin should not be abruptly discontinued because severe hyperglycemia and ketosis may ensue. Patients who remain critically ill should remain on a continuous intravenous insulin infusion.

Postoperative recovery in the ICU may be accompanied by reduced levels of counterregulatory hormones and cytokines and may require reduced insulin doses. An increase in insulin requirements in the postoperative period may signify increasing insulin resistance and should prompt the search for infection or another complication.

TABLE 100.3

DIABETES TREATMENT GOALS IN CRITICALLY ILL AND SURGICAL PATIENTS[a]

Zone	Target Blood Glucose (mg/dL)
Too low for safety	<120
Goal	140–180
Hyperglycemia	181–300
Severe hyperglycemia	>300
Surgical range	140–200

[a] At our institutions, we recommend that all intensive care unit patients with blood glucose concentrations >140 mg/dL be treated with a continuous intravenous infusion of regular insulin with a target as close as possible to 140 [48]. A less stringent target range may be preferred during the perioperative period and whenever staffing or training constraints prevent the implementation of more intensive therapy. Patients with type 1 diabetes must be treated with insulin at all times.

Hyperalimentation and Diabetes

If blood glucose rises above 140 mg per dL in a severely ill patient on hyperalimentation, an insulin infusion should be administered. The hyperalimentation should be continuous. The admixture of insulin with parenteral nutrition formulations, although a common practice, can be problematic. There is too much variability among severely ill patients to rely on a fixed ratio of insulin to carbohydrate. If insulin is added to parenteral nutrition formulations, the dose should be limited to less than 50% of the individuals total insulin requirement, with the residual administered by intravenous insulin infusion or subcutaneous injection. This allows rapid adjustment of the insulin dose for changing metabolic needs. If an obese patient receiving hyperalimentation develops severe hyperglycemia and a large insulin requirement, consideration should be given to reducing the amount of carbohydrate administered [69,70]. ICU physicians should be aware that infusions of fructose, sorbitol, and other total parenteral nutrition formulations have occasionally led to lactic acidosis [71].

PITFALLS IN THE CARE OF THE CRITICALLY ILL PATIENT WITH HYPERGLYCEMIA

Sliding Scales

We cannot overstate the need to obtain frequent blood glucose specimens for evaluating glucose control. In an ICU, these should be used to guide adjustments of the rate of insulin infusion. There is no role for intermittent insulin boluses that are given only after hyperglycemia has occurred [72]; the use of "sliding scales" should be actively discouraged [73]. Patients with type I diabetes whose insulin is withheld until hyperglycemia occurs can quickly become ketoacidotic.

A patient who has begun taking insulin should continue to receive it daily until the need has unequivocally disappeared. A previously normoglycemic patient who develops hyperglycemia in the course of a severe illness should be treated continuously with insulin until the stress of the illness has been reduced to the point at which an independent assessment of the need for insulin can be made.

Sporadic Insulin Administration

Unfortunately, some patients are treated with regular insulin injections on an intermittent schedule, whenever a very high blood glucose concentration is noticed. This disorganized approach to the management of hyperglycemia leads to erratic glycemic control and potentially serious shifts in fluids and electrolytes. The best way to avoid these problems is to maintain

ICU patients with hyperglycemia on a continuous infusion of regular insulin.

Hypoglycemia Due to Sensitivity to Short-Acting Insulin

Unusual sensitivity to insulin can be observed in two situations. The first is in some patients presenting with hyperosmolar hyperglycemic syndrome. When treated with short-acting insulin, their glucose concentration may decline very rapidly. This problem is discussed in Chapter 106. The second situation occurs in patients with long-standing type 1 diabetes. They sometimes develop extreme sensitivity to the glucose-lowering effects of short-acting insulin. The reason is unclear, but this sensitivity frequently contributes to increased risk of hypoglycemia. This is principally a problem in outpatient management and should rarely complicate insulin infusion therapy. However, in the insulin-dependent patient with long-standing diabetes, the initial use of short-acting insulin should be approached with some caution. Hypoglycemia can result from the use of as little as 5 to 10 units given either subcutaneously or intravenously. When short-acting insulin is needed for patients who are suspected to be sensitive, the initial doses should be small (2 to 4 units) and the response monitored by bedside blood glucose determinations.

The Diabetic Kidney and Radiographic Contrast Agents

Acute hyperglycemia appears to be an independent risk factor for the development of contrast-induced nephropathy (CIN). The risk of CIN is even greater for the diabetic patient with preexisting renal insufficiency, hypotension, congestive heart failure, or anemia. Mehran et al. [74] have developed a scoring system that can be used to quantify the risk of CIN. The evidence that any pharmaceutical intervention (e.g., acetylcysteine) can prevent CIN is limited [75]. Current evidence supports the use of an infusion of sodium bicarbonate (154 mEq per L) at a rate of 3 mL per kg per hour for 1 hour before contrast exposure, followed by an infusion of 1 mL per kg per hour for 6 hours after the procedure.

CONCLUSIONS

The key to successful care of the very ill patient with diabetes is careful monitoring of glycemia and fastidious treatment with a continuous infusion of insulin. These patients have a defect in normal metabolic regulation, and only attentive treatment can compensate for the diabetes during the metabolic stress of critical illness or surgery. Careful monitoring of blood glucose followed by adjustment of insulin infusion rates minimizes swings to either hyperglycemia or hypoglycemia. Point of care glucose determinations make this intensive metabolic care possible not only in the ICU but also in the operating room, recovery room, emergency department, and procedure suite. Evidence-based glycemic targets have now been developed. Advances in therapy, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 100.4. Although achieving recommended targets demands time and attention, achieving them will minimize the special risks faced by patients with hyperglycemia complicating the stress of severe illness or surgery.

TABLE 100.4

ADVANCES IN MANAGEMENT OF DIABETES IN CRITICALLY ILL PATIENTS

Recommendation	Comments
Anticipate hyperglycemia at any time during an ICU admission.	New onset of hyperglycemia due to stress is very common [25,77]. We recommend treating diabetes in all patients whose plasma glucose concentration is >140 mg/dL [48]. ICU patients with newly recognized hyperglycemia should be evaluated for persistence of impaired glucose tolerance after recovery.
Avoid hyperglycemia in the ICU because it is associated with poor outcome.	Observational studies have documented an adverse association of hyperglycemia with wound infection, congestive heart failure, recovery from stroke, and overall mortality [38,39,41,42].
Avoid hypoglycemia in the ICU because it is associated with increased mortality	Two recent clinical studies document increased mortality in critically ill patients who experience hypoglycemia during hospitalization [59,60].
With current technology it is not safe to seek to lower glucose concentration to <110 mg/dL in ICU patients	Five large randomized clinical trials have demonstrated either no reduction [25,55,57,58] or an increase in ICU mortality [56] associated with intensive insulin treatment. All showed increased risk of hypoglycemia. Only one of these showed reduced morbidity [25].
Be alert to the presence of type 1 diabetes.	Patients with type 1 diabetes are absolutely insulin dependent, and they must be treated with insulin at all times.
Treatment of diabetes using only "sliding scale" boluses of insulin, whether intravenous or subcutaneous, should be avoided.	Sliding scale prescriptions given only after hyperglycemia has occurred amplify the risk of hypoglycemia, recurrent hyperglycemia, and even ketoacidosis. There is no role for them in the ICU [72] and their use is actively discouraged [73]. Continuous insulin infusion is the treatment of choice for diabetes in the ICU.
Oral hypoglycemic agents should not be used in the ICU.	Insulin is the only acceptable agent for control of diabetes in the ICU. The absorption, metabolism, distribution, and excretion of oral agents cannot be predicted in the critically ill patient. As a result, for example, sulfonylureas can cause persistent hypoglycemia [62] and metformin can cause lactic acidosis in the setting of renal failure [63].

CHAPTER 101 ■ HYPERGLYCEMIC DIABETIC COMA

SAMIR MALKANI, ALDO A. ROSSINI, DAVID M. HARLAN, MICHAEL J. THOMPSON AND JOHN P. MORDES

INTRODUCTION

The Acute Metabolic Complications of Diabetes: The Overlap Concept

The most urgent metabolic complications of diabetes are the four diabetic comas: hypoglycemia, diabetic ketoacidosis (DKA), hyperglycemic hyperosmolar syndrome (HHS), and alcoholic ketoacidosis (ethanol-induced hypoglycemia). These diagnostic possibilities must be considered in any lethargic or comatose patient. In addition to being life-threatening conditions, they account for thousands of hospitalizations and substantial costs [1]. Recognition of these diabetic comas is particularly important because these conditions are reversible with appropriate treatment. We use diabetic coma as a generic term that encompasses both frank coma and the milder metabolic abnormalities that precede loss of consciousness. This chapter considers the hyperglycemic crises; hypoglycemia and alcoholic ketoacidosis are discussed in Chapter 106.

Although DKA and HHS are discussed separately, it is important to recognize that metabolic decompensation related to hyperglycemia can take many forms depending on the severity of insulin deficiency, underlying genetic predispositions, and intercurrent illnesses. There is frequent overlap in clinical phenotypes, and clinicians should be aware of this concept [1,2]. DKA can occur in a patient with type 2 diabetes; up to a third of patients with HHS have no prior history of diabetes [1]; both DKA and HHS can be complicated by lactic, uremic, or other form of metabolic acidosis, and ketoacidosis itself can occur in the setting of profound hypoglycemia [3]. These metabolic disturbances can overlap to yield both classical DKA and nonclassical presentations of HHS and other ketotic and acidotic states.

In a comatose patient if the blood glucose concentration is less than 50 mg per dL or if for any reason the blood glucose cannot be measured rapidly, the first diagnostic and therapeutic step should be the infusion of 50 mL of a 50% dextrose solution. The hypoglycemic patient who awakens is resuscitated; coma of any other origin is not adversely affected.

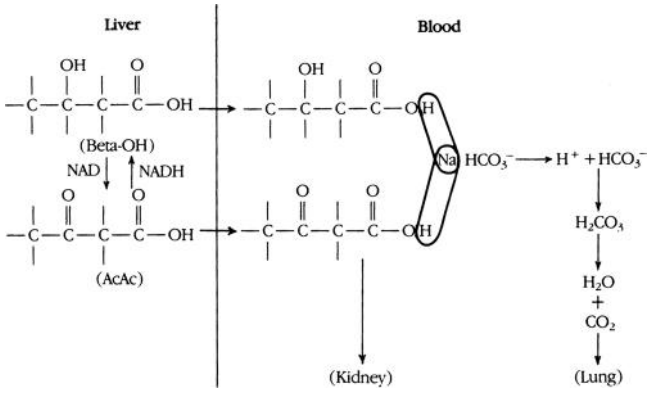

FIGURE 101.1. Neutralization of ketoacids. Hydrogen ion from ketoacids is neutralized by bicarbonate, producing carbonic acid that then decomposes to H_2O and CO_2. The latter is expelled by the lungs. The neutralized salts of ketone bodies are excreted in the urine. NAD, nicotinamide adenine dinucleotide; NADH, reduced form of NAD; AcAc, acetoacetate; Beta-OH, β-hydroxybutyrate.

DIABETIC KETOACIDOSIS

DKA comprises the triad of hyperglycemia, metabolic acidosis, and ketonemia. Any person with diabetes can develop DKA [4], but it most often occurs in those with type 1 diabetes. Before the discovery of insulin, most patients with type 1 diabetes died of DKA. With the advent of insulin and intensive care, mortality from DKA has fallen to less than 5% [5]. Deaths are associated with intercurrent heart disease or infection in older

patients, cerebral edema in younger patients, and, occasionally, therapeutic errors.

Pathophysiology and Etiology

Normal Glucose Homeostasis

After a meal, pancreatic islet β cells release insulin into the circulation, enabling fuels to enter cells and activating enzymes for their storage or metabolism. Glucose enters most tissues only in the presence of insulin; erythrocytes, heart, and brain are exceptions. Glucose is stored in liver and muscle as glycogen. Some glucose is metabolized; some is converted into triglyceride.

In adipose tissue, insulin activates lipoprotein lipase, clears lipoproteins from the circulation, and stores them intracellularly. Insulin also inhibits the breakdown and release of previously stored fat. Insulin has similar effects on skeletal muscle, permitting both amino acids and glucose to enter cells for oxidation or storage [6,7].

During starvation, insulin concentrations decrease, catabolic pathways are activated, and stored fuels (glucose, amino acids, and fats) are mobilized to meet energy needs. Liver glycogen provides glucose for only several hours. Muscle glycogen is not directly available due to lack of glucose-6-phosphatase in muscle. To support plasma glucose, muscle glycogen undergoes anaerobic glycolysis, generating lactate that is converted into glucose in the liver. After glycogen stores are exhausted, the liver synthesizes glucose from muscle-derived amino acids through the process of gluconeogenesis [8]. To conserve muscle mass during starvation, glucose consumption is reduced and fatty acids released from adipose tissue become the principal fuel source. Some fatty acids are transformed by the liver into ketoacids [9].

The rate of catabolism is regulated by insulin. As circulating glucose concentration decreases, insulin concentration also decreases—but never to zero. Low insulin levels permit lipolysis and proteolysis while stimulating gluconeogenesis, and maintaining normal glucose concentration. Increased glucose concentration stimulates insulin secretion, which in turn reduces or halts catabolism. Precise regulation of insulin secretion, even in the absence of food intake, achieves continuous control of carbohydrate metabolism.

Abnormal Glucose Homeostasis

DKA can be viewed as a "super-fasted" state that occurs when there is insufficient insulin available to regulate carbohydrate metabolism [7]. Without insulin, glucose no longer enters most cells and is neither stored nor metabolized. Glucagon secretion is increased and hepatic glucose production increases without restraint. When the renal threshold for glucose is exceeded (180 to 200 mg per dL), an osmotic diuresis ensues and water and electrolytes are lost. If insulin deficiency persists, the stress-response hormones cortisol, epinephrine, norepinephrine, glucagon, and growth hormone are released and accelerate catabolism. Glucagon excess is responsible for oxidation of fatty acids to ketone bodies in the liver. Once this happens, DKA ensues with the life-threatening combination of hyperglycemia, acidemia, ketonemia, loss of free water, and depletion of electrolytes.

The cause of ketoacidosis is insulin deficiency. New onset type 1 diabetes commonly presents as ketoacidosis, but most cases occur in individuals known to have diabetes. Dietary indiscretion in a person with known treated diabetes may produce classic hyperglycemia, polydipsia, and polyuria but never ketosis. Ketonuria in any hyperglycemic diabetic patient should suggest the presence of DKA. Such patients must be carefully evaluated for the presence of acidemia. Ketoacidosis occurs most often in patients who have omitted their insulin or who have an intercurrent infection.

Infection and other stressors produce a state of insulin resistance, in part because of the presence of high levels of tumor necrosis factor α; infection may be the most common trigger of DKA in the ICU setting [10]. Severe stress occasionally causes ketosis in patients with type 2 diabetes [4]. African Americans with type 2 diabetes may be particularly susceptible to the development of ketosis [11,12]. Other factors that can precipitate ketosis include acute myocardial infarction, emotional stress, cancer, drugs that interfere with insulin release or action, pregnancy, menstruation, and various endocrinopathies. Occasionally, no precipitating factor can be identified.

Clinical Manifestations

Most patients with DKA are lethargic; about 10% are comatose [13]. They have lost large quantities of fluid; their skin, lips, and tongue are dry; and their eyes are soft to palpation. Postural hypotension is common, but shock is rare [14].

Patients with DKA have rapid deep (Kussmaul) respiration, and their breath has a sweet fruity odor. Some patients with new-onset DKA have been misdiagnosed as having psychological hyperventilation [15]. If a patient with DKA is not tachypneic, the physician should suspect that severe acidosis (pH <7.1) is depressing the respiratory drive [16].

It is important to measure the temperature accurately. Because the patient is hyperventilating, rectal or tympanic temperature should be measured. Patients with DKA do not have fever unless an intercurrent process, usually infection, is present. Similarly, the rare cases of hypothermia in DKA are associated with sepsis [17].

Abdominal pain is common and may be accompanied by a tender guarded abdomen with diminished or absent bowel sounds. DKA should always be excluded when evaluating abdominal pain [18]. What may appear to be a surgical condition will resolve with correction of the acidosis.

Patients with DKA may be nauseous and vomit guaiac-positive coffee grounds–like material. This is probably due to gastric atony, distention, and rupture of mucosal blood vessels. Pleuritic chest pain may also be present. The cause is unknown, but it resolves with treatment of the DKA.

The nose and sinuses of all patients with DKA should be examined. Acute sinusitis and a black intranasal eschar should suggest mucormycosis, an opportunistic fungal infection that disseminates rapidly in acidotic patients. Mucormycosis is often fatal; survival requires prompt diagnosis [19].

DKA can complicate pregnancy. When DKA in pregnancy is due to new onset of diabetes, due to noncompliance in a woman known to have diabetes, or is complicated by infection, rates of fetal loss are high [20].

Laboratory Diagnosis

Hyperglycemia, acidemia, and ketosis in the appropriate clinical setting are the criteria for the diagnosis of DKA.

Blood Glucose. Normal plasma glucose concentration is 60 to 120 mg per dL (3.3 to 6.7 mmol). Whole blood glucose concentrations are 15% to 20% lower. Fingerstick blood glucose determinations are performed on whole capillary blood, and most meters correct for this offset. Calibrated glucose meters suitable for use in the ICU are accurate over a wide range of concentrations, but very high and low concentrations are less consistently accurate and should be confirmed by a clinical laboratory. Meters intended for home use may give less reproducibly accurate results [21].

In DKA, blood glucose concentration of 400 to 800 mg per dL is typical, but as many as 15% of cases of DKA may present

with blood glucose concentrations less than 300 mg per dL—so called euglycemic DKA [22]. Typically, these are younger patients with a high glomerular filtration rate (GFR). In one series, approximately 1% of patients with DKA presented with a blood glucose concentration less than 180 mg per dL and a bicarbonate concentration less than 10 mEq per L [23]. More often, the solute diuresis causes dehydration, decreases the GFR, and further increases circulating blood glucose concentration.

Electrolytes

Sodium. Serum sodium concentration is quite variable in DKA and must be interpreted in the context of serum glucose and lipid concentrations. If extremely abnormal, it may need special attention during management. Large amounts of sodium are lost during the osmotic diuresis of DKA, and the serum concentration does not necessarily reflect this loss. Because sodium resides principally in the extracellular fluid space, elevated sodium concentration may simply reflect the degree of dehydration and free water loss.

Abnormally low sodium concentrations may be due to the osmotic effect of large amounts of extracellular glucose. The osmotic activity of glucose, drawing free water from the intracellular to the extracellular space, produces a fall of 1.6 mEq per L of sodium for every increase of 100 mg per dL in blood glucose concentration more than 100 mg per dL [24]. The "corrected" serum sodium in a patient with a measured concentration of 135 mEq per L and a glucose concentration of 600 mg per dL is $[1.6 \times (6 - 1) + 135]$, or 143 mEq per L. The patient presenting with an elevated serum sodium concentration despite hyperglycemia has a severe total body free water deficit.

It is also important to be certain that abnormally low serum sodium concentrations in DKA are not factitious. Sodium resides only in the aqueous phase of plasma and when the nonaqueous constituents such as triglycerides increase substantially, the reported concentration of sodium will be spuriously low unless "ion-specific" technology is used for the measurement [4].

Chloride. Chloride concentrations are usually not helpful in the diagnosis of DKA, although they may provide useful information. Hyperchloremia may sometimes represent a more chronic ketoacidotic state [25] and may be associated with slower recovery [26]. Extremely low levels of chloride may result from vomiting [27]. Hyperchloremic acidosis can also occur during recovery from DKA as a consequence of the loss of neutralized ketone body salts [28].

Potassium. Potassium is the electrolyte that must be watched most carefully and often during therapy. All patients with DKA are at risk for life-threatening hypokalemia during treatment, despite the fact that the serum potassium concentration is usually elevated at presentation [26,29]. This elevation is due to catabolism of tissue, dehydration, and shifts of potassium from the intracellular to the extracellular space as hydrogen ions are buffered. An initially elevated serum potassium concentration should never obscure the fact that total body potassium loss (in the range of 200 to 700 mEq) occurs in ketoacidosis. The greatest potassium loss accompanies the osmotic diuresis of glucose. Additional losses are due to the excretion of ketone bodies as potassium salts, dehydration-induced secondary hyperaldosteronism, and vomiting. Potassium replacement early in the course of therapy for DKA is always necessary. It should be started as soon as the potassium concentration is at the upper end of the normal range because continued insulin therapy will invariably cause the potassium concentration to fall further. Normal or low concentrations of potassium early in ketoacidosis reflect a very severe potassium deficit.

TABLE 101.1

CALCULATIONS

Anion gap	$(Na^+ + K^+) - (Cl^- + HCO_3^-) + 17 = 0$
or	
	$Na^+ - (Cl^- + HCO_3^-) + 12 = 0$
Osmolality[a]	$2(Na^+ + K^+) + Glucose/18 + BUN/2.8$

[a]Normal osmolality: 285–295 mOsm/kg.
BUN, blood urea nitrogen.

Magnesium. Like potassium, serum magnesium concentrations in patients with untreated DKA tend to be elevated initially, but they fall with subsequent hydration.

Bicarbonate. Serum bicarbonate concentration is low in ketoacidosis [16] because of neutralization of ketone bodies, which are acids. Bicarbonate buffer in the extracellular compartment represents the first line of defense in acid–base homeostasis. The process is summarized in Figure 101.1. Hydrogen ion (H^+) from ketoacids is neutralized by bicarbonate, producing carbonic acid, water, and CO_2. As CO_2 is expelled through the lungs, the neutralized salts of the ketone bodies are excreted in the urine. In patients with established DKA, the serum bicarbonate concentration is less than 15 mEq per L.

Phosphorous. Elevated serum phosphate concentrations are common in untreated DKA; the mechanism is not clear. After therapy, there is a precipitous decline to subnormal levels [30]. It has been estimated that as much as 1 mM per kg of phosphate is lost during DKA. Hypophosphatemia of less than 0.5 mM per L has been described in both DKA and HHS [30].

Acidosis. Arterial blood gas and pH measurements are essential in the management of all but the mildest cases of DKA. The arterial pH in DKA is almost always less than 7.3. If arterial samples cannot be obtained, venous or capillary samples may be used, although they provide less information [31]. DKA classically presents as an anion gap acidosis. The anion gap should be calculated for all acidemic patients (Table 101.1). In addition to confirming the diagnosis of DKA, the anion gap can be used together with plasma ketone measurements to obtain important additional insight into the nature and severity of a given case [32]. More chronic ketoacidotic states may be associated with hyperchloremic rather than anion gap acidosis [25], probably as a consequence of the loss of neutralized ketone body salts [28]. Rare cases of DKA are complicated by intercurrent metabolic alkalosis, most often from severe vomiting [27,33].

Plasma Ketones and β-Hydroxybutyrate

Plasma ketones should be measured in all comatose patients with diabetes at the time of presentation. When the nitroprusside test is used, the results are usually expressed as the highest dilution of serum that gives a positive reaction. This test is always positive (>1:2 dilution) in DKA, but its result may not reflect the full extent of ketogenesis. This is because the test measures only acetoacetate (AcAc) and acetone. It does not measure beta-hydroxybutyrate (BOHB), which, although a "ketone body," is a hydroxyacid and not a ketone (Fig. 101.2). Normally, the BOHB-to-AcAc ratio is 3:1, but acidosis increases the ratio to 6:1 or even 12:1 as pH decreases. The BOHB-to-AcAc ratio at pH 7.1 is at least 6:1.

BOHB can be measured directly, and the test is available in many hospital laboratories. Measurement of BOHB concentration, if the result is available rapidly, can also be used to establish the diagnosis of DKA. The advantage of BOHB measurement derives from the fact that it is the major ketone

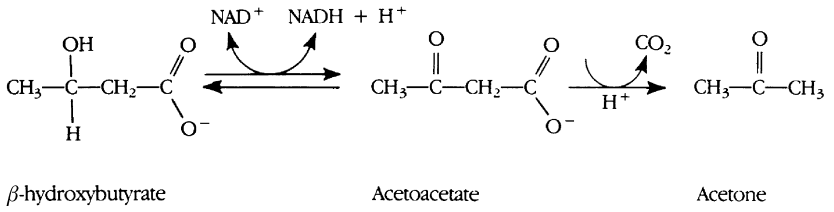

FIGURE 101.2. Biochemical interrelationships of the ketone bodies. Acetoacetate and acetone are ketones, whereas β-hydroxybutyrate, although a "ketone body," is β-hydroxy carboxylic acid and not a ketone. NAD^+, nicotine adenine dinucleotide; NADH, reduced form of NAD.

body and its concentration is a better indicator of the severity of ketoacidosis.

The results of plasma ketone, BOHB, anion gap, and arterial pH measurements can be used to determine whether a pure or mixed anion gap acidosis is present. The highest positive ketone dilution is multiplied by 0.1 mM per L to obtain an estimate of AcAc concentration; the BOHB can be measured directly. If a patient's anion gap as calculated in Table 101.1 is greater than the estimated contribution of ketone bodies (AcAc plus BOHB), the presence of an additional unmeasured anion should be considered (e.g., lactate, salicylate, uremic compounds, methanol, or ethylene glycol; see Chapter 119).

Ketone body measurements are also useful for monitoring the resolution of DKA. In cases of severe acidosis, ketones initially rise rather than fall as the acidosis improves. This is due to conversion of BOHB back to AcAc. Clearance of ketone bodies occurs slowly; measurement of ketones and BOHB more often than every 12 hours is generally unnecessary.

It is worth noting that certain newer home blood monitors have the capacity to measure not only glucose but also "ketones." These meters measure BOHB rather than AcAc using strips distinct from those used to measure glucose. They can warn patients of impending or established ketoacidosis prior to hospital presentation.

Blood Urea Nitrogen and Creatinine. The blood urea nitrogen (BUN) of patients with DKA is typically elevated to values between 25 and 50 mg per dL due not only to prerenal azotemia from volume depletion but also to increased ureagenesis. Patients with DKA are in a state of uncontrolled gluconeogenesis; the large quantities of amino acids released from muscle for conversion to glucose produce hyperaminoacidemia. These amino acids increase substrate availability for ureagenesis. Although the serum creatinine concentration usually reflects the degree of dehydration and prerenal azotemia in DKA accurately [34], spurious elevations occasionally occur because AcAc interferes with some older creatinine assays [35].

Complete Blood Count. Hematocrit and hemoglobin in DKA are usually high and in proportion to the degree of dehydration. Low values suggest preexisting anemia or acute blood loss. A characteristic hematologic finding in DKA is leukocytosis. White blood cell counts in the range of 15,000 to 90,000 per μL with a significant left shift often occur in the absence of intercurrent illness [13,36]. Leukocytosis and a left shift in DKA do not necessarily imply concurrent infection. The absence of leukocytosis suggests possible folic acid or vitamin B_{12} deficiency.

Triglycerides. Insulin deficiency impairs clearance of lipid from the circulation and accelerates hepatic production of very low-density lipoprotein (VLDL) [6]. In DKA, there is marked elevation of serum triglyceride concentrations that may be clinically obvious in the form of lactescent serum. With insulin therapy, this biochemical derangement reverses. If a patient can eat during the onset of DKA, hyperchylomicronemia may also be present.

Urine. Urinary glucose and acetone should be measured. If pyuria is present, a urine specimen should be sent for culture and sensitivity. To avoid iatrogenic infection, catheterization should be avoided unless the patient is comatose or anuric. A pregnancy test should be performed in women of childbearing age, as pregnancy can precipitate DKA.

Serum Amylase and Lipase. Serum amylase and lipase concentrations are sometimes elevated in acute ketoacidosis, but they do not necessarily imply exocrine pancreatic disease [37,38]. In some cases, the amylase may be of salivary gland origin.

Other Laboratory Findings. Uric acid concentrations may be elevated during acute DKA [39] as a result of impaired renal function or competition from ketone bodies at sites of tubular secretion. Hepatic enlargement with fatty infiltration of parenchymal cells may occur during acute DKA. Increased levels of C-reactive protein and interleukin-6 may be indicative of underlying infection in DKA [40].

Treatment

Patients with severe DKA should be hospitalized in an intensive care unit (ICU). Delaying intensive care greatly increases morbidity, and detaining patients in the emergency room long after the diagnosis is established should be avoided. Treatment should be directed at three main problems—fluid, electrolytes, and insulin—in that order [41].

Recording of Data

The comprehensive flow sheet of vital signs, laboratory data, and treatment that is part of the modern electronic ICU greatly enhances management. For ICUs that do not have advanced capabilities, a comprehensive paper flow sheet is essential to follow the response to therapy.

Fluid Replacement

Fluid and electrolyte therapy always takes precedence over insulin administration in the treatment of DKA. As described later in "Complications" section of this chapter, insulin administration before volume and potassium repletion can cause shock and arrhythmias [42].

The free water deficit in adults with DKA generally ranges between 5 and 11 L, typically about 100 mL per kg, and is due primarily to the osmotic diuresis of glucose [41,43]. Vomiting and hyperventilation may also contribute to water loss. Initial fluid resuscitation should be an infusion of 0.9% saline. Approximately 2 L should be given during the first hour to restore blood volume, stabilize blood pressure, and establish urine flow. Another liter of 0.9% saline can typically be given during the next 2 hours. The subsequent rate of fluid replacement depends on individual clinical circumstances. During the first 24 hours, 75% of the estimated total water deficit should be replaced. Urine flow should be maintained at approximately

30 to 60 mL per hour. Fluid replacement after the first 2 L may be changed to hypotonic 0.45% saline if hypernatremia is present [44].

Electrolytes

Sodium, Chloride, and Potassium. Sodium and chloride are replaced together with free water as just described. Potassium must be added to the saline. Because serum potassium concentration does not accurately reflect total body potassium, replacement should be initiated early in treatment. Until the serum potassium concentration is known, replacement should be carried out cautiously. The recommended initial repletion rate is 20 mEq per hour as KCl or K_3PO_4. When the serum value is known, the rate of potassium administration can be adjusted. If a nasogastric tube is in place, electrolyte losses due to gastric suctioning must also be considered. Typical potassium deficits in DKA are 3 to 5 mEq per kg, but if hypokalemia or normokalemia is present at the time of admission, the deficit may be much higher, up to 10 mEq per kg.

Potassium concentration often falls precipitously after starting therapy. K^+ shifts from the extracellular to the intracellular space in the presence of glucose and insulin. As acidemia resolves, buffered intracellular H^+ is exchanged for extracellular K^+, further lowering the serum potassium concentration. The electrocardiogram can be helpful in monitoring potassium treatment but cannot substitute for serum potassium determinations. A sudden reduction in serum potassium concentration can cause flaccid paralysis, respiratory failure, and life-threatening cardiac arrhythmias. If a patient in mild DKA is alert and able to tolerate liquids, potassium should be given orally.

Phosphate. Depletion of phosphate occurs in DKA. Initially, the concentration of phosphate is elevated, but levels may decrease to less than 1 mM per L within 4 to 6 hours of starting insulin treatment. Persistent severe hypophosphatemia can cause neurological disturbances, arthralgias, muscle weakness with respiratory impairment, rhabdomyolysis, and liver dysfunction [45].

Except when hypophosphatemia is severe ($\leq$1.0 mg per dL), however, the need for phosphate replacement in DKA may be more theoretical than real. No studies have demonstrated that replacement of phosphate affects the course or outcome of ketoacidosis [46–48].

For treating severe hypophosphatemia, potassium phosphate (20 mEq K^+; 16 mM PO_4^{3-}) can be added to replacement fluids in place of KCl. Because phosphate deficits in DKA average only 1.0 mM per kg, it is rarely necessary to administer more than one 5-mL ampule of potassium phosphate. Thereafter, potassium should be replaced as KCl. The hazards of parenteral phosphate administration include hypomagnesemia, hypocalcemia, and metastatic calcification [49]. If a patient with DKA can tolerate oral medication, phosphate-containing antacids (e.g., Neutra-Phos®) can be given.

Bicarbonate. Despite the presence of a low serum bicarbonate concentration and severe acidemia, most authorities now concur that there is no need for the routine use of bicarbonate therapy in DKA [50–55]. Neutralization is intuitively appealing, but fluid and electrolyte replacement alone will ameliorate acidosis, and bicarbonate therapy may produce adverse effects. These include severe acute hypokalemia [56], late alkalosis due to paradoxical cerebrospinal fluid acidosis [57], a shift of the oxygen dissociation curve to the left that results in tissue hypoxia and lactic acidosis [58], and increased hepatic ketogenesis [52]. In children, bicarbonate therapy may increase the risk of cerebral edema [59]. Bicarbonate replacement in DKA should be used only when hypotensive shock is unresponsive to rapid fluid replacement [60], buffering capability is completely exhausted, respiratory responses are maximal, and acidemia is worsening [41]. Even in these circumstances, bicarbonate can only "buy time" until metabolic treatment reverses the acidosis. On those rare occasions when it may possibly be beneficial, two ampules of sodium bicarbonate (100 mEq each) should be given over 1 hour.

Magnesium. Hypermagnesemia may occur early in the course of DKA [61], but serum Mg^{2+} concentrations generally return to normal without specific treatment. In some patients, Mg^{2+} stores may be depleted, and hypomagnesemia may rarely lead to cardiac arrest [62]. Dysrhythmia should alert the physician to the possible need for magnesium supplementation.

Insulin

Insulin therapy in DKA is essential but should be instituted only after fluid and electrolyte resuscitation is underway [41]. Continuous low-dose infusion after an intravenous loading dose is the preferred method [63]. For adults, we recommend a bolus of 10 U of short-acting insulin followed by a continuous intravenous infusion starting at 5 to 10 U per hour. In children, the recommended initial bolus is 0.1 U per kg of body weight and the infusion rate is 0.1 U per kg per hour [64–66]. If for some reason continuous infusion cannot be given, the older bolus method can still be used. For adults, initially give 10 to 25 U of short-acting insulin intravenously plus 10 to 25 U subcutaneously. Regular (crystalline) insulin is typically used in intravenous infusions; semisynthetic rapid acting insulins approved for intravenous administration offer no advantage by this route. The onset of action of intravenous regular insulin occurs within minutes; bolus doses peak within 30 minutes, and the duration of action is 2 to 3 hours.

If DKA is treated with frequent subcutaneous insulin injections, very short-acting analogues may be advantageous because of their rapid onset of action. Their shorter duration of action may, however, require more frequent monitoring of blood glucose concentration. The safety and efficacy of repeated subcutaneous injections of rapid acting insulin analogues every 1 to 2 hours for the treatment of uncomplicated DKA is well documented [67].

Insulin for infusion should be added to 0.45% saline (at a concentration of 0.5 U per mL), and the container swirled before use. Blood glucose concentration should be measured every 1 to 2 hours after starting the infusion. If the glucose concentration has not decreased by 100 mg per dL, the insulin infusion rate should be doubled. When the glucose concentration has fallen by more than 150 mg per dL, the infusion rate should be decreased by 50%, but it should never be stopped.

The minimum blood glucose concentration during the first 24 hours of treatment should be $\approx$200 mg per dL. If it falls to below 200 mg per dL, glucose infusion (D5 W) should be started, and the insulin infusion rate should be adjusted to $\approx$1.0 U per hour to maintain insulinization and inhibit ketogenesis. Never stop insulin entirely during the treatment of DKA, even if the infusion rate is reduced to only 0.5 U per hour or less. This is particularly important in children with DKA because their high GFR and high rate of urinary glucose excretion can lead to a low blood glucose concentration before ketone production has been reversed by insulin.

As noted above, resolving DKA is often accompanied by an increase in plasma ketones (principally AcAc) as BOHB is reoxidized. Total ketone bodies (AcAc plus BOHB) slowly fall throughout treatment, and the increase in measured ketones is transient. An increase in conventionally measured "plasma ketones" during the early hours of DKA treatment does not

necessarily mean that treatment is inadequate and that more insulin is needed. The entire clinical picture must be assessed, and if the acidosis and hyperglycemia are resolving, the rise in ketones should be interpreted as a sign of improvement.

Complications

The morbidity and mortality associated with DKA are proportional to the severity of coma and acidemia at the time of presentation. Many complications can occur despite appropriate therapy.

Hypotension and Shock

Hypotension is an important complication of DKA. It is usually caused by volume depletion, and normally fluid replacement alone will reverse it [68]. Persistent hypotension should prompt consideration of fluid shifts, bleeding, severe acidosis, hypokalemia, arrhythmia, myocardial infarction, sepsis, and adrenal insufficiency.

When insulin is administered to a patient with DKA, both glucose and water move to the intracellular space. Blood pressure may then fall as extracellular and intravascular volumes decrease. Increasing the rate of fluid replacement can usually reverse this.

If shock persists despite fluid replacement, occult blood loss should be considered. Patients with gastric ulcer, colitis, or hemorrhagic pancreatitis can bleed into the gut lumen or peritoneum. Physical examination and an inappropriately low hematocrit in the face of dehydration are clues to this complication.

A shift in K^+ from the extracellular to the intracellular fluid space after insulin administration can lower serum potassium concentration and cause cardiac arrhythmias which may compromise blood pressure.

Patients with hypotension and increased central venous pressure should be investigated for heart disease. Myocardial infarction is the most common finding, but other conditions such as cardiac tamponade can occur. Myocardial infarction is a common complication in long-standing diabetes, and its classic symptoms may be less obvious in the diabetic population. Patients in DKA who have had a myocardial infarction have a poorer prognosis [69].

Gram-negative sepsis is another cause of shock in ketoacidosis [60]. Pyelonephritis and pneumonia are common in such cases and must be treated appropriately when encountered. Ketoacidosis per se does not cause fever.

It is not uncommon for patients with type 1 diabetes to have other autoimmune diseases, and adrenal insufficiency should be considered in cases of ketoacidosis with refractory shock. The stress of DKA may uncover a state of partial adrenal insufficiency requiring glucocorticoid replacement.

The initial approach to the patient in shock is additional fluid replacement. (See Chapters 157 and 158 for a detailed discussion of the subsequent management of this problem.) Thereafter, further diagnostic procedures are necessary. Cardiovascular monitoring systems should be used as needed.

Thrombosis

The dehydration and intravascular volume contraction common in DKA may activate coagulation factors [70]. Thrombosis of cerebral vessels and stroke are recognized complications of DKA. Some authorities suggest the routine use of low-dose heparin in the management of DKA, but there are no controlled studies to document its efficacy [71].

Cerebral Edema

Subclinical brain edema may be common in DKA [72], but clinically important cerebral edema is a rare complication in adults. It occurs more commonly in children [65], with a reported frequency of 0.3% to 0.5% in pediatric cases of DKA [64,73]. Cerebral edema has been associated with very high mortality (24%) [73]. It usually occurs a few hours after the initiation of therapy. Children who develop cerebral edema during treatment for DKA may initially have a relatively normal serum osmolality and then experience a progressive decline in serum sodium concentration [74]. Treatment with bicarbonate increases the risk of cerebral edema in children with DKA who present with azotemia and a low PCO_2 [59]. Greater baseline acidosis, higher potassium and urea concentrations, and large volumes of administered fluid are also risk factors for cerebral edema [75].

The exact mechanism of cerebral edema is unknown, but it may involve a combination of fluid shifts, thrombosis of intracerebral vessels, and effects on ion exchange mechanisms [76]. The most effective treatment for cerebral edema is probably mannitol [77]. Hypertonic saline has also been used [78]. Steroids are not recommended [79,80]. Unfortunately, even when diagnosed early, cerebral edema may cause permanent neurologic damage or death.

Renal Failure

Hyperglycemic patients given intravenous fluids should have brisk urine flow. Patients in DKA who do not void within a few hours of therapy should be considered oliguric. A common cause of oliguria is postrenal obstruction. A dilated atonic bladder is common in comatose patients and even more common in diabetic patients with severe neuropathy and DKA. Occasionally, patients with DKA precipitated by pyelonephritis develop acute tubular necrosis. Acute renal failure in the absence of infection is an uncommon complication of DKA [81].

Recurrent Diabetic Ketoacidosis

If ketoacidosis reappears in a patient who has received adequate amounts of insulin, infection or a severe contra-insulin state (e.g., Cushing's syndrome) should be suspected. More commonly, the problem is iatrogenic. The physician treating DKA notes that the blood glucose concentration has fallen, mistakenly assumes the condition has been cured, and discontinues insulin treatment. Because the duration of action of intravenous insulin is brief and these patients make no insulin, ketone production resumes and ketosis soon recurs [2]. Insulin infusions should be continued, if only at 0.5 to 1 U per hour, until the patient is well enough to be switched to subcutaneous injections of longer-acting insulin. The intravenous infusion of insulin can be discontinued 2 to 3 hours after the first subcutaneous injection of intermediate-acting insulin is given. Cases of insulin-resistant DKA with recurrent hyperglycemia that respond to treatment with insulin-like growth factor I have been described [82], but these are extremely uncommon.

Low Blood Glucose Concentration

The blood glucose concentration in DKA usually decreases rapidly as a result of renal excretion as soon as fluid is administered and urine flow is established [68]. After insulin is given, glucose is metabolized as well as excreted, and blood glucose concentrations may fall rapidly. The physician must be alert to the possibility of precipitous reductions in glycemia. To avoid cerebral edema, the goal of the first 24 hours of DKA treatment is a blood glucose concentration not less than 200 mg per dL.

When the blood glucose concentration falls to 200 mg per dL, D5 W should be administered together with insulin. Use of D10 W is unnecessary [83]. Dual therapy inhibits ketone

production while precluding hypoglycemia. For the first 24 hours of treatment, continuous intravenous infusion of insulin is recommended.

Follow-up Care of Diabetic Ketoacidosis

After a patient has recovered from DKA, the physician's goal should be the prevention of further episodes [84]. This requires the identification of any precipitating factors. Lack of education regarding diabetes should be remedied.

HYPERGLYCEMIC HYPEROSMOLAR SYNDROME

Severe hyperglycemia, dehydration, and coma have long been known to occur in the absence of significant acidosis or ketonemia in older patients with diabetes [85]. This syndrome is designated as HHS. Mortality in HHS has historically been high, on the order of approximately 50%, but increasing recognition and improved ICU-based treatment have substantially improved this figure; mortality more recently is on the order of 15% [69,86]. With optimal care, HHS managed in an ICU setting can carry a relatively favorable prognosis. Of note is the fact that, with the increasing prevalence of obesity and type 2 diabetes in children, a similar disorder is being reported in the pediatric population [87–89]. The syndrome can be the initial presentation of type 2 diabetes and, in the United States, may occur with disproportionate frequency in African American youth.

Pathophysiology and Etiology

The pathophysiology that gives rise to HHS requires that three interrelated elements be present: insulin deficiency, renal impairment, and cognitive impairment.

Insulin Deficiency

Relative lack of insulin is the fundamental defect in HHS. Patients have sufficient insulin to inhibit ketone body formation but not enough to prevent hyperglucagonemia, glycogenolysis, and gluconeogenesis [90]. The resulting hyperglycemia induces an osmotic diuresis, with resultant fluid and electrolyte losses.

Paradoxically, venous insulin concentration levels in patients with HHS are comparable with those sometimes observed in DKA [91]. Animals with experimentally induced HHS have portal insulin concentrations higher than those of animals with experimental ketoacidosis [92]. The data suggest that partial insulinization of the liver in HHS enables affected patients to metabolize free fatty acids and thereby avoid ketogenesis in the face of severe hyperglycemia. Additional data indicate, however, that hepatic insulinization alone cannot account for the absence of ketosis in HHS. Ketone bodies can be induced when medium-chain triglycerides (precursors of fatty acids) are administered to animals with an experimental HHS syndrome [93]. The result suggests that patients with HHS would produce ketones despite hepatic insulinization if enough substrate in the form of free fatty acids were present. Their resistance to ketosis must therefore depend on limited availability of circulating free fatty acids [94].

The low concentrations of free fatty acids in HHS may be due to relatively low concentrations of lipolytic hormones [95] including growth hormone and cortisol. Concentrations of these hormones are lower in HHS than in DKA [96]. Another explanation is that hyperosmolality itself inhibits the release of free fatty acids [97]. Additional unidentified factors may play a role.

Renal Impairment

Some degree of renal impairment accompanies all cases of HHS. Younger patients with diabetes have a normal GFR and, even in the event of DKA, filter enough glucose into the urine to prevent extreme hyperglycemia. In contrast, typical patients with HHS are older. Their renal blood flow and GFR are reduced, and they cannot readily excrete a glucose load. When they become hyperglycemic, the glucose is neither metabolized nor excreted. It remains in the extracellular fluid space. The resulting increase in osmolality, together with the decreased GFR, causes still less glucose to be excreted (Fig. 101.3).

The underlying renal abnormality in HHS may be prerenal, renal, or postrenal. The common result is that affected patients are unable to compensate for the hyperglycemia with an osmotic diuresis. The result is an extremely high glucose

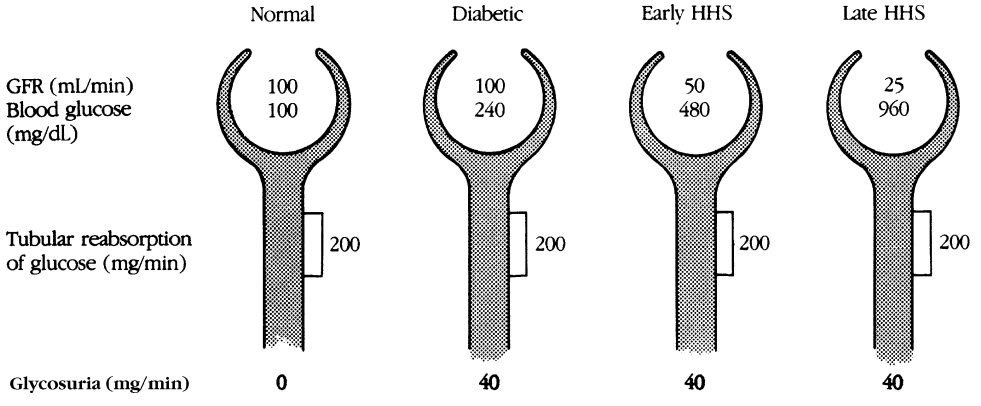

FIGURE 101.3. Interrelationship of blood glucose concentration, glomerular filtration rate (GFR), and renal excretion of glucose. This diagram illustrates the importance of dehydration and diminished GFR in the development of extreme hyperglycemia in hyperglycemic hyperosmolar syndrome (HHS). The normal individual, with normal GFR and normoglycemia, is never glycosuric. A diabetic individual with normal renal function and normal thirst response may become hyperglycemic if glycemic control is poor, but the high GFR leads to glycosuria, and severe hyperglycemia does not usually develop. In a patient with HHS, in contrast, osmotic diuresis and impairment of thirst response lead to progressive deterioration in GFR. The kidney's ability to excrete glucose declines and extreme hyperglycemia develops.

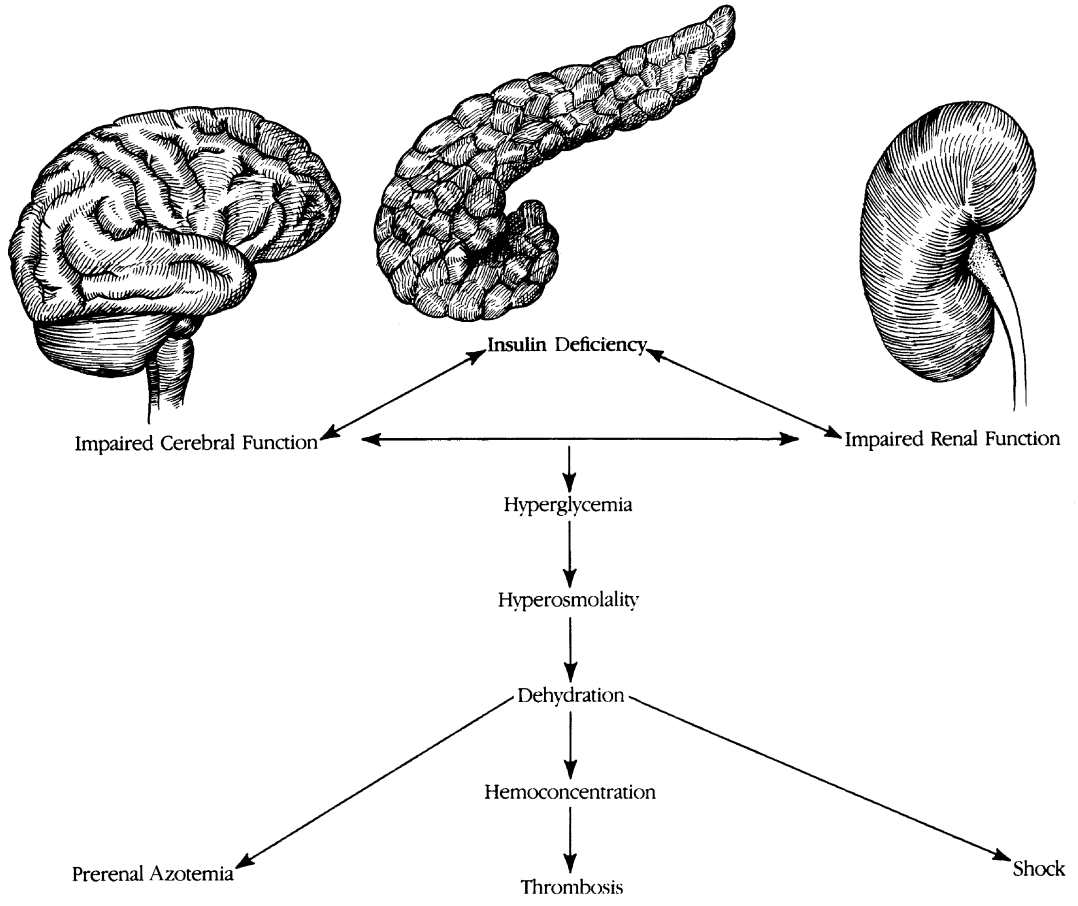

FIGURE 101.4. Pathogenesis of hyperglycemic hyperosmolar syndrome (HHS). Three interrelated factors give rise to HHS: insufficient insulin leads to hyperglycemia and glycosuria, impaired renal function exaggerates the hyperglycemia and hyperosmolality, and impaired cognition leads to decreased free water intake. Together, these factors lead to dehydration and the hyperosmolar hyperglycemic state.

concentration. Severe hyperglycemia itself can cause prerenal azotemia because glycosuria causes a hypotonic osmotic diuresis resulting in urinary loss of free water. If not replaced orally, this loss causes a reduction in intravascular volume and renal perfusion.

Cerebral Impairment

Hyperglycemia leading to hyperosmolality normally activates thirst. The combination of mild diabetes and azotemia does not lead to HHS unless the affected individual cannot drink sufficient water to prevent hyperosmolality. Invariably, HHS involves acute or chronic impairment of cerebral function. A common history involves an elderly patient with impaired cognitive function due to cerebrovascular disease, dementia, or central nervous system–depressant medications. This impairment may involve either concurrent impairment of the normal thirst mechanism or an inability to respond to thirst due to speech or motor deficits. Patients with trauma or burns have large insensible water losses, are often unable to drink, and are also susceptible to HHS in the absence of adequate parenteral fluids.

Animal studies confirm that fluid restriction is necessary to produce an HHS-like disorder. Diabetic rats do not develop HHS unless they are deprived of water [98]. Decreased thirst leads to increased dehydration, increased stupor, and further decreases in fluid intake. Other factors, such as angiotensin, may also be involved [99].

Interrelationships

To summarize, three interrelated factors are required for HHS. Insulin deficiency leads to hyperglycemia and glycosuria. Impaired renal function exaggerates the hyperglycemia and leads to hyperosmolality. Decreased free water intake precludes dilutional compensation and further exacerbates prerenal azotemia. Together, these three factors produce dehydration and the hyperosmolar hyperglycemic state (Fig. 101.4).

The severe dehydration that occurs in this syndrome is due to the osmotic diuresis of glucose in the absence of compensatory free water intake. Dehydration, in turn, leads to hemoconcentration, setting the stage for severe prerenal azotemia, thrombosis, and shock. As glucose and osmolality rise, cerebral function is progressively compromised. Coma ensues when the serum osmolality is 350 mOsm per kg [100]. Severe HHS may take several days to develop.

Clinical Findings in Hyperglycemic Hyperosmolar Syndrome

Patients who develop HHS are typically middle aged or elderly [101,102]. The syndrome may occur in younger patients and even infants, but this is unusual [103,104] and may represent overlap with DKA [2]. Patients often have a history of type 2 diabetes treated with diet and/or oral hypoglycemic agents. There may be a prodrome of progressive polyuria and polydipsia and, occasionally, polyphagia lasting days to several weeks.

Most patients have underlying diseases. Renal and cardiovascular disorders are most common. Other intercurrent problems include infection, myocardial infarction, stroke, hemorrhage, and trauma [102]. Additional predisposing factors include dialysis [105], hyperalimentation [106], and medications. Diazoxide [107], phenytoin [108], propranolol [109], immunosuppressive agents [110], cimetidine [111], and the antipsychotic drugs clozapine and olanzapine [112,113] all impair insulin secretion or action and have been implicated as causes of HHS. The disorder has also been associated with treatment of HIV with nucleoside analogue didanosine [114] and lithium-induced diabetes insipidus [115,116].

Fever is a common finding in HHS even in the absence of infection, but infection must be rigorously excluded in all cases. Patients may have hypotension and tachycardia due to dehydration, and they frequently hyperventilate. Neurological manifestations include tremors and fasciculations. Mental status ranges from mild disorientation to obtundation and coma depending on the degree of abnormalities in osmolality and perfusion [117]. Up to a third of patients with HHS may seize [118], and many in this group are misdiagnosed as having primary intracerebral disease. Once treatment has been instituted, neurologic symptoms may clear rapidly. The hyperventilation may reflect lactic acidosis, a common complication of severe dehydration and hypotension. Rapid respiration in a hyperglycemic patient does not always imply ketoacidosis.

Diagnosis

The key to the diagnosis of HHS is the demonstration of hyperglycemia and hyperosmolality without significant ketosis in the appropriate clinical setting.

Blood Glucose Concentration

Blood glucose concentrations in HHS are generally higher than in DKA, usually greater than 600 mg per dL. Values as high as 2,000 mg per dL occur.

Acetone

Most patients in HHS are not ketonemic. Serum acetone levels are usually normal or only slightly elevated, seldom exceeding 1:2. Occasional patients in HHS develop a severe intercurrent metabolic acidosis. In these very ill patients, a severe hyperosmolar state may overlap with ketoacidosis. Such cases are uncommon.

Osmolality

Serum osmolality in comatose patients is usually more than 350 mOsm per kg. It can be measured directly in the laboratory but is easily and quickly approximated from BUN, sodium, potassium, and glucose concentrations as shown in Table 101.1.

Acid–Base Balance

Most patients in HHS are only mildly acidotic. Serum bicarbonate concentration and arterial pH are usually close to normal. The average pH is about 7.25 before treatment, and HCO_3 is typically $\geq$15 mEq per L. The acidemia most often represents either mild lactic acidosis or uremic acidosis. If there is a significant anion gap (see Table 101.1), other causes of acidosis should be considered. These include salicylate, methanol, and ethylene glycol ingestions.

