Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

CONTRIBUTORS

Cynthia K. Aaron, MD, FACMT, FACEP
Professor of Emergency Medicine and Pediatrics
Program Director, Medical Toxicology
Department of Emergency Medicine
Wayne State University School of Medicine
Detroit Medical Center
Regional Poison Center at Children's Hospital of Michigan
Detroit, MI

Wissam Abouzgheib, MD, FCCP
Attending Physician
Department of Pulmonary and Critical Care
Sparks Health System
Fort Smith, AR

Gregory A. Abrahamian, MD
Associate Professor of Surgery
Department of Surgery
University of Texas Health Science Center at San Antonio
San Antonio, TX

Konstantin Abramov, MD
Assistant Professor of Medicine
Division of Renal Medicine
UMass Memorial Medical Center
Worcester, MA

Christopher D. Adams, PharmD, BCPS
Clinical Pharmacist
Department of Pharmacy Services
Brigham and Women's Hospital
Boston, MA

Suresh Agarwal, MD, FACS, FCCM
Chief, Surgical Critical Care
Associate Professor of Surgery
Boston Medical Center
Boston, MA

Lauren Alberta-Wszolek, MD
Assistant Professor of Medicine
Division of Dermatology
University of Massachusetts Medical School
Worcester, MA

Alfred Aleguas Jr, PharmD, DABAT
Managing Director
Northern Ohio Poison Center
Rainbow Babies & Children's Hospital
Cleveland, OH

Satya Allaparthi, MD
Fellow in Robotic and Laparoscopic Urology
Department of Urology/Surgery
UMass Memorial Medical Center
Worcester, MA

Gilman B. Allen, MD
Assistant Professor
Director, Medical Intensive Care Unit
Department of Medicine
Division of Pulmonary and Critical Care Medicine
University of Vermont
Fletcher Allen Health Care
Burlington, VT

Luis F. Angel, MD
Associate Professor of Medicine
Department of Medicine
University of Texas Health Sciences Center at San Antonio
San Antonio, TX

Kevin E. Anger, PharmD, BCPS
Clinical Pharmacy Specialist in Critical Care
Department of Pharmacy Services
Brigham and Women's Hospital
Boston, MA

Derek C. Angus, MD, MPH
Professor and Vice Chair for Research
Department of Critical Care Medicine
University of Pittsburgh Medical Center
Pittsburgh, PA

Neil Aronin, MD
Professor of Medicine and Cell Biology
Chief of Endocrinology and Metabolism
Department of Medicine
University of Massachusetts Medical School
Worcester, MA

Samuel J. Asirvatham, MD, FACC, FHRS
Professor of Medicine and Pediatrics
Division of Cardiovascular Diseases
Mayo Clinic College of Medicine
Rochester, MN

Seth M. Arum, MD, FACE
Assistant Professor of Medicine
Department of Endocrinology
UMass Memorial Medical Center
Worcester, MA

Philip J. Ayvazian, MD
Assistant Professor
Department of Urology
UMass Memorial Medical Center
Worcester, MA

Riad Azar, MD
Associate Professor of Medicine
Department of Internal Medicine
Division of Gastroenterology
Washington University School of Medicine
Barnes Jewish Hospital
St. Louis, MO

Ruben J. Azocar, MD
Associate Professor and Residency Program Director
Department of Anesthesiology
Boston University Medical Center
Boston, MA

Ednan K. Bajwa, MD, MPH
Associate Director, Medical ICU
Department of Pulmonary and Critical Care
Massachusetts General Hospital
Boston, MA

K.C. Balaji, MD
Professor, Department of Surgery
Division of Urology
UMass Memorial Medical Center
Worcester, MA

Jerry P. Balikian, MD, FACR
Professor and Vice Chair of Radiology
Department of Radiology
University of Massachusetts Medical School
Worcester, MA

Ian M. Ball, MD, DABEM, FRCPC
Assistant Professor
Program in Critical Care Medicine and
Departments of Clinical Pharmacology/Toxicology
and Emergency Medicine
Queen's University Kingston
Ontario, Canada

Meyer S. Balter, MD, FRCPC
Professor
Department of Medicine
University of Toronto
Director, Asthma Education Clinic
Mount Sinai Hospital
Toronto, Ontario, Canada

Gisela I. Banauch, MD, MS
Assistant Professor of Medicine Division of Pulmonary,
Allergy, Critical Care and Sleep Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Daniel T. Baran, MD
Region Medical Director
Merck
Adjunct Professor of Medicine, Cell Biology, and Orthopedics
UMass Memorial Medical Center
Worcester, MA

Stephen L. Barnes, MD, FACS
Associate Professor and Chief, Division of Acute
Care Surgery
Department of Surgery
University of Missouri
Columbia, MO

Suzanne J. Baron, MD
Cardiology Fellow
Department of Cardiology
Massachusetts General Hospital
Boston, MA

Thaddeus C. Bartter, MD, FCCP
Professor of Medicine
Department of Medicine
Division of Pulmonary and Critical Care
University of Arkansas for the Medical Sciences
Little Rock, AR

Amit Basu, MD
Assistant Professor of Surgery and Attending Physician
Department of Surgery
University of Pittsburgh Medical Center
Thomas E Starzl Transplantation Institute
Pittsburgh, PA

Kenneth L. Baughman, MD (DECEASED)

Richard C. Becker, MD
Professor of Medicine
Department of Medicine
Duke University School of Medicine
Durham, NC

Robert W. Belknap, MD
Assistant Professor of Medicine
Division of Infectious Diseases
Denver Health and Hospital Authority
University of Colorado
Denver, CO

Isabelita R. Bella, MD
Associate Professor of Clinical Neurology
Department of Neurology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Andrew C. Bernard, MD
Associate Professor of Surgery
Department of Surgery
University of Kentucky Healthcare
Lexington, KY

Megan Bernstein, MD
Resident
Department of Dermatology
University of Massachusetts Medical School
Worcester, MA

Mary T. Bessesen, MD
Associate Professor of Medicine
Department of Medicine
University of Colorado at Denver
Department of Veterans Affairs Medical Center—Denver
Denver, CO

Michael C. Beuhler, MD
Medical Director
Department of Emergency Medicine
Carolinas Poison Center
Charlotte, NC

Bonnie J. Bidinger, MD
Assistant Professor of Medicine
Department of Internal Medicine
Division of Rheumatology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Steven B. Bird, MD
Associate Professor
Department of Emergency Medicine
Division of Medical Toxicology
University of Massachusetts Medical School
Worcester, MA

Bruce R. Bistrian, MD, PhD
Professor of Medicine
Harvard Medical School
Department of Medicine
Beth Israel Deaconess Medical Center
Boston, MA

Robert M. Black, MD
Professor of Clinical Medicine
UMass Medical School
Chief, Nephrology
Division of Renal Medicine
St. Vincent Hospital
Worcester, MA

Ernest F.J. Block, MD, MBA, FACS, FCCM
Professor of Surgery, University of Central Florida
Department of Acute Care Surgery
Holmes Regional Medical Center
Melbourne, FL

Jeremiah Boles, MD
Hematology/Oncology Fellow
Department of Medicine
Division of Hematology/Oncology
University of North Carolina at Chapel Hill
Chapel Hill, NC

Naomi F. Botkin, MD
Assistant Professor of Medicine
Division of Cardiovascular Medicine
UMass Memorial Medical Center
Worcester, MA

Suzanne F. Bradley, MD
Professor
Department of Internal Medicine
Division of Infectious Diseases and Geriatric Medicine
Veterans Affairs Ann Arbor
University of Michigan Healthcare Systems
Ann Arbor, MI

William F. Bria, MD
Chief Medical Information Officer
Department of Medical Affairs
Shriners Hospital for Children
Tampa, FL

Veronica Brito, MD
Pulmonary and Critical Care Medicine Fellow
Department of Medicine
Winthrop-University Hospital
Mineola, NY

Traci L. Buescher, RN
Department of Heart Rhythm Services
Mayo Clinic
Rochester, MN

Keith K. Burkhart, MD, FACMT, FAACT, FACEP
Senior Advisor for Medical Toxicology
FDA Center for Drug Evaluation and Research
Office of New Drugs
Silver Spring, MD

Michael J. Burns, MD, FACEP, FACMT
Chief of Emergency Medicine
Saint Vincent Hospital
Worcester, MA
Division of Medical Toxicology
Department of Emergency Medicine
Beth Israel Deaconess Medical Center
Boston, MA

Tuesday E. Burns, MD
Assistant Professor of Psychiatry
Department of Psychiatry
Eastern Virginia Medical School
Norfolk, VA

Scott W. Byram, MD
Assistant Professor of Anesthesiology
Department of Anesthesiology
Loyola University Medical Center
Maywood, IL

Brian T. Callahan, MD
Interventional Radiology Fellow
Department of Radiology
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, MA

Christine Campbell-Reardon, MD
Associate Professor of Medicine
Department of Pulmonary and Critical Care Medicine
Boston University School of Medicine
Boston Medical Center
Boston, MA

Christopher P. Cannon, MD
TIMI Study Group
Cardiovascular Division
Brigham and Women's Hospital
Associate Professor of Medicine, Harvard Medical School
Boston, MA

Jason P. Caplan, MD
Chief of Psychiatry
Department of Psychiatry
Creighton University School of Medicine at St. Joseph's Hospital and Medical Center
Phoenix, AZ

Raphael A. Carandang, MD
Assistant Professor
University of Massachusetts Medical School
Department of Neurology and Surgical Intensive Care
UMass Memorial Medical Center
Worcester, MA

Paul A. Carpenter, MD
Associate Professor
Clinical Research Division
Fred Hutchinson Cancer Research Center
Seattle, WA

Karen C. Carroll, MD
Professor Pathology and Medicine
Department of Pathology
Division of Medical Microbiology
Johns Hopkins Hospital
Baltimore, MD

David A. Chad, MD
Associate Professor of Neurology
Harvard Medical School
Department of Neurology
Massachusetts General Hospital
Neuromuscular Diagnostic Center
Boston, MA

Eugene Chang, MD
Martin Boyer Professor of Medicine
Department of Medicine, Section of Gastroenterology
University of Chicago
Chicago, IL

Steven Y. Chang, MD, PhD
Assistant Professor of Medicine
Division of Pulmonary & Critical Care Medicine
Director of the Medical Intensive Care Unit
University of Medicine & Dentistry of New Jersey—
New Jersey Medical School
Newark, NJ

Michael L. Cheatham, MD, FACS, FCCM
Director, Surgical Intensive Care Units
Department of Surgical Education
Orlando Regional Medical Center
Orlando, FL

Sarah H. Cheeseman, MD
Professor of Medicine, Pediatrics, Microbiology and
Molecular Genetics
University of Massachusetts Medical School
Division of Infectious Diseases
UMass Memorial Medical Center
Worcester, MA

Annabel A. Chen-Tournoux, MD
Cardiology Fellow
Department of Medicine
Division of Cardiology
Massachusetts General Hospital
Boston, MA

William K. Chiang, MD
Chief of Service and Associate Professor of Emergency
Medicine
Department of Emergency
Bellevue Hospital Center
New York, NY

Victor G. Cimino, MD, FACS
Associate Professor
Department of Surgery
Loyola University Medical Center
Maywood, IL

Mary Dawn T. Co, MD
Assistant Professor of Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Shawn Cody, MSN, MBA, RN
Associate Chief Nursing Officer for Critical Care
UMass Memorial Medical Center
Worcester, MA

Felipe B. Collares, MD, MSc
Interventional Radiologist
Department of Radiology
Beth Israel Deaconess Medical Center
Instructor in Radiology
Harvard Medical School
Boston, MA

Bryan R. Collier, MD
Assistant Professor of Surgery
Division of Trauma & Surgical Critical Care
Vanderbilt University Medical Center
Nashville, TN

Nancy A. Collop, MD
Professor of Medicine
Department of Medicine
Emory University
Atlanta, GA

John B. Cone, MD, FACS, FCCM
Professor of Surgery
Norma & Nolie Mumey Chair in General Surgery
Department of Surgery
University of Hospital of Arkansas
Little Rock, AR

Associate Professor of Medicine
Division of Infectious Disease
Johns Hopkins Medical Institutions
Baltimore, MD

Filippo Cremonini, MD, PhD
Attending Physician
Department of Gastroenterology
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, MA

Jonathan F. Critchlow, MD
Assistant Professor of Surgery
Harvard University
Beth Israel Deaconess Medical Center
Boston, MA

Ruy J. Cruz Jr, MD, PhD
Assistant Professor of Surgery
Department of Surgery
University of Pittsburgh Medical Center
Pittsburgh, PA

Frederick J. Curley, MD
Associate Professor of Medicine
University of Massachusetts Medical School
Lung, Allergy & Sleep Specialists
Hopedale, MA

Armagan Dagal, MD, FRCA
Assistant Professor
Department of Anesthesiology and Pain Medicine
University of Washington, Harborview Medical Center
Seattle, WA

Seth T. Dahlberg, MD
Associate Professor of Medicine and Radiology
Department of Medicine and Radiology
University of Massachusetts Medical School
Division of Cardiology
UMass Memorial Medical Center
Worcester, MA

Frank F. Daly, MBBS
Clinical Toxicologist and Emergency Physician
Department of Emergency Medicine
Royal Perth Hospital
Western Australia, Australia

Jennifer S. Daly, MD
Professor of Medicine
Clinical Chief, Infectious Diseases and Immunology
Department of Medicine
University of Massachusetts Medical School
Worcester, MA

Lloyd E. Damon, MD
Professor of Clinical Medicine
Department of Medicine
University of California, San Francisco
San Francisco, CA

Raul E. Davaro, MD
Associate Professor, Clinical Medicine
Department of Medicine
University of Massachusetts Medical School
Worcester, MA

Wellington J. Davis III, MD
Assistant Professor of Surgery and Pediatrics
Section of Plastic and Reconstructive Surgery
St. Christopher's Hospital for Children
Philadelphia, PA

Ronald J. DeBellis, PharmD, FCCP
Professor and Chair
Department of Pharmacy Practice
Albany College of Pharmacy and Health Sciences—Vermont
Colchester, VT

G. William Dec, MD
Chief, Cardiology Division
Massachusetts General Hospital
Department of Cardiology
Boston, MA

Paul F. Dellaripa, MD
Assistant Professor of Medicine
Harvard Medical School
Division of Rheumatology
Brigham and Women's Hospital
Boston, MA

Gregory J. Della Rocca, MD, PhD, FACS
Assistant Professor
Co-Director, Orthopaedic Trauma Service
Department of Orthopaedic Surgery
University of Missouri
Columbia, MO

Thomas G. DeLoughery, MD, FACP
Professor of Medicine, Pathology and Pediatrics
Department of Hematology
Oregon Health and Science University
Portland, OR

Mario De Pinto, MD
Assistant Professor
Department of Anesthesiology
University of Washington
Harborview Medical Center
Seattle, WA

Mark Dershwitz, MD, PhD
Professor and Vice Chair of Anesthesiology
Professor of Biochemistry & Molecular Pharmacology
UMass Memorial Medical Center
Worcester, MA

Akshay S. Desai, MD
Instructor in Medicine
Harvard Medical School
Associate Physician
Cardiovascular Division
Department of Medicine
Brigham and Women's Hospital
Boston, MA

Asha Devereaux, MD, MPH
Pulmonary Physician
Sharp Coronado Hospital
Coronado, CA

Christopher R. DeWitt, MD
Medical Toxicologist and Emergency Physician
Department of Emergency and British Columbia Poison Center
Saint Paul's Hospital
University of British Columbia
Vancouver, BC

Peter Doelken, MD
Associate Professor
Department of Medicine
Division of Pulmonary, Critical Care, Allergy & Sleep Medicine
Medical University of South Carolina
Charleston, SC

Robert P. Dowsett, FACEM
Senior Staff Specialist
Department of Emergency Medicine
Westmead Hospital
Wentworthville, NSW, Australia

David A. Drachman, MD
Professor of Neurology
Chairman Emeritus
Department of Neurology
University of Massachusetts Medical School
Worcester, MA

David F. Driscoll, PhD
Vice President
Stable Solutions LLC
Easton Industrial Park
Easton, MA

Cathy Dudick, MD, FACS
Medical Director, Surgical Intensive Care Unit
Department of Surgery
Jersey Shore University Medical Center
Neptune, NJ

David L. Dunn, MD, PhD
Vice President for Health Sciences
Professor of Surgery, Microbiology and Immunology
University at Buffalo, School of Medicine Biomedical Sciences
Buffalo, NY

Cheryl H. Dunnington, RN, MS, CCRN
Operations Director, eICU Support Center Program
Critical Care Operations
UMass Memorial Medical Center
Worcester, MA

Kevin Dwyer, MD, FACS
Director of Trauma
Vice-Chair of Surgery
Stamford Hospital
Stamford, CT

Steven B. Edelstein, MD
Professor of Anesthesiology
Vice-Chairman Education & Compliance
Department of Anesthesiology
Loyola University Medical Center
Loyola University Stritch School of Medicine
Maywood, IL

W. Thomas Edwards, PhD, MD
Director, Fellowship in Pain Medicine
Associate Professor of Anesthesiology
Department of Anesthesiology
University of Washington
Harborview Medical Center
Seattle, WA

Richard T. Ellison III, MD
Professor of Medicine, Molecular Genetics and Microbiology
University of Massachusetts Medical School
Department of Medicine
Division of Infectious Diseases and Immunology
UMass Memorial Medical Center
Worcester, MA

Ashkan Emadi, MD, PhD
Adjunct Faculty
Division of Adult Hematology
Department of Internal Medicine
Johns Hopkins Hospital
Johns Hopkins University
Baltimore, MD

Charles H. Emerson, MD
Professor Emeritus of Medicine
Department of Medicine
UMass Memorial Medical Center
Worcester, MA

Timothy A. Emhoff, MD
Chief, Trauma, Surgical Critical Care
Department of Surgery
UMass Memorial Medical Center
Worcester, MA

Jennifer L. Englund, MD
Medical Toxicology Fellow
Department of Emergency Medicine
Division of Medical Toxicology
University of Massachusetts Medical School
Worcester, MA

Department of Internal Medicine
Mayo Clinic
Rochester, MN

Shirin Haddady, MD
Assistant Professor of Medicine and Neurology
Department of Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Pegge M. Halandras, MD
Assistant Professor
Department of Surgery
Division of Vascular Surgery and Endovascular Therapy
Loyola University Chicago Stritch School of Medicine
Maywood, IL

Wiley R. Hall, MD
Assistant Professor in Neurology and Surgery
Director of Neuroscience Critical Care
University of Massachusetts Medical School
Medical Director of the Neuro/Trauma ICU
Neurology Department
UMass Memorial Medical Center
Worcester, MA

Stephen B. Hanauer, MD
Professor of Medicine and Clinical Pharmacology
Department of Gastroenterology
University of Chicago
Chicago, IL

Charles William Hargett, III, MD
Associate in Medicine
Division of Pulmonary & Critical Care
Duke University Medical Center
Durham, NC

David M. Harlan, MD
Chief, Diabetes Division
Co-Director, Diabetes Center of Excellence
Department of Medicine
UMass Memorial Medical Center
University of Massachusetts School of Medicine
Worcester, MA

Laura Harrell, MD, MS
Assistant Professor of Medicine
Department of Gastroenterology
University of Chicago Medical Center
Chicago, IL

Lawrence J. Hayward, MD, PhD
Professor of Neurology
Department of Neurology
University of Massachusetts Medical School
Worcester, MA

Kennon Heard, MD
Associate Professor
Rocky Mountain Poison and Drug Center,
Denver Health
Department of Emergency Medicine
University of Colorado School of Medicine
Denver, CO

Stephen O. Heard, MD
Professor and Chair
University of Massachusetts Medical School
Department of Anesthesiology
UMass Memorial Medical Center
Worcester, MA

John E. Heffner, MD
Garnjobst Chair and Professor of Medicine
Department of Medicine
Providence Portland Medical Center
Portland, OR

Jeremy S. Helphenstine, DO
Clinical Instructor
Toxicology Fellow
Department of Emergency Medicine
Emory School of Medicine
Atlanta, GA

Robert J. Heyka, MD
Director, Outpatient Hemodialysis
Department of Nephrology & Hypertension
Cleveland Clinic Foundation
Cleveland, OH

Thomas L. Higgins, MD, MBA, FACP, FCCM
Professor of Medicine
Department of Anesthesia and Surgery
Interim Chair
Department of Medicine
Baystate Medical Center
Springfield, MA

Nicholas Hill, MD
Chief
Department of Pulmonary, Critical Care and Sleep Division
Tufts Medical Center
Boston, MA

Professor
Department of Medicine and Physiology
Mayo Clinic
Rochester, MN

Abhinav Humar, MD
Professor of Surgery
Division Chief, Transplant Surgery
Department of Surgery
University of Pittsburgh
Pittsburgh, PA

Thomas L. Husted, MD
Assistant Professor of Surgery
Department of Surgery
University of Cincinnati
Cincinnati, OH

Richard S. Irwin, MD, Master FCCP
Professor of Medicine and Nursing
University of Massachusetts
Chair, Critical Care
UMass Memorial Medical Center
Worcester, MA

John M. Iskander
Fellow in Gastroenterology
Division of Gastroenterology
St. Louis, MO

Eric M. Isselbacher, MD
Professor of Medicine
Harvard Medical School
Co-Director, Thoracic Aortic Center
Massachusetts General Hospital
Boston, MA

Rao R. Ivatury, MD
Chair
Department of Surgery
Division of Trauma, Critical Care, Emergency Surgery
Virginia Commonwealth University
Richmond, VA

William L. Jackson Jr, MD, MBA
Medical Director, Adult Critical Care
Inova Health System
Falls Church, VA

Eric W. Jacobson, MD
Associate Professor of Medicine
University of Massachusetts Medical School
Senior Vice President, Clinical Research and Regulatory Affairs
Chief Medical Officer
Synta Pharmaceuticals Corp.
Lexington, MA

Donald H. Jenkins, MD, FACS
Trauma Director
Associate Professor of Surgery
Division of Trauma, Critical Care and Emergency General Surgery
Mayo Clinic
Rochester, MN

Jing Ji, MD
Neurology Resident
Department of Neurology
University of Massachusetts Medical School
Worcester, MA

Tun Jie, MD, MS
Assistant Professor of Surgery
Department of Surgery
University of Arizona, College of Medicine
Tucson, AZ

Thanjira Jiranantakan, MD
Preventive and Social Medicine Department
Siriraj Hospital Faculty of Medicine
Mahidol University, Thailand
Medical Toxicology Fellow
Department of Clinical Pharmacology and Medical Toxicology
San Francisco General Hospital, University of California
The California Poison Control System—San Francisco Division
San Francisco, CA

Paul G. Jodka, MD
Assistant Professor of Medicine and Anesthesiology
Tufts University School of Medicine
Adult Critical Care Division
Baystate Medical Center
Springfield, MA

Scott B. Johnson, MD, FACS, FCCP
Associate Professor
Chief of General Thoracic Surgery
Department of Cardiothoracic Surgery
University of Texas Health Science Center, San Antonio
San Antonio, TX

Sreenivasa S. Jonnalagadda, MD, FASGE
Professor of Medicine
Director of Pancreatic and Biliary Endoscopy
Washington University School of Medicine
Division of Gastroenterology
St. Louis, MO

Bryan S. Judge, MD
Associate Program Director
Assistant Professor
Spectrum Health
Grand Rapids MERC/Michigan State University Program in Emergency Medicine
Grand Rapids, MI

Eias E. Jweied, MD, PhD
Cardiovascular/Thoracic Surgeon
Department of Cardiothoracic and Vascular Surgical Associates, S.C.
Advocate Christ Medical Center
Oak Lawn, IL

Marc J. Kahn, MD
Professor of Medicine
SR. Associate Dean
Department of Medicine
Tulane University School of Medicine
New Orleans, LA

Raja Kandaswamy, MD
Axline Professor of Surgery
Director of the University of Florida Institute of Transplantation
Department of Surgery
Shands Hospital—University of Florida Gainesville
Gainesville, FL

Abhishek Katiyar, MD
Medical and Toxicology and Emergency Medicine
Department of Emergency Medicine
UIC/Advocate Christ Hospital
Oak Lawn, IL

Carol A. Kauffman, MD
Professor Internal Medicine
University of Michigan Medical School
Chief, Infectious Diseases
Veterans Affairs Ann Arbor Healthcare System
Ann Arbor, MI

Christoph R. Kaufmann, MD, MPH
Professor of Surgery, East Tennessee State University
Department of Trauma and Emergency Surgery
Johnson City Medical Center
Johnson City, TN

Shubjeet Kaur, MD
Clinical Professor and Vice Chair
Department of Anesthesiology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Glenn Kershaw, MD
Associate Professor of Clinical Medicine
Division of Renal Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Mark A. Kirk, MD
Medical Toxicology Fellowship Director
Department of Emergency Medicine
University of Virginia
Charlottesville, VA

Meghan S. Kolodziej, MD
Instructor in Psychiatry
Department of Psychiatry
Brigham and Women's Hospital
Boston, MA

Scott E. Kopec, MD
Assistant Professor of Medicine
Division of Pulmonary, Allergy and Critical Care Medicine
UMass Memorial Medical Center
University of Massachusetts Medical School
Worcester, MA

Bruce A. Koplan, MD
Assistant Professor of Medicine
Harvard Medical School
Cardiac Arrhythmia Service
Department of Cardiac Arrhythmia
Brigham and Women's Hospital
Boston, MA

Richard Kremsdorf, MD
Clinical Professor of Medicine, Voluntary
University of California, San Diego School of Medicine
President
Five Rights Consulting, Inc.
San Diego, CA

Stephen J. Krinzman, MD
Assistant Professor of Medicine
Division of Pulmonary, Allergy, and Critical Care Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Gowri Kularatna, MD
Fellow in Gastroenterology
Washington University School of Medicine/Barnes Jewish Hospital
Division of Gastroenterology
St. Louis, MO

Sonal Kumar, MD
Internal Medicine Resident
Department of Internal Medicine
Barnes Jewish Hospital
St. Louis, MO

Margaret Laccetti, PhD, RN, AOCN, ACHPN
Director, Nursing Professional Development
UMass Memorial Medical Center
Worcester MA

Hoa Thi Lam, BS
Research Assistant
Department of Child Psychiatry
Massachusetts General Hospital
Boston, MA

Robert A. Lancy, MD, MBA
Chief of Cardiac Surgery
Department of Cardiac Surgery
Bassett Medical Center
Cooperstown, NY