Renal Function

As outlined above, renal function is always impaired in patients with HHS. In addition to any preexisting renal disease, dehydration induces prerenal azotemia, and the ratio of BUN to creatinine is usually greater than 30:1. BUN and creatinine should be repeated after treatment to determine the degree of intrinsic renal impairment.

Electrolytes

The serum sodium concentration in early HHS is highly variable, ranging between 100 and 180 mEq per L. Hyponatremia may result from the dilutional effect of osmotically active glucose in patients with high free water intake in the face of impaired renal function. As mentioned previously, for each 100 mg per dL increase in blood glucose in excess of 100 mg

TABLE 101.2

EVIDENTIARY BASIS OF MANAGEMENT

Recommendation	Comments
Begin fluid resuscitation of DKA and HHS before insulin therapy.	Studies have shown that hydration lowers plasma glucose by improvement in glomerular filtration and increase in net urinary glucose loss. There is partial correction of pH and plasma bicarbonate with hydration [41].
Low dose (0.1 unit/kg/h) infusion of rapid-acting insulin is recommended.	Randomized controlled trials (RCTs) have shown lower rates of insulin infusion to be as effective as higher rates. Lower insulin rates confer reduced risk of hypokalemia and hypoglycemia [63].
Potassium replacement should begin early.	Studies have shown that insulin administration before volume and potassium repletion can cause shock and arrhythmias [26,29].
Bicarbonate replacement is not recommended in managing DKA.	Trials have shown no benefit of bicarbonate use in patients with pH >6.9 with respect to resolution of ketonemia, acidosis, or hyperglycemia [50–55]. No trials of bicarbonate use in patients with pH <6.9 have been reported.
Phosphate replacement has not been shown to be of benefit in DKA.	Randomized trials have not demonstrated clinical benefit from the routine use of phosphate replacement in DKA [46–48].
Intravenous insulin infusion is preferred for moderate to severe DKA, whereas repeated doses of subcutaneous insulin may be used instead in mild DKA.	Trials comparing intravenous insulin infusion to subcutaneous insulin injections showed similar eventual outcomes, but quicker resolution of ketosis and hyperglycemia with intravenous insulin. In patients with mild DKA, trials show subcutaneous injections of fast-acting insulin every 1–2 hours to be as effective as intravenous infusion of regular insulin [67].

Note: Treatment of the diabetic comas has evolved incrementally over many decades. This table summarizes the validation of key components of therapy.

per dL, serum sodium concentration falls approximately 1.6 mEq per L. When severe hypotonic fluid losses occur in the later stages of HHS, patients may become hypernatremic. Because sodium remains in the extracellular fluid compartment, this electrolyte should be followed to assess the state of hydration.

Serum potassium concentration in HHS syndrome is also variable. It may range from 2.2 to 7.8 mEq per L [85]. Hypokalemia requires immediate potassium replacement. As mentioned later, serum potassium concentrations decrease after treatment with insulin is begun. Hyperkalemia often responds to fluid replacement and improvement in urinary output. Patients with HHS, like those with DKA, lose substantial quantities of electrolytes.

Treatment

Overview

The best treatment for HHS is prevention. The condition can be avoided by periodic attention to blood glucose control and mental status. Susceptible individuals are those with mildly impaired glucose metabolism. They are often the elderly living alone. They may be hospitalized inpatients who have experienced trauma, undergone extensive surgery, or been placed on hyperalimentation regimens. They may also be residents of nursing homes, although improvements in care appear to have reduced this risk [102]. Individuals in all of these settings can be at risk for hyperglycemia and hyperosmolality. When HHS does occur, continuous vigilance in monitoring the details of the patient's clinical progress at the bedside is the key to achieving a successful outcome.

Fluid Replacement

Patients with HHS are, without exception, profoundly dehydrated. Within the first 2 hours, 1 to 2 L of 0.9% saline should be given. Normal saline is recommended, even if hypernatremia is present, to expand the extracellular fluid compartment rapidly. After initial volume expansion and restoration of normotension, subsequent treatment for dehydration in this syndrome emphasizes free water replacement. The osmotic diuresis of glucose produces free water loss in excess of solute loss. The initial infusion of normal saline must never be overlooked, however, because it rapidly expands the extracellular compartment and helps reestablish adequate perfusion pressure. The corrected serum sodium can be used to help decide when the switch from 0.9% saline to 0.45% saline should be made.

The typical HHS patient requires 6 to 8 L of fluids (100 to 200 mL per kg) during the first 12 hours of treatment. The rate of fluid administration must be adjusted as appropriate to the patient's clinical status. Elderly patients with cardiovascular impairment may require less aggressive replacement.

Electrolytes

As soon as adequate urine flow has been established and the degree of hypokalemia estimated, potassium supplementation should be added to the intravenous fluids. During the initial phases of therapy, serum potassium concentration should be checked frequently and the electrocardiogram monitored for changes in morphology and rhythm. A sudden fall in serum potassium concentration frequently accompanies the initiation of insulin therapy [94]. Cardiac arrhythmias induced by hypokalemia may be irreversible, particularly in the elderly. The potassium deficit in HHS can be $\geq$5 mEq per kg [85], but generally, the magnitude of the loss is not as great as that encountered in DKA [119].

Insulin

Most patients with HHS are more sensitive to insulin than are patients with DKA [94]. In addition, blood glucose concentration in HHS can fall rapidly when urine output is reestablished after volume expansion with saline. The combination of insulin sensitivity and glucose diuresis puts patients in HHS at risk of sudden unexpected hypoglycemia. Treatment with insulin is essential but should be instituted with careful monitoring and only after fluid and electrolyte resuscitation is underway.

Only short-acting insulin should be used. Continuous infusion is now standard but must be used with great caution. We do not recommend an initial intravenous insulin bolus. For the infusion, we recommend a starting dose of 1 to 5 U per hour, depending on individual circumstances. This dose is sufficient to insulinize the patient and is usually not high enough to cause severe hypoglycemia. If continuous insulin infusion therapy is not possible, treatment should be with boluses of intravenous regular insulin. The initial dose should not exceed 10 to 30 U. Boluses should be given every 2 to 4 hours, with dose adjusted on the basis of blood glucose determinations.

As emphasized repeatedly, normalization of glucose is not the primary goal of treatment; fluid and electrolyte resuscitation take precedence and often improve glycemia substantially before any insulin is given. An attempt should be made to maintain blood glucose concentration near 250 mg per dL for the first 24 hours. Rapid fall in blood glucose concentration correlates with the development of cerebral edema [100,120].

Complications

Hypotension

When insulin is administered to patients with HHS syndrome, glucose shifts from the extracellular to the intracellular compartment. Because glucose is osmotically active, the movement of glucose intracellularly draws free water from the extracellular compartment. The rapid intracellular movement of free water compromises intravascular volume and may precipitate hypotension and shock [121]. The use of normal (0.9%) saline for initial volume replacement helps prevent hypotension. The higher osmolality of normal (308 mOsm per L) compared with half-normal (154 mOsm per L) saline reduces the osmotic effect of the glucose shifts that follow insulin administration [122].

The magnitude of the fluid shifts that can be induced by insulin was illustrated in a dramatic case report. A patient with congestive heart failure and preexisting renal disease was found to have severe hyperglycemia. Because fluid replacement was contraindicated, the patient was treated with insulin alone. The insulin treatment resulted in a shift of fluid from the extracellular to the intracellular compartment sufficient to ameliorate the congestive heart failure [123].

Cerebral Edema

Blood glucose concentrations should never be reduced precipitously. Rapid reduction is a major contributor to the development of cerebral edema and a fatal outcome in HHS. The exact cause of cerebral edema in HHS is unknown, but animal studies suggest that neuronal intracellular osmolality increases in HHS. The osmotically active solute has not been identified. The term idiogenic osmoles is used to describe these uncharacterized, osmotically active, nondiffusible substances [124]. They draw water into neurons when the extracellular osmolality drops as a result of the intracellular movement of glucose. This is followed by severe edema, increased intracranial pressure, and disturbed hypothalamic function.

Thrombosis

Large vessel thromboembolic events are an important cause of mortality in HHS. Severe dehydration and hyperosmolality lead to reduced cardiac output and hyperviscosity, predisposing

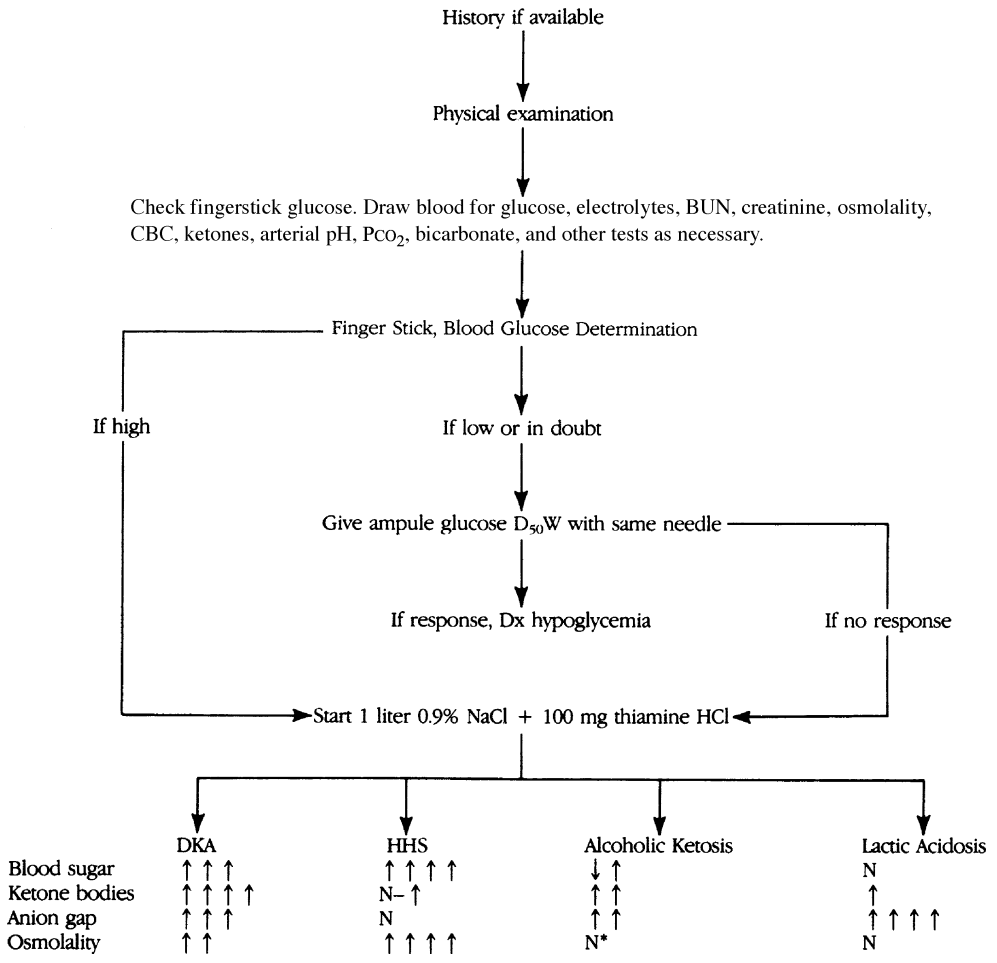

FIGURE 101.5. Algorithm for the diagnosis of diabetic coma. Measured osmolality is greater than predicted; result in freezing point depression test is increased by 1 mOsm/5 mg% EtOH. CBC, complete blood count; N, normal; ↑, mildly elevated; ↓, mildly depressed; ↑↑, moderately elevated; ↑↑↑, severely elevated; ↑↑↑↑, extremely elevated. BUN, blood urea nitrogen. to venous and arterial thrombosis. Use of low-dose heparin prophylaxis is recommended in high-risk patients [125].

CONCLUSIONS

The diabetic comas are often described as discrete entities, but they frequently present as overlapping disorders [2]. Patients in DKA often have concurrent mild lactic acidosis and may also develop hyperosmolality. Initial treatment of all diabetic comas must always emphasize fluid and electrolytes. DKA and HHS also require careful management of insulin therapy. Physicians must obtain the relevant history, perform a thorough physical examination, classify the disorder, and treat appropriately. The approach to treatment is summarized in Fig. 101.5. With care, nearly all patients with DKA and most with HHS can survive.

CHAPTER 102 ■ SEVERE HYPERTHYROIDISM

MARJORIE S. SAFRAN

Patients with thyrotoxicosis rarely need hospitalization. However, some patients with severe thyrotoxicosis develop a decompensated clinical presentation called *thyroid storm*. It is characterized by hyperpyrexia, tachycardia, and delirium [1] and generally occurs in a patient with severe thyrotoxicosis who then experiences a stressful event. The cause of this rapid decompensation is unknown, but it may be partly due to a sudden inhibition in thyroid hormone binding to plasma proteins, resulting in a rise in the already elevated free hormone pool [2]. Thyroid storm accounts for no more than 2% of hospital admissions for all forms and complications of thyrotoxicosis, and the diagnosis is often difficult to make because there is a fine line between severe thyrotoxicosis and thyroid storm. Even when properly treated, thyroid storm has a mortality rate of 7% to 30% [3].

ETIOLOGY

Before the preoperative use of iodides and the antithyroid drugs propylthiouracil (PTU) and methimazole (MMI; Tapazole), thyroid storm was most frequently seen during and after subtotal thyroidectomy. Because these agents are used to restore euthyroidism before surgery, thyroid storm is rarely seen in this context. Thyroid storm now occurs most commonly in patients with severe underlying thyrotoxicosis, frequently undiagnosed, who become ill for other reasons, such as infections, trauma, labor, diabetic ketoacidosis, or pulmonary and cardiovascular disorders. It can occur during or after nonthyroid surgery, and has been reported after external beam radiation to the neck [4], ingestion of sympathomimetic drugs (such as

pseudoephedrine) in a thyrotoxic patient [5], and rarely with intentional or accidental overdoses [6,7]. Thyroid storm may rarely occur approximately 10 to 14 days after the administration of large doses of iodine 131 in patients with large goiters who have not been adequately pretreated with PTU or MMI to deplete the gland of stored thyroxine (T_4) and triiodothyronine (T_3) [8]. Beta-blockers are used to decrease symptoms of excess thyroid hormone release, but *may not* prevent thyroid storm.

CLINICAL MANIFESTATIONS

There is no absolute level of circulating thyroid hormones indicative of thyroid storm, and the diagnosis is made on a clinical basis [3]. Patients with thyroid storm are almost always febrile (temperature usually higher than 100°F) and have rapid sinus tachycardia and tachyarrhythmias (especially atrial fibrillation in elderly patients) out of proportion to the degree of fever that can frequently result in congestive heart failure. Patients are often agitated, delirious, and tremulous, with hot, flushed skin due to vasodilation. The skin may be moist or dry, depending on the state of hydration. Diarrhea occurs frequently and contributes to dehydration and hypovolemia. Vascular collapse and shock, which are poor prognostic signs, may occur in these patients. Hepatomegaly with abnormal liver enzymes and splenomegaly can be present; jaundice portends a poor prognosis.

Most patients display the classic signs of thyrotoxic Graves' disease, including ophthalmopathy, or toxic uninodular or multinodular goiter. However, in elderly patients, apathy, severe myopathy, profound weight loss, and congestive heart failure may be the predominant findings. As thyroid storm progresses, coma, hypotension, vascular collapse, and death may ensue unless active therapy is instituted.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of thyroid storm is made on clinical grounds. Thyroid function tests do not differentiate between severe thyrotoxicosis and thyroid storm. Serum T_4 concentrations are usually similar, although it has been suggested that the serum-free T_4 concentration is significantly higher in patients with thyroid storm [2], which might partially explain their more severe symptoms. On the other hand, the serum T_3 concentrations are not higher and in fact may be less elevated or even normal in these patients when the precipitating cause is an intercurrent illness or surgery because peripheral T_3 production from T_4 is markedly impaired in a wide variety of acute and chronic systemic illnesses. Liver function tests are frequently abnormal, especially in elderly patients with congestive heart failure. Elevations in total and free serum calcium concentrations may occur.

The differential diagnosis for a patient presenting with hyperpyrexia, delirium, and tachycardia includes severe infection, malignant hyperthermia [9], neuroleptic malignant syndrome, and acute mania with lethal catatonia. Thyroid storm can be distinguished from these disorders clinically by a history of thyroid disease, thyroid hormone, or iodine ingestion and the presence on physical examination of a goiter or the stigmata of Graves' disease, including ophthalmopathy, onycholysis, and pretibial myxedema. However, any of the disorders mentioned in the differential diagnosis can coexist with thyroid storm since they may precipitate decompensation in a patient with preexisting hyperthyroidism.

TREATMENT

Treatment of thyroid storm is directed toward therapy of the underlying illness, supportive care, blocking peripheral effects of thyroid hormone, and inhibition of thyroid hormone synthesis and release (Table 102.1).

Underlying Illness

Nonthyroidal illness and surgery in previously undiagnosed or only partially treated patients with hyperthyroidism are the most common causes of thyroid storm. Thus, the precipitating disease should be vigorously treated. Cardiac arrhythmias and congestive heart failure require approximately twice the dose of digoxin needed in euthyroid patients, and refractory arrhythmias should alert the physician to the presence of thyrotoxicosis. Patients may also be refractory to heparin and insulin, with higher doses required. It is evident that these patients must receive adequate antibiotic therapy; careful fluid, electrolyte, and vitamin supplementation; vigorous pulmonary therapy; and careful pre- and postoperative care. If emergency surgery is required in a thyrotoxic patient, propranolol, PTU or MMI, iodides, and perhaps corticosteroids should be given before, during, and after surgery.

Supportive Care

A cooling blanket can be used if the temperature rises above 101°F, but the shivering response should be decreased by using drugs that block the central thermoregulatory centers, such as chlorpromazine or meperidine, 25 to 50 mg every 4 to 6 hours. Antipyretics other than salicylates may also be given because salicylates displace thyroid hormones from serum-binding proteins and can increase the free hormone concentrations [10]. Dehydration is frequently present and should be treated while monitoring for congestive heart failure.

Blockade of Peripheral Effects of Thyroid Hormone

Many of the clinical manifestations of hyperthyroidism can be alleviated by the administration of drugs that deplete or block the peripheral action of the catecholamines. Beta-adrenergic blocking agents are currently the drugs of choice in alleviating the catecholamine-dependent signs and symptoms of thyrotoxicosis and thyroid storm. The widest experience has been achieved with propranolol, which also has the advantage of decreasing T_4 to T_3 conversion (see later). Tachycardia and tremors can be improved within minutes of intravenous administration. Oral doses in the range of 60 to 120 mg every 6 hours may be required [11].

Because propranolol may be contraindicated in patients with congestive heart failure, it is frequently debated whether to use beta-blockers in patients with severe thyrotoxicosis or thyroid storm. However, tachycardia and tachyarrhythmias are major contributing factors to the congestive failure in many of these patients, so beta-blockers may be used cautiously along with digoxin and other cardiotropic drugs and diuretics. Rarely, hypotension and cardiac arrest occur after intravenous administration of beta-blockers in patients with severe congestive failure and severe thyrotoxicosis [12]. In patients with asthma, the more selective $beta_1$-blocking drugs, such as metoprolol and atenolol, may be used with less risk. A short-acting $beta_1$-blocker, esmolol [13], and diltiazem can also be used to control the tachyarrhythmias associated with thyrotoxicosis [14].

TABLE 102.1

TREATMENT OF THYROID STORM

Therapy of underlying intercurrent illness	
Digoxin, diuretics, antibiotics, IV fluid supplemented with B-complex vitamins, and insulin for diabetic ketoacidosis	
Supportive care	
Cooling blanket, antipyretics (*not* aspirin), or both for hyperpyrexia	
Block peripheral effects of thyroid hormone	
β-Adrenergic blocking drugs	
Propranolol (beta$_1$- and beta$_2$-blocker)	1 mg IV/min for a total of 2–10 mg 40–120 mg PO q4–6h
Metoprolol (beta$_1$-blocker)	100–400 mg PO q12h
Atenolol (beta$_1$-blocker)	50–100 mg PO daily
Esmolol (beta$_1$-blocker)	500 μg/kg over 1 min, then 50–100 μg/kg/min
Deplete catecholamines	
Reserpine	Test dose of 0.25 mg IM, then initial dose of 1–5 mg 1.0–2.5 mg IM q4–6h
Guanethidine	1–2 mg/kg PO q4–6h
Inhibition of synthesis of thyroid hormones	
Propylthiouracil (PTU)	~ 800mg PO stat and 200–300 mg q8h 600 mg in 90 mL of water by rectum as a retention enema, followed by 250 mg q4h
Methimazole (MMI)	~ 80mg PO stat and 40 mg PO q12h 40 mg dissolved in aqueous solution by rectum q6h
Block release of thyroid hormone from thyroid gland	
Saturated solution of potassium iodide	5 drops PO q8h
Lugol's solution	10 drops PO q8h
Lithium	300 mg q6h, adjust to serum lithium level ~1 mEq/L
Inhibition of peripheral 5′-monodeiodination of thyroxine (T_4) to triiodothyronine (T_3)	
Corticosteroids	Equivalent to 300–400 mg hydrocortisone daily, especially dexamethasone, 2 mg q6h
Propranolol, metoprolol, atenolol, and possibly esmolol	
Propylthiouracil	
Remove thyroid hormones from the circulation	
Plasmapheresis	
Charcoal hemoperfusion	
Cholestyramine	4 g PO q6h

IM, intramuscularly; IV, intravenous; PO, oral.

Inhibition of Thyroid Hormone Synthesis

The antithyroid drugs, PTU and MMI, are potent inhibitors of the synthesis of both T_4 and T_3. Although the onset of action is rapid, PTU and MMI only partially block thyroid hormone synthesis. Weeks are required to deplete the thyroid of stored hormone and observe clinical effects of these drugs. Intravenous MMI is available in Europe, but in the United States, administration by either nasogastric tube or by rectum may be used [15]. PTU has the added advantage of partially blocking the peripheral conversion of T_4 to T_3 and therefore may be the drug of choice. These drugs are not effective if thyroid storm is due to excess ingestion of thyroid hormone (see the section Thyrotoxicosis Factitia) or painful or silent thyroiditis because they affect the synthesis of thyroid hormone and do not affect its release or peripheral activity.

Blockade of Thyroid Hormone Release

Iodide administration plays a major role in the treatment of thyroid storm because of its rapid inhibition of thyroid hormone release from the gland [16]. This effect occurs almost immediately after oral or intravenous administration. Some inhibition of hormone synthesis may also occur in the hyperfunctioning gland. As with PTU and MMI, iodide therapy is not useful in thyroid storm caused by ingestion of excess amounts of thyroid hormone (thyrotoxicosis factitia) because it affects the synthesis and release of endogenously synthesized thyroid hormone.

Lugol's solution or saturated solution of potassium iodide can be given orally or as a potassium iodide enema, 1 g in 60 mL of water, followed by 500 mg of potassium iodide in 20 mL of water every 6 hours, given rectally in a patient who is unable to receive oral medication. Iodide therapy results in dramatic improvement and should be maintained until the serum T_4 and T_3 concentrations are normal or near-normal. However, iodides can exacerbate hyperthyroidism if the patient is not pretreated with PTU or MMI and also delay the option of radioactive iodine for subsequent, definitive treatment. Escape from the iodide effect often occurs when PTU or MMI is not concomitantly used [17]. In patients allergic to iodine, lithium has been used to inhibit thyroid hormone release and partially inhibit thyroid hormone synthesis [18].

Inhibition of Peripheral Generation of Triiodothyronine

It is generally believed that the major bioactive hormone is T_3, that the major source of circulating T_3 is derived from T_4, and that most, if not all, of the metabolic effects of T_4 result from the intracellular generation of T_3 from T_4. A variety of drugs impair the outer-ring monodeiodination of T_4 to T_3, thus decreasing the peripheral generation of T_3. Propranolol, some selective beta$_1$-blocking drugs [19], and PTU are relatively weak inhibitors of T_4 to T_3 conversion. The corticosteroids, especially dexamethasone, are potent inhibitors when administered in high doses and also have an inhibitory effect on thyroid hormone hypersecretion. Their importance in treating thyroid storm has been well documented; the survival rate in thyroid storm was improved when corticosteroids were added to the treatment regimen. Because relative adrenal insufficiency may be present in patients with thyroid storm, glucocorticoid therapy would also correct this possibility. Indeed, combination therapy of severe hyperthyroidism with PTU, iodides, and dexamethasone has resulted in a marked reduction of serum T_3 concentration within 24 hours.

The gallbladder dyes, iopanoic acid (Telepaque) and ipodate (Oragrafin), are potent inhibitors of T_4 to T_3 conversion, but are no longer available in the United States. Similarly, amiodarone also decreases T_3 levels. In addition, it is rich in iodine, and may also block entrance of T_4 into the cell. Although this drug has been used in the short-term (2 weeks) treatment of thyrotoxicosis, it should not be used in the treatment of thyroid storm because its long half-life and high iodide content can cause persistent, severe hyperthyroidism [20].

Removal of Thyroid Hormone from the Circulation

Direct removal of thyroid hormone from the circulation is occasionally required in patients who do not respond to conventional medical treatment. There are case reports of successful use of plasmapheresis [21] and charcoal plasma perfusion [22]. Cholestyramine, which binds T_3 and T_4 in the gut and decreases serum T_3 and T_4 concentrations by increasing the fecal excretion of these hormones [23], may also be useful, particularly if used early in a patient with an overdose.

Thyrotoxicosis Factitia

The inadvertent ingestion of excess amounts of thyroid hormone most commonly occurs in children, although adults may also ingest excess hormone for weight reduction or as a suicide attempt [6,7,24]. Gastric lavage or emesis induction should be performed as soon as possible after ingestion. Occasionally, oral charcoal administration can be useful. As previously mentioned, this form of thyrotoxicosis is not due to endogenous production of thyroid hormone; therefore, drugs that inhibit the synthesis of T_4 and T_3 or those that block thyroid hormone release are not helpful. Therapy should focus on preventing the peripheral effects of excessive thyroid hormone with β-adrenergic blocking drugs and possibly high-dose corticosteroids Cholestyramine may also be useful to decrease serum thyroid hormone levels, as above.

CONCLUSIONS

It is evident that each patient must be treated individually and that a set protocol cannot be advised for all patients. Specific therapy should be directed toward inhibiting the synthesis and release of T_4 and T_3 from the thyroid, blocking the peripheral conversion of T_4 to T_3, relieving the catecholamine-mediated effects by β-adrenergic blockade, and treating the possibility of decreased adrenal reserve with corticosteroids. Associated and precipitating diseases should, of course, be vigorously treated. Iodine often works quickly to improve thyroid hormone levels, but will delay the use of radioactive iodine treatment of hyperthyroidism and thus should be saved for patients with thyroid storm, not just severe thyrotoxicosis.

CHAPTER 103 ■ MYXEDEMA COMA

MIRA SOFIA TORRES AND CHARLES H. EMERSON

Myxedema coma is a syndrome that occurs in advanced untreated hypothyroidism [1–5]. It is defined by a group of characteristic clinical features and not by laboratory evidence of severe hypothyroidism (Table 103.1). Myxedema coma is generally preceded by increasingly severe signs and symptoms of thyroid insufficiency. Fortunately, it is quite rare. Hypothyroid patients who are neglectful or whose contact with family and friends is limited are most vulnerable. Despite early and intensive treatment, mortality from myxedema coma is still as high as 30% to 50% [2,4,6–8].

ETIOLOGY AND PATHOPHYSIOLOGY

By definition, myxedema coma does not occur in the absence of hypothyroidism. If hypothyroidism is due to hypothalamic or pituitary insufficiency, the condition is even more serious because it is also accompanied by adrenal failure. Pituitary tumors are the major cause of central hypothyroidism in the United States. In countries with poor access to health care, postpartum pituitary necrosis is quite prevalent and is therefore another important cause of secondary hypothyroidism.

More than 95% of patients with hypothyroidism have primary thyroid disease. Most patients with primary hypothyroidism have either autoimmune thyroid failure or hypothyroidism secondary to ablative procedures on the thyroid. These include radioactive iodine and surgery for hyperthyroidism, thyroid resection for thyroid cancer, and external thyroid irradiation for head and neck tumors. Certain drugs, such as lithium carbonate and amiodarone, can cause hypothyroidism but are only rarely associated with myxedema coma.

Myxedema coma is distinguished from uncomplicated hypothyroidism by a variety of features that relate to central nervous system (CNS) dysfunction. The pathophysiology of myxedema coma will become clearer when there is a better understanding of the effects of thyroid hormone on the brain. Narcotics and hypnotics should be used with caution in hypothyroid patients because these patients are very sensitive to their sedative effects. These agents, alone or in combination with other factors, may precipitate myxedema coma in hypothyroid patients. Other precipitating factors are trauma, surgery, and severe infection [1–9]. The most important factor in temperate climates, however, is cold stress. In one series, 9 of 11 patients with myxedema coma were admitted in the late fall or winter [2].

TABLE 103.1

CLINICAL FEATURES OF MYXEDEMA COMA

Mental obtundation
Course, dry skin
Myxedema facies
Hypothermia
Hypoglycemia
Bradycardia and hypotension
Electrocardiographic changes
Atonic gastrointestinal tract
Atonic bladder
Pleural, pericardial, and peritoneal effusions

CLINICAL MANIFESTATIONS

Patients are partially or completely obtunded. Therefore, the history must often be obtained from other sources. Friends, relatives, and acquaintances might have noted increasing lethargy, complaints of cold intolerance, and changes in the voice. An outdated container of L-thyroxine discovered with the patient's belongings suggests that he or she has been remiss in taking medication. The medical record may also indicate that the patient was taking thyroid hormone or may refer to previous treatment with radioactive iodine. A thyroidectomy scar suggests the possibility of hypothyroidism. Other than coma itself, the cardinal manifestations are hypothermia and hypotension. Hypotonia of the gastrointestinal tract is common and often so severe as to suggest an obstructive lesion. Urinary retention due to a hypotonic bladder is related but less frequent. Most patients have the physical features of severe hypothyroidism, including bradycardia and slow relaxation of the deep tendon reflexes. A myxedematous facies (Fig. 103.1) results from the dry puffy skin, pallor, hypercarotenemia, periorbital edema, and patchy hair loss.

FIGURE 103.1. Characteristic facies of severe hypothyroidism. Note the facial and periorbital puffiness and the dull, lethargic expression.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of myxedema coma is based on the presence of the characteristic clinical syndrome in a patient with hypothyroidism. The laboratory's role is to confirm that the patient is hypothyroid and determine whether there are treatable complications of myxedema coma, such as hypoventilation, hypoglycemia, and hyponatremia. Because of the gravity of hypothyroidism, treatment must be instituted before laboratory tests confirm the diagnosis.

The diagnostic laboratory features of primary hypothyroidism are a subnormal serum-free thyroxine index or serum-free thyroxine (T_4) concentration and an elevated serum thyroid-stimulating hormone (TSH) concentration. The serum-free thyroxine index is also low in severely ill patients with a wide variety of conditions. This is the so-called "sick euthyroid syndrome" or nonthyroidal illness. Unlike patients with myxedema coma, however, serum TSH concentrations are not elevated in patients with the sick euthyroid syndrome, except in a small percentage, and only as they are clearly recovering from their severe illness. Distinction between hypothyroidism secondary to pituitary or hypothalamic disease (i.e., central hypothyroidism) and the sick euthyroid syndrome is difficult because serum TSH concentrations are low or, when TSH bioactivity is reduced as in secondary hypothyroidism, only mildly elevated in patients with central hypothyroidism. It is important to measure TSH as well as the serum-free thyroxine or free thyroxine index in patients presenting with myxedema coma. In central hypothyroidism, the typical clinical presentation of the myxedematous patient would help establish the diagnosis. The sick euthyroid syndrome is discussed in Chapter 107. The measurement of the total serum triiodothyronine (T_3) concentration is of no value in the diagnosis of hypothyroidism or myxedema coma. It lacks sensitivity in the diagnosis of hypothyroidism and is depressed not only by illness but also by fasting.

Alone, few of the signs and symptoms described in this chapter are unique to myxedema coma. For example, the differential diagnosis of hypothermia (see Chapter 65) includes numerous conditions, such as protein-calorie malnutrition, sepsis, hypoglycemia, and exposure to certain drugs and toxins [10]. Hypotension and hypoventilation, other cardinal features of myxedema coma, occur in other disease states. What distinguishes myxedema coma from other disorders is laboratory evidence of hypothyroidism, characteristic myxedema facies with periorbital puffiness, skin changes, obtundation, and, frequently, a constellation of other physical signs characteristic of severe hypothyroidism.

TREATMENT

As noted earlier, in most patients with myxedema coma, hypothyroidism is due to primary thyroid disease. The initial management of myxedema coma due either to primary thyroid disease or central (pituitary or hypothalamic) disease is similar, since glucocorticoids are recommended in all patients. The only proviso is that in patients with central hypothyroidism, additional evaluation of the CNS for the presence of space-occupying lesions may be warranted. Therefore, the management team must be alert for evidence of space-occupying lesions within or in the region of the pituitary in all patients with myxedema coma.

Treatment of myxedema coma consists of management of hypoglycemia, respiratory depression, hyponatremia, hypothermia, hypotension, and administration of thyroid hormone (Table 103.2). All patients require continuous monitoring of the electrocardiogram and an intravenous line to administer fluids and drugs. Baseline thyroid function tests, serum cortisol, complete blood count, blood urea nitrogen, creatinine, plasma glucose, and electrolytes are mandatory. Pneumonia commonly develops or may be the precipitating factor and must be treated promptly (see Chapter 68). Hypothyroidism and myxedema coma are also associated with hemostatic abnormalities, particularly capillary bleeding and cerebral hemorrhage. Although bleeding should be anticipated in many patients, few strategies have evolved to counter this disorder.

TABLE 103.2

TREATMENT OF MYXEDEMA COMA

Assisted ventilation for hypoventilation
Intravenous glucose for hypoglycemia
Water restriction or hypertonic saline for severe hyponatremia
Passive rewarming for hypothermia
Administration of T_4 or T_3 IV[a]
Administration of hydrocortisone[a]
Treatment of underlying infection and other illnesses, if present
Avoidance of all sedatives, hypnotics, and narcotics

IV, intravenously; T_3, triiodothyronine; T_4, thyroxine.
[a]Dosage must be individualized (see text).

Hypoglycemia

Because hypoglycemia is not unusual in myxedema coma, 50 mL of 50% glucose should immediately be administered intravenously to avoid any delay in confirming the presence of this complication. Chapter 106 details the management of hypoglycemia.

Hypoventilation

Respiratory center depression is common in severe hypothyroidism and myxedema coma. Arterial blood gases should be routinely obtained, therefore, to rule out hypoventilation. If respiratory center depression is clinically obvious, assisted ventilation with oxygen supplementation must be started without delay, taking care not to correct chronic hypercapnia too rapidly (see Chapter 62).

Hyponatremia

Hyponatremia, which results from impaired free water clearance, is most deleterious to CNS function when it develops rapidly. Although hyponatremia is present in some patients, it is usually not the cause of coma because its onset is likely to be gradual. A limiting factor is that water intake decreases as myxedema coma develops, offsetting the tendency toward hyponatremia. Treatment consists of restriction of free water. If the serum sodium concentration is less than 110 mEq per L, hypertonic saline and, in some cases, furosemide should be administered (see Chapter 72).

Hypothermia

Hypothermia is one of the hallmarks of myxedema coma. It can be overlooked or its severity underestimated, however,

if an out-of-date or poorly calibrated thermometer is used. Regardless of the cause, hypothermia is associated with a decrease in the basal metabolic rate, myocardial irritability, and blood pressure alterations. Blood pressure initially rises and then gradually falls. Changes in the cardiovascular status are accompanied by electrocardiographic changes. First, there is sinus bradycardia, then T wave inversion, and finally the development of a J wave [10]. At core temperatures below 28°C, ventricular fibrillation is a major threat to life. For an in-depth discussion of this complication, see Chapter 65.

Despite its gravity, the management of the hypothermia of myxedema coma differs from the treatment of exposure-induced hypothermia in euthyroid subjects. In myxedema coma, the patient should be kept in a warm room and covered with blankets. Active heating should be avoided because it increases oxygen consumption and promotes peripheral vasodilation and circulatory collapse. Active heating is recommended only for situations of severe hypothermia in which ventricular fibrillation is an immediate threat. In these cases, the rate of rewarming should not exceed 0.5°C per hour and core temperature should be raised to approximately 31°C.

Hypotension

Hypotension is another ominous feature of myxedema coma. Hypothermia and thyroid hormone deficiency per se are the two most important causes of hypotension, but bleeding and, perhaps in some cases, decreased adrenal reserve may also play a role. Because hypothermia itself produces hypotension, some improvement in blood pressure can be expected if passive measures to restore body temperature are successful. Intravenous fluids should be administered carefully as patients undergo rewarming. Anemia is common in hypothyroidism and has a multifactorial basis. In patients in whom anemia is severe or there appears to be active bleeding, a case can be made for transfusion. If this course is chosen, it must be done with great caution because patients with myxedema coma are extremely prone to circulatory collapse. Sympathomimetic vasoconstrictors or drugs intended to increase myocardial contractility, such as isoproterenol or digitalis, have very limited use in myxedema coma. The response to these drugs is poor, and myxedematous patients are very sensitive to their toxic effects.

Glucocorticoid Therapy

Although there is little evidence that hypotension in myxedema coma results from adrenal insufficiency, there are at least theoretic reasons for considering that these patients have decreased adrenal reserve. Furthermore, it is sometimes unclear whether the myxedema coma is due to primary or pituitary-hypothalamic hypothyroidism. Therefore, one of the immediate measures in treating myxedema coma is to administer 300 mg hydrocortisone intravenously in three divided doses during the first 24 hours. Gradually decreasing doses of hydrocortisone should be administered over the next few days, depending on the patient's response. This protocol is recommended even in the absence of hypotension.

Sepsis

Infections, especially pneumonia and urosepsis, are precipitants or comorbidities in up to 80% of patients with myxedema coma, and sepsis is an important cause of death in these patients [2,4,6–8]. Some signs of sepsis such as tachycardia and fever may be absent in the initial presentation of patients with myxedema. A careful evaluation for underlying infections should be conducted in each patient. When suspected, such infections should be treated aggressively. The management of sepsis is discussed in detail in Chapter 159.

Thyroid Hormone

Administration of thyroid hormone is the definitive treatment of myxedema coma and is essential for reversing hypotension, hypothermia, and depressed consciousness. The sensorium may be improved in a few patients when glucose is given or hypoventilation corrected, but deterioration recurs if thyroid hormone is not given. The gastrointestinal absorption of thyroid hormone is often markedly reduced in myxedema coma. Therefore, thyroid hormone must be given by the intravenous route. To ensure proper dosing, synthetic preparations should be used.

There are no large controlled studies of the optimum form of thyroid hormone for myxedema coma or, for that matter, any aspect of the treatment of myxedema coma. Both T_4 and T_3 have been used with varying degrees of success, and each has its theoretic advantages. T_4 is advantageous because most thyroid hormone is secreted in the form of T_4. For this and other reasons, plasma and intracellular T_4 and T_3 profiles are more stable and representative of the normal condition if T_4 rather than T_3 is administered. Conversely, T_3 is advantageous because it has a more rapid onset of action than T_4.

The best doses for treating myxedema coma have not been studied in a rigorous fashion. As is the case when deciding between T_4 and T_3, the choice is not straightforward. In patients with long-standing untreated hypothyroidism, thyroid hormone treatment is usually initiated at low doses. These patients frequently have underlying arteriosclerotic cardiovascular disease, and initial therapy with full replacement doses of thyroid hormone can precipitate angina or myocardial infarction. On the other hand, in near-terminal patients with myxedema coma, the need for thyroid hormone is urgent. In this setting, the blood pressure and body temperature can increase within hours after thyroid hormone is started.

We prefer to use T_4 in all but the most severe cases of myxedema coma. Except in elderly patients, the initial intravenous dose of T_4 should be between 0.2 and 0.5 mg, with the larger doses in this range used for more comatose patients, those with more severe hypotension or hypothermia, and those with large body mass. In the elderly patient or those with a history of heart disease, the initial T_4 dose should probably not exceed 0.4 mg. If there is no improvement in the state of consciousness, blood pressure, or core temperature at first 6 to 12 hours after the initial dose, T_4 should again be administered to bring the total dose during the first 24 hours to 0.5 mg. Thyroid hormone should then be given again 24 hours later and every 24 hours thereafter. After the first 24 hours, the subsequent doses should range from 0.05 to 0.2 mg daily, depending on the clinical response. If the treatment is not maintained, coma may recur. A recent prospective study randomly assigned 11 patients to two groups: one received a loading dose of 0.5 mg of T_4 intravenously followed by a daily maintenance dose of 0.1 mg intravenously ("high-dose" group); the other group received only the maintenance dose of 0.1 mg daily ("low-dose" group). Four of eleven patients died, but only one of them was in the high-dose group. The mortality rate was lower in the high-dose group, but did not reach statistical significance [7]. However, the sample size was small. Based on this information, it was suggested that patients who receive a loading dose fared better than those on less vigorous regimens. A smaller dose in comatose patients is probably indicated in very elderly patients [6], or in patients who are normotensive and euthermic and have another explanation for their comatose state, such as CNS trauma or recent sedative ingestion. Another situation

that calls for lower doses is the patient who has had an acute myocardial infarction and whose hypotension appears to be secondary to the myocardial infarction, which is a major contributor to the patient's depressed sensorium. In these cases, ventilatory support should be given and intravenous doses of as little as 0.05 to 0.1 mg of T_4 administered in the first 24 hours. Care must be taken in making the diagnosis of myocardial infarction, however, since creatine kinase-MB activity is increased in the absence of myocardial infarction in a few patients with myxedema coma [11,12].

In the most severe cases of myxedema coma, intravenous T_3 may be a better choice as the initial therapy. If T_3 is used, however, greater caution must be exercised to avoid overstimulation of the cardiovascular system [2] and too rapid an increase in oxygen consumption. It is clear that T_3 has been lifesaving in some patients, but an inverse correlation between survival and calculated plasma T_3 concentrations has actually been reported in myxedema coma [2]. Although doses as high as 0.2 mg of T_3 in the first 24 hours have been used, as little as 0.0025 mg has been reported to increase cardiac output, heart rate, ventricular stroke work, oxygen consumption, and oxygen delivery in myxedema coma [13]. Based on these and other considerations, a reasonable starting dose of T_3 is 0.0125 mg (12.5 μg) given intravenously [1]. This dose should be repeated every 6 hours for the first 48 hours. If there is no apparent response after 15 to 21 hours, as shown by heart rate, blood pressure, and body temperature, the next two doses could be increased to 0.025 mg (25 μg). If, on the other hand, signs of myocardial ischemia develop, the dose should be reduced. Particularly worrisome would be a decrease in blood pressure in the face of an increase in body temperature, suggesting that cardiovascular decompensation is occurring in the face of increased oxygen demands. If there is gradual improvement of metabolic parameters, the T_3 should be tapered and T_4 treatment introduced, starting with doses of 0.05 mg given intravenously every 24 hours. When the patient stabilizes and is fully conscious, T_4 can be given by the oral instead of the intravenous route. T_4 therapy must be closely monitored, however, as T_4 malabsorption can be a serious problem in a variety of clinical settings. If the clinical response to oral T_4 is not maintained or serum T_4 concentrations fall, the patient should be switched back to intravenous T_4 therapy.

Although myxedema coma is associated with a high mortality, many patients survive by using judicious therapy aimed at correcting the secondary metabolic disturbances and reversing the hypothyroid state. This must be done in a sustained but gradual fashion, however, because an effort to correct hypothyroidism too rapidly may completely negate the beneficial effects of the initial treatment.

Pertinent clinical studies of myxedema coma are listed in Table 103.3.

TABLE 103.3

PERTINENT CLINICAL STUDIES OF MYXEDEMA COMA

- Myxedema coma has a high mortality rate and is often the first manifestation of thyroid disease [2,5–8].
- Old age is associated with increased mortality in myxedema coma [2,6].
- Sepsis and infection are important contributors to mortality [2,4,6–8].
- High-dose thyroid hormone treatment has been associated with a worse outcome in myxedema coma. It is not known if this association is due to patients with more severe forms of myxedema coma being treated with higher doses of thyroid hormone [2,6].

CHAPTER 104 ■ HYPOADRENAL CRISIS AND THE STRESS MANAGEMENT OF THE PATIENT ON CHRONIC STEROID THERAPY

NEIL ARONIN

The adrenal glands secrete five types of hormone, but two are critical in the intensive care unit (ICU) setting. Mineralocorticoids (primarily aldosterone) regulate electrolyte balance. Glucocorticoids (primarily cortisol) promote gluconeogenesis and have many other actions. Aldosterone and cortisol are life sustaining; deficiency of either can result in hypoadrenal crisis. The other three types of adrenal hormones (dehydroepiandrosterone and its sulfate, estrone, and catecholamines) do not play a major role in acute care settings.

Hypoadrenal crisis can occur as an acute event in individuals lacking a prior history of adrenal disorders. A high index of suspicion arises in patients who have inadequate responses to initial therapies. Patients treated with glucocorticoids have a heightened risk for inadequate cortisol response to stress. Diagnosis of cortisol deficiency can be elusive; conditions that contribute to ICU admission (e.g., sepsis, acute respiratory failure) might interfere with traditional tests of adrenal function.

The sometime uncertainty in biochemical diagnosis of adrenal hypofunction invokes the use of clinical judgment in starting therapy. Recent studies indicate that varied disease in ICU patients do not allow a unified algorithm of treatment. Because excess cortisol is beset with side effects and exacerbation of illness, it is prudent to have mastery of the normal regulation and actions of aldosterone and cortisol; the strengths and foibles of diagnostic tests of adrenal insufficiency; and the evidence for appropriate, effective, and safe use of glucocorticoids in ICU patients.

ETIOLOGY

The most common cause of primary adrenal failure is Addison's disease, an autoimmune disease that is frequently known before the ICU admission. Addison's disease often coexists with additional autoimmune endocrinopathies, especially Hashimoto's thyroiditis. Other causes of adrenal failure present a difficult diagnosis in the ICU: overwhelming sepsis, hemorrhage secondary to trauma, circulating anticoagulants or anticoagulant therapy, tuberculosis, fungal disease, amyloidosis, acquired immune deficiency syndrome, antiphospholipid syndrome, infarction, irradiation, metastatic disease, and drugs [1–5]. Critical illness can cause or unmask adrenal insufficiency.

The most common cause of secondary adrenal insufficiency is suppression of corticotrophin (adrenocorticotrophic hormone [ACTH]) release by prior glucocorticoid therapy. ACTH regulates the maintenance of cells in the zona fasciculata and the synthesis and release of cortisol from these cells. Glucocorticoid therapy suppresses ACTH, thereby causing involution of the cortisol-producing cells. The anterior pituitary regains its ability to respond to stress before normal adrenal function is restored. There are no cutoffs on duration of glucocorticoid therapy, its route of administration, and its dosage that can cause adrenal cortical atrophy (zona fasciculata) and inadequate cortisol reserve. Adrenal suppression may occur in patients without obvious clinical signs of Cushing's syndrome. Symptoms of withdrawal mimic those of Addison's disease, such as weakness, lethargy, abdominal discomfort, arthralgias, myalgias, and weight loss. After short-term glucocorticoid treatment, symptoms may arise despite an intact hypothalamic-pituitary-adrenal axis by standard tests of adrenal reserve. These findings underscore the widespread and differential action of glucocorticoids in selected patients.

Pituitary dysfunction can also result in cortisol insufficiency, but not aldosterone lack. Noteworthy causes of impaired pituitary function are tumors in the region of the sella turcica and irradiation of the pituitary or hypothalamus.

Actions of Aldosterone and Cortisol

The adrenal cortex secretes aldosterone from the zona glomerulosa and cortisol from the zona fasciculata. Aldosterone promotes the reabsorption of sodium and the secretion of potassium and hydrogen in the renal tubule [6]. This mineralocorticoid is controlled mainly by the renin-angiotensin system; regulation of blood pressure is coordinated in the short term (angiotensin action on a membrane-bound receptor) and in the longer term (aldosterone, nuclear action on gene expression). Glucocorticoid suppression of ACTH, or primary ACTH loss, does not suppress aldosterone in the zona glomerulosa. Glucocorticoids promote gluconeogenesis and protein wasting and increase the secretion of free water by the kidney [7,8]. In large doses, cortisol binds to aldosterone receptors in the kidney, thereby increasing sodium reabsorption and potassium and hydrogen ion excretion. Glucocorticoids act on numerous tissues, including the central nervous system, and affect the sense of well-being, appetite, and mood. They inhibit ACTH release through hypothalamic and pituitary actions. Glucocorticoids have direct effects on the cardiovascular system and maintain blood pressure, although mechanisms are not established. Critical illness and glucocorticoid deficiency affect physiological systems in common.

Excess glucocorticoid therapy causes lymphopenia, leukocytosis, and eosinopenia [9], can lead to osteoporosis and reduction of hypercalcemia [10], and can impair host defenses to infectious diseases. These properties should be considered in the decision to treat ICU patients with glucocorticoids; the decision is not risk free.

Aldosterone deficiency results in sodium wasting, with concomitant loss of water and an increase in renal reabsorption of potassium. A decrease in plasma volume and dehydration occurs, with subsequent increases in blood urea nitrogen and plasma renin activity.

Reduction in circulating levels of cortisol causes a marked increase in circulating levels of ACTH and a corresponding increase in β-lipotropin, from which melanocyte-stimulating hormone activity increases; in longstanding adrenal insufficiency, the skin (especially creases and scars) develops hyperpigmentation [11]. Orthostatic hypotension can progress to frank shock in a crisis. Hypoglycemia and an increase in sensitivity to insulin are commonplace. Hyponatremia is a hallmark of aldosterone deficiency, but may also be found in cortisol deficiency. The mechanism for the latter may invoke increased sensitivity to vasopressin [12–14]; serum potassium levels would be normal.

DIAGNOSIS

Clinical manifestations that suggest adrenal insufficiency include a nonspecific history of progressive weakness, lassitude, fatigue, anorexia, vomiting, and constipation. Patients in adrenal crisis are volume depleted and hypotensive or in frank shock [15–18]. They often have fever and stupor or coma. As a precipitous event (adrenal hemorrhage, overwhelming infection, anticoagulant therapy, trauma, surgery), adrenal crisis lacks hyperpigmentation. Flank pain may be present in adrenal hemorrhage or infection. Severely ill patients are suspected of developing adrenal hypofunction, but actual incidence is not established, a conundrum in making the diagnosis of adrenal crisis. To further complicate recognition of adrenal dysfunction, glucocorticoid resistance has been postulated in critical illness.

In critical illness, the diagnosis of adrenal hypofunction is less apparent than it is in ambulatory medicine. Severe illness can interfere with the adrenal response to ACTH, making difficult interpretation of cortisol reserve and adrenal function. Lack of ACTH shares symptoms of primary glucocorticoid deficiency, in particular hypoglycemia. ACTH deficiency in pituitary disease generally occurs after deficiency in other pituitary hormones; deficits in overall pituitary secretion can lead to signs of other endocrine gland dysfunctions.

In primary adrenal insufficiency, plasma concentrations of cortisol are usually low or in the low normal range. Response to ACTH stimulation is inadequate and is the definitive test for a diagnosis of adrenal hypofunction. After administering 250 μg of cosyntropin (Cortrosyn; synthetic ACTH 1–24) intravenously to the patient, an adequate adrenal response shows a 10 μg increase of cortisol over baseline at 30 or 60 minutes, or a stimulated cortisol level >20 μg per dL.

The altered adrenal response to ACTH in critical illness limits its interpretation of standard stimulation tests. Recognition of the complexity of adrenal hypofunction has led to reconsideration of its diagnosis in the ICU. Serum-free cortisol measurement is shown to be more accurate than total serum cortisol in determining cortisol adequacy [19]. ICU patients often have hypoproteinemia. Most circulating cortisol is bound to protein. Changes in protein abundance or dynamics therefore affect interpretation of total cortisol measurements. A serum-free cortisol of <9 μg per dL is sufficient to initiate glucocorticoid replacement [20]. However, measurement of free cortisol is unavailable in most hospitals. A random total cortisol of <10 μg per dL is useful as a threshold for glucocorticoid therapy. It is a practical guideline, but not supported by extensive clinical study. The American College of Critical Care considers this recommendation to be weak with moderate quality of evidence [18]. The concept of situational adrenal insufficiency is an idea inchoate, but a threshold concentration of total cortisol provides a mark for intervention. The term *critical illness-related corticosteroid insufficiency* is preferred in assessing adrenal function in severe illness, because of the uncertainties in diagnosis.

Other diagnostic clues are useful in the diagnosis of adrenal crisis in ICU patients. Computed tomography scan can reveal adrenal hemorrhage or infiltration. Electrolytes vary, but hyponatremia is found in primary adrenal failure with hyperkalemia (sometimes not to a major degree) and in secondary adrenal failure without hyperkalemia. Hypoglycemia, elevated blood urea nitrogen, hypercalcemia, eosinophilia, lymphocytosis, and a normocytic, normochromic anemia are noted.

TREATMENT

The management of the hypoadrenalism has been vetted by a committee of international experts and the American College of Critical Care Medicine [18]. Recommendations have been provided as guidelines for the usefulness of glucocorticoid therapy in hypoadrenal function and critical illness (Fig. 104.1). There is agreement that hypoadrenalism needs to be treated. In critical illness in which primary adrenal function is suspected (e.g., evidence of hemorrhage), a bolus of 100 mg of hydrocortisone should be administered intravenously and then 100 mg over the next 24 hours. The patient ought to receive saline to maintain volume. After the initial therapy and stabilization of the patient, hydrocortisone can be decreased by 50% each day. Maintenance is 20 to 30 mg per day. Fludrocortisone 0.1 mg per day is started at the time of the maintenance glucocorticoid dose.

Dexamethasone can be used in place of initial hydrocortisone therapy if adrenal reserve of cortisol needs to be studied. Saline infusion is necessary with glucocorticoid administration. Fludrocortisone (because its main activity is regulation of gene transcription) does not act quickly; the saline will maintain circulating volume. Hydrocortisone has mineralocorticoid properties; dexamethasone does not.

In patients with functional adrenals, use of glucocorticoids in septic shock or early severe adult respiratory distress syndrome has not been established. A recommendation should be based on strong evidence of at least moderate quality. Few studies have sufficiently large subject groups for proper analysis. Intravenous hydrocortisone (50 mg q6 h) has been indicated in patients with septic shock [21]. A caveat is that the placebo-treated group had an unusually high mortality, which might have skewed the results to favor the treatment group. The study also promoted the use of fludrocortisones, a recommendation that was not explained.

The Corticosteroid Therapy of Septic Shock (CORTICUS) trial showed no effect of glucocorticoid treatment on outcome in shock [22]. Like Annane et al. 2002 [21], in CORTICUS subjects received either hydrocortisone 50 mg q6 h for 5 days or placebo. An important distinction in CORTICUS is that the placebo treatment group yielded a 32% mortality rate whereas glucocorticoid-treated subjects had a 35% mortality rate.

There is no ready explanation for the difference in placebo deaths, 73% in Annane et al. [21] compared with 32% in

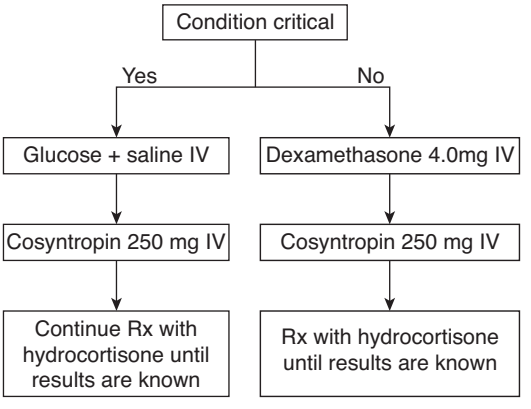

FIGURE 104.1. Management of suspected hypoadrenal crisis. IV, intravenously; Rx, treatment.

CORTICUS, except possibly the severity of shock in test subjects. Both trials were randomized and had seemingly sufficient subjects. Annane et al. [21] enrolled subjects in more severe shock than did the CORTICUS trial and started the glucocorticoid therapy sooner (8 hours vs. 72 hours, respectively). The difference in severity of shock might have accounted for the disparity in placebo mortality. Therefore, the trials do not have comparable study groups. Based on these studies that lack compelling, high-quality data, glucocorticoid therapy would not be expected to be effective in reducing mortality in subjects with less severe shock. In patients with severe shock, the evidence indicates (with caveats) that glucocorticoid therapy is useful if given early in the course of the shock. Rationale for fludrocortisone treatment is unclear and not established.

Studies on the use of mineralocorticoids (fludrocortisone), the rate of tapering of glucocorticoids in treated ICU patients, and duration of the use of glucocorticoids in septic shock and respiratory failure have weak evidence of moderate or low quality. High-dose methylprednisolone (continuous infusion; 1 mg per kg per day) might be useful in acute respiratory distress syndrome, but additional confirmation is needed. Offering definitive recommendations could be misleading in these settings. The compelling evidence, to date, is the use of glucocorticoids early in severe shock, data leading to a weak recommendation based on moderate-quality study.

GLUCOCORTICOID USE IN STRESSED PATIENTS ON GLUCOCORTICOID TREATMENT

General Principles

In healthy subjects, the secretion rate of cortisol increases from 10 mg per day to 50 to 150 mg per day during surgical procedures, but rarely exceeds 200 mg per day [17]. The degree of response depends, in part, on the extent and duration of surgery.

Historically, the withdrawal of chronic glucocorticoid therapy (and adrenal suppression) has been linked to the development of shock. Although in theory glucocorticoid withdrawal could lead to hypotension, documentation is sparse. Shock in the acutely ill or surgical patient on steroid therapy (or within 1 year of withdrawal) should not be attributed solely to decreased adrenal responsiveness. Adrenal glucocorticoids should be administered, but other causes of hypotension should be sought. Suppression of the hypothalamic-pituitary-adrenal axis can occur after only 5 days of glucocorticoid treatment and, after their long-term administration, the adrenal axis may respond inadequately to appropriate stimulation up to 1 year after glucocorticoid withdrawal. To emphasize, adrenal suppression cannot be predicted based on glucocorticoid dosage and duration, or the measurement of normal serum, basal cortisol [23].

Diagnosis and Treatment

Patients with high risk for adrenal suppression took pharmacologic or replacement doses of glucocorticoids for at least 4 weeks or stopped this treatment within the prior year. The cosyntropin test provides an assessment of adrenal cortisol reserve and estimates the adequacy of a stress response. A subnormal response (see earlier) predicts the need for supplemental glucocorticoids. For minor surgical procedures, the patient's usual dose of glucocorticoid is often sufficient, but a single dose of 25 mg hydrocortisone or its equivalent can be given. The glucocorticoid dose should be increased from 50 to 75 mg per day hydrocortisone (or equivalent) for 2 days in surgery of moderate severity and duration and to 150 mg hydrocortisone (or equivalent) for up to 3 days in the most severe surgery. Excessive glucocorticoid dosing can have untoward effects [24]; more is not necessarily better.

Hydrocortisone can be rapidly tapered and the patient returned to the usual dose of glucocorticoid, if needed.

TABLE: SUMMARY OF ADVANCES IN MANAGING HYPOADRENAL CRISIS

- Primary adrenal hypofunction in crisis (glucocorticoid and aldosterone insufficiency) presents with hypotension, fever, volume depletion, and often stupor and coma [13,25].
- The most common cause of secondary adrenal failure is glucocorticoid suppression, which can occur in as few as 5 days after prednisone treatment and last up to 1 year after chronic glucocorticoid withdrawal [26–28].
- Because cortisol is bound to corticosteroid-binding globulin and albumin, which is often reduced in critical care patients, interpretation of the cosyntropin stimulation test should consider the serum albumin concentration [19].
- Supplementation with glucocorticoid and mineralocorticoid improves survival in a subset of critically ill patients (renal failure, hypotension with poor response to pressor agents, lactic acidosis) who have documented inadequate cortisol response to cosyntropin [29].
- In patients with functional adrenals, use of glucocorticoids has not been established with high-quality data. Use of glucocorticoids early in severe shock might be useful [18,21].

CHAPTER 105 ■ DISORDERS OF MINERAL METABOLISM

SETH M. ARUM AND DANIEL T. BARAN

Disorders of mineral metabolism, although common, are rarely the primary cause of admission to an intensive care unit (ICU). However, these disorders frequently exacerbate life-threatening medical situations. Calcium, magnesium, and phosphorus are the main, clinically relevant minerals that can have an important impact on general health and on the course of a critical care admission. Calcium ions regulate membrane potentials, the coagulation cascade, neurotransmitter release, hormone-receptor interactions, and intercellular communication through channels and ion exchange. Magnesium is necessary for parathyroid hormone (PTH) secretion and maintenance of serum calcium, neuromuscular function, and membrane sodium-potassium adenosine triphosphatase (ATPase) activity. Phosphate, the major intracellular anion, is also instrumental for normal cellular function. It is a component of nucleic acids, phospholipids, and high-energy nucleotides and is necessary to facilitate oxygen delivery to cells. Phosphorus can also bind calcium in the body, and thus phosphorus metabolism is related to calcium and magnesium homeostasis. Therefore, symptoms of abnormal phosphorus metabolism often reflect the abnormalities in circulating calcium and magnesium. Calcium, magnesium, and phosphate balance are controlled through the interactions of PTH, 1α, 25-dihydroxyvitamin D (1,25 D), and calcitonin (CT).

CALCIUM DISORDERS

Calcium Physiology

Ninety-nine percent of total body calcium is stored in bone, whereas less than 1% is located in extracellular fluids. The calcium found in the extracellular fluids is either free (40%) or bound to albumin or other anions (60%) [1]. It is the free ionized calcium that is biologically active. Acid-base balance affects the binding of calcium to albumin. Hyperventilation, and the resultant respiratory alkalosis, enhances the binding of calcium to albumin, thereby acutely decreasing the ionized calcium and causing symptoms of hypocalcemia despite unchanged levels of total calcium. Similarly, changes in serum protein levels affect total serum calcium. The measured total calcium level in the serum can be corrected to account for changes in serum proteins by using the following formula:

$$\text{Corrected total calcium (mg/dL)} = \text{measured total calcium (mg/dL)} + (0.8 \times [4 - \text{measured albumin (g/dL)}])$$

Although the formula takes into account changes in serum proteins, it does not consider the impact of alterations in pH which frequently occur during acute illness. Measuring the ionized calcium directly is another option which should not be affected by either the serum proteins or the pH.

Calcium homeostasis is a function of absorption from the intestine (primarily the small intestine by active transport and facilitated diffusion), bone resorption/formation, and urinary excretion. The average diet contains 500 to 1,500 mg of calcium per day. In young individuals, the efficiency of intestinal absorption varies inversely with the amount of calcium ingested. Approximately 300 mg of calcium is exchanged daily between plasma and bone. Serum calcium is in equilibrium with intracellular calcium and calcium in bone and is filtered through the kidney. Urinary calcium excretion (normally 100 to 300 mg of calcium per day) depends on the glomerular filtration rate and the tubular sodium resorption. Loop diuretics enhance urinary calcium excretion in conjunction with their effect on sodium excretion. It is this property that serves as a useful adjunct to lower elevated serum calcium levels in the hydrated patient.

Hormonal Regulation of Calcium

Calcium absorption, excretion, and bone resorption/formation are in large part regulated by three hormones: PTH, 1,25 D, and CT.

Parathyroid Hormone

PTH is an 84-amino acid polypeptide produced and secreted by the chief cells of the parathyroid gland [1]. Secretion of PTH is stimulated by low levels of calcium in the cytoplasm of the parathyroid chief cells. The rapid release of PTH in response to hypocalcemia is essential for calcium homeostasis. The target organs for PTH are bone and kidneys. Chronic PTH secretion stimulates osteoclasts. This results in bone resorption and dissolution of hydroxyapatite crystals, resulting in the release of calcium and phosphate. This effect is augmented in the presence of 1,25 D. The renal effects of PTH include decreased proximal tubular reabsorption of phosphate (phosphate wasting), enhanced distal tubular calcium reabsorption (calcium retention), and increased renal mitochondrial 1α-hydroxylase activity (enhanced 1,25 D production). It is through the increased production of 1,25 D that PTH indirectly increases intestinal absorption of calcium.

Magnesium is mandatory for PTH secretion and end-organ response. Studies have shown that hypomagnesemia impairs PTH secretion and the renal response to PTH administration. Much of this seems reversible with magnesium repletion [2]. Clinically, correction of the hypocalcemia can often only be achieved after correcting the hypomagnesemia.

PTH can have both anabolic and catabolic effects on bone. Anabolic effects occur with intermittent administration of low-dose PTH [3]. In fact, daily subcutaneous injections of PTH derivatives have been shown to increase bone density and decrease fracture risk in various populations [4,5]. The catabolic, bone-resorptive effects of chronic PTH secretion are likely mediated through its effects on osteoprotegerin (OPG) and receptor activator of nuclear factor kappa ligand (RANK-ligand), resulting in increased osteoclast maturation and activity. Intermittent administration of PTH does not impact the OPG/RANK-ligand system as it does with constant administration, likely explaining the differing effects on bone mass [6].

Vitamin D

Vitamin D is a steroid hormone that is essential for calcium balance and is also likely important in numerous other cellular functions [7]. Activation of vitamin D requires 25-hydroxylation in the liver and 1-hydroxylation in the kidney to form the active hormone 1,25 D. Negative feedback is exerted by 1,25 D on its own production by suppressing 1-hydroxylase activity and stimulating the enzyme 24-hydroxylase to produce the biologically inactive steroids $24,25(OH)_2D$ and $1,24,25\ (OH)_3D$ [8].

The effects of 1,25 D are exerted through interactions with nuclear receptors located in a variety of cells, including enterocytes, parathyroid chief cells, osteoblasts, and renal tubular cells. 1,25 D increases intestinal absorption of calcium and phosphate. It has also been shown to suppress PTH gene expression as a negative feedback mechanism [8].

Calcitonin

CT is a 32-amino acid polypeptide produced by the C-cells of the thyroid [9]. It is secreted in response to elevations in serum calcium. It can also be stimulated by certain gastrointestinal (GI) tract hormones (e.g., gastrin). The primary physiologic function of CT in humans remains unclear. Medullary carcinoma of the thyroid is a malignant neoplasm of the C-cells and is characterized by elevated CT levels. However, calcium, phosphate, and PTH levels remain normal. Also, patients can have undetectable levels of CT after a thyroidectomy with no clear detrimental systemic effects.

Despite the lack of clinical consequences from endogenous CT excess or deficiency, exogenous CT is a potent inhibitor of bone resorption. It also acts on the kidneys to enhance excretion of calcium, phosphate, magnesium, and sodium [9]. Both of these mechanisms make CT useful in the treatment of hypercalcemia. The effect of CT on bone resorption is lost over time due to tachyphylaxis [9]. This phenomenon, possibly due to downregulation of CT receptors, is of clinical importance when treating patients with hypercalcemia. The excellent short-term effects of CT to lower serum calcium (within 12 to 48 hours) allow the institution of therapies that require several days to attain maximal effectiveness (e.g., bisphosphonates).

CT can also be used in the treatment of osteoporosis. The administration of a salmon CT nasal spray has been shown to decrease markers of bone turnover, increase bone mineral density at the spine, and decrease the risk of vertebral fractures in postmenopausal women with osteoporosis [10].

Hypercalcemia

Hypercalcemia is an abnormality of the balance between different body compartments and can result from increased bone resorption, decreased renal excretion, increased GI absorption, or any combination of these mechanisms.

The signs and symptoms of hypercalcemia are protean and can be divided into four groups: (a) mental, (b) neurologic and musculoskeletal, (c) GI and urologic, and (d) cardiovascular. The mental manifestations of hypercalcemia include stupor, obtundation, apathy, lethargy, confusion, disorientation, and coma. In general, for a given level of hypercalcemia, older patients exhibit more of the mental signs than younger patients. The neurologic and musculoskeletal effects of hypercalcemia are reduced muscle tone and strength, myalgias, and decreased deep tendon reflexes. The GI and urologic signs are vomiting, constipation, polyuria, and polydipsia. The major cardiovascular effect of hypercalcemia, which the intensive care physician must address, is shortening of the QT interval. In the presence of ventricular ectopic beats, the calcium-induced shortening of the QT interval increases the potential for fatal arrhythmias or asystole.

Differential Diagnosis

Elevated serum calcium measurements have been reported in approximately 1% of the general population [11]. The causes of hypercalcemia can be differentiated into two broad groups defined by whether or not the process is driven by abnormal parathyroid tissue. Hence, the groups are termed: (a) PTH-independent hypercalcemia; and (b) PTH-dependent hypercalcemia. In PTH-independent hypercalcemia, the hypercalcemia is not mediated by abnormal parathyroid tissue, and the PTH level should be appropriately suppressed. In PTH-dependent hypercalcemia, the process is driven by abnormal parathyroid tissue, and the PTH level should be elevated, or inappropriately normal.

PTH-independent hypercalcemia is more common in hospitalized patients. Hypercalcemia of malignancy is the most common cause of PTH-independent hypercalcemia. The malignancies most often associated with hypercalcemia include lung (35%), breast (25%), hematologic (myeloma and lymphoma [14%]), head and neck (6%), and renal (3%) [12]. The hypercalcemia can be mediated by secretion of parathyroid hormone–related peptide (PTH-RP), most commonly seen in squamous cell carcinomas (often lung or head and neck tumors); autonomous activation of 1,25 D (occasionally seen with lymphomas); or by lytic bone lesions/metastases [13]. See Chapter 116 for a complete discussion of the hypercalcemia of malignancy.

Other possible causes of PTH-independent hypercalcemia include granulomatous diseases, immobilization, milk-alkali syndrome, thyrotoxicosis, vitamin D or A intoxication, or Addison's disease.

Granulomatous diseases, such as sarcoidosis and tuberculosis, can cause hypercalcemia due to autonomous 1,25 D

production by the granulomas (similar to certain lymphomas). These patients have increased intestinal calcium absorption and sensitivity to vitamin D intake. Hypercalcemia occurs in 10% of patients, though hypercalciuria has been documented in as many as 20% [14].

Immobilization causes hypercalcemia as a result of decreased bone formation and persistent bone resorption. Hypercalcemia in the immobilized individual occurs most commonly in patients with high bone turnover (e.g., adolescents during the growth spurt or individuals with Paget's disease or thyrotoxicosis).

PTH-dependent hypercalcemia is much more common in the outpatient setting, though these patients can be hospitalized due to other issues. PTH-dependent hypercalcemia can be caused by primary or tertiary hyperparathyroidism. Another possible cause is familial hypocalciuric hypercalcemia (FHH). The routine measurement of serum calcium has altered the clinical presentation of hyperparathyroidism with most patients presenting with asymptomatic hypercalcemia.

Primary or tertiary hyperparathyroidism results from autonomous secretion of PTH despite elevated serum calcium levels. The latter occurs typically after chronic secondary hyperparathyroidism in the setting of end-stage renal failure. Hypercalcemia develops due to increased bone resorption, increased intestinal calcium absorption from stimulation of 1,25 D production, and increased renal tubular calcium reabsorption. The patient can be hypophosphatemic due to the phosphaturic effect of PTH. The hormone also induces renal bicarbonate wasting, resulting in a mild hyperchloremic acidosis. In primary hyperparathyroidism, a single adenoma is present in 80% to 85% of cases, whereas four-gland hyperplasia occurs in 15% to 20% of cases [15]. Parathyroid cancer is present in less than 1% of these patients and typically presents with much higher serum calcium levels [16].

Parathyroid hyperplasia or adenomas can also occur as part of the multiple endocrine neoplasia (MEN) syndromes. Type I MEN involves tumors of the pituitary, pancreas, and parathyroid (usually hyperplasia), whereas type II is associated with pheochromocytoma, medullary cancer of the thyroid, and primary hyperparathyroidism (hyperplasia or adenoma).

FHH is an autosomal dominant disorder characterized by hypercalcemia with inappropriately normal or elevated PTH levels. It is usually caused by a mutation in the calcium-sensing receptor gene [17]. In contrast to primary hyperparathyroidism, patients with FHH have relative hypocalciuria (fractional excretion of calcium <0.01), do not develop nephrolithiasis or bone disease, and cannot be cured surgically, unless rendered hypocalcemic by removal of all parathyroid tissue [18].

Several medications can induce hypercalcemia as well. Hypercalcemia associated with the use of thiazide diuretics is often an indicator of underlying primary hyperparathyroidism. Vitamins D and A intoxication can also cause hypercalcemia. Lithium may also affect parathyroid function and is associated with hypercalcemia and either elevated or inappropriately normal PTH levels [19].

Laboratory Evaluation

Hypercalcemia should always be considered in the patient with altered mental status. A total serum calcium level alone usually makes the diagnosis. However, altered binding of calcium to proteins, as can occur with hypoalbuminemia or with abnormal proteins (e.g., myeloma), or an acid–base imbalance may affect the free calcium level. Ionized calcium levels should not be affected by these issues. Because of the interrelationships of calcium, magnesium, and phosphorus, the latter two minerals should be measured in all cases involving altered calcium metabolism. An electrocardiogram to determine the QT interval is very important to assess the severity and urgency of the patient's hypercalcemia.

The differential diagnosis of the hypercalcemia can be narrowed down with a serum intact PTH measurement. If PTH levels are physiologically suppressed by the hypercalcemia, then PTH-independent sources should be sought, with malignancy being the most common. If malignancy is suspected, obtaining PTH-RP and 1,25 D levels can provide useful clues. In the absence of PTH, elevated 1,25 D levels imply autonomous production, most commonly associated with lymphomas and granulomatous diseases [13,14]. A bone scan may identify a metastatic process. Because myeloma is characterized by bone resorption with little bone formation, the bone scan is usually negative, but a skeletal survey may find lytic lesions. The diagnosis would then be confirmed by urine immunoelectrophoresis, serum protein electrophoresis, and bone marrow examination.

The diagnosis of milk-alkali syndrome is made by the patient's history, often revealing large quantities of calcium carbonate ingestion. In this instance, the patient should also be alkalotic with an elevated bicarbonate level. Thyrotoxicosis and Addison's disease can be ruled out with thyroid function tests and a Cortrosyn stimulation test, respectively (see Chapter 104 for a discussion about evaluating adrenal function in the critically ill). Vitamin D intoxication is quite rare, but the possibility can be eliminated by measuring 25-hydroxyvitamin D levels. Vitamin A levels can be measured if the diagnosis remains unclear.

If PTH-dependent hypercalcemia is confirmed with elevated or inappropriately normal PTH levels, a 24-hour urine for a fractional excretion of calcium can be done to differentiate primary or tertiary hyperparathyroidism from FHH, though this test may be altered by renal failure or the use of various diuretics.

Management

The aim of treatment of hypercalcemia is to minimize its effects on central nervous system (CNS), renal, and cardiovascular function. Appropriate treatment of hypercalcemia depends, in part, on the cause. General concepts in the management involve attempts to (a) increase renal calcium clearance, (b) decrease bone resorption, and (c) decrease intestinal calcium absorption. To this end, it is critical that the pathophysiology of the disease process be understood. If, for example, the hypercalcemia in a patient with myeloma is due to a combination of increased bone resorption plus decreased renal calcium clearance, successful management of the hypercalcemia requires that both processes be treated. Specific measures directed toward the pathophysiology of the hypercalcemia are discussed next.

Hydration and Diuresis. Saline hydration creates a diuresis that increases renal calcium excretion by decreasing calcium reabsorption in the proximal tubule. Hydration plays a critical role in the initial management of hypercalcemia because the onset of the therapeutic response is rapid. The aim of therapy is to achieve a urine output of 3 to 5 L per 24 hours. This often requires the administration of 200 to 500 mL per hour of normal saline [13]. Because a potential complication of administration of this amount of saline is congestive heart failure, extreme care must be taken in treating the patient with underlying cardiac disease or renal insufficiency. The concomitant administration of a loop diuretic helps prevent fluid overload and further increases renal calcium excretion by inhibiting distal tubular calcium reabsorption. Furosemide 20 to 40 mg can be administered by intravenous (IV) route once rehydration has been achieved. Measurement of serum electrolytes, phosphorus, and magnesium is mandatory during saline hydration to replace adequately the quantities lost in the urine. If renal or cardiac failure precludes the use of saline hydration, dialysis with a calcium-free dialysate is an effective alternative.

Calcitonin. CT reduces the resorption of calcium from bone by inhibiting osteoclasts. It also exerts transient effects to increase the renal excretion of calcium, along with sodium, potassium, magnesium, and phosphate. The benefits of CT in the treatment of hypercalcemia include (a) rapid onset within 2 hours, (b) maximal effect within 24 to 48 hours, and (c) low toxicity [9]. It can be used safely in patients with renal failure, and its side effects are limited to transient nausea, facial flushing, and occasional hypersensitivity at the injection site. The dose is 4 to 8 IU per kg body weight subcutaneously or intramuscularly every 12 hours [13]. Usually CT is effective for only 4 to 7 days [9], but it is still used for the rapid response, as bisphosphonates often require several days to attain maximal effectiveness.

Bisphosphonates. Bisphosphonates are organic compounds that are potent inhibitors of bone resorption through inhibition of osteoclastic activity and survival. Because of the delay in reduction of serum calcium with bisphosphonates, these agents are often used in conjunction with other therapies. Pamidronate can be infused intravenously as 60 or 90 mg over 2 hours with hydration. Zoledronate, at a dose of 4 mg intravenously over not less than 15 minutes, has been shown to be more effective at normalizing serum calcium in patients with hypercalcemia of malignancy [20]. Renal function must be monitored, and the doses of either medication may be repeated after a minimum of 7 days to allow a full response to the initial dose.

Denosumab. Denosumab is a monoclonal antibody directed against RANK-ligand, preventing the binding of RANK-ligand to osteoclasts, thereby inhibiting their development/activity and decreasing bone resorption [21]. This agent has recently been approved for the treatment of postmenopausal women with osteoporosis and has been shown to reduce the incidence of vertebral, non-vertebral, and hip fractures [21]. It has also been approved for the prevention of skeletal related events in patients with bone metastases from solid tumors [22]. It is also being studied in hypercalcemia of malignancy [23]. Therefore, this class of agents may prove to offer another treatment option for hypercalcemia of malignancy in the near future.

Hypocalcemia

Hypocalcemia is frequently encountered in critically ill patients. Although low serum albumin concentrations may explain some hypocalcemia, up to 18% of hospitalized patients and 85% of patients in ICUs were found to have hypocalcemia [24]. The symptoms of hypocalcemia can range from paresthesias and tetany to seizures or fatal laryngospasm. A positive Chvostek's sign (muscle spasm in response to tapping the facial nerve) is suggestive, but not diagnostic, of hypocalcemia. Trousseau's sign (carpal spasm precipitated by inflation of a blood pressure cuff above the systolic blood pressure) is more sensitive and specific. In contrast to the QT interval shortening in hypercalcemia, hypocalcemia is attended by an increase in the QT interval on the electrocardiogram, predisposing patients to cardiac arrhythmias. Chronic hypocalcemia is associated with basal ganglia calcification, cataract formation, and behavioral abnormalities [25].

Differential Diagnosis

Risk factors for the development of hypocalcemia in hospitalized patients include alkalosis, renal failure, and multiple transfusions. Although pancreatitis is associated with hypocalcemia, the mechanism is unclear. Hyperphosphatemia is the suspected cause of hypocalcemia attending tumor lysis and rhabdomyolysis.

Inadequate, or absent, PTH secretion is a cause of hypocalcemia. Hypoparathyroidism can occur after surgery, neck irradiation, as a result of iron deposition in hemochromatosis or thalassemia, or in severe magnesium deficiency [25]. Idiopathic hypoparathyroidism can be familial or sporadic. An autoimmune phenomenon may explain the idiopathic variety and may be found together with other autoimmune endocrine dysfunction. Target tissue unresponsiveness due to a defect in the cell membrane G protein is characterized by hypocalcemia and hyperphosphatemia in the presence of elevated PTH levels. This is commonly known as pseudohypoparathyroidism, and can be associated with somatic abnormalities (short, stocky habitus; round facies; and short metacarpals, metatarsals, or both).

Hypocalcemia can also signify vitamin D deficiency. Although nutritional rickets is rare in the United States, vitamin D deficiency is not [8]. Vitamin D deficiency may be the result of liver or renal failure with impaired hydroxylation of the parent compound, but is most often caused by inadequate sun exposure or malabsorption.

Laboratory Evaluation

A low corrected serum calcium or ionized calcium level confirms the diagnosis. Studies to discern the cause may include creatinine, phosphate, amylase, and magnesium levels; liver function tests; and 25-hydroxyvitamin D and PTH levels. In hypoparathyroidism due to the absence of PTH or target tissue unresponsiveness, serum phosphate levels tend to be high as a result of the absent phosphaturic effect of PTH.

Management

Treatment of hypocalcemia depends on its severity and chronicity. Symptomatic patients should be treated with IV calcium. A 10-mL vial of 10% calcium gluconate provides 93 mg of elemental calcium. One or two 10-mL vials should be administered in 100 mL 5% dextrose in water over 10 minutes. Calcium to be administered intravenously should always be diluted because concentrated solutions are very irritating to veins. Electrocardiographic monitoring during calcium supplementation is recommended as arrhythmias can occur from overcorrection. Often, the initial bolus needs to be followed by a continuous infusion which can be started with 10 vials of calcium gluconate in 1 L of 5% dextrose in water running at 50 mL per hour. This can then be adjusted to maintain the serum calcium levels in the lower portion of the normal range [24]. Hypocalcemia may mask digitalis toxicity. In these situations, a slower rate of calcium administration is recommended to prevent cardiac arrhythmias.

Oral supplementation should be instituted concurrently to provide 500 to 1,000 mg of elemental calcium three times daily. If calcium supplementation alone cannot maintain serum calcium levels, vitamin D preparations may be administered. Ergocalciferol (vitamin D_2) has a wide safety margin and relatively low cost. The usual dose is 25,000 to 100,000 IU daily. This preparation has a slow onset of action because it must be 25-hydroxylated in the liver and 1α-hydroxylated in the kidney. The preparation has a long half-life because it is stored in fat. Activated vitamin D preparations that act more rapidly are also available. Calcitriol is 1,25 D_3 and can be given as 0.25 to 1.0 μg, once or twice daily. This has a shorter half-life than vitamin D but is more potent. It can be used for long-term management but has a narrower therapeutic window [25].

The goal of treating hypocalcemia is to prevent symptoms attributable to low calcium and to avoid hypercalciuria and hypercalcemia. In a hypoparathyroid patient, total serum calcium should be maintained between 8.0 and 8.5 mg per dL. In the absence of PTH, circulating calcium levels greater than 9.0 mg per dL are often attended by hypercalciuria and an increased risk of nephrolithiasis or nephrocalcinosis. If hypercalciuria occurs despite lower serum calcium concentrations, thiazide diuretics can be used to try and enhance tubular reabsorption of calcium [25].

MAGNESIUM DISORDERS

Magnesium Physiology

Magnesium is the major intracellular divalent cation. Two-thirds of the total body content of magnesium is found in bone and only 2% is found in the extracellular space. Muscle and liver are the soft tissues that contain the greatest amount of magnesium. Thirty percent of extracellular magnesium circulates bound to protein [1]. Therefore, as with circulating calcium levels, albumin concentration must be known to interpret total magnesium levels. Magnesium absorption occurs throughout the small intestine. Absorption is enhanced by 1,25 D. Like calcium, magnesium is reabsorbed in the kidney tubules.

Magnesium is necessary for normal sodium- and potassium-activated ATPase, PTH secretion, and neuromuscular function. Decreased sodium- and potassium-activated ATPase due to hypomagnesemia can result in intracellular potassium depletion [26]. Magnesium-induced decreases in PTH secretion result in hypocalcemia that can only be corrected by magnesium replacement. Magnesium inhibits the release of acetylcholine by presynaptic fibers and decreases the sensitivity of the motor end plate to the neurotransmitter. Therefore, hypomagnesemia is often attended by CNS hyperexcitability, whereas hypermagnesemia results in CNS depression.

Hypermagnesemia

Hypermagnesemia is often attended by a loss of deep tendon reflexes and CNS depression. Flaccid paralysis, hypotension, confusion, and coma may result from magnesium levels greater than 6 mg per dL [26]. The most common cause of hypermagnesemia in the hospitalized patient is renal failure. The hypermagnesemia may be aggravated by the administration of magnesium-containing antacids. Diabetic ketoacidosis is usually attended by hypermagnesemia, but this typically reflects dehydration, which masks the total body magnesium depletion resulting from the glucose-induced osmotic diuresis.

Management

The actions of magnesium on neuromuscular function are antagonized by calcium. Emergency treatment of the magnesium-induced CNS depression includes IV administration of one to two 10-mL vials of calcium gluconate diluted in 100 mL 5% dextrose in water over 5 to 10 minutes to prevent venous irritation [26]. The dose may be repeated as necessary. Total serum calcium must be monitored and not allowed to exceed 11 mg per dL.

Definitive treatment of the hypermagnesemia requires increasing renal magnesium excretion. In the presence of normal renal function, increased magnesium excretion can be achieved by IV administration of furosemide, 20 to 40 mg IV, every 1 to 2 hours, along with fluid hydration, though there is little literature to support its use [26]. Serum electrolytes, particularly potassium, must be closely monitored. Dialysis is the treatment of choice when kidney function is impaired and the patient is symptomatic from the hypermagnesemia.

Hypomagnesemia

Hypomagnesemia is much more common than hypermagnesemia in the hospitalized patient [1]. The increased CNS excitability in the patient with hypomagnesemia is partly due to the accompanying hypocalcemia, which results from impaired PTH secretion and decreased peripheral tissue responsiveness to PTH. The intracellular potassium depletion seen with hypomagnesemia can also exacerbate digitalis toxicity.

Hypomagnesemia may result from decreased intestinal absorption (e.g., steatorrhea), or more commonly from increased renal excretion due to an osmotic diuresis (e.g., hyperglycemia), or drugs (e.g., ethanol, aminoglycosides, or cisplatin). Dietary deficiency alone is rarely the explanation for hypomagnesemia. The exceptions are starvation or prolonged parenteral feeding [26].

The drugs that most commonly increase renal magnesium excretion are alcohol and diuretics. Hypomagnesemia in the alcohol abuser may also be partly attributable to dietary deficiency. Hypomagnesemia is encountered in 30% of alcoholics [26].

Management

Magnesium may be administered orally or parenterally. If serum magnesium levels are below 1 mg per dL, or if the patient is symptomatic, parenteral treatment is indicated. The patient with symptoms usually has a total body magnesium deficit of 1 to 3 mEq per kg body weight. Because approximately half of the administered magnesium is lost due to renal excretion, replacement of the deficit requires administration of 2 to 6 mEq per kg body weight. It is recommended to give 8 to 12 g of magnesium sulfate over the first 24 hours followed by 4 to 6 g per day for 3 to 4 days to replete body stores [26]. Serum magnesium and calcium levels should be monitored. The dose should be reduced by 75% in patients with renal failure.

In the patient with mild magnesium deficiency, oral therapy is usually satisfactory. Magnesium oxide 400 mg (241 mg of elemental magnesium) can be given as 1 to 2 tablets daily. Diarrhea is the most common side effect. As with all magnesium supplementation, levels must be monitored closely in the patient with renal insufficiency.

PHOSPHORUS DISORDERS

Phosphorus Physiology

Eighty-five percent of total body phosphorus is found in bone [1]. Extracellular phosphate accounts for only 1% of total body phosphorus. Because of shifts in phosphate between intracellular and extracellular compartments, serum phosphate levels do not accurately reflect total body stores. For example, because acidosis causes a shift in phosphate from within cells to the extracellular compartment, serum phosphate levels may be normal in the acidotic patient despite depletion of total body stores [27]. As the acidosis is corrected, serum phosphate levels may fall.

Phosphorus is a component of nucleic acids and phospholipids and is a cofactor for a number of enzymes. Low phosphate levels increase renal 1α-hydroxylase activity and 1,25 D production, whereas high phosphate levels suppress its production [1]. Thus, phosphorus metabolism is closely related to calcium and magnesium metabolism.

Hyperphosphatemia

Increased phosphate levels are most often encountered in patients with renal failure or hypoparathyroidism. Both of these conditions result in impaired phosphate excretion. Hyperphosphatemia can also be seen from cellular leaks as in hemolysis, rhabdomyolysis, or the tumor lysis syndrome. The hyperphosphatemia, along with diminished renal 1,25 D production,

results in hypocalcemia. The symptoms are usually attributable to the accompanying hypocalcemia, and not the hyperphosphatemia per se [27]. Therefore, in the symptomatic patient, therapy should be directed at correction of the hypocalcemia.

Chronic management of hyperphosphatemia can be accomplished with limiting phosphate intake as well as using phosphate binders, such as calcium acetate 667 mg, 2 tablets with meals or sevelamer 800 mg, 1 to 2 tablets with meals [27].

Hypophosphatemia

Hypophosphatemia can be seen in up to 3% of hospitalized patients or 34% of patients in the ICU [28]. It can result from impaired intestinal phosphate absorption or increased renal phosphate excretion. The cause of hypophosphatemia in alcoholics is often multifactorial but most likely reflects malnutrition and the accompanying vomiting. When taken in excess, phosphate-binding antacids impair phosphate absorption. The resulting hypophosphatemia can stimulate 1,25 D production and cause hypercalcemia, which has been confused with hyperparathyroidism.

Renal phosphate excretion is increased in hyperparathyroidism, vitamin D deficiency, and with osmotic diuresis. There are also rare genetic and paraneoplastic conditions that cause excess phosphate excretion due to excess "phosphatonins" such as fibroblast growth factor 23 [1]. PTH inhibits renal tubular phosphate reabsorption, resulting in hypophosphatemia when secreted in excess. Serum phosphate levels are reduced in vitamin D deficiency due to impaired intestinal phosphate absorption and increased renal phosphate excretion (the result of secondary hyperparathyroidism in response to the associated hypocalcemia). The patient in diabetic ketoacidosis has a total body phosphorus deficit, despite normal serum phosphorus levels. In the early stages of the illness, the rising serum glucose levels cause an osmotic diuresis with increased renal phosphate loss. However, the developing acidosis causes a shift in phosphorus from the intracellular to the extracellular compartment. This shift, along with the accompanying volume depletion, tends to normalize the serum phosphorus levels. Rehydration and insulin treatment with resolution of the acidosis may cause a rapid fall in serum phosphorus levels.

The potential consequences of severe hypophosphatemia are impaired oxygen delivery to the tissues due to decreased 2,3-diphosphoglycerate levels, muscle weakness, and rhabdomyolysis. The latter is most likely to occur when severe hypophosphatemia occurs after prolonged mild hypophosphatemia (e.g., in the hospitalized alcoholic in whom phosphate level falls precipitously during carbohydrate administration).

Management

Severe hypophosphatemia (<1.5 mg per dL) requires parenteral therapy [27]. Potassium phosphate or sodium phosphate can be used depending on the patient's potassium level. Fifteen mmol may be added to 5% dextrose in water and given intravenously over 2 hours [28]. Further treatment depends on the serum phosphate levels and clinical condition. The dose may be repeated up to three times in the first 24 hours until phosphate levels normalize.

Parenteral therapy should be limited in the patient with renal failure or hypocalcemia. In the patient with renal failure, IV therapy can cause hyperphosphatemia, worsen hypocalcemia, and cause metastatic calcification, primarily in the kidney. The latter can occur if the patient is hypercalcemic or if the phosphate is administered too rapidly. Initial doses should be 50% lower if the patient is under renal failure or hypercalcemic [27].

Oral preparations of potassium phosphate (K-Phos Neutral) can be used for milder hypophosphatemia or for chronic management. The usual oral dose is 1 to 4 g per day in divided doses. The most common side effect is diarrhea.

CHAPTER 106 ■ HYPOGLYCEMIA

JOHN P. MORDES, MICHAEL J. THOMPSON, DAVID M. HARLAN AND SAMIR MALKANI

Hypoglycemia occurs often in the intensive care unit (ICU) as both an admission diagnosis and a consequence of therapy. In a 2001 study of intensive insulin therapy in a surgical ICU population, hypoglycemia occurred in up to 5.1% of patients [1]. Another study of more than 2,200 ICU patients reported that nearly 7% experienced at least one episode of hypoglycemia [2]. Estimates of prevalence range as high as 25% [3]. Hypoglycemia is a marker of poor outcome in hospitalized patients in general [4–6], and among the critically ill in particular [7,8]. Severe, prolonged hypoglycemia can cause permanent neurological and cardiovascular damage.

DEFINITION OF HYPOGLYCEMIA

No specific blood glucose concentration defines hypoglycemia. Whipple proposed a symptom-based definition of hypoglycemia in the 1930s that remains valid [9]. "Whipple's triad" defines hypoglycemia as (a) documentation of a low blood glucose concentration, (b) concurrent symptoms of hypoglycemia, and (c) resolution of symptoms after administration of glucose. Typically, this concentration in serum is less than 50 mg per dL (2.8 mM). The physiologic definition is a blood glucose concentration low enough to cause the release of counterregulatory hormones (e.g., catecholamines) and impair the function of the central nervous system (CNS).

SYMPTOMS AND SIGNS OF HYPOGLYCEMIA

Counterregulatory hormones released in response to low glucose concentrations cause sympathoadrenal symptoms and signs. Prominent symptoms include hunger, tingling, shakiness, weakness, palpitations, and anxiety [10]. Corresponding signs include diaphoresis, tachycardia, peripheral vasoconstriction, and widening of the pulse pressure. These findings may be absent in patients receiving sympatholytic drugs (e.g., beta-blockers) and in patients with diabetes who have autonomic neuropathy.

Early symptoms and signs of neuroglycopenia include difficulty thinking and sensations of warmth, weakness, and fatigue. These may be followed by confusion, slurred speech, and other nonspecific behavioral changes [10]. Severe neuroglycopenia can cause disturbances of integrative function, obtundation, seizures, coma, and, rarely, a permanent vegetative state.

Hypoglycemia can be associated with acute pulmonary edema [11], supraventricular and ventricular tachycardias, atrial fibrillation, and junctional dysrhythmias [12–14]. Electrocardiographic abnormalities associated with hypoglycemia include T wave flattening, increased Q-T interval, ST segment depression, and repolarization abnormalities [15–17]. Bradycardias have also been attributed to hypoglycemia, but only rarely [18]. Prolonged hypoglycemia can be associated with hypothermia [19–21], respiratory failure [22], and hypokalemia and hypophosphatemia [23].

NORMAL GLUCOSE REGULATORY PHYSIOLOGY

Glucose Utilization

Plasma glucose concentration is maintained in a narrow range (~60 to ~120 mg per dL; ~3.3 to ~6.7 mmol). The organ most dependent on glucose is the brain, which consumes ~150 g per day. Unlike fat or muscle, the CNS does not require insulin for glucose transport. During starvation, the brain uses ketone bodies as a substitute fuel (see Chapter 100), but acquisition of the capability to use this alternate substrate requires hours to days. Even during prolonged starvation, the brain still needs ~44 g per day of glucose. Other tissues with obligate glucose needs include erythrocytes (~36 g per day) and renal medulla (~25 g per day).

Sources of Plasma Glucose

There are two sources of blood glucose: endogenous and ingested carbohydrate. In the postprandial state, the concentration of circulating insulin rises in response to the increase in glucose concentration. The insulin promotes (a) transport of glucose into skeletal muscle for immediate use or storage as muscle glycogen and (b) hepatic storage of glucose in the form of liver glycogen. When all other metabolic demands for glucose are being met, some excess glucose is used for synthesis of triglyceride.

During brief starvation, such as when asleep, the principal source of glucose is hepatic glycogen. During prolonged starvation, glucose is derived principally from conversion of muscle-derived amino acids. Smaller contributions to gluconeogenesis are made by (a) glycerol derived from fat and (b) lactate produced by anaerobic glycolysis. When euglycemia is maintained by glycogenolysis or gluconeogenesis, insulin levels are low but never zero.

The liver stores only 60 to 80 g of glycogen, a supply that is exhausted by an overnight fast. Muscle glycogen stores are ~120 g, but this glycogen is not directly available for the maintenance of systemic glucose concentrations due to the lack of glucose-6-phosphatase in muscle. Muscle glycogen contributes to plasma glucose only via anaerobic glycolysis, leading to the production of lactate, which is transported to the liver and converted into glucose. The shuttling of glucose to muscle and lactate to the liver comprises the Cori cycle. Muscle can also amidate pyruvate to form alanine, which is then exported to the liver and converted to glucose. Gluconeogenesis occurs principally in the liver using amino acids, glycerol, and lactate as substrates. The enzymes and pathways required for gluconeogenesis are shown in Figure 106.1.

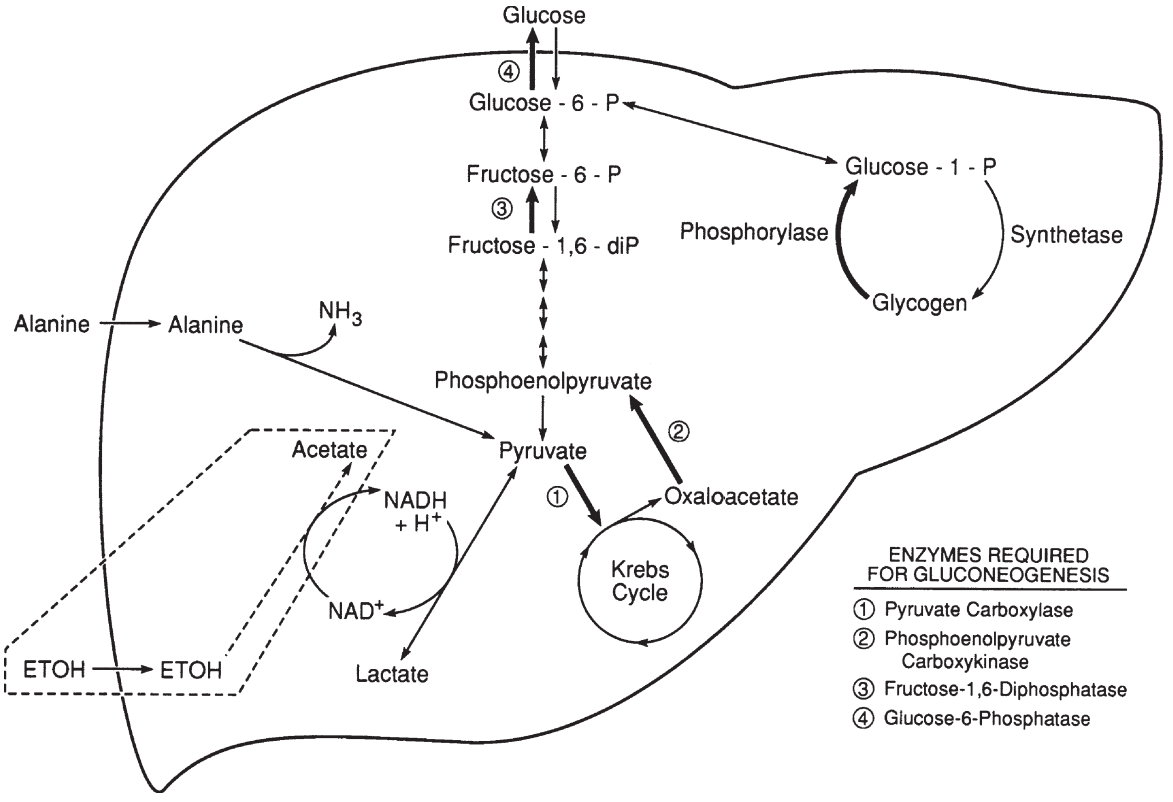

FIGURE 106.1. Metabolic pathways important in the response to hypoglycemia. The thick, annotated arrows indicate the key steps in glycogen breakdown and gluconeogenesis. In the presence of low circulating insulin concentrations, phosphorylase activity is increased, leading to the release of glucose-1-phosphate, which is then converted to glucose-6-phosphate and finally to glucose through the action of glucose-6-phosphatase. Glucose is also generated from three carbon precursors by gluconeogenesis. This process essentially reverses glycolysis and is controlled by four enzymes: (**1**) pyruvate carboxylase, (**2**) phosphoenolpyruvate carboxykinase, (**3**) fructose-1,6-diphosphatase, and (**4**) glucose-6-phosphatase. Within the box delimited by dotted lines, the metabolic effects of ethanol ingestion are indicated. Ethanol is converted to acetaldehyde and then to acetate, producing reduced nicotinamide adenine dinucleotide (NADH). The high concentration of NADH favors the generation of lactate from pyruvate, decreasing the concentration of the latter. As the availability of pyruvate as a gluconeogenic precursor declines, glucose production via gluconeogenesis also declines, and hypoglycemia can ensue.

Hormonal Regulation of Plasma Glucose Concentration

Insulin is the most important regulator of glycemia, promoting glucose uptake and storage in the fed state, and regulating glycogenolysis, gluconeogenesis, and lipolysis in the fasted state. Glucagon, glucocorticoids, catecholamines, growth hormone, and, to a lesser degree, thyroxine promote the formation of glucose in the fasted state and in general counteract the actions of insulin. Foremost among these "counterregulatory" hormones is glucagon, which is secreted in response to low glucose. It promotes both glycogenolysis (an immediate effect) and gluconeogenesis (a delayed but more enduring effect). Glucocorticoids antagonize the action of insulin, stimulating gluconeogenesis and inhibiting extrahepatic glucose utilization. Catecholamines also promote glycogenolysis and gluconeogenesis. The mechanism by which growth hormone promotes blood glucose elevation is not fully understood. The influence of thyroxine on blood glucose concentration is probably indirect. Fasting glucose tends to be elevated and decreased in hyperthyroid and hypothyroid patients, respectively. Absence of liver glycogen has been observed in hyperthyroid animals [24].

CLASSIFICATION OF HYPOGLYCEMIA

Hypoglycemia can be classified as fasting (or postabsorptive) or postprandial (or "reactive"). The former always represents a major health problem that requires further evaluation. Hypoglycemia that occurs only after eating can be more difficult to assess. It is usually minimally symptomatic and is attributed variously to exaggerated insulin response, renal glycosuria, defects in glucagon responses, and high insulin sensitivity [25,26]. Some cases of postprandial hypoglycemia, however, are severe and associated with health issues including mutations in the insulin receptor [27], autoantibodies against insulin [28], gastric "dumping" after bypass surgery, and nesidioblastosis, all of which are described later. Postprandial hypoglycemia generally does not require intensive care.

DIFFERENTIAL DIAGNOSIS OF HYPOGLYCEMIA

Hypoglycemia that fulfills Whipple's triad always implies a major disturbance in glucose homeostasis, which is dependent on

three factors: (a) the hormonal milieu, (b) the viability of organs responsible for gluconeogenesis, and (c) availability of substrate for conversion to glucose. The differential diagnosis of medically important hypoglycemia subsumes three corresponding categories: (a) states of hormonal imbalance, principally excess insulin, (b) states of impaired endogenous glucose production, and (c) states in which gluconeogenic substrates are unavailable.

Hypoglycemia Due to Hormonal Imbalance

Insulin

Insulin Overdoses in Diabetic Patients. Insulin overdose is the most common cause of hypoglycemia. In an outpatient setting, it is frequently the result of a missed meal or an increased amount of exercise and less often the result of inadvertent injection of short acting in place of long-acting insulin. Occasionally, an overdose is intentional, particularly among adolescents. Rarely, overdoses represent attempts at suicide and homicide [29]. The rapidity of onset [30] and duration of hypoglycemia [31] depend on the type of insulin (see Table 106.1).

Hypoglycemia is often more severe among patients with long-standing type 1 diabetes due to the presence of a defective counterregulatory response and hypoglycemia unawareness. Impaired glucagon and epinephrine responses are common [32]. When counterregulation is impaired, adrenergic warning signals like tremor, diaphoresis, and tachycardia may not occur and neuroglycopenic symptoms can develop rapidly. The phenomenon is sometimes described as hypoglycemia-associated autonomic failure [33]. Inadequate counterregulatory responses can also delay recovery from hypoglycemia.

Hypoglycemia in ICU patients can result from rapid changes in clinical status, medications that impair counterregulation (e.g., high-dose β-adrenergic blockers), and the presence of intercurrent disease processes. Although insulin-induced hypoglycemia is easily diagnosed in the ICU, it is crucial to determine exactly why it occurred.

Intensive insulin management is demanding [34]; occasionally, insulin is administered either in the wrong dose or in response to a factitiously elevated blood glucose measurement or to the wrong patient. Even the most careful attempts to lower blood glucose in the ICU to levels less than 110 mg per dL can frequently be associated with hypoglycemia [35–39]. Failure to adjust insulin infusion rate after decreasing nutritional support is common [2]. Total parenteral nutrition solutions containing insulin can produce hypoglycemia [3], particularly if improvement in a patient's underlying condition leads to reduced peripheral insulin resistance. Insulin-induced hypoglycemia in the ICU can be related to adrenal insufficiency, renal failure, sepsis or drug toxicity, continuous venovenous hemofiltration with bicarbonate replacement fluid, and need for inotropic support [3].

Intentional Insulin and Oral Hypoglycemic Agent Overdoses in Nondiabetic Patients. "Factitious" hypoglycemia should be suspected in anyone with access to insulin or oral hypoglycemic agents, including healthcare workers and relatives of persons with diabetes. The diagnosis can be difficult. These patients are trying to frustrate rather than facilitate a diagnosis, and they may devise ingenious methods to conceal their actions. Insulin intended for surreptitious injection has been found hidden in electronic devices and body cavities. Surreptitious use of oral hypoglycemic agents, which act by increasing endogenous insulin secretion, can be particularly problematic to diagnose [40,41]. Factitious hypoglycemia can represent malingering, attempted suicide or homicide, Münchausen syndrome, and Münchausen-by-proxy syndrome [29]. It has also been reported to result from adulteration of herbal and counterfeit prescription drugs with oral agents [42,43].

Insulinoma. Insulinomas are insulin-secreting pancreatic islet tumors. They are uncommon but do represent the most common form of pancreatic islet neoplasm. Most (>90%) are nonmalignant. They are typically small and difficult to visualize radiographically. To evaluate a patient with suspected

TABLE 106.1

INSULIN PREPARATIONS

Class	Preparation	Onset of action	Peak	Duration
Short-acting				
	Aspart (NovoLog™)[a]	15 min	45–90 min	3–5 h
	Glulisine (Apidra™)[a]	15 min	50–60 min	~ 4 h
	Lispro (Humalog™)[a]	15–30 min	30 min–2.5 h	3–6 h
	Regular (Humulin R™, Novolin R™)	30–60 min	1–5 h	5–10 h
Intermediate-acting				
	NPH (Humulin N™, Novolin N™)	1–2 h	4–14 h	16–24 h
Long-acting				
	Glargine (Lantus™)[a]	1.5–5 h	No peak	18 to >24 h[b]
	Detemir (Levemir™)[a]	1 h	No peak	Up to 24 h
Combinations				
	70% NPH, 30% Regular (Humulin 70/30™, Novolin 70/30™)	30 min	4–8 h	24 h
	75% Protamine lispro, 25% lispro[a]	15 min	1.5 h	10–16 h
	70% Protamine aspart, 30% aspart[a]	15 min	1.5 h	10–16 h
	50% Protamine lispro, 50% lispro[a]	15 min	1.5 h	10–16 h

Notes: Data are for recombinant human insulin or semisynthetic insulin administered subcutaneously. Protamine lispro and protamine aspart insulins are available only in fixed-ratio combinations.
[a] Semisynthetic insulin.
[b] Study ended at 24 h. Trade names are given in parentheses. Additional semisynthetic insulins are under development.

insulinoma, fasting immunoreactive insulin (IRI; measured in microunits [μU] per milliliter) and glucose (milligrams per deciliter) should be obtained. Insulinoma is usually associated with an IRI/glucose ratio >0.3. Elevated levels of C-peptide and proinsulin help confirm the diagnosis by documenting that the source of insulin is endogenous. Proinsulin is typically elevated up to 25% of the insulin concentration in cases of insulinoma [44].

It can be difficult to differentiate among insulinoma, factitious hypoglycemia due to self-administration of insulin, and abuse of oral hypoglycemic agents. When intentional insulin overdose is suspected, insulin measurements are of limited value. Patients with factitious hypoglycemia may have circulating anti-insulin antibodies that interfere with the radioimmunoassay for insulin. This is true even if human insulin is injected. These patients may appear to have elevated levels of insulin, just as would patients with an insulinoma. In this circumstance, simultaneous glucose, insulin, and C-peptide concentrations are helpful. Insulin and C-peptide are normally cosecreted by the pancreas in equimolar quantities, but the latter is not present in insulin for injection. Absence of C-peptide in a patient with unexplained fasting hypoglycemia strengthens the possibility of surreptitious use of insulin. If oral hypoglycemic agent abuse is suspected, both serum and urine should be screened.

Nonislet Tumors that Secrete Insulin. Rarely, complex endocrine tumors may secrete insulin [45]. Hypoglycemia due to ectopic secretion of insulin by nonendocrine tumors is very rare [46–49].

Nesidioblastosis or Persistent Hyperinsulinemic Hypoglycemia (PHH). Nesidioblastosis (nonmalignant islet cell hyperplasia) is a rare form of nonmalignant islet cell adenomatosis that leads to insulin-mediated hypoglycemia. In infants, nesidioblastosis is typically characterized by islet hyperplasia, β-cell hypertrophy, and increased β-cell mass. It can be either diffuse or focal and is sometimes termed persistent hyperinsulinemic hypoglycemia of infancy (PHHI) [50–53]. Rapid diagnosis of the childhood form is crucial to avoid hypoglycemic damage to the maturing CNS. Several different genetic mutations have been associated with the disorder cases [51,52,54–57]. Special cases of hyperinsulinemic hypoglycemia in infancy include Costello syndrome [58] and the Beckwith–Wiedemann syndrome, which is due to defects in pancreatic β-cell potassium channels [59].