Angeline A. Lazarus, MD
Professor of Medicine
Department of Pulmonary Medicine
Division of Pulmonary
National Naval Medical Center
Bethesda, MD

Jason Lee-Llacer, MD
Fellow
Department of Critical Care Medicine and Anesthesia
George Washington University
Washington, DC

Anthony J. Lembo, MD
Associate Professor of Medicine
Department of Medicine
Beth Israel Deaconess Med Center
Boston, MA

James A. de Lemos, MD
CCU and Cardiology Fellowship Director
Department of Cardiology/Medicine
The University of Texas Southwestern Medical Center
Dallas, TX

Adam B. Lerner, MD
Director, Cardiac Anesthesia
Department of Anesthesia and Critical Care
Beth Israel Deaconess Medical Center
Boston, MA

Phillip A. Letourneau, MD
Research Fellow/General Surgery Resident
Department of Surgery
University of Texas Medical School at Houston
Houston, TX

Howard B. Levene, MD, PhD
Assistant Professor of Neurological Surgery
Department of Neurosurgery
University of Miami Hospital
Miami, FL

Nikki A. Levin, MD, PhD
Associate Professor of Medicine
Division of Dermatology
University of Massachusetts Medical School
Worcester, MA

Stephanie M. Levine, MD
Professor of Medicine
Department of Medicine
University of Texas Health Science Center at San Antonio
San Antonio, TX

William J. Lewander, MD
Professor and Associate Vice Chair of Pediatric Emergency Medicine
The Warren Alpert Medical School of Brown University
Department of Emergency Medicine
Rhode Island Hospital
Providence, RI

Daniel H. Libraty, MD
Associate Professor
Department of Medicine/Infectious Diseases
University of Massachusetts Medical School
Worcester, MA

Craig M. Lilly, MD
Professor of Medicine, Anesthesiology and Surgery
Department of Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Sonia Lin, PharmD, BCPS
Clinical Pharmacy Specialist
Department of Pharmacy
University of Colorado Hospital
Aurora, CO

Christopher H. Linden, MD
Professor, Department of Emergency Medicine
Division of Medical Toxicology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Michael Linenberger, MD, FACP
Professor, Division of Hematology
Department of Medicine
University of Washington
Associate Member, Clinical Research Division
Fred Hutchinson Cancer Research Center
Seattle Cancer Care Alliance
Seattle, WA

Mark S. Link, MD
Professor of Medicine
Department of Cardiac Electrophysiology
Tufts Medical Center
Boston, MA

Carol F. Lippa, MD
Professor of Neurology
Department of Neurology
Drexel University College of Medicine
Philadelphia, PA

Alan Lisbon, MD
Associate Professor, Anaesthesia, Harvard Medical School
Department of Anaesthesia, Critical Care and Pain Medicine
Beth Israel Deaconess Medical Center
Boston, MA

Mauricio Lisker-Melman, MD
Professor of Medicine
Director, Hepatology Program
Department of Internal Medicine
Division of Gastroenterology
Washington University School of Medicine
Barnes-Jewish Hospital
St. Louis, MO

N. Scott Litofsky, MD, FACS
Professor and Chief
Director of Neuro-Oncology and Radiosurgery
Division of Neurological Surgery
University of Missouri School of Medicine
Columbia, MO

Afroza Liton, MD
Fellow
Department of Infectious Disease
University of Massachusetts
UMass Memorial Medical Center
Worcester, MA

Frederic F. Little, MD
Assistant Professor of Medicine
Pulmonary Center and Department of Pulmonary, Allergy, and Critical Care Medicine
Boston University School of Medicine
Attending Physician
Boston Medical Center
Boston, MA

Nancy Y.N. Liu, MD
Associate Professor of Clinical Medicine
Department of Medicine
Division of Rheumatology
University of Massachusetts Medical School
Worcester, MA

Randall R. Long, MD, PhD
Cheshire Medical Center/Dartmouth Hitchcock Keene
Keene, NH

Robert B. Love, MD, FACS
Professor and Vice Chairman
Department of Thoracic and Cardiothoracic
Loyola University Medical Center
Maywood, IL

Matthew W. Lube, MD
Assistant Professor of Surgery and Surgical Clerkship Director
University of Central Florida College of Medicine
Associate Director of Medical Education
Department of Surgical Education
Orlando Regional Medical Center
Orlando, FL

Fred A. Luchette, MD, MSc
The Ambrose and Gladys Bowyer Professor of Surgery
Stritch School of Medicine
Medical Director, General Surgery III Service
Department of Surgery
Maywood, IL

Alice D. Ma, MD
Associate Professor of Medicine
Department of Medicine
Division Hematology/Oncology
University of North Carolina
Chapel Hill, NC

Theresa R. (Roxie) Macfarlan, RN, MSN, CCRN, ACNP-BC
Advanced Practice Nurse 2
Department of Thoracic-Cardiovascular Postoperative Intensive Care Unit
University of Virginia Health System
Charlottesville, VA

J. Mark Madison, MD
Professor of Medicine and Physiology
Chief, Division of Pulmonary, Allergy and Critical Care Medicine
UMass Memorial Medical Center
University of Massachusetts Medical School
Worcester, MA

Ajai K. Malhotra, MBBS, MD, MS, DNB, FRCS
Associate Professor and Vice Chair
Associate Medical Director, Level 1 Trauma Center
Department of Surgery
Division of Trauma, Critical Care and Emergency General Surgery
Virginia Commonwealth University Medical Center
Richmond, VA

Atul Malhotra, MD
Associate Professor of Medicine
Department of Medicine
Brigham and Women's Hospital
Boston, MA

Samir Malkani, MD
Clinical Associate Professor of Medicine
Division of Diabetes
Department of Medicine
UMass Memorial Medical Center
Worcester, MA

Avinash V. Mantravadi, MD
Resident Physician
Department of Otolaryngology—Head and Neck Surgery
Loyola University Medical Center
Maywood, IL

Paul E. Marik, MD, FCCM, FCCP
Professor of Medicine
Department of Pulmonary and Critical Care Medicine
Eastern Virginia Medical School and Norfolk General Hospital
Eastern Virginia Medical School Internal Medicine
Norfolk, VA

William L. Marshall, MD
Associate Professor of Medicine
Department of Medicine
UMass Memorial Medical Center
Worcester, MA

Arthur J. Matas, MD
Professor of Surgery
Department of Surgery
University of Minnesota
Minneapolis, MN

Paul H. Mayo, MD
Professor of Clinical Medicine
Hofstra Northshore—LIJ School of Medicine
Long Island Jewish Medical Center
New Hyde Park, NY

Guy Maytal, MD
Director of Urgent Care and Primary Care Psychiatry
Department of Psychiatry
Massachusetts General Hospital
Boston, MA

Melanie Maytin, MD
Instructor in Medicine
Department of Cardiovascular Medicine
Brigham and Women's Hospital
Boston, MA

Kathleen M. McCauley, PhD, RN, ACNS-BC, FAAN, FAHA
Associate Dean for Academic Programs
Class of 1965 25th Reunion Term Professor of Cardiovascular Nursing
Cardiovascular Clinical Specialist
University of Pennsylvania School of Nursing
Hospital of the University of Pennsylvania
Philadelphia, PA

Sara L. Merwin, MPH
Assistant Professor of Medicine
Department of Medicine
Hofstra North Shore—LIJ School of Medicine
North Shore University Hospital
Manhasset, NY

Marco Mielcarek, MD
Assistant Professor
University of Washington
Assistant Member
Department of Medical Oncology
Fred Hutchinson Cancer Research Center
Seattle, WA

Ross Milner, MD
Associate Professor of Surgery
Chief, Division of Vascular Surgery and Endovascular Therapy
Department of Vascular Surgery
Loyola University Medical Center
Maywood, IL

Ann L. Mitchell, MD
Associate Professor of Clinical Neurology
Department of Neurology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Lawrence C. Mohr Jr, MD, ScD, FACP, FCCP
Professor of Medicine, Biometry and Epidemiology
Director, Environmental Biosciences Program
Medical University of South Carolina
Charleston, SC

Takki Momin, MD
Vascular Surgery Fellow
Department of Vascular Surgery
Georgetown University/Washington Hospital Center
Washington, DC

Jahan Montague, MD
Assistant Professor of Medicine
Department of Nephrology
UMass Memorial Medical Center
Worcester, MA

Bruce Montgomery, MD
Associate Professor
Department of Medicine, Oncology
University of Washington
VA Puget Sound HCS
Seattle, WA

Majaz Moonis, MD, MRCP(1), DM, FRCP (Edin)
Professor of Neurology
Director, Stroke Services
Director, Vascular Fellowship Program
UMass Memorial Medical Center
Worcester, MA

John P. Mordes, MD
Professor of Medicine
Department of Medicine/Endocrinology
UMass Memorial Medical Center
University of Massachusetts Medical School
Worcester, MA

PREFACE

It is with great pleasure that we present the seventh edition of *Irwin and Rippe's Intensive Care Medicine*. As with previous editions, the editorial challenge that we faced with the seventh edition was to continue to ensure that the textbook evolved as the field has evolved and improved to meet the varied and rigorous demands placed on it by the diverse group of specialty physicians and nonphysicians practicing in the adult intensive care environment without losing strengths that have made previous editions so useful and popular. We hope and believe that the seventh edition of *Irwin and Rippe's Intensive Care Medicine* has risen to meet these challenges.

Over the past 27 years since the publication of the first edition of our textbook, dramatic changes have occurred in virtually every area of critical care, and these are reflected in the evolution of our textbook. While our textbook initially focused primarily on medical intensive care, it now provides an interdisciplinary emphasis on anesthesia, surgery, trauma, and neurointensive care as well as medical intensive care with strong collaboration across all these disciplines. With this edition, a critical care nursing-centric section has been added. This reflects the reality that intensive care medicine has inevitably become more interdisciplinary and collaborative.

The seventh edition is approximately the same length as the previous edition. To make this happen, we challenged every section editor and author to carefully balance edited materials emphasizing new evidence-based as well as state-of-the-art information by discarding outdated information. All of our section editors and chapter authors have done a superb job meeting this challenge. All chapters in every section have been updated with recent references and other materials that reflect current information, techniques, and principles. New chapters have been added to reflect emerging areas of interest. As stated earlier, an entirely new section has been added on "Nursing Issues in the ICU" that was ably coedited by Dorrie Fontaine and Shawn Cody. This section was meant to focus on issues related to collaboration, healthy work environments, and the expanding roles of nurses not the specifics of nursing care that have been brilliantly covered in textbooks of ICU nursing; and Dorrie and Shawn have admirably succeeded in this regard. Another new section on "Critical Care Consequences of Weapons (or Agents) of Mass Destruction" reflects the changing realities of our world and has been ably edited by Larry Mohr.

Evidenced-based medicine continues to play an ever more prominent role in all branches of medicine including critical care. With this in mind, we have asked every chapter author to make recommendations that specifically reflect recent trials with a particular emphasis on randomized prospective controlled trials. Authors have summarized such evidence, when the data have allowed, with helpful tables.

In medical intensive care, important changes and advances have occurred since the publication of the sixth edition. These include managing our ICUs according to the following guiding principles: (i) making our ICUs safer for our patients; (ii) decreasing variability by following clinical practice guidelines based upon the best available evidence to ensure better outcomes for our patients; and (iii) doing more with less to decrease the cost of caring for our patients. While these principles have always been espoused, it has become clear that we must more consistently follow them. With respect to specific issues, the day-to-day use of ultrasonography by critical care specialists is a very recent change and this is reflected in the liberal use of ultrasonographic images throughout the book and a new chapter entitled Interventional Ultrasound; these are prominently featured in the procedure and monitoring chapters. Moreover, there is an imperative to increasingly utilize information technology in the everyday practice of intensive care medicine. This not only includes using electronic medical records, computer physician order entry, and clinical decision support tools but also tele-ICU. All of these issues are covered in the section entitled "Contemporary Challenges in the Intensive Care Unit" edited by Craig Lilly.

In coronary care, rapid advances in techniques and interventions continue to occur. These changes are reflected in the "Cardiovascular Problems and Coronary Care" section of the seventh edition. It is interesting to see how cardiovascular intensive care has dramatically changed since the publication of our first few editions, as the advances in cardiology and cardiac surgery became known from the large, multicenter, randomized controlled clinical trials. We welcome Akshay Desai who has joined Patrick O'Gara as co-section editor for this section.

Equally important advances have occurred in surgical critical care, including new therapies and techniques in a variety of conditions treated in this environment. Our "Surgical Problems in the Intensive Care Unit" section remains a great strength of this book. Fred Luchette did his usual magnificent job on this edition. We recognize Arthur Trask and Stephen Barnes who have done an admirable job of updating the "Shock and Trauma" section of the textbook as well.

While our textbook has been updated and broadened to include new understandings, information and techniques, our goal has been to maintain the practical, clinically oriented approach that readers have come to expect from previous editions. Our editorial focus remains on clinically relevant studies and information that readers have found so useful in the previous six editions.

As in the past, our textbook opens with a detailed section on commonly performed "Procedures and Techniques in the Intensive Care Unit." This section, along with the "Minimally Invasive Monitoring" section, has also been simultaneously published as a smaller book entitled "Procedures, Techniques, and Minimally Invasive Monitoring in Intensive Care Medicine. All chapters in these sections have been updated with new figures and descriptions of techniques which have been added to reflect changes since the sixth edition of the textbook. We are indebted that section editors Stephen Heard and Alan Lisbon who have done a superb job on these sections.

The "Pharmacology, Overdoses, and Poisoning" section, consisting of 29 chapters, remains a great strength of this book and essentially represents a textbook on these topics embedded into our larger book. In this edition, we welcome new section editors Luke Yip and Kennon Heard who have joined Steven Bird as section editors for this outstanding and comprehensive section.

Because intensive care cannot be divorced from public policy, we continue to emphasize this with a major section of our textbook entitled "Contemporary Challenges in the Intensive Care Unit." This section includes not only more ethical and legal issues but also issues related to ICU organization and management, economics, safety, and information technology. With this edition, we welcome Craig Lilly, who has done an outstanding job on this section.

Our team of section editors continue to do a wonderful job coordinating large bodies of information that comprise the core of modern intensive care. Many of our section editors have been with us for one or more editions. Richard Ellison III (Infectious Disease), Neil Aronin (Endocrinology), Stephanie Levine (Transplantation), Dominic Nompleggi (Metabolism/Nutrition), Mark Madison (Pulmonary), John Querques (Psychiatry), and Joseph Frassica (Appendix, Calculations Commonly used in Critical Care) all fall into this category and have done their usual, excellent job. A new table on Antidotes has been added to the Appendix based on the efforts of Luke Yip, Jeremy Helphenstine, Jerry Thomas, and Ian Ball.

Some new section editors have joined us for the seventh edition and done great work. In addition to the individuals that we have already mentioned, we would like to specifically acknowledge the excellent efforts by the following new section editors or co-section editors: Pang-Yen Fan (Renal), Dominic Nompleggi (Gastrointestinal Problems), Patrick Fogarty (Hematologic Problems), David Paydarfar (Neurologic Problems), David Harlan (Endocrine Problems), and Nancy Liu (Rheumatologic, Immunologic and Dermatologic Problems).

As with previous editions, our emphasis remains on clinical management. Discussions of basic pathophysiology are also included and guided and supplemented by extensive references to help clinicians and researchers who wish to pursue more in-depth knowledge of these important areas. When therapies reflect institutional or individual bias or are considered controversial, we have attempted to indicate this.

We hope and believe that the outstanding efforts of many people over the past 4 years have continued to result in an evidence-based and state-of-the-art and comprehensive textbook that will elucidate the important principles in intensive care and will continue to guide and support the best efforts of practitioners in this challenging environment in their ongoing efforts to diagnosis and treat complicated diseases and relieve human suffering.

Richard S. Irwin, MD, Master FCCP
James M. Rippe, MD

ACKNOWLEDGMENTS

Numerous outstanding individuals have made significant contributions to all phases of writing and production of this textbook and deserve special recognition and thanks. First and foremost is our managing editor, Elizabeth Grady. Beth literally lives and breathes this textbook as it works its way through the production cycle every 4 years. She is the guiding and organizing force behind this textbook. It would simply not be possible without Beth's incredible organizational skills, good humor, and enormous energy. She has guided this book through six editions—this book is as much hers as it is ours.

Our administrative assistants, office assistant, and clinical coordinators, Carol Moreau, Debra Adamonis, Karen Barrell, Mary Garabedian, and Cynthia French have helped us continue to coordinate and manage our complex professional and personal lives and create room for the substantial amount of time required to write and edit. Our section editors have devoted enormous skill, time, and resources to every edition of this textbook. We have very much appreciated their deep commitment to this book and to advancing the field of intensive care medicine.

Our editors at Lippincott Williams & Wilkins including Brian Brown, executive editor, have been a source of great help and encouragement. As with the last edition, Nicole Dernoski continues to be extremely helpful and accommodating in supervising and coordinating all phases of production in an outstanding way.

Lastly, we are grateful to Indu Jawwad and her staff for the outstanding job they have done copyediting the manuscript for this edition.

Our families support our efforts with unfailing encouragement and love. To them, and the many others who have helped in ways too numerous to count, we are deeply grateful.

Richard S. Irwin, MD, Master FCCP
James M. Rippe, MD

SECTION I PROCEDURES, TECHNIQUES, AND MINIMALLY INVASIVE MONITORING

Chapter 1 **Airway Management and Endotracheal Intubation** 1
J. Matthias Walz, Shubjeet Kaur and Stephen O. Heard

Chapter 2 **Central Venous Catheters** 16
Jason Lee-Llacer and Michael G. Seneff

Chapter 3 **Arterial Line Placement and Care** 36
Jason Lee-Llacer and Michael G. Seneff

Chapter 4 **Pulmonary Artery Catheters** 45
Harvey S. Reich

Chapter 5 **Temporary Cardiac Pacing** 64
Seth T. Dahlberg

Chapter 6 **Cardioversion and Defibrillation** 71
Mark S. Link and Naomi F. Botkin

Chapter 7 **Pericardiocentesis** 77
Craig S. Smith and Richard C. Becker

Chapter 8 **Chest Tube Insertion and Care** 83
Ulises Torres and Robert A. Lancy

Chapter 9 **Bronchoscopy** 89
Stephen J. Krinzman, Paulo J. Oliveira and Richard S. Irwin

Chapter 10 **Thoracentesis** 95
Mark M. Wilson and Richard S. Irwin

Chapter 11 **Arterial Puncture for Blood Gas Analysis** 102
Kimberly A. Robinson and Richard S. Irwin

Chapter 12 **Tracheostomy** 105
Scott E. Kopec and Timothy A. Emhoff

Chapter 13 **Gastrointestinal Endoscopy** 116
Anupam Singh, Randall S. Pellish and Wahid Y. Wassef

Chapter 14 **Paracentesis and Diagnostic Peritoneal Lavage** 122
Lena M. Napolitano

Chapter 15 **Gastroesophageal Balloon Tamponade for Acute Variceal Hemorrhage** 130
Marie T. Pavini and Juan Carlos Puyana

Chapter 16 **Endoscopic Placement of Feeding Tubes** 136
Lena M. Napolitano

Chapter 17 **Cerebrospinal Fluid Aspiration** 143
John P. Weaver

Chapter 18 **Percutaneous Suprapubic Cystostomy** 150
Satya Allaparthi, K.C. Balaji and Philip J. Ayvazian

Chapter 19 **Aspiration of the Knee and Synovial Fluid Analysis** 155
Bonnie J. Bidinger and Eric W. Jacobson

Chapter 20 **Anesthesia for Bedside Procedures** 160
Mark Dershwitz

Chapter 21 **Interventional Ultrasound** 168
Gisela I. Banauch and Paul H. Mayo

Chapter 22 **Interventional Radiology: Percutaneous Drainage Techniques** 175
Brian T. Callahan, Salomao Faintuch and Felipe B. Collares

Chapter 23 **Cardiopulmonary Resuscitation** 181
Bruce Greenberg and John A. Paraskos

Chapter 24 **Management of Pain in the Critically Ill Patient** 206
Armagan Dagal, Mario De Pinto and W. Thomas Edwards

Chapter 25 **Therapeutic Paralysis** 219
Khaldoun Faris

SECTION II ■ MINIMALLY INVASIVE MONITORING

Chapter 26 **Routine Monitoring of Critically Ill Patients** 227
Patrick Troy, Nicholas A. Smyrnios and Michael D. Howell

Chapter 27 **Minimally Invasive Hemodynamic Monitoring** 245
Andrew J. Goodwin, Ednan K. Bajwa and Atul Malhotra

Chapter 28 **Neurologic Multimodal Monitoring** 258
Raphael A. Carandang, Wiley R. Hall and Donald S. Prough

Chapter 29 **Echocardiography in the Intensive Care Unit** 271
Achikam Oren-Grinberg, Sajid Shahul and Adam B. Lerner

Chapter 30 **Monitoring Gastrointestinal Tract Function** 286
Ruben J. Azocar, Laura Santos Pavia and Suresh Agarwal

Chapter 31 **Respiratory Monitoring during Mechanical Ventilation** 294
Todd W. Sarge, Ray Ritz and Daniel Talmor

SECTION III ■ CARDIOVASCULAR PROBLEMS AND CORONARY CARE

Chapter 32 **Approach to the Patient with Hypotension and Hemodynamic Instability** 307
Michael M. Givertz and James C. Fang

Chapter 33 **Management of Advanced Heart Failure** 318
G. William Dec

Chapter 34 **Valvular Heart Disease** 328
Garrick C. Stewart and Patrick T. O'Gara

Chapter 35 **Critical Care of Pericardial Disease** 347
Akshay S. Desai and Kenneth L. Baughman

Chapter 36 **Acute Aortic Syndromes** 358
Leon M. Ptaszek, Eric M. Isselbacher and Amy E. Spooner

Chapter 37 **Evaluation and Management of Hypertension in the Intensive Care Unit** 373
Benjamin M. Scirica and Robert J. Heyka

Chapter 38 **Unstable Angina/Non–ST-Segment Elevation Myocardial Infarction** 382
Suzanne J. Baron, Christopher P. Cannon and Marc S. Sabatine

Chapter 39 **ST-Segment Elevation Myocardial Infarction** 402
James A. de Lemos and David A. Morrow

Chapter 40 **Mechanical Complications of Myocardial Infarction** 419
Annabel A. Chen-Tournoux and Michael A. Fifer

Chapter 41 **Ventricular Tachycardia** 428
Melanie Maytin and Bruce A. Koplan

Chapter 42 **Supraventricular Tachycardias: Recognition and Management in the Intensive Care Setting** 441
Ammar Habib, Joseph J. Gard, Traci L. Buescher and Samuel J. Asirvatham

Chapter 43 **Bradyarrhythmias and Temporary Pacing** 455
Gaurav A. Upadhyay and Jagmeet P. Singh

Chapter 44 **How to Manage Cardiac Pacemakers and Implantable Defibrillators in the Intensive Care Unit** 466
Melanie Maytin and Usha B. Tedrow

Chapter 45 **Mechanical Support for Heart Failure** 477
Jeffrey J. Teuteberg and Firas E. Zahr

SECTION IV ■ PULMONARY PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 46 **Respiratory Failure Part I: A Physiologic Approach to Respiratory Failure** 488
Thaddeus C. Bartter, Melvin R. Pratter, Wissam Abouzgheib and Richard S. Irwin

Chapter 47 **Respiratory Failure Part II: Acute Respiratory Distress Syndrome** 493
Gilman B. Allen and Polly E. Parsons

Chapter 48 **Respiratory Failure Part III: Asthma** 512
J. Mark Madison and Richard S. Irwin

Chapter 49 **Respiratory Failure Part IV: Chronic Obstructive Pulmonary Disease** 525
Meyer S. Balter and Ronald F. Grossman

Chapter 50 **Respiratory Failure Part V: Extrapulmonary Causes of Respiratory Failure** 534
Helen M. Hollingsworth, Melvin R. Pratter and Richard S. Irwin

Chapter 51 **Respiratory Failure Part VI: Acute Respiratory Failure in Pregnancy** 548
Christine Campbell-Reardon and Helen M. Hollingsworth

Chapter 52 **Venous Thromboembolism: Pulmonary Embolism and Deep Venous Thrombosis** 565
Charles William Hargett, III and Victor F. Tapson

Chapter 53 **Managing Hemoptysis** 578
Richard S. Irwin and Kimberly A. Robinson

Chapter 54 **Aspiration** 587
Kimberly A. Robinson and Richard S. Irwin

Chapter 55 **Drowning** 594
Nicholas A. Smyrnios and Richard S. Irwin

Chapter 56 **Pulmonary Hypertension in the Intensive Care Unit** 601
Kimberly A. Fisher and Harrison W. Farber

Chapter 57 **Pleural Disease in the Critically Ill Patient** 608
Peter Doelken and Steven A. Sahn

Chapter 58 **Mechanical Ventilation Part I: Invasive** 624
Richard A. Oeckler, Rolf D. Hubmayr and Richard S. Irwin

Chapter 59 **Mechanical Ventilation Part II: Non-invasive Mechanical Ventilation for the Adult Hospitalized Patient** 641
Samy S. Sidhom and Nicholas Hill

Chapter 60 **Mechanical Ventilation Part III: Discontinuation** 658
Richard S. Irwin, Nicholas A. Smyrnios and Rolf D. Hubmayr

Chapter 61 **Gas Embolism Syndromes: Venous Gas Emboli, Arterial Gas Emboli, and Decompression Sickness** 669
Mark M. Wilson

Chapter 62 **Respiratory Adjunct Therapy** 684
Scott E. Kopec and Richard S. Irwin

Chapter 63 **Chest Radiographic Examination** 700
Cynthia B. Umali and Jerry P. Balikian

Chapter 64 **Acute Inhalation Injury** 731
David J. Prezant, Dorsett D. Smith and Lawrence C. Mohr Jr

Chapter 65 **Disorders of Temperature Control Part I: Hypothermia** 745
M. Kathryn Steiner, Frederick J. Curley and Richard S. Irwin

Chapter 66 **Disorders of Temperature Control Part II: Hyperthermia** 761
M. Kathryn Steiner, Frederick J. Curley and Richard S. Irwin

Chapter 67 **Severe Upper Airway Infections** 776
Stephen J. Krinzman, Sunil Rajan and Richard S. Irwin

Chapter 68 **Acute Infectious Pneumonia** 791
Veronica Brito and Michael S. Niederman

Chapter 69 **Lung Biopsy** 815
Scott E. Kopec and Richard S. Irwin

Chapter 70 **Sleep Issues in the Intensive Care Unit Setting** 823
Kim L. Goring and Nancy A. Collop