A small number of cases of adult nesidioblastosis have been reported [51,60,61]. The pathological findings are reportedly less consistent than in infants [62], and the cause is unknown. Additional cases of PHH have been diagnosed in adults who had previously undergone Roux-en-Y gastric bypass surgery for weight reduction [63]. Whether these cases represent nesidioblastosis [63,64], "dumping syndrome," or a reactive process leading to or unmasking a defect in β-cell function [65] is unclear, perhaps in part because the pathological diagnosis of nesidioblastosis is difficult [62]. Treatment options include diazoxide, streptozocin, calcium channel blockade [66], octreotide (discussed later), percutaneous gastrostomy into the remnant stomach [67], as well as partial pancreatectomy [64].

Antibody-Mediated ("Autoimmune") Hypoglycemia. Autoimmune hypoglycemia can result from autoantibodies directed against insulin itself or autoantibodies directed against the insulin receptor [68]. Both can occur in either insulin-treated [69] or nondiabetic individuals, and both types of autoantibodies can be found in the same patient [70]. About 90% of cases have been reported from Japan [71]. Serum insulin concentrations typically are extremely high, usually higher than those produced by insulinomas. It is assumed that in these cases, glucose administration causes excessive insulin response because the antibodies buffer most of the insulin secreted [72].

Endogenous antibodies that bind to and activate the insulin receptor can also cause hypoglycemia [73]. Some, but not all cases, are associated with other autoimmune disorders [74–76], and a few have occurred in patients with myeloma [77]. Previous exposure to exogenous insulin is not necessary, but some patients may have an abnormal insulin molecule [78]. Metformin may be helpful in the management of some cases [79]. Some cases respond to immunosuppressive therapy [73]. The natural history of this syndrome is that the antireceptor antibodies disappear and the syndrome resolves over a time course of months to years [28].

Pancreas and Islet Transplantation. Hypoglycemia can occur after pancreas and islet transplantation [80], but it is generally not a significant clinical problem [81,82]. Islet transplantation has been reported to resolve hypoglycemia unawareness [83]. There is a report of nesidioblastosis-like transformation of a successful pancreas allograft [84].

Nonislet Tumors with Insulin-Like Activity. Certain tumors not of pancreatic islet origin are associated with fasting hypoglycemia clinically indistinguishable from that caused by islet cell neoplasms. Whereas insulinomas are typically quite small, nonpancreatic neoplasms associated with hypoglycemia tend to be large mesenchymal tumors. The large size initially suggested that excessive glucose utilization by the tumor was the cause of the hypoglycemia, but subsequent studies suggest that most cases result from secretion of high-molecular-weight insulin-like growth factor II (pro-IGF-II or "big IGF-II") [85,86]. Pro-IGF-II levels decrease significantly and hypoglycemia resolves after successful tumor resection [87–92]. Abnormal processing of the IGF-II molecule may play a role in some cases [88,90,93]. Nonislet cell neoplasms associated with hypoglycemia include gastrointestinal stromal cell tumors [94], hemangiopericytoma [95–97], hepatoma [98,99], uterine tumors [100], renal tumors [101], mesenteric sarcomas [102], colorectal cancer [103], gastric cancer [104], adrenocortical carcinoma, lymphoma, poorly differentiated thyroid cancer [105], somatostatinoma [106], phylloides tumor [107], and leukemia [108]. Multiple myeloma may also cause hypoglycemia via an antibody-mediated mechanism described later [76].

The diagnosis of hypoglycemia due to production of pro-IGF-II by nonislet cell tumors requires the exclusion of insulinoma. As noted earlier, this can be done by obtaining simultaneous insulin and glucose measurements during hypoglycemia. The observation of increased blood glucose concentration after intravenous administration of glucagon, an index of adequate glycogen stores, may also help discriminate between insulin and IGF-secreting tumors [109]. Methods have been developed for measuring serum pro-insulin-like growth factor-II directly [86]. Hypoglycemia associated with high levels of IGF-I has rarely been reported [110].

Hypoglycemia Due to Noninsulin Hypoglycemic Agents

Pharmaceuticals other than insulin that are used to treat type 2 diabetes fall into two classes. "Hypoglycemic agents" enhance insulin secretion and can cause hyperinsulinemic hypoglycemia. The sulfonylureas and meglitinides belong to this class; all are taken orally. "Antidiabetic agents" promote normoglycemia through mechanisms other than enhancement of insulin secretion; they include both oral and injectable agents. When given as monotherapy they do not cause hypoglycemia, but they can amplify the glucose-lowering activity of insulin

TABLE 106.2

ORAL HYPOGLYCEMIC AGENTS

	Usual total daily dose (mg)	Half-life (h)	Duration of action (h)
First-generation sulfonylureas			
Acetohexamide (Dymelor™)	500–750	0.8–2.4	12–24
Chlorpropamide (Diabinese™)	250–375	25–60	24–72
Tolazamide (Tolinase™)	250–500	5–11	14–16
Tolbutamide (Orinase™)	1,000–2,000	4–25	6–12
Second- and third-generation sulfonylureas			
Glimepiride (Amaryl™)	1–4	2–8	12–24
Glipizide (Glucotrol™)	10–20	1.1–3.7	12–24
Glyburide (DiaBeta™, Glynase™, Micronase™)	3–20	0.7–3.0	12–24
Other insulin secretagogues			
Nateglinide (Starlix™)	180–360	1.5	<4
Repaglinide (Prandin™)	1.5–16	1	4

Notes: Oral hypoglycemic agents available in the United States. Glipizide is also known as glibenclamide. Gliclazide and gliquidone are second-generation sulfonylureas available outside the United States. Overdoses with any of these drugs can cause hypoglycemia. Some trade names are given in parentheses.

and oral hypoglycemic agents. The thiazolidinediones (TZDs), biguanides, α-glucosidase inhibitors, glistens, and bromocriptine mesylate (Cycloset™) are oral antidiabetic agents. Exenatide, liraglutide, and pramlintide are injectable antidiabetic agents. As discussed later, many drugs not used in the treatment of diabetes can also amplify the glucose-lowering activity of oral hypoglycemic agents, and a complete medication history can be critical in the diagnosis of hypoglycemia.

Sulfonylureas. After insulin, these are the most common cause of hypoglycemia [111] (Tables 106.2 and 106.3). Sulfonylureas reduce serum glucose by increasing insulin secretion, inhibiting glycogenolysis and gluconeogenesis, and enhancing the response of target tissues to the effects of insulin [112]. Severe hypoglycemia is not common with appropriate administration of these drugs [113], but it can be observed in several contexts [114]. In all age groups, the condition is most often observed in the context of decreased carbohydrate intake. Maternal treatment of diabetes with glyburide can lead to postpartum hypoglycemia in neonates [115]. In patients between the ages of 11 and 30 years, perhaps two-thirds of hypoglycemic comas are due to sulfonylurea agents [41]. Half of these cases are suicide attempts [111]. In patients with type 2 diabetes older than 60 years, sulfonylurea-induced hypoglycemia is a frequent complication [114,116].

Liver disease decreases the clearance of tolbutamide, acetohexamide, tolazamide, glipizide, glyburide, and glimepiride (Table 106.2). Metabolites of sulfonylureas are excreted in urine with one exception; 50% of glyburide metabolites are excreted in bile. Accordingly, sulfonylurea-induced hypoglycemia is often observed in older individuals in the setting of acute or chronic starvation superimposed on mild to moderate liver or renal failure.

The half-life of some sulfonylureas is >24 hours and the duration of action is often even longer (Table 106.1). Hepatic and renal insufficiency can extend their half-lives. Patients with sulfonylurea-induced hypoglycemia should therefore be hospitalized after initial resuscitation with glucose. They require continued treatment with oral and intravenous glucose for a minimum of 18 to 24 hours.

When oral agent overdosage is suspected, serum and urine should be screened for sulfonylurea compounds. Sulfonylurea drugs circulate bound to proteins, and drugs of several classes can displace sulfonylureas and enhance their hypoglycemic effect (Table 106.3). The constellation of insulin concentration $\geq$3.9 μU per mL, C-peptide $\geq$1.4 ng per mL, and glucose <49 mg per dL may be helpful in diagnosing sulfonylurea-induced hypoglycemia [40].

Repaglinide and Nateglinide. Repaglinide (Prandin™) and nateglinide (Starlix™) belong to a different class of oral hypoglycemic agents (Table 106.1). Like the sulfonylureas, they increase endogenous insulin secretion but do so by a different mechanism. They appear to be associated with fewer episodes of hypoglycemia than are sulfonylureas. Both are rapidly eliminated. Surreptitious use of repaglinide has been reported [117].

Antidiabetic Agents. Biguanides, when given as monotherapy, induce hypoglycemia much less often than do sulfonylureas [118,119], probably by inhibiting gluconeogenesis. Metformin is the only biguanide currently available in the United States. It is also available in combination with the oral hypoglycemic agents glyburide (Glucovance™), glipizide (Metaglip™), and repaglinide (PrandiMet™); overdosage with these combination drugs can cause severe hypoglycemia. Thiazolidinediones and gliptins are also available in fixed ratio combinations with metformin; some of these have been associated with hypoglycemia.

Drugs of the thiazolidinedione class, including pioglitazone (Actos™) and rosiglitazone (Avandia™) in the United States, do not cause hypoglycemia when used as monotherapy but can potentiate hypoglycemia caused by insulin or sulfonylureas. They act by increasing insulin sensitivity.

Acarbose (Precose™) and miglitol (Glyset™) are α-glucosidase inhibitors that inhibit the digestion of complex carbohydrates; they have not been reported to cause hypoglycemia when used as monotherapy. Patients treated with insulin or sulfonylureas in addition to acarbose who experience hypoglycemia may not respond to the oral administration of complex sugars, but should respond to monomeric glucose.

TABLE 106.3

DRUGS AND TOXINS ASSOCIATED WITH HYPOGLYCEMIA

Agents that increase circulating insulin	Agents that impair gluconeogenesis	Uncertain or other mechanisms of action	
Direct stimulants of insulin secretion	*Hepatotoxins*	ACE inhibitors	Haloperidol [223]
Oral hypoglycemic agents (Table 106.2)	Acetaminophen (Tylenol™, Tempra™)	Acetazolamide (Diamox™)	Halothane
β_2-Adrenergic agonists (e.g., Albuterol™ [225])	Propoxyphene (Darvon™)	Aspirin	Herbal extracts
Calcium	Amanitotoxin	Aluminum hydroxide (Dialume™)	Imatinib (Gleevec™) [224]
Chloroquine (Aralen™)	*Inhibition of gluconeogenesis*	Anabolic steroids	Indomethacin
Cibenzoline	Akee fruit	Azapropazone	Interferon-α
Disopyramide (Norpace™)	Ethanol	Chlorpromazine (Thorazine™)	Isoxsuprine
Quinidine	Metformin	Cimetidine	Lidocaine
Quinine	Metoprolol (Lopressor™)	Ciprofloxacin, gatifloxacin, clinafloxacin	Lithium
Ritodrine (Yutopar™)	Nadolol (Corgard™)	Clofibrate	Mefloquine
Terbutaline	Phenformin	Dandelions [217]	Nefazodone
Trimethoprim/sulfamethoxazole (Bactrim™) [141,142]	Pindolol (Visken™)	Dexmedetomidine [218]	NSAIDs
Destruction of β cells with insulin release	Propranolol (Inderal™)	Diphenhydramine	Orphenadrine
Pentamidine (Pentam™)		Doxepin (Sinequan™, Adapin™)	Oxytetracycline
Streptozotocin		"Ecstasy" (MDMA) [219]	Para-aminobenzoic acid
Agents that enhance the action of oral agents		Enflurane Formestane	Para-aminosalicylic acid
Clarithromycin [226]		Ethylenediaminetetraacetic acid (Versene™)	Perhexiline
Imipramine (Tofranil™)		Etanercept [220,221]	Phenytoin (Dilantin™)
NSAIDs		Etomidate [222]	Ranitidine (Zantac™)
Phenylbutazone (Butazolidin™)		Fenoterol	Salicylates
Salicylates		Fluoxetine	Selegiline
Sulfonamides			Sulfadiazine
Warfarin (Coumadin™)			Sulfisoxazole (Gantrisin™)
			Valproate

Notes: A sampling of common trade names is shown in parentheses; the enumeration of trade names is not exhaustive. Data for some listed agents is very limited or anecdotal or involved treatment with more than one drug. Drugs for which better documentation is available are indicated in bold italic.
ACE, angiotensin-converting enzyme; MDMA, methylenedioxymethamphetamine; NSAIDs, nonsteroid anti-inflammatory drugs.
Adapted from Seltzer [111], Marks and Teale [29], and Murad et al. [124].

Exenatide (Byetta™) and liraglutide (Victoza™) are injectable mimetics of gut incretins [120,121]. They augment glucose-dependent insulin secretion and reduce postprandial glucagon secretion. When given with a sulfonylurea, they can cause hypoglycemia. Gliptins are inhibitors of the enzyme dipeptidyl peptidase-4. They inhibit the degradation of endogenous gut incretins and have glucose lowering effects similar to those of exenatide. Drugs in this class include sitagliptin (Januvia™) and saxagliptin (Onglyza™). Pramlintide (Symlin™) is a mimetic of the islet hormone amylin [121]. It suppresses postmeal glucagon secretion and delays gastric emptying. It is targeted at controlling postmeal hyperglycemia in diabetic patients who are also taking insulin. Like exenatide, it has been associated with hypoglycemia.

Bromocriptine is an oral dopamine agonist that is used in the treatment of pituitary tumors and Parkinson's disease. A micronized formulation (Cycloset™) is approved for treating type 2 diabetes [122]. Its mechanism of action is unclear. It has not been reported to cause hypoglycemia, but experience with the drug is limited.

Medication Errors. Severe hypoglycemia can result from inadvertent substitution of an oral hypoglycemic agent for a different medication. Medication errors due to phonetic similarity in name are exemplified by cases in which acetazolamide (Diamox™) has been prescribed but acetohexamide (Dymelor™) inadvertently dispensed [111,123]. Examples of such substitution errors are listed in Table 106.4.

Other Drugs and Poisons That Cause Hypoglycemia

Hundreds of drugs and toxins have been reported to cause or predispose to hypoglycemia (Table 106.3). For some, like ethanol, the association is well documented and the mechanism well understood. For most, however, the evidence supporting an association is poor and the mechanism of action is unknown. Some are based only on a single case report. In some instances, drug–drug interactions may be amplifying the hypoglycemic

TABLE 106.4

MEDICATION ERRORS THAT CAN RESULT IN HYPOGLYCEMIA

Prescribed medication	Dispensed medication
Acetazolamide (Diamox)	Acetohexamide (Dymelor)
Chlorpromazine	Chlorpropamide
Chloroquine	Chlorpropamide
Dyazide	Dymelor
Dialume	Diabinese
Tolectin	Tolinase
Diamox	Diabinese

effect of concurrently administered oral hypoglycemic agents. In other instances, the data are contaminated by intercurrent sepsis or other disease. Few rechallenge data to support the association are available. An analysis of the quality of the evidence implicating many drugs as the cause of hypoglycemia is available [124]. Some drugs with stronger supporting evidence are indicated in Table 106.3.

Ethanol-Induced Hypoglycemia (Alcoholic Ketoacidosis)

Ethanol-induced hypoglycemia is most often observed in children and chronic alcohol abusers. The most common history is binge drinking in the setting of poor intake of other dietary carbohydrates. Patients usually present in a stuporous or comatose state; nausea, vomiting, and abdominal pain are common. Ethanol concentration is typically low, and alcoholic hypoglycemia can occur up to 30 hours after the ingestion of alcoholic beverages. Blood glucose as low as 5 mg per dL has been recorded. Ketonuria and ketonemia are frequently present and reflect the appropriately low circulating insulin concentration [125].

Ethanol causes hypoglycemia by suppressing hepatic gluconeogenesis. Glycogenolysis is not affected. When ethanol is oxidized to acetaldehyde and acetate, NAD^+ is reduced to NADH. The reduced NAD^+:NADH ratio produces an unfavorable intracellular environment for the oxidation of substrates of gluconeogenesis such as lactate and glutamate to pyruvate and α-ketoglutarate, respectively (Fig. 106.1). As a result, intracellular levels of pyruvate are below the Michaelis constant (Km) of pyruvate carboxylase, one of the rate-limiting steps in gluconeogenesis. Ethanol also inhibits hepatic uptake of the gluconeogenic precursors glycerol, alanine, and lactate and inhibits the release of alanine from muscle [126].

Management consists of rehydration with intravenous fluids and glucose to correct hypoglycemia. Parenteral thiamine (100 mg) should be given to prevent Wernicke's encephalopathy. Treatment with glucose and fluids rapidly reverses the condition and sodium bicarbonate is generally unnecessary.

β-Adrenergic Receptor Antagonists

The nonselective beta-blockers propranolol, pindolol, and nadolol reportedly predispose to hypoglycemia in diverse clinical settings. Both diabetic and nondiabetic patients undergoing hemodialysis are susceptible. Neonates may also have hypoglycemia during their first 24 hours of life as a result of propranolol treatment of the mother for cardiac arrhythmias, hypertension, or thyrotoxicosis. Hypoglycemia in infants treated with propranolol for cyanotic heart disease or neonatal thyrotoxicosis has also been reported. These drugs increase the risk of hypoglycemia in patients who are undernourished or who have liver disease [126] and occasionally when administered prior to cardiac surgery [111,127].

Antiarrhythmic Agents

Quinidine can enhance insulin secretion and produce hypoglycemia in ill, fasting patients [128]. Hypoglycemia has been reported in patients treated with disopyramide, an antiarrhythmic agent with pharmacologic properties similar to those of quinidine [129,130]. In neither case is supporting evidence strong. The investigational antiarrhythmic cibenzoline is more convincingly associated with hypoglycemia [131].

Antibiotics

There is evidence [124] that pentamidine, used to treat *Pneumocystis carinii* infection, can be toxic to pancreatic β cells, causing transient hypoglycemia due to the release of stored insulin. It eventually results in diabetes in some patients [111]. Similarly, quinine, chemically related to quinidine, is known to elevate insulin concentrations in patients being treated for malaria [132,133]. Those with cerebral malaria are most prone to hypoglycemia, possibly due to the high intake of glucose by malarial parasites, coupled with the increased insulin release. Quinine may rarely cause hypoglycemia in normal individuals [134].

Gatifloxacin (Tequin™) [135–138], levofloxacin (Levaquin™) [135], ciprofloxacin (Cipro™) [139,140], and other fluoroquinolones reportedly cause hypoglycemia, particularly when administered to patients who are also receiving sulfonylureas. Gatifloxacin may carry the highest risk of hypoglycemia, yet paradoxically some patients treated with this drug also experience new onset of hyperglycemia [135]. Trimethoprim/sulfamethoxazole has also been reported to cause hyperinsulinemic hypoglycemia in the setting of malnutrition and infection, renal failure [141], and oral hypoglycemic therapy [142].

Salicylates

Salicylate intoxication reportedly causes hypoglycemia occasionally in children but only very rarely in adults [111,143]. In children, it may be a component of aspirin-associated Reye's syndrome [144]. The frequency of salicylate-induced hypoglycemia is difficult to ascertain due to intercurrent acidosis and renal or hepatic impairment in many cases of intoxication.

Angiotensin-Converting Enzyme Inhibitors

Cases of hypoglycemia associated with angiotensin-converting enzyme inhibitors have been reported in persons with both types 1 and 2 diabetes [145–148], but the quality of the evidence is low [124]. No mechanism for the effect has been identified, and a retrospective analysis of nearly 14,000 persons with diabetes failed to identify an increased risk of hypoglycemia associated with this class of drugs [149].

Poisons

Several plant substances can cause hypoglycemia. Hypoglycin A toxin is found in akee fruit, a staple of the Jamaican diet. The ripe fruit is edible, but immature fruit causes vomiting a few days after ingestion. Affected patients have severe hypoglycemia due to inhibition of hepatic gluconeogenesis by hypoglycin [150]. Amanita toxins produced by the mushroom *Amanita phalloides* are inhibitors of RNA polymerase and cause hepatocellular necrosis. Fatal hypoglycemia can result from the ensuing complete depletion of hepatic glycogen and decreased capacity for gluconeogenesis [126].

Hypoglycemia Associated with Deficiencies in Counterregulatory Hormones

Glucocorticoid insufficiency can cause hypoglycemia in children by decreasing glycogenolysis and gluconeogenesis. In adults, it causes hypoglycemia uncommonly [151]. Malnutrition may contribute to the development of hypoglycemia in these cases. Patients with panhypopituitarism are prone to hypoglycemia and have increased sensitivity to insulin [151]. Although catecholamines play a significant role in preventing and reversing hypoglycemia, their absence does not commonly predispose to hypoglycemia. Adrenalectomized patients with sympathetic denervation due to spinal cord transection maintain euglycemia. Glucagon deficiency may very rarely cause hypoglycemia.

Fasting Hypoglycemia Due to Inadequate Production of Endogenous Glucose

Liver Damage

About 90% of gluconeogenesis occurs in the liver. Hepatic injury can cause hypoglycemia but only when the insult is very severe; only about 20% of normal liver biosynthetic capability is needed to maintain normal glucose homeostasis [152]. Hypoglycemia seldom occurs in the setting of isolated, limited hepatic failure and is not the cause of hepatic coma [126]. Hypoglycemia due to toxic or infectious hepatitis is rare but does occur when the disorder is fulminant. Hepatotoxins that can impair gluconeogenesis and cause hypoglycemia include carbon tetrachloride, the *A. phalloides* mushroom toxin, and urethane. Drugs that cause hypoglycemia by inducing hepatocellular necrosis include acetaminophen, isoniazid, sodium valproate, methyldopa, tetracycline, and halothane [126]. Neither tests of hepatocellular integrity (e.g., transaminases) nor tests of hepatic function (e.g., bilirubin concentration) nor the presence of structural damage (e.g., cirrhosis, chronic active hepatitis, and metastatic liver disease) correlate well with the capability of the liver to maintain normoglycemia.

Congestive heart failure (CHF) from any cause can lead to hepatic congestion and hypoglycemia in adults and children. Patients with this syndrome usually have severe failure with cardiac cachexia, malnutrition, and muscle wasting. The mechanism by which CHF leads to hypoglycemia is not completely understood. Changes in hepatic blood flow may alter the delivery of gluconeogenic precursors or changes in intracellular redox state may decrease the gluconeogenic capacity of the hepatocyte. Hypoglycemia in this setting resolves with successful treatment of the CHF [126].

Renal Damage

Some patients with diabetes develop improved glucose tolerance with the onset of renal failure. A decrease in insulin requirements and more frequent episodes of hypoglycemia may also occur [153]. There is no correlation between degree of renal failure and severity of hypoglycemia in these patients, and the underlying mechanisms are not completely understood. Investigators variously implicate delayed insulin clearance, deficiencies in the delivery of gluconeogenic substrate [151], and hepatic insufficiency secondary to uremia [154].

Symptomatic hypoglycemia occurs in many diabetic patients receiving either hemodialysis or ambulatory peritoneal dialysis [155,156]. Any dialysis patient who experiences a change in mental status should be evaluated for hypoglycemia. The symptoms and signs of neuroglycopenia resemble those of the dialysis disequilibrium syndrome commonly induced by fluid shifts. These include fatigue, confusion, lethargy, and even coma. Postdialysis hypoglycemia in diabetic patients, if prolonged, can be fatal [157].

Spontaneous fasting hypoglycemia has also been reported to occur in nondiabetic patients with end-stage renal disease [158–160]. It is not clear, however, whether these rare cases represent a distinct clinical entity [161] or instances of renal failure enhancing intercurrent disorders that predispose to hypoglycemia [162]. These might include drug ingestion, liver disease, and adrenal or pituitary insufficiency.

Fasting Hypoglycemia Due to the Unavailability of Gluconeogenic Substrate

Substrate deficiency leads to hypoglycemia in ketotic hypoglycemia of childhood [163]. Patients with this condition, a variant of the normal response to starvation, are usually diagnosed between 18 months and 5 years of age. The hallmark of the condition is a low basal concentration of the gluconeogenic precursor alanine, and the hypoglycemia can be corrected with either glucose or alanine.

Other Causes of Hypoglycemia

Sepsis

Sepsis has occasionally been implicated as a cause of hypoglycemia [164–167]. Shock and liver failure were intercurrent problems in some cases [165]. Under conditions of decreased hepatic reserve, the combination of circulatory failure and impairment of gluconeogenesis by endotoxin may lead to hypoglycemia. Septic hypoglycemic patients are often acidotic, and the fatality rate is high [164,165]. In one report, only 1 of 15 such patients survived 1 month after the onset of hypoglycemia and hypotension [165].

Congenital Disorders

The commonest cause of neonatal hypoglycemia is maternal diabetes [168]. Congenital enzyme deficiencies and other abnormalities in the function of specific enzymes typically produce hypoglycemia in the context of glycogen storage disease, impaired hepatic gluconeogenesis, or respiratory chain defects [169]. Mutations of the sulfonylurea receptor can also cause this disorder [55]. These uncommon conditions usually present as hypoglycemia in infancy, but they can rarely present as unexplained persistent hypoglycemia in a critically ill adult [70,170]. The pediatric disorders are reviewed elsewhere [52,53].

Exercise-Induced Hypoglycemia

Exercise-induced hyperinsulinemic hypoglycemia is an autosomal-dominant hyperinsulinemia syndrome [171]. The cause appears to be failure of β-cell–specific transcriptional silencing of a gene, monocarboxylate transporter 1, important in pyruvate stimulated insulin release [172].

LABORATORY DIAGNOSIS OF HYPOGLYCEMIA

Normal Blood Glucose Concentration

Normal plasma glucose is 60 to 120 mg per dL (3.3 to 6.7 mmol). Whole blood glucose concentrations are 15% to 20% lower. Fingerstick blood glucose determinations are performed on whole capillary blood, and most meters reflect this offset. Symptoms of hypoglycemia generally occur when plasma glucose is <50 mg per dL (2.8 mmol) or the whole blood glucose concentration is <40 mg per dL (2.2 mmol). Calibrated hospital-quality glucose meter technology is accurate over a wide range of concentrations; values between 40 and 350 mg per dL generally agree well with values obtained using standard laboratory methods. Glucose meters for home use can be less accurate [173]. Because fingerstick blood glucose determinations can be less accurate at the lower end of their scale, they may require confirmation by a clinical laboratory. Interpretation of fingerstick glucose should take into account the clinical context, symptoms, and response to glucose administration. They can be misleading in patients who are hypoperfused [174,175], in shock [176], or undergoing cardiopulmonary resuscitation [177]. Certain meter technologies

are inaccurate in the presence of various interfering substances [178,179].

There are several physiologic exceptions to guideline values for diagnosing hypoglycemia in very ill patients. After about 48 hours of starvation, many individuals, particularly women, have a plasma glucose concentration <50 mg per dL (2.8 mmol). After 72 hours of fasting, the plasma glucose may approach 40 mg per dL (2.2 mmol). Starved individuals are nonetheless asymptomatic, do not fulfill Whipple's triad, and are not physiologically or clinically hypoglycemic. The absence of symptoms is due to the shift to ketones for CNS metabolism. Comparably low plasma glucose, 60 mg per dL (3.3 mmol) or less, is also encountered in pregnancy. Again, there are no symptoms of hypoglycemia per se in these cases. Finally, rare individuals may have an anomalously low "set point" for blood glucose concentration, and such individuals appear asymptomatic in the face of persistent glycemia in the range of 35 to 45 mg per dL [180].

Spurious Hypoglycemia

This term applies to glucose concentrations that are reported to be low but come from a normoglycemic patient. This most commonly occurs as a result of storing blood samples at room temperature for long periods before laboratory analysis. As a result of anaerobic glycolysis by blood elements, the actual glucose concentration in the test tube may decline. The effect is enhanced if large numbers of white blood cells are present in the sample as a result of severe leukocytosis or leukemia [181].

Spurious Hyperglycemia Leading to Insulin Overdose

Falsely elevated glucose readings can lead to inappropriate insulin administration and hypoglycemia. The commonest cause of spurious hyperglycemia in the ICU is measurement of glucose in blood obtained from an extremity into which glucose is being infused. An uncommon cause of hypoglycemia in the ICU results from a "drug–device interaction" affecting patients receiving parenteral nutrition products containing maltose or galactose. These products cause certain monitoring systems to give falsely elevated glucose readings leading to inappropriate insulin treatment [178].

Testing for Ketonuria

Urinary ketone testing can facilitate the differential diagnosis of hypoglycemia. Normally, fasting is associated with low circulating insulin that promotes gluconeogenesis and lipolysis. Hypoglycemia in association with ketonuria enhances the likelihood that the cause is not excess insulin.

Other Studies

In addition to glucose and urinary ketones, additional tests should be ordered as appropriate to the patient's underlying medical condition. In general, these should always include studies of hepatic and renal function. Additional serum and plasma samples from any comatose, hypoglycemic patient, when they are first seen, should be obtained. This permits assays for medications, IRI/glucose ratios, proinsulin, and C-peptide to be performed later, if indicated. Testing for oral hypoglycemic agents requires sophisticated laboratory methods, and it is recommended that laboratory personnel be consulted to ensure that appropriate specimens (urine, blood, or both) are ordered. A cosyntropin (Cortrosyn™) test should be performed if adrenal insufficiency is suspected.

MANAGEMENT OF HYPOGLYCEMIA

Initial Management with Glucose

When symptomatic hypoglycemia is suspected, remember Whipple's triad. After fingerstick glucose determination, the treatment is glucose administration, and the diagnostic outcome is resolution of symptoms. It is important to document the presence of hypoglycemia before giving glucose. Most patients with depressed mental status are not hypoglycemic [182] (Table 106.5).

The practice of giving intravenous glucose empirically assumes that it could be useful and is always harmless [183]. This belief has been called into question. In cases of stroke, in particular ischemic stroke, hyperglycemia may be predictive of poor outcome [184,185], and empiric use of hypertonic dextrose has been discouraged by many authors [177,182,186,187]. In addition, even in those cases in which empiric glucose appears to be resuscitative, there is no way to back-calculate what might have been the antecedent glucose concentration [188]. In the hospital, treatment of hypoglycemia is with intravenous D-glucose (dextrose) if a patient is unresponsive or might aspirate, but if a patient is alert and cooperative, oral carbohydrate (e.g., sucrose in orange juice or glucose tablets or gel) is preferable.

In general, all comatose patients, including trauma patients, should undergo fingerstick glucose determination, and the threshold for administration of intravenous glucose in addition to standard life-support measures should be low. Treatment with glucose is lifesaving in the presence of hypoglycemic coma. Early responders recognize that altered mental status due to hypoglycemia is sometimes the root cause of an accident [189].

The initial treatment of hypoglycemia in the patient with stupor or coma has traditionally consisted of the intravenous injection of 50 mL of 50% dextrose in water ($D_{50}W$) over 3 to 5 minutes. Care must be taken to avoid subcutaneous extravasation; the solution is hypertonic and can cause local tissue damage and severe pain. Alternatively, 10% dextrose delivered in 5 g (50 mL) aliquots can be equally efficacious and results in lower posttreatment blood glucose levels [190]. If hypoglycemia is present, treatment with glucose usually leads to improved mental status within minutes. It is difficult, however, to predict the magnitude of the glucose response to a bolus of intravenous glucose [187], and elderly patients and patients with very prolonged hypoglycemia may have a delayed response.

Subsequent Management

Glucose

The prompt improvement that usually occurs in hypoglycemic patients treated with intravenous glucose can be misleading. When hypoglycemia occurs in a diabetic patient taking insulin, no additional treatment may be needed, but there are many other causes of hypoglycemia. The initial bolus of glucose treats the symptoms of hypoglycemia but *not their cause*. The most common error in the management of hypoglycemia is inadequate treatment leading to recurrence of symptoms.

After the first bolus of $D_{50}W$, an infusion of D_5W or $D_{10}W$ glucose should be started in any patient whose hypoglycemic episode is not clearly due simply to excess short- or intermediate-acting insulin. The choice of D_5W or $D_{10}W$ glucose depends on the severity of the initial hypoglycemia. This infusion allows the critical care physician to evaluate the cause

TABLE 106.5

HYPOGLYCEMIA: DIAGNOSIS, MANAGEMENT, EVIDENCE

Recommendation	Comments
Suspect hypoglycemia in all cases of altered mental status	Hypoglycemia is a very common reversible cause of altered mental status.
Be aware that intensive therapy with insulin infusions carries a risk of hypoglycemia	Attempting to lower blood glucose in the ICU to levels <110 mg/dL is frequently associated with hypoglycemia [35–39]. (See Chapter 100 on Diabetes Management.)
Always determine blood glucose concentration before administering glucose	Most patients with altered mental status are not hypoglycemic [182] and empiric glucose administration should not be assumed to be completely risk free [177,182,184–186].
Consider 10% dextrose rather than 50% dextrose	D_{10} W can be as efficacious as D_{50} W while lessening the risk of subsequent hyperglycemia [190].
Fingerstick glucose concentrations can at times be misleading	Measurements from an extremity in which glucose is being infused or in the setting of shock [176], CPR [177], and parenteral nutrition products containing maltose or galactose [227] may be inaccurate.
Suspect overdose of an antidiabetic medication when unexplained hypoglycemia is encountered in the ICU	Medication errors are common in hospitals [228]. Hypoglycemia is commonly caused by overdosage with exogenous insulin and overdosage with oral hypoglycemic agents that enhance endogenous insulin secretion.
If hypoglycemia is thought to be due to a drug not used to treat diabetes, evaluate the case thoughtfully	Many medications reportedly cause hypoglycemia (Table 106.3), but evidence supporting the association is often poor [124]. Hypoglycemia may be due to a drug–drug interaction, and discontinuation of a suspect medication may not always be appropriate.
When treating refractory hypoglycemia always exclude adrenal insufficiency	Cortisol is an important glucose-counterregulatory hormone and renal insufficiency predisposes to hypoglycemia in persons being treated for diabetes.
The role of continuous glucose monitoring in the ICU is promising but still investigational	Continuous monitoring of glucose concentration holds out the promise of enhanced detection and reduced frequency of hypoglycemia in the ICU setting. How this technology will affect glycemic control [215] or the management of neonatal hypoglycemia [214] remains to be determined, and studies to validate its use in the setting of intercurrent illness are at an early stage [216].

Key elements in the diagnosis and management of hypoglycemia in the intensive care unit (ICU). CPR, cardiopulmonary resuscitation.

of the hypoglycemic episode while protecting the patient from recurrence. An appropriate target glucose concentration is 100 mg per dL (5.6 mM). It is advisable not to overtreat with glucose, especially in the case of oral hypoglycemic agent poisoning. Extremely high serum glucose may stimulate endogenous insulin secretion, causing rebound hyperinsulinemia and recurrent hypoglycemia [191].

Hypoglycemia Due to Long-Acting Insulin

If long-acting insulin (Table 106.1) might have caused the hypoglycemic episode, continuation of the glucose infusion, fingerstick blood glucose testing, and periodic adjustment of the infusion rate may be required. The duration of therapy depends on the particular insulin preparation and the dose taken. Massive insulin overdose (2,500 units of NPH) has been associated with persistent hypoglycemia for up to 6 days [189].

Hypoglycemia Due to Sulfonylureas

When the cause of hypoglycemia is sulfonylurea ingestion (Table 106.2), the patient should usually be admitted to hospital because of the prolonged duration of action of most members of this class of drugs. Efforts to prevent drug absorption and increase elimination should be considered. Activated charcoal adsorbs sulfonylureas, and urinary alkalinization may enhance excretion [192,193]. Charcoal hemoperfusion is probably not indicated, except in the setting of renal failure and massive overdose [194]. Continuous intravenous glucose is mandatory. Oral carbohydrate should be provided if the patient can eat. It is particularly important that the glucose infusion be continued while the patient recovering from a sulfonylurea overdose is asleep. Cases of persistent sulfonylurea-induced hypoglycemia requiring up to 27 days of intravenous glucose have been reported [195]. The typical patient with this condition requires 2 to 3 days of intravenous glucose therapy [111,196]. As discussed later, octreotide and diazoxide may be helpful adjuvant therapies in some cases.

Refractory Hypoglycemia

If the history and physical examination do not immediately establish the underlying cause of hypoglycemia, continuation of the infusion and glycemia monitoring are required. Persistent severe hypoglycemia requires intensive monitoring. Blood glucose should be measured every 1 to 3 hours and the serum glucose concentration maintained at a target level of 100 mg per dL (5.6 mmol per L). Diagnostic studies can be obtained as appropriate during continuous glucose infusion.

Intravenous glucose should continue until normoglycemia is achieved. To determine whether parenteral glucose is no longer needed, the infusion should be discontinued and blood glucose concentration measured every 15 minutes. If blood glucose falls to <50 mg per dL or if the patient becomes symptomatic, glucose infusion is resumed. Depending on the etiology of the hypoglycemia, parenteral glucose infusion may be required for many days and the use of additional drugs should be considered (see below). When hypoglycemia is due to impaired gluconeogenesis in the setting of liver disease, renal disease, or CHF, only treatment of the underlying condition will prevent recurrence. When a tumor is the course of hypoglycemia, surgery is the definitive therapy.

Drugs Other Than Glucose in the Management of Hypoglycemia

Most cases of hypoglycemia in the ICU can be treated with glucose alone. When recurrent severe hypoglycemia and volume management are problems, intensivists may consider the addition of adjunctive therapies. Particularly when hypoglycemia is due to an insulinoma, nesidioblastosis, or other tumor, it may be necessary to supplement the glucose infusion with drugs that inhibit insulin secretion.

Glucocorticoids

Parenteral adrenocortical steroids can increase gluconeogenic substrates and inhibit insulin action in the periphery. Hydrocortisone sodium succinate can be given at a dose of 100 mg per L of glucose infused. This therapy is beneficial in patients whose hypoglycemia is in the context of adrenocortical insufficiency; one case report describes utility in hemangiopericytoma-associated hypoglycemia [96]. It is not helpful in sulfonylurea poisoning [197].

Octreotide (Sandostatin™)

Somatostatin is produced in pancreatic islet delta cells and inhibits insulin secretion. The long-acting analog octreotide can inhibit sulfonylurea-induced insulin secretion, and it has been used as supplemental therapy for insulinomas [198], oral agent-induced hypoglycemia [199–205], and quinine-induced hypoglycemia in malaria [133]. The dose is 1 to 2 units per kg every 8 hours [202].

Diazoxide (Hyperstat™)

Diazoxide is a benzothiadiazine nondiuretic antihypertensive agent that blocks the secretion of insulin from both normal and neoplastic β cells. To treat hypoglycemia, diazoxide is infused at a dose of 300 mg (1 to 3 mg per kg in children) in D_5W over 30 minutes every 4 hours, or as a constant infusion of 1 mg per kg per hour. It has been reported to be effective in reversing severe, refractory hypoglycemia due to sulfonylurea poisoning [197] and neonatal hyperinsulinemic hypoglycemia due to certain gene mutations [206].

Glucagon

The primary action of exogenous glucagon in the treatment of hypoglycemia is the promotion of glycogenolysis. It is most effective in patients with ample liver glycogen stores. Glucagon is a useful drug for out-of-hospital treatment of hypoglycemia due to excess insulin in known diabetic patients. It is good practice to teach family members of diabetic patients to administer parenteral glucagon. In the intensive care setting, however, there is seldom a need to administer glucagon unless vascular access cannot be maintained. In addition, glucagon can stimulate insulin secretion and promote recurrent hypoglycemia [207]. It has also been associated with hypoglycemia when used as premedication for endoscopy [208].

Rapamycin

In a single case report, rapamycin was effective in controlling intractable hypoglycemia in a patient with metastatic insulinoma [209]. The drug was thought to act both by reducing the malignant β-cell proliferation and by inhibiting insulin production.

PREVENTION OF HYPOGLYCEMIA IN THE ICU

With reported prevalence rates of 5% and higher [1–3], prevention of hypoglycemia is central to the metabolic management of the ICU patient. In general, oral antidiabetic agents like sulfonylureas should be discontinued in seriously ill patients [210]. Insulin infusions require meticulous management. Several studies have demonstrated that hypoglycemia can be avoided while achieving glycemic control by using structured insulin orders and management algorithms [211,212]. Such protocols are discussed in detail in Chapter 100. Up to a third of patients admitted to an emergency department with severe hypoglycemia may experience recurrent hypoglycemia in the hospital [213]. Strategies for preventing recurrent hypoglycemia have been outlined earlier.

Finally, it is becoming clear that promising new technology for continuous monitoring of glucose concentration has the potential to prevent hypoglycemia in ICU. Initial reports suggest that this technology enhances the detection of hypoglycemia in neonates [214] and reduces the frequency of hypoglycemic events in the adult ICU [215,216]. How this technology will affect glycemic control [215] or the management of neonatal hypoglycemia [214] or ICU outcomes remains to be determined but is potentially transformative.

CONCLUSION

Hypoglycemia is a serious problem in all hospitalized patients and a predictor of mortality in the critically ill [7,8]. It must be considered in all cases of stupor and coma. Diagnosis is based on Whipple's triad, and evaluation should take no more than a few minutes. After initial therapy with glucose, remember that only the symptoms and not the cause have been treated. The most common cause of hypoglycemia is insulin overdosage in individuals with diabetes; in the ICU, this is often a complication of strict glucose control protocols. Hypoglycemia due to intercurrent medical conditions requires correction of the underlying disorder. Patients with sulfonylurea- or insulinoma-induced hypoglycemia may require aggressive treatment of hypoglycemia with parenteral glucose for many days.

CHAPTER 107 ■ NONTHYROIDAL ILLNESS SYNDROME (SICK EUTHYROID SYNDROME) IN THE INTENSIVE CARE UNIT

SHIRIN HADDADY AND ALAN P. FARWELL

INTRODUCTION

Critical illness causes multiple alterations in thyroid hormone concentrations in patients who have no previously diagnosed intrinsic thyroid disease [1–6]. These effects are nonspecific and relate to the severity of the illness. Despite abnormalities in serum thyroid hormone parameters, there is little evidence that these patients have clinically significant thyroid dysfunction. Because a wide variety of illnesses tend to result in the same changes in serum thyroid hormones, such alterations in thyroid hormone indexes have been termed the *sick euthyroid syndrome* or, more recently, the *nonthyroidal illness syndrome*. These changes are rarely isolated and often are associated with alterations in other endocrine systems, such as reductions in serum gonadotropin and sex hormone concentrations [7] and increases in serum corticotropin and cortisol levels [8]. Similar changes in endocrine function have been shown experimentally by the administration of cytokines from the interleukin (IL) and interferon families as well as tumor necrosis factor-α (TNF-α) [9]. Thus, the sick euthyroid syndrome should not be viewed as an isolated pathologic event but as part of a coordinated systemic reaction to illness that involves both the immune and endocrine systems.

The differentiation between patients with the sick euthyroid syndrome and those with intrinsic thyroid disease is a frequent diagnostic problem in the intensive care unit (ICU). This chapter will first review normal thyroid physiology and discuss the changes in thyroid hormone metabolism seen with critical illness. Management of these patients and the identification of those with intrinsic thyroid disease will then be discussed. Finally, the use of thyroid hormone replacement in the sick euthyroid syndrome will be reviewed.

NORMAL THYROID HORMONE ECONOMY

Regulation

The synthesis and secretion of thyroid hormone is under the control of the anterior pituitary hormone, thyrotropin (TSH). In a classic negative feedback system, TSH secretion increases when serum thyroid hormone levels fall and decreases when they rise (Fig. 107.1). TSH secretion is also under the regulation of the hypothalamic hormone, thyrotropin-releasing hormone (TRH). The negative feedback of thyroid hormone is targeted mainly at the pituitary level but likely affects TRH release from the hypothalamus as well. In addition, input from higher cortical centers can affect hypothalamic TRH secretion.

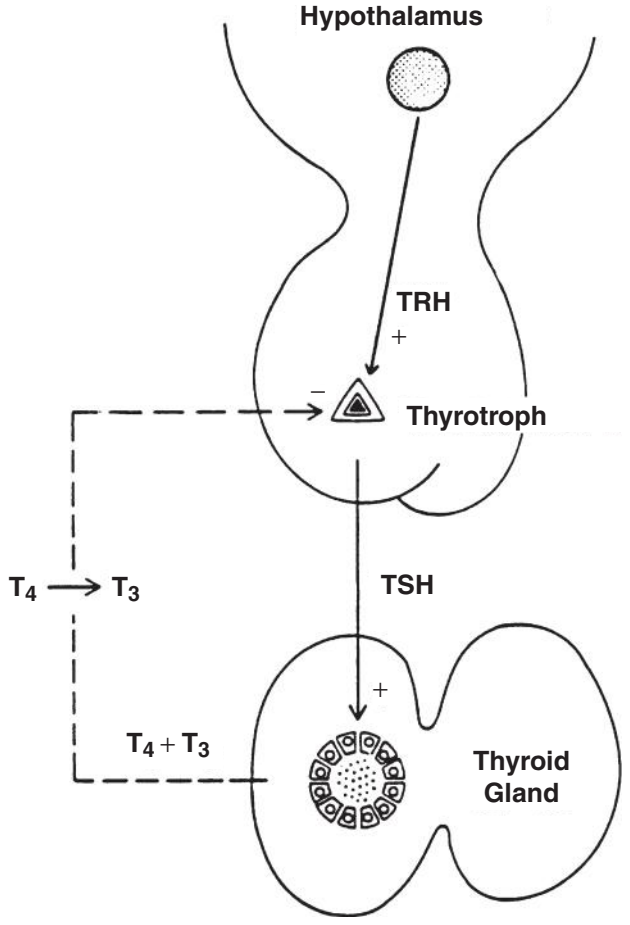

FIGURE 107.1. Diagram of the hypothalamic-pituitary-thyroid axis. The inhibitory effect of T_4 and T_3 on thyrotropin (TSH) secretion is shown by the dashed line and minus sign, and the stimulatory effects of thyrotropin-releasing hormone (TRH) on TSH secretion and TSH on thyroid secretion are shown by the solid lines and plus signs. T_4 and T_3 may also have an inhibitory effect on TRH secretion. [From Toft AD: Thyrotropin: assay, secretory physiology, and testing of regulation, in Braverman LE, Utiger RD (eds): *The Thyroid: A Fundamental and Clinical Text*. Philadelphia, JB Lippincott, 1991, with permission.]

Under the influence of TSH, the thyroid gland synthesizes and releases thyroid hormone. Thyroxine (T_4, 65% iodine by weight) is the principal secretory product of the thyroid gland, comprising ~90% of secreted thyroid hormone under normal conditions [10]. While T_4 may have direct actions in some tissues, T_4 primarily functions as a hormone precursor that is metabolized in peripheral tissues to the transcriptionally active 3,5,3′-triiodothyronine (T_3, 59% iodine by weight).

Metabolic Pathways

The major pathway of metabolism of T_4 is by sequential monodeiodination [11] (Fig. 107.2). At least three deiodinases, each with its unique expression in different organs, catalyze the deiodination reactions involved in the metabolism of T_4. Removal of the 5′-, or outer ring, iodine by type 1 iodothyronine 5′deiodinase (type 1 deiodinase, D1) is the "activating" metabolic pathway, leading to the formation of T_3. Removal of the inner ring, or 5-, iodine by type 3 iodothyronine deiodinase (type 3 deiodinase, D3) is the "inactivating" pathway, producing the metabolically inactive hormone, 3,3′,5′-triiodothyronine (reverse T_3, rT_3). Type 1 deiodinase (D1) is found most abundantly in the liver, kidneys, and thyroid. It is upregulated in hyperthyroidism and downregulated in hypothyroidism. Type 3 deiodinase is expressed primarily in the brain, in skin, and in placental and chorionic membranes. The actions of D3 also include the inactivation of T_3 to form T_2, another inactive metabolite. Under normal conditions, ~41% of T_4 is converted to T_3, ~38% is converted to rT_3, and ~21% is metabolized via other pathways, such as conjugation in the liver and excretion in the bile [4,5].

T_3 is the metabolically active thyroid hormone and exerts its actions via binding to chromatin-bound nuclear receptors and regulating gene transcription in responsive tissues [12]. Important in the understanding of the alterations in circulating thyroid hormone levels seen in critical illness is the fact that only ~10% of circulating T_3 is secreted directly by the thyroid gland while >80% of T_3 is derived from conversion of T_4 in peripheral tissues [10,11]. Thus, factors that affect peripheral T_4 to T_3 conversion will have significant effects on circulating T_3 levels. Serum levels of T_3 are approximately 100-fold less than those of T_4, and, like T_4, T_3 is metabolized by deiodination to form diiodothyronine (T_2) and by conjugation in the liver. The half-lives of circulating T_4 and T_3 are 5 to 8 days and 1.3 to 3 days, respectively [13].

Serum-Binding Proteins

Both T_4 and T_3 circulate in the serum as bound hormones to several proteins synthesized by the liver [14]. thyroxine-binding globulin (TBG) is the predominant transport protein and binds

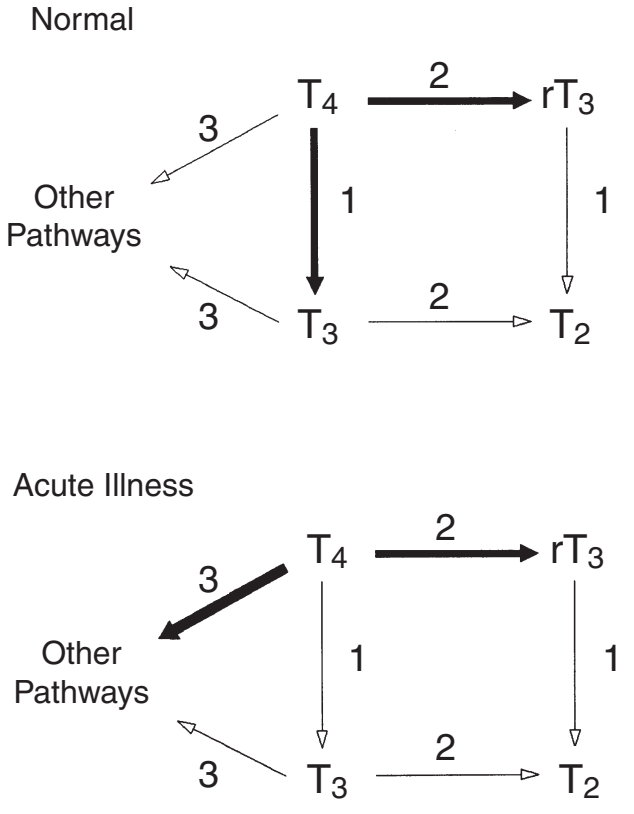

FIGURE 107.2. Pathways of thyroid hormone metabolism. Thyroid hormones are metabolized by outer ring deiodination (*1*, type 1 and type 2 5′-deiodinase), inner ring deiodination (*2*, type 3 5-deiodinase) or by nondeiodinative pathways (*3*). Deiodination is the major route of T_4 metabolism in healthy individuals, and nondeiodinative pathways of metabolism assume a greater role in critically ill patients.

~80% of the circulating serum thyroid hormones. The affinity of T_4 for TBG is approximately 10-fold greater than that of T_3 and is part of the reason that circulating T_4 levels are higher than T_3 levels. Other serum-binding proteins include transthyretin [15], which binds ~15% of T_4 but little, if any T_3, and albumin, which has a low affinity but a very large binding capacity for T_4 and T_3. Overall, 99.97% of circulating T_4 and 99.7% of circulating T_3 is bound to plasma proteins.

Free Hormone Concept

Essential to the understanding of the regulation of thyroid function and the alterations of circulating thyroid hormones seen in critical illness is the "free hormone" concept, which is that only the unbound hormone has any metabolic activity. Under the regulation by the pituitary, overall thyroid function is affected when there are any changes in free hormone concentrations. Changes in either the concentrations of binding proteins or the binding affinity of thyroid hormone to the serum-binding proteins have significant effects on the total serum hormone levels due to the high degree of binding of T_4 and T_3 to these proteins. Despite these changes, this does not necessarily translate into thyroid dysfunction.

THYROID HORMONE ECONOMY IN CRITICAL ILLNESS

The widespread changes in thyroid hormone economy in the critically ill patient occur as a result of: (a) alterations in the peripheral metabolism of the thyroid hormones, (b) alterations in TSH regulation, and (c) alterations in the binding of thyroid hormone to TBG.

Peripheral Metabolic Pathways

One of the initial alterations in thyroid hormone metabolism in acute illness is the acute inhibition of type 1 deiodinase, resulting in the impairment of T_4 to T_3 conversion in peripheral tissues [16]. D1 is inhibited by a wide variety of factors, including acute illness (Table 107.1) [11], resulting in the acute decrease in T_3 production in critically ill patients. In contrast, inner ring deiodination by D3 may be increased by acute illness, resulting in increased levels of rT_3 [17,18]. Additionally, since rT_3 is subsequently deiodinated by D1, degradation of rT_3 decreases and levels of this inactive hormone rise in proportion to the fall in T_3 levels. Recent studies on postmortem tissues have confirmed that alterations in deiodinase enzymes occur in patients who died during an acute critical illness, with decrease in type 1 and increase in type 3 deiodinases and, surprisingly, an increase in skeletal muscle type 2 deiodinase [18,19]. Finally, there is impaired transport of T_4 into peripheral tissues, such as the liver and kidney where much of the circulating T_3 is produced, further contributing to the decrease in production of T_3 [20].

TABLE 107.1

FACTORS THAT INHIBIT TYPE 1 5′-DEIODINASE ACTIVITY

Acute and chronic illness
Caloric deprivation
Malnutrition
Glucocorticoids
β-Adrenergic blocking drugs (e.g., propranolol)
Oral cholecystographic agents (e.g., iopanoic acid, sodium ipodate)
Amiodarone
Propylthiouracil
Fatty acids
Fetal/neonatal period
Selenium deficiency
Cytokines (interleukin 1 and 6)

TSH Regulation

Serum TSH levels are usually normal early in acute illness. However, TSH levels often fall as the illness progresses due to the effects of a variety of inhibitory factors that are common in the treatment of the critically ill patient (Table 107.2). Many medications used in the treatment of the critically ill patient may also have inhibitory effects on serum TSH levels. Van den Berghe et al. [21] reported that intravenous administration of dopamine for as short a time as 15 to 21 hours is able to acutely decrease TSH levels and its withdrawal results in a tenfold increase in serum TSH levels. In one study, children who received dopamine infusions during a pediatric ICU admission for meningococcal sepsis had lower TSH levels than those who did not [22,23]. Increased levels of glucocorticoids, whether from endogenous or exogenous sources, also have direct inhibitory effects on TSH secretion.