SECTION V ■ RENAL PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 71 **Metabolic Acidosis and Metabolic Alkalosis** 831
Robert M. Black

Chapter 72 **Disorders of Plasma Sodium and Plasma Potassium** 843
Robert M. Black

Chapter 73 **Acute Kidney Injury in the Intensive Care Unit** 867
Jahan Montague and Konstantin Abramov

Chapter 74 **Drug Dosing in Renal and Hepatic Failure: A Pharmacokinetic Approach to the Critically Ill Patient** 893
Sonia Lin, Keith J. Foster, Ronald J. DeBellis and Brian S. Smith

Chapter 75 **Renal Replacement Therapy in the Intensive Care Unit** 917
Glenn Kershaw, Matthew J. Trainor and Pang-Yen Fan

SECTION VI ■ INFECTIOUS DISEASE PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 76 **Approach to Fever in the ICU Patient** 932
Raul E. Davaro and Richard H. Glew

Chapter 77 **Use of Antimicrobials in the Treatment of Infection in the Critically Ill Patient** 939
Iva Zivna, Richard H. Glew and Jennifer S. Daly

Chapter 78 **Prevention and Control of Healthcare-Acquired Infections in the Intensive Care Unit** 952
Mireya Wessolossky and Richard T. Ellison, III

Chapter 79 **Central Nervous System Infections** 959
Heidi L. Smith and Alan L. Rothman

Chapter 80 **Infective Endocarditis and Infections of Intracardiac Prosthetic Devices** 969
Karen C. Carroll, Sarah H. Cheeseman and Sara E. Cosgrove

Chapter 81 **Infections Associated with Vascular Catheters** 986
Suzanne F. Bradley and Carol A. Kauffman

Chapter 82 **Urinary Tract Infections** 994
Steven M. Opal

Chapter 83 **Life-Threatening Community-Acquired Infections: Toxic Shock Syndrome, Overwhelming Postsplenectomy Infection, Meningococcemia, Malaria, Rocky Mountain Spotted Fever, and Others** 1004
Mary T. Bessesen

Chapter 84 **Acute Infection in the Immunocompromised Host** 1014
Jennifer S. Daly and Robert W. Finberg

Chapter 85 **Intensive Care of Patients with HIV Infection** 1023
Sarah H. Cheeseman and Mark J. Rosen

Chapter 86 **Infectious Complications of Drug Abuse** 1030
Afroza Liton and William L. Marshall

Chapter 87 **Tuberculosis** 1036
Robert W. Belknap and Randall R. Reves

Chapter 88 **Botulism** 1044
Mary Dawn T. Co and Richard T. Ellison, III

Chapter 89 **Tetanus** 1046
Mary Dawn T. Co and Richard T. Ellison, III

Chapter 90 **Serious Epidemic Viral Pneumonias** 1049
Daniel H. Libraty

SECTION VII ■ GASTROINTESTINAL DISEASE PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 91 **Upper and Lower Gastrointestinal Bleeding** 1059
Ryan F. Porter, Gary R. Zuckerman and Chandra Prakash Gyawali

Chapter 92 **Stress Ulcer Syndrome** 1067
Sonal Kumar, Chandra Prakash Gyawali and Gary R. Zuckerman

Chapter 93 **Gastrointestinal Motility in the Critically Ill Patient** 1072
Filippo Cremonini, Anthony J. Lembo, Brennan M.R. Spiegel and Inder M. Singh

Chapter 94 **Fulminant Colitis and Toxic Megacolon** 1079
Stephen B. Hanauer

Chapter 95 **Evaluation and Management of Liver Failure** 1083
Gowri Kularatna and Mauricio Lisker-Melman

Chapter 96 **Diarrhea** 1095
Colin T. Swales, Laura Harrell, Eugene Chang and John K. Zawacki

Chapter 97 **Severe and Complicated Biliary Tract Disease** 1103
John M. Iskander, Sreenivasa S. Jonnalagadda and Riad Azar

Chapter 98 **Hepatic Dysfunction** 1108
Mauricio Lisker-Melman and Gowri Kularatna

Chapter 99 **Acute Pancreatitis** 1115
Michael L. Steer

SECTION VIII ■ ENDOCRINE PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 100 **Management of Hyperglycemia in Critically Ill Patients** 1130
Michael J. Thompson, David M. Harlan, Samir Malkani and John P. Mordes

Chapter 101 **Hyperglycemic Diabetic Coma** 1139
Samir Malkani, Aldo A. Rossini, David M. Harlan, Michael J. Thompson and John P. Mordes

Chapter 102 **Severe Hyperthyroidism** 1151
Marjorie S. Safran

Chapter 103 **Myxedema Coma** 1155
Mira Sofia Torres and Charles H. Emerson

Chapter 104 Hypoadrenal Crisis and the Stress Management of the Patient on Chronic Steroid Therapy 1159
Neil Aronin

Chapter 105 Disorders of Mineral Metabolism 1162
Seth M. Arum and Daniel T. Baran

Chapter 106 Hypoglycemia 1168
John P. Mordes, Michael J. Thompson, David M. Harlan and Samir Malkani

Chapter 107 Nonthyroidal Illness Syndrome (Sick Euthyroid Syndrome) in the Intensive Care Unit 1182
Shirin Haddady and Alan P. Farwell

SECTION IX ■ HEMATOLOGIC AND ONCOLOGIC PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 108 Disorders of Hemostasis in Critically Ill Patients 1195
Jeremiah Boles and Alice D. Ma

Chapter 109 Thrombocytopenia 1211
Thomas G. DeLoughery

Chapter 110 Antithrombotic Pharmacotherapy 1224
Christopher D. Adams, Kevin E. Anger, Bonnie C. Greenwood and John Fanikos

Chapter 111 Diagnosis and Management of Prothrombotic Disorders in the Intensive Care Unit 1243
Ashkan Emadi and Michael B. Streiff

Chapter 112 Anemia in the Critical Care Setting 1253
Marc S. Zumberg, Marc J. Kahn and Alice D. Ma

Chapter 113 Therapeutic Apheresis: Technical Considerations and Indications in Critical Care 1267
Theresa A. Nester and Michael Linenberger

Chapter 114 Transfusion Therapy: Blood Components and Transfusion Complications 1276
Terry Gernsheimer

Chapter 115 Critical Care of Patients with Hematologic Malignancies 1284
Matthew J. Wieduwilt and Lloyd E. Damon

Chapter 116 Oncologic Emergencies 1296
Damian J. Green, John A. Thompson and Bruce Montgomery

SECTION X ■ PHARMACOLOGY, OVERDOSES, AND POISONINGS

Chapter 117 General Considerations in the Evaluation and Treatment of Poisoning 1309
Ian M. Ball and Christopher H. Linden

Chapter 118 Acetaminophen Poisoning 1329
Steven B. Bird

Chapter 119	**Alcohols and Glycol Poisoning** *Jennifer L. Englund, Marco L.A. Sivilotti and Marsha D. Ford*	1337
Chapter 120	**Antiarrhythmic Agents** *Michael Ganetsky*	1353
Chapter 121	**Anticholinergic Poisoning** *Keith K. Burkhart*	1363
Chapter 122	**Anticonvulsant Poisoning** *Steven B. Bird*	1366
Chapter 123	**Antidepressant Poisoning** *Cynthia K. Aaron and Abhishek Katiyar*	1376
Chapter 124	**Antipsychotic Poisoning** *Michael J. Burns and Christopher H. Linden*	1386
Chapter 125	**Beta-Blocker Poisoning** *Shan Yin and Javier C. Waksman*	1397
Chapter 126	**Calcium Channel Antagonist Poisoning** *Christopher R. DeWitt*	1403
Chapter 127	**Cardiac Glycoside Poisoning** *Mark A. Kirk and Bryan S. Judge*	1409
Chapter 128	**Cholinergic Poisoning** *Cynthia K. Aaron*	1413
Chapter 129	**Cocaine Poisoning** *Richard D. Shih and Judd E. Hollander*	1418
Chapter 130	**Corrosive Poisoning** *Robert P. Dowsett and Christopher H. Linden*	1423
Chapter 131	**Salicylate and Other Nonsteroidal Anti-Inflammatory Drug Poisoning** *Marco L.A. Sivilotti and Christopher H. Linden*	1430
Chapter 132	**Envenomations** *Robert L. Norris*	1439
Chapter 133	**Heavy Metal Poisoning** *Luke Yip*	1449
Chapter 134	**Hydrocarbon Poisoning** *William J. Lewander and Alfred Aleguas Jr*	1464
Chapter 135	**Hydrofluoric Acid Poisoning** *Kennon Heard*	1471
Chapter 136	**Iron Poisoning** *Milton Tenenbein*	1473
Chapter 137	**Isoniazid Poisoning** *James B. Mowry and R. Brent Furbee*	1478
Chapter 138	**Lithium Poisoning** *Kent R. Olson and Thanjira Jiranantakan*	1481
Chapter 139	**Methylxanthine Poisoning** *Michael W. Shannon*	1486
Chapter 140	**Opioid Poisoning** *Robert P. Dowsett and Luke Yip*	1492
Chapter 141	**Pesticide Poisoning** *William K. Chiang and Richard Y. Wang*	1499

Chapter 142 **Phencyclidine and Hallucinogen Poisoning** 1516
Frank F. Daly and Luke Yip

Chapter 143 **Sedative–Hypnotic Agent Poisoning** 1521
Andis Graudins

Chapter 144 **Amphetamines** 1529
Michael C. Beuhler

Chapter 145 **Withdrawal Syndromes** 1536
Paul M. Wax and Jennifer Smith

SECTION XI ■ SURGICAL PROBLEMS IN THE INTENSIVE CARE UNIT

Chapter 146 **Epistaxis** 1548
Avinash V. Mantravadi, Chad A. Zender and Louis G. Portugal

Chapter 147 **Esophageal Perforation and Acute Mediastinitis** 1555
Jason W. Smith, Christopher H. Wigfield and Robert B. Love

Chapter 148 **Management of the Postoperative Cardiac Surgical Patient** 1562
Sajid Shahul, Cathy Dudick and Alan Lisbon

Chapter 149 **Noncardiac Surgery in the Cardiac Patient** 1575
Steven B. Edelstein and Scott W. Byram

Chapter 150 **Diagnosis and Management of Intra-abdominal Sepsis** 1591
Dennis I. Sonnier, Shrawan G. Gaitonde, Patrick D. Solan and Thomas L. Husted

Chapter 151 **Mesenteric Ischemia** 1605
Takki Momin and John Ricotta

Chapter 152 **Compartment Syndrome of the Abdominal Cavity** 1612
Ajai K. Malhotra and Rao R. Ivatury

Chapter 153 **Necrotizing Soft Tissue Infections** 1619
Richard L. Gamelli and Joseph A. Posluszny Jr

Chapter 154 **Acute Limb Ischemia: Etiology, Diagnosis, and Treatment Strategies** 1626
Pegge M. Halandras and Ross Milner

SECTION I ■ PROCEDURES, TECHNIQUES, AND MINIMALLY INVASIVE MONITORING

STEPHEN O. HEARD

CHAPTER 1 ■ AIRWAY MANAGEMENT AND ENDOTRACHEAL INTUBATION

J. MATTHIAS WALZ, SHUBJEET KAUR AND STEPHEN O. HEARD

In the emergency room and critical care environment, management of the airway to ensure optimal ventilation and oxygenation is of prime importance. Although initial efforts should be directed toward improving oxygenation and ventilation without intubating the patient (see Chapter 59) [1], these interventions may fail and the placement of an endotracheal tube may be required. Although endotracheal intubation is best left to the trained specialist, emergencies often require that the procedure be performed before a specialist arrives. Because intubated patients are commonly seen in the intensive care unit (ICU) and coronary care unit, all physicians who work in these environments should be skilled in the techniques of airway management, endotracheal intubation, and management of intubated patients.

ANATOMY

An understanding of the techniques of endotracheal intubation and potential complications is based on knowledge of the anatomy of the respiratory passages [2]. Although a detailed anatomic description is beyond the scope of this book, an understanding of some features and relationships is essential to performing intubation.

Nose

The roof of the nose is partially formed by the cribriform plate. The anatomic proximity of the roof to intracranial structures dictates that special caution be exercised during nasotracheal intubations. This is particularly true in patients with significant maxillofacial injuries.

The mucosa of the nose is provided with a rich blood supply from branches of the ophthalmic and maxillary arteries, which allow air to be warmed and humidified. Because the conchae provide an irregular, highly vascularized surface, they are particularly susceptible to trauma and subsequent hemorrhage. The orifices from the paranasal sinuses and nasolacrimal duct open onto the lateral wall. Blockage of these orifices by prolonged nasotracheal intubation may result in sinusitis.

Mouth and Jaw

The mouth is formed inferiorly by the tongue, alveolar ridge, and mandible. The hard and soft palates compose the superior surface, and the oropharynx forms the posterior surface. Assessment of the anatomic features of the mouth and jaw is essential before orotracheal intubation. A clear understanding of the anatomy is also essential when dealing with a patient who has a difficult airway and when learning how to insert airway devices such as the laryngeal mask airway (LMA; discussed in Management of the Difficult Airway section).

Nasopharynx

The base of the skull forms the roof of the nasopharynx, and the soft palate forms the floor. The roof and the posterior walls of the nasopharynx contain lymphoid tissue (adenoids), which may become enlarged and compromise nasal airflow or become injured during nasal intubation, particularly in children. The Eustachian tubes enter the nasopharynx on the lateral walls and may become blocked secondary to swelling during prolonged nasotracheal intubation.

Oropharynx

The soft palate defines the beginning of the oropharynx, which extends inferiorly to the epiglottis. The palatine tonsils protrude from the lateral walls and in children occasionally become so enlarged that exposure of the larynx for intubation becomes difficult. A large tongue can also cause oropharyngeal obstruction. Contraction of the genioglossus muscle normally moves the tongue forward to open the oropharyngeal passage during inspiration. Decreased tone of this muscle (e.g., in the anesthetized state) can cause obstruction. The oropharynx connects the posterior portion of the oral cavity to the hypopharynx.

Hypopharynx

The epiglottis defines the superior border of the hypopharynx, and the beginning of the esophagus forms the inferior boundary. The larynx is anterior to the hypopharynx. The pyriform sinuses that extend around both sides of the larynx are part of the hypopharynx.

Larynx

The larynx (Fig. 1.1) is bounded by the hypopharynx superiorly and is continuous with the trachea inferiorly. The thyroid, cricoid, epiglottic, cuneiform, corniculate, and arytenoid cartilages compose the laryngeal skeleton. The thyroid and cricoid cartilages are readily palpated in the anterior neck. The cricoid cartilage articulates with the thyroid cartilage and is joined to it by the cricothyroid ligament. When the patient's head is extended, the cricothyroid ligament can be pierced with a scalpel or large needle to provide an emergency airway (see

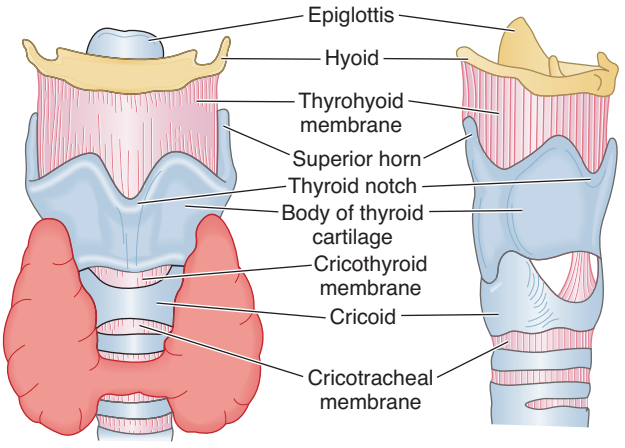

FIGURE 1.1. Anatomy of the larynx, anterior, and lateral aspects. [From Ellis H: *Anatomy for Anaesthetists*. Oxford, Blackwell Scientific, 1963, with permission.]

Chapter 12). The cricoid cartilage completely encircles the airway. It is attached to the first cartilage ring of the trachea by the cricotracheal ligament. The anterior wall of the larynx is formed by the epiglottic cartilage, to which the arytenoid cartilages are attached. Fine muscles span the arytenoid and thyroid cartilages, as do the vocal cords. The true vocal cords and space between them are collectively termed the *glottis* (Fig. 1.2). The glottis is the narrowest space in the adult upper airway. In children, the cricoid cartilage defines the narrowest portion of the airway. Because normal phonation relies on the precise apposition of the true vocal cords, even a small lesion can cause hoarseness. Lymphatic drainage to the true vocal cords is sparse. Inflammation or swelling caused by tube irritation or trauma may take considerable time to resolve. The superior and recurrent laryngeal nerve branches of the vagus nerve innervate the structures of the larynx. The superior laryngeal nerve supplies sensory innervation from the inferior surface of the epiglottis to the superior surface of the vocal cords. From its takeoff from the vagus nerve, it passes deep to both branches of the carotid artery. A large internal branch pierces the thyrohyoid membrane just inferior to the greater cornu of the hyoid. This branch can be blocked with local anesthetics for oral or nasal intubations in awake patients. The recurrent laryngeal branch of the vagus nerve provides sensory innervation below the cords. It also supplies all the muscles of the larynx except the cricothyroid, which is innervated by the external branch of the superior laryngeal nerve.

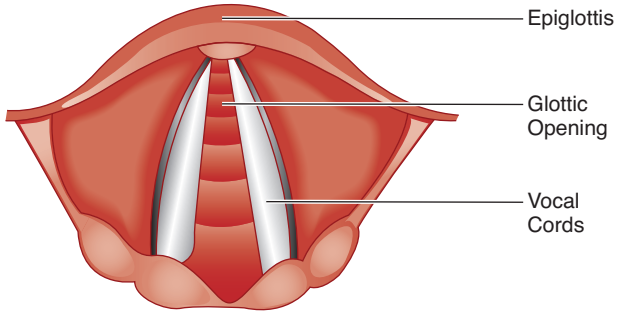

FIGURE 1.2. Superior view of the larynx (inspiration). [From Stoelting RH, Miller RD: *Basics of Anesthesia*. 2nd ed. New York, Churchill Livingstone, 1989, with permission.]

Trachea

The adult trachea averages 15 cm long. Its external skeleton is composed of a series of C-shaped cartilages. It is bounded posteriorly by the esophagus and anteriorly for the first few cartilage rings by the thyroid gland. The trachea is lined with ciliated cells that secrete mucus; through the beating action of the cilia, foreign substances are propelled toward the larynx. The carina is located at the fourth thoracic vertebral level (of relevance when judging proper endotracheal tube positioning on chest radiograph). The right main bronchus takes off at a less acute angle than the left, making right main bronchial intubation more common if the endotracheal tube is in too far.

EMERGENCY AIRWAY MANAGEMENT

In an emergency situation, establishing adequate ventilation and oxygenation assumes primary importance [3]. Too frequently, inexperienced personnel believe that this requires immediate intubation; however, attempts at intubation may delay establishment of an adequate airway. Such efforts are time consuming, can produce hypoxemia and arrhythmias, and may induce bleeding and regurgitation, making subsequent attempts to intubate significantly more difficult and contributing to significant patient morbidity and even mortality [4,5]. Some simple techniques and principles of emergency airway management can play an important role until the arrival of an individual who is skilled at intubation.

Airway Obstruction

Compromised ventilation often results from upper airway obstruction by the tongue, by substances retained in the mouth, or by laryngospasm. Relaxation of the tongue and jaw leading to a reduction in the space between the base of the tongue and the posterior pharyngeal wall is the most common cause of upper airway obstruction. Obstruction may be partial or complete. The latter is characterized by total lack of air exchange. The former is recognized by inspiratory stridor and retraction of neck and intercostal muscles. If respiration is inadequate, the head-tilt–chin-lift or jaw-thrust maneuver should be performed. In patients with suspected cervical spine injuries, the jaw-thrust maneuver (without the head tilt) may result in the least movement of the cervical spine. To perform the head-tilt maneuver, place a palm on the patient's forehead and apply pressure to extend the head about the atlanto-occipital joint. To perform the chin lift, place several fingers of the other hand in the submental area and lift the mandible. Care must be taken to avoid airway obstruction by pressing too firmly on the soft tissues in the submental area. To perform the jaw thrust, lift up on the angles of the mandible [3] (Fig. 1.3). Both of these maneuvers open the oropharyngeal passage. Laryngospasm can be treated by maintaining positive airway pressure using a face mask and bag valve device (see the following section). If the patient resumes spontaneous breathing, establishing this head position may constitute sufficient treatment. If obstruction persists, a check for foreign bodies, emesis, or secretions should be performed [6].

Use of Face Mask and Bag Valve Device

If an adequate airway has been established and the patient is not breathing spontaneously, oxygen can be delivered via face mask and a bag valve device. It is important to establish a

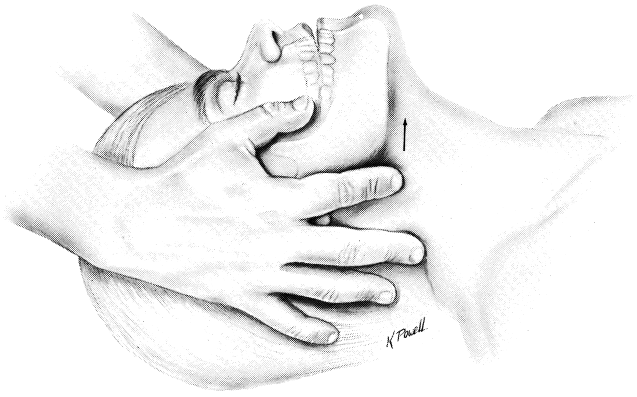

FIGURE 1.3. In an obtunded or comatose patient, the soft tissues of the oropharynx become relaxed and may obstruct the upper airway. Obstruction can be alleviated by placing the thumbs on the maxilla with the index fingers under the ramus of the mandible and rotating the mandible forward with pressure from the index fingers *(arrow)*. This maneuver brings the soft tissues forward and therefore frequently reduces the airway obstruction.

tight fit with the face mask, covering the patient's mouth and nose. To perform this procedure apply the mask initially to the bridge of the nose and draw it downward toward the mouth, using both hands. The operator stands at the patient's head and presses the mask onto the patient's face with the left hand. The thumb should be on the nasal portion of the mask, the index finger near the oral portion, and the rest of the fingers spread on the left side of the patient's mandible so as to pull it slightly forward. The bag is then alternately compressed and released with the right hand. A good airway is indicated by the rise and fall of the chest; moreover, lung–chest wall compliance can be estimated from the amount of pressure required to compress the bag. The minimum effective insufflation pressure should be used to decrease the risk of insufflating the stomach with gas and subsequently increase the risk of aspiration.

Airway Adjuncts

If proper positioning of the head and neck or clearance of foreign bodies and secretions fails to establish an adequate airway, several airway adjuncts may be helpful if an individual who is skilled in intubation is not immediately available. An oropharyngeal or nasopharyngeal airway occasionally helps

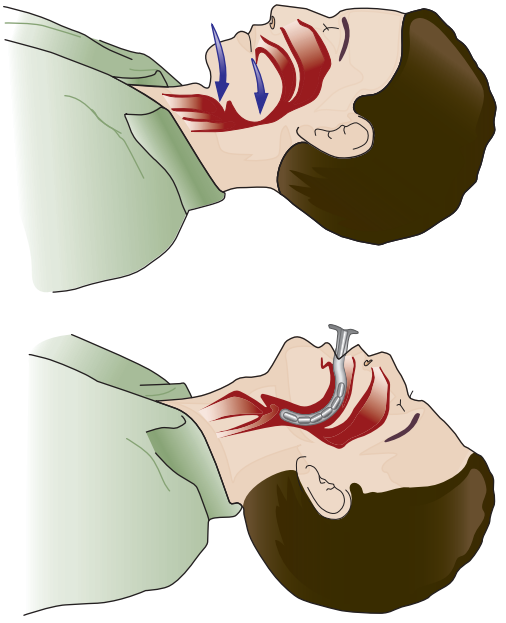

FIGURE 1.5. The mechanism of upper airway obstruction and the proper position of the oropharyngeal airway. [From *Textbook of advanced cardiac life support*. Dallas, TX, American Heart Association, 1997, with permission.]

to establish an adequate airway when proper head positioning alone is insufficient (Figs. 1.4 and 1.5). The oropharyngeal airway is semicircular and made of plastic or hard rubber. The two types are the Guedel airway, with a hollow tubular design, and the Berman airway, with airway channels along the sides. Both types are most easily inserted by turning the curved portion toward the palate as it enters the mouth. It is then advanced beyond the posterior portion of the tongue and rotated downward into the proper position (Fig. 1.5). Often, depressing the tongue or moving it laterally with a tongue blade helps to position the oropharyngeal airway. Care must be exercised not to push the tongue into the posterior pharynx, causing or exacerbating obstruction. Because insertion of the oropharyngeal airway can cause gagging or vomiting, or both, it should be used only in unconscious patients.

The nasopharyngeal airway is a soft tube approximately 15 cm long, which is made of rubber or plastic (Figs. 1.4 and 1.6). It is inserted through the nostril into the posterior

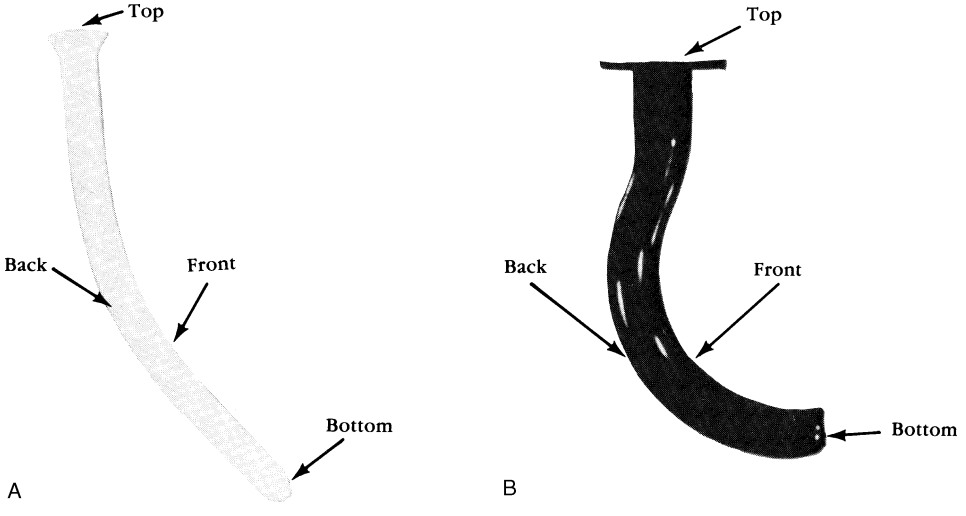

FIGURE 1.4. Nasopharyngeal (**A**) or oropharyngeal (**B**) airways can be used to relieve soft tissue obstruction if elevating the mandible proves ineffective.

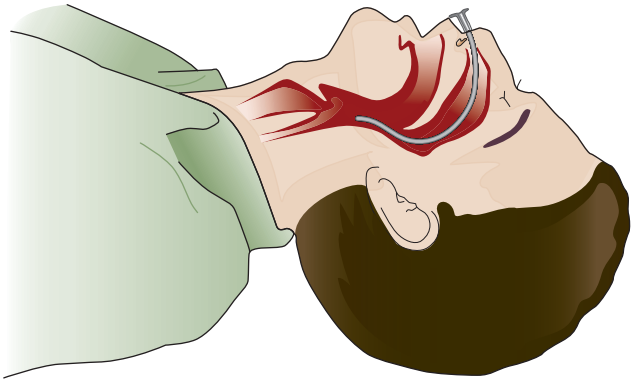

FIGURE 1.6. The proper position of the nasopharyngeal airway. [From *Textbook of advanced cardiac life support*. Dallas, TX, American Heart Association, 1997, with permission.]

pharynx. Before insertion, the airway should be lubricated with an anesthetic gel, and, preferably, a vasoconstrictor should be administered into the nostril. The nasopharyngeal airway should not be used in patients with extensive facial trauma or cerebrospinal rhinorrhea, as it could be inserted through the cribriform plate into the brain.

INDICATIONS FOR INTUBATION

The indications for endotracheal intubation can be divided into four broad categories: (a) acute airway obstruction, (b) excessive pulmonary secretions or inability to clear secretions adequately, (c) loss of protective reflexes, and (d) respiratory failure (Table 1.1).

Preintubation Evaluation

Even in the most urgent situation, a rapid assessment of the patient's airway anatomy can expedite the choice of the proper route for intubation, the appropriate equipment, and the most useful precautions to be taken. In the less emergent situation, several minutes of preintubation evaluation can decrease the likelihood of complications and increase the probability of successful intubation with minimal trauma.

Anatomic structures of the upper airway, head, and neck must be examined, with particular attention to abnormalities that might preclude a particular route of intubation. Evaluation of cervical spine mobility, temporomandibular joint function, and dentition is important. Any abnormalities that might prohibit alignment of the oral, pharyngeal, and laryngeal axes should be noted.

Cervical spine mobility is assessed by flexion and extension of the neck (performed only after ascertaining that no cervical spine injury exists). The normal range of neck flexion–extension varies from 165 to 90 degrees, with the range decreasing approximately 20% by age 75 years. Conditions associated with decreased range of motion include any cause of degenerative disk disease (e.g., rheumatoid arthritis, osteoarthritis, ankylosing spondylitis), previous trauma, or age older than 70 years. Temporomandibular joint dysfunction can occur in any form of degenerative arthritis (particularly rheumatoid arthritis), in any condition that causes a receding mandible, and in rare conditions such as acromegaly.

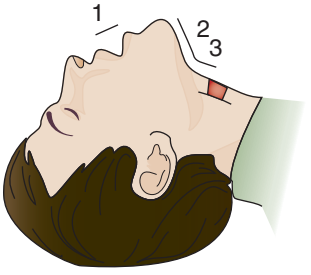
Examination of the oral cavity is mandatory. Loose, missing, or chipped teeth and permanent bridgework are noted, and removable bridgework and dentures should be taken out. Mallampati et al. [7] (Fig. 1.7) developed a clinical indicator

TABLE 1.1

INDICATIONS FOR ENDOTRACHEAL INTUBATION

- Acute airway obstruction
  - Trauma
    - Mandible
    - Larynx (direct or indirect injury)
  - Inhalation
    - Smoke
    - Noxious chemicals
    - Foreign bodies
  - Infection
    - Acute epiglottitis
    - Croup
    - Retropharyngeal abscess
  - Hematoma
  - Tumor
  - Congenital anomalies
    - Laryngeal web
    - Supraglottic fusion
  - Laryngeal edema
  - Laryngeal spasm (anaphylactic response)
- Access for suctioning
  - Debilitated patients
  - Copious Secretions
- Loss of protective reflexes
  - Head injury
  - Drug overdose
  - Cerebrovascular accident
- Respiratory failure
  - Hypoxemia
    - Acute respiratory distress syndrome
    - Hypoventilation
    - Atelectasis
    - Secretions
    - Pulmonary edema
  - Hypercapnia
    - Hypoventilation
    - Neuromuscular failure
    - Drug overdose

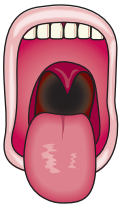
based on the size of the posterior aspect of the tongue relative to the size of the oral pharynx. The patient should be sitting, with the head fully extended, protruding the tongue and phonating [8]. When the faucial pillars, the uvula, the soft palate, and the posterior pharyngeal wall are well visualized, the airway is classified as class I, and a relatively easy intubation can be anticipated. When the faucial pillars and soft palate (class II) or soft palate only (class III) are visible, there is a greater chance of problems visualizing the glottis during direct laryngoscopy. Difficulties in orotracheal intubation may also be anticipated if (a) the patient is an adult and cannot open his or her mouth more than 40 mm (two-finger breadths), (b) the distance from the thyroid notch to the mandible is less than three-finger breadths (less than or equal to 7 cm), (c) the patient has a high arched palate, or (d) the normal range of flexion–extension of the neck is decreased (less than or equal to 80 degrees) [9]. The positive predictive values of these tests alone or in combination are not particularly high; however, a straightforward intubation can be anticipated if the test results are negative [10]. In the emergency setting, only about 30% of airways can be assessed in this fashion [11]. A different evaluation method (LEMON) has been devised by Murphy and Walls [12]. LEMON stands for *l*ook, *e*valuate, *M*allampati class, *o*bstruction, and *n*eck mobility (Fig. 1.7). In the emergency setting, there are still limitations



L Look externally

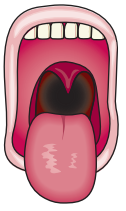
Look at the patient externally for characteristics that are known to cause difficult laryngoscopy, intubation or ventilation.

E Evaluate the 3-3-2 rule

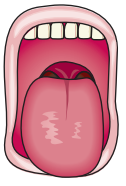


In order to allow alignment of the pharyngeal, laryngeal, and oral axes and therefore simple intubation, the following relationships should be observed. The distance between the patient's incisor teeth should be at least 3 finger breadths (3), the distance between the hyoid bone and the chin should be at least 3 finger breadths (3), and the distance between the thyroid notch and the floor of the mouth should be at least 2 finger breadths (2).

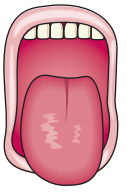
1 – Inter-incisor distance in fingers
2 – Hyoid mental distance in fingers
3 – Thyroid to floor of mouth in fingers



M Mallampati



The hypopharynx should be visualized adequately. This has been done traditionally by assessing the Mallampati classification. The patient is sat upright, told to open the mouth fully and protrude the tongue as far as possible. The examiner then looks into the mouth with a light torch to assess the degree of hypopharynx visible. In the case of a supine patient, Mallampati score can be estimated by getting the patient to open the mouth fully and protrude the tongue and a laryngoscopy light can be shone into the hypopharynx from above.



Class I: soft palate, uvula, fauces, pillars visible

Class II: soft palate, uvula, fauces visible

Class III: soft palate, base of uvula visible

Class IV: hard palate only visible

O Obstruction?

Any condition that can cause obstruction of the airway will make laryngoscopy and ventilation difficult. Such conditions are epiglottis, peritonsillar abscesses, and trauma.

N Neck mobility

This is a vital requirement for successful intubation. It can be assessed easily by getting the patient to place his or her chin down onto the chest and then to extend the neck so the patient is looking towards the ceiling. Patients in hard collar neck immobilization obviously have no neck movement and are therefore harder to intubate.

FIGURE 1.7. The LEMON airway assessment method. [From Reed MJ, Dunn MJ, McKeown DW: Can an airway assessment score predict difficulty at intubation in the emergency department? *Emerg Med J* 22(2):99–102, 2005, with permission.]

with the use of LEMON since it is difficult to ascertain the Mallampati class. Nonetheless, using elements of LEMON that could be incorporated into the emergency evaluation of patients, Reed et al. [13] found that large incisors, a reduced interincisor distance, and a reduced distance between the thyroid and floor of the mouth were associated with a limited laryngoscopic view in emergency department patients. Whenever possible, patients in need of elective and emergent airway management should be assessed for indicators of difficult mask ventilation as this may significantly influence the decision on the primary approach to airway management. In the largest analysis published to date, five independent predictors of impossible mask ventilation were identified by the authors; these include neck radiation changes, male sex, a diagnosis of sleep apnea, Mallampati class III or IV airway, and the presence of a beard [14]. Among these factors, neck radiation changes were the most significant predictor of impossible mask ventilation.

Education and Intubation Management

Emergent intubation in the acute care setting is associated with a high complication rate. It is therefore important to provide adequate training to practitioners working in this environment, and have an adequate number of trained personnel be available

to assist the operator. Furthermore, a standardized approach to emergency airway management can improve patient outcomes. Although training on a mannequin is an important first step in acquiring competency in performing endotracheal intubation, an investigation including nonanesthesia trainees has shown that approximately 50 supervised endotracheal intubations in the clinical setting are needed to achieve a 90% probability of competent performance [15]. Whenever possible, residents and licensed independent practitioners should be supervised by an attending physician trained in emergency airway management during the procedure. This approach has led to a significant reduction in immediate complications from 21.7% to 6.1% in one pre- and postintervention analysis [16].

In addition, the use of a management bundle consisting of interventions that, in isolation have been shown to decrease complications during emergency airway management can further improve patient outcomes. Elements that should be included in this approach are preoxygenation with noninvasive positive pressure ventilation (NIPPV) if feasible, presence of two operators, rapid sequence intubation (RSI) with cricoid pressure, capnography, lung protective ventilation strategies (LPVS), fluid loading prior to intubation unless contraindicated, and preparation and early administration of sedation and vasopressor use if needed [17].

EQUIPMENT FOR INTUBATION

Assembly of all appropriate equipment before attempted intubation can prevent potentially serious delays in the event of an unforeseen complication. Most equipment and supplies are readily available in the ICU but must be gathered so they are immediately at hand. A supply of 100% oxygen and a well-fitting mask with attached bag valve device are mandatory, as is suctioning equipment, including a large-bore tonsil suction attachment (Yankauer) and suction catheters. Adequate lighting facilitates airway visualization. The bed should be at the proper height, with the headboard removed and the wheels locked. Other necessary supplies include gloves, Magill forceps, oral and nasal airways, laryngoscope handle and blades (straight and curved), endotracheal tubes of various sizes, stylet, tongue depressors, a syringe for cuff inflation, and tape for securing the endotracheal tube in position. Table 1.2 is a checklist of supplies needed.

TABLE 1.2

EQUIPMENT NEEDED FOR INTUBATION

- Supply of 100% oxygen
- Face mask
- Bag valve device
- Suction equipment
  - Suction catheters
  - Large-bore tonsil suction apparatus (Yankauer)
- Stylet
- Magill forceps
- Oral airways
- Nasal airways
- Laryngoscope handle and blades (curved, straight; various sizes)
- Endotracheal tubes (various sizes)
- Tongue depressors
- Syringe for cuff inflation
- Headrest
- Supplies for vasoconstriction and local anesthesia
- Tape
- Tincture of benzoin

Laryngoscopes

The two-piece laryngoscope has a handle containing batteries that power the bulb in the blade. The blade snaps securely into the top of the handle, making the electrical connection. Failure of the bulb to illuminate suggests improper blade positioning, bulb failure, a loose bulb, or dead batteries. Modern laryngoscope blades with fiberoptic lights obviate the problem of bulb failure. Many blade shapes and sizes are available. The two most commonly used blades are the curved (MacIntosh) and straight (Miller) blades (Fig. 1.8). Although pediatric blades are available for use with the adult-sized handle, most anesthesiologists prefer a smaller handle for better control in the pediatric population. The choice of blade shape is a matter of personal preference and experience; however, one study has suggested that less force and head extension are required when performing direct laryngoscopy with a straight blade [18]. Recently, video assisted laryngoscopes have become widely available in many perioperative and acute care specialties. These have been shown to improve the success rate for difficult endotracheal intubation performed by experienced physicians [19], as well as the rate of successful intubation by untrained individuals when performing normal intubations [20]. Several online tutorials are available demonstrating the use of video laryngoscopes. Two of them can be found here: Turk M, Gravenstein D (2007): Storz DCI Video Laryngoscope. Retrieved March 15, 2010, from University of Florida Department of Anesthesiology, Center for Simulation, Advanced Learning and Technology Web site: http://vam.anest.ufl.edu/airwaydevice/storz/index.html and http://www.youtube.com/watch?v=WdooBCJ79Xc&NR=1. Hagberg has compiled an extensive list of commercially available videolaryngoscopes [21].

Endotracheal Tubes

The internal diameter of the endotracheal tube is measured using both millimeters and French units. This number is stamped on the tube. Tubes are available in 0.5-mm increments, starting at 2.5 mm. Lengthwise dimensions are also marked on the tube in centimeters, beginning at the distal tracheal end.

Selection of the proper tube diameter is of utmost importance and is a frequently underemphasized consideration. The resistance to airflow varies with the fourth power of the radius of the endotracheal tube. Thus, selection of an inappropriately small tube can significantly increase the work of breathing. Moreover, certain diagnostic procedures (e.g., bronchoscopy) done through endotracheal tubes require appropriately large tubes (see Chapter 9). In general, the larger the patient, the larger the endotracheal tube that should be used. Approximate guidelines for tube sizes and lengths by age are summarized in Table 1.3. Most adults should be intubated with an endotracheal tube that has an inner diameter of at least 8.0 mm, although occasionally nasal intubation in a small adult requires a 7.0-mm tube.

Endotracheal Tube Cuff

Endotracheal tubes have low-pressure, high-volume cuffs to reduce the incidence of ischemia-related complications. Tracheal ischemia can occur any time cuff pressure exceeds capillary pressure (approximately 32 mm Hg), thereby causing inflammation, ulceration, infection, and dissolution of cartilaginous rings. Failure to recognize this progressive degeneration sometimes results in erosion through the tracheal wall (into the

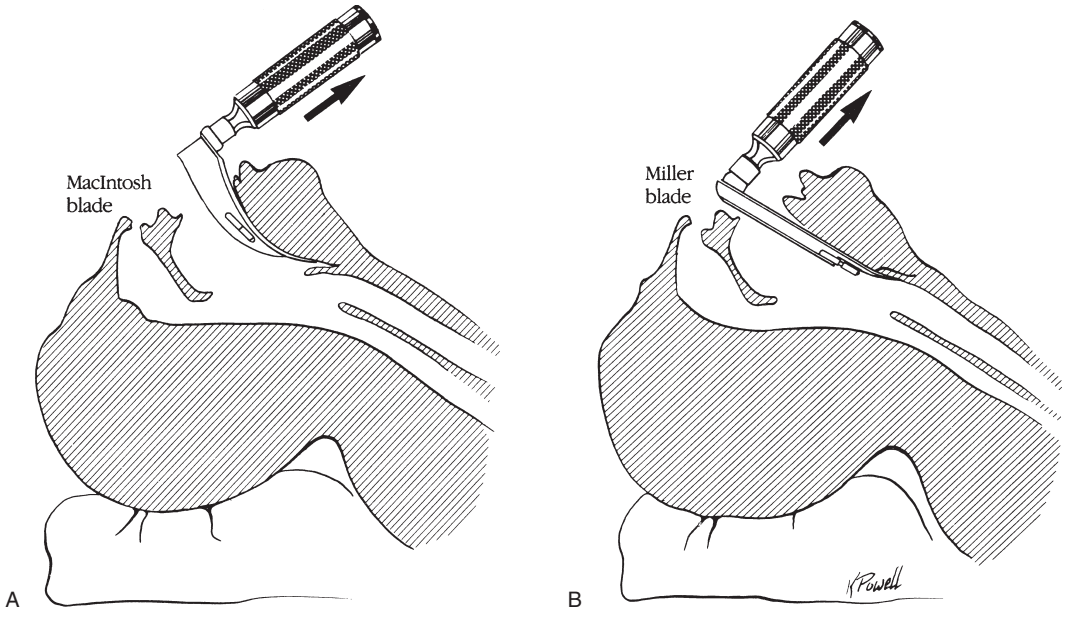


FIGURE 1.8. The two basic types of laryngoscope blades, MacIntosh (**A**) and Miller (**B**). The MacIntosh blade is curved. The blade tip is placed in the vallecula and the handle of the laryngoscope pulled forward at a 45-degree angle. This allows visualization of the epiglottis. The Miller blade is straight. The tip is placed posterior to the epiglottis, pinning the epiglottis between the base of the tongue and the straight laryngoscope blade. The motion on the laryngoscope handle is the same as that used with the MacIntosh blade.

innominate artery if the erosion was anterior or the esophagus if the erosion was posterior) or long-term sequelae of tracheomalacia or tracheal stenosis. With cuff pressures of 15 to 30 mm Hg, the low-pressure, high-volume cuffs conform well to the tracheal wall and provide an adequate seal during positive-pressure ventilation. Although low cuff pressures can cause some damage (primarily ciliary denudation), major complications are rare. Nevertheless, it is important to realize that a low-pressure, high-volume cuff can be converted to a high-pressure cuff if sufficient quantities of air are injected into the cuff.

ANESTHESIA BEFORE INTUBATION

Because patients who require intubation often have a depressed level of consciousness, anesthesia is usually not required. If intubation must be performed on the alert, responsive patient, sedation or general anesthesia exposes the individual to potential pulmonary aspiration of gastric contents because protective reflexes are lost. This risk is a particularly important consideration if the patient has recently eaten and must be

TABLE 1.3

DIMENSIONS OF ENDOTRACHEAL TUBES BASED ON PATIENT AGE

Age	Internal diameter (mm)	French unit	Distance between lips and location in midtrachea of distal end (cm)[a]
Premature	2.5	10–12	10
Full term	3.0	12–14	11
1–6 mo	3.5	16	11
6–12 mo	4.0	18	12
2 y	4.5	20	13

TABLE 1.4

DRUGS USED TO FACILITATE INTUBATION

Drug	IV dose (mg/kg)	Onset of action (sec)	Side effects
Induction drugs			
Thiopental	2.5–4.5	20–50	Hypotension
Propofol	1.0–2.5	<60	Pain on injection Hypotension
Midazolam	0.02–0.20	30–60	Hypotension
Ketamine	0.5–2.0	30–60	Increases in intracranial pressure Increase in secretions Emergence reactions
Etomidate	0.2–0.3	20–50	Adrenal insufficiency Pain on injection
Muscle relaxants			
Succinylcholine	1–2	45–60	Hyperkalemia Increased intragastric pressure Increased intracranial pressure
Rocuronium	0.6–1.0	60–90	—

weighed against the risk of various hemodynamic derangements that might occur secondary to tracheal intubation and initiation of positive-pressure ventilation. Laryngoscopy in an inadequately anesthetized patient can result in tachycardia and an increase in blood pressure. This may be well tolerated in younger patients but may be detrimental in a patient with coronary artery disease or raised intracranial pressure. Sometimes laryngoscopy and intubation may result in a vasovagal response, leading to bradycardia and hypotension. Initiation of positive-pressure ventilation in a hypovolemic patient can lead to hypotension from diminished venous return.

Some of these responses can be attenuated by providing local anesthesia to the nares, mouth, and/or posterior pharynx before intubation. Topical lidocaine (1% to 4%) with phenylephrine (0.25%) or cocaine (4%, 200 mg total dose) can be used to anesthetize the nasal passages and provide local vasoconstriction. This allows the passage of a larger endotracheal tube with less likelihood of bleeding. Aqueous lidocaine–phenylephrine or cocaine can be administered via atomizer, nose dropper, or long cotton-tipped swabs inserted into the nares. Alternatively, viscous 2% lidocaine can be applied via a 3.5-mm endotracheal tube or small nasopharyngeal airway inserted into the nose. Anesthesia of the tongue and posterior pharynx can be accomplished with lidocaine spray (4% to 10%) administered via an atomizer or an eutectic mixture of local anesthetics cream applied on a tongue blade and oral airway [22]. Alternatively, the glossopharyngeal nerve can be blocked bilaterally with an injection of a local anesthetic, but this should be performed by experienced personnel.

Anesthetizing the larynx below the vocal cords before intubation is controversial. The cough reflex can be compromised, increasing the risk of aspiration. However, tracheal anesthesia may decrease the incidence of arrhythmias or untoward circulatory responses to intubation and improve patient tolerance of the endotracheal tube. Clinical judgment in this situation is necessary. Several methods can be used to anesthetize these structures. Transtracheal lidocaine (4%, 160 mg) is administered by cricothyroid membrane puncture with a small needle to anesthetize the trachea and larynx below the vocal cords. Alternatively, after exposure of the vocal cords with the laryngoscope, the cords can be sprayed with lidocaine via an atomizer. Aerosolized lidocaine (4%, 6 mL) provides excellent anesthesia to the mouth, pharynx, larynx, and trachea [23]. The superior laryngeal nerve can be blocked with 2 mL of 1.0% to 1.5% lidocaine injected just inferior to the greater cornu of the hyoid bone. The rate of absorption of lidocaine differs by method, being greater with the aerosol and transtracheal techniques. The patient should be observed for signs of lidocaine toxicity (circumoral paresthesia, agitation, and seizures).

If adequate topical anesthesia cannot be achieved or if the patient is not cooperative, general anesthesia may be required for intubation. Table 1.4 lists common drugs and doses that are used to facilitate intubation. Ketamine and etomidate are two drugs that are used commonly because cardiovascular stability is maintained. Caution should be exercised when using etomidate in patients with signs and symptoms consistent with severe sepsis or septic shock. In an analysis of risk factors of relative adrenocortical deficiency in intensive care patients needing mechanical ventilation, single bolus etomidate administration was independently associated with relative adrenocortical deficiency [24]. Similarly, when studied for rapid sequence intubation in acutely ill patients both ketamine and etomidate provided adequate intubating conditions but the percentage of patients with adrenal insufficiency was significantly higher in the etomidate group [25]. Lastly, post hoc analysis of the corticosteroid therapy of septic shock study revealed an increased rate of death at 28 days among patients who received etomidate before randomization in both groups (hydrocortisone group and in the placebo group), as compared with patients who did not receive etomidate [26]. Taken together these findings warrant a careful analysis of risks and benefits before etomidate is used to facilitate endotracheal intubation in acutely ill patients with, or at risk for, severe sepsis.

Use of opioids such as morphine, fentanyl, sufentanil, alfentanil, or remifentanil allow the dose of the induction drugs to be reduced and may attenuate the hemodynamic response to laryngoscopy and intubation. Muscle relaxants can be used to facilitate intubation, but unless the practitioner has extensive experience with these drugs and airway management, alternative means of airway control and oxygenation should be used until an anesthesiologist arrives to administer the anesthetic and perform the intubation. Although the use of muscle relaxants is associated with improved laryngoscopy grade during intubation, their use may not be associated with a decrease in overall airway related complications, hypotension or hypoxemia.

Recent reviews have extolled the virtue of rapid sequence intubation (RSI) [27,28]: The process by which a drug such as etomidate, thiopental, ketamine, or propofol (Table 1.4) is administered to the patient to induce anesthesia and is followed

immediately by a muscle relaxant to facilitate intubation. Although numerous studies exist in the emergency medicine literature attesting to the safety and efficacy of this approach, the practitioner who embarks on this route to intubation in the ICU must be knowledgeable about the pharmacology and side effects of the agents used *and* the use of rescue methods should attempt(s) at intubation fail. Again, experience and an approached based on a validated algorithm will increase patient safety. In a recent analysis of 6,088 trauma patients undergoing emergency airway management in a single center over 10 years, intubation by anesthesiologists experienced in the management of trauma patients utilizing a modification of the American Society of Anesthesiologists difficult airway algorithm was very effective, resulting in a rate of surgical airway management in only 0.3% of patients included in the analysis [29].

TECHNIQUES OF INTUBATION

In a true emergency, some of the preintubation evaluation is necessarily neglected in favor of rapid control of the airway. Attempts at tracheal intubation should not cause or exacerbate hypoxia. Whenever possible, an oxygen saturation monitor should be used. Preoxygenation (denitrogenation), which replaces the nitrogen in the patient's functional residual capacity with oxygen, can maximize the time available for intubation. During laryngoscopy, apneic oxygenation can occur from this reservoir. Preoxygenation is achieved by providing 100% oxygen at a high flow rate via a tight-fitting face mask for 3.5 to 4.0 minutes. Extending the time of preoxygenation from 4 to 8 minutes does not seem to increase the PaO_2 to a clinically relevant extent and may actually reduce the PaO_2 in the interval from 6 to 8 minutes in some patients [30]. In patients who are being intubated for airway control, preoxygenation is usually efficacious; whereas, the value of preoxygenation in patients with acute lung injury is less certain [31]. Whenever possible, NIPPV should be utilized as the mode of preoxygenation prior to intubation of hypoxemic patients. This approach has been shown to be more effective than the standard approach in maintaining SpO_2 values before, during and even after the intubation procedure resulting [32]. In obese patients, use of the 25-degree head-up position improves the effectiveness of preoxygenation [33].

Just before intubation, the physician should assess the likelihood of success for each route of intubation, the urgency of the clinical situation, the likelihood that intubation will be prolonged, and the prospect of whether diagnostic or therapeutic procedures such as bronchoscopy will eventually be required. Factors that can affect patient comfort should also be weighed. In the unconscious patient in whom a secure airway must be established immediately, orotracheal intubation with direct visualization of the vocal cords is generally the preferred technique. In the conscious patient, direct laryngoscopy or awake fiberoptic intubation may be performed after adequate topicalization of the airway. Alternatively, blind nasotracheal intubation is an option but requires significant skill by the clinician. Nasotracheal intubation should be avoided in patients with coagulopathies or those who are anticoagulated for medical indications. In trauma victims with extensive maxillary and mandibular fractures and inadequate ventilation or oxygenation, cricothyrotomy may be mandatory (see Chapter 12). In patients with cervical spine injury or decreased neck mobility, intubation using the flexible bronchoscope or specialized laryngoscope (Bullard) may be necessary. Many of these techniques require considerable skill and should be performed only by those who are experienced in airway management [34].