TSH secretion also occurs as a result of altered TRH secretion. Decreased TRH secretion due to inhibitory signals from higher cortical centers, impaired TRH metabolism [24], the alteration of pulsatile TSH [25], and the decrease or absence of a nocturnal TSH surge [25,26] may all decrease TSH levels. Serum levels of Leptin, the ob gene product that has been shown to vary directly with thyroid hormone levels [27], also fall as illness progresses [28] and hypothalamic TRH secretion falls, which in turn leads to lowered TSH levels [29]. The decrease of hypothalamic TRH gene expression in animal models is, however, not associated with increased serum T_4 and T_3

TABLE 107.2

FACTORS THAT ALTER TSH SECRETION

Increase	Decrease
Chlorpromazine	Acute and chronic illness
Cimetidine	Adrenergic agonists
Domperidone	Caloric restriction
Dopamine antagonists	Carbamazepine
Haloperidol	Clofibrate
Iodide	Cyproheptadine
Lithium	Dopamine and dopamine agonists
Metoclopramide	Endogenous depression
Sulfapyridine	Glucocorticoids
Radiographic contrast agents	Insulin-like growth factor-1
	Metergoline
	Methysergide
	Opiates
	Phenytoin
	Phentolamine
	Pimozide
	Somatostatin
	Serotonin
	Surgical stress
	Thyroid hormone metabolites

TABLE 107.3

FACTORS THAT ALTER BINDING OF T_4 TO TBG

Increase binding	Decrease binding
	Drugs
Estrogens	Glucocorticoids
Methadone	Androgens
Clofibrate	L-Asparaginase
5-Fluorouracil	Salicylates
Heroin	Mefenamic acid
Tamoxifen	Antiseizure medications (phenytoin,
Raloxifene	Tegretol)
Liver disease	Furosemide
Porphyria	Heparin
HIV infection	Systemic factors
Inherited	Inherited
	Acute illness
	Nonesterified free fatty acids

HIV, human immunodeficiency virus.

levels [30]. Finally, certain thyroid hormone metabolites that are increased during acute nonthyroidal illness may play a role in the inhibition of TSH and TRH secretion [1].

Serum-Binding Proteins

The affinity of thyroid hormones binding to transport proteins and the concentrations of serum-binding proteins are altered with acute illness (Table 107.3). Serum levels of transthyretin and albumin decrease, especially during prolonged illness, malnutrition, and in high catabolic states. TBG levels may be increased, as seen with liver dysfunction and HIV infection, or decreased, as seen with severe or prolonged illness [14]. TBG may also be rapidly degraded by protease cleavage during cardiac bypass, thereby partially explaining the rapid fall of serum T_3 levels in patients undergoing cardiac surgery [31].

An acquired binding defect of T_4 to TBG is commonly seen in patients with critical illness. This is believed to result from the release of some as yet unidentified factor from injured tissues that has the characteristics of unsaturated nonesterified fatty acids (NEFA) [32], which also inhibit T_4 to T_3 conversion [33]. In systemically ill patients, NEFA levels rise in parallel with the severity of the illness [34], and drugs such as heparin stimulate the generation of NEFA [35]. Many drugs, including high-dose furosemide, antiseizure medications, and salicylates also alter binding of T_4 to TBG. The alterations in serum-binding proteins in critical illness make the estimation of the free hormone concentrations difficult (see later).

Role of Cytokines in the Pathogenesis of the Sick Euthyroid Syndrome

Cytokines are medium-sized polypeptide hormones secreted by mononuclear cells of the lymphoid system in response to a variety of stimuli, including infection by foreign organisms, invasion by foreign cells, metabolic derangements, and organ system dysfunction [36]. Cytokines have an array of systemic and local actions characteristic of illness, such as fever, prostration, inflammation, and the initiation of wound repair. Cytokine production by lymphoid cells is essential for the development and maintenance of immunity. The actions of cytokines include both autocrine and paracrine effects on cell proliferation and differentiation and on induction of other cytokines. Classes of cytokines include the interleukins (1 to 12), interferons (α, β, and γ), tumor necrosis factors (α and β), and other assorted growth factors. Of these cytokines, TNF-α and several interleukins (IL-1, 6, and 10) have been extensively studied for their role in the pathogenesis of the sick euthyroid syndrome [9,37].

TNF-α, IL-1, and IL-6 concentrations are increased in systemic illness and are implicated as mediators of endotoxemia-induced shock, fever, and metabolic acidosis. TNF-α and IL-1 both induce the production of IL-6 and TNF-α also induces IL-1 production [38] and activates nuclear factor-kappa B (NF-κB), which has been shown to inhibit hepatic type 1 5′-deiodinase activity [39]. Serum concentrations of these cytokines have shown to be inversely proportional to serum T_3 concentrations in children (IL-6 and TNF-α [40]); postoperative patients (IL-6 [41]); hospitalized patients, including those with acute myocardial infarction (IL-6 [42–44]) and after bone marrow transplant (IL-6 and TNF-α [45]); and nursing home patients (TNF-α [46]). However, there have been reports of a lack of correlation between IL-6 and TNF-α after abdominal surgery [47] and in rheumatoid arthritis [48].

The administration of cytokines to animals produces an acute fall in serum T_3 concentrations in rats (TNF-α [49], IL-1 [50,51], IL-6 [52]) and mice (IL-1 [53,54], IL-6 [55]) and shows a direct inhibitory effect on thyroid cells in culture (TNF-α [49,56,57] and IL-1 [57–59]). Variable effects on deiodinase enzymes have been reported, including an inhibition of type 1 5′-deiodinase (IL-1β [60], NF-κB [39]) and inhibition (TNF-α, IL-1, and IL-6 [61]) and induction of type 2 5′-deiodinase (response to lipopolysaccharide [62]).

The administration of TNF-α [63] or IL-6 [64] to healthy human volunteers as well as isolated limb perfusion of cancer patients with TNF-α [65] also produced an acute decrease in both serum T_3 and TSH concentrations and a rise in serum rT_3 concentrations, while the administration of an IL-1α receptor antagonist failed to alter the decrease in serum thyroid hormone concentrations observed after infusion of endotoxin in healthy males [66]. In addition, recovery from these changes in thyroid hormone parameters was associated with a rise in TSH [65], similar to the recovery phase of the sick euthyroid syndrome (see later).

Other cytokines have been variably investigated as to their role in the pathogenesis of the sick euthyroid syndrome. Interferon α causes a decrease in serum T_3 and TSH and a rise in serum rT_3 concentrations in both humans [67] and mice [58] and has been shown to directly inhibit thyroidal type 1 5′-deiodinase activity [56,57] while interferon γ appears to have no effect on thyroid hormone parameters [68]. An increase in TSH has been observed in patients treated with IL-2 [69]. Soluble cytokine receptors may play a regulatory role in the cytokine cascade by functioning either as carrier proteins or cytokine inhibitors [36,38], and serum T_3 levels were found to be inversely proportional to soluble receptors for TNF-α, IL-1, and IL-2 in hospitalized patients [58].

From the data discussed earlier, it is likely that cytokines play a role in the alterations in thyroid hormone metabolism that occurs with systemic illness. While all cytokines examined to date can produce the sick euthyroid syndrome in either man or rodents when administered in pharmacologic doses, no one cytokine can be singled out as the primary mediator of the syndrome. This is not unexpected, given the diverse interrelationships and cascade nature of the cytokine network. Whether the sick euthyroid syndrome results from activation of the cytokine network or simply represents an endocrine response to systemic illness resulting from the same mediators that trigger the cytokine cascade remains to be determined.

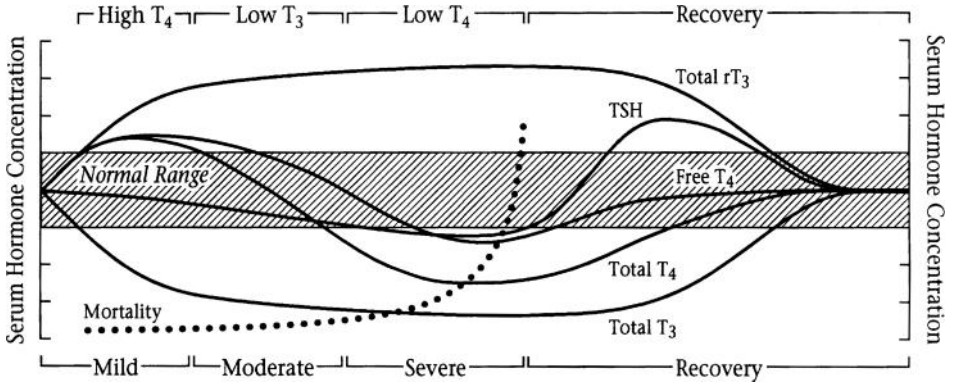

FIGURE 107.3. Alterations in thyroid hormone concentrations with critical illness. Schematic representation of the continuum of changes in serum thyroid hormone levels in patients with nonthyroidal illness. These alterations become more pronounced with increasing severity of the illness and return to the normal range as the illness subsides and the patient recovers. A rapidly rising mortality accompanies the fall in total and free T_4 levels.

Stages of the Sick Euthyroid Syndrome

As discussed earlier, critical illness causes multiple nonspecific alterations in thyroid hormone concentrations in patients without intrinsic thyroid dysfunction that relate to the severity of the illness [3,70,71]. One author has postulated that sick euthyroid syndrome may be a compensatory mechanism in response to the oxidative stress of acute illness [72]. Whatever the underlying cause, these alterations in thyroid hormone parameters represent a continuum of changes that depends on the severity of the illness and that can be categorized into several distinct stages (Fig. 107.3) [1]. The wide spectrum of changes observed often results from the differing points in the course of the illness that the thyroid function tests were obtained. Importantly, these changes are rarely isolated and often associated with alterations of other endocrine systems, such as decreases in serum gonadotropin and sex hormone concentrations [73] and increases in serum adrenocorticotropic hormone and cortisol levels [74]. Thus, the sick euthyroid syndrome should not be viewed as an isolated pathologic event but as part of a coordinated systemic reaction to illness involving both the immune and endocrine systems.

Low T_3 State

Common to all of the abnormalities in thyroid hormone concentrations seen in critically ill patients is a substantial depression of serum T_3 levels, which can occur as early as 24 hours after the onset of illness. Over half of the patients admitted to the medical service will demonstrate depressed serum T_3 concentrations [75,76]. The development of the low T_3 state arises from the impairment of peripheral T_4 to T_3 conversion through the inhibition of type 1 deiodinase (discussed earlier). This results in the marked reduction of T_3 production and rT_3 degradation [77], thereby leading to the reciprocal changes in serum T_3 and serum rT_3 concentrations. Low T_3 levels are also found in the peripheral tissues [18]. Previously, it was thought that the inhibition of type 1 deiodinase was the sole cause of the low T_3 syndrome by decreasing T_3 production. Recent studies suggest that increased type 3 deiodinase in critical illness increases T_3 disposal, adding to the decrease in serum T_3 levels [17,18]. Thyroid hormone receptor expression is also decreased in acute nonthyroidal illness [78], possibly in response to the decrease in tissue T_3 levels.

High T_4 State

Serum T_4 levels may be elevated early in acute illness due to either the acute inhibition of type 1 deiodinase or increased TBG levels. This is seen most often in the elderly and in patients with psychiatric disorders. As the duration of illness increases, nondeiodinative pathways of T_4 degradation increase serum T_4 levels to the normal range [75].

Low T_4 State

As the severity and the duration of the illness increases, serum total T_4 levels decrease into the subnormal range. Contributors to this decrease in serum T_4 levels are (a) a decrease in the binding of T_4 to serum carrier proteins, (b) a decrease in serum TSH levels leading to decreased thyroidal production of T_4, and (c) an increase in nondeiodinative pathways of T_4 metabolism. The decline in serum T_4 levels correlates with prognosis in the ICU, with mortality increasing as serum T_4 levels drop below 4 μg per dL and approaching 80% in patients with serum T_4 levels below 2 μg per dL [79–81]. Despite marked decreases in serum total T_4 and T_3 levels in the critically ill patient, the free hormone levels have been reported to be normal or even elevated [82,83], providing a possible explanation for why most patients appear euthyroid despite thyroid hormone levels in the hypothyroid range. Thus, the low T_4 state is unlikely to be a result of a hormone-deficient state and is probably more of a marker of multisystem failure in these critically ill patients.

Recovery State

As acute illness resolves, so do the alterations in thyroid hormone concentrations. This stage may be prolonged and is characterized by modest increases in serum TSH levels [84]. Full recovery, with restoration of thyroid hormone levels to the normal range, may require several weeks [85] or months after hospital discharge [76]. One study reported that 35 of 40 patients with nonthyroidal illness after coronary artery bypass grafting were able to regain normal thyroid function within 6 months after surgery [86].

ALTERATIONS IN THYROID FUNCTION IN SPECIFIC CRITICAL ILLNESSES

Caloric Deprivation

Most, if not all, nonthyroidal illness is associated with decreased caloric intake, catabolism, and/or malnutrition. Caloric deprivation is the most common inhibitory factor of type 1 5′-deiodinase [11,87,88]. Serum T_3 levels decrease and rT_3 levels increase within 24 hours of the onset of a fast. The decrease in serum T_3 levels may possibly be an adaptive

response in order to preserve the total body protein stores. Indeed, restoring the serum T_3 to normal during starvation results in a marked increase in urinary nitrogen excretion [89]. Thus, the inhibition of T_4 to T_3 conversion in starvation can be viewed as a condition of adaptive hypothyroidism. Further support for the role of caloric deprivation in the development of the sick euthyroid syndrome is the demonstration that serum thyroid hormone levels in critically ill patients receiving nutritional support return to normal levels [90].

HIV Infection

A unique pattern of changes in circulating thyroid hormone levels is seen in patients with HIV infection and in those with AIDS [91]. A progressive increase in TBG levels is commonly observed and T_4 levels rarely decrease below the normal range. Serum rT_3 levels fail to rise with advancing infections and are only modestly increased in preterminal AIDS patients. Most striking is the observation that serum T_3 levels remain in the normal range despite progression of the HIV infection and are only mildly decreased in the critically ill AIDS patient, suggesting that these "inappropriately normal" T_3 levels play a role in the wasting and weight loss seen in the terminal phases of this disease. In contrast to T_4 levels in the sick euthyroid syndrome, it is the decreased serum T_3 levels in AIDS patients admitted to the ICU with *Pneumocystis carinii* infections that correlate with increased mortality [92].

Liver Disease

In contrast to the decrease in thyroid hormone levels seen in critically ill patients, individuals suffering from acute and chronic hepatocellular dysfunction often have marked elevations in total T_4 levels similar to those seen in patients with thyrotoxicosis [93]. T_3 levels are also higher than expected with illness and tend to fall late in the course of terminal liver disease. The etiology of these increased thyroid hormone concentrations is the increased discharge of TBG following destruction of hepatocytes. Free hormone measurements remain in the normal range. As with other illnesses, the low T_4 syndrome can be seen in patients with cirrhosis and is associated with increased mortality [94].

Cardiac Disease

Thyroid hormones have profound effects on the cardiovascular system [95]. Cardiac contractility, systolic time intervals, and heart rate are all increased in thyrotoxicosis and decreased in hypothyroidism. Multiple cardiac genes are either positively or negatively altered by thyroid hormone [96,97]. Serum T_4 and T_3 levels fall acutely following myocardial infarction [98], cardiac arrest [99–101], and cardiopulmonary bypass [86,102–105]. A significant inverse relationship between free T_3 and global oxygen consumption has been demonstrated after coronary artery bypass grafting with and without cardiopulmonary bypass [105]. Nonthyroidal illness syndrome has also been found with prevalence of 62.2% in patients with stress cardiomyopathy [106]. In contrast to other medical illnesses where serum T_4 levels are correlated with prognosis, serum T_3 concentrations are a negative prognostic factor in patients with congestive heart failure [107,108] and with coronary artery disease [109], raising a question as to what, if any, role thyroid hormones play in acute cardiac injury.

MANAGEMENT OF THE CRITICALLY ILL PATIENT WITH ABNORMAL THYROID FUNCTION TESTS

Evaluation

The identification of the critically ill patient with intrinsic thyroid disease is often difficult and always a diagnostic challenge. The routine screening of an ICU population for the presence of thyroid dysfunction is not recommended due to the high prevalence of abnormal thyroid function tests and low prevalence of true thyroid dysfunction. Whenever possible, it is best to defer evaluation of the thyroid-pituitary axis until the patient has recovered from his or her acute illness. In principal, when thyroid function tests are ordered in a hospitalized patient, it should be with a high clinical index of suspicion for the presence of thyroid dysfunction. For example, thyroid function should be evaluated in the patient admitted to the ICU with tachyarrhythmias when that patient also has a goiter, proptosis, and a tremor. Similarly, the patient with a large pericardial effusion, hypothermia, a goiter, and "hung-up" deep tendon reflexes should suggest the diagnosis of hypothyroidism. In practice, however, thyroid function tests are ordered in the patient with less-specific clinical findings and often present a diagnostic dilemma. Because every test of thyroid hormone function can be altered in the critically ill patient, no single test can definitively rule in or rule out the presence of intrinsic thyroid dysfunction.

Primary Tests

Sensitive Thyrotropin Assays

The development of the sensitive TSH assay has both helped and hindered the evaluation of thyroid function in the critically ill. These new assays have greatly expanded the lower range of the TSH assay, so the typical sensitive TSH assay has a lower limit of detection of 0.01 to 0.03 mU per L, which is 20- to 30-fold lower than the lower limit of the normal range. With this improved sensitivity has come the recognition of an increased frequency of subnormal TSH values in hospitalized patients, indicating that transient abnormalities in TSH secretion are commonplace in acute illness. To what degree this TSH dysregulation represents clinically significant alterations in thyroid function is uncertain.

Abnormal thyroid function tests have been reported in 20% to 40% of acutely ill patients, of which >80% have no intrinsic thyroid dysfunction after the resolution of the illness [75,76,110]. In a study of 1,580 hospitalized patients, only 24% of patients with suppressed TSH values (TSH < assay limit of detection) and 50% of patients with TSH values >20 mU per L were found to have thyroid disease [75,76]. More importantly, none of the patients with subnormal but detectable TSH values and only 14% of patients with elevated TSH values <20 mU per L were subsequently diagnosed with intrinsic thyroid dysfunction. The development of sensitive third-generation TSH assays has led to small improvements in discerning between overt hyperthyroidism and nonthyroidal illness [76]. Overall, however, while a normal TSH level has a high predictive value of normal thyroid function, an abnormal TSH value alone is not helpful in the evaluation of thyroid function in the critically ill patient.

Serum T_4 Assays

Measurement of free thyroid hormone concentrations in the patient with nonthyroidal illness is fraught with difficulty [83]. The gold standard of the determination of free hormone levels is by equilibrium dialysis. However, this technique is labor intensive and time consuming and, thus, is rarely used. The most commonly available laboratory tests of thyroid hormone concentrations, the free T_4 index, free T_4, and free T_3, are measured by analog methods, which represent estimates of the free hormone concentration and are therefore subject to inaccuracies [82].

The free T_4 index is determined by multiplying the total T_4 concentration by the T_3- or T_4-resin uptake, which is an inverse estimate of serum TBG concentrations [111]. Recent developments have allowed the measurement of free T_4 levels by the analog method, a less-expensive alternative to the free T_4 index [112], but the two tests are likely comparably accurate [113]. In a healthy population, there is a close correlation between the free T_4 index and free T_4 levels. In the critically ill patient, this association is no longer seen, mainly due to difficulties in estimating TBG binding with resin uptake tests. In spite of this, the sensitivity of the free T_4 index in a large study of hospitalized patients was 92.3%, as compared to 90.7% for the sensitive TSH test [76].

Secondary Tests

Serum T_3 and rT_3 Assays

As previously discussed, serum T_3 concentrations are affected to the greatest degree by the alterations in thyroid hormone economy resulting from acute illness. Therefore, there is no indication for the routine measurement of serum T_3 levels in the initial evaluation of thyroid function in the critically ill patient. This test should only be obtained if thyrotoxicosis is clinically suspected in the presence of a suppressed sensitive TSH value and an elevated or high normal free T_4 index or free T_4 determination. Thus, in patients with an elevated free T_4 index or free T_4 and a suppressed TSH, the finding of an elevated serum T_3 concentration will differentiate between thyrotoxicosis and the high T_4 state of the sick euthyroid syndrome. The total T_3 assay is preferable to the free T_3 (analog) assay, due to the variability between laboratories with the latter test [111].

Although some investigators have reported that serum rT_3 levels are a significant prognostic indicator of mortality in the ICU [114], rT_3 levels are generally unreliable and should not be used to distinguish between intrinsic thyroid dysfunction and nonthyroidal illness [115].

Serum Thyroid Autoantibodies

Autoantibodies to thyroglobulin and thyroid peroxidase (TPO), two intrinsic thyroid proteins, are commonly ordered tests [111]. While significant titers of either or both of these antibodies indicate the presence of autoimmune thyroid disease, the presence of thyroid autoantibodies alone does not necessarily indicate thyroid dysfunction, as they are present in approximately 12% to 26% of the general population [116]. Thyroid autoantibodies do, however, add to the sensitivity of abnormal TSH and free thyroxine index values in diagnosing known intrinsic thyroid disease [75,76].

Imaging Studies

Imaging studies are rarely essential to the diagnosis of thyroid disorders in the critically ill patient. Occasionally, functional analysis of the thyroid gland using the radioisotope ^{123}I may be useful in the patient with suspected thyrotoxicosis and equivocal laboratory tests. However, these studies are labor intensive and the management of the underlying acute illness often overshadows the benefits of obtaining these studies. While anatomical studies such as ultrasound, isotopic imaging, CT, and MRI are useful in the evaluation of thyroid nodules and goiter, these conditions rarely are the cause of acute illness; as such, these studies are not usually helpful in the critically ill patient.

Diagnosis

As indicated, the diagnostic significance of a single abnormal thyroid function test is low. The best single test to screen for thyroid dysfunction is either the free T_4 index or the free T_4, realizing that subtle changes in thyroid function will be missed. However, a reasonable approach to the initial evaluation of the thyroid function in the critically ill patient is to obtain either free T_4 index or free T_4 and TSH measurements in patients with a high clinical suspicion for intrinsic thyroid dysfunction. Assessment of these values in the context of the duration, severity, and stage of illness of the patient will allow the correct diagnosis in most patients. For example, a mildly elevated TSH coupled with a low free T_4 index or free T_4 is more likely to indicate primary hypothyroidism early in an acute illness as opposed to the same values obtained during the recovery phase of the illness. Similarly, the combination of an elevated TSH and low normal free T_4 index or free T_4 is more likely to indicate thyroid dysfunction in the hypothermic, bradycardic patient than the tachycardic, normothermic individual. If both the free T_4 index or free T_4 and TSH are normal, thyroid dysfunction is effectively eliminated as a significant contributing factor to the clinical picture. If the diagnosis is still unclear, measurement of thyroid antibodies is helpful as a marker of intrinsic thyroid disease and increases the sensitivity of both the free T_4 index or free T_4 and the TSH. Only in the case of a suppressed TSH and a mid-to-high normal free T_4 index or free T_4 is measurement of serum T_3 levels indicated.

Prognosis

Both serum T_4 and serum T_3 concentrations have been associated as negative indicators of prognosis when they are low. As mentioned previously, a direct relationship exists between low serum T_4 levels and poor outcomes in critically ill patient [110]. In acutely ill older patients with nonthyroidal illness syndrome, mortality rate was significantly higher, with an inverse relationship between free T_3 values and death rate [117]. The same relationship was found in burn patients, with free T_3 and TSH levels lower in nonsurvivors compared to survivors [118]. In patients on mechanical ventilation, patients with low free T_3 had higher mortality rate and longer duration of mechanical ventilation and ICU length of stay [119]. In different types of cardiac disease the prognostic value of low T_3 has been shown, including coronary artery disease and chronic heart failure [107–109]. Whether this is a causal association or simply reflecting multiorgan failure is unclear.

TREATMENT OF THE SICK EUTHYROID SYNDROME WITH THYROID HORMONE

Thyroid Hormone Therapy of General ICU Patients

There are only a few studies examining the use of supplemental thyroid hormone therapy in the critically ill general medical patient. The initial study in medical ICU patients by Brent and

Hershman examined the effect of thyroid hormone therapy in patients with serum T_4 levels <5 μg per dL but with no evidence of intrinsic thyroid dysfunction [120]. Either T_4 or placebo was given intravenously on a daily basis, with subsequent normalization of serum T_4 levels by day 5 in the T_4-treated group. There was no difference in mortality between the two groups and the elevation of TSH and serum T_3 concentrations seen in the recovery phase of acute illness was delayed in the T_4-treated group, suggesting that T_4 replacement was detrimental to the restoration of normal pituitary-thyroid regulation. A double-blind study with T_4 in patients with acute renal failure [121] showed that the mortality in the non-T_4-treated control group was significantly less than in the T_4-treated group; however, the mortality in the T_4-treated group was similar to that institution's experience and in historical controls, so a specific deleterious effect of T_4 could not be proved. A follow-up double-blind study with T_4 in patients after renal transplant by the same group [122] also failed to show any benefit.

One could argue that L-T_4 therapy in the sick euthyroid syndrome would be unlikely to have any effect due to the marked inhibition of T_4 to T_3 conversion in the patients, preventing significant increases in serum T_3 concentrations. Addressing this issue, Becker et al. [123] examined the effect of treatment with T_3 in 36 patients with acute burn injuries. Treatment with L-T_3 200 μg daily in four divided doses orally normalized serum T_3 concentrations but resulted in no change in either mortality or basal metabolic rate. Thus, despite the poor prognosis of the general ICU patients with the sick euthyroid syndrome [110], it does not appear that treatment with either L-T_4 or L-T_3 provides any benefit to these patients.

Thyroid Hormone Therapy in Premature Infants

Fetal thyroid function begins between 8 and 10 weeks' gestation and continues to mature throughout pregnancy [124,125]. Serum T_4 concentrations remain low throughout most of the second trimester and then steadily increase, with a twofold rise occurring between 24 and 34 weeks, at which time serum T_4 levels plateau [126]. There has been a remarkable increase in the number of surviving premature infants, especially in those <30 weeks' gestation. All premature infants have some degree of transient hypothyroxinemia, with serum T_4 concentrations varying directly with the gestational age [127]. Approximately 50% of infants born <30 weeks' gestation have serum T_4 concentrations <6.5 μg per dL [126,128,129]. Superimposed on this physiological hypothyroxinemia often are concurrent illnesses such as respiratory distress syndrome, infections, and malnutrition that contribute to the development of the sick euthyroid syndrome. Severe hypothyroxinemia with concentrations <4 μg per dL were seen in 21% of preterm babies, ranging from 40% at 23 weeks' gestation to 10.2% at 29 weeks [127]. Unlike adults, in whom most abnormalities resulting from clinical hypothyroxinemia are reversible, untreated congenital hypothyroxinemia can potentially have a devastating effect on brain development in the neonate [130–132].

Reuss et al. [133] showed that severe hypothyroxinemia in premature infants of <33 weeks' gestation correlated with a fourfold increase in a diagnosis cerebral palsy. In the study with the longest follow-up, hypothyroxinemia in premature infants of <32 weeks' gestation was associated with a 30% increase in school failure, poor school performance, and need for special education by 9 years of age [134].

The initial double-blind study of T_4 treatment in 23 premature infants of gestational age 26 to 28 weeks with hypothyroxinemia showed no differences between the groups in developmental indices at 1 year of age [135]. In the largest study to date, 200 infants born at 25 to 30 weeks' gestation received either thyroxine or placebo for 6 weeks and neurological development was assessed periodically up to 24 months [136]. While there appeared to be a beneficial effect for thyroxine in the very young (25 to 26 weeks' gestation), there also appeared to be a deleterious effect on the infants of 27 to 30 weeks' gestation. This study group was reevaluated 3 years later at early school age and reported a trend toward a benefit of T_4 supplementation on IQ and behavioral issues at 24/25 weeks' gestation but a significant deleterious effect on IQ and no effect on behavioral issues in those treated at 29 weeks' gestation [137]. Three other studies, two using T_4 [138,139] and one using T_3 [140], failed to show any significant effects of thyroid hormone treatment. Finally, an extensive meta-analysis and review of the literature concluded that thyroid hormone treatment failed to reduce neonatal mortality, improve neurodevelopmental outcome, or reduce the severity of the respiratory distress syndrome [141]. Thus, there is no indication currently for the use of thyroid hormone treatment in premature infants.

Thyroid Hormone Therapy in Cardiac Surgery

Within 15 to 30 minutes after placing the patient on bypass, serum T_4 and T_3 levels fall and serum rT_3 levels increase [142]. These alterations may persist for several days postoperatively [86,102]. These changes also have been observed in off-pump cardiopulmonary bypass [104]. Alterations in thyroid hormone parameters during and after cardiopulmonary bypass have been confirmed in multiple human and animal studies [86,102,103,143–146]. The etiology of these rapid changes in thyroid hormone concentrations remains unclear; one proposal suggests that these alterations may result from enhanced degradation of TBG [31]. Experimental studies in animals have shown that T_3 replacement after cardiopulmonary bypass significantly improves cardiac contractility and left ventricular function and decreases systemic vascular resistance [147–150]. Initial studies on the use of T_3 in humans undergoing cardiac surgery suggested that hormone-treated patients may require less ionotropic support [151] and have improved hemodynamic parameters [152]. However, the clearly demonstrable benefit of T_3 repletion in animals has not been translated into similar benefit in humans undergoing coronary artery bypass in controlled clinical trials.

A large placebo-controlled trial [153] found no effect of T_3 on any postoperative hemodynamic parameters, although a follow-up report of this same patient group suggested a lower incidence in atrial fibrillation in the T_3-treated group after the first postoperative day [154]. However, a lack of effect for T_3 was shown conclusively in a double-blind, placebo controlled trial [155], as there was no significant difference in the incidence of arrhythmia or the need for ionotropic support or vasodilator drugs in the 24 hours following surgery or in perioperative mortality or morbidity between the T_3 and the placebo groups. Somewhat more promising results have been reported in children undergoing cardiac surgery with improved hemodynamic parameters and a suggestion that the need for intensive postoperative care is decreased with intravenous L-T_3 [156,157]. Further studies may be indicated in this population. However, despite the promise in animal studies, there is no indication for the routine use of T_3 in adult patients undergoing cardiac surgery.

T_3 in Brain-Dead Potential Heart Donors

After brain death occurs, there is a progressive reduction in cardiac contractility, depletion of high-energy phosphates, and

accumulation of tissue lactate [158,159]. These changes coincide with a rapid decline in serum T_3 concentrations and an increase in serum rT_3 concentrations within minutes to hours. An initial study in human heart donors [159] showed that T_3 treatment in human heart donors results in hemodynamic stability, a decrease in ionotropic support required, and preservation of cardiac function prior to transplantation. At least four other groups have subsequent beneficial effects of T_3 therapy in conjunction with other hormones in organ donors, especially those that are unstable [160]. Two other groups found no significant clinical effects of T_3 over placebo on human donor cardiac function [158,161], provided there was no antecedent cardiac dysfunction in the donor. Another study examined the use of T_3 to resuscitate impaired donor hearts with lower ejection fractions, higher filling pressures, and increased ionotropic support prior to transplantation [158,162]. Subsequently, several consensus conferences held in the United States and Canada have recommended the use of hormonal resuscitation consisting of T_3 (4 μg bolus followed by a 3 μg per hour infusion), vasopressin, methylprednisolone, and insulin in donors whose cardiac ejection fraction is less than 45% in an effort to increase the suitability of hearts for transplantation [160,163]. Thus, T_3 may be beneficial to stabilize or improve cardiac function in donors prior to cardiac transplantation.

Thyroid Hormone Therapy in Congestive Heart Failure

When T_3 and thyroid hormone analogs were initially studied as adjuncts to the treatment of heart failure [164,165], the rationale for the use of these hormones had been as pharmacological agents for their potential ionotropic properties and interactions with the adrenergic system rather than as hormonal replacement therapy to correct abnormal serum thyroid hormone concentrations. Recently, more attention has been paid to the interactions between the heart and the thyroid hormones in cardiac disease states. In both cardiac failure and in hypothyroidism, cardiac output and cardiac contractility is decreased. Decreased serum T_3 concentrations typical of the sick euthyroid syndrome are often observed in patients with congestive heart failure, while serum T_4 concentrations remain normal [166–168]. Importantly, the T_3 found in cardiac myocytes appears to come from the circulating T_3 pool rather than from local deiodination of T_4, indicating that the heart may be more responsive to changes in circulating serum T_3 concentrations [96,97]. Consistent with this observation, similar decreases in cardiac genes, including α-myosin heavy chain, SR calcium ATPase, and β1 adrenergic receptors, have been observed in both hypothyroidism and in heart failure [96,97]. Finally, low T_3 levels have been determined to be a strong predictor of mortality in patients with congestive heart failure [107,108]. These observations have led several investigators to examine the role of thyroid hormone treatment in patients with congestive heart failure.

An initial uncontrolled study examined the effect of oral T_4 therapy on 20 patients with dilated cardiomyopathy [169]. Cardiac output and functional capacity was increased and systemic vascular resistance decreased. Hamilton et al. [170] examined the effect of a supraphysiologic intravenous infusion of T_3 on cardiac function in patients with New York Heart Association (NYHA) Class III or IV heart failure. Cardiac output increased and systemic vascular resistance decreased without any untoward effects. More recently, Pingitore et al. [171] randomized 20 patients with NYHA Class III or less heart failure to a 3-day intravenous infusion of T_3 or placebo. During the first day of the T_3 infusion, serum T_3 levels were supraphysiologic and then declined to the high normal range on day 2 and 3. The T_3 infusion produced a significant improvement in the neurohumoral profile, with a decrease in serum noradrenaline, N-terminal pro-B-type natriuretic peptide, and aldosterone concentrations, and an increase in the left ventricular end diastolic volume. Since above-normal serum T_3 concentrations were achieved during all or part of these two studies, there is a question of whether the beneficial effects of T_3 are a pharmacologic effect rather than a physiologic one. There are currently no studies on the long-term use of T_3 in the treatment of congestive heart failure. However, as with children undergoing cardiac surgery, more studies may be indicated in this patient population.

Thyroid Hormone Therapy in the Hypothyroid Patient in the Intensive Care Unit

This chapter has discussed the evaluation and management of patients without intrinsic thyroid dysfunction who present with abnormal thyroid hormone parameters as a result of nonthyroidal illness. However, thyroid hormone therapy is needed when the hypothyroid patient presents to the ICU. By definition, the nonthyroidal illness syndrome excludes patients with intrinsic thyroid dysfunction; however, all of the changes in TSH secretion, thyroid hormone metabolism, and thyroid-binding proteins discussed earlier also occur in the hypothyroid patient. As such, the same caveats toward measuring thyroid hormone parameters exist. Most importantly, an admission to the ICU is not the time to determine the adequacy of thyroid hormone replacement in a hypothyroid patient on a previously stable outpatient regimen.

Hypothyroid patients should be continued on their outpatient L-T_4 dose. Oral L-T_4 is the preferred method for replacing thyroid hormone in a hypothyroid patient. Because of the long half-life of about 7 days of L-T_4, the L-T_4 dose can be held for 1 to 2 days if the oral route is unavailable. If oral therapy cannot be resumed within 3 days, intravenous L-T_4 should be administered. Because 50% to 70% of an oral dose of L-T_4 is absorbed, the intravenous L-T_4 dose should be 30% to 50% less than the oral dose. Neither oral nor intravenous L-T_3 is indicated in the hypothyroid patient in the absence of myxedema coma.

If hypothyroidism is diagnosed in the ICU setting and initiation of thyroid hormone replacement is required, special consideration should be given to the patients with coronary artery disease. In patients with significant preexisting coronary artery disease, starting thyroid hormone may aggravate the angina. It is recommended that the initial dose of L-T_4 should not exceed 25 μg for those with known ischemic hearth disease and 50 μg for patients aged 65 years or older without such a preexisting diagnosis.

The oral dose of L-T_4 may differ in the ICU setting, due to pharmacological agents or gastrointestinal conditions that may decrease the absorption of L-T_4. Patients with jejunoileal bypass surgery, bowel resection, malabsorptive disorders (like celiac disease), and conditions that impair gastric acidity may need adjustment in the dose of L-T_4. L-T_4 should not be administered within 2 to 3 hours of calcium carbonate, bile acid sequestrants, ferrous sulfate, phosphate binders, sucralfate, and aluminium-containing antacids since they may interfere with the absorption of L-T_4. Also by their effect on decreasing the gastric acidity, proton pump inhibitors, if given for a long period, may decrease the absorption of L-T_4.

SUMMARY

In summary, the spectrum of alterations in thyroid hormone concentrations and regulation seen in the critically ill patient are the result of a coordinated systemic reaction to illness. The

TABLE 107.4

SUMMARY OF CLINICAL TRIALS ON THE EFFECTS OF TREATMENT OF THE SICK EUTHYROID SYNDROME WITH THYROID HORMONE [70]

General ICU patients
- No benefit of L-T_4 on general medical patients [120], patients with acute renal failure [121], or renal transplant [122].
- No benefit of L-T_3 on burn patients [123].

Premature infants
- No benefit of L-T_4 on developmental indices of premature infants at 26–28 weeks' gestation [135].
- Possible beneficial effect of L-T_4 on infants of at 25–26 weeks' gestation but possible deleterious effects on infants of 27–30 weeks' gestation [136].
- No benefit of L-T_3 [140].
- Meta-analysis shows no significant effects of thyroid hormone treatment of premature infants [141].

Cardiac surgery patients
- Small studies suggest improved hemodynamic parameters with L-T_3 [151,152].
- Large trials show no benefit of L-T_3 noted in patients undergoing cardiac bypass [153,155,176].
- Possible improvement in hemodynamic parameters and hospital stay with L-T_3 in children undergoing cardiac surgery [156,157].

Cardiac donors
- Variable results (helpful [159,160], no benefit [158,161]) on the effects of L-T_3 in preserving function of normal hearts in brain-dead cardiac donors prior to transplantation.
- Possible benefits of L-T_3 in improving function of impaired hearts prior to transplant, potentially increasing the pool of organs available for transplantation [158,162].
- Consensus conferences recommend the use of L-T_3 as part of the hormonal resuscitation in donors whose cardiac ejection fraction is <45% [160].

Congestive heart failure
- Small uncontrolled study suggested short term L-T_4 therapy increased cardiac output and functional capacity and decreased systemic vascular resistance [169].
- Improved hemodynamic parameters and neurohumoral profiles with short-term intravenous L-T_3 infusion, possibly requiring supraphysiologic concentrations [170,171].

question of whether the sick euthyroid syndrome in critically ill patients represents pathologic alterations in thyroid function that negatively impacts these patients or simply reflects the multisystem failure (i.e., respiratory, cardiac, renal, hepatic failure) that occurs in critically ill patients is still debatable [172–175]. The interpretation of thyroid function tests in the ICU patient and the identification of those patients with intrinsic thyroid dysfunction is often difficult and must take into consideration both the clinical assessment of the patient and the duration and severity of the illness. Whenever possible, it is best to defer the evaluation of thyroid function until the patient has recovered from the critical illness. Thyroid hormone replacement therapy has not been shown to be of benefit in the vast majority of these patients in the published studies to date (Table 107.4 [70]). At the present time, in the absence of any clinical evidence of hypothyroidism, there does not appear to be any compelling evidence for the use of thyroid hormone therapy in any patient with decreased thyroid hormone parameters due to the sick euthyroid syndrome.

CHAPTER 108 ■ DISORDERS OF HEMOSTASIS IN CRITICALLY ILL PATIENTS

JEREMIAH BOLES AND ALICE D. MA

Disorders of hemostasis are common in critically ill patients. This chapter will review hemostasis, pathophysiology of commonly encountered congenital and acquired bleeding disorders along with their associated symptoms, laboratory findings, and management.

REVIEW OF NORMAL HEMOSTASIS

Hemostasis can be broken into a series of steps occurring in overlapping sequence. Primary hemostasis refers to the interactions between the platelet and the injured vessel wall, culminating in the formation of a platelet plug. The humoral phase of clotting, or secondary hemostasis, encompasses a series of enzymatic reactions, resulting in a hemostatic fibrin plug. Finally, fibrinolysis and wound repair occur. Each of these steps is carefully regulated, and perturbations can predispose to either hemorrhage or thrombosis. Depending on the nature of the defect, the hemorrhagic or thrombotic tendency can be either profound or subtle.

Primary hemostasis begins at the site of vascular injury, with platelets adhering to the subendothelium, utilizing interactions between molecules such as collagen and von Willebrand factor (vWF) in the vessel wall with glycoprotein (GP) receptors on the platelet surface. Upon exposure to agonists present at a wounded vessel, signal transduction leads to platelet activation. Via a process known as inside-out signaling, the platelet membrane integrin $\alpha_{2b}\beta_3$ (also known as GP IIbIIIa) undergoes a conformational change to be able to bind fibrinogen, which cross-links adjacent platelets, leading to platelet aggregation. Secretion of granular contents is also triggered by outside signals, potentiating further platelet activation (Fig. 108.1). Lastly, the surface of the platelet changes to serve as an adequate scaffold for the series of biochemical reactions resulting in thrombin generation.

Following platelet activation, a series of enzymatic reactions take place on phospholipid surfaces, culminating in the formation of a stable fibrin clot. Several models have attempted to make sense of these reactions. The cascade model was developed by two groups nearly simultaneously [1,2] and explained the extrinsic, intrinsic, and common pathways leading to fibrin formation (Fig. 108.2). While the cascade model accounts for the physiologic reactions underlying the prothrombin time (PT) and the activated partial thromboplastin time (aPTT), it fails to explain completely the bleeding diathesis seen in individuals deficient in factors XI, IX, and VIII, as well as the lack of bleeding in those deficient only in contact factors. A cell-based model of hemostasis has been developed to address these deficiencies. In this model, upon vascular injury, the membrane of a tissue factor (TF)-bearing cell such as an activated monocyte or fibroblast serves as a platform for generation of a small amount of thrombin and FIXa, which then serves to activate platelets and cleave FVIII from vWF. Newly formed FVIIIa participates in the tenase complex on the surface of activated platelets to form FXa that interacts with the FVa generated on the platelet surface to form the prothrombinase complex. This complex generates a large burst of thrombin which is sufficient to cleave fibrinogen, activate FXIII, and activate the thrombin activatable fibrinolysis inhibitor (TAFI), thus allowing for formation of a stable fibrin clot (Fig. 108.2).

Fibrinolysis leads to clot dissolution once wound healing has occurred, in order to restore normal blood flow. Plasminogen is activated to plasmin by the action of either tissue plasminogen activator (t-PA) or urokinase plasminogen activator (u-PA). Plasmin degrades fibrin and fibrinogen and can thus dissolve both formed clot as well as its soluble precursor. Plasmin is inhibited by a number of inhibitors, of which α_2-plasmin inhibitor is the most significant. Plasminogen activation is also inhibited by a number of molecules; chief among them is plasminogen activator inhibitor-1 (PAI-1). Lastly, cellular receptors act to localize and potentiate or clear plasmin and plasminogen activators (see Chapter 111 for further discussion).

APPROACH TO THE BLEEDING PATIENT

Physicians in the intensive care unit (ICU) often encounter bleeding patients and it can be difficult to identify which of these patients require further evaluation. Patients who experience bleeding that is excessive, spontaneous, or delayed following surgery or tissue injury require further investigation, which must begin with a thorough clinical history. A bleeding history should assess a patient's exposure and response to all hemostatic challenges in the past such as trauma, surgery, and childbirth. Characterization of menses in females also may be revealing. Several bleeding assessment tools have been developed and are useful in the evaluation for an underlying coagulopathy, particularly von Willebrand disease (vWD) [3]. This history should also identify coexisting medical conditions such as liver, kidney, or thyroid disorders. A careful medication history is also important, including use of all over-the-counter medications which may contain aspirin, as well as any herbal preparations. Also of cardinal importance is an evaluation for a family history of abnormal bleeding. An inherited or congenital bleeding disorder is suggested by abnormal bleeding with onset shortly after birth and persistence throughout life. It is further supported by a family history with a consistent genetic pattern. However, it is important to note that a negative family history does not exclude a congenital bleeding disorder. For instance, approximately one third of all cases of hemophilia A arise from spontaneous mutations. Many of the rare coagulation disorders, including deficiency of factors II, V, VII, X,

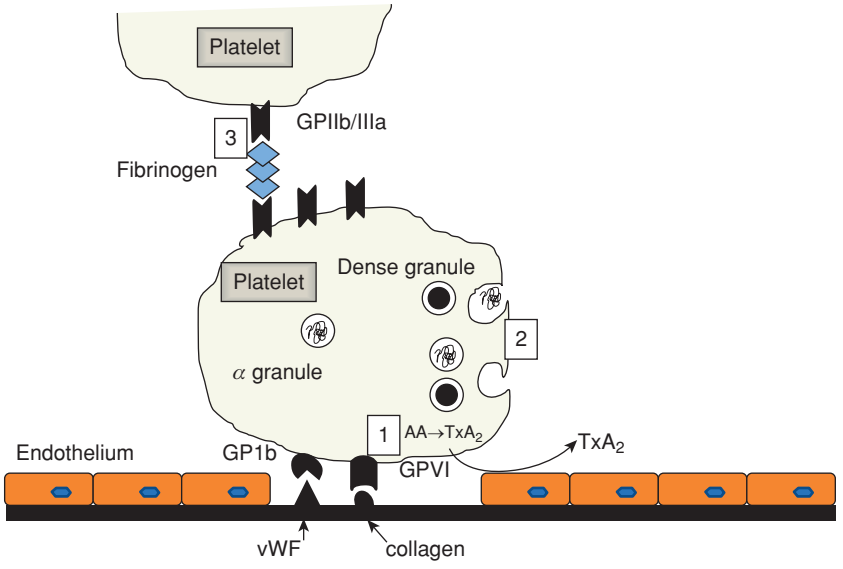

FIGURE 108.1. Primary hemostasis. (1) Exposure of subendothelium at sites of vascular disruption results in platelet adhesion via GPIb and GP VI with exposed von Willebrand factor (vWF) and collagen, respectively. Following platelet adhesion TxA_2 is produced and released which promotes vasoconstriction and platelet aggregation. (2) Platelet adhesion also results in fusion of cytoplasmic granules to the plasma membrane. Release of alpha and dense granules activates nearby platelets. (3) Platelet activation results in exposure of GPIIb/IIIa on the platelet surface allowing fibrinogen to cross bridge platelets resulting in a platelet plug.

as well as vWD type 2 N, among others, are inherited in an autosomal recessive fashion, and the parents of the patient may be entirely asymptomatic.

A bleeding history should also ascertain past sites/mechanisms of bleeding. Surgical bleeding in patients with an underlying hemorrhagic condition is typically described as "diffuse oozing," without the readily identifiable bleeding source seen with a surgical mishap such as a severed vessel. Patients with platelet disorders typically manifest mucocutaneous bleeding such as gingival bleeding and epistaxis as well as menorrhagia, petechiae, and ecchymoses. Platelet defects impact primary hemostasis and therefore the bleeding in these disorders is often immediate following surgery or trauma, whereas delayed bleeding is more classically associated with coagulation disorders. Patients with coagulation defects typically present with hemorrhages into soft tissues such as muscles and joints.

A physical examination should pay particular attention to the skin, joints, mucosal surfaces, and liver and spleen size.

LABORATORY ASSAYS OF PRIMARY AND SECONDARY HEMOSTASIS

While the history and physical examination can increase suspicion for the presence of a bleeding disorder, laboratory confirmation is required for precise diagnosis and treatment.

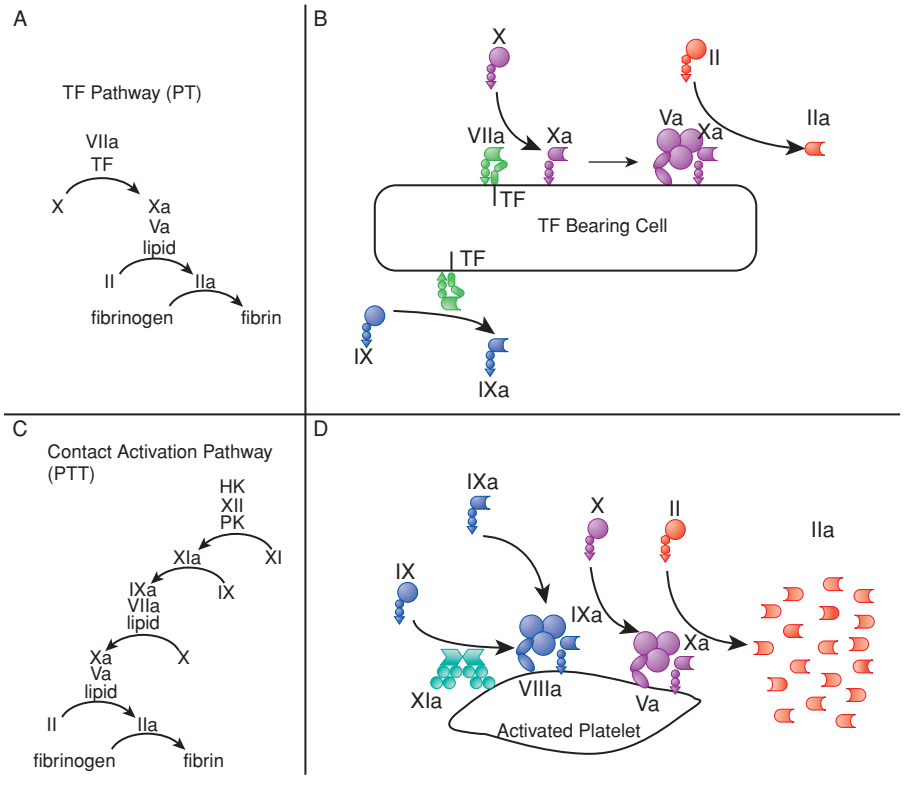

FIGURE 108.2. Secondary hemostasis. **A:** Tissue factor (TF) pathway cascade model of coagulation—basis for prothrombin time (PT) laboratory assay. **B:** Circulating FVIIa binds TF on a TF-bearing cell. TF/FVIIa along with calcium (Ca) and phospholipid (lipid) form the "extrinsic tenase" complex and converts FX to FXa. FXa combines with FVa, calcium, and phospholipid, "prothrombinase" complex, to activate FII to FIIa which in turn converts fibrinogen into fibrin. **C:** Contact activation pathway model of coagulation—basis for partial thromboplastin time (PTT) laboratory assay. **D:** On an activated platelet surface, FXIa activates FIXa. FIXa is also formed on the surface of a TF-bearing cell (B). FIXa, along with FVIIIa, Ca, and lipid, constitute the "intrinsic tenase" complex. This complex converts FX to FXa with subsequent FIIIa generation through the prothrombinase complex. (Courtesy of Dougald Monroe.)

Laboratory evaluation is particularly crucial in individuals who are suspected of having a bleeding disorder but in whom prior bleeding is absent, such as those with mild congenital bleeding disorders who never previously underwent a sufficient hemostatic challenge, or those with acquired hemorrhagic disorders.

Initial Evaluation of Primary Hemostasis—Platelet Function

An assessment of a patient's platelet count is fundamental in evaluating primary hemostasis. This is typically part of a complete blood count (CBC). Reduced platelet counts, or thrombocytopenia, may be seen in a large number of acquired and congenital conditions. Evaluation and management of thrombocytopenia is further discussed in Chapter 109.

An evaluation of the peripheral smear is also cardinal in any evaluation of a bleeding patient. It allows one to assess platelet size and morphology, presence of platelet clumping (pseudothrombocytopenia), leukocyte inclusions, and red cell fragments, among other aberrancies, which may further direct workup and treatment.

Traditionally, platelet function was evaluated by bleeding time (BT). However, many institutions have discontinued using this test given the difficulty in standardization. Furthermore, the BT has been shown to be an inadequate predictor of bleeding, particularly in preoperative risk assessment [4]. More recently, automated tests have been developed to assess platelet function. The most widely used is the platelet function analyzer (PFA-100®). This assay measures the time required (closure time) for flowing whole, citrated blood to occlude an aperture in a membrane impregnated with a combination of either collagen and epinephrine or collagen and adenosine diphosphate (ADP). Closure time is affected by platelet count, hematocrit, platelet function, and vWF [5]. The PFA-100® appears to assess platelet function with greater sensitivity and reproducibility than the BT; however, a recent position statement from the Platelet Physiology Subcommittee of the Scientific and Standardization Committee of the International Society of Thrombosis and Hemostasis noted that although the PFA-100® is abnormal in some platelet disorders, it was not felt to have sufficient sensitivity or specificity to be used as a screening tool for platelet disorders [6].

Evaluation of Secondary Hemostasis—Coagulation

The PT and the aPTT are assays performed on citrated plasma, which require enzymatic generation of thrombin on a phospholipid surface. Prolongation of the PT and the aPTT can be seen in individuals with either deficiencies of, or inhibitors to, humoral clotting factors, though not all patients with prolongations of these assays will have bleeding diatheses (Table 108.1).

The PT measures the time needed for formation of an insoluble fibrin clot once citrated plasma has been recalcified and thromboplastin has been added, indicating activity of factors VII, V, X, and II and fibrinogen. It commonly is used to monitor anticoagulation with vitamin K antagonists such as warfarin. Since thromboplastin from various sources and different lots can affect the rates of clotting reactions, the International Normalized Ratio (INR) measurement was developed

TABLE 108.1

LABORATORY TEST ABNORMALITIES IN COMMON ACQUIRED AND CONGENITAL BLEEDING DISORDERS

	Acquired bleeding disorders	Congenital bleeding disorders
PT elevated, aPTT wnl	Liver disease DIC Vitamin K deficiency Vitamin K antagonists (e.g., warfarin)	FVII deficiency

wnl, within normal limits; DIC, disseminated intravascular coagulation; LMWH, low-molecular-weight heparin; PT, prothrombin time; PTT; partial thromboplastin time; vWD, von Willebrand disease.

to avoid some of this variability in PT measurement. Each batch of thromboplastin reagent has assigned to it a numerical International Sensitivity Index (ISI) value, which is used in the formula:

$$INR = (PT_{patient}/PT_{normal\ mean})^{ISI}$$

The INR is less predictive of bleeding in patients with liver disease, and can be inaccurate in patients with lupus anticoagulants that are strong enough to affect the PT.

The aPTT tests the activity of factors XII, XI, IX, VIII, X, V, and II, and fibrinogen, high-molecular-weight kininogen (HMWK), and plasma prekallikrein (PK) [7]. Citrated plasma is recalcified, and phospholipids (to provide a scaffold for the clotting reactions) and an activator of the intrinsic system such as kaolin, celite, or silica are added. The reagents used show variable sensitivities to inhibitors such as lupus anticoagulants and heparin, and to deficiencies (if any) in involved clotting factors, and normal ranges will vary from laboratory to laboratory. aPTT values that are vastly different from one laboratory to another should prompt suspicion of a lupus anticoagulant.

The Thrombin Clotting Time and Reptilase Time

The thrombin clotting time (TCT) or thrombin time (TT) measures the time needed for clot formation once thrombin is added to citrated plasma. Thrombin enzymatically cleaves fibrinopeptides A and B from the α- and β-chains of fibrinogen, allowing for polymerization into fibrin. The TT is prolonged in the presence of any thrombin inhibitor such as heparin, lepirudin, or argatroban; by low levels of fibrinogen or structurally abnormal fibrinogen (dysfibrinogens); and by elevated levels of fibrinogen or fibrin degradation products, which can serve as nonspecific inhibitors of the reaction. Patients with paraproteins can have a prolonged TT because of the inhibitory effect of the paraprotein on fibrin polymerization.

Reptilase is snake venom from *Bothrops atrox* which also enzymatically cleaves fibrinogen. Reptilase cleaves only fibrinopeptide A from the α-chain of fibrinogen, but fibrin polymerization still occurs. Reptilase time (RT) is not affected by heparin but may be more sensitive than the TT to the presence of a dysfibrinogenemia.