Specific Techniques and Routes of Endotracheal Intubation

Orotracheal Intubation

Orotracheal intubation is the technique most easily learned and most often used for emergency intubations in the ICU. Traditional teaching dictates that successful orotracheal intubation requires alignment of the oral, pharyngeal, and laryngeal axes by putting the patient in the "sniffing position" in which the neck is flexed and the head is slightly extended about the atlanto-occipital joint. However, a magnetic resonance imaging (MRI) study has called this concept into question, as the alignment of these three axes could not be achieved in any of the three positions tested: neutral, simple extension, and the "sniffing position" [35]. In addition, a randomized study in elective surgery patients examining the utility of the sniffing position as a means to facilitate orotracheal intubation failed to demonstrate that such positioning was superior to simple head extension [36].

In a patient with a full stomach, compressing the cricoid cartilage posteriorly against the vertebral body can reduce the diameter of the postcricoid hypopharynx. This technique, known as *Sellick's maneuver*, may prevent passive regurgitation of stomach contents into the trachea during intubation [37]. However, an MRI study of awake volunteers demonstrated that the esophagus was lateral to the larynx in more than 50% of the subjects. Moreover, cricoid pressure *increased* the incidence of an unopposed esophagus by 50% and caused airway compression of greater than 1 mm in 81% of the volunteers [38]. These findings are in contrast to a more recent MRI study demonstrating that the location and movement of the esophagus is irrelevant to the efficacy of Sellick's maneuver to prevent gastric regurgitation into the pharynx. Of note, compression of the alimentary tract was demonstrated with midline and lateral displacement of the cricoid cartilage relative to the underlying vertebral body [39]. In addition, cadaver studies have demonstrated the efficacy of cricoid pressure [40] and clinical studies have shown that gastric insufflation with gas during mask ventilation is reduced when cricoid pressure is applied [41]. In aggregate, these data suggest that it is prudent to continue to use cricoid pressure in patients suspected of having full stomachs. In addition, placing the patient in the partial recumbent or reverse Trendelenburg position may reduce the risk of regurgitation and aspiration.

The laryngoscope handle is grasped in the left hand while the patient's mouth is opened with the gloved right hand. Often, when the head is extended in the unconscious patient, the mouth opens; if not, the thumb and index finger of the right hand are placed on the lower and upper incisors, respectively, and moved past each other in a scissor-like motion. The laryngoscope blade is inserted on the right side of the mouth and advanced to the base of the tongue, pushing it toward the left. If the straight blade is used, it should be extended below the epiglottis. If the curved blade is used, it is inserted in the vallecula.

With the blade in place, the operator should lift forward in a plane 45 degrees from the horizontal to expose the vocal cords (Figs. 1.2 and 1.8). This motion decreases the risk of the blade striking the upper incisors and either chipping or dislodging teeth. Both lips should be swept away from between the teeth and blade to avoid soft tissue damage. The endotracheal tube is then held in the right hand and inserted at the right corner of the patient's mouth in a plane that intersects with the laryngoscope blade at the level of the glottis. This prevents the endotracheal tube from obscuring the view of the vocal cords. The endotracheal tube is advanced through the vocal cords until the cuff just disappears from sight. The cuff is inflated with enough air

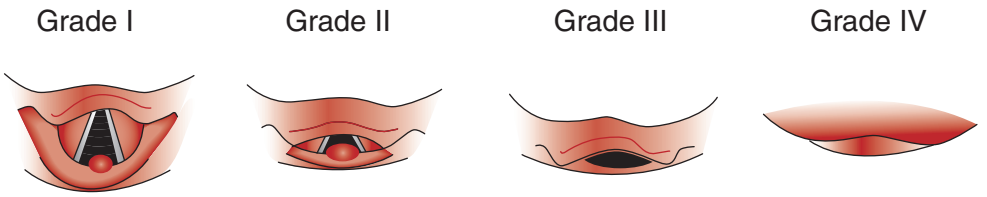

FIGURE 1.9. The four grades of laryngeal view during direct laryngoscopy. Grade I: the entire glottis is seen. Grade II: only the posterior aspect of the glottis is seen. Grade III: only the epiglottis is seen. Grade IV: the epiglottis is not visualized. [From Cormack RS, Lehane J: Difficult tracheal intubation in obstetrics. *Anaesthesia* 39:1105–1111, 1984, with permission.]

to prevent a leak during positive-pressure ventilation with a bag valve device.

A classification grading the view of the laryngeal aperture during direct laryngoscopy has been described [42] and is depicted in Figure 1.9. Occasionally, the vocal cords cannot be seen entirely; only the corniculate and cuneiform tubercles, interarytenoid incisure, and posterior portion of the vocal cords or only the epiglottis is visualized (grades II to IV view; Fig. 1.9). In this situation, it is helpful to insert the soft metal stylet into the endotracheal tube and bend it into a hockey-stick configuration. The stylet should be bent or coiled at the proximal end to prevent the distal end from extending beyond the endotracheal tube and causing tissue damage. The stylet should be lubricated to ensure easy removal. The BURP maneuver (*b*ackward–*u*pward–*r*ightward *p*ressure on the larynx) improves the view of the laryngeal aperture [43]. Alternatively, a control-tip endotracheal tube can be used. This tube has a nylon cord running the length of the tube attached to a ring at the proximal end, which allows the operator to direct the tip of the tube anteriorly. Another aid is a stylet with a light (light wand). With the room lights dimmed, the endotracheal tube containing the lighted stylet is inserted into the oropharynx and advanced in the midline. When it is just superior to the larynx, a glow is seen over the anterior neck. The stylet is advanced into the trachea, and the tube is threaded over it. The light intensity is diminished if the wand enters the esophagus [44]. The gum elastic bougie (flexible stylet) is another alternative device that can be passed into the larynx; once in place, the endotracheal tube is advance over it and the stylet is removed. Endotracheal tubes and stylets are now available that have a fiberoptic bundle intrinsic to the tube or the stylet that can be attached to a video monitor. If the attempt to intubate is still unsuccessful, the algorithm that is described in the Management of the Difficult Airway section should be followed.

Proper depth of tube placement is clinically ascertained by observing symmetric expansion of both sides of the chest and auscultating equal breath sounds in both lungs. The stomach should also be auscultated to ensure that the esophagus has not been entered. If the tube has been advanced too far, it will lodge in one of the main bronchi (particularly the right bronchus), and only one lung will be ventilated. If this error goes unnoticed, the nonventilated lung may collapse. A useful rule of thumb for tube placement in adults of average size is that the incisors should be at the 23-cm mark in men and the 21-cm mark in women [45]. Alternatively, proper depth (5 cm above the carina) can be estimated using the following formula: (height in cm/5) minus 13 [46]. Palpation of the anterior trachea in the neck may detect cuff inflation as air is injected into the pilot tube and can serve as a means to ascertain correct tube position. Measurement of end-tidal carbon dioxide by standard capnography if available or by means of a calorimetric chemical detector of end-tidal carbon dioxide (e.g., Easy Cap II, Nellcor, Inc., Pleasanton, CA) can be used to verify correct endotracheal tube placement or detect esophageal intubation. The latter device is attached to the proximal end of the endotracheal tube and changes color on exposure to carbon dioxide. An additional method to detect esophageal intubation uses a bulb that attaches to the proximal end of the endotracheal tube [47]. The bulb is squeezed. If the tube is in the trachea, the bulb reexpands, and if the tube is in the esophagus, the bulb remains collapsed. It must be remembered that none of these techniques is foolproof. Bronchoscopy is the only method to be absolutely sure the tube is in the trachea. After estimating proper tube placement clinically, it should be confirmed by chest radiograph or bronchoscopy because the tube may be malpositioned. The tip of the endotracheal tube should be several centimeters above the carina (T-4 level). It must be remembered that flexion or extension of the head can advance or withdraw the tube 2 to 5 cm, respectively.

Nasotracheal Intubation

Many of the considerations concerning patient preparation and positioning outlined for orotracheal intubation apply to nasal intubation as well. Blind nasal intubation is more difficult to perform than oral intubation, because the tube cannot be observed directly as it passes between the vocal cords. However, nasal intubation is usually more comfortable for the patient and is generally preferable in the awake, conscious patient. Nasal intubation should not be attempted in patients with abnormal bleeding parameters, nasal polyps, extensive facial trauma, cerebrospinal rhinorrhea, sinusitis, or any anatomic abnormality that would inhibit atraumatic passage of the tube.

As previously discussed in Airway Adjuncts section, after the operator has alternately occluded each nostril to ascertain that both are patent, a topical vasoconstrictor and anesthetic are applied to the nostril that will be intubated. The nostril may be dilated with lubricated nasal airways of increasing size to facilitate atraumatic passage of the endotracheal tube. The patient should be monitored with a pulse oximeter, and supplemental oxygen should be given as necessary. The patient may be either supine or sitting with the head extended in the sniffing position. The tube is guided slowly but firmly through the nostril to the posterior pharynx. Here the tube operator must continually monitor for the presence of air movement through the tube by listening for breath sounds with the ear near the open end of the tube. The tube must never be forced or pushed forward if breath sounds are lost, because damage to the retropharyngeal mucosa can result. If resistance is met, the tube should be withdrawn 1 to 2 cm and the patient's head repositioned (extended further or turned to either side). If the turn still cannot be negotiated, the other nostril or a smaller tube should be tried. Attempts at nasal intubation should be abandoned and oral intubation performed if these methods fail.

Once positioned in the oropharynx, the tube should be advanced to the glottis while listening for breath sounds through the tube. If breath sounds cease, the tube is withdrawn several centimeters until breath sounds resume, and the plane of entry is adjusted slightly. Passage through the vocal cords should be timed to coincide with inspiration. Entry of the tube into

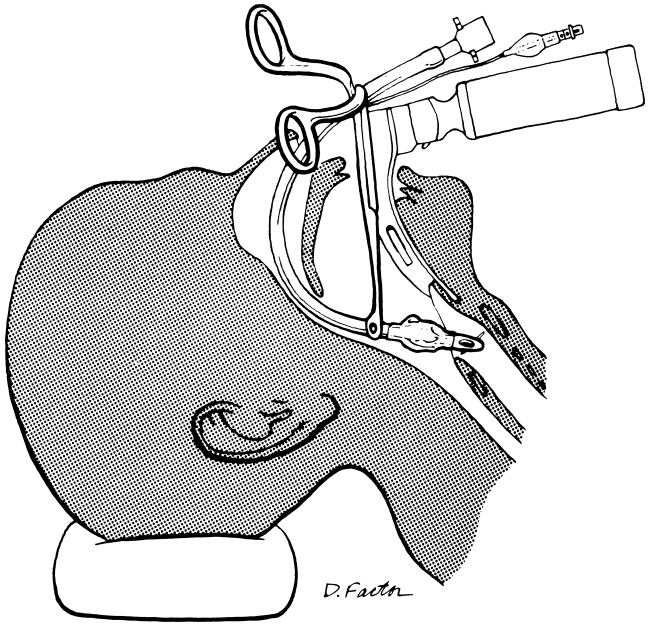

FIGURE 1.10. Magill forceps may be required to guide the endotracheal tube into the larynx during nasotracheal intubation. [From Barash PG, Cullen BF, Stoelting RK: *Clinical Anesthesia*. 2nd ed. Philadelphia, PA, JB Lippincott Co, 1992, with permission.]

the larynx is signaled by an inability to speak. The cuff should be inflated and proper positioning of the tube ascertained as previously outlined.

Occasionally, blind nasal intubation cannot be accomplished. In this case, after adequate topical anesthesia, laryngoscopy can be used to visualize the vocal cords directly and Magill forceps used to grasp the distal end of the tube and guide it through the vocal cords (Fig. 1.10). Assistance in pushing the tube forward is essential during this maneuver, so that the operator merely guides the tube. The balloon on the tube should not be grasped with the Magill forceps.

Occasionally, one may not be able to successfully place the endotracheal tube in the trachea. The technique of managing a difficult airway is detailed later.

Management of the Difficult Airway

A difficult airway may be recognized (anticipated) or unrecognized at the time of the initial preintubation airway evaluation. Difficulty managing the airway may be the result of abnormalities such as congenital hypoplasia, hyperplasia of the mandible or maxilla, or prominent incisors; injuries to the face or neck; acromegaly; tumors; and previous head and neck surgery. Difficulties ventilating the patient with a mask can be anticipated if two of the following factors are present: age older than 55 years, body mass index greater than 26 kg per m^2, beard, lack of teeth, and a history of snoring [48]. When a difficult airway is encountered, the algorithm as detailed in Figure 1.11

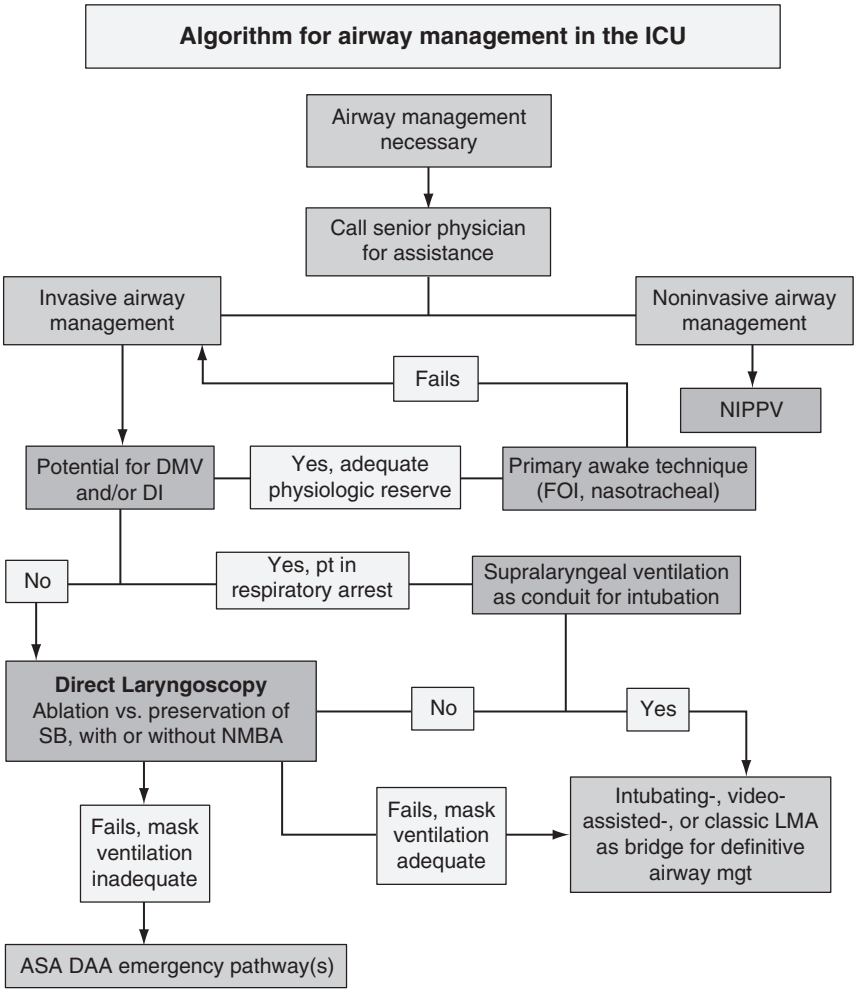

FIGURE 1.11. Modification of the difficult airway algorithm. ASA DAA, American Society of Anesthesiologists difficult airway algorithm; DMV, difficult mask ventilation; FOI, fiberoptic intubation; LMA, laryngeal mask airway; NIPPV, noninvasive positive pressure ventilation; NMBA, neuromuscular blocking agents; SB, spontaneous breathing. [From Walz JM, Zayaruzny M, Heard SO, et al. *Chest* 131(2):608–620, 2007, with permission.]

should be followed [49]. When a difficult airway is recognized before the patient is anesthetized, an awake tracheal intubation is usually the best option. Multiple techniques can be used and include (after adequate topical or local anesthesia) direct laryngoscopy, LMA (or variants), blind or bronchoscopic oral or nasal intubation, retrograde technique, rigid bronchoscopy, lighted stylet, or a surgical airway.

Flexible Bronchoscopic Intubation

Flexible bronchoscopy is an efficacious method of intubating the trachea in difficult cases. It may be particularly useful when the upper airway anatomy has been distorted by tumors, trauma, endocrinopathies, or congenital anomalies. This technique is sometimes valuable in accident victims in whom a question of cervical spine injury exists and the patient's neck cannot be manipulated. An analogous situation exists in patients with severe degenerative disk disease of the neck or rheumatoid arthritis with markedly impaired neck mobility. After adequate topical anesthesia is obtained as described in the section Anesthesia before Intubation, the bronchoscope can be used to intubate the trachea via either the nasal or oral route. An appropriately sized warmed and lubricated endotracheal tube that has been preloaded onto the bronchoscope is advanced through the vocal cords into the trachea and positioned above the carina under direct vision. The flexible bronchoscope has also been used as a stent over which endotracheal tubes are exchanged and as a means to assess tracheal damage periodically during prolonged intubations. (A detailed discussion of bronchoscopy is found in Chapter 9.) Intubation by this technique requires skill and experience and is best performed by a fully trained operator.

If the operator is able to maintain mask ventilation in a patient with an unrecognized difficult airway, a call for experienced help should be initiated (Fig. 1.11). If mask ventilation cannot be maintained, a cannot ventilate–cannot intubate situation exists and immediate lifesaving rescue maneuvers are required. Options include an emergency cricothyrotomy or insertion of a supraglottic ventilatory device, such as an LMA or a Combitube. (Puritan Bennett, Pleasanton, CA.)

Other Airway Adjuncts

The LMA is composed of a plastic tube attached to a shallow mask with an inflatable rim (Fig. 1.12). When properly inserted, it fits over the laryngeal inlet and allows positive-pressure ventilation of the lungs. Although aspiration can occur around the mask, the LMA can be lifesaving in a cannot ventilate–cannot intubate situation. An intubating LMA (LMA-Fastrach, LMA North America, Inc., San Diego, CA) has a shorter plastic tube and can be used to provide ventilation as well as to intubate the trachea with or without the aid of a flexible bronchoscope (Fig. 1.13). The Combitube (Puritan Bennett, Pleasanton, CA) combines the features of an endotracheal tube and an esophageal obturator airway and reduces the risk of aspiration. Personnel who are unskilled in airway management can easily learn how to use the LMA and the Combitube together [50].

Cricothyrotomy

In a truly emergent situation, when intubation is unsuccessful, a cricothyrotomy may be required. The technique is described in detail in Chapter 12. The quickest method, needle cricothyrotomy, is accomplished by introducing a large-bore

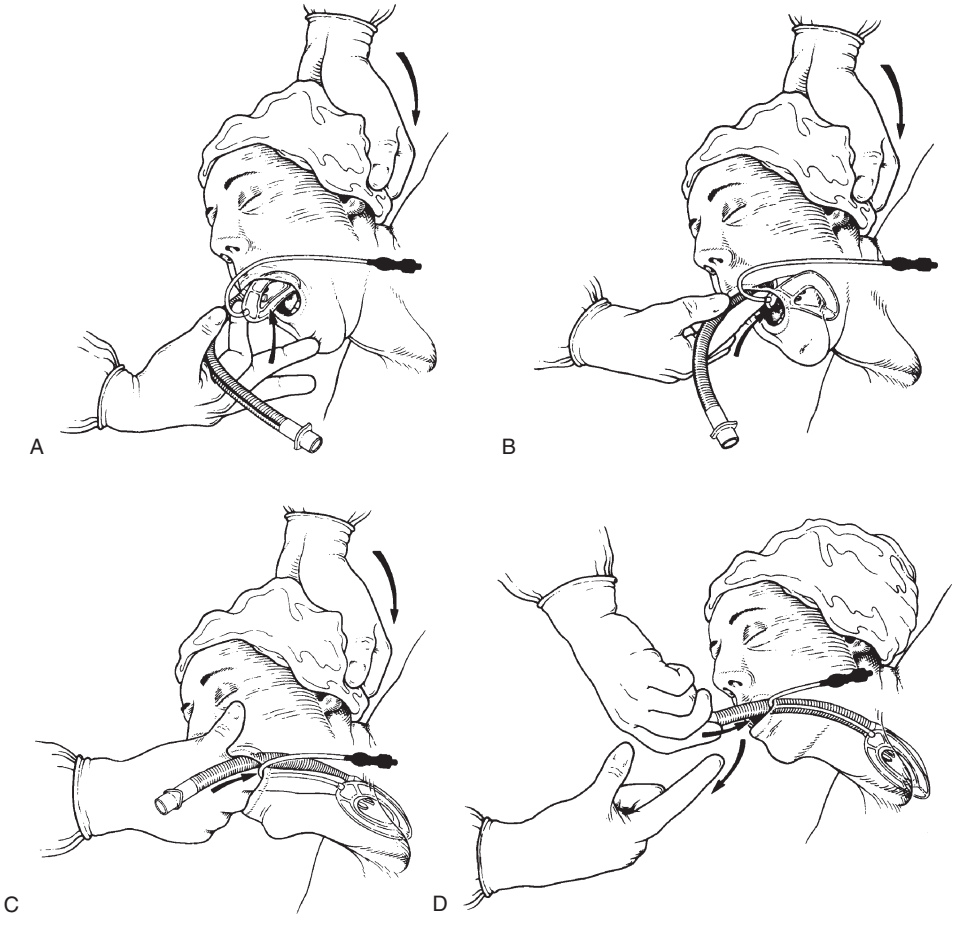

FIGURE 1.12. Technique for insertion of the laryngeal mask airway. [From Civetta JM, Taylor RW, Kirby RR: *Critical Care*. 3rd ed. Philadelphia, PA, Lippincott–Raven Publishers, 1997, with permission.]

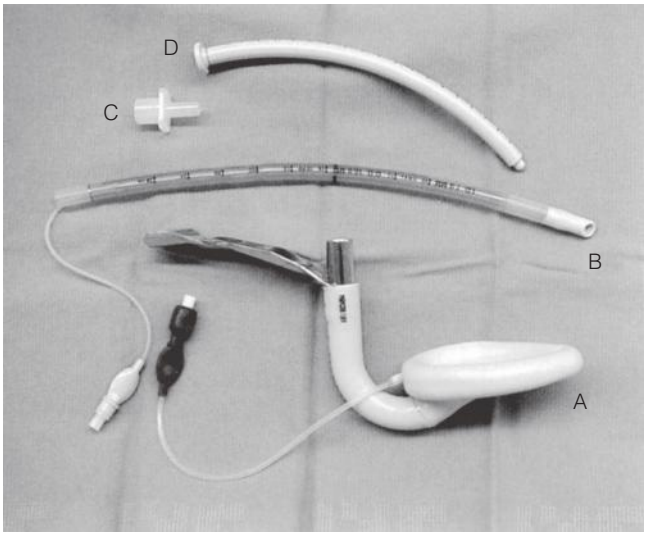

FIGURE 1.13. The laryngeal mask airway (LMA)-Fastrach (**A**) has a shorter tube than a conventional LMA. A special endotracheal tube (**B**) [without the adapter (**C**)] is advanced through the LMA-Fastrach into the trachea. The extender (**D**) is attached to the endotracheal tube, and the LMA-Fastrach is removed. After the extender is removed, the adapter is placed back on the tube.

(i.e., 14-gauge) catheter into the airway through the cricothyroid membrane while aspirating with a syringe attached to the needle of the catheter. When air is aspirated, the needle is in the airway and the catheter is passed over the needle into the trachea. The needle is attached to a high-frequency jet ventilation apparatus. Alternatively, a 3-mL syringe barrel can be connected to the catheter. Following this, a 7-mm inside diameter endotracheal tube adapter is fitted into the syringe and is connected to a high-pressure gas source or a high-frequency jet ventilator. An algorithm with suggestions for the management of the difficult airway is provided in Figure 1.11.

Management of the Airway in Patients with Suspected Cervical Spine Injury

Any patient with multiple trauma who requires intubation should be treated as if cervical spine injury were present. In the absence of severe maxillofacial trauma or cerebrospinal rhinorrhea, nasal intubation can be considered. However, in the profoundly hypoxemic or apneic patient, the orotracheal approach should be used. If oral intubation is required, an assistant should maintain the neck in the neutral position by ensuring axial stabilization of the head and neck as the patient is intubated [51]. A cervical collar also assists in immobilizing the cervical spine. In a patient with maxillofacial trauma and suspected cervical spine injury, retrograde intubation can be performed by puncturing the cricothyroid membrane with an 18-gauge catheter and threading a 125-cm Teflon-coated (0.025-cm diameter) guidewire through the catheter. The wire is advanced into the oral cavity, and the endotracheal tube is then advanced over the wire into the trachea. Alternatively, the wire can be threaded through the suction port of a 3.9-mm bronchoscope.

Airway Management in the Intubated Patient

Securing the Tube

Properly securing the endotracheal tube in the desired position is important for three reasons: (a) to prevent accidental extubation, (b) to prevent advancement into one of the main bronchi, and (c) to minimize damage to the upper airway, larynx, and trachea caused by patient motion. The endotracheal tube is usually secured in place with adhesive tape wrapped around the tube and applied to the patient's cheeks. Tincture of benzoin sprayed on the skin provides greater fixation. Alternatively, tape, intravenous (IV) tubing, or umbilical tape can be tied to the endotracheal tube and brought around the patient's neck to secure the tube. Care must be taken to prevent occlusion of neck veins. Other products (e.g., Velcro straps) to secure the tube are available. A bite block can be positioned in patients who are orally intubated to prevent them from biting down on the tube and occluding it. Once the tube has been secured and its proper position verified, it should be plainly marked on the portion protruding from the patient's mouth or nose so that advancement can be noted.

Cuff Management

Although low-pressure cuffs have markedly reduced the incidence of complications related to tracheal ischemia, monitoring cuff pressures remains important. The cuff should be inflated just beyond the point where an audible air leak occurs. Maintenance of intracuff pressures between 17 and 23 mm Hg should allow an adequate seal to permit mechanical ventilation under most circumstances while not compromising blood flow to the tracheal mucosa. The intracuff pressure should be checked periodically by attaching a pressure gauge and syringe to the cuff port via a three-way stopcock. The need to add air continually to the cuff to maintain its seal with the tracheal wall indicates that (a) the cuff or pilot tube has a hole in it, (b) the pilot tube valve is broken or cracked, or (c) the tube is positioned incorrectly, and the cuff is between the vocal cords. The tube position should be reevaluated to exclude the latter possibility. If the valve is broken, attaching a three-way stopcock to it will solve the problem. If the valve housing is cracked, cutting the pilot tube and inserting a blunt needle with a stopcock into the lumen of the pilot tube can maintain a competent system. A hole in the cuff necessitates a change of tube.

Tube Suctioning

A complete discussion of tube suctioning can be found in Chapter 62. Routine suctioning should not be performed in patients in whom secretions are not a problem. Suctioning can produce a variety of complications, including hypoxemia, elevations in intracranial pressure, and serious ventricular arrhythmias. Preoxygenation should reduce the likelihood of arrhythmias. Closed ventilation suction systems (Stericath) may reduce the risk of hypoxemia but have not been shown to reduce the rate of ventilator-associated pneumonia (VAP) compared to open suction systems [52].

Humidification

Intubation of the trachea bypasses the normal upper airway structures responsible for heating and humidifying inspired air. It is thus essential that inspired air be heated and humidified (see Chapter 62).

Tube Replacement

At times, endotracheal tubes may need to be replaced because of an air leak, obstruction, or other problems. Before attempting to change an endotracheal tube, one should assess how difficult it will be. After obtaining appropriate topical anesthesia or IV sedation and achieving muscle relaxation, direct laryngoscopy can be performed to ascertain whether there will be difficulties in visualizing the vocal cords. If the cords can be seen, the defective tube is removed under direct visualization and reintubation performed using the new tube. If the cords cannot be seen on

direct laryngoscopy, the tube can be changed over an airway exchange catheter (e.g., Cook Critical Care, Bloomington, IN) which allows insufflation of oxygen via either standard oxygen tubing or a bag valve device [53].

COMPLICATIONS OF ENDOTRACHEAL INTUBATION

Table 1.5 is a partial listing of the complications associated with endotracheal intubation. Factors implicated in the etiology of complications include tube size, characteristics of the tube and cuff, trauma during intubation, duration and route of intubation, metabolic or nutritional status of the patient, tube motion, and laryngeal motor activity.

During endotracheal intubation, traumatic injury can occur to any anatomic structure from the lips to the trachea. Possible complications include aspiration; damage to teeth and dental work; corneal abrasions; perforation or laceration of the pharynx, larynx, or trachea; dislocation of an arytenoid cartilage; retropharyngeal perforation; epistaxis; hypoxemia; myocardial ischemia; laryngospasm with noncardiogenic pulmonary edema; and death [5,54]. Many of these complications can be avoided by paying careful attention to technique and ensuring that personnel with the greatest skill and experience perform the intubation. Complications during endotracheal intubation vary according to the location of the patient in need of emergency airway management. Although the complication rates on the regular hospital floor and in the ICU appear to be high at around 28% for both locations, they can be modified with standardized algorithms as outlined previously. The most frequent complications encountered in these two settings are multiple intubation attempts and esophageal intubation in the general hospital units, and severe hypoxemia and hemodynamic collapse in the ICU. Presence of acute respiratory failure and presence of shock appear to be an independent risk factor for the occurrence of complications in the latter setting [55,56].

TABLE 1.5

COMPLICATIONS OF ENDOTRACHEAL INTUBATION

- Complications during intubation
  - Spinal cord injury
  - Excessive delay of cardiopulmonary resuscitation
  - Aspiration
  - Damage to teeth and dental work
  - Corneal abrasions
  - Perforation or laceration of
    - Pharynx
    - Larynx
    - Trachea
  - Dislocation of an arytenoid cartilage
  - Passage of endotracheal tube into cranial vault
  - Epistaxis
  - Cardiovascular problems
    - Ventricular premature contractions
    - Ventricular tachycardia
    - Bradyarrhythmias
    - Hypotension
    - Hypertension
    - Hypoxemia
  - Complications while tube is in place
    - Blockage or kinking of tube
    - Dislodgment of tube
    - Advancement of tube into a bronchus
    - Mechanical damage to any upper airway structure
    - Problems related to mechanical ventilation (see Chapter 58)
- Complications following extubation
  - Immediate complications
    - Laryngospasm
    - Aspiration
  - Intermediate and long-term complications
    - Sore throat
    - Ulcerations of lips, mouth, pharynx, or vocal cords
    - Tongue numbness (hypoglossal nerve compression)
    - Laryngitis
    - Vocal cord paralysis (unilateral or bilateral)
    - Laryngeal edema
    - Laryngeal ulcerations
    - Laryngeal granuloma
    - Vocal cord synechiae
    - Tracheal stenosis

Complications During Intubation

A variety of cardiovascular complications can accompany intubation. Ventricular arrhythmias have been reported in 5% to 10% of intubations. Ventricular tachycardia and ventricular fibrillation are uncommon but have been reported. Patients with myocardial ischemia are susceptible to ventricular arrhythmias, and lidocaine prophylaxis (100 mg IV bolus) before intubation may be warranted in such individuals. Bradyarrhythmias can also be observed and are probably caused by stimulation of the laryngeal branches of the vagus nerve. They may not require therapy but usually respond to IV atropine (1 mg IV bolus). Hypotension or hypertension can occur during intubation. In the patient with myocardial ischemia, short-acting agents to control blood pressure (nitroprusside, nicardipine) and heart rate (esmolol) during intubation may be needed.

Complications While the Tube is in Place

Despite adherence to guidelines designed to minimize damage from endotracheal intubation, the tube can damage local structures. Microscopic alterations to the surface of the vocal cords can occur within 2 hours after intubation. Evidence of macroscopic damage can occur within 6 hours. As might be expected, clinically significant damage typically occurs when intubation is prolonged. The sudden appearance of blood in tracheal secretions suggests anterior erosion into overlying vascular structures, and the appearance of gastric contents suggests posterior erosion into the esophagus. Both situations require urgent bronchoscopy, and it is imperative that the mucosa underlying the cuff be examined. Other complications include tracheomalacia and stenosis and damage to the larynx. Failure to secure the endotracheal tube properly or patient agitation can contribute to mechanical damage.

Another complication is blockage or kinking of the tube, resulting in compromised ventilation. Placing a bite block in the patient's mouth can minimize occlusion of the tube caused by the patient biting down on it. Suctioning can usually solve blockage from secretions, although changing the tube may be necessary.

Unplanned extubation and endobronchial intubation are potentially life threatening. Judicious use of sedatives and analgesics and appropriately securing and marking the tube should minimize these problems. Daily chest radiographs with the head always in the same position can be used to assess the position of the tube. Other complications that occur while the

tube is in position relate to mechanical ventilation (e.g., pneumothorax) and are discussed in detail in Chapter 58.

Complications After Extubation

Sore throat occurs after 40% to 100% of intubations. Using a smaller endotracheal tube may decrease the incidence of postextubation sore throat and hoarseness. Ulcerations of the lips, mouth, or pharynx can occur and are more common if the initial intubation was traumatic. Pressure from the endotracheal tube can traumatize the hypoglossal nerve, resulting in numbness of the tongue that can persist for 1 to 2 weeks. Irritation of the larynx appears to be due to local mucosal damage and occurs in as many as 45% of individuals after extubation. Unilateral or bilateral vocal cord paralysis is an uncommon but serious complication following extubation.

Some degree of laryngeal edema accompanies almost all endotracheal intubations. In adults, this is usually clinically insignificant. In children, however, even a small amount of edema can compromise the already small subglottic opening. In a newborn, 1 mm of laryngeal edema results in a 65% narrowing of the airway. Laryngeal ulcerations are commonly observed after extubation. They are more commonly located at the posterior portion of the vocal cords, where the endotracheal tube tends to rub. Ulcerations become increasingly common the longer the tube is left in place. The incidence of ulceration is decreased by the use of endotracheal tubes that conform to the anatomic shape of the larynx. Laryngeal granulomas and synechiae of the vocal cords are extremely rare, but these complications can seriously compromise airway patency. Surgical treatment is often required to treat these problems.

A feared late complication of endotracheal intubation is tracheal stenosis. This occurs much less frequently now that high-volume, low-pressure cuffs are routinely used. Symptoms can occur weeks to months after extubation. In mild cases, the patient may experience dyspnea or ineffective cough. If the airway is narrowed to less than 5 mm, the patient presents with stridor. Dilation may provide effective treatment, but in some instances surgical intervention is necessary.

EXTUBATION

The decision to extubate a patient is based on (a) a favorable clinical response to a carefully planned regimen of weaning from mechanical ventilation (see Chapter 60), (b) recovery of consciousness following anesthesia, or (c) sufficient resolution of the initial indications for intubation.

Technique of Extubation

The patient should be alert, lying with the head of the bed elevated to at least a 45-degree angle. The posterior pharynx must be thoroughly suctioned. The procedure is explained to the patient. The cuff is deflated, and positive pressure is applied to expel any foreign material that has collected above the cuff as the tube is withdrawn. Supplemental oxygen is then provided.

In situations in which postextubation difficulties are anticipated, equipment for emergency reintubation should be assembled at the bedside. Some clinicians have advocated the "leak test" as a means to predict the risk of stridor after extubation. The utility of this procedure is limited in routine practice, but for patients with certain risk factors (e.g., traumatic intubation, prolonged intubation, and previous accidental extubation), a leak volume of greater than 130 mL or 12% of the tidal volume has a sensitivity and specificity of 85% and 95%, respectively, for the development of postextubation stridor [57]. Probably the safest means to extubate the patient if there are concerns about airway edema or the potential need to reintubate a patient with a difficult airway is to use an airway exchange catheter. This device is inserted through the endotracheal tube, and then the tube is removed over the catheter. Supplemental oxygen can be provided via the catheter to the patient, and the catheter can be used as a stent for reintubation if necessary.

One of the most serious complications of extubation is laryngospasm, and it is more likely to occur if the patient is not fully conscious. The application of positive pressure can sometimes relieve laryngospasm. If this maneuver is not successful, a small dose of succinylcholine (by the IV or intramuscular route) can be administered. Succinylcholine can cause severe hyperkalemia in a variety of clinical settings; therefore, only clinicians who are experienced with its use should administer it. Ventilation with a mask and bag unit is needed until the patient has recovered from the succinylcholine.

Tracheostomy

The optimal time of conversion from an endotracheal tube to a tracheostomy remains controversial. The reader is referred to Chapter 12 for details on tracheostomy.

CHAPTER 2 ■ CENTRAL VENOUS CATHETERS

JASON LEE-LLACER AND MICHAEL G. SENEFF

The art and science of central venous catheter (CVC) insertion, maintenance, and management continues to evolve. Increased emphasis on patient safety and prevention of nosocomial complications has focused attention on the impact of CVCs on patient health. Catheter-related infection (CRI), often with a resistant organism such as methicillin-resistant *Staphylococcal aureus* or vancomycin-resistant *enterococci* (VRE) remains an important cause of increased patient morbidity and mortality, and it is simply inexcusable for institutions not to fully adapt proven protocols and procedures that have been shown to significantly reduce CRI and other catheter complications [1]. Patient safety is also the main impetus for increased availability of simulation laboratories [2,3] for operator training in the use of portable ultrasound [4,5] to facilitate catheter insertion. Insertion of CVCs is a procedure at the crossroads of the controversy of the need for training versus patient safety.

Training of physicians in the United States has been guided for years by the mantra "see one, do one, teach one," but this approach can no longer be defended as the best practice. Different institutions have developed different solutions, ranging from specially designated "catheter teams" responsible for all hospital-wide catheter insertions, to well equipped simulation laboratories that provide certification of competence and which have been shown to reduce subsequent clinical complications [2].

Because of the availability and relatively low cost of portable ultrasound units, many nonradiologists have been performing bedside image-guided central venous cannulation. Ultrasound guidance allows visualization of the vessel showing its precise location and patency in real time. It is especially useful for patients with suboptimal body habitus, volume depletion, shock, anatomic deformity, previous cannulation, underlying coagulopathy, and intravenous drug use. The use of ultrasound guidance has significantly decreased the failure rate, complication rate, and the number of attempts in obtaining central venous access and, as a result, has become routine in many centers [4,6]. Experts all over the world argue that ultrasound guidance should be viewed as standard of care for all CVC insertions, a recommendation met with resistance by many clinicians [6,7].

In 2001, the Agency for Healthcare Research and Quality Report listed bedside ultrasonography during central venous access as one of the "Top 11 Highly Proven" patient safety practices that are not routinely used in patient care, and it recommended all CVC insertions be guided by real-time, dynamic ultrasound [8]. The Third Sonography Outcomes Assessment Program (SOAP-3) trial, a concealed, randomized, controlled multicenter study, had an odds ratio 53.5 times higher for success with ultrasound guidance compared with the landmark technique. It also demonstrated a significantly lower average number of attempts and average time of catheter placement [9].

Given the existing data and recommendations, it appears no longer defensible to lack an active ultrasound training and utilization program in the intensive care unit (ICU). Ultrasound can be used in obtaining central venous access from multiple sites, especially the internal jugular and femoral veins (FV) [6,10]. Ultrasound has been less useful in cannulating the subclavian vein [11]. The subclavian vein is more difficult to access using ultrasound due to its deeper and posterior location to the clavicle which prevents the transmission of ultrasound waves. The subclavian vein may be accessed at the midpoint of the clavicle using a long-axis view or by a supraclavicular approach. Similarly, the infraclavicular axillary vein, which lies a few centimeters lateral to the subclavian vein, can be accessed with the short-axis ultrasound view [12].

Because of the success of ultrasound, some experts have argued for the complete elimination of all nonultrasound-guided CVC insertions. Although we recognize that even very experienced operators will benefit from ultrasound (if nothing else, by detection of anatomic variations and thrombosed vessels), it is not yet feasible to insist on 100% ultrasound availability. We also feel that there are still circumstances where standard subclavian catheterization is warranted and that this access site should not be abandoned. Therefore, it is important that one learns to obtain CVC via landmark techniques.

In this chapter, we review the techniques and complications of the various routes available for central venous catheterization, and present a strategy for catheter management that incorporates all of the recent advances.

INDICATIONS AND SITE SELECTION

Like any medical procedure, CVC has specific indications and should be reserved for the patient who has potential to benefit from it. After determining that CVC is necessary, physicians often proceed with catheterization at the site they are most experienced with, which might not be the most appropriate route in that particular patient. Table 2.1 lists general priorities in site selection for different indications of CVC; the final choice of site in a particular patient should vary based on individual institutional and operator experiences. In general, we recommend that all internal jugular and femoral vein cannulations

TABLE 2.1

INDICATIONS FOR CENTRAL VENOUS CATHETERIZATION (CVC)

Indication	Site selection		
	First	Second	Third
1. Pulmonary artery catheterization	RIJV	LSCV	LIJV
With coagulopathy	IJV	FV	
With pulmonary compromise or high-level positive end-expiratory pressure (PEEP)	RIJV	LIJV	EJV
2. Total parenteral nutrition (TPN)	SCV	IJV (tunneled)	
Long term (surgically implanted)	SCV	PICC	
3. Acute hemodialysis/plasmapheresis	IJV	FV	
4. Cardiopulmonary arrest	FV	SCV	IJV
5. Emergency transvenous pacemaker	RIJV	SCV	
6. Hypovolemia, inability to perform peripheral IV	IJV	SCV	FV
7. Preoperative preparation	IJV	SCV	AV/PICC
8. General purpose venous access, vasoactive agents, caustic medications, radiologic procedures	IJV	SCV	FV
With coagulopathy	IJV	EJV	FV
9. Emergency airway management	FV	SCV	IJV
10. Inability to lie supine	FV	EJV	AV/PICC
11. Central venous oxygen saturation monitoring	IJV	SCV	
12. Fluid management of ARDS (CVP monitoring)	IJV	EJV	SCV

AV, antecubital vein; EJV, external jugular vein; FV, femoral vein; IJV, internal jugular vein; L, left; PICC, peripherally inserted central venous catheter; R, right; SCV, subclavian vein. IJV and FV assume ultrasound guidance. see text for details.

be performed under ultrasound guidance. As noted earlier, we feel the traditional subclavian route offers many advantages for central access and should not be abandoned. However, only experienced operators should use the traditional infraclavicular approach; others should use ultrasound guidance with a modified approach that is described later.

Volume resuscitation alone is not an indication for CVC. A 2.5-inch, 16-gauge catheter used to cannulate a peripheral vein can infuse twice the amount of fluid as an 8-inch, 16-gauge CVC [13]. However, peripheral vein cannulation can be impossible in the hypovolemic, shocked individual. Previously, we recommended the subclavian vein (SCV) as the most reliable central site because it remains patent due to its fibrous attachments to the clavicle. But recently, use of real-time ultrasound-guided CVC placement by direct visualization of the internal jugular vein (IJV) has increased success rate and decreased complications in the shocked or hypovolemic patient [5,6].

Long-term total parenteral nutrition is best administered through SCV catheters, which should be inserted by interventional radiology or surgically implanted if appropriate. The IJV is the preferred site for acute hemodialysis, and the SCV should be avoided because of the relatively high incidence of subclavian stenosis following temporary dialysis, which then limits options for an AV fistula should long-term dialysis become necessary [14,15]. The FV is also suitable for acute short-term hemodialysis or plasmapheresis in nonambulatory patients [16].

Emergency trans-venous pacemakers and flow-directed pulmonary artery catheters are best inserted through the right IJV because of the direct path to the right ventricle. This route is associated with the fewest catheter tip malpositions. The SCV is an alternative second choice for pulmonary artery catheterization even in many patients with coagulopathy [17]. The left SCV is preferred to the right SV due to a less torturous route to the heart. The reader is referred to Chapter 4 for additional information on the insertion and care of pulmonary artery catheters.

Preoperative CVC is desirable in a wide variety of clinical situations. One specific indication for preoperative right ventricular catheterization is the patient undergoing a posterior craniotomy or cervical laminectomy in the sitting position. These patients are at risk for air embolism, and the catheter can be used to aspirate air from the right ventricle [18]. Neurosurgery is the only common indication for (but used only rarely) antecubital approach, as IJV catheters are in the operative field and theoretically can obstruct blood return from the cranial vault and increase intracranial pressure. Subclavian catheters are an excellent alternative for preoperative neurosurgical patients if pneumothorax is ruled out prior to induction of general anesthesia.

Venous access during cardiopulmonary resuscitation warrants special comment. Peripheral vein cannulation in circulatory arrest may prove impossible, and circulation times of drugs administered peripherally are prolonged when compared with central injection [19]. Drugs injected through femoral catheters also have a prolonged circulation time unless the catheter tip is advanced beyond the diaphragm, although the clinical significance of this is debated. Effective drug administration is an extremely important element of successful cardiopulmonary resuscitation, and all physicians should understand the appropriate techniques for establishing venous access. It is logical to establish venous access as quickly as possible, either peripherally or centrally if qualified personnel are present. Prolonged attempts at arm vein cannulation are not warranted, and under these circumstances, the FV is a good alternative. Despite the potential of longer drug circulation times, the FV is recommended for access in a code situation as cardiopulmonary resuscitation (CPR) is interrupted the least with its placement. If circulation is not restored after administration of appropriate drugs and defibrillation, central access should be obtained by the most experienced operator available with a minimum interruption of CPR. Emergency ultrasound-guided femoral CVC placement has been shown to be slightly faster with fewer complications than the landmark technique [20].

The placement of CVC is now common in patients with severe sepsis, septic shock, or acute respiratory distress syndrome (ARDS), to monitor central venous pressure (CVP) and central venous oxygen saturation ($ScvO_2$). Rivers showed a 16% absolute reduction of in-hospital mortality with early goal-directed therapy for patients with severe sepsis, which included keeping the $ScvO_2$ greater than 70% [21]. Early goal-directed therapy was subsequently shown to be achievable in "real-world" settings [22]. For these patients, the relationship between superior vena caval and inferior vena caval oxygen saturations has not been definitively elucidated [23]. Likewise, the ARDS network reported that CVP monitoring using a CVC is as effective as a pulmonary artery catheter in managing patients with acute lung injury and ARDS [24]. Because many of these patients are on high levels of positive end expiratory pressure (PEEP) and at high risk for complications from pneumothorax, IJV catheterization under ultrasound guidance represents the safest approach.

GENERAL CONSIDERATIONS AND COMPLICATIONS

General considerations for CVC independent of the site of insertion are the need for signed informed consent, insuring patient comfort and safety, ultrasound preparation, catheter tip location, vascular erosions, catheter-associated thrombosis, air and catheter embolism, and the presence of coagulopathy. Catheter-associated infection is reviewed separately.

Informed Consent

It seems intuitively obvious that a signed informed consent is mandatory before CVC insertion, but in clinical practice, it is not that straightforward. CVC insertions in the ICU are extremely common, occur at all hours of the day, and may be crucial for early and appropriate resuscitation and commencement of care. Many critically ill patients, especially in urban settings, have no available family members or legal net of kin. Obtaining informed consent for these patients may inappropriately delay completion of the procedure and impact quality of care. Because of these considerations, there is no uniform clinical or legal opinion regarding the necessity of individual informed consent prior to all CVC insertions or other ICU procedures [25]. Some institutions have dealt with this matter by developing a single general "consent form for critical care" that is signed one time for each individual ICU admission and covers all commonly performed bedside procedures. A recent review reported that 14% of all surveyed ICUs used such a consent form, and overall consent practice varied widely. In general, providers in medical ICUs sought consent for CVC insertion more often than providers in surgical ICUs [25]. Given the lack of agreement on this topic, it seems prudent to make a few recommendations: (1) Written informed consent should be obtained prior to all truly elective CVC insertion or other procedures (2). Whenever possible, competent patients or legal next of kin of incompetent/incapacitated patients should be thoroughly informed of the indications, risks, and benefits of emergency CVC insertion prior to the performance of the procedure. If informed consent is not possible prior to CVC insertion, then consent should be obtained as soon as possible after completion of the procedure. A signed consent form

is always preferable, but sometimes not feasible. Oral consent should be documented in the procedure note by the person obtaining assent. (3) Emergent CVC placement should not be delayed inappropriately by efforts to obtain consent—oral or written. Patients and family should be told as soon as possible after insertion why the CVC was required. (4) A general consent form that is signed one time as close as possible to ICU admission is a reasonable way to try and inform patients of the benefits/risks of procedures without incurring unnecessary delays or consumption of clinical time. This form can also serve as a useful reference for patients and families of all the various common procedures that are performed in the ICU. (5) Finally, it is good practice to document the practice that is used in the ICU "Policies and Procedures" book and the rationale for it.

Patient Comfort and Safety

Many patients requiring CVC have an unstable airway or are hemodynamically unstable. These considerations should impact preparation and choice of site. For example, many patients are claustrophobic and will not tolerate their face being covered; others who are dyspneic will not tolerate lying flat. In our experience, significant physiologic decompensation or even "code blues" may occur during CVC placement because the operator is focused on establishing access and/or interprets the silent patient as one who is having no problems. Every patient should be specifically assessed prior to CVC regarding their positioning, airway, and hemodynamic stability. On more than one occasion, we have placed a femoral catheter because a patient could not lie flat or needed emergency venous access for endotracheal intubation. Once the patient is stabilized, the appropriate site/catheter can then be inserted under less unstable/rigorous conditions.

Ultrasound Preparation

Ultrasound enables immediate identification of anatomic variation, confirmation of vessel patency, and direct visualization of the needle entering the vessel. The difference between vein and artery can be determined by compressibility, shape, Doppler flow, and increasing size with the Valsalva or other maneuvers. Veins are usually ovoid in shape, completely compressible, and have thin walls; in contrast, arteries are circular, difficult to compress, and have thick walls.

When performing ultrasound, the same general technique is followed regardless of the site of puncture [6]. A quick, nonsterile survey should be made with the vascular probe to quickly identify the presence of a suitable vein for catheterization. After sterile preparation of the patient and site, the vascular probe should be used with a sterile probe cover kit. This kit contains a sterile sleeve, sterile jelly, and rubber bands. To apply the sterile sleeve, have an assistant place nonsterile jelly inside the sleeve and then place probe in the sleeve. Extend the sleeve over the cord and fasten the sleeve with rubber bands. One band should be fastened toward the head of the probe to ensure the jelly remains in place for optimal imaging. Sterile jelly is then applied to the tip of probe on the outside of sleeve.

The target vessels may be visualized using a transverse or longitudinal view. The transverse approach is technically easier than the longitudinal approach and is the best approach for beginners. The transverse view allows identification of the target vein in relation to the artery, which helps decrease risk of unintentional puncture of the artery. Once identified, the vein should be centered underneath the probe. An 18-gauge needle should slowly be advanced with the skin puncture site proximal to the probe, so that vessel puncture is directly visualized. With this approach, the needle traverses diagonally across the ultrasound plane and appears as single bright echogenic foci on ultrasound image. Needle position may be better ascertained by slightly moving the needle back and forth displacing the surrounding soft tissue and possible tenting of vessel wall. It is important to note the depth of the vessel on the ultrasound image to be mindful of how far to penetrate safely with the needle. The return of blood flow confirms intravascular placement of the needle tip, and CVC placement may proceed in the usual fashion. It is good practice to confirm guidewire placement within the vein as well. The longitudinal approach gives more information but is more difficult. When using the longitudinal approach, the plane of the ultrasound and of the needle must be perfectly aligned and is best for one operator to be holding both probe and needle. First, the vein artery must be visualized using the transverse view. The probe should then be turned 90 degrees to image just the vein in the long-axis view. Enter the skin just adjacent to the probe at a 45-degree angle. The needle and needle tip can be directly viewed as it is advanced through the vessel. Once in place, advance the guidewire under direct visualization.

Mobile Catheter Cart

Availability of a mobile catheter cart that contains all necessary supplies and that can be wheeled to the patient's bedside is good practice and likely reduces overall catheter infection rate by decreasing breaks in sterile technique [26]. In our experience, the mobile cart is also an excellent way to standardize all catheter insertions, facilitate communication of procedural tasks (such as use of a time-out), and allow for staff to timely complete mandatory forms.

Catheter Tip Location

Catheter tip location is a very important consideration in CVC placement. The ideal location for the catheter tip is the distal innominate or proximal superior vena cava (SVC), 3 to 5 cm proximal to the caval–atrial junction. Positioning of the catheter tip within the right atrium or right ventricle should be avoided. Cardiac tamponade secondary to catheter tip perforation of the cardiac wall is uncommon, but two thirds of patients suffering this complication die [27]. Perforation likely results from vessel wall damage from infused solutions combined with catheter tip migration that occurs from the motion of the beating heart as well as patient arm and neck movements. Migration of catheter tips can be impressive: 5 to 10 cm with antecubital catheters and 1 to 5 cm with IJV or SCV catheters [28,29]. Other complications from intracardiac catheter tip position include provocation of arrhythmias from mechanical irritation and infusion of caustic medications or unwarmed blood [30].