Mixing Studies

Mixing studies are used to evaluate prolongations of the aPTT (less commonly the PT or the TT) and are useful in making the distinction between an inhibitor and a clotting factor deficiency. The patient's plasma is mixed 1:1 with normal control plasma, and the assay is repeated (with or without prolonged incubation at 37°C). Correction of the clotting test signifies factor deficiency, since the normal plasma will supply the deficient factor. Incomplete correction of the clotting test after mixing suggests the presence of an inhibitor, since an inhibitor will prolong clotting in normal plasma. Incomplete correction can sometimes be seen with nonspecific inhibitors such as lupus anticoagulants, elevated fibrin split products, or a paraprotein. Less commonly, deficiencies of multiple clotting factors can lead to incomplete correction of the mixing study, since the mixing study was designed to correct deficiency of a single factor.

Tests of specific factor activity levels as well as evaluation for vWD will be discussed in the following sections.

CONGENITAL DISORDERS OF HEMOSTASIS

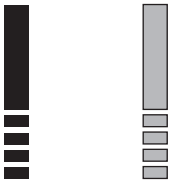
Due to a requirement for specialized management, all cases of suspected or proven congenital hemostatic defects require consultation with a hematologist upon admission to the critical care setting.

Von Willebrand Disease

It has been estimated that lower-than-reference levels of vWF occur in 1% of the population worldwide and therefore vWD is the most common congenital bleeding disorder [8]. However, only a fraction of the aforementioned individuals are symptomatic (approximately 5% of those with low levels) [9]. vWD is inherited in an autosomal manner with the more common type I disease being autosomal dominant.

vWD constitutes a quantitative or qualitative deficiency in vWF, and is divided into three subtypes according to the pathophysiology. Types 1 and 3 are the result of a partial (type 1) or virtually a complete (type 3) quantitative deficiency of vWF, while type 2 is a qualitative defect in vWF. Type 1 vWD represents the most common subtype accounting for approximately 70% of patients, while type 2 accounts for 15% to 20% and type 3 for only 2% to 5% of vWD patients [10].

Because bleeding symptoms in persons with vWD may be absent or overlooked until a major hemorrhage due to surgery or trauma has occurred, the diagnosis should be considered in an ICU patient with otherwise unexplained excessive bleeding, particularly if there is a significant family history including an autosomal pattern of inheritance. The most common historical bleeding symptoms include epistaxis, increased bleeding after dental extractions, and menorrhagia. A validated bleeding assessment tool has been developed to screen outpatients who may benefit from formal vWD laboratory testing [3], but its usefulness in the critical care setting has not been established.



A formal diagnosis of vWD should be based on three components: (a) a history of excessive bleeding, either spontaneous mucocutaneous and/or postsurgical, (b) a positive family history for excessive bleeding, and (c) confirmatory laboratory testing. Diagnostic tests for vWD, reviewed elsewhere [11], should be performed in a specialized laboratory and are summarized in Table 108.2.

The goals of treatment in vWD are to correct the quantitative or qualitative deficiencies in vWF, platelets, and FVIII. Treatment options include desmopressin (DDAVP), vWF-containing concentrates, and/or antifibrinolytics. See Tables 108.3 and 108.4 for general treatment guidelines.

In normal volunteers, DDAVP increases plasma levels of FVIII, vWF, and tissue plasminogen activator [12]. It may be given IV or SQ [13]. When given intravenously, the FVIII and vWF levels are usually increased three- to fivefold above basal levels within 30 minutes. vWD patients should undergo a DDAVP trial to gauge their individual response since there is considerable interindividual variability. Dosing of DDAVP for vWD is generally recommended at 0.3 μg per kg (IV or SQ), or 300 μg intranasally, which can be repeated at intervals of 12 to 24 hours. Tachyphylaxis (due to depletion of FVIII/vWF from repeated endothelial exocytosis into plasma) following repeated dosing is expected; DDAVP given as a second dose is 30% less effective than the first dose [14]. For this reason, and due to the risk of hyponatremia (which can lead to seizures), serial dosing should be limited to two to three doses in a 72-hour period with concurrent free water restriction and monitoring of serum sodium levels. DDAVP is most effective in type 1 vWD. It is relatively contraindicated in type 2B vWD because of the transient induction of thrombocytopenia [15]. Patients

with type 3 vWD are usually unresponsive to DDAVP. Certain hemophilia treatment centers caution against use of DDAVP in patients with coronary artery disease, since this agent may also activate platelets.

Antifibrinolytic agents (epsilon aminocaproic acid and tranexamic acid) can be used alone or as adjunctive treatment in vWD patients with mucosal bleeding. These drugs inhibit fibrinolysis by inhibiting plasminogen activation, thereby promoting clot stability. They are contraindicated in the setting of gross hematuria as resultant ureteral obstruction by insoluble clot has been described. Given a concern for thrombosis, antifibrinolytics should be avoided in patients with

TABLE 108.3

DOSING GUIDELINES FOR VON WILLEBRAND DISEASE (vWD) TREATMENT

Medication	Dose	Comments
DDAVP	Nasal spray: 300 μg (1 spray in each nostril) If weight <50 kg 150 μg (1 spray in 1 nostril) IV: 0.3 μg/kg (not to exceed 20–25 μg)	Most useful in type 1 vWD, ineffective in type 3. Requires challenge to document efficacy. Relatively contraindicated in type 2B as may exacerbate thrombocytopenia May repeat dose in 12 h and/or 24 h. Tachyphylaxis occurs with repeat dosing. Due to risk of hyponatremia, if dosing serially, limit doses to no more than 2–3 in a 72-h period, fluid restrict, and follow serum sodium levels. Avoid in patients with coronary disease.
Antifibrinolytic agents: epsilon-aminocaproic acid (EACA)	50 mg/kg PO up to q 6h (lower doses may be effective) or 1 g/h IV continuous infusion Do not exceed 24 g/24 h	Especially useful for mucocutaneous bleeding, especially for dental procedures May be used as adjunctive treatment (DDAVP, factor concentrates)
Tranexamic acid	25 mg/kg q 8 h (not yet available in the United States)	Avoid in upper urinary tract bleeding
vWF-containing FVIII concentrates (e.g., Humate-P, Alphanate)	60–80 RCoF U/kg as an initial dose, then 40–60 u/kg IV every 12 h (see Table 108.4)	FVIII activity levels are often used in the monitoring of response to vWF-containing products as real-time vWF activity measures are not always available Dosed in RCoF units. Individual product is labeled with ratio of RCoF units:FVIII

DDAVP, desmopressin; vWD, von Willebrand disease; vWF, von Willebrand factor; RCoF, ristocetin cofactor.

TABLE 108.4

SUGGESTED INITIAL DOSING OF vWF CONCENTRATES FOR PREVENTION OR MANAGEMENT OF BLEEDING

Major surgery/bleeding	
Loading dose[a]	60–80 RCoF U/kg
Maintenance dose	40–60 RCoF U/kg, typically every 12 h initially
Monitoring	vWF:RCo and FVIII trough and peak, at least daily
Therapeutic goal	Trough vWF:RCo and FVIII >50 IU/dL for 7–14 d
Safety parameter	Do not exceed vWF:RCo 200 IU/dL or FVIII 250–300 IU/dL
May alternate with DDAVP for latter part of treatment	
Minor surgery/bleeding	
Loading dose[a]	30–60 U/kg
Maintenance dose	20–40 U/kg every 12–48 h
Monitoring	vWF:RCo and FVIII trough and peak, at least once
Therapeutic goal	Trough vWF:RCo and FVIII >50 IU/dL for 3–5 d
Safety parameter	Do not exceed vWF:RCo 200 IU/dL or FVIII 250–300 IU/dL
May alternate with DDAVP for latter part of treatment	

[a]Loading dose is in vWF:RCo IU/dL.

prothrombotic conditions, disseminated intravascular coagulation (DIC), or when receiving prothrombin complex concentrates (PCCs).

vWF factor-containing FVIII concentrates are appropriate for patients with severe vWD or in situations when other therapies (including DDAVP) are ineffective and are preferred to cryoprecipitate, which contains vWF, but has not undergone viral inactivation. When used in the treatment of vWD, they are dosed in ristocetin cofactor (RCoF) units, as opposed to FVIII units (Table 108.4). Limited data suggest a role for rFVIIa in patients with type 3 vWD who have developed alloantibodies to vWF [16].

The National Heart Lung and Blood Institute has recently published guidelines for the diagnosis, evaluation, and management of vWD [17].

Hemophilia

The hemophilias are congenital bleeding disorders characterized by X-linked inheritance and result in a deficiency of FVIII (hemophilia A) or FIX (hemophilia B). In the United States, they have a combined incidence of 1 in 5,000 male births. Hemophilia A is more common than hemophilia B and accounts for approximately 80% of cases. Since hemophilia is an X-linked disorder, all daughters of affected males are obligate carriers and all sons are healthy. Females may rarely manifest bleeding symptoms if they (a) are the homozygous offspring from a carrier mother and affected father, (b) have a high degree of lyonization, or (c) are a carrier with concomitant Turner's syndrome (XO).

The clinical phenotype of hemophilia patients depends on the residual level of circulating procoagulant protein (FVIII or FIX). It is possible to differentiate three degrees of clinical severity: (a) mild hemophilia (5% to 50% factor activity) in which bleeding is prolonged but typically only occurs following trauma or surgery, (b) moderate hemophilia (1% to 5% factor activity) in which prolonged bleeding follows minor trauma, and (c) severe hemophilia (<1% factor activity) where patients experience spontaneous hemorrhage into joints (hemarthrosis) and muscles.

In severe and moderate hemophilia, the PT is normal and the aPTT is prolonged. However, the PTT may be normal in patients with mild hemophilia whose residual factor activity is >20%. If the aPTT is prolonged, it should correct with a mixing study, since hemophilia is a factor deficiency syndrome. Specific factor assays should be performed to confirm a diagnosis of hemophilia A or B.

The management of most cases of hemophilia, thanks to the availability of replacement clotting factor concentrates, occurs in the outpatient setting, but individuals who previously have escaped diagnosis (mild or moderate hemophilia) or who have sustained major trauma or complications from a bleeding episode (compartment syndrome) may present to critical care. If not previously diagnosed, hemophilia should be suspected in male patients who have a personal history of bleeding into joints or muscles, a history of excessive bleeding upon surgical challenge, and/or a positive sex-linked family history of bleeding.

Hemarthrosis, a hallmark of hemophilia, accounts for approximately 85% of all bleeding events in severe hemophilia and most commonly involves the ankles, knees, and elbows [18]. Intramuscular hematomas in persons with hemophilia may expand to the point where blood flow is compromised to surrounding neurovascular structures resulting in tissue gangrene and compartment syndrome; the condition requires surgery and aggressive clotting factor replacement therapy [19] (Table 108.5). Gastrointestinal bleeding is uncommon in hemophilia. However, patients with an underlying structural lesion may present with hematemesis, hematochezia, or melena. Hemophilia patients who present with evidence for gastrointestinal bleeding should have a complete endoscopic evaluation to assess for and treat any underlying lesion. Approximately 90% of persons with severe hemophilia will develop hematuria during their life, although the condition is typically painless, benign, and unassociated with a structural lesion. As discussed earlier, antifibrinolytic agents are contraindicated in patients with genitourinary bleeding.

TABLE 108.5

RECOMMENDED HEMOSTATIC LEVELS IN HEMOPHILIA[a]

Clinical situation	Hemophilia target factor activity (%)[a]
Mild hemorrhage (joint, muscle)	30–40
Mucosal hemorrhage (oral, dental)	30–40 with EACA
Major hemorrhage	>50
Life-threatening hemorrhage or perioperative management (major and orthopedic procedures)	100

[a]Minimum recommended goal factor activity levels.
EACA, epsilon-aminocaproic acid.

Hemorrhage into head and neck structures is a medical emergency in persons with hemophilia. Retropharyngeal hematoma, which may occur spontaneously or following dental or surgical procedures, may present with inability to control saliva, neck swelling, and pain. If untreated, it may result in airway compromise and in some cases may require tracheostomy. Hemorrhage into the central nervous system is a severe and potentially fatal (albeit rare) complication of hemophilia. Intracranial hemorrhage (ICH) may occur spontaneously in severe hemophilia or as the result of trauma. Prompt recognition of ICH is paramount and factor replacement therapy should be given immediately while the diagnostic workup is underway (Table 108.5).

The approach to treating major bleeding episodes in hemophilia A and B is similar. The clinical scenario dictates the target factor activity level (Table 108.5). For example, an ICH requires a target activity level of 100% initially, while levels of 30% to 40% may be sufficient for minor bleeds such as uncomplicated hemarthrosis. Prior to completion of the diagnostic (radiologic or otherwise) workup, clotting factor concentrate should be administered immediately to a person with hemophilia and a suspected life- or limb threatening bleed. Plasma-derived and recombinant factor concentrates [20] contain much higher concentrations of the desired factor compared to fresh frozen plasma (FFP) or cryoprecipitate. If possible, avoidance of FFP or cryoprecipitate is advised to avoid volume overload, transfusion-related lung injury (TRALI), and potential viral transmission (see Chapter 114).

DDAVP may be used instead of factor concentrate in selected patients with mild hemophilia A who have minor bleeding or a requirement for an enhanced FVIII activity level prior to a short-lived bleeding challenge. Any mild hemophilia A patient should undergo a DDAVP trial to gauge his or her individual response in lieu of assuming efficacy of the agent. FVIII levels in plasma increase two- to six-fold following administration. For mild hemophilia A, the recommended dose is 0.3 μg per kg (IV or SQ) or 300 μg intranasally; as previously discussed, tachyphylaxis and hyponatremia may develop after serial dosing.

Antifibrinolytic agents are a useful adjunctive treatment in hemophilia patients with mucosal bleeding. However, hemophilic patients with hematuria, DIC, receiving a PCC, or other prothrombotic conditions should not be treated with antifibrinolytics.

One of the most significant complications of hemophilia treatment is the development of an inhibitor. Inhibitors are alloantibodies against exogenously administered clotting factor that neutralize the factor. The development of a new inhibitor is more common in hemophilia A than in hemophilia B [21], in severe hemophilia, and among previously untreated patients (as opposed to adults who typically have been extensively exposed to clotting factor concentrate).

Inhibitors, if present at high titer, neutralize exogenous factor rendering factor concentrates ineffective. Therefore, an inhibitor should be suspected when administration of factor concentrate at a dose previously sufficient to achieve hemostasis, or improve bleeding, fails to do so. Once suspected, a Bethesda assay should be performed to document the titer of the inhibitor (reported in Bethesda units, BU). Of the two goals of treatment in patients with inhibitors, namely, to achieve adequate hemostasis and to eradicate the inhibitor, only the former is typically relevant to the critical care setting. Bleeding should be treated with bypassing agents, typically an activated prothrombin complex concentrate (aPCC) or rFVIIa [22]. If the titer is <5 BU, high doses of FVIII or FIX may be given as initial treatment in cases of life- or limb-threatening bleeding episodes. In patients with a long-standing inhibitor, however, the anamnestic response negates factor activity after 5 to 7 days, at which point bypassing agents become necessary.

RARE CONGENITAL COAGULATION DISORDERS

Less Common Coagulation Factor Deficiencies

The hemophilias and vWD represent approximately 85% of congenital bleeding disorders. The remaining disorders will be briefly discussed next.

Disorders of Fibrinogen

Congenital fibrinogen disorders result from a quantitative (afibrinogenemia) or qualitative (dysfibrinogenemia) defect in fibrinogen synthesis. Congenital afibrinogenemia has a variable bleeding phenotype with the majority of patients experiencing moderate bleeding [23]. Afflicted individuals present typically in the neonatal period with umbilical stump bleeding or bleeding following circumcision [23]. Patients may also experience hemarthrosis, intramuscular hemorrhage, spontaneous abortion, mucosal surface bleeds, ICH, or spontaneous splenic rupture [24]. Heterozygotes are typically asymptomatic. The clinical phenotype in patients with congenital dysfibrinogenemia is variable and includes (a) asymptomatic (55%), (b) hemorrhagic (25%), (c) thrombotic (10% to 20%), or (d) a combination of both hemorrhagic and thrombotic complications (1% to 2%) [25]. Treatment of congenital fibrinogen disorders should be individualized given the clinical variability. In general, replacement therapy in the form of fibrinogen concentrates, cryoprecipitate, or (not recommended) FFP should be given to patients with a hemorrhagic presentation to achieve a goal fibrinogen level of 50 to 100 mg per dL [26].

Prothrombin (FII) Deficiency

Congenital prothrombin deficiency is characterized by a concordant decrease in prothrombin antigen and activity [27]. Aprothrombinemia has not been reported. Patients with hypoprothrombinemia present with severe hemorrhage including ICH, mucocutaneous bleeding, hemarthrosis, spontaneous abortions, and significant postoperative bleeding. Heterozygotes are usually asymptomatic; however, they may experience

increased postoperative bleeding [28]. Prothrombin deficiency is treated with factor replacement in the form of FFP or PCC to a goal prothrombin level of 30% [29].

Factor V Deficiency

FV deficiency is associated with mucocutaneous bleeding and rarely with ICH [30]. There are mild, moderate, and severe deficiency states. Patients with severe deficiency usually present with umbilical stump and mucocutaneous bleeding. Older individuals may present with postoperative bleeding or menorrhagia. FV deficiency is treated with FFP to a goal activity level of 20% to 30%. Alpha granules in platelets contain FV and platelet transfusions have been used in the treatment of FV deficiency when patients have developed neutralizing inhibitors to FV with varying success [31]. Combined deficiency of FV and FVIII should always be considered in the differential diagnosis of patients who present with FV deficiency. This is discussed next [32].

Combined Factor V and VIII Deficiency

Combined FV and FVIII deficiency (F5F8D) is a rare disorder where patients have detectable, but low antigen and activity levels of both factors, typically in the 5% to 15% range. Patients present with increased bleeding following trauma or surgery. Patients are treated with a combination of FFP and FVIII concentrates.

Factor VII Deficiency

Patients with less than 1% FVII activity manifest a severe bleeding disorder, predominantly involving the mucous membranes, muscles, joints, and following surgery or trauma, while those with more than 5% have relatively mild symptoms. Factor VII activity correlates poorly with bleeding severity, but in general, only modest amounts of circulating FVII are required for adequate hemostasis, and bleeding is uncommon, even with surgery, in individuals with FVII activity levels >15% to 20% [33,34]. In the United States, rFVIIa is used to treat FVII deficiency. Plasma-derived FVII concentrates are available in Europe to treat this disorder [35,36]. When rFVIIa and/or FVII concentrates are unavailable, PCC (depending on factor formulation) or FFP may be used.

Factor X Deficiency

In congenital FX deficiency, severity of bleeding appears to correlate with residual FX activity and may be quite severe. In a case series of Iranian patients with congenital FX deficiency, the most common symptoms were epistaxis, menorrhagia, and hemarthrosis [37]. FX deficiency is treated with PCCs.

Factor XI Deficiency

FXI deficiency, previously known as hemophilia C, is common amongst Ashkenazi Jews where the gene frequency is 8% to 9% [38]. The inheritance is autosomal rather than X linked as with hemophilia A and B. Severe FXI deficiency (<15% to 20% FXI activity) occurs in homozygotes or compound heterozygotes. Heterozygous individuals have a partial FXI deficiency (20% to 70% FXI activity) [39]. Bleeding is unpredictable as some severe FXI deficiency patients are asymptomatic, while an analysis of 50 kindreds demonstrated that 30% to 50% of heterozygotes experienced significant bleeding [40].

Treatment for FXI deficiency includes FFP, antifibrinolytic agents [41], FXI concentrates (available in the United Kingdom and France) [42], and rFVIIa (not FDA approved for this purpose) [43]. There is concern of a prothrombotic potential associated with FXI concentrates as DIC and arterial thrombosis have been described in up to 10% of patients. Heparin has been added to these concentrates to reduce this thrombotic potential, but there is a general recommendation to maintain FXI levels at no greater than 70 IU per dL [44].

Factor XIII Deficiency

The most common presentation for FXIII-deficient patients is umbilical stump bleeding [45]. FXIII-deficient patients may also experience ICH, hemarthrosis, menorrhagia, and increased bleeding following surgery or trauma [46]. FXIII has a half-life of 8 to 12 days and levels required to maintain hemostasis are only in the range of 2% to 5%. Treatment includes FXIII concentrates, FFP, or cryoprecipitate. Given FXIII's long half-life, factor concentrates may be given once every several weeks as prophylactic therapy [47].

Vitamin K-Dependent Factor Deficiencies

Patients with combined deficiency of the vitamin K-dependent factors (FII, FVII, FIX, FX, proteins C and S) may present with umbilical stump bleeding or ICH [48]. Factor activity levels are variable and generally range from 1% to 30%. High doses of supplemental vitamin K may significantly improve or completely correct deficient factor activities. In acute bleeding episodes, patients may be treated with FFP or PCCs.

Congenital Qualitative Platelet Disorders

Defects in Platelet Adhesion

Bernard–Soulier syndrome (BSS) is a rare, autosomal recessive, severe bleeding disorder characterized by thrombocytopenia, giant platelets, and severe mucocutaneous bleeding [49]. Deficient platelet binding to subendothelial vWF is due to abnormalities (either qualitative or quantitative) in the GP Ib/IX/V complex. The mainstay of treatment in BSS is platelet transfusion during clinically significant hemorrhagic episodes. However, alloimmunization to transfused platelets is often encountered when patients develop neutralizing antibodies to GP Ib/IX/V on transfused platelets which renders those platelets useless. rFVIIa has been used to treat patients with these inhibitors and has proven successful in many cases [50].

Defects in Platelet Aggregation

Glanzmann thrombasthenia is a rare, autosomal recessive disorder characterized by absent platelet aggregation secondary to defective GP IIb/IIIa on the platelet surface. Affected patients present with severe to life-threatening mucocutaneous bleeding. Treatment includes platelet transfusion. However, many patients may become refractory as alloantibodies to transfused platelets form. rFVIIa has been used to treat bleeding in this disorder [51].

Disorders of Platelet Secretion: The Storage Pool Diseases

Platelets contain two types of intracellular granules, alpha and delta (or dense), which are required for an optimal secondary wave of platelet aggregation. The gray platelet syndrome is the most common alpha granule storage pool disease (SPD) and may predispose to early onset myelofibrosis, a

probable consequence of the impaired storage of growth factors such as PDGF [52]. Hermansky–Pudlak syndrome and Chediak–Higashi syndrome are SPDs affecting dense granules. The Hermansky–Pudlak syndrome is associated with oculocutaneous albinism and increased accumulation of an abnormal fat-protein compound, ceroid, in the reticuloendothelial system [53]. The Chediak–Higashi syndrome is characterized by oculocutaneous albinism, neurologic abnormalities, immune deficiency with a tendency to infections, and giant inclusions in the cytoplasm of platelets and leukocytes [54]. The primary treatment for clinically significant bleeding in patients with SPDs is platelet transfusion.

ACQUIRED COAGULATION DISORDERS

Anticoagulant Drugs

Use of anticoagulants in the critical care setting is ubiquitous. The pharmacology, monitoring, and appropriate reversal of anticoagulant drugs are reviewed in detail in Chapter 110.

Generally, patients on anticoagulants who develop clinically insignificant bleeding may be closely monitored while the drug is continued; appropriate therapeutic monitoring (e.g., INR, aPTT, anti-Xa) should also be obtained and followed closely. Major bleeding, except in rare instances, typically should prompt discontinuation of anticoagulant drugs. Consideration should also be given to holding subsequent doses or reducing doses based on laboratory or clinical evolution.

Heparins, Low-Molecular-Weight Heparins, and Fondaparinux

These agents, and management of associated bleeding complications, are discussed in Chapter 110.

Warfarin (Coumadin)

Given its widespread use, warfarin is a common cause of iatrogenic, serious bleeding that frequently requires critical care. Warfarin is an oral vitamin K antagonist that exerts its anticoagulant effects through inhibition of vitamin K-dependent γ carboxylation of the vitamin K-dependent factors (FII, FVII, FIX, and FX). γ carboxylation is required for these coagulation factors to become biologically active. Warfarin also inhibits γ carboxylation of the vitamin K-dependent regulatory proteins C and S. Treatment with warfarin reduces the biologically active levels of all these vitamin K-dependent factors, both pro- and anti-coagulant. However, the net effect at steady state is anticoagulation. Given the half-life of the independent factors affected by warfarin, patients may become relatively prothrombotic in the first several days after warfarin initiation as proteins C and S are the first to become significantly reduced. This is the rationale for "bridging" with unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) for the first several days of warfarin administration to abrogate extension of existing thrombosis or development of new ones [55].

Warfarin is monitored via the PT and INR with a typical therapeutic range of 2.0 to 3.0 but this is patient and indication specific [55]. At supratherapeutic doses, the aPTT may also become prolonged.

When asymptomatic, supratherapeutic anticoagulation with warfarin does not generally require treatment beyond reducing the dose or holding warfarin for a period of time to allow for correction in the INR. Consideration may also be given to administering a small dose of vitamin K (1 to 5 mg) which will significantly lower the INR within 24 hours, depending on the INR and clinical scenario. If the patient is experiencing significant or life-threatening bleeding, reversal of anticoagulation is indicated and accomplished by replenishing the vitamin K-dependent factors. This can be achieved using either FFP or PCCs (Table 108.6).

TABLE 108.6

REVERSAL OF WARFARIN-INDUCED ANTICOAGULATION MANAGEMENT OF SUPRATHERAPEUTIC INR

Clinical situation	INR	Actions
No significant bleeding	<5.0	■ Lower dose, or ■ Hold dose and restart at a lower dose once INR in desired range, or ■ Check INR in 24 h if INR only mildly prolonged
	5.0–9.0	■ Hold warfarin, repeat INR in 24 h ■ Give vitamin K_1 1–2.5 mg PO × 1 if at increased risk of bleeding ■ Check INR in 24 h—when INR in desired range, restart warfarin at adjusted dose
	≥9.0	■ Hold warfarin and give vitamin K_1 2.5–5 mg PO × 1 (may repeat in 24 h if INR not improved) ■ When INR in desired range, restart warfarin at adjusted dose
Serious or life-threatening bleeding	Any prolongation in INR due to warfarin administration	■ Hold warfarin ■ Give vitamin K_1 10 mg slow IV push (over 30 min); may repeat in 12–24 h ■ Give FFP, prothrombin complex concentrate (PCC), or rFVIIa for acute reversal ■ Monitor INR and repeat intervention as necessary

Adapted from Ansell J, Hirsh J, Hylek E, et al: Pharmacology and management of the vitamin K antagonists: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). *Chest* [6, Suppl]:175s, 2008.

PCCs are plasma-derived products enriched in vitamin K-dependent factors. The typical dose is 25 to 50 U per kg depending on the degree of anticoagulation. There are two types of PCCs available, activated PCC (aPCC) and nonactivated (simply referred to as PCC). The activated form contains activated coagulation proteases that are used in the treatment of hemophilia with inhibitors. The nonactivated formulations were originally licensed for the treatment of hemophilia B, given their high FIX content. Furthermore, there are two types of nonactivated PCCs: 4-factor (FII, FVII, FIX, FX)–containing products and a 3-factor (FII, FIX, FX) product. While the 3-factor product does contain some FVII, it is at a low concentration (less than one-third that of FIX) and therefore is considered a 3-factor concentrate. If a 3-factor concentrate is used for warfarin reversal, rFVIIa may be required as adjunctive treatment to replenish FVII [55]. Notably, only 3-factor PCCs are currently available in the United States; however, a phase III clinical trial is currently enrolling to evaluate the efficacy and safety of a 4-factor PCC in reversal of oral vitamin K antagonist-induced bleeding. Both activated and nonactivated PCCs contain heparin and are therefore contraindicated in patients with heparin-induced thrombocytopenia [56]. As the effects of FFP, PCC, and rFVIIa are transient, 10 mg of parenteral vitamin K (IV over 30 minutes) should also be given to reverse the INR more durably [55]. When available, PCCs are preferred over FFP because they are concentrated into much smaller volumes, can be virally inactivated, and have a lower risk of TRALI (see Chapter 114). The pharmacodynamics of warfarin is discussed further in Chapter 110.

Superwarfarins

The superwarfarins are a group of pharmacologic compounds that are long-acting rat poisons. They have considerably longer half-lives than warfarin (weeks to months versus 1 to 2 days) and are considerably more potent. Superwarfarin poisoning has been associated with homicide and suicide attempts, accidental ingestion, and occupational exposure. Patients typically present with bleeding symptoms and laboratory findings similar to those of warfarin overdose; however, the PT/INR does not appropriately normalize with standard doses of vitamin K. An assay for each of the superwarfarins is necessary to confirm the diagnosis. Patients require high doses of vitamin K for prolonged periods to control bleeding risk. FFP or rFVIIa may be required in episodes of life-threatening bleeding [57].

Direct Thrombin Inhibitors (Argatroban, Lepirudin, Bivalirudin)

Reversal of anticoagulation due to direct thrombin inhibitors (DTIs) in cases of clinically significant bleeding is typically achieved through cessation of drug given a short half-life (<1 hour). No specific antidote is available and supportive care is the standard. The pharmacodynamics of DTIs are discussed in greater detail in Chapter 110.

Vitamin K Deficiency

Vitamin K deficiency is a frequently encountered problem in hospitalized medical patients. It is particularly common in those with chronic malabsorption syndromes (e.g., cystic fibrosis), malnutrition, and those on broad-spectrum antibiotics [58]. Patients on warfarin and with vitamin K deficiency present with similar laboratory and physical findings, namely prolongation primarily of the PT as well as easy bruising or soft tissue bleeding. Vitamin K deficiency is managed by supplementation of vitamin K. If a patient has a malabsorptive syndrome, parenteral vitamin K is typically recommended.

Since vitamin K-dependent coagulation factors are synthesized in the liver, it can be difficult to distinguish between vitamin K deficiency and a coagulopathy of liver disease (decreased hepatic synthesis of coagulation factors). In clinical scenarios where underlying liver disease is present, it may be beneficial to evaluate coagulation factor levels, both vitamin K-dependent and independent (e.g., FII and FV, respectively). In this example, if both FII and FV levels are decreased, then the patient likely has hepatic synthetic dysfunction. If FV is normal and FII is decreased, then the patient likely has vitamin K deficiency.

Coagulopathy of Liver Disease

An unfortunate hallmark of liver disease is coagulopathy. It stands to reason that since all of the coagulation factors (except FVIII, which is also synthesized in extrahepatic endothelial cells) are made in the liver, end-stage liver disease (ESLD) is marked by multiple coagulation factor deficiencies [59,60]. However, increased extravascular redistribution and increased factor consumption also contribute. The degree of coagulation factor reduction as well as the number of factors reduced typically parallel the severity of liver disease [61]. Factors V and VII appear to be sensitive markers of hepatic synthetic dysfunction with FVII levels typically the most notably affected secondary to its short half-life [62]. A prolongation in the PT is therefore an early marker of liver disease. As hepatic dysfunction progresses and other coagulation factors in the common and contact activation pathway are decreased, the aPTT prolongs. In contrast, FVIII levels are typically elevated in compensated cirrhosis. This may be secondary to an increase in vWF that is seen in cirrhotics [60]. In addition, proteins required for FVIII clearance such as low-density lipoprotein receptor-related protein (LRP) are present in decreased amounts, thus raising FVIII levels. Patients with liver disease may have normal fibrinogen levels, given its long half-life, but they may develop an acquired dysfibrinogenemia associated with abnormal fibrinogen glycosylation that disrupts fibrin polymerization [63,64]. This may be reflected by a normal fibrinogen quantitative assay but an abnormal functional assay such as the TT or RT.

In addition to coagulation factor deficiency, a number of other variables associated with advanced liver disease may contribute to coagulopathy in this population. These include (a) vitamin K deficiency secondary to malnutrition, malabsorption/maldigestion from bile salt insufficiency, and altered intestinal motility [63]; (b) portal hypertension with resultant hypersplenism and secondary thrombocytopenia [65]; (c) decreased thrombopoietin (the principle regulator of platelet production) synthesis by hepatocytes with resultant thrombocytopenia [66]; (d) impaired platelet function as demonstrated by abnormal platelet function, as assessed by PFA-100® [66]; and (e) hyperfibrinolysis secondary to impaired synthesis of plasminogen activator inhibitors and decreased clearance of plasminogen activators (reviewed in reference [67]). Chronic, low-grade DIC may also contribute to coagulopathy (discussed later).

Despite evidence for a significant coagulopathy based on laboratory tests as well as evident petechiae, ecchymosis, purpura, and bleeding after invasive procedures, patients with ESLD rarely bleed spontaneously. It is much more common for them to present with hemorrhage as a result of an underlying anatomic lesion such as from an esophageal varix. There remains active debate as to the actual net degree of coagulopathy in these patients. For instance, Mannucci has argued that defects in platelet number and function may be balanced by increased levels of vWF. Furthermore, decreased levels of

coagulation factors and inhibitors of fibrinolysis are balanced by decreased levels of inhibitors of coagulation and profibrinolytic factors [68]. The end result is a potential rebalancing of hemostasis. The fact that the degree of PT and aPTT prolongation correlates poorly with bleeding after liver biopsy and other potentially hemorrhagic procedures supports this rebalancing notion [69,70]. Ultimately, a more comprehensive assessment of hemostasis is needed as PT and aPTT only assess thrombin generation in a closed system devoid of anticoagulant factors and do not address fibrinolysis at all.

Given that we lack a comprehensive hemostatic assessment tool, many physicians prefer to prophylactically give FFP or other hemostatic agents to patients with ESLD who are to undergo procedures or who have significantly abnormal coagulation laboratory values. Unfortunately, we have little data to support these measures. The current guidelines recommend FFP transfusions only when hemostasis is needed for bleeding or invasive procedures and the PT or aPTT is >1.5 times normal (reviewed in reference [71]). FFP is generally given at a dose of 10 to 15 mL per kg repeated every 8 hours. Notably, despite repeated infusions of FFP, the PT may not completely correct and therefore clinical response should be monitored rather than relying on the PT as a measure of efficacy [72]. As discussed earlier, patients with ESLD may also develop hypofibrinogenemia or a dysfibrinogenemia. This should be suspected in a patient with a prolonged TT or RT or in a patient who continues to bleed despite FFP infusion. Cryoprecipitate may be required to treat hypo/dysfibrinogenemia as FFP typically does not sufficiently replace fibrinogen. Cryoprecipitate is typically given in doses of 10 pooled units. Patients should be transfused to a goal fibrinogen level of >100 mg per dL. There are a number of human fibrinogen concentrates available in Europe, and in 2009 the Food and Drug Administration approved the first human fibrinogen concentrate in the United States. It is currently indicated for the treatment of patients with congenital afibrinogenemia and hypofibrinogenemia. Some authors have reported beneficial outcomes in patients given rFVIIa and PCCs in ESLD. However, there are currently no guidelines or randomized trials that address dosing or efficacy [63]. However, given the hypervolemia typical of patients with ESLD, multiple infusions of FFP may not be possible and treatment with PCCs may be considered to reduce volume overload as well as decrease the risk of TRALI. If a 3-factor PCC is used, adjunctive rFVIIa may be indicated [73].

Many have argued for controlled trials to evaluate the role of prophylactic hemostatic agents in this patient population as current practice typically involves using expert opinion and case series data [74].

Disseminated Intravascular Coagulation

DIC is a well-recognized syndrome characterized by both thrombotic and hemorrhagic complications in the setting of a number of defined disorders that are typically associated with systemic inflammation (Table 108.7) [75]. The pathogenesis of DIC is complex and is characterized by widespread activation of the TF coagulation pathway with a marked imbalance between procoagulant and anticoagulant processes resulting in unopposed thrombin generation and diffuse fibrin clot formation with subsequent microvascular occlusion and tissue hypoxia [76]. When severe, these changes may culminate in multiple organ dysfunction syndrome (MODS). The pathogenesis is further reviewed elsewhere [75,77].

The clinical presentation of DIC is variable and the majority of patients do not demonstrate a significant hemorrhagic phenotype [78]. A clinical suspicion for DIC is paramount in establishing its diagnosis. In addition to a compatible underlying condition (e.g., sepsis), abnormal laboratory studies consistent with increased thrombin generation and fibrinolysis (consumptive coagulopathy) are also required. A DIC screening panel is typically composed of PT, aPTT, platelet count, fibrinogen, and D-dimer. DIC is suggested when the laboratories demonstrate increased activation of coagulation (elevated PT/aPTT, decreased fibrinogen) as well as evidence of fibrinolysis (elevated D-dimer or fibrin degradation products). An elevation in PT is a very sensitive measure for DIC but has lower specificity since it may be normal, especially in chronic DIC [79]. Since fibrinogen is an acute phase reactant, it may be normal or even elevated in chronic DIC, thereby limiting its specificity in low-grade DIC. Elevation of D-dimer is a sensitive marker for DIC, in the range of 90% to 100% in one report; however, its specificity limits its utility as a single screening test [80].

The International Society on Thrombosis and Hemostasis established a subcommittee on DIC to develop and validate a scoring system to aid in the diagnosis of DIC. This system is based on platelet count, fibrin degradation products, PT, and fibrinogen level [81]. A prospective validation study demonstrated this scoring system to be 91% sensitive and 97% specific for the diagnosis of DIC, with higher scores correlated with higher 28-day mortality (Table 108.8) [82].

Identification and treatment of the underlying disorder remains the hallmark of treatment for DIC [78]. Treatment of DIC should be based on both the clinical presentation as well as the laboratory results [75]. Recommendations for the management of DIC are based on expert opinion given a lack of published, randomized data. In general, patients who experience

TABLE 108.7

DISORDERS ASSOCIATED WITH DISSEMINATED INTRAVASCULAR COAGULATION

Infection
Gram-negative or Gram-positive septicemia
Rickettsiae—especially Rocky Mountain spotted fever
Spirochetes
Fungi
Viruses—especially herpes
Protozoa—especially malaria
Tissue damage
Trauma
Crush injury
Burn
Heat stroke
Hemolytic transfusion reaction
Neoplasia
Metastatic carcinoma
Leukemia—especially acute promyelocytic leukemia
Chemotherapy
Obstetric disasters
Abruptio placentae
Retained dead fetus
Preeclampsia/eclampsia
Amniotic fluid embolism
Placenta previa, accreta, and percreta
Miscellaneous
Fat embolism
Shock
Cardiac arrest
Giant hemangioma (Kasabach–Merritt syndrome)
Vasculitis
Toxins (snake venom, brown recluse spider bite)
Near drowning—especially fresh water

TABLE 108.8

DIAGNOSTIC SCORE FOR DISSEMINATED INTRAVASCULAR COAGULATION

1. Underlying disorder associated with DIC—if yes → proceed, if no → do not proceed, search for alternative process
2. Obtain global coagulation tests: platelet count, PT, fibrinogen, D-dimer
3. Assign score based on laboratory tests
   a. Platelet count
      i. >100 = 0, <100 = 1, <50 = 2
   b. D-dimer or fibrin degradation products
      i. No increase = 0, moderate increase = 2, strong increase = 3
   c. Prolonged PT
      i. <3 s = 0, >3 s but <6 s = 1, >6 s = 2
   d. Fibrinogen level
      i. >1.0 g/L = 0, <1.0 g/L = 1
4. Calculate score
   a. If ≥5, compatible for DIC
   b. If <5, suggestive, but not confirmed DIC, repeat in 1–2 d

Adapted from Bakhtiara K, Meijers JC, de Jonge E, et al: Prospective validation of the International Society of Thrombosis and Haemostasis scoring system for disseminated intravascular coagulation. *Crit Care Med* 32(12):2416–2421, 2004.

significant bleeding or who require invasive procedures should be treated with FFP to replace coagulation factors. PCCs may also be considered when hypervolemia complicates FFP administration, but they may lack certain depleted factors such as FV. Furthermore, the literature discusses increased risk for thrombosis given trace amounts of activated factors contained in the preparations [83]. It is unclear if this risk is still present in today's products. Cryoprecipitate should be used to replace fibrinogen if the plasma level is <100 g per dL. While there is no established threshold at which to transfuse platelets in DIC, in the setting of active bleeding or in anticipation of invasive procedures, platelet transfusions may be indicated.

In contrast to replacing coagulation factors, fibrinogen, and platelets, some investigators have evaluated the role of anticoagulants, namely UFH, in the treatment of DIC. This putative measure is based on the pathologic activation of coagulation-associated with DIC as well as the depletion of endogenous anticoagulants. Initial animal studies evaluating anticoagulants in DIC suggested a benefit [84]; however, subsequent human trials have yielded conflicting results [78,85,86]. To date there are no data from randomized, controlled trials to support the use of UFH in the management of DIC.

More recently, trials of recombinant anticoagulant proteins have been conducted in patients with sepsis-related DIC. Similar to UFH, early trials evaluating tissue factor pathway inhibitor (TFPI) were promising; however, a subsequent phase III trial did not demonstrate survival benefit [87,88]. Large trials evaluating the use of antithrombin concentrates to restore the anticoagulant pathway have also been disappointing [89]. Most recently, considerable attention has been directed toward activated protein C (APC) and sepsis/DIC. Animal models suggest a link between downregulation of the protein C/thrombomodulin system and endotoxin-induced DIC (reviewed in reference [90]). Recombinant human APC (drotrecogin alfa) has been demonstrated to improve mortality and organ function in septic patients. Furthermore, it appears that patients with the most severe sepsis (APACHE score >25) received the largest benefit [91]. Drotrecogin alfa is not used in DIC unassociated with severe sepsis.

DIC is discussed in further detail in Chapter 109.

Trauma-Induced Coagulopathy

Trauma-induced coagulopathy includes the coagulopathy associated with the stresses of trauma as well as unintended consequences of its treatment. Historically it was felt that the coagulopathy associated with trauma was largely secondary to dilution of the coagulation system with volume and blood replacement. However, it is becoming increasingly apparent that this process is much more dynamic and complicated. Traumatic events requiring massive transfusion of blood lead to significant coagulopathy through a number of mechanisms that include (a) dilution of coagulation proteins and platelets from volume resuscitation, (b) consumptive coagulopathy and thrombocytopenia (through DIC associated with trauma), (c) acidemia which impairs function of the coagulation cascade, (d) hypothermia which impairs function of platelets and coagulation factors, and (e) electrolyte perturbations, particularly hypocalcemia which impairs the calcium-dependent coagulation processes [92]. Prompt attention is required to mitigate the coagulopathy associated with trauma and to rapidly correct it. Clinically, patients have a compatible history of massive trauma requiring aggressive resuscitation and typically have a prolongation of PT and aPTT that corrects on mixing study, as well as thrombocytopenia and often hypofibrinogenemia. Treatment is targeted at correcting or preventing the occurrence of the above listed mechanisms that have been associated with the development of trauma induced coagulopathy. Most guidelines recommend transfusion of red blood cells to a target hemoglobin of 7 to 10 g per dL to maintain rheology, FFP administration to a goal PT/aPTT of <1.5 × upper limit of normal, platelet transfusion to keep platelets $>50 \times 10^9$/L (or $>100 \times 10^9$ in patients with brain injury), and fibrinogen >100 mg per dL [93,94]. Notably, recent large animal models of dilutional coagulopathy suggest that treatment with PCC was as effective as FFP in correcting coagulopathy and warranted further investigation [95]. Some studies also suggest that rFVIIa may be beneficial (reviewed in reference [96]).

Acquired Hemophilia A

The most common antibodies that affect clotting factor activity with a resultant hemorrhagic phenotype are directed against FVIII. Acquired hemophilia A, or acquired FVIII deficiency, is a rare disorder with an estimated incidence of 1.0 per million that is caused by autoantibodies directed against a patient's endogenous FVIII, resulting in low FVIII activity levels [97]. Acquired hemophilia A is most commonly an idiopathic condition that occurs in the elderly but can also be associated with malignancy, drugs, autoimmune disorders, and the postpartum state.

Acquired hemophilia should be suspected in patients without a prior bleeding history who present later in life with significant, large ecchymoses, hematomas, mucosal, gastrointestinal bleeding, or who experience significant bleeding following surgery or trauma. Hemarthroses that are a hallmark of congenital hemophilia are not typical of acquired hemophilia.

Patients with acquired hemophilia present with bleeding symptoms and a prolonged aPTT in contrast to patients with a lupus anticoagulant who typically present with a prolonged aPTT and thrombotic complications [97]. Once acquired hemophilia is suspected based on clinical presentation and a prolonged aPTT, an incubated aPTT mixing study should be performed. Since FVIII inhibitors are commonly time and temperature dependent, the mixing study should be performed

at 37°C for 1 to 2 hours. In the case of an acquired FVIII inhibitor, the incubated aPTT will not completely correct into the normal range which indicates the presence of an inhibitor. A FVIII activity level may also be helpful to identify the inhibitor as FVIII specific. The strength of the inhibitor may be quantified in a Bethesda assay. The strength of the inhibitor has treatment implications.

Treatment goals of these patients are twofold: (a) control of bleeding and (b) eradication of the inhibitor. Bleeding in patients with low-titer inhibitors (<5 BU) can often be treated with high doses of FVIII concentrates [98]. Bleeding in patients with high-titer inhibitors is treated with a FVIII inhibitor bypassing agent, such as an aPCC or rFVIIa [99]. Porcine FVIII was also an option for patients with a low-titer inhibitor since the inhibitor titer to porcine FVIII is only 5% to 10% of the titer against human FVIII [100]. Unfortunately, this product was removed from production in 2004 given concerns for porcine parvovirus contamination. Clinical trials are currently underway evaluating recombinant porcine FVIII. Inhibitor eradication typically involves immunosuppression, though spontaneous resolution of the inhibitor can occur [98]. There is an unfortunate relapse rate of approximately 20%; however, 70% of these patients can be brought back into a second remission [101].

ACQUIRED PLATELET DISORDERS/DYSFUNCTION

Medications

The antiplatelet effect of medications is the most common cause for acquired platelet dysfunction. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most commonly used medications that affect platelet function (Table 108.9) [102]. Their predominant antiplatelet effect is achieved through the inhibition of platelet cyclooxygenase (COX-1) which in turn ultimately inhibits vasoconstriction and platelet aggregation [103]. Inhibition of COX-1 by aspirin is irreversible for the life of the platelet and is dose-dependent. There is an increased risk of bleeding in patients taking aspirin, and two recent meta-analyses have described an approximate 1% increase in absolute risk of bleeding in patients taking aspirin compared to placebo [104,105]. Notably, this bleeding risk does not appear to be dose dependent when the total daily dose is ≤325 mg per day but does increase with concomitant administration of other anticoagulants or antiplatelet agents [106,107]. The primary site of bleeding associated with aspirin is gastrointestinal. NSAIDs, on the other hand, reversibly inhibit COX-1 for the length of time that the medication remains metabolically active. Platelet function is not affected by the newer COX-2 specific inhibitors or acetaminophen.

Dipyridamole is a less frequently used antiplatelet drug with an unclear mechanism of action. It has historically been used for stroke prophylaxis. There does not appear to be a significant increase in bleeding risk for patients taking dipyridamole versus placebo in several randomized trials evaluating the efficacy of dipyridamole in stroke prevention [108].

Clopidogrel (Plavix) belongs to a class of antiplatelet agents known as the thienopyridines and is being used with increasing frequency in the treatment of cardio- and cerebrovascular disease. Thienopyridines are irreversible antagonists to the platelet P2Y12 receptor which inhibits ADP-mediated platelet aggregation. The thienopyridines, particularly ticlopidine (Ticlid), have been implicated in the development of thrombotic thrombocytopenic purpura (TTP) [109].

The GP IIb/IIIa antagonists are a group of antiplatelet agents that are primarily used during coronary procedures. These drugs impair aggregation by inhibiting the cross bridging of platelets by fibrinogen. This class is associated with an increased risk of bleeding, particularly at the puncture site for percutaneous coronary intervention. There does not appear to be an increased risk for intracerebral hemorrhage for patients receiving GP IIb/IIIa inhibitors versus heparin [110]. These agents are also associated with thrombocytopenia, often profound, that may result in significant bleeding complications [111].

Many other medications including large doses of penicillins, psychotropic drugs such as fluoxetine, dietary supplements such as fish oil, gingko, garlic, and cumin may impair platelet function, although not typically to a significant degree [102].

Laboratory testing to confirm an acquired platelet defect secondary to medication is rarely necessary as clinical history and medication record usually suffice. However, if needed for confirmation, platelet function testing may be useful. Treatment for drug-induced platelet dysfunction depends on the severity of bleeding as well as the medication involved. In most cases, minor bleeding may be addressed by withholding the medication. In more severe cases, platelet transfusion may be indicated depending on timing of the last dose as well as its specific platelet effect. In general, platelets have a life span on average of 7 to 10 days. As a result, the bone marrow replaces approximately 10% of the body's platelets each day. Therefore, if a medication irreversibly inhibits platelet function, platelet transfusion may be needed to reverse the antiplatelet effect until the bone marrow has sufficiently replenished the affected platelets. For most situations, a single platelet transfusion is sufficient to correct bleeding association with disordered platelets.

Acquired platelet dysfunction due to antiplatelet agents is discussed in further detail in Chapter 109.

TABLE 108.9

DRUGS THAT COMMONLY AFFECT PLATELET FUNCTION

Analgesics
Aspirin
NSAIDs
Cardiovascular medications
Dipyridamole
P2Y12 receptor blockers—thienopyridines
Ticlid (ticlopidine)
Plavix (clopidogrel)
Effient (prasugrel)
GP IIb/IIIa inhibitors
ReoPro (abciximab)
Aggrastat (tirofiban)
Integrilin (eptifibatide)
Antibiotics
β-Lactam antibiotics—e.g., PCN, cephalosporins
Psychotropic
Antidepressants (fluoxetine)
Phenothiazines
Herbal supplements
Fish oil
Cumin
Garlic
Ginkgo biloba
Turmeric

Uremia

The multisystem organ dysfunction encountered in critically ill patients often includes acute kidney injury and subsequent uremia. Bleeding associated with uremia has long been recognized

and has historically been associated with a prolonged bleeding time. However, the degree of BT prolongation neither correlates with the degree of azotemia nor the severity of bleeding symptoms. The clinical manifestations of uremic bleeding are predominantly mucocutaneous though patients may present with epistaxis, gastrointestinal bleeding, hematuria, or increased bleeding following surgery or procedures [112].

Despite this long-recognized association between uremia and a bleeding diathesis, the exact pathophysiology remains poorly defined though impairment in platelet function appears integral [113]. There are data to suggest that this is a multifactorial process and includes an acquired platelet defect as well as impairment in platelet–endothelium interaction. Additional factors include vWF abnormalities, anemia which affects rheology, thrombocytopenia, uremic toxins, and increased nitrous oxide (NO) production [114]. The presence of a uremic toxin is supported by the improvement in platelet function in patients following dialysis. Notably, urea is unlikely to be the primary toxin as there is no positive correlation between blood urea nitrogen and bleeding risk [115]. NO is produced by endothelial cells and platelets and inhibits platelet aggregation. Plasma from uremic patients has increased NO and the addition of an NO synthesis inhibitor to uremic rats improved BT [116,117].

Treatment for uremic bleeding often includes aggressive dialysis which may correct the bleeding and has been suggested to prevent uremic bleeding. DDAVP has been recommended as the first-line therapy for uremic bleeding (2 to 4 μg per kg intranasally or 0.3 μg per kg by slow intravenous infusion); it improves platelet function in uremia, most likely due to release of FVIII and vWF [118]. If no improvement is noted after the first dose, further doses should not be given. If DDAVP is ineffective or contraindicated, cryoprecipitate may be given (10 units every 12 to 14 hours). Improvement in bleeding in response to cryoprecipitate is likely related to FVIII and vWF [119]. Correction of anemia to a goal hematocrit of 30% corrects the BT in many patients through improved rheology. This may be accomplished via red cell transfusions in the acute period or erythropoietin over prolonged periods. Erythropoietin may also have beneficial effects on platelet function [120]. Conjugated estrogens may improve uremic bleeding and appears to do so in a dose-dependent manner presumably by reducing NO production [121,122] (reviewed in reference [123]).

Hematologic Disorders

Abnormal platelet function is frequently noted in patients with a number of primary hematologic disorders, including myelodysplastic syndromes and myeloproliferative disorders. The bleeding diathesis occurs out of proportion to what would be expected in patients with similar quantitative platelet defects. In general, the mechanisms underlying the platelet dysfunction seen in these disorders are poorly understood but probably reflect the genetic and developmental abnormalities in stem cells that underlie these disorders. The severity of the predisposition to bleeding cannot be reliably predicted from the results of the bleeding time, platelet count, or in vitro platelet function tests.

The bleeding complications of the myeloproliferative disorders have been estimated in the literature to range from 1.7% to 37%, depending on the disorder and population screened [124]. The bleeding manifestations in both polycythemia vera (PV) and essential thrombocythemia (ET) involve the skin and mucous membranes and include menorrhagia, epistaxis, ecchymosis, and gastrointestinal bleeding. This pattern of bleeding suggests an underlying platelet or vWD defect. It has long been assumed that dysfunctional platelets derived from abnormal stem cells were responsible for increased bleeding with these disorders. Recently, however, there are increasing data to suggest that extreme thrombocytosis may paradoxically result in an acquired type 2 vWD which contributes to the bleeding diathesis [125]. Other conditions associated with acquired vWD include Heyde's syndrome, which is the association of tight aortic stenosis with gastrointestinal arteriovenous malformations. In this condition, the shear stress associated with the stenotic aortic valve consumes the high-molecular-weight multimers of vWF [126].

Treatment of the underlying disorder remains the mainstay though platelet transfusions may be needed for clinically significant bleeding. If acquired vWD is suspected, it should be confirmed through appropriate testing (to be discussed later) prior to initiating directed treatment. Treatment depends largely on the degree of defect and could include intravenous immune globulin, DDAVP, or vWF replacement [125].

OTHER ACQUIRED BLEEDING DISORDERS

Acquired vWD

Acquired vWD is a heterogenous disorder that is associated with a number of different disease states. Several distinct pathophysiological mechanisms are involved which include increased vWF clearance or proteolysis, vWF adsorption to cells with subsequent increased clearance, decreased synthesis, and antibody formation against vWF [127]. Lymphoproliferative and autoimmune disorders are most commonly associated with acquired vWD.

In general, mechanisms underlying acquired vWD are divided into immune- and nonimmune-mediated categories. Immune-mediated acquired vWD is suggested by mixing studies which show an inhibition of vWF in a functional assay. Proposed nonimmune mechanisms include (a) vWF being adsorbed onto cells (e.g., Wilm's tumor, platelets in myeloproliferative disorders, plasma cells in multiple myeloma, and Waldenström's macroglobulinemia), (b) increased proteolysis of HMW multimers at sites of high blood shear flow rates in patients with aortic stenosis, angiodysplasia, and congenital heart disease, (c) decreased synthesis in hypothyroidism, and (d) proteolysis by plasmin during increased periods of fibrinolysis such as with thrombolytic therapy and DIC. A diagnosis should be expected if a patient has a bleeding phenotype similar to a patient with vWD, a compatible underlying disorder, an absence of lifelong bleeding symptoms, and a negative family history [128]. Treatment for acquired vWD is aimed at correcting the underlying disorder if possible and while promoting hemostasis as one would in patients with congenital vWD (e.g., DDAVP, factor concentrates, antifibrinolytics).