Correct placement of the catheter tip is relatively simple, beginning with an appreciation of anatomy. The caval–atrial junction is approximately 16 to 18 cm from right-sided skin punctures and 19 to 21 cm from left-sided insertions and is relatively independent of patient gender and body habitus [31,32]. Insertion of a standard 20-cm triple-lumen catheter to its full length frequently places the tip within the heart, especially following right-sided insertions. A chest radiograph should be obtained following every initial CVC insertion to ascertain catheter tip location and to detect complications. The right tracheobronchial angle is the most reliable landmark on plain film chest X-ray for the upper margin of the SVC, and is always at least 2.9 cm above the caval–atrial junction. The catheter tip should lie about 1 cm below this landmark, and above the right upper cardiac silhouette to ensure placement outside of the pericardium [33].

Vascular Erosions

Large-vessel perforations secondary to CVCs are uncommon and often not immediately recognized. Vessel perforation typically occurs 1 to 7 days after catheter insertion. Patients usually present with sudden onset of dyspnea and often with new pleural effusions on chest radiograph [34]. Catheter stiffness, position of the tip within the vessel, and the site of insertion are important factors causing vessel perforation. The relative importance of these variables is unknown. Repeated irritation of the vessel wall by a stiff catheter tip or infusion of hyperosmolar solutions may be the initiating event. Vascular erosions are more common with left IJV and EJV catheters, because for anatomical reasons the catheter tip is more likely to be positioned laterally under tension against the SVC wall [35]. Positioning of the catheter tip within the vein parallel to the vessel wall must be confirmed on chest radiograph. Free aspiration of blood from one of the catheter ports is not always sufficient to rule out a vascular perforation.

Air and Catheter Embolism

Significant air and catheter embolism are rare and preventable complications of CVC. Catheter embolism can occur at the time of insertion when a catheter-through- or over-needle technique is used and the operator withdraws the catheter without simultaneously retracting the needle. It more commonly occurs with antecubital or femoral catheters after insertion, because they are prone to breakage when the agitated patient vigorously bends an arm or leg. Prevention, recognition, and management of catheter embolism are covered in detail elsewhere [36].

Air embolism is of greater clinical importance, often goes undiagnosed, and may prove fatal. This complication is totally preventable with compulsive attention to proper catheter insertion and maintenance. Factors resulting in air embolism during insertion are well known, and methods to increase venous pressure, such as use of the Trendelenburg position, should not be forgotten. Catheter disconnection and passage of air through a patent tract after catheter removal are more common causes of catheter-associated air embolism. An air embolus should be suspected in any patient with an indwelling or recently discontinued CVC who develops sudden unexplained hypoxemia or cardiovascular collapse, often after being moved or transferred out of bed. A characteristic mill wheel sound may be auscultated over the precordium. Treatment involves placing the patient in the left lateral decubitus position and using the catheter to aspirate air from the right ventricle. Hyperbaric oxygen therapy to reduce bubble size has a controversial role in treatment [37]. The best treatment is prevention which can be effectively achieved through comprehensive nursing and physician-in-training educational modules and proper supervision of inexperienced operators [38].

Coagulopathy

Central venous access in the patient with a bleeding diathesis can be problematic. The SCV and IJV routes have increased risks in the presence of coagulopathy, but the true risk is frequently overestimated and it is not known at what degree of abnormality it becomes unacceptable. A coagulopathy is generally defined as an international normalized ratio (INR) greater than 1.5 or platelet count less than 50,000. Although it is clear that safe venipuncture is possible (even with the subclavian approach) with greater degrees of coagulopathy [39], the literature is also fraught with case reports of serious hemorrhagic complications. In patients with severe coagulopathy, IJV cannulation under ultrasound guidance has proven to be very safe, while the FV offers a viable alternative for general-purpose venous access. In nonemergent patients, peripherally inserted central venous catheters (PICC) can be used.

Thrombosis

Catheter-related thrombosis is very common but usually of little clinical significance. The spectrum of thrombotic complications includes a fibrin sleeve surrounding the catheter from its point of entry into the vein distal to the tip, mural thrombus, a clot that forms on the wall of the vein secondary to mechanical or chemical irritation, or occlusive thrombus, which blocks flow and may result in collateral formation. All of these lesions are usually clinically silent; therefore, studies that do not use venography or color flow Doppler imaging to confirm the diagnosis underestimate its incidence. Using venography, fibrin sleeve formation can be documented in a majority of catheters, mural thrombi in 10% to 30%, and occlusive thrombi in 0% to 10% [40–45]. In contrast, clinical symptoms of thrombosis occur in only 0% to 3% of patients. The incidence of thrombosis probably increases with duration of catheterization but does not appear reliably related to the site of insertion. However, the clinical importance of femoral vein catheter-associated thrombosis compared to upper extremity thrombosis caused by IJ and SCV catheters is unknown [46]. The presence of catheter-associated thrombosis is also associated with a higher incidence of infection [47].

ROUTES OF CENTRAL VENOUS CANNULATION

Antecubital Approach

The antecubital veins are used in the ICU for CVC with PICC and midline catheters. Use of PICCs in critically ill adults is becoming increasingly important. Specialized nursing teams are now able to insert PICCs at beside with use of real-time ultrasonography and sterile technique thereby increasing safety and reducing the potential for infection. There are now triple lumen catheters that may be inserted with this approach. PICCs may be useful in ICU patients undergoing neurosurgery, with coagulopathy, or in the rehabilitative phase of critical illness for which general purpose central venous access is required for parenteral nutrition or long-term medication access (Table 2.1) [48,49]. Although many hospitals have a designated “PICC” insertion team, they may have significant work hour limitations that delay insertion of catheters and result in significant delays in delivery of care or throughput. For that reason, we believe intensivists should be familiar with the antecubital route, and as a result, the technique of percutaneous insertion of catheters using the basilic vein is described later.

Anatomy

The basilic vein is preferred for CVC because it is almost always of substantial size and the anatomy is predictable. The basilic vein provides an unimpeded path to the central venous circulation via the axillary vein [50,51]. The basilic vein is formed at the ulnar aspect of the dorsal venous network of the hand. It may be found in the medial part of the antecubital fossa, where it is usually joined by the median basilic vein. It then ascends in the groove between the biceps brachii and pronator teres on the medial aspect of the arm to perforate the deep fascia distal to the midportion of the arm, where it joins the brachial vein to become the axillary vein.

Technique of Cannulation

Several kits are available for antecubital CVC. The PICC and midline catheters are made of silicone or polyurethane and, depending on catheter stiffness and size, are usually placed through an introducer. The method described below is for a PICC inserted through a tear-away introducer.

The success rates from either arm are comparable, though the catheter must traverse a greater distance from the left. With the patient's arm at his or her side, the antecubital fossa is prepared with chlorhexidine and draped using maximum barrier precautions (mask, cap and sterile gown, gloves and large drape covering the patient). A tourniquet is placed proximally by an assistant and a portable ultrasound device used to identify the basilic or its main branches. A vein can be distinguished from an artery by visualizing compressibility, color flow, and Doppler flow (Fig. 2.1). After a time-out and administration of local anesthesia subcutaneously, venipuncture is performed with the thin wall entry needle a few centimeters proximal to the antecubital crease to avoid catheter breakage and embolism. When free backflow of venous blood is confirmed, the tourniquet is released and the guidewire carefully threaded into the vein for a distance of 15 to 20 cm. Leaving the guidewire in place, the thin-wall needle is withdrawn and the puncture site enlarged with a scalpel blade. The sheath-introducer assembly is threaded over the guidewire with a twisting motion, and the guidewire removed. Next, leaving the sheath in place, the dilator is removed, and the introducer is now ready for PICC insertion. The length of insertion is estimated by measuring the distance along the predicted vein path from the venipuncture site to the manubriosternal junction, using the measuring tape provided in the kit. The PICC is typically supplied with an inner obturator that provides stiffness for insertion. The PICC is trimmed to the desired length and flushed with saline and the obturator is inserted into the PICC up to the tip. The PICC/obturator assembly is inserted through the introducer to the appropriate distance, the introducer peeled away, and the obturator removed. The PICC is secured in place and a chest X-ray obtained to determine tip position.

If resistance to advancing the PICC is met, options are limited. Techniques such as abducting the arm are of limited value. If a catheter-through- or over-needle device has been used, the catheter must never be withdrawn without simultaneously retracting the needle to avoid catheter shearing and embolism. If the catheter cannot be advanced easily, another site should be chosen.

FIGURE 2.1. Ultrasound view of the basilica vein at the antecubital fossa.

Success Rate and Complications

Using the above-mentioned technique, PICC catheters have a 75% to 95% successful placement rate. Overall, PICCs appear to be at least as safe as CVCs, but important complications include sterile phlebitis, thrombosis (especially of the SCV and IJV), infection, limb edema, and pericardial tamponade. Phlebitis may be more common with antecubital CVCs, probably due to less blood flow in these veins as well as the proximity of the venipuncture site to the skin [52,53]. The risk of pericardial tamponade may also be increased if the catheter tip is inserted too deep because of greater catheter tip migration occurring with arm movements [54]. Complications are minimized by strict adherence to recommended techniques for catheter placement and care.

Internal Jugular Approach

The IJV has been used for venous access in pediatric and adult patients for many years but its use in some circumstances has been limited by a relatively lower rate of success due to its compressibility and propensity to collapse in hypovolemic conditions. In our opinion, ultrasound has had its greatest impact by improving the efficiency of IJV cannulation, since real-time direct visualization of the vein is easily obtained. This minimizes the impact of hypovolemia or anatomical variations on overall success, and has rendered the need for EJV catheterization almost extinct. Furthermore, under ultrasound guidance, the central approach is almost always used, and as a result, we will no longer review the anterior or posterior approaches. In general, these techniques will differ only in the point of skin puncture (Fig. 2.2), and readers are referred to previous editions of this text for a thorough description of these approaches.

Anatomy

The IJV emerges from the base of the skull through the jugular foramen and enters the carotid sheath dorsally with the internal carotid artery (ICA). It then courses posterolaterally to the artery and runs beneath the sternocleidomastoid (SCM) muscle. The vein lies medial to the anterior portion of the SCM muscle superiorly and then runs beneath the triangle formed by the two heads of the muscle in its medial portion before entering the SCV near the medial border of the anterior scalene muscle at the sternal border of the clavicle. The junction of the right IJV (which averages 2 to 3 cm in diameter) with the right SCV forming the innominate vein follows a straight path to the SVC. As a result, catheter malposition and looping of the catheter inserted through the right IJV are unusual. In contrast, a catheter passed through the left IJV must negotiate a sharp turn at the left jugulosubclavian junction, which results in a greater percentage of catheter malpositions [55]. This sharp turn may also produce tension and torque at the catheter tip, resulting in a higher incidence of vessel erosion.

Knowledge of the structures neighboring the IJV is essential as they may be compromised by a misdirected needle. The ICA runs medial to the IJV but, rarely, may lie directly posterior or, rarely, anterior. Behind the ICA, just outside the sheath, lie the stellate ganglion and the cervical sympathetic trunk. The dome of the pleura, which is higher on the left, lies caudal to the junction of the IJV and SCV. Posteriorly, at the root of the neck, course the phrenic and vagus nerves. The thoracic duct lies posterior to the left IJV and enters the superior margin of the SCV near the jugulosubclavian junction. The right lymphatic duct has the same anatomical relationship but is much smaller,

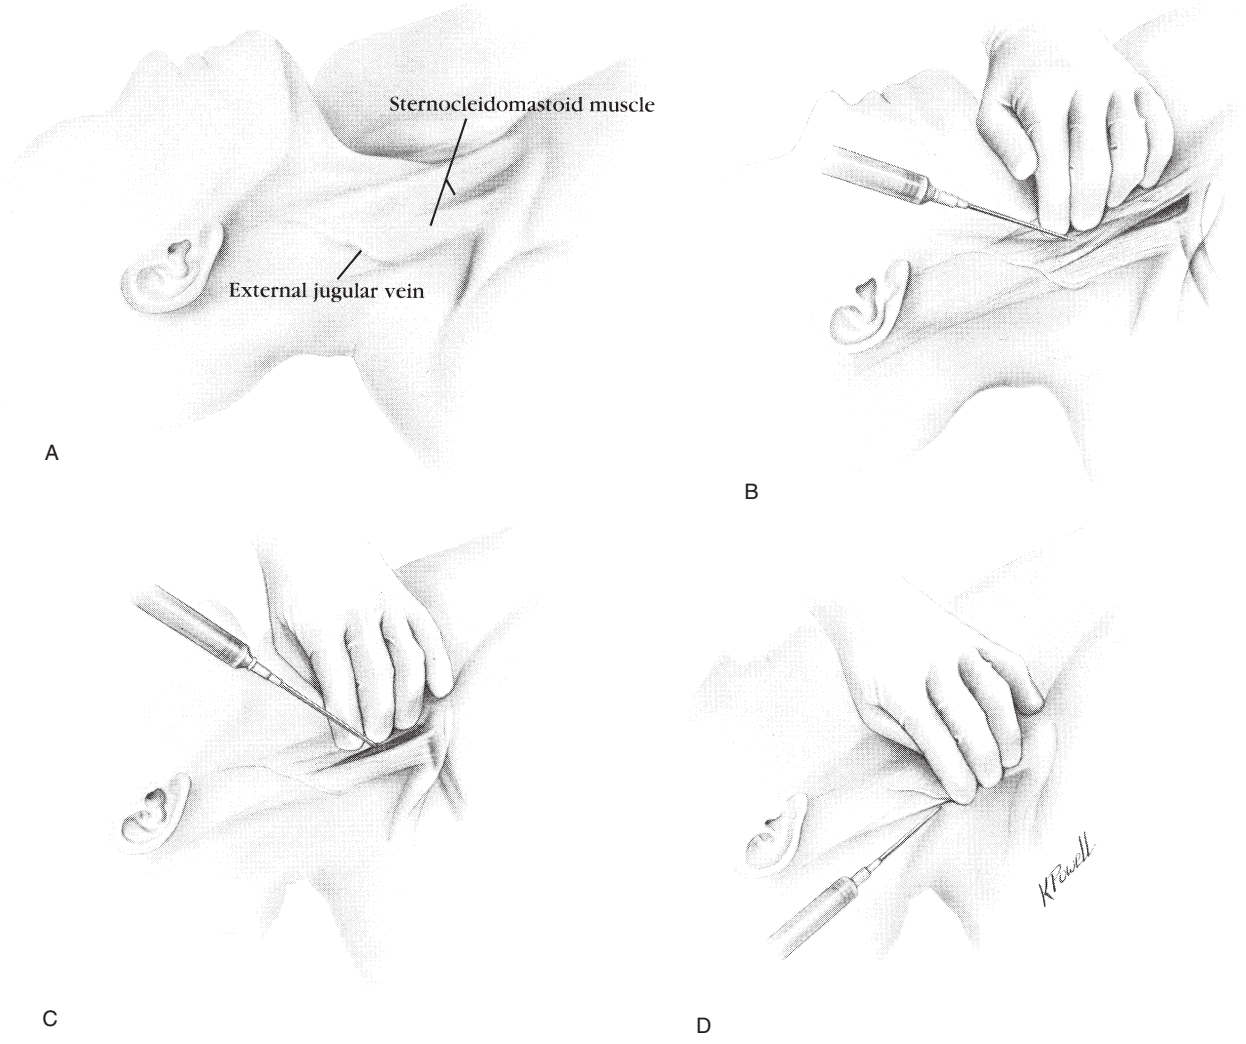

FIGURE 2.2. Surface anatomy and various approaches to cannulation of the internal jugular vein. **A:** Surface anatomy. **B:** Anterior approach. **C:** Central approach. **D:** Posterior approach. The external jugular vein is also shown.

and chylous effusions typically occur only with left-sided IJV cannulations.

Technique of Cannulation

With careful preparation of equipment and attention to patient comfort and safety as described earlier, the patient is placed in a 15-degree Trendelenburg position to distend the vein and minimize the risk of air embolism. The head is turned gently to the contralateral side. The surface anatomy is identified, especially the angle of the mandible, the two heads of the SCM, the clavicle, the EJV, and the trachea (Fig. 2.2). We recommend preliminary ultrasound examination of the IJV before skin preparation to quickly identify anatomical variations and suitability for catheterization. The probe should initially be placed in the center of the triangle formed by the clavicle and two heads of the SCM. If on the ultrasound the IJV is very small, thrombosed, or there is a significant anatomical variant, it is best to choose another site since successful cannulation is directly dependent on cross-sectional luminal size of the vessel. The neck is then prepared with chlorhexidine and fully draped, using maximum barrier precautions. Before the procedure is begun, a time-out is performed.

The IJV is usually readily identified by ultrasound (Fig. 2.3), and if the anatomy is normal and the IJV of substantial size, use of a finder needle is not required. The operator can directly visualize the needle entering the vein, and then proceed with insertion of the guidewire and catheter as described later. It is important not to be "mesmerized" or to have a false sense of confidence because ultrasound is being used. Always follow standard catheterization technique and always confirm (using multiple techniques) venous puncture. For example, it is good practice to document that the needle or short cannula is in the IJV through the use of manometry or to visualize the guidewire within the vein by using ultrasound before proceeding with catheter insertion.

If ultrasound is unavailable, skin puncture is at the apex of the triangle formed by the two muscle bellies of the SCM and the clavicle. The ICA pulsation is usually felt 1 to 2 cm medial to this point, beneath or just medial to the sternal head of the SCM. The skin at the apex of the triangle is infiltrated with 1% lidocaine using the smallest needle available. Use of a small-bore finder needle to locate the IJV should prevent unintentional ICA puncture and unnecessary probing with a larger bore needle. To avoid collapsing the IJV, the operator should maintain minimal to no pressure on the ICA with the left hand

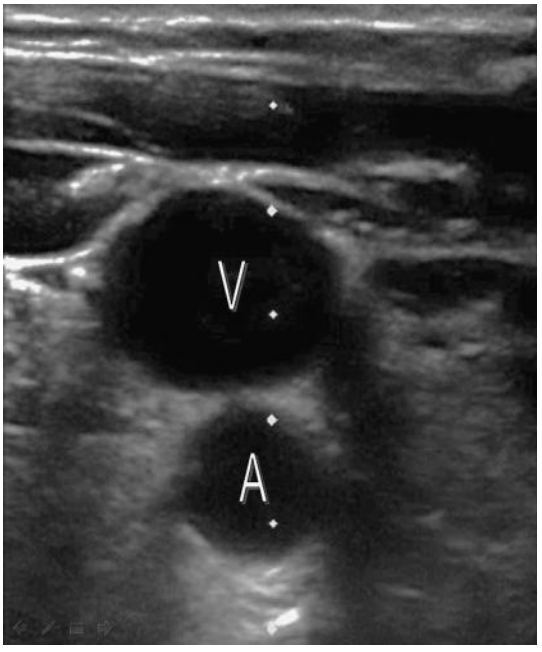

FIGURE 2.3. Ultrasound appearance of the right internal jugular vein and normal relationship with the internal carotid artery.

and insert the finder needle with the right hand at the apex of the triangle at a 45-degree angle with the frontal plane, directed at the ipsilateral nipple. The needle is advanced steadily with constant negative pressure in the syringe, and venipuncture occurs within 1 to 5 cm. If venipuncture does not occur on the initial attempt, negative pressure should be maintained and the needle slowly withdrawn, as often, the needle will compress the vein on advancement and penetrate the back wall without blood return. Once the needle is pulled back past the posterior wall of the vessel, it achieves free flow of blood from the vessel. If the first attempt is unsuccessful, the operator should reassess patient position, landmarks, and techniques to ensure that he or she is not doing anything to decrease IJV lumen size (see later). Subsequent attempts may be directed slightly laterally or medially to the initial direction, as long as the ICA is not entered. If venipuncture does not occur after three to five attempts, further attempts are unlikely to be successful and only increase complications [56–58].

When venipuncture has occurred with the finder needle, the operator can either withdraw the finder needle and introduce the large-bore needle in the identical plane or leave the finder needle in place and introduce the larger needle directly superior to it. Leaving the finder needle in place has been shown to facilitate successful puncture with the introducer needle [59]. Many kits provide both an 18-gauge thin-wall needle through which a guidewire can be directly introduced and a 16-gauge catheter-over-needle device. With the latter apparatus, the catheter is threaded over the needle into the vein, the needle withdrawn, and the guidewire inserted through the catheter. Both techniques are effective; the choice is strictly a matter of operator preference. Regardless of which large-bore needle is used, once venipuncture has occurred the syringe is removed after ensuring that the backflow of blood is not pulsatile and the hub is then occluded with a finger to prevent air embolism or excessive bleeding. The guidewire, with the J-tip oriented appropriately, is then inserted and should pass freely up to 20 cm, at which point the thin-wall needle or catheter is withdrawn. The tendency to insert the guidewire deeper than 15 to 20 cm should be avoided, as it is the most common cause of ventricular arrhythmias during insertion and also poses a risk for cardiac perforation. Furthermore, if the patient has an IVC filter in place, the guidewire can become entangled in the filter. Occasionally, the guidewire does not pass easily beyond the tip of the thin-wall needle. The guidewire should then be withdrawn, the syringe attached, and free backflow of blood reestablished and maintained while the syringe and needle are brought to a more parallel plane with the vein. The guidewire should then pass easily. If resistance is still encountered, rotation of the guidewire during insertion often allows passage, but extensive manipulation and force lead only to complications.

With the guidewire in place, a scalpel is used to make two 90-degree stab incisions at the skin entry site to facilitate passage of the 7-Fr vessel dilator. The dilator is inserted down the wire to the hub, ensuring that control and sterility of the guidewire is not compromised. The dilator is then withdrawn and pressure used at the puncture site to control oozing and prevent air embolism down the needle tract. The proximal and middle lumens of a triple-lumen catheter are flushed with saline and capped. The catheter is then inserted over the guidewire, ensuring that the operator has control of the guidewire, either proximal or distal to the catheter, at all times to avoid intravascular loss of the wire. The catheter is then advanced 15 to 17 cm (17 to 19 cm for left IJV) into the vein, the guidewire withdrawn, and the distal lumen capped. The catheter is sutured securely to limit tip migration and bandaged in a standard manner. A chest radiograph should be obtained to detect complications and tip location.

Success Rates and Complications

Non–ultrasound-guided IJV catheterization is associated with a high rate of successful catheter placement. Elective procedures are successful more than 90% of the time, generally within the first three attempts, and catheter malposition is rare. Use of ultrasound clearly improves the success rate, decreases the number of attempts and complications, avoids unnecessary procedures by identifying unsuitable anatomy, and minimally impacts insertion time. Emergent IJV catheterization is less successful and is not the preferred technique during airway emergencies or other situations that may make it difficult to identify landmarks in the neck.

The incidence and types of complications are similar regardless of the approach. Operator inexperience appears to increase the number of complications, but to an undefined extent, and probably does not have as great an impact as it does on the incidence of pneumothorax in subclavian venipuncture [60].

The overall incidence of complications in IJV catheterization (without ultrasound guidance) is 0.1% to 4.2%. Important complications include ICA puncture, pneumothorax, vessel erosion, thrombosis, and infection. Although the impact of ultrasound use on other complications has not been conclusively demonstrated, it has been shown to significantly reduce the number of attempts and the incidence of arterial puncture, which is by far the most common complication [6]. In the absence of a bleeding diathesis, arterial punctures are usually benign and are managed conservatively by applying local pressure for 10 minutes. Even in the absence of clotting abnormalities, a sizable hematoma may form, frequently preventing further catheterization attempts or, rarely, exerting pressure on vital neck structures [61,62]. Unrecognized arterial puncture can lead to catheterization of the ICA with a large-bore catheter or introducer and can have disastrous consequences, especially if heparin is subsequently administered [63]. Management of carotid cannulation with a large-bore catheter, such as a 7-Fr introducer, is controversial. Options include pulling the catheter and applying pressure, percutaneous closure devices, internal stent grafting, or surgical repair [64,65]. Some experts advise administration of anticoagulants to prevent thromboembolic complications, whereas others advise the opposite. Our

approach is to remove small bore catheters and avoid heparinization if possible, as hemorrhage appears to be a greater risk than thromboembolism. For larger bore catheters and complicated cases, we involve interventional radiology and vascular surgery before removal, and individualize the management based on the circumstances.

Pneumothorax, which may be complicated by blood, infusion of intravenous fluid, or tension, is considered an unusual adverse consequence of IJV cannulation; however, it has an incidence of 1.3% in a large meta-analysis, statistically the same as 1.5% found for subclavian puncture [66]. It usually results from a skin puncture too close to the clavicle or, rarely, from other causes. Logically, ultrasound should decrease or even eliminate pneumothorax as a complication during IJV catheterization.

An extraordinary number of case reports indicate that any complication from IJV catheterization is possible, even the intrathecal insertion of a pulmonary artery catheter [67]. In reality, the IJ route is reliable, with a low incidence of major complications. Operator experience is not as important a factor as in SCV catheterization; the incidence of catheter tip malposition is low, and patient acceptance is high. It is best suited for acute, short-term hemodialysis and for elective or urgent catheterizations in volume-replete patients, especially pulmonary artery catheterizations and insertion of temporary transvenous pacemakers. It is not the preferred site during airway emergencies, for parenteral nutrition, or for long-term catheterization because infectious complications are higher with IJV compared with SCV catheterizations.

External Jugular Vein Approach

The EJV is now rarely used for CVC, but in selected cases, it remains an excellent alternative. The main advantages to the EJV route for CVC are that it is part of the surface anatomy, the risk of hemorrhage is low even in the presence of coagulopathy, and the risk of pneumothorax is all but eliminated. The main disadvantage is the unpredictability of passage of the catheter to the central compartment.

Anatomy

The EJV is formed anterior and caudal to the ear at the angle of the mandible by the union of the posterior auricular and retromandibular veins (Fig. 2.2). It courses obliquely across the anterior surface of the SCM, then pierces the deep fascia just posterior to the SCM and joins the SCV behind the medial third of the clavicle. In 5% to 15% of patients, the EJV is not a distinct structure but a venous plexus, in which case it may receive the ipsilateral cephalic vein. The EJV varies in size and contains valves throughout its course. Its junction with the SCV may be at a severe, narrow angle that can be difficult for a catheter to traverse [50,51].