Acquired FII (Prothrombin) Inhibitors

Clinically, patients with antiphospholipid antibodies most commonly have a thrombotic phenotype; however, rarely these patients may also have an antibody directed against prothrombin. This antibody binds to prothrombin and increases its clearance, which results in low FII activity levels and clinically significant bleeding. This disorder should be considered in a bleeding patient with evidence for prolongation in PT and PTT. The PT should correct with mixing, the PTT will not. Tests for the lupus inhibitor will be positive, and measurements of FII activity as well as FII antigen will be low. Treatment for acute hemorrhage involves FFP, typically at a dose of 15 to 20 mL per kg with a goal FII activity of >30% [129]. PCCs may also be used.

Acquired FV Inhibitors

Acquired FV inhibitors are noted to occasionally occur following cardiac surgery after exposure to topical thrombin or fibrin-glue preparations. These preparations may be contaminated with bovine FV and antibodies may form which cross-react with human FV. A recent retrospective analysis of acquired FV patients noted that 68% of patients presented with bleeding events that most commonly manifested as mucocutaneous events [130]. Patients typically present with a significant prolongation in both the PT and PTT. This prolongation fails to correct in a mixing study. Inhibitor specificity to FV is demonstrated with a low FV activity. FFP is not recommended as a treatment since FV is present in such a low concentration that it is quickly neutralized by the inhibitor. PCCs are likewise felt to be unhelpful given their low FV content. Plasma exchange and platelet transfusions have been used successfully to control bleeding. It is thought that FV contained in the alpha granules of circulating platelets is protected from inhibition until the platelet becomes activated at the site of vessel damage. More recently, rFVIIa has been reported to successfully promote hemostasis in a small case series [131].

Acquired FX Deficiency

Acquired FX deficiency is associated with amyloidosis. It is thought that amyloid fibrils bind to FX and thereby remove it from circulation. Treatment of the underlying amyloidosis and/or splenectomy has been shown to improve the circulating FX level [132]. PCCs are the preferred treatment for acute bleeding episodes.

ACKNOWLEDGMENT

This work was supported in part by a grant from the National Hemophilia Foundation-Baxter Fellowship (JB).

CHAPTER 109 ■ THROMBOCYTOPENIA

THOMAS G. DELOUGHERY

Thrombocytopenia is common in the intensive care unit (ICU). Platelet counts below 100,000 per μL occur in 25% to 38% of ICU patients and counts fewer than 10,000 per μL occur in 2% to 3% [1–4]. A variety of disease processes can lead to thrombocytopenia, ranging from an epiphenomenon of the illnesses that lead to the ICU admission to a devastating complication of therapy (Table 109.1).

The immediate priorities in thrombocytopenic patients are to establish the validity and severity of the thrombocytopenia, evaluate for life-threatening processes such as heparin-induced thrombocytopenia or thrombotic thrombocytopenic purpura, and initiate therapy. In the critical care setting, therapeutic decisions often have to be made before a definitive cause of the thrombocytopenia is established.

INITIAL EVALUATION

The initial assessment should be rapid, focusing on whether the patient is bleeding or experiencing thrombosis; the underlying disorder(s) leading to ICU admission; current medications; and (if available) past medical history.

In the assessment of bleeding, one should detect whether the patient is suffering from "structural" aberrancies (e.g., bleeding from a gastric ulcer) or generalized bleeding, which may suggest a hemostatic defect such as may occur due to thrombocytopenia. One should inspect sites of instrumentation, such as IV sites or chest tube drainage, and the mucosa for bleeding. The fingertips and toes should be examined for evidence of emboli or ischemia.

TABLE 109.1

DIFFERENTIAL DIAGNOSIS OF THROMBOCYTOPENIA

Disseminated intravascular coagulation
Drug-induced thrombocytopenia
HELLP syndrome
Hemophagocytic syndrome
Heparin-induced thrombocytopenia
Liver disease
Posttransfusion purpura
Pseudothrombocytopenia
Thrombotic thrombocytopenia purpura

HELLP, hemolysis, elevated liver tests, and low platelets.

TABLE 109.2

LABORATORY TESTS IN EVALUATION OF THROMBOCYTOPENIA

Prothrombin time/INR
Activated partial thromboplastin time
D-dimer
LDH
Creatinine
Bun
Peripheral smear

LDH, lactate dehydrogenase level.

Exposure to medicines is a common cause of thrombocytopenia [5,6]. One should carefully review the record of current and recently administered medications and ask the patient (if possible) and family about medications (prescribed, over the counter, and herbal) [7,8] that the patient has recently taken.

Laboratory Testing

In the patient with thrombocytopenia, examination of the blood smear can quickly reveal whether pseudothrombocytopenia (artifactual platelet clumping) [9] is present and verify the degree of thrombocytopenia (Table 109.2). Although exceptions do exist, the magnitude of thrombocytopenia can be an aid in the differential diagnosis of low platelet counts (Table 109.3). Heparin-induced thrombocytopenia and thrombotic microangiopathy (including thrombotic thrombocytopenic purpura, TTP) often present with modest thrombocytopenia (50 to 100 $\times$ 10^9 per L). The smear should be carefully reviewed for presence of fragmented red cells (schistocytes). Laboratory assessment of liver function and renal function also should be assessed. A markedly elevated level of lactate dehydrogenase level (LDH) out of proportion to other liver function abnormalities characteristically occurs in TTP and hantavirus infection [10,11]. If there is any suspicion of HIT, all heparin should be stopped and alternative antithrombotic agents should be started [12,13]. Assessment of platelet function can be difficult and must be based largely on clinical judgment. The bleeding time or the platelet function assay (PFA) is rarely useful in the evaluation of a thrombocytopenic patient, because the low platelet count leads to prolongations in the test endpoint [14].

TABLE 109.3

TYPICAL PLATELET COUNTS IN VARIOUS DISEASE STATES

Moderate thrombocytopenia (50–100,000 per μL)
Thrombotic thrombocytopenic purpura
Heparin-induced thrombocytopenia
Disseminated intravascular coagulation
Hemophagocytic syndrome
Severe thrombocytopenia (<20,000 per μL)
Drug-induced thrombocytopenia
Posttransfusion purpura
Immune thrombocytopenia

Diagnostic Clues

The reason for the ICU admission is a very important indicator in evaluation of thrombocytopenia (Table 109.4) [15]. For example, thrombocytopenia in patients who present with sudden-onset multiorgan system failure may indicate TTP or sepsis. In long-term critical care patients, new-onset thrombocytopenia may be a manifestation of HIT, drug-induced thrombocytopenia, occult or established sepsis, or bacteremia [16].

IMMEDIATE THERAPY—PLATELET TRANSFUSION

Although platelet thresholds below which critically ill patients are at risk for severe bleeding are likely to vary among patients, clinical practice generally dictates that a platelet count above 10,000 per μL does not require platelet transfusion, as long as the patient is stable without signs of bleeding, is not receiving platelet inhibitors, has preserved renal function, does not require an invasive procedure, and does not have aggressive DIC [17]. If any of these is present, especially major or life-threatening hemorrhage (such as intracranial), then a threshold of greater than 50,000 per μL is reasonable [18,19]. An exception is thrombocytopenia due to thrombotic microangiopathy (TTP), wherein platelet transfusion is contraindicated unless perhaps the platelets are transfused slowly and plasma exchange already is underway. Platelet transfusions should comprise six to eight platelet concentrates or one single-donor plateletpheresis unit. Additional discussion regarding transfusion of blood products in critically ill patients is found in Chapter 114.

THROMBOCYTOPENIA

Heparin-Induced Thrombocytopenia

HIT occurs due to the formation of antibodies directed against the complex of heparin and platelet factor 4 [12,20]. This complex in a minority of cases binds to the FcγRIIA receptor, activating platelets and macrophages. The frequency of HIT is 1% to 5% when unfractionated heparin is used but less than 1% with low-molecular-weight heparin [21]. HIT is more common in women and more common in surgery patients than medical patients [22].

HIT should be suspected when there is a sudden onset of thrombocytopenia with either at least a 50% drop in the platelet count from baseline or the platelet count falling to less than 100 $\times$ 10^9/L in a patient receiving heparin in *any* form. HIT usually occurs at least 4 days after starting heparin but may occur suddenly in patients with recent (less than 3 months) exposure [23]. An often overlooked feature of HIT is recurrent thrombosis in a patient receiving heparin despite a normal platelet count [24]. Recently, a scoring system—the four Ts—has been validated in several critical care studies as a means of assessing the pretest probability of HIT [25,26] (Table 109.5).

Patients with very low scores are very unlikely to have HIT and can forgo PF4-heparin antibody testing and empiric therapy. A biphasic pattern of thrombocytopenia following cardiac surgery—namely, recovery from the postsurgical thrombocytopenia followed by recurrent thrombocytopenia—is strongly predictive for HIT [27].

The diagnosis of HIT can be challenging in the critical care patient who has multiple reasons for being thrombocytopenic.

TABLE 109.4

DIAGNOSTIC CLUES TO THROMBOCYTOPENIA

Clinical setting	Differential diagnosis
Cardiac surgery	Cardiopulmonary bypass, HIT, dilutional thrombocytopenia, TTP
Interventional cardiac procedure	Abciximab or other IIb/IIIa blockers, HIT
Sepsis syndrome	DIC, ehrlichiosis, sepsis hemophagocytic syndrome, drug-induced, misdiagnosed TTP, mechanical ventilation, pulmonary artery catheters
Pulmonary failure	DIC, H1N1, infection hantavirus pulmonary syndrome, mechanical ventilation, pulmonary artery catheters
Mental status changes/ seizures	TTP, ehrlichiosis
Renal failure	TTP, dengue, HIT, DIC
Cardiac failure	HIT, drug-induced, pulmonary artery catheter
Postsurgery	Dilutional, drug-induced, HIT, TTP
Pregnancy	HELLP syndrome, fatty liver of pregnancy, TTP/HUS
Acute liver failure	Splenic sequestration, HIT, drug-induced, DIC

DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver function tests, and low platelets; HIT, heparin-induced thrombocytopenia; TTP, thrombotic thrombocytopenic purpura.

In this situation, the laboratory assay for HIT may be helpful. Two levels of HIT testing exist. Increasingly, an ELISA assay that detects the presumed pathogenic antiheparin-platelet factor 4 antibodies is evaluated initially [13]. This test is very sensitive but in some populations not specific. For example, 25% to 50% of cardiac surgery patients will show positive results (presumably due to platelet activation in the bypass circuit) [28,29]. A negative test rules out HIT in all but the highest-risk patients.

A second type of test, a (functional) platelet aggregation assay, such as the serotonin release assay, comprises patient plasma, donor platelets, and heparin. If added heparin induces platelet aggregation, the test is considered to be positive. The test is technically demanding, but if performed carefully can be sensitive and specific [12,13,30]. One caveat is that early in the HIT disease process, the test can be negative but then turns positive 24 hours later as the antibody titer increases. Due to substantial frequency of false positivity of PF4-heparin ELISA among cardiovascular, dialysis, and vascular surgery patients, a diagnosis of HIT should be confirmed by a serotonin release assay, even if treatment for HIT already has been initiated.

The first step in therapy of HIT consists of stopping *all* heparin. Low-molecular-weight heparins cross-react with the HIT antibodies and therefore these agents are also contraindicated. Institution of warfarin therapy alone following a diagnosis of HIT has been associated with an increased risk of thromboses and is also contraindicated. Due to the high risk of thrombosis (53% in one study) [21] among HIT patients, antithrombotic therapy should be administered to all patients [12]. For immediate therapy of HIT patients, several antithrombotic agents are available [12,20,31] (Table 109.6).

Argatroban is a synthetic thrombin inhibitor with a short half-life of 40 to 50 minutes [12,32]. Dosing is 2 μg per kg per minute with the infusion adjusted to keep the aPTT 1.5 to 3 times normal. One advantage of argatroban is that it is not renally excreted and no dose adjustment is necessary in renal disease [33]. These characteristics make it the most useful agent for patients in the critical care unit. However, argatroban

TABLE 109.5

PREDICTION RULE FOR HEPARIN-INDUCED THROMBOCYTOPENIA

Points	2	1	0
Thrombocytopenia	>50% fall from baseline and nadir 20–100 $\times$ 10^9/L	30%–50% fall or nadir 10–19 $\times$ 10^9/L	Fall <30% or nadir <10 $\times$ 10^9/L
Timing of platelet fall	Onset day 5–10 of heparin or <1 d if patient recently exposed to heparin	Consistent but not clear records or count falls after day 10	Platelets fall <5 d and no recent (100 d) heparin
Thrombosis	New thrombosis or skin necrosis or systemic reaction with heparin	Progressive or recurrent thrombosis or suspected but not proven thrombosis	None
Other cause for thrombocytopenia	None	Possible	Definite

Notes: Patients with a low probability score are very unlikely to have HIT and can forgo PF4-heparin antibody testing and empiric therapy. Patients with intermediate and high scores should receive empiric therapy until definitive testing can be obtained.
Total score: 6–8, high probability; 4–5, intermediate probability; 0–3, low probability.
Adapted from Lo et al. [25] and Crowther et al. [26].

TABLE 109.6

TREATMENT OF HEPARIN-INDUCED THROMBOCYTOPENIA

Argatroban
Therapy: initial dose of 2 μg/kg/min adjusted to an aPTT of 1.5–3.0 times normal
Reversal: no antidote but $T_{1/2} \sim 40$ min
In severe liver disease (jaundice) dose at 0.5 μg/kg/min adjusted to an aPTT 1.5–3.0 times normal
For patients with multiorgan system failure: 1 μg/kg/min adjusted to aPTT 1.5–3.0 times normal
Post-CABG—0.5–1 μg/kg/min adjusted to aPTT 1.5–3.0 times normal
Indication: prevention and treatment of thrombosis in HIT

Bivalirudin
Bolus: 1 mg/kg
Infusion: 2.5 mg/kg/h for 4 h and then 0.2 mg/kg/h for 14–20 h
Renal adjustment:
For creatinine clearance of 30–59 mL/min, decrease dose by 20%
For creatinine clearance of 10–29 mL/min, decrease dose by 60%
For creatinine clearances less than 10 mg/min, decrease dose by 90%
Note: Antilepirudin antibodies may cross-react with bivalirudin
Indication: Percutaneous coronary intervention, in patients with or without HIT

Lepirudin
Therapy: VERY sensitive to renal function—half-life can go from less than an hour to over 100 h in renal failure. Not recommended in renal insufficiency. May be used in hepatic failure.
- Initial IV bolus 0.4 mg/kg IV push (may be omitted or reduced to 0.2 mg/kg, unless there is life- or limb-threatening thrombosis):
- Continuous infusion: initial rate determined by renal function:
  - GFR >60 mL/min: 0.10 mg/kg/h
  - GFR 45–60 mL/min: 0.075 mg/kg/h
  - GFR <45 mL/min: lepirudin not recommended (consider argatroban)
- Perform aPTT at 4-h intervals until steady state within the therapeutic range (1.5–2.0 times patient baseline aPTT) is achieved

Notes: Antilepirudin antibodies form in 60%–80% of patients on lepirudin and can prolong lepirudin effect. Rare patients may have fatal anaphylaxis.
Indication: Prevention and treatment of thrombosis in HIT

Fondaparinux[a]
Therapy: 7.5 mg every 24 h (consider 5.0 mg in patients under 50 kg and 10 mg in patients over 100 kg)
Reversal: protamine ineffective; see Chapter 110: Antithrombotic Therapy.

[a]Fondaparinux is not approved for treatment of HIT. Its use, however, may be considered after initial anticoagulation with a direct thrombin inhibitor has been administered and the platelet count has recovered, while awaiting a therapeutic INR from therapy with warfarin.
Adapted from Laposata et al. [31], Kondo et al. [32], Hyers et al. [212], Hirsh et al. [213], Hirsh et al. [214].

must be used with caution in patients with severe liver disease by using an initial dose of 0.5 μg per kg per minute [32]. Also metabolism appears to be decreased in patients with multiorgan system failure and these patients should receive a dose of 1 μg per kg [34]. Argatroban (like all thrombin inhibitors) prolongs the prothrombin time/INR (PT/INR) making initiation of warfarin therapy difficult. If available, the chromogenic Xa assay can be used to adjust warfarin therapy [35]. Also, if the patient is on a drip of 2 μg per kg per minute or less, one can simply aim for a PT/INR of more than 4.0 as therapeutic. Unfortunately, there is no agent that can reverse argatroban.

Lepirudin, another direct inhibitor of thrombin, is also monitored using the aPTT. The half-life of lepirudin is short, but the drug accumulates in renal insufficiency with the half-life increasing to more than 50 to 100 hours. Recent data indicate that a lower dosing regimen that is recommended on the package insert may result in lower bleeding rates [12]. There is no antidote for lepirudin. Patients with even slight renal insufficiency (creatinine greater than 1.5) must have their lepirudin doses adjusted to avoid overanticoagulation [36]. Up to 80% of patients receiving long-term lepirudin therapy will develop antibodies that reduce the metabolism of hirudin and *increase* the therapeutic effect of lepirudin [37,38]. Patients on long-term (>6 days) lepirudin therapy should still continue to have monitoring to avoid overanticoagulation.

Bivalirudin is a semisynthetic direct thrombin inhibitor. Its indication involves patients undergoing percutaneous coronary intervention, but other patients may receive it as a treatment for HIT.

The indirect anti-Xa inhibitor fondaparinux does not cross-react with HIT antibodies [12,39], suggesting a potential role in therapy of HIT [40]. However, it has not been studied as extensively in HIT as have the DTIs. Additionally, exposure to fondaparinux has been rarely associated with a syndrome similar to delayed-onset HIT [41]. In the future, newer agents such as dabigatran and rivaroxaban may be suitable for management of patients with HIT.

The issue of platelet transfusion remains controversial [42]. Patients with HIT rarely bleed, which reduces clinical concern over the potential for platelet transfusions, but a prudent

approach would be to reserve transfusion of platelets for the rare patient with severe thrombocytopenia who also has life-threatening bleeding.

As mentioned earlier, initiation of warfarin as the sole antithrombotic agent in the initial treatment of HIT has been associated with limb gangrene. In patients receiving a direct thrombin inhibitor, warfarin can be started in small doses (2 to 5 mg daily) once the platelet count has recovered. These often malnourished patients tend to have a dramatic response to warfarin therapy and excessive anticoagulation can easily occur. One should overlap warfarin and parental therapy by 2 to 3 days as there is evidence that patients may do worse if therapy with a DTI is truncated [32].

Patients with HIT should be carefully screened for any thrombosis, at least by performing lower extremity Doppler ultrasound. If thrombosis is present, at least 3 months of therapeutic anticoagulation are required, whereas HIT without thrombosis usually is treated with 30 days of therapeutic anticoagulation.

Thrombotic Thrombocytopenic Purpura

TTP should be suspected when any patient presents with thrombocytopenia and microangiopathic hemolytic anemia (as evidenced by schistocytes on the blood smear and biochemical evidence of hemolysis); end-organ damage, mostly manifesting as renal insufficiency or neurologic phenomena, and fever also may occur, although the minority of patients with TTP present with all of the aforementioned features [43–45]. Critical care patients with TTP most often present with intractable seizures, strokes, or sequela of renal insufficiency. Postsurgical TTP may occur 1 to 2 weeks after major surgery, and is heralded by decreasing platelet counts and renal insufficiency [46]. Many patients who present to the critical care unit with TTP have been misdiagnosed as having sepsis, "lupus flare," or vasculitis.

Evidence is strong that many patients with the classic form of TTP have an inhibitor against an enzyme that is responsible for cleaving newly synthesized von Willebrand factor (vWF) [45,47,48]. vWF is synthesized as an ultra large multimer that can spontaneously aggregate platelets. The enzyme, ADAMTS13, cleaves vWF into a smaller form that can circulate [48,49]. Presumably when ADAMTS13 is inhibited in TTP, the ultra large multimers can spontaneously aggregate platelets leading to the clinical syndrome of TTP. However, many patients with classic TTP have normal activity of ADAMTS13 and reduced levels are found in other diseases implying other factors are important in pathogenesis of TTP [50–52].

There is currently not a single diagnostic test for TTP but rather the diagnosis is based on the clinical presentation [43,45]. Patients uniformly will have a microangiopathic hemolytic anemia with the presence of schistocytes on the peripheral smear. Renal insufficiency and not frank renal failure is the most common renal manifestation. Thrombocytopenia may range from a mild decrease in platelet number to platelets being undetectable. The findings of thrombocytopenia with a relative normal prothrombin time help eliminate DIC from the differential [53]. The LDH is often extremely elevated and is a prognostic factor in TTP [54]. Finding very low levels of ADAMTS13 due to an inhibitor may also be a negative prognostic factor [55]. However, lack of standardization and slow turnaround time still make this assay difficult to use clinically.

Untreated TTP is rapidly fatal. Mortality in the preplasma exchange era ranged from 95% to 100%. Today plasma exchange therapy is the cornerstone of TTP treatment and has reduced mortality to less than 20% [11,43,56–58].

Glucocorticoid therapy, either 1 to 2 mg per kg of methylprednisolone until remission or 1 g of methylprednisolone initially, may be given to patents presumed to have TTP, although this intervention is not practiced in all centers [45]. The glucocorticoid may be continued until the patient has fully recovered and perhaps longer, given the presumed autoimmune nature of the disease and the high relapse rates. Plasma infusion is beneficial but [47] plasma exchange has been shown to be superior to simple plasma infusion in therapy of TTP [56]. This may be due to the ability of plasma exchange to give very large volumes of fresh frozen plasma and removal of inhibitory antibodies. In patients who cannot be immediately exchanged, plasma infusions should be started at a dose of one unit every 4 hours. Patients with all but the mildest cases of TTP should receive 1 to 1.5 plasma volume exchange each day for at least 5 days [43]. Daily plasma exchange should be continued daily until the LDH has normalized, at which point the frequency of exchange may be taped, starting with every-other-day exchange. If the platelet count falls or LDH level rises, daily exchange should be reinstated [59]. Since the platelet count can be affected by a variety of external influences, the LDH level tends to be the most reliable marker of disease activity [60]. There is increasing evidence that the use of the anti-CD20 therapy may reduce the incidence of relapses and shorten the duration of therapy in refractory disease [48].

Renal insufficiency should be managed in the typical fashion. About 50% of patients require renal replacement therapy.

Hemolytic Uremic Syndrome

Classically, hemolytic uremic syndrome (HUS) comprises the triad of renal failure, microangiopathic anemia, and thrombocytopenia [61,62]. Two major forms are recognized: a "typical" form, which occurs in young children with an antecedent diarrheal illness, and an "atypical" form.

Typical HUS

Typical HUS (also referred to as HUS D+) occurs typically in children under the age of 4, although cases in adolescents and adults may occur. Children often have a prodrome of diarrhea, usually bloody [63,64]. Children come to medical attention due to symptoms of renal failure. In HUS, thrombocytopenia can be mild in the 50,000 per μL range. Extrarenal involvement is common in typical HUS. Neurologic involvement can be seen in 40% of patients with seizure being the predominant feature. Elevated liver function tests are seen in 40% of patients and 10% of patients will have pancreatitis. Patients with classic HUS will respond to conservative therapy and renal replacement therapy, but severe cases or those with prominent extrarenal manifestations may require response to plasma exchange [65]. Unfortunately, although most patients recover some renal function, many patients will have long-term renal damage.

Atypical HUS

Atypical HUS is best described as HUS without preceding *Escherichia coli* infection [66,67]. This description obviously lacks diagnostic precision, but in general, this term has been applied to HUS which has prominent extrarenal symptomatology, and the prognosis is thought to be worse for atypical HUS [65]. HUS in older patients and HUS without preceding diarrhea may also better be described as having atypical HUS. Therapy for atypical HUS is plasma exchange but the effectiveness of this intervention is debatable [68]. Patients with atypical HUS, especially older patients, may require months of plasma exchange several times each week to control the disease. Chronic renal insufficiency or failure often ensues. Some patients are found to have defects in the regulatory proteins of complement such as factor H [69].

Therapy-Related TTP/HUS

TTP/HUS syndromes can complicate a variety of therapies [70,71]. TTP/HUS can be associated with medications such as cyclosporine, tacrolimus, gemcitabine, and clopidogrel. Cyclosporine/tacrolimus-associated TTP/HUS occurs within days after the agent is started manifesting as a falling platelet count, falling hematocrit, and rising serum LDH level [71,72]. Some cases have been fatal but often the TTP/HUS resolves with decreasing the dose of the calcineurin inhibitor or changing to another agent.

In the past TTP/HUS was most commonly seen with the antineoplastic agent mitomycin C, with a frequency of 10% when a dose of more than 60 mg was used [73]. Anecdotal reports indicated that treatment with staphylococcal A columns was useful for this condition [74]. Now, the most common antineoplastic drug causing TTP/HUS is gemcitabine [75–78]. Like with mitomycin, the appearance of the TTP/HUS syndrome associated with gemcitabine can be delayed, and the condition often is fatal. Severe hypertension often precedes the clinical appearance of the TTP/HUS [79]. The use of plasma exchange is controversial [80], since advanced cancer itself can be associated with a TTP-like syndrome that is typically poorly responsive to plasma exchange. The increasing use of vascular endothelial growth factor (VEGF) inhibitors such as bevacizumab and sunitinib has been associated with observation of related TTP/HUS syndromes as well [81–83].

TTP/HUS has been reported with other drugs including the thienopyridines, ticlopidine, and clopidogrel [84]. The frequency of ticlopidine-associated TTP may be as high as 1:1,600, and since this drug was often prescribed for patient with vascular disease, these patients may have been initially misdiagnosed as having recurrent strokes or angina [75,78]. The frequency of TTP using clopidogrel is much less—0.0001%—but since it is widely prescribed, it is the second most common cause of drug-induced TTP [84]. Almost all cases of clopidogrel-induced TTP occur within 2 weeks of starting the drug. All patients with thienopyridine-associated TTP should receive plasma exchange.

TTP/HUS can complicate both autologous and allogeneic hematopoietic stem cell transplants [85–89]. The frequency ranges widely, depending on the criteria used to diagnose TTP/HUS, but it is in the range of 15% for allogeneic and 5% for autologous hematopoietic stem cell transplantation procedures [86,87]. One type, characterized by fulminant multiorgan failure occurs early after transplantation (e.g., within 20 to 60 days), has multiorgan system involvement, is often fatal, and has been associated with severe cytomegalovirus (CMV) infection. Another type of TTP/HUS is similar to cyclosporine/tacrolimus-associated HUS. TTP/HUS that is associated with the conditioning regimen used in the transplantation protocol occurs 6 months or more after total body irradiation, and is associated with primary renal involvement. Finally, patients with systemic CMV infections may present with a TTP/HUS syndrome related to vascular infection with CMV. The etiology of hematopoietic stem cell transplantation-related TTP appears to be different from that of "classic" TTP since alterations of ADAMTS13 have not been found in bone marrow transplant-related TTP implicated in therapy-related vascular damage [90]. The best management of hematopoietic stem cell transplantation-related TTP/HUS is uncertain. Patients should have doses of cyclosporine or tacrolimus decreased, if taking calcineurin inhibitors. Although plasma exchange is often tried, patients with fulminant or conditioning-related TTP/HUS or those with TTP/HUS and concomitant acute graft versus host disease typically do not respond [91–93].

Pregnancy-Related Thrombocytopenic Syndromes

One should consider three syndromes in the critically ill pregnant woman who presents with thrombocytopenia. These are the HELLP syndrome, fatty liver of pregnancy, and TTP (Table 109.7) [94,95].

The acronym HELLP syndrome (**H**emolysis, **E**levated **L**iver tests, **L**ow **P**latelets) describes a variant of pre-eclampsia [96,97]. Classically, HELLP syndrome occurs after 28 weeks of gestation in a patient suffering from pre-eclampsia but can occur as early as 22 weeks in patients with the antiphospholipid antibody syndrome [98]. The pre-eclampsia need not be severe. The first sign of HELLP is a decrease in the platelet count followed by abnormal liver function tests. Signs of hemolysis are present with abundant schistocytes on the smear and a high LDH. HELLP can progress to liver failure and deaths are also reported due to hepatic rupture. Unlike TTP, fetal involvement is present in the HELLP syndrome with fetal thrombocytopenia reported in 30% of cases. In severe cases, elevated D-dimers consistent with DIC are also found. Delivery of the child will most often result in cessation of the HELLP syndrome but refractory cases will require dexamethasone and plasma

TABLE 109.7

PREGNANCY-RELATED DISEASES—TTP/HUS, HELLP SYNDROME, AND ACUTE FATTY LIVER OF PREGNANCY (AFLP)

	HELLP	TTP/HUS	AFLP
Hypertension	Always present	Sometimes present	Sometimes present
Proteinuria	Always present	Sometimes present	Sometimes present
Thrombocytopenia	Always	Always	Always
LDH elevation	Present	Marked	Present
Fibrinogen	Normal to low	Normal	Normal to very low
Schistocytes	Present	Present	Absent
Liver tests	Elevated	Normal	Elevated
Ammonia	Normal	Normal	Elevated
Glucose	Normal	Normal	Low

HELLP, hemolysis, elevated liver tests, and low platelets; TTP/HUS, thrombotic thrombocytopenic purpura/hemolytic uremia syndrome.

exchange [99]. About a quarter of women who suffer from HELLP will have a recurrence with a later pregnancy [100].

Fatty liver of pregnancy also occurs late in pregnancy and is only associated with pre-eclampsia in 50% of cases [101–103]. Patients first present with nonspecific symptoms of nausea and vomiting but can progress to fulminant liver failure. Patients develop thrombocytopenia early in the course but in the later stages can develop DIC and very low fibrinogen levels. Mortality rates without therapy can be as high as 90%. Low glucose and high ammonia levels can help distinguish fatty liver from other pregnancy complications [104]. Treatment consists of prompt delivery of the child and aggressive blood product support.

TTP can occur anytime during pregnancy often leading to diagnostic confusion due to the overlap symptoms between TTP and HELLP syndrome [100,104]. There does appear to be a unique presentation of TTP that occurs in the second trimester at 20 to 22 weeks [105]. The fetus is uninvolved with no evidence of infarction or thrombocytopenia if the mother survives. The pregnancy appears to promote the TTP since the TTP will resolve with termination of the pregnancy and can recur with the next pregnancy [106]. Therapy includes terminations of the pregnancy or attempting to support the patient with plasma exchange until delivery. Many patients will have relapses with future pregnancies so this information must be weighed in planning future pregnancies. An unusual complication of pregnancy is a HUS-type syndrome seen up to 28 weeks' postpartum. This form of HUS is severe, and permanent renal failure often results despite aggressive therapy. When evaluated, many of these patients will be found to have defects in regulatory proteins of complement such as factor H deficiency, perhaps explaining the virulence of their renal failure [107].

Disseminated Intravascular Coagulation

At the most basic level, DIC is the clinical manifestation of inappropriate thrombin activation [108–111]. Inappropriate thrombin activation can be due to causes such as sepsis, obstetric disasters, etc. The activation of thrombin leads to (a) conversion of fibrinogen to fibrin, (b) activation of platelets (and their consumption), (c) activation of factors V and VIII, (d) activation of protein C (and degradation of factors Va and VIIIa), (e) activation of endothelial cells, and (f) activation of fibrinolysis.

The clinical manifestations of DIC in a given patient depend on the balance of thrombin activations and secondary fibrinolysis plus the patient's ability to compensate for the DIC. Patients with DIC can present in one of four patterns [108,110]:

1. Asymptomatic. Patients can present with laboratory evidence of DIC but no bleeding or thrombosis. This is often seen in patients with sepsis or cancer. However, with further progression of the underlying disease, these patients can rapidly become symptomatic.
2. Bleeding. The bleeding is due to a combination of factor depletion, platelet dysfunction, thrombocytopenia, and excessive fibrinolysis [108]. These patients may present with diffuse bleeding from multiple sites—IV sites, areas of instrumentation, etc.
3. Thrombosis. Despite the general activation of the coagulation process, thrombosis is unusual in most patients with acute DIC. The exceptions include cancer patients, trauma patients, and certain obstetrical patients. Most often the thrombosis is venous, but arterial thrombosis and nonbacterial thrombotic endocarditis have been reported [112].
4. Purpura fulminans. This severe form of DIC is described in more detail later.

TABLE 109.8

MANAGEMENT OF DISSEMINATED INTRAVASCULAR COAGULATION (DIC): TRANSFUSION

The five basic tests of hemostasis[a]
- Hematocrit
- Platelet count
- Prothrombin time (PT)
- Activated partial thromboplastin time (aPTT)
- Fibrinogen level

Guidelines for transfusion in patients at high risk of bleeding[b]
- A. Platelets <50,000 per μL: give platelet concentrates or 1 unit of single-donor platelets.
- B. Fibrinogen <80–100 mg/dL: give 10 units of cryoprecipitate[c]
- C. Hematocrit below 30%: give red cells
- D. Protime >twofold the upper limit of normal *and* aPTT abnormal: give 2–4 units of FFP[d]

[a]These laboratory tests should be repeated after administering blood products serially. A record of the test and the blood products administered should be maintained.
[b]Patients with DIC who are not actively bleeding generally do not require replacement of platelets or coagulation factors, unless an invasive procedure is planned or other circumstances are present; see text.
[c]For a fibrinogen level less then 100 mg/dL, transfusion of 10 units of cryoprecipitate is expected to increase the plasma fibrinogen level by 100 mg/dL.
[d]In patients with DIC and a markedly prolonged PT and aPTT, one can give 2–4 units of fresh frozen plasma (FFP) initially.

The best way to treat DIC is to treat the underlying cause that is driving the thrombin generation [108,109,111, 113,114]. In the past, there was concern about replacement of depleted blood cells and coagulation proteins in DIC due to fears of "feeding the fire." However, such hesitation has not been well validated, and one must provide replacement if depletion occurs and bleeding ensues [115]. Measurement of laboratory tests that will reflect the basic parameters essential for both blood volume and hemostasis may be helpful [18,116]. Replacement therapy is based on the results of these laboratories and the clinical situation of the patient (Table 109.8). Additional discussion regarding transfusion of blood products in critically ill patients is found in Chapter 114. DIC complicating acute promyelocytic leukemia is discussed in detail in Chapter 115.

Heparin therapy is reserved for the patient who has thrombosis as a component of their DIC [109,117,118]. Given the coagulopathy that is often present, one should use specific heparin levels instead of the aPTT to monitor anticoagulation [119,120].

Purpura Fulminans

DIC in association with necrosis of the skin may occur in two situations [121,122]. One, primary purpura fulminans, is most often seen after a viral infection [123]. In these patients, the purpura fulminans starts with a painful red area on an extremity that rapidly progresses to a black ischemic lesion. In many patients, acquired deficiency of protein S is found [121, 124,125].

Secondary purpura fulminans is most often associated with meningococcemia infections, but it can occur in any patient with overwhelming infection [126–128]. Postsplenectomy sepsis syndrome patients and those with functional hyposplenism

due to chronic liver diseases are also at risk [129]. Patients present with signs of sepsis, and the skin lesions often involve the extremities that may lead to amputation. As opposed to primary purpura fulminans, those with secondary purpura fulminans will have symmetrical ischemic at the distal parts of the body (toes and fingers) that ascend as the process progresses. Rarely, adrenal infarction (Waterhouse–Friderichsen syndrome) can occur which leads to severe hypotension [130].

Therapy for purpura fulminans is controversial. Primary purpura fulminans, especially cases with postvaricella autoimmune protein S deficiency, may respond to plasma infusion titrated to keep the protein S level more than 25% [121]. Intravenous immune globulin has also been reported to help decrease the antiprotein S antibodies. Heparin has been reported to control the DIC and extent of necrosis [131]. The starting dose in these patients is 5 to 8 units per kg per hour [109].

Sick patients with secondary purpura fulminans have been treated with plasma drips, plasmapheresis, and continuous plasma ultrafiltration [131–134]. Heparin therapy alone has not been shown to improve survival [135]. Much attention has been given to replacement of natural anticoagulants such as protein C and antithrombin as therapy for purpura fulminans but unfortunately randomized trials using antithrombin have shown mostly negative results [121,125,136–138]. Trials using either zymogen protein C concentrates or rAPC have shown more promise in controlling the coagulopathy of purpura fulminans and improving outcomes in sepsis [132,139–143]. Although bleeding is a concern with use of protein C, most complications occur in patients with platelet counts under 30×10^9/L or in those who have meningitis [144]. If recombinant activated protein C is used, one should also very carefully monitor other parameters of coagulation. Unfortunately, many patients will need debridement and amputation; in one review approximately 66% of patients required amputation [122].

Drug-Induced Hemolytic-DIC Syndromes

A severe variant of the drug-induced immune complex hemolysis associated with DIC has been recognized. Rare patients who receive certain second- and third-generation cephalosporins (especially cefotetan and ceftriaxone) [145] have developed this syndrome [146–151]. The clinical syndrome starts 7 to 10 days after receiving the drug, and often the patient has only received the antibiotic for surgical prophylaxis. Severe Coombs'-positive hemolysis with hypotension and DIC develops. The patients are often believed to have sepsis and often re-exposed to the cephalosporin, resulting in worsening of the clinical status. The outcome is often fatal due to massive hemolysis and thrombosis [148,152–154].

Quinine is associated with a unique syndrome of drug-induced DIC [155–158]. Approximately 24 to 96 hours after quinine exposure, the patient becomes acutely ill with nausea and vomiting. The patient then develops a microangiopathic hemolytic anemia, DIC, and renal failure. Some patients, besides having antiplatelet antibodies, also have antibodies that bind to red cells and neutrophils that may lead to the more severe syndrome. Despite therapy, patients with quinine-induced TTP frequently manifest chronic renal failure.

Treatment of the drug-induced hemolytic-DIC syndrome is based on anecdotal reports. Patients have responded to aggressive therapy including plasma exchange, dialysis, and prednisone. Early recognition of the hemolytic anemia (and the suspicion that it is drug-related) is important for early diagnosis so that the incriminating drug can be discontinued. DIC associated with acute promyelocytic leukemia is discussed in detail in Chapter 115.

Drug-Induced Thrombocytopenia

Patients with drug-induced thrombocytopenia typically present with very low platelet counts 1 to 3 weeks after starting a new medication [159,160]. One of the agents most commonly associated with drug-induced thrombocytopenia in the critical care setting is vancomycin. The thrombocytopenia is acute and severe (below $<10 \times 10^9$/L), is durably refractory to platelet transfusions, and resolves within days of stopping the drug [161]. In patients with a possible drug-induced thrombocytopenia, the primary therapy is to stop the suspect drug, although patients with severe thrombocytopenia generally should receive platelet transfusions due to the risk of fatal bleeding [159,162]. However, with vancomycin-induced thrombocytopenia, the patient may be refractory to platelet transfusion [161,163]. If there are multiple new medications, the best approach is to stop any drug that is strongly associated with thrombocytopenia [164] (Table 109.9). Immune globulin, corticosteroids, and intravenous anti-D have been suggested as useful in drug-related thrombocytopenia. However, since most of these thrombocytopenic patients recover when the agent is cleared from the body, this therapy is probably not necessary and avoids exposing the patient to additional drug-associated adverse events.

TABLE 109.9

CRITICAL CARE DRUGS COMMONLY IMPLICATED IN THROMBOCYTOPENIA

Antiarrhythmics
Procainamide
Quinidine
Anti-GP IIb/IIIa agents
Abciximab
Eptifibatide
Tirofiban
Antimicrobial
Amphotericin B
Fluoroquinolones
Rifampin
Trimethoprim-sulfamethoxazole
Vancomycin
H_2-blockers
Cimetidine
Ranitidine
Acetaminophen
Bevacizumab
Carbamazepine
Danazol
Efalizumab
Gold
Heparin
Hydrochlorothiazide
Interferon
Methyldopa
Nonsteroidal anti-inflammatory agents
Trastuzumab
Quinine

Sepsis

Thrombocytopenia associated with sepsis syndromes classically has been attributed to DIC or destruction by autoimmune mechanisms [165–167]. Increasing evidence, however, points to cytokine-driven hemophagocytosis of platelets [168–171]. Patients with hemophagocytosis appear to have higher rates of multiple organ system failure and higher mortality rates. Inflammatory cytokines, especially monocyte-colony stimulating factor (M-CSF), are thought responsible for inducing the hemophagocytosis [166,172].

Thrombocytopenia may be a diagnostic clue to infection with unusual organisms [173]. Three members of the Ehrlichia family have been reported to cause infections in humans [174,175]. They are transmitted by ticks and the diseases that they produce are similar. Most patients have a febrile illness with high fevers, headaches, and myalgias [174,176]. Patients may have central nervous system signs and marked elevation of the serum levels of liver enzymes. Rarely patients may present with a toxic shock-like syndrome [177]. Although many cases are mild, severe disease is common and the case fatality rate is 2% to 5% [176]. The typical hematologic picture is leukopenia (1.3 to 4×10^9 per L) and mild thrombocytopenia (30 to 60×10^9 per L). In many patients, the buffy coat reveals the organisms bundled in a 2 to 5 μm morula in the cytoplasm of the granulocytes or monocytes. Consideration of ehrlichiosis is important because highly specific therapy is doxycycline, which is a drug not routinely used for therapy of sepsis syndrome.

The classical hematological presentation of Hantavirus pulmonary syndrome (HPS) can be helpful in the diagnosis of this severe illness. Patients suffer a flu-like prodrome and then rapidly develop a noncardiac pulmonary edema resulting in profound respiratory failure [10,178]. Ventilatory support is required in 75% of cases and the mortality is approximately 50%. A powerful indicator to the presence of Hantavirus is found on the peripheral smear [10,179]. The triad of thrombocytopenia, increased and left-shifted white cell count, and more than 10% circulating immunoblasts can identify all cases of HPS and was seen in only 2.6% non-HPS controls in a recent study [10]. Marked hemoconcentration is also present due to capillary leak syndrome with the hematocrit reaching in some patients as high as 68%.

Viral Hemorrhagic Fevers

Viral hemorrhagic fevers (VHFs) are a diverse group of viral infections that can result in massive bleeding [180–182]. VHFs are an important problem in certain parts of the world but travelers may carry the disease anywhere. In the Southern United States, dengue is becoming an increasing problem and fatal cases of arenavirus have been reported in California [183]. As described in Table 109.10, there are four groups of viruses which can lead to VHFs [184,185].

The typical pattern is a febrile illness that proceeds over a few days to shock and diffuse bleeding with the patient developing signs of thrombocytopenia and in some cases DIC. A key sign is that patients will experience profuse bleeding from the gastrointestinal track and mucosal bleeding often out of proportion to the observed coagulation defects. This finding should serve as a diagnostic clue. Most VHFs are also associated with leukopenia and hemoconcentration. Therapy is aggressive supportive care of the patients and replacement of coagulation factors. As noted in Table 109.10, ribavirin can treat certain VHFs. Given the propensity of many of these infections to spread to healthcare workers, precautions should be taken to prevent nosocomial spread [186].

TABLE 109.10

VIRAL HEMORRHAGIC FEVER-ASSOCIATED THROMBOCYTOPENIA

Arenaviridae
- Diseases: Lassa fever, New World arenaviruses
- Distribution: West Africa (Lassa), South America [rare California] (New World)
- Vector: rodents
- Incubation: 5–16 d
- Therapy: ribavirin
- Unique clinical features: pharyngitis, late deafness (Lassa); neurological involvement–seizures (New World)

Bunyaviridae
- Diseases: Crimean–Congo hemorrhagic virus (CCHF), Rift Valley fever, hemorrhagic fever with renal syndrome (HFRS)
- Distribution: Africa, central Asia, eastern Europe, Middle East (CCHF), Africa, Middle East (Rift), Asia, Balkans, Europe (HFRS)
- Vector: ticks (CCHF), mosquitoes (Rift Valley), rodents (HFRS)
- Incubation: 1–6 d (CHHF), 2 wk to 2 mo (HFRS)
- Therapy: ribavirin
- Unique clinical features: retinitis, hepatitis (Rift Valley), prominent bleeding with DIC, jaundice (CCHF); renal disease (CCHF)

Filoviridae
- Diseases: Ebola, Marburg viruses
- Distribution: Africa
- Vector: ?
- Incubation: 2–21 d
- Unique clinical features: maculopapular rash, high mortality

Flaviviridae
- Diseases: dengue, yellow fever
- Distribution: widespread (dengue), Africa, tropical Americans (yellow)
- Vector: mosquitoes
- Incubation: 3–15 d
- Unique clinical feature: liver involvement (yellow)

Bleeding in the Platelet-Refractory Patient

Bleeding in patients who are refractory to platelet transfusion presents a difficult clinical problem (Table 109.11) [187,188]. If patients are demonstrated to have HLA antibodies, one can transfuse HLA-matched platelets [189]. Unfortunately, matched platelet transfusions do not work in 20% to 70% of these patients. Also, since some loci are difficult to match, effective products may be unavailable. As many as 25% of patients have antiplatelet antibodies in which HLA-matched products will be ineffective. One can perform platelet crossmatching to find compatible units for these patients but this may not always be successful. In the patient who is totally refractory to platelet transfusion, consider drugs as an etiology of antiplatelet antibodies (especially vancomycin) [163]. Use of antifibrinolytic agents such as epsilon aminocaproic acid or tranexamic acid may decrease the incidence of minor bleeding but are ineffective for major bleeding [190]. “Platelet drips” consisting of infusing either a platelet concentrate per hour or one plateletpheresis unit every 6 hours may be given as a continuous infusion [191,192]. For life-threatening bleeding

TABLE 109.11

EVALUATION AND MANAGEMENT OF PLATELET ALLOIMMUNIZATION

1. Check platelet count 15 min after platelet transfusion.
2. If rise in platelet count is less than 5,000 per μL, check for HLA antibodies.
3. Administer HLA-matched platelets and evaluate for response.
4. If three sequential HLA-matched platelet transfusions are ineffective, discontinue HLA-matched platelets.
5. In completely refractory patients:
   A. Evaluate for other causes of thrombocytopenia (HIT, drugs).
   B. Consider institution of antifibrinolytic therapy
1. Epsilon aminocaproic acid 1 g/h IV, or
2. Tranexamic acid 10 mg/kg IV every 8 h
   C. Platelet "drip"—continuous infusion of platelets at the rate of 1 unit over 6 h
   D. Recombinant activated VII for life-threatening bleeding

rVIIa may be of use [193]. For platelet refractory patients with arterial bleeding, the use of angiographic delivery of platelets has been reported to be successful in stopping bleeding [194].

Catastrophic Antiphospholipid Antibody Syndrome

Rarely patients with antiphospholipid antibody syndrome can present with fulminant multiorgan system failure [195–199]. Catastrophic antiphospholipid antibody syndrome is caused by widespread microthrombi in multiple vascular fields. These patients will develop renal failure, encephalopathy, adult respiratory distress syndrome (often with pulmonary hemorrhage), cardiac failure, dramatic livedo reticularis, and worsening thrombocytopenia. Many of these patients have preexisting autoimmune disorders and high titer-anticardiolipin antibodies. It appears that the best therapy for these patients is aggressive immunosuppression, plasmapheresis, and anticoagulation, then (perhaps) IV cyclophosphamide monthly [198]. Early recognition of this syndrome can lead to quick therapy and resolution of the multiorgan system failure.

Posttransfusion Purpura

Patients with this disorder develop severe thrombocytopenia ($<10 \times 10^9$ per L), and often severe bleeding, 1 to 2 weeks after receiving blood products [200]. Affected patients usually lack the platelet antigen PLA1. For unknown reasons, exposure to the antigens from the transfusion leads to rapid destruction of the patient's own platelets. The diagnostic clue is thrombocytopenia in a patient, typically female, who has received a red cell or platelet blood product in the past 7 to 10 days. Treatment consists of intravenous immunoglobulin [201] and plasmapheresis to remove the offending antibody. If patients with a history of posttransfusion purpura require further transfusions, only PLA1-negative platelets should be given.

Liver Disease

Patients with severe liver disease have multiple hemostatic defects [202–206] (see Chapter 108, Disorders of Hemostasis). Splenomegaly (due to cirrhosis) and infections (e.g., HCV) may be contributory. Additionally, the liver is the source of thrombopoietin and lack of this platelet growth factor may worsen thrombocytopenia [207–209]. Patients may have platelet dysfunction due to the increase in fibrinogen degradation products and circulating plasmin [210]. Platelet transfusion should be given only to patients with platelet counts that are reliably less than 10×10^9 per L who are actively bleeding, or who require a higher platelet count due to an invasive procedure. The thrombopoietin receptor agonist eltrombopag has been used in patients with HCV-associated thrombocytopenia enabling administration of eradication therapy for HCV [211], but the delayed onset of action may make use in the critical care unit, where a need for immediate correction in the platelet count is more likely to be encountered, less feasible.

CHAPTER 110 ■ ANTITHROMBOTIC PHARMACOTHERAPY

CHRISTOPHER D. ADAMS, KEVIN E. ANGER, BONNIE C. GREENWOOD AND JOHN FANIKOS

INTRODUCTION

Thromboembolic disease is commonly encountered among critically ill patients [1]. While these patients are at high risk for developing arterial and venous thrombosis due to underlying comorbidities, central venous catheter placement, and immobility, they are also at high risk for hemorrhagic complications resulting from gastrointestinal stress ulcerations, invasive procedures, liver dysfunction, uremia, or coagulopathy [2]. These divergent features often complicate antithrombotic treatments for prevention or management of thrombosis. Limitations in administration routes, hemodynamic instability, alterations in renal and hepatic function, and drug interactions further complicate the administration of these high-risk medications [3].

This chapter focuses on the mechanism of action, pharmacokinetics, pharmacodynamics, clinical indications, complications of therapy, and reversal options for antithrombotic pharmacotherapy in critically ill patients.

ANTIPLATELET PHARMACOTHERAPY

Overview of Antiplatelet Pharmacotherapy

Antiplatelet agents target mechanisms in platelet activation, adhesion, and aggregation. Pharmacological inhibitors of platelet function fall into four general categories: thromboxane (TXA) inhibitors, antagonists of adenosine diphosphate (ADP)-mediated platelet activation, glycoprotein (GP) IIb/IIIa inhibitors, and phosphodiesterase inhibitors (Fig. 110.1).

Antiplatelet "resistance" and "nonresponse" are terms applied to clinical outcomes characterized by failure to prevent a thrombotic event due to inadequate platelet inhibition [4]. Resistance is conferred by underlying clinical, cellular, and genetic mechanisms. It is best confirmed by platelet function testing [5]. While several methods are available for measuring overall and drug-specific platelet aggregation, standard testing protocols have yet to be established [6].

Aspirin and Aspirin Derivatives

Pharmacology, Pharmacodynamics, and Monitoring

Aspirin, or acetylsalicylic acid, is a prodrug of salicylic acid that blocks platelet activation. Aspirin irreversibly inhibits both cyclooxygenase enzymes (COX-1, COX-2), reducing prostaglandin and TXA byproducts generated from arachidonic acid. Thromboxane A_2 stimulates platelet activation, aggregation, and recruitment. COX-1 enzymes are present in most tissues, but larger amounts are found in the stomach, kidneys, and platelets. The prostaglandin products of COX enzyme activity provide protection from gastrointestinal mucosal injury. COX-2 is found in both nucleated and nonnucleated cells and is responsive to inflammatory stimuli. Inhibition of COX-1 appears to be the primary mechanism by which aspirin inhibits hemostasis. The acetylation of platelet COX-1 enzymes by aspirin causes inhibition of platelet TXA_2 production. The irreversible antiplatelet effect lasts for the life of platelet (7 to 10 days). Saturation of the mechanism occurs at doses as low as 30 mg. Large doses of aspirin (>3,000 mg daily) are required to inhibit COX-2 and produce systemic anti-inflammatory effects. Consequently, there is a 50- to 100-fold variation between the daily doses required to suppress inflammation and inhibit platelet function [7,8].

Enteric-coated and delayed release formulations have diminished bioavailability, take 3 to 4 hours to reach peak plasma levels, and have delayed onset. Rectally administered aspirin has variable absorption with a bioavailability of 20% to 60% over a 2- to 5-hour retention time [9]. For acute thrombosis, immediate-release aspirin is preferred [10].

The optimal aspirin dose that maximizes efficacy and minimizes toxicity is controversial. Evidence-based recommendations vary from 75 to 325 mg daily. There is currently no data suggesting inferiority of lower (75 to 100 mg) to higher (>100 mg) maintenance dosing in preventing thromboembolic events [11].

Recurrent vascular thrombotic episodes despite aspirin therapy occur at rates between 2% and 6% of patients per year [4]. Aspirin resistance occurs in 5.5% to 45% of aspirin-treated patients. Possible mechanisms of aspirin resistance

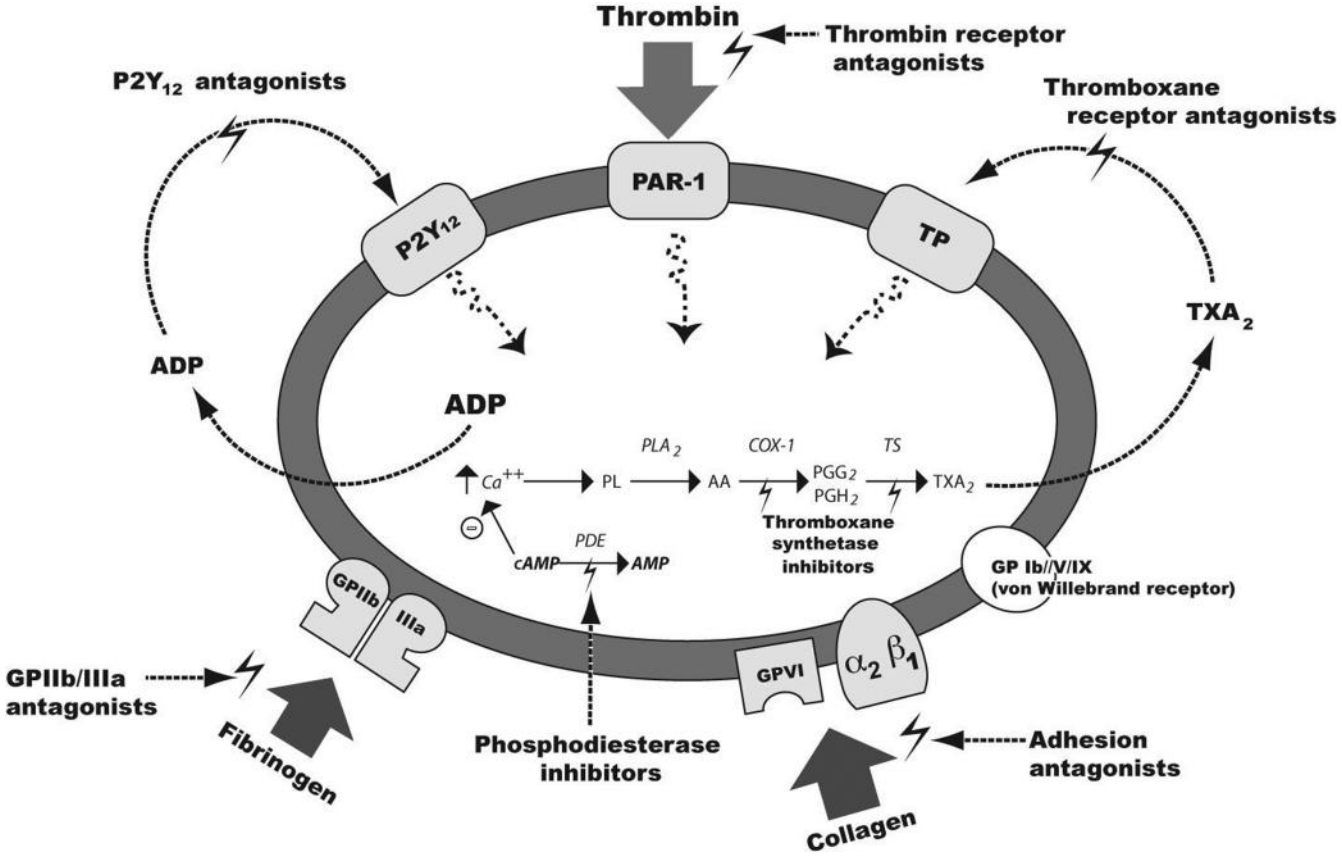

FIGURE 110.1. Platelet activation and pharmacological inhibitors of platelet function. Platelet activation involves four mechanisms: adhesion to sites of vascular injury, release of stimulatory compounds, aggregation, and priming of coagulation. Pharmacological inhibitors of platelet function target adhesion, release, and aggregation mechanisms. Platelet adhesion is a four-step process involving tethering of von Willebrand factor (VWF) to glycoprotein (GP) Ib platelet receptors, a potential target of investigational agents. The rolling phase of adhesion involves interaction between vascular collagen with GP VI and GP Ia/IIa receptors, another potential target of investigational agents. The activation phase of adhesion involves release of thromboxane A_2 (TXA_2) and adenosine diphosphate (ADP) which can be blocked with use of aspirin and $P2Y_{12}$ inhibitors, respectively. The stable adhesion phase involves the interaction of GP IIb/IIIa receptors with fibrinogen and VWF, which can be blocked with the use of GP IIb/IIIa inhibitors.

include extrinsic factors (compliance, absorption, dosage formulation, and smoking) and intrinsic factors (pharmacodynamic alterations, receptor polymorphisms, upregulation of nontargeted platelet activation pathways). In clinical trials, aspirin resistance has been associated with an increased risk of death, acute coronary syndromes (ACS), and stroke [5,12,13].

Clinical Indications

Aspirin is indicated for the primary and secondary prevention of arterial and venous thrombosis (Table 110.1). Aspirin is effective in reducing atherothrombotic disease morbidity and mortality in ACS, stable angina, coronary bypass surgery, peripheral arterial disease (PAD), transient ischemic attack, acute ischemic stroke, and polycythemia vera. A meta-analysis of 145 randomized studies in patients with coronary artery and cerebrovascular disease demonstrated that aspirin 75 to 300 mg per day reduced the risk of nonfatal myocardial infarction (MI) by 35% and the risk of vascular events by 18% [14]. Aspirin provides effective thromboprophylaxis in patients on warfarin with prosthetic heart valves and in patients with nonvalvular atrial fibrillation [15].

Complications and Reversal of Effect

Aspirin increases the incidence of major, gastrointestinal, and intracranial bleeding [15]. The recommended interval for discontinuation of aspirin prior to elective surgery or procedures is 7 to 10 days. Therapy can be resumed approximately 24 hours or the next morning after surgery when there is adequate hemostasis [16]. For patients exhibiting clinically significant bleeding or requiring emergent surgery, platelet transfusion may be warranted. Intravenous desmopressin antagonizes aspirin's effect, suggesting a role in emergent situations as well [17].

Aspirin produces gastrointestinal ulcerations and hemorrhage through direct irritation of the gastric mucosa and via inhibition of prostaglandin synthesis. Aspirin, in recommended doses, increases the risk of gastrointestinal bleeding 1.5- to 3-fold [14,18]. Enteric-coated and buffered aspirin doses $\leq$325 mg do not reduce the incidence of gastrointestinal bleeding [19]. Aspirin-induced gastric toxicity can be prevented with concurrent use of acid-suppressive therapy [20].

Underlying aspirin allergy can exacerbate respiratory tract disease, angioedema, urticaria, or anaphylaxis and is estimated

TABLE 110.1

CLINICAL USES OF ASPIRIN

Drug	Indications	Dosing, timing, duration	Precautions
Acetylsalicylic acid (aspirin)	Treatment of acute coronary syndromes	Load 162–325 mg orally Initial dosing for stents 162–325 mg orally/d: Bare metal 1 mo Sirolimus 3 mo Paclitaxel 6 mo Maintenance: 81–325 mg/d orally	■ Thrombocytopenia ■ Bleeding disorders ■ Pregnancy (third trimester) ■ Gastrointestinal disorders ■ Renal failure ■ Severe hepatic insufficiency ■ Concomitant antithrombotic medication use ■ Alcohol consumption
	Primary and secondary prevention of myocardial infarction in patients with chronic stable angina, previous MI, or unstable angina	81–325 mg/d orally	
	Secondary prevention in stroke and TIA patients	75–325 mg/d orally	
	Acute thrombotic stroke	160–325 mg/d, initiated within 48 h (in patients who are not candidates for fibrinolytics and are not receiving systemic anticoagulation)	
	Secondary prevention in CABG, carotid endarterectomy patients	75–325 mg/d starting 6 h following procedure; if bleeding prevents administration at 6 h after CABG, initiate as soon as possible	

CABG, coronary artery bypass graft; MI, myocardial infarction; TIA, transient ischemic attack.

to occur in 10% of the general population. These patients may be converted to alternative antiplatelet therapies. Leukotriene-modifying agents may reduce aspirin-provoked respiratory reactions but do not eliminate the risk. For patients with a compelling indication for therapy, aspirin desensitization may be considered [21].

$P2Y_{12}$ Inhibitors

Pharmacology, Pharmacodynamics, and Monitoring

$P2Y_{12}$ inhibitors prevent platelet activation by blocking ADP binding to $P2Y_{12}$ receptors. This action prevents activation of the GP IIb/IIIa receptor complex on the platelet surface [10].

Thienopyridine derivatives, clopidogrel, prasugrel, and ticlopidine, are prodrugs requiring hepatic activation via the cytochrome P450 (CYP450) isoenzyme system (Table 110.2). Metabolism by CYP450 plays a key role in the onset of action, potency, and drug interaction profile of these agents [22,23]. A loading dose provides a rapid increase in plasma concentration and a faster onset of action. Both clopidogrel and ticlopidine require a two-step activation process via CYP450. Prasugrel undergoes one-step oxidation by multiple CYP450 isoenzyme pathways which are believed to be responsible for its more predictable action.

While thienopyridine metabolites have a short plasma elimination half-life (1 to 8 hours), their irreversible activity at $P2Y_{12}$ receptors spans the life of the platelet (7 to 10 days). The onset of action, duration of antiplatelet effect, and unpredictable levels of platelet inhibition have led to the development of newer agents [24–26]. Three investigational nonthienopyridine derivatives are currently under investigation for the management of ACS. These agents do not require hepatic activation resulting in immediate, short-acting, dose-dependent inhibition of platelet aggregation [26].

Resistance to clopidogrel occurs in 4% to 34% of patients and depends on the agent, type, and timing of platelet function test, as well as underlying comorbidities such as diabetes and obesity [23]. Possible mechanisms of $P2Y_{12}$ inhibitor resistance include extrinsic factors and intrinsic factors. Recent literature highlighted the importance of genetic and drug-induced alterations of CYP3A4 enzymes, the pathway responsible for thienopyridine activation [27]. Clopidogrel resistance has been associated with an increased risk of death, MI, and stroke. For patients with presumed or confirmed clopidogrel resistance, maintenance dosing up to 150 mg daily or use of more potent agents may be necessary, particularly in patients with in-stent thrombosis [27].

Monitoring the antiplatelet effect of $P2Y_{12}$ inhibitors using platelet function testing is an evolving area of research [27]. The high incidence of varied responses to thienopyridines due to CYP450 polymorphisms and potential drug interactions have suggested a strategy for improving response by using point-of-care platelet function testing.

Clinical Indications

$P2Y_{12}$ inhibitors are indicated for primary and secondary thrombosis prevention in a variety of disease states (Table 110.3). Ticlopidine reduces thrombotic events in patients with stroke, but is associated with neutropenia, thrombocytopenia, and thrombotic thrombocytopenic purpura [28]. Clopidogrel is indicated alone or in combination with aspirin for primary and secondary prevention of ischemic events in ACS, PAD, stroke, and coronary artery disease. Prasugrel is indicated alone or in combination with aspirin for the prevention of thrombotic cardiovascular events, including in-stent

TABLE 110.2

thrombosis, in ACS patients who are managed with percutaneous coronary intervention (PCI) [23].

Complications and Reversal of Effect

The incidence of major bleeding with $P2Y_{12}$ inhibitors varies between agents, dosing, patient populations, and concomitant antithrombotic therapies. Gastrointestinal hemorrhage is a common complication of $P2Y_{12}$ inhibitor therapy [20]. Endoscopic evaluations at 1 week demonstrated less gastrointestinal damage with clopidogrel 75 mg daily than with aspirin 325 mg daily [29]. For patients exhibiting clinically significant bleeding, platelet transfusion may be warranted.

$P2Y_{12}$ inhibitors should be avoided in patients undergoing neuraxial analgesia due to the risk of subdural hematoma [30]. Therapy should be discontinued 7 to 10 days prior to elective surgery or invasive procedure and resumed approximately 24 hours or the next morning after surgery.

TABLE 110.3

CLINICAL USES OF $P2Y_{12}$ INHIBITORS

Drug	Indications	Dosing, timing, duration	Precautions
Clopidogrel (Plavix™)	Treatment of acute coronary syndromes +/− percutaneous intervention	Load 300 mg ×1 PCI load: 300–600 mg × 1 Maintenance 75 mg/d orally Drug-eluting stents: duration of clopidogrel ideally 12 mo following drug-eluting stent	■ Age >75 y (prasugrel) ■ Interruption of clopidogrel may cause in-stent thrombosis with subsequent fatal and nonfatal myocardial infarction
	Primary and Secondary prevention of myocardial infarction in patients with chronic stable angina, previous MI, or unstable angina	75 mg orally once daily	■ Indwelling epidural catheter ■ Combination of aspirin and clopidogrel in patients with recent TIA or stroke
	Cerebrovascular accident Arteriosclerotic vascular disease		■ Liver disease ■ Thrombotic thrombocytopenic purpura may occur (rare)
	Peripheral arterial occlusive disease		■ Recent trauma, surgery/biopsy ■ Hematologic disorders
Ticlopidine (Ticlid™)	Placement of stent in coronary artery Secondary prevention in thromboembolic stroke	250 mg orally twice a day	■ Discontinue if ANC less than 1,200/μL or platelet count less than 80,000/μL (ticlopidine)
Prasugrel (Effient™)	Treatment of acute coronary syndromes +/− percutaneous intervention	Load 60 mg × 1 Maintenance: 10 mg/d orally Weight <60 kg, consider using a lower maintenance dose of 5 mg/d	■ Elevated triglycerides (ticlopidine)

ANC, absolute neutrophil count; MI, myocardial infarction; PCI, percutaneous coronary intervention; TIA, transient ischemic attack.

CrCl; creatinine clearance using Cockcroft–Gault equation.

Glycoprotein IIb/IIIa Inhibitors

Pharmacology, Pharmacodynamics, and Monitoring

GP IIb/IIIa receptors are expressed on the platelet surface, with approximately 50,000 to 80,000 copies per platelet. Blocking GP IIb/IIIa receptors prevents platelet activation, aggregation, and fibrinogen-mediated platelet to platelet bridging.

Intravenous GP IIb/IIIa inhibitors (abciximab, eptifibatide, and tirofiban) vary in their structure and pharmacokinetic properties (Table 110.4) [10,31]. Although the exact threshold required for efficacy with these agents has not been established, >80% platelet inhibition is thought to be a target associated with adequate antiplatelet activity in patients with ACS and in those undergoing PCI [32].

Abciximab is a human–murine chimeric monoclonal antibody that demonstrates a dose-dependent inhibition of GP IIb/IIIa receptors. After an initial intravenous bolus and infusion, the onset of platelet inhibition is rapid (5 minutes) and 80% to 90% of ADP-induced platelet aggregation is suppressed [31]. Abciximab has a strong affinity for the receptor, resulting in occupancy that persists for weeks. Once discontinued, platelet function recovers gradually, with bleeding time normalizing at 12 hours and ADP-induced aggregation returning at 24 to 48 hours [31,32].

Both eptifibatide, a synthetic peptide, and tirofiban, a synthetic small molecule, demonstrate high selectivity, but reduced affinity for the GP IIb/IIIa receptor when compared to abciximab. Both exhibit platelet inhibition that is linear and dose dependent. An intravenous eptifibatide or tirofiban bolus dose followed by an infusion provides >80% inhibition of ADP-induced platelet aggregation. For patients undergoing PCI, a second eptifibatide bolus 10 minutes after the initial dose further enhances platelet inhibition at 1 hour. Since both agents dissociate from the GP IIb/IIIa receptor rapidly, normal platelet aggregation is restored within 4 to 8 hours after drug discontinuation [33–35].

Platelet counts should be monitored within the first 24 hours while taking GP IIb/IIIa inhibitors. For abciximab, platelet counts should be evaluated within 2 to 4 hours of initiation due to a higher risk of thrombocytopenia.

Clinical Indication

GP IIb/IIIa inhibitors are included in evidence-based guidelines as adjunctive therapy for patients with ACS and those undergoing PCI (Table 110.5).

Optimal use of GP IIb/IIIa inhibitors involves appropriate patient risk stratification, use with other antithrombotic agents, appropriate dose, and duration of therapy [36].

Complications and Reversal of Effect

The frequency of major bleeding with GP IIb/IIIa therapy ranges from 1% to 14% of patients and depends on the agent, concomitant therapies, and settings of ACS or PCI [32–34]. Failure to adjust dosing in renal dysfunction further increases the risk of bleeding [37]. Factors associated with bleeding risk include age, female gender, body weight, diabetes, congestive heart failure, renal function, concomitant fibrinolytic use, prolonged femoral sheath placement, and heparin dosing [38,39].

The duration of the antiplatelet effect is agent specific and is influenced by platelet binding (abciximab binds to platelets for up to 10 days) and renal function (tirofiban and eptifibatide have half-lives of 1.5 to 3 hours with normal renal function). An intravenous desmopressin dose of 0.3 μg per kg may be beneficial in reducing bleeding time [17].

Nonhemorrhagic side effects of GP IIb/IIIa inhibitors include severe thrombocytopenia. The incidence of thrombocytopenia with eptifibatide and tirofiban is similar to placebo, with rates ranging from 0.2% to 0.3% of treated patients. With abciximab, the incidence is reported as 5%; however, up to 4% of cases can be due to pseudothrombocytopenia as a result of platelet clumping. The onset of thrombocytopenia usually occurs within the first 24 hours of infusion, but delayed onset has been reported [40,41].

Platelet or red blood cell transfusions may be warranted for patients with persistent thrombocytopenia or clinically significant bleeding and must take into account drug concentrations in the plasma or drug bound to platelets [31]. Abciximab has been associated with antibody formation in 6% of patients. The risk of thrombocytopenia and immune-mediated reactions may limit repeat use [8,10,32]. GP IIb/IIIa inhibitor administration should be avoided in patients requiring neuraxial analgesia due to risk of subdural hematoma [30].

Dipyridamole

Pharmacology, Pharmacodynamics, and Monitoring

Dipyridamole inhibits adenosine binding to platelets and endothelial cells. The increase in adenosine leads to a rise in cyclic adenosine monophosphate (cAMP), which in turn decreases platelet responsiveness to various stimuli. Dipyridamole is

TABLE 110.5

CLINICAL USES OF GLYCOPROTEIN IIB/IIIA INHIBITORS

Drug	Indications	Dosing, timing, duration	Precautions
Eptifibatide (Integrilin™)	Treatment of acute coronary syndromes +/− percutaneous coronary intervention	IV bolus 180 μg/kg ABW (maximum 22.6 mg) as soon as possible, followed by 2 μg/kg ABW/min (maximum 15 mg/h) infusion until discharge or CABG surgery, up to 72 h If undergoing PCI, administer a second 180 μg/kg IV bolus 10 min after the first and continue the infusion up to discharge, or for up to 18–24 h after procedure, whichever comes first, allowing for up to 96 h of therapy Renal adjustment CrCl <50 mL/min, 180 μg/kg actual body weight (maximum 22.6 mg) IV bolus as soon as possible, followed by 1 μg/kg/min (maximum 7.5 mg/h) infusion	■ Concomitant use of fibrinolytics, anticoagulants, antiplatelet agents, and nonsteroidal anti-inflammatory agents ■ Indwelling epidural catheter ■ Do not remove arterial sheath unless aPTT is less than 45 s or ACT less than 150 s and heparin discontinued for 3–4 h ■ Platelet count below 150,000/μL ■ Renal insufficiency (eptifibatide) ■ Severe renal insufficiency, chronic hemodialysis (tirofiban) ■ Readministration of abciximab may result in hypersensitivity, thrombocytopenia, or diminished benefit due to antibody formation ■ Hemorrhagic retinopathy
Abciximab (Reopro™)	Treatment of acute coronary syndromes +/− percutaneous coronary intervention	Initial, 0.25 mg/kg IV bolus (over 5 min), followed by 0.125 μg/kg/min (maximum 10 μg/min) IV infusion for 12 h in combination with fibrinolytic treatment or after PCI, unless complications No adjustment required for renal dysfunction	
Tirofiban (Aggrastat™)	Treatment of acute coronary syndromes	0.4 μg/kg/min IV for 30 min, then 0.1 μg/kg/min for 12–24 h after PCI Severe renal impairment (CrCl less than 30 mL/min): give half the usual dose–0.2 μg/kg/min IV for 30 min, then 0.05 μg/kg/min	

ABW, actual body weight; ACT, activated clotting time; aPTT, activated thromboplastin time; CABG, coronary artery bypass graft; CrCl; creatinine clearance using Cockcroft–Gault equation; IV, intravenous; PCI, percutaneous coronary intervention.

metabolized hepatically and has a half-life of approximately 10 hours [10].

Clinical Indications

Dipyridamole is indicated as adjunctive therapy for the prevention of thromboembolism in patients with cardiac valve replacement. Combined with aspirin, dipyridamole is indicated for secondary prevention of cerebrovascular accidents and TIA. The combination of aspirin and extended-release dipyridamole was associated with reductions in major vascular events in patients with stroke or TIA (Table 110.6) [10,42].

Complications and Reversal of Effect

While headache is the most common adverse effect associated with dipyridamole therapy, hemorrhage may also occur. For patients exhibiting clinically significant bleeding, platelet transfusion may be warranted.

Cilostazol

Pharmacology, Pharmacodynamics, and Monitoring

Cilostazol blocks platelet activation via phosphodiesterase 3 (PDE3) inhibition. PDE3 inhibition increases cAMP concentrations resulting in inhibition of platelet aggregation and an increase in vasodilation [43].

Cilostazol is extensively metabolized by CYP 450-3A4 subclass. Avoidance of therapy or reduced dosing may be required for patients taking potent CYP3A4 inhibitors [44].

Clinical Indication

Cilostazol is indicated for treatment of intermittent claudication symptoms and has shown benefit in reducing symptoms and improving walking distance [44].

Complications and Reversal of Effect

Nonhemorrhagic complications of cilostazol therapy include headache, peripheral edema, and tachycardia [44].

Overview of Anticoagulant Pharmacotherapy

Blood coagulation has been summarized previously in Chapter 108. Anticoagulant agents inhibit thrombosis and propagation by inhibiting thrombin directly or indirectly by attenuating thrombin generation (Fig. 110.2). Unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) are effective in acute thrombosis due to their rapid onset. Since heparins are dependent on the presence of antithrombin (AT) for clotting factor inhibition, they are considered indirect anticoagulants. Heparins contain a pentasaccharide sequence that binds to AT, producing a conformational change that accelerates AT inactivation of coagulation factors XIIa, IXa, XIa, Xa, and IIa (thrombin). Of these, thrombin and Xa play the most critical role in the coagulation cascade. The active pentasaccharide sequence responsible for catalyzing AT is found on one-third and one-fifth of the chains of heparin and LMWH, respectively. Fondaparinux is a synthetic analog of this naturally occurring pentasaccharide [45–47].

TABLE 110.6

CLINICAL USES OF PHOSPHODIESTERASE INHIBITORS

Drug	Indications	Dosing, timing, duration	Precautions
Dipyridamole (Persantine™)	Radionuclide myocardial perfusion study VTE prophylaxis after heart valve replacement	0.142 mg/kg/min IV for 4 min (0.57 mg/kg total) prior to thallium; maximum 60 mg With concomitant warfarin therapy: 75–100 mg orally four times daily	■ Aminophylline injection should be readily available for relieving adverse effects such as chest pain and bronchospasm ■ Hypotension ■ Severe coronary artery disease, abnormal cardiac rhythm
Dipyridamole extended-release/aspirin (Aggrenox™)	Secondary prevention in stroke and TIA patients	200 mg dipyridamole, 25 mg aspirin (1 capsule) orally twice daily Patients with intolerable headache 200 mg dipyridamole, 25 mg aspirin orally daily at bedtime, with 81 mg of aspirin in the morning Return to usual dose as soon as tolerance to headache develops (usually within a week)	■ Avoid in patients with severe hepatic insufficiency ■ Avoid in patients with severe renal failure (CrCl less than 10 mL/min) ■ Severe coronary artery disease ■ Coagulation abnormalities ■ Severe renal impairment
Cilostazol (Pletal™)	Intermittent claudication	100 mg orally twice a day	

CrCl, creatinine clearance using Cockcroft–Gault equation; IV, intravenous; TIA, transient ischemic attack; VTE, venous thromboembolism.

Unfractionated Heparin

Pharmacology, Pharmacodynamics, and Monitoring

UFH is composed of a heterogeneous mixture of highly sulfated polysaccharide chains that vary in molecular weight, anticoagulant activity, and pharmacokinetic properties. A minimum of 18 saccharide units are required for UFH to form a ternary complex with AT and inhibit thrombin. Once bound to AT molecules, UFH can readily dissociate and bind to other AT molecules. Alternatively, the only requirement for factor Xa inhibition is for the heparin-AT complex to be formed. Heparin has equal inhibitory activity against factor Xa and thrombin, binding in a 1:1 ratio.

Since UFH is poorly absorbed orally, intravenous or subcutaneous injections are the preferred administration routes [47]. When given as subcutaneous injection with therapeutic intent, UFH doses need to be large enough (>30,000 units per day) to overcome erratic bioavailability. UFH readily binds to plasma proteins after parenteral administration which contributes to variable anticoagulant response. Despite these limitations, intravenous administration rapidly achieves therapeutic plasma concentrations that can be monitored and adjusted based on infusion rates [45].

UFH clearance from systemic circulation is dose related and occurs through two independent mechanisms [46,48]. The initial phase is rapid and saturable binding to endothelial cells, macrophages, and local proteins where UFH is depolymerized. The second phase is a slower, nonsaturable, renal-mediated clearance. At therapeutic doses, UFH is cleared primarily in the initial phase with higher-molecular-weight chains being cleared more rapidly than lower-weight counterparts. As elimination becomes dependent on renal clearance, increased or prolonged UFH dosing provides a disproportionate increase in both the intensity and duration of anticoagulant effect. With therapeutic intravenous doses of heparin, the half-life of UFH is approximately 60 minutes [46,48].

The anticoagulant response to UFH is monitored using activated partial thromboplastin time (aPTT), a measurement sensitive to the inhibitory effects of thrombin. The aPTT should be measured every 6 hours, and doses adjusted accordingly, until the patient sustains therapeutic levels. Once steady state is reached, the frequency of monitoring can be extended.

Weight-based dosing nomograms are recommended for treatment of thromboembolic disease. Such nomograms have been associated with a shorter time to reach a therapeutic level without an increase in bleeding events. Heparin dosing nomograms differ between hospitals due to differences in thromboplastin agents and interlaboratory standards in aPTT measurements [49].

Clinical Indications

Clinical indications for UFH include treatment of ACS, treatment or prevention of venous thromboembolism (VTE), bridge therapy for atrial fibrillation, and cardioversion (Table 110.7) [36,48,50]. Due to UFH's short half-life and reversibility, it remains the best option in patients with bleeding risk or organ dysfunction. Patients with fluctuating renal function or a calculated creatinine clearance less than 30 mL per minute are not candidates for LMWH or fondaparinux due to the risk of accumulation and increased bleeding risk, and should be given UFH [51]. When used for thromboprophylaxis in medical patients, three times daily heparin dosing provides better efficacy in reducing VTE events compared to twice daily dosing, but generates more major, but not minor, bleeding episodes [52].

Complications and Reversal of Effect

The major complications of UFH therapy include bleeding (major bleeding, 0% to 7%; fatal bleeding, 0% to 3%), heparin-induced thrombocytopenia (1% to 5%), and osteoporosis (2% to 3% risk of vertebral fracture with less than 1 month of treatment) [53]. Hemorrhagic episodes are associated with anticoagulation intensity, route of administration (continuous infusions are associated with lower rates), and concomitant use of

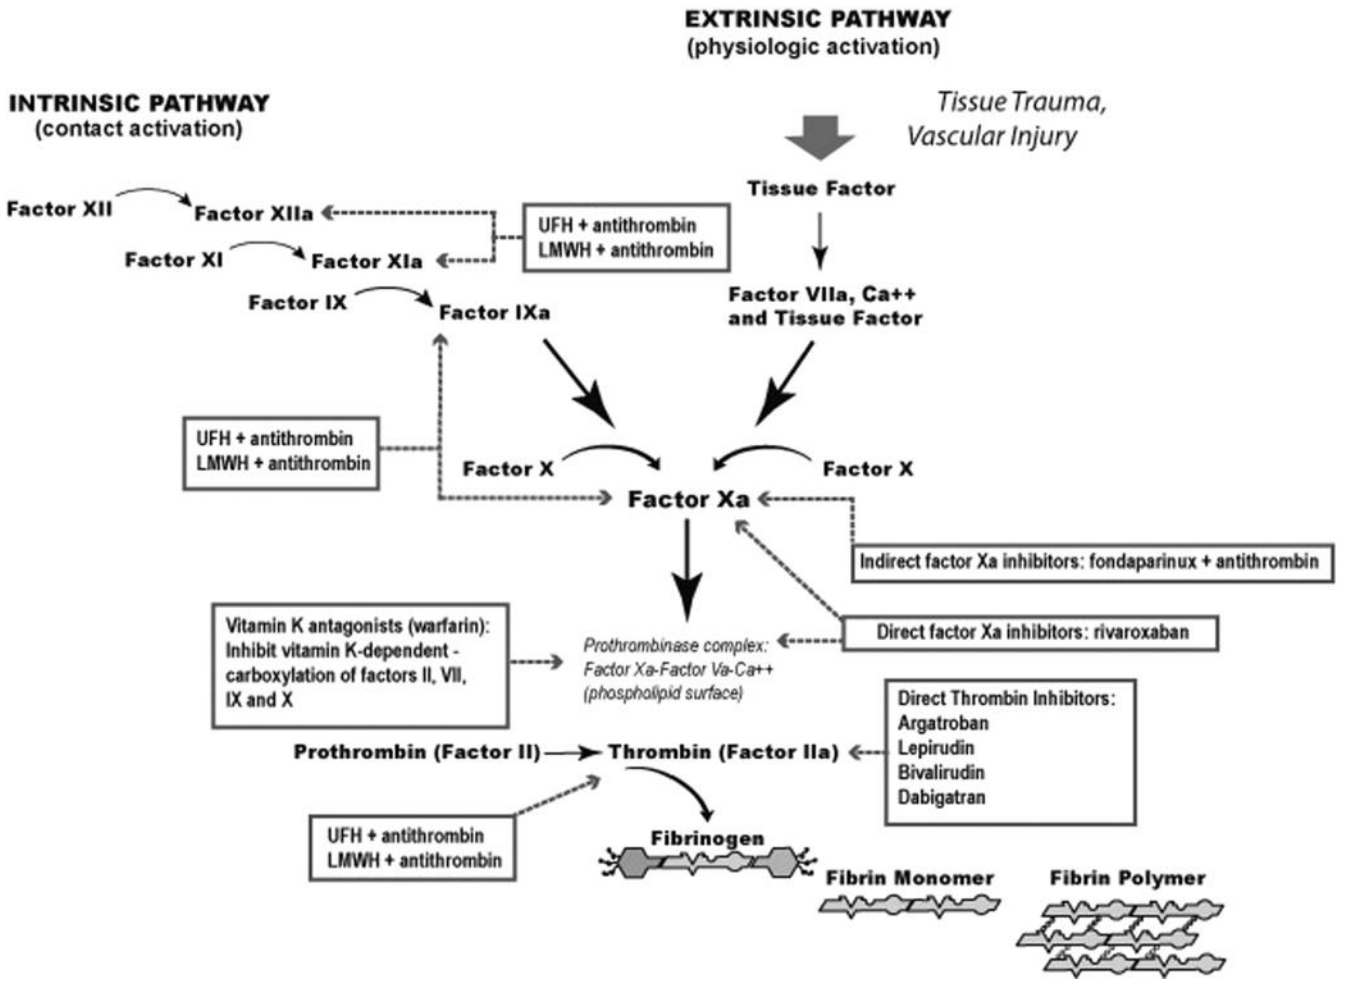

FIGURE 110.2. The coagulation cascade comprises the intrinsic (contact activation) pathway and the extrinsic (tissue factor) pathway. Each pathway generates a series of reactions in which inactive circulating enzymes and their cofactors are activated. These activated factors then catalyze the next reaction in the cascade. Thrombin plays a pivotal role by triggering the conversion of soluble fibrinogen in insoluble fibrin monomers, which serve as the foundation for thrombus formation. Thrombin also activates factors VIII, V, and XIII. Factor XIII generates the covalent bonds that link fibrin strands, ensuring structural integrity. Anticoagulants, either through their interaction with antithrombin, or through a direct inhibition of thrombin, interrupt these enzymatic reactions.

TABLE 110.7

CLINICAL USES OF UNFRACTIONATED HEPARIN

Drug	Indications	Dosing, timing, duration	Precautions
Unfractionated heparin	Treatment of VTE	80 units/kg bolus, then 18 units/kg/h infusion adjusted per local heparin nomogram	■ Allergic or hypersensitivity-type reactions ■ Congenital or acquired bleeding disorders ■ Indwelling epidural catheter ■ Gastrointestinal ulceration and ongoing tube drainage of the small intestine or stomach ■ Hepatic disease with impaired hemostasis ■ Hereditary antithrombin III deficiency and concurrent use of antithrombin ■ Menstruation ■ Neonates and infants weighing <10 kg ■ Premature infants weighing less than 1 kg
	Treatment of ACS	IV bolus: 60 units/kg (max 4,000 units) 12 units/kg/h (max 1,000 units) +/− fibrinolysis, adjusted to maintain aPTT 1.5–2 times control or per local heparin nomogram	
	Bridge therapy for atrial fibrillation, cardioversion	IV infusion: 60–80 units/kg bolus Target aPTT, 60 s, range, 50–70 s	
	Prophylaxis of VTE in the medically ill or surgical population	5,000 units SC every 8–12 h	
	Prophylaxis of VTE in pregnancy (with prior VTE)	7,500–15,000 units SC every 12 h

[a] This model assumes a half-life for UFH of 1 h and for LMWH 8 h.
[b] Estimated amounts of UFH remaining at 1 h following initiation of a continuous infusion may be overestimated in this model.
[c] Administer no more than 20 mg of protamine per minute, in divided doses, with no more than 50 mg over any 10-min period.
UFH, unfractionated heparin, LMWH, low-molecular-weight heparin.

GP IIb/IIIa inhibitors, aspirin or fibrinolytic agents [53–55]. Patient-specific risk factors for bleeding include age, gender, renal failure, low body weight, and excessive alcohol consumption [53].

Perioperative anticoagulation must be individualized based on the surgery or procedure and the patient's risks for thrombosis and bleeding. Discontinuing therapeutic doses of heparin 4 hours before surgery and measuring an aPTT is usually sufficient since normal hemostasis is restored in this time frame [16,56,57]. Therapeutic-dose heparin therapy can be restarted 12 hours after major surgery, but should be delayed if evidence of bleeding is present. There is no contraindication to neuraxial techniques in patients receiving twice daily, low-dose UFH subcutaneously, as the risk for developing spinal hematoma appears to be minimal [16,30].

Treatment of UFH-related bleeding includes protamine sulfate, transfusion, and supportive care. Protamine sulfate binds to UFH to form a stable salt, which renders heparin inactive. Protamine dosing is dependent on timing of the last heparin dose. For immediate reversal (<30 minutes since last heparin dose), 1 mg of protamine is administered for every 100 units of heparin and a followup aPTT can evaluate the reversal response. When UFH is given as a continuous IV infusion, only UFH delivered during the preceding 2 to 2.5 hours should be included in the calculation to determine the protamine dose (Table 110.8) [58]. If the dose of heparin is unknown, the maximal tolerated protamine dose of 50 mg can be slowly administered followed by serial measurements of aPTT. Adverse reactions, such as hypotension and bradycardia, are common. However, reaction severity can be reduced by slowly administering protamine over 1 to 3 minutes. Allergic responses to protamine are more common in patients who have been previously exposed to the drug, but patients can be pretreated with corticosteroids and antihistamines [53,59,60].

Low-Molecular-Weight Heparins

Pharmacology, Pharmacodynamics, and Monitoring

LMWHs are derived from UFH by chemical or enzymatic depolymerization, yielding fragments approximately one-third the molecular weight of UFH. All LMWH molecules contain the active pentasaccharides that catalyze AT inhibition of factor Xa. Because of their smaller size, LMWHs have decreased affinity for plasma proteins and cellular binding sites, resulting in a superior pharmacokinetic profile compared to UFH. LMWHs also have increased bioavailability after subcutaneous injection, renal clearance that is dose-independent, and a longer half-life (17 to 21 hours). LMWHs are administered in fixed doses for thromboprophylaxis or in total body weight-adjusted doses for therapeutic anticoagulation (Table 110.9) [45,61].

With their predictable dose response (peak anti-Xa activity occurs 3 to 5 hours after injection), laboratory monitoring is usually not necessary. Anti-Xa monitoring is optional in high-risk patient populations, specifically renal insufficiency, obesity, and pregnancy. In these cases, anti-Xa plasma levels are drawn 4 hours after administration, and subsequent doses are adjusted to a target range of 0.5 to 1.1 IU per mL [62].

Clinical Indications

LMWHs are suitable replacements for UFH for many indications [63]. LMWHs require fewer injections and produce fewer adverse events. In hospitalized medical patients receiving thromboprophylaxis, LMWH was associated with a lower risk of DVT, fewer injection site hematomas, and no difference in bleeding when compared with UFH [64]. LMWHs have largely replaced intravenous UFH in patients with acute VTE who are able to receive unmonitored anticoagulation in the ambulatory setting. UFH remains the preferred option for ACS patients,

TABLE 110.9

CLINICAL USES OF LOW-MOLECULAR-WEIGHT HEPARINS

Drug	Indications	Dosing, timing, duration	Precautions
Enoxaparin (Lovenox™)	Treatment of VTE	1 mg/kg SC every 12 h OR 1.5 mg/kg SCevery 24 h CrCl <30 mL/min: 1 mg/kg SC every 24 h	■ Indwelling epidural catheter ■ Recent spinal or ophthalmologic surgery ■ History of recent major bleed (gastrointestinal, intracranial, etc.) ■ Congenital or acquired bleeding disorders ■ History of heparin-induced thrombocytopenia ■ Liver disease ■ Renal impairment (CrCl <30 mL/min), consider unfractionated heparin ■ Concomitant use of antithrombotic drugs ■ Diabetic retinopathy ■ Uncontrolled hypertension
	Treatment of ACS	30 mg bolus IV followed by 1 mg/kg SC every 12 h WITH tenecteplase CrCl <30 mL/min: not recommended	
	Prophylaxis/bridge therapy for atrial fibrillation/ cardioversion	1 mg/kg SC every 12 h OR 1.5 mg/kg SC every 24 h CrCl <30 mL/min: 1 mg/kg SC every 24 h	
	Prophylaxis of VTE in the medically ill or surgical population	40 mg SC every 24 h CrCl <30 mL/min: 1 mg/kg SC daily	
	Prophylaxis of VTE in the trauma patients	30 mg SC every 12 h OR 40 mg SC every 24 h	
Dalteparin (Fragmin™)	Treatment of VTE	<56 kg: 10,000 IU daily 57–68 kg: 12,500 IU daily 69–82kg: 15,000 IU daily 83–98 kg: 18,000 IU daily >99 kg: 18,000 IU daily	
	Treatment of ACS	120 IU/kg SC every 12 h (MAX 10,000 IU/dose)	
	Prophylaxis of VTE after hip or other major surgery (first month)	Initial dose: 2500 IU once Maintenance: 2,500–5,000 IU SC every 24 h	
	Prophylaxis of VTE in the medically ill or surgical population	5,000 IU SC every 24 h	
Tinzaparin (Innohep™)	Treatment of DVT	175 international units anti-Xa/kg SC daily

those who may require an urgent surgical intervention, those with compromised renal function, or those requiring intensive monitoring for other reasons [48].

Complications and Reversal of Effect

Hemorrhage is the major complication of LMWH therapy, with data suggesting lower rates when compared to UFH. Major bleeding is reported to occur in 0% to 3% of patients [53]. Preprocedural thromboembolic risk assessment, bleeding risk assessment, and physician preference will play a role in determining whether LMWH prophylaxis is continued or withheld in the surgical setting. For patients receiving therapeutic LMWH, therapy should be discontinued 12 to 24 hours prior to the procedure, or earlier in patients with renal dysfunction. Therapeutic doses of LMWH should not be restarted for 24 hours after a major procedure or with neuraxial anesthesia [16,30].

In the setting of overdose or hemorrhage, protamine completely reverses the antithrombin activity of LMWH, but only reverses 60% of the antifactor Xa activity. If immediate reversal is warranted within 8 hours of LMWH administration, a protamine dose of 1 mg neutralizes 100 anti-Xa units or 1 mg of LMWH (Table 110.8). Should bleeding continue, a second dose of 0.5 mg of protamine per 100 anti-Xa units may be administered. Smaller protamine doses are required if the LMWH administration interval is beyond 8 hours [65,66].

Heparin-induced thrombocytopenia (HIT) is an immune-mediated, hypercoagulable disorder that results from antibodies formed against the heparin-platelet factor 4 complex. The incidence in critically ill patients ranges from 1% to 5% and is associated with thrombocytopenia and life-threatening thrombosis in approximately 30% to 50% of antibody-positive patients [67]. HIT typically occurs in patients who have been exposed to UFH or LMWH for 5 to 7 days, or even sooner in patients with prior exposure. A 50% decrease in platelet count occurring 4 to 10 days after the initiation of UFH or LMWH therapy or formation of a new thrombus during therapy may be indicative of HIT. Platelet counts should be measured prior to the initiation of UFH or LMWH and monitored every other day for the first 4 to 10 days of therapy. Since heparin alternatives must be used in patients with HIT, direct thrombin inhibitors are the treatment of choice [68,69].

Patients receiving heparin for a period of greater than 1 month are at risk for developing osteoporosis and vertebral

TABLE 110.10

CLINICAL USES OF FONDAPARINUX

Drug	Indications	Dosing, timing, duration	Precautions
Fondaparinux (Arixtra™)	Treatment of VTE Treatment is for 5–9 d; continue treatment until a therapeutic oral anticoagulant effect is established	<50 kg: 5.0 mg SC daily 50–100 kg: 7.5 mg SC daily >100 kg: 10 mg SC daily Renal impairment CrCL 50–80 mL/min—25% reduction in total clearance; consider empiric dosage reduction CrCL 30–50 mL/min—40% reduction in total clearance; consider empiric dosage reduction CrCL less than 30 mL/min—contraindicated	■ Indwelling epidural catheter ■ Recent spinal or ophthalmologic surgery ■ History of recent major bleed (gastrointestinal, intracranial, etc.) ■ Congenital or acquired bleeding disorders
	Treatment of STEMI and NSTEMI[a]	2.5 mg SC daily	
	Prophylaxis of VTE in major surgery and acute medically ill[a]	2.5 mg SC daily	

[a]Indicates off-label use of medication.
CrCl, creatinine clearance using Cockcroft–Gault equation; NSTEMI, non ST-elevation myocardial infarction; SC, subcutaneous; STEMI, ST-elevation myocardial infarction; VTE, venous thromboembolism.

fractures. Osteoporosis reportedly occurs less frequently in patients treated with LMWHs as compared to UFH [48].

Fondaparinux

Fondaparinux is a synthetic analog of the naturally occurring pentasaccharide found in heparins. Fondaparinux selectively and irreversibly binds to AT. This results in neutralization of factor Xa, which ultimately inhibits thrombin formation and thrombus development [48].

Pharmacology, Pharmacodynamics, and Monitoring

After subcutaneous administration, fondaparinux has a half-life of 17 to 21 hours in patients with normal renal function. Fondaparinux is excreted in the urine with clearance reduced in patients with renal impairment. As with LMWHs, monitoring of anti-Xa levels is not required during fondaparinux administration (Table 110.10) [48].

Clinical Indications

Fondaparinux is as safe and effective as the heparins for treatment of deep venous thrombosis (DVT) and pulmonary embolism (PE) and for thromboprophylaxis in surgical and medically ill patients [70–73]. Fondaparinux showed superior efficacy in reducing VTE in patients undergoing knee arthroplasty, hip arthroplasty, and hip fracture surgery [74–76]. In a combined analysis, the overall incidence of major bleeding was statistically higher with fondaparinux (2.7%) compared with LMWH (1.7%) [77]. However, the incidence of clinically relevant bleeding, defined as bleeding leading to death, reoperation, or occurring in a critical organ, did not differ between the agents. Differences in efficacy and safety outcomes could be related to the timing of perioperative drug administration. Fondaparinux given less than 6 hours after surgery has been associated with an increased frequency of major bleeding [77]. Fondaparinux may be an option for thromboprophylaxis in the setting of HIT but conclusive data are not available [78].

Complications and Reversal of Effect

Fondaparinux is contraindicated in patients with severe renal impairment (calculated creatinine clearance <30 mL per minute) and should not be used for VTE prophylaxis in patients weighing less than 50 kg. No antidote exists for fondaparinux-related hemorrhage and reversal is further complicated by its prolonged half-life [79]. Recombinant factor VIIa (rVIIa) reverses the coagulation defect induced by fondaparinux, but the clinical utility is unknown [80,81]. With a short half-life (2 to 3 hours), rVIIa may require repeat dosing. The use of fondaparinux and neuraxial anesthesia or analgesia should follow the conditions used in clinical trials as closely as possible [30].

Direct Thrombin Inhibitors

The direct thrombin inhibitors (DTIs) are lepirudin, bivalirudin, and argatroban. They exert their antithrombotic effect by binding to the active site of thrombin and inhibiting thrombin-catalyzed reactions. This prevents fibrin formation, activation of coagulant factors V, VIII, XIII, protein C, and platelet aggregation [82].

Pharmacology, Pharmacodynamics, and Monitoring

Lepirudin (*r*-hirudin) is a recombinant derivative of hirudin, produced from leech salivary glands. Bivalirudin is the synthetic analog of r-hirudin. Argatroban, derived from the amino acid arginine, is a small synthetic molecule. The DTIs differ in their pharmacokinetic parameters (Table 110.11) [82]. Lepirudin is eliminated through renal clearance, argatroban by hepatic metabolism, and bivalirudin by proteolytic cleavage in the plasma. Bivalirudin has the shortest half-life, making it a particularly useful agent in the procedural or periprocedural period. DTI selection is predicated on patient-specific characteristics such as hemodynamic stability, hepatic function, and renal function. Critically ill patients typically require lower doses than recommended by the manufacturer [82,83]. DTIs are monitored using aPTT (Table 110.12). The aPTT level should be measured every 6 hours until the patient has sustainable therapeutic levels, then the monitoring frequency can be extended [69].

Clinical Indications

Lepirudin and argatroban significantly reduce the rates of thromboembolic complications in patients with HIT [84,85].

TABLE 110.11

PHARMACOKINETIC AND PHARMACODYNAMIC PROPERTIES OF DIRECT THROMBIN INHIBITORS

Feature	Lepirudin	Argatroban	Bivalirudin
Molecular weight (Da)	6,979	526	2,180
FDA-approved indication	Management of HIT	Management of HIT, or use in patients with HIT who are undergoing PCI	Use in patients with or at risk for HIT or HITTS who are undergoing PCI
Primary elimination route	Renal	Hepatic	Enzymatic
Elimination half-life	1.3 h	39–51 min	10–24 min
Fraction eliminated unchanged by kidney (%)	35	16	20
Laboratory test to monitor	aPTT, ECT	aPTT, ECT	aPTT, ACT, ECT
Target range	aPTT: 1.5–2.5 × control	aPTT: 1.5–3 × control	aPTT: 1.5–2.5 × control
Effects on INR	Minimal	Moderate to clinically significant	Minimal to moderate

ACT, activated clotting time; aPTT, activated partial thromboplastin time; Da, dalton; ECT, ecarin clotting time; FDA, Food and Drug Administration; HIT, heparin-induced thrombocytopenia; HITTS, HIT with thrombosis syndrome; INR, international normalized ratio; PCI, percutaneous coronary intervention.

Bivalirudin has been safely used in critically ill HIT patients [86]. Argatroban and bivalirudin are indicated for prophylaxis of thrombosis in patients with, or at risk for, HIT undergoing PCI. Bivalirudin is also indicated in the treatment of patients undergoing PCI as well as those with unstable angina/non-ST segment elevation myocardial infarction undergoing PCI (see Table 110.12) [87].

Complications and Reversal of Effect

No specific reversal agent is available for DTI-induced hemorrhage.

For lepirudin, hemofiltration may be an alternative in the setting of life-threatening hemorrhage. Anecdotally, rVIIa has been reported to be useful as well [88]. DTIs can produce elevation in the international normalized ratio (INR), an effect that is most pronounced with argatroban, and magnified when coadministered with warfarin. This laboratory interaction has misled clinicians to discontinue argatroban therapy prematurely, predisposing patients to venous limb gangrene [78]. With concurrent administration, the argatroban infusion should be stopped and the INR measured 4 to 6 hours. If the INR is within therapeutic range on warfarin alone, warfarin monotherapy can be continued, otherwise argatroban therapy should be resumed.

Oral Anticoagulants—Vitamin K Antagonists

Warfarin, a vitamin K antagonist (VKA), inhibits the enzyme vitamin K epoxide reductase complex (VKORC), which converts vitamin K to an active form. The absence of vitamin K reduces the hepatic production of functional coagulation factors II (thrombin), VII, IX, and X and the regulatory anticoagulant proteins C, S, and Z. Since thrombin has a longer half-life (60 to 72 hours) compared to the other factors (6 to 24 hours), at least 6 days of warfarin treatment is required for an antithrombotic effect [89].

Warfarin is extensively metabolized by the CYP450 isoenzyme system including CYP2C9, CYP1A1, CYP1A2, and CYP3A4. Several genetic polymorphisms have been identified with CYP2C9 and VKORC that may influence warfarin clearance and dose sensitivity [90,91].

In critically ill patients, alterations in coagulation factors, caused by reduced dietary vitamin K intake, hypoalbuminemia, antibiotic administration, acute hepatic injury, or hypermetabolic states, will impact the effects of warfarin [90,91]. Furthermore, drug interactions alter warfarin absorption, clearance, and plasma protein binding. The interactions could have either synergistic or antagonistic effects [89].

Warfarin's anticoagulant effect is measured using the INR [92]. The INR uses the international sensitivity index of the local thromboplastin reagent to standardize the laboratory result. The INR target range will vary based on indication and the patient's risk for thromboembolic and bleeding complications (see Table 110.13). Nomogram-based warfarin dosing is considered safer and more effective for reaching target INR goals. To prevent excessive anticoagulation, loading doses are avoided and low doses are employed for the elderly [93]. Frequent INR monitoring is necessary during initiation of therapy until steady state is reached.

Clinical Indications

Warfarin is effective for primary and secondary prevention of venous thromboembolism, for prevention of systemic embolism in patients with prosthetic heart valves or atrial fibrillation, and for prevention of stroke, recurrent infarction, or death in patients with acute myocardial infarction [89,94–96].

Complications and Reversal of Effect

Treatment with warfarin increases the risk of major bleeding by 0.3% to 0.5% per year and the risk of intracerebral hemorrhage by approximately 0.2% per year compared to controls [53]. Important risk factors for hemorrhage include anticoagulant intensity, time within therapeutic range, and patient age. Higher goal INR (INR >3) has been directly associated with increased hemorrhage rates. Elevated INR can be managed by withholding or decreasing warfarin doses. In patients experiencing or at risk of bleeding, vitamin K administration will reverse the anticoagulant effects of warfarin. Vitamin K is given orally or parenterally. Oral vitamin K normalizes supratherapeutic INRs more rapidly than subcutaneous vitamin K [97]. Intravenous vitamin K corrects excessive warfarin anticoagulation quicker and more completely than subcutaneous administration [98].

For patients with an INR >5.0 but <9.0 and no significant bleeding, the next two doses of warfarin should be held, and low dose (1 to 2.5 mg) oral vitamin K administered. For patients with an INR >9.0, the vitamin K dose can be increased to 2.5 to 5 mg [89].

In the setting of serious or life-threatening hemorrhage, warfarin should be held and vitamin K 10 mg administered by slow IV infusion. The supplementation of coagulation factors with

TABLE 110.12

CLINICAL USES OF DIRECT THROMBIN INHIBITORS

Drug	Indications	Dosing, timing, duration	Precautions
Bivalirudin (Angiomax™)	PCI (with glycoprotein IIB/IIIA inhibitor)	0.75 mg/kg IV bolus dose, followed by an infusion of 1.75 mg/kg/h for the duration of the procedure CrCl less than 30 mL/min, a reduction of initial infusion rate to 1 mg/kg/h should be considered; no bolus dose reduction is necessary	■ Indwelling epidural catheter ■ Recent major, spinal or ophthalmologic surgery, or cerebrovascular accident ■ History of recent major bleed (gastrointestinal, intracranial, etc.) ■ Congenital or acquired bleeding disorders
	Treatment of ACS[a]	Initial IV bolus dose of 0.1 mg/kg, followed by 0.25 mg/kg/h. Titration to aPTT 1.5–2 times control	■ Repeat lepirudin courses may require more frequent monitoring due to antibody formation
	Treatment and prophylaxis of HITT[a]	0.1–0.2 mg/kg/h, titration to aPTT 1.5–2 times control	■ Hepatic impairment (argatroban) ■ Renal dysfunction (bivalirudin and lepirudin)
Argatroban	Treatment and prophylaxis of HITT	0.5–1.2 μg/kg/min continuous IV infusion to start titration to goal aPTT between 50 and 85 s. Begin VKA therapy, measure INR daily. Stop argatroban when INR >4. Repeat INR in 4–6 h, if INR is below desired range then resume argatroban infusion	
	Treatment of ACS	Bolus: 100 μg/kg Initial infusion: 1–3 μg/kg/min for 6–72 h; maintain aPTT between 50 and 85 s	
Lepirudin (Refludan™)	Treatment and prophylaxis of HITT ■ aPTT ratio target: between 1.5 and 2.5; begin monitoring aPTT 4 h after initiation of infusion and daily thereafter; recheck aPTT 4 h after any dosage changes ■ aPTT greater than 2.5: discontinue infusion for 2 h, decrease infusion rate by 50% when reinstated ■ aPTT less than 1.5: increase infusion rate in 20% increments until target aPTT is achieved	Bolus: 0.4 mg/kg IV (up to 44 mg) Initial infusion: 0.05–0.15 mg/kg/h (up to 16.5 mg/h) for 2–10 d, adjust infusion rate according to aPTT ratio Renal impairment CrCl <60 mL/min): Bolus: 0.2 mg/kg IV Initial infusion: 0.001–0.01 mg/kg/h (up to 16.5 mg/h) for 2–10 d, adjust infusion rate according to aPTT ratio	

[a]Indicates off-label use of medication.
ACS, acute coronary syndrome; ACT, activated clotting time; aPTT, activated partial thromboplastin time; CBC, complete blood count; CrCl, creatinine clearance using Cockcroft–Gault equation; HITT, heparin-induced thrombocytopenia and thrombosis; INR, international normalized ratio; IV, intravenous; PCI, percutaneous coronary intervention; PT, prothrombin time; VKA, vitamin K antagonist.

fresh frozen plasma (FFP) or prothrombin complex concentrate may be more effective in cases where immediate reversal of the INR is necessary [98]. Recombinant factor VIIa may be beneficial in patients with refractory bleeding in the setting of elevated INRs, or those requiring an invasive procedure [89,99–101].

Nonhemorrhagic adverse events of warfarin include acute skin necrosis and limb gangrene. These complications are typically observed on the third to eighth day of therapy [89].

In patients scheduled for surgery, warfarin may be continued, interrupted for approximately 5 days, or replaced with short-term parenteral or bridge therapy depending on the patient's risk for venous or arterial thromboembolism. Warfarin is resumed after surgery. Most bridging regimens have been developed from observational studies since there is not a standardized definition of bridging [101,102].

For warfarin-treated patients receiving neuraxial anesthesia with an indwelling catheter, the catheter should be removed when the INR is less than 1.5. Patients with a low risk of bleeding may undergo surgery with an INR of 1.3 to 1.5 [30,101].

TABLE 110.13

CLINICAL USES OF WARFARIN

Drug	Indications	Dosing, timing, duration	Precautions
Warfarin (Coumadin™)	Treatment of VTE	Initial dosing: 2.5–10 mg every 24 h (see precautions) titrated to range INR: 2.0–3.0; target of 2.5	■ Lower initial dosing (<5 mg may be warranted in patients who are debilitated, or are taking medications known to increase sensitivity to warfarin ■ Cerebrovascular disease ■ Coronary disease ■ CYP2C9 and VKORC1 genetic variation ■ Moderate to severe hypertension ■ Malignancy ■ Renal impairment ■ Recent trauma ■ Malignancy ■ Collagen vascular disease ■ Conditions that increase risk of hemorrhage, necrosis, and/or gangrene, pre-existing ■ Congestive heart failure ■ Excessive dietary vitamin K ■ Vitamin K deficiency ■ Elderly or debilitated patients (lower dosing may be required) ■ Hepatic impairment ■ Hyperthyroidism/hypothyroidism ■ Epidural catheters ■ Infectious diseases or disturbances of intestinal flora, such as sprue or antibiotic therapy ■ Poor nutritional state ■ Protein C deficiency ■ Heparin-induced thrombocytopenia
	Atrial fibrillation	Initial dosing: 2.5–10 mg every 24 h (see precautions) titrated to range INR: 2.0–3.0; target of 2.5	
	Post MI	Initial dosing: 2.5–10 mg every 24 h (see precautions) titrated to range INR 2.0–3.0; target of 2.5	
	Mechanical valve in the atrial position	Initial dosing: 2.5–5 mg every 24 h (see precautions) titrated to range INR 2.0–3.0; target of 2.5	
	Mechanical valve in the mitral position	Initial dosing: 2.5–5 mg every 24 h (see precautions) titrated to range INR 2.5–3.5; target of 3.0