Technique

The EJV should be cannulated using the 16-gauge catheter-over-needle, since guidewire manipulations are often necessary, and secure venous access with a catheter is preferable. The patient is placed in a comfortable supine position with arms to the side and head turned slightly to the contralateral side. The right EJV should be chosen for the initial attempt and can be identified where it courses over the anterior portion of the clavicular belly of the SCM. After skin preparation with chlorhexidine, use of maximum barrier precautions, administration of local anesthesia subcutaneously and a time-out, venipuncture is performed with the 16-gauge catheter-over-needle using the left index finger and thumb to distend and anchor the vein. Skin puncture should be well above the clavicle and the needle advanced in the axis of the vein at 20 degrees to the frontal plane. The EJV may be more difficult to cannulate than expected because of its propensity to roll and displace rather than puncture in response to the advancing needle. A firm, quick thrust is often required to effect venipuncture. When free backflow of blood is established, the needle tip is advanced a few millimeters further into the vein and the catheter is threaded over the needle. The catheter may not thread its entire length because of valves, tortuosity, or the SCV junction, but should be advanced at least 3 to 5 cm to secure venous access. The syringe and needle can then be removed and the guidewire, J-tip first, threaded up to 20 cm and the catheter removed. Manipulation and rotation of the guidewire, especially when it reaches the SCV junction, may be necessary but should not be excessive. Various arm and head movements are advocated to facilitate guidewire passage; abduction of the ipsilateral arm and anterior–posterior pressure exerted on the clavicle may be helpful. Once the guidewire has advanced 20 cm, two 90-degree skin stabs are made with a scalpel, and the vein dilator inserted to its hub, maintaining control of the guidewire. The triple-lumen catheter is then inserted an appropriate length (16 to 17 cm on the right, 18 to 20 cm on the left). The guidewire is withdrawn, the catheter bandaged, and a chest radiograph obtained to screen for complications and tip placement.

Success Rates and Complications

Central venous catheterization via the EJV is successful in 80% of patients (range 75% to 95%) [68,69]. Inability to perform venipuncture accounts for up to 10% of failures [70,71] and the remainders are a result of catheter tip malpositioning. Failure to position the catheter tip is usually due to inability to negotiate the EJV–SCV junction, loop formation, or retrograde passage down the ipsilateral arm. Serious complications arising from the EJV approach are rare and almost always associated with catheter maintenance rather than venipuncture. A local hematoma forms in 1% to 5% of patients at the time of venipuncture [72] but has little consequence unless it distorts the anatomy leading to catheterization failure. External jugular venipuncture is safe in the presence of coagulopathy. Infectious, thrombotic, and other mechanical complications are no more frequent than with other central routes.

Femoral Vein Approach

The FV has many practical advantages for CVC; it is directly compressible, it is remote from the airway and pleura, the technique is relatively simple, and the Trendelenburg position is not required during insertion. During the mid-1950s, percutaneous catheterization of the IVC via a femoral vein approach became popular until 1959 when Moncrief [73] and Bansmer et al. [74] reported a high incidence of complications, especially infection and thrombosis, after which, it was largely abandoned. In the subsequent two decades, FV cannulation was restricted to specialized clinical situations. Interest in short-term (<48 hour) FV catheterization was renewed by positive experiences during the Vietnam conflict and with patients in the emergency department [75]. Some reports on long-term FV catheterization [76] suggest an overall complication rate no higher than that with other routes, although deep vein thrombosis remains a legitimate concern. Furthermore, Centers for Disease Control and Prevention (CDC) guidelines for the prevention of catheter-related bloodstream infection recommend against the use of the femoral site for catheterization if possible [77].

Anatomy

The FV (Fig. 2.4A) is a direct continuation of the popliteal vein and becomes the external iliac vein at the inguinal ligament. At

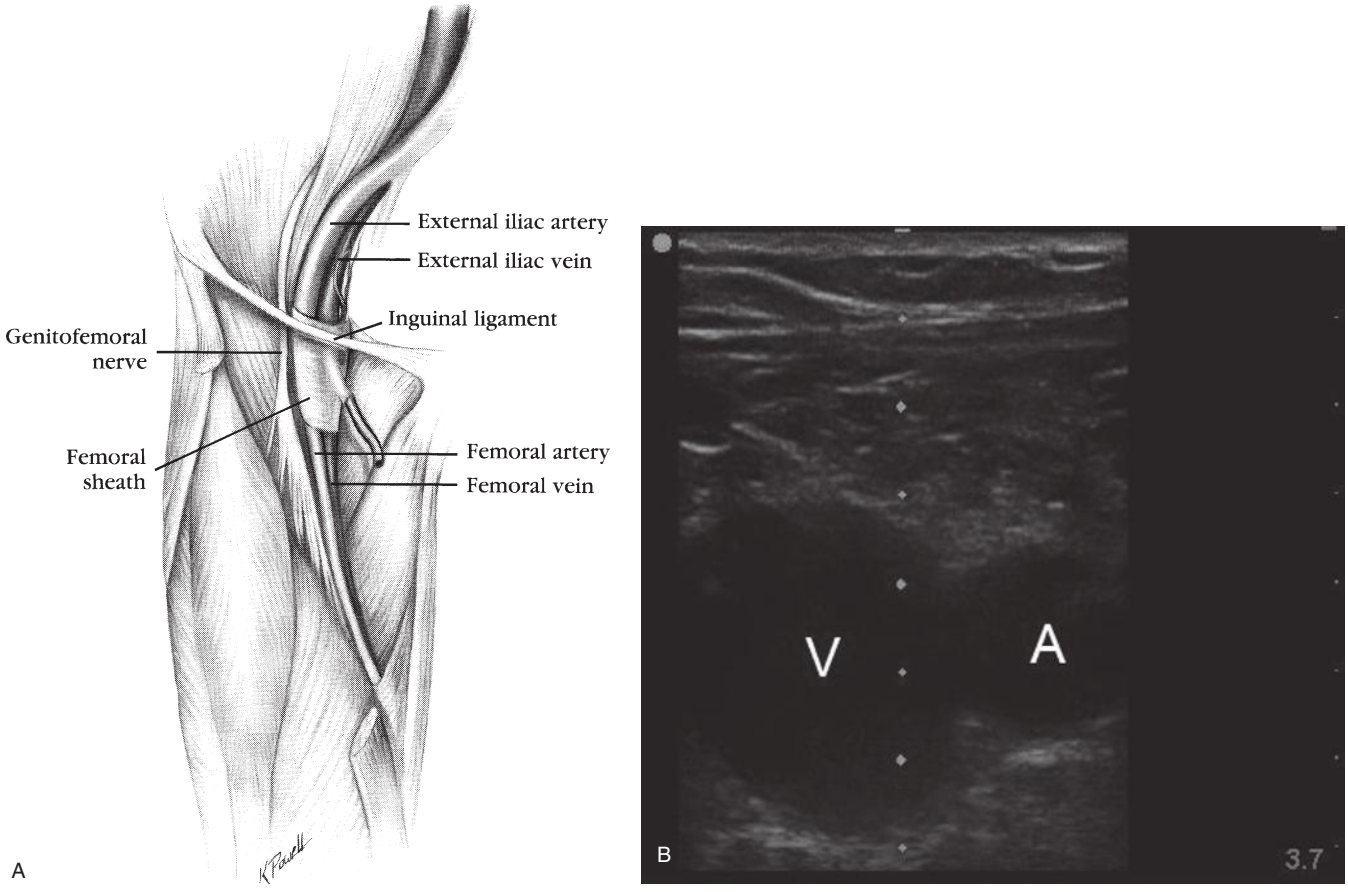

FIGURE 2.4. A: Anatomy of the femoral vein. **B:** Ultrasound appearance of femoral vein and artery.

the inguinal ligament, the FV lies within the femoral sheath a few centimeters from the skin surface. The FV lies medial to the femoral artery, which in turn lies medial to the femoral branch of the genitofemoral nerve. The medial compartment contains lymphatic channels and Cloquet's node. The external iliac vein courses cephalad from the inguinal ligament along the anterior surface of the iliopsoas muscle to join its counterpart from the other leg and form the (IVC) anterior to and to the right of the fifth lumbar vertebra. Using ultrasound, the femoral vein can be readily identified by placing the probe a few centimeters caudal to the inguinal ligament, just medial to the arterial pulsation (Fig. 2.4B).

Technique

Femoral vein cannulation is the easiest of all central venous procedures to learn and perform. Either side is suitable, and the side chosen is based on operator convenience. Ultrasound guidance is not usually required but for elective situations, we believe it is optimal practice. Ultrasound confirms the anatomy, identifies the depth needed for venipuncture, rules out preexisting thrombosis, and should not unduly delay time to catheterization. It may be particularly useful in the obese [21]. The patient is placed in the supine position (if tolerated) with the leg extended and slightly abducted at the hip. Excessive hair should be clipped with scissors and the skin prepped with chlorhexidine. Maximum barrier precautions should be used. The FV lies 1 to 1.5 cm medial to the arterial pulsation, and the overlying skin is infiltrated with 1% lidocaine. In a patient without femoral artery pulsations, the FV can be located by dividing the distance between the anterior superior iliac spine and the pubic tubercle is divided into three equal segments. The femoral artery is usually found where the medial segment meets the two lateral ones, and the FV lies 1 to 1.5 cm medial. Following a time-out, an 18-gauge thin-wall needle is inserted at this point, 2 to 3 cm inferior to the inguinal ligament, ensuring that venipuncture occurs caudal to the inguinal ligament, which minimizes the risk of retroperitoneal hematoma in the event of arterial puncture. While maintaining constant back pressure on the syringe, the needle, tip pointed cephalad, is advanced at a 45-degree angle to the frontal plane. Insertion of the needle to its hub is sometimes required in obese patients. Blood return may not occur until slow withdrawal. If the initial attempt is unsuccessful, landmarks should be reevaluated and subsequent attempts oriented slightly more medial or lateral. A common error is to direct the needle tip too medially, toward the umbilicus. The femoral vessels lie in the sagittal plane at the inguinal ligament (Fig. 2.4), and the needle should be directed accordingly. If unintentional arterial puncture occurs, pressure is applied for 5 to 10 minutes.

When venous blood return is established, the syringe angle is depressed slightly and free aspiration of blood reconfirmed. The syringe is removed, ensuring that blood return is not pulsatile. The guidewire should pass easily and never forced, although rotation and minor manipulation are sometimes required. The needle is then withdrawn, two scalpel blade stab incisions made at 90 degrees at the guidewire insertion site, and the vein dilator inserted over the wire to the hub. The dilator is then withdrawn and a catheter appropriate to clinical requirements inserted, taking care never to lose control of the guidewire. The catheter is secured with a suture and bandage applied.

Success Rate and Complications

FV catheterization is successful in 90% to 95% of patients, including those in shock or cardiopulmonary arrest [77,78]. Unsuccessful catheterizations are usually a result of venipuncture failure, hematoma formation, or inability to advance the guidewire into the vein. Operator inexperience may increase the number of attempts and complication rate but does not appear to significantly decrease the overall success rate.

Three complications occur regularly with FV catheterization: arterial puncture with or without local bleeding, infection, and thromboembolic events. Other reported complications are rare and include scrotal hemorrhage, right lower quadrant bowel perforation, retroperitoneal hemorrhage, puncture of the kidney, and perforation of IVC tributaries. These complications occur when skin puncture sites are cephalad to the inguinal ligament or when long catheters are threaded into the FV.

Femoral artery puncture occurs in 5% to 10% of adults. Most arterial punctures are uncomplicated, but major hematomas may form in 1% of patients, especially in the presence of anticoagulants, fibrinolytics, or antithrombotic agents. As is the case with other routes, ultrasound should essentially eliminate this complication. Even in the presence of coagulopathy, arterial puncture with the 18-gauge thin-wall needle is usually of minor consequence, but there is a potential for life-threatening thigh or retroperitoneal hemorrhage [79]. Arteriovenous fistula and pseudoaneurysm are rare chronic complications of arterial puncture; the former is more likely to occur when both femoral vessels on the same side are cannulated concurrently [80].

Infectious complications with FV catheters are probably more frequent than SCV catheters but comparable to IJV catheters [81–83]. Modern series involving both short- and long-term FV catheterization in adults and children have reported significant CRI rates of about 5% or less [77,84]. Further evidence that the inguinal site is not inherently "dirty" is provided by experience with femoral artery catheters, which have an infection rate comparable to that with radial artery catheters [85]. Although more recent reports suggest that a catheter properly placed and cared for has a similar rate of infection regardless of venipuncture site, CDC guidelines recommend avoidance of the femoral site unless absolutely necessary [77,86].

Two reports in 1958 highlighted the high incidence of FV catheter-associated deep venous thrombosis, but these studies were primarily autopsy based and prior to modern technological advances. Catheter-associated thrombosis is a risk of all CVCs, regardless of the site of insertion, and comparative studies using contrast venography, impedance plethysmography, or Doppler ultrasound suggest that FV catheters are no more prone to thrombosis than upper extremity catheters. Pulmonary emboli have been reported following CVC-associated upper extremity thrombosis [46] and the relative risk of femoral catheter-related thrombosis is unknown. Clearly, the potential thromboembolic complications of FV catheters cannot be discounted [87], but they do not warrant total abandonment of this approach.

In summary, available evidence supports the view that the FV may be cannulated safely in critically ill adults. It is particularly useful for inexperienced operators because of the high rate of success and lower incidence of major complications. FV catheterizations may be performed during airway emergencies and cardiopulmonary arrest, in patients with coagulopathy, in patients who are unable to lie flat, and for access during renal replacement therapy. The most common major complication during FV catheterization is arterial puncture, which can be lessened or eliminated by ultrasound guidance. Infection is no more common than with IJV catheters. Catheter-associated thrombosis occurs with similar frequency as with IJ and SV catheters, but it may be more clinically relevant.

Subclavian Vein Approach

This route has been used for central venous access for many years and is associated with the most controversy, largely because of the relatively high incidence of pneumothorax and the occasional mortality associated with it. With the added safety of ultrasound-guided IJV catheterization, there has been some debate about abandonment of landmark guided SCV catheterization. Ultrasound guidance is possible with the SCV, but it is more technically demanding and may require a different site for venipuncture [12]. Given these factors, we still believe the SCV is a valuable alternative in certain situations for experienced operators, who should have a pneumothorax rate well under 1%. Inexperienced operators have a far greater rate of pneumothorax; therefore, in settings where relatively inexperienced physicians perform the majority of CVC, the SCV should be used more selectively or perhaps, not at all. The advantages of this route include consistent identifiable landmarks, easier long-term catheter maintenance with a comparably lower rate of infection, and relatively high patient comfort. Assuming an experienced operator is available, the SCV is the preferred site for CVC in patients with hypovolemia, for long-term total parenteral nutrition (TPN), and in patients with elevated intracranial pressure who require hemodynamic monitoring. It should not be considered the primary choice in the presence of thrombocytopenia (platelets <50,000), for acute hemodialysis, or in patients with high PEEP (i.e., >12 cm H_2O).

Anatomy

The SCV is a direct continuation of the axillary vein, beginning at the lateral border of the first rib, extending 3 to 4 cm along the undersurface of the clavicle and becoming the brachiocephalic vein where it joins the ipsilateral IJV at Pirogoff's confluence behind the sternoclavicular articulation (Fig. 2.5). The vein is 1 to 2 cm in diameter, contains a single set of valves just distal to the EJV junction, and is fixed in position directly beneath the clavicle by its fibrous attachments. These attachments prevent collapse of the vein, even with severe volume depletion. Anterior to the vein throughout its course lie the subclavius muscle, clavicle, costoclavicular ligament, pectoralis muscles, and epidermis. Posteriorly, the SCV is separated from the subclavian artery and brachial plexus by the anterior scalenus muscle, which is 10 to 15 mm thick in the adult. Posterior to the medial portion of the SCV are the phrenic nerve and internal mammary artery as they pass into the thorax. Superiorly, the relationships are the skin, platysma, and superficial aponeurosis. Inferiorly, the vein rests on the first rib, Sibson's fascia, the cupola of the pleura (0.5 cm behind the vein), and pulmonary apex [88]. The thoracic duct on the left and right lymphatic duct cross the anterior scalene muscle to join the superior aspect of the SV near its union with the IJV.

The clavicle presents a significant barrier for ultrasound visualization of the SCV, which mandates using a different approach [12]. Typically, we identify the axillary/subclavian vein junction by placing the probe inferior to the clavicle in the deltopectoral groove. We usually initially produce an axial view of the vein by placing the probe in the cranial–caudal direction. The probe is then rotated 90 degrees to produce a longitudinal view of the vein, which is maintained during venipuncture and guidewire insertion (Fig. 2.6). Although this method is usually successful it tends to be more time consuming and in our experience, not as useful.

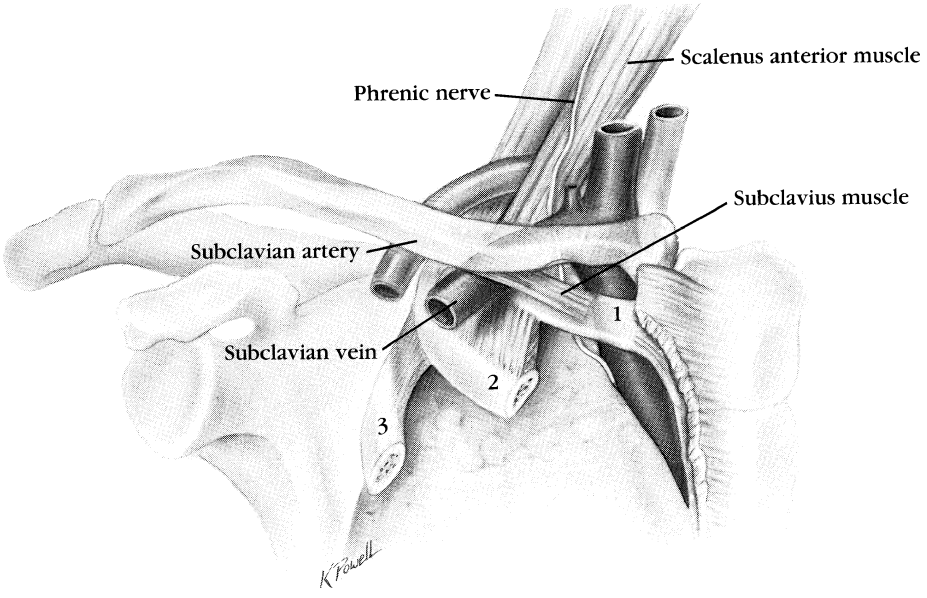

FIGURE 2.5. Anatomy of the subclavian vein and adjacent structures.

Technique

Although there are many variations, the SCV may be cannulated using surface landmarks by two basic techniques: the infraclavicular [89] or supraclavicular [90,91] approach (Fig. 2.7). The differences in success rate, catheter tip malposition, and complications between the two approaches are negligible, although catheter tip malposition and pneumothorax may be less likely with supraclavicular cannulation [92,93]. In general, when discussing the success rate and incidence of complications of SV catheterization, there is no need to specify the approach used.

The 18-gauge thin-wall needle is preferable for SCV cannulation. The patient is placed in a 15- to 30-degree Trendelenburg position, and in our experience, use of a small bedroll between the scapulae tends move the humeral head out of the plane of needle insertion. The head is turned slightly to the contralateral side and the arms are kept to the side. The pertinent landmarks are the clavicle, the two muscle bellies of the SCM, the suprasternal notch, the deltopectoral groove, and the manubriosternal junction. For the infraclavicular approach (Fig. 2.7), the operator is positioned next to the patient's shoulder on the side to be cannulated. For reasons cited earlier, the left SCV should be chosen for pulmonary artery catheterization; otherwise, the success rate appears to be equivalent regardless of the side chosen. Skin puncture is 2 to 3 cm caudal to the clavicle at the deltopectoral groove, corresponding to the area where the clavicle turns from the shoulder to the manubrium. Skin puncture should be distant enough from the clavicle to avoid a downward angle of the needle in clearing the inferior surface of the clavicle, which also obviates any need to bend the needle. The path of the needle is toward the suprasternal notch. Using maximum barrier precautions, the skin is prepped with chlorhexidine. After skin infiltration and liberal injection of the clavicular periosteum with 1% lidocaine and a time-out, the 18-gauge thin-wall needle is mounted on a 10-mL syringe. Skin puncture is accomplished with the needle bevel up, and the needle is advanced in the plane already described until the tip abuts the clavicle. The needle is then

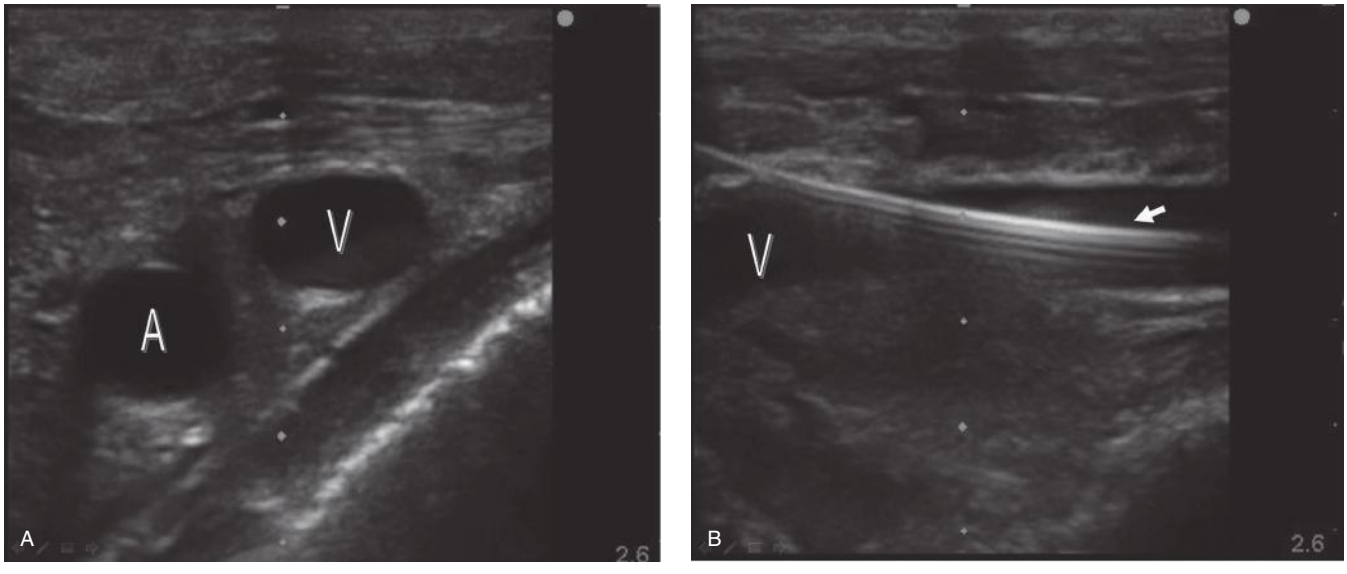

FIGURE 2.6. Ultrasound view of the subclavian vein. **A:** Axial view; **B:** longitudinal view. See text for details.

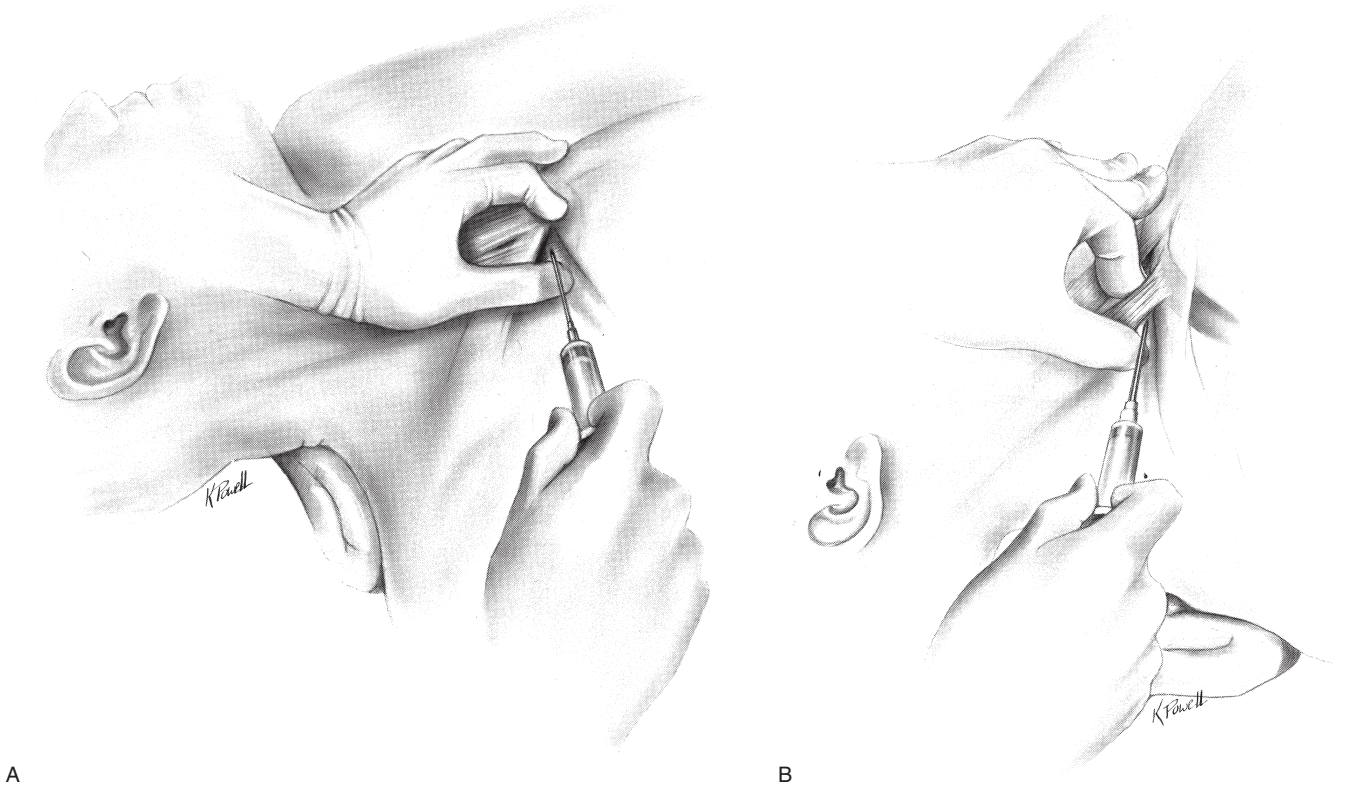

FIGURE 2.7. A: Patient positioning for subclavian cannulation. **B:** Cannulation technique for supraclavicular approach.

"walked" down the clavicle until the inferior edge is cleared. To avoid pneumothorax, it is imperative the needle stay parallel to the floor and not angle down toward the chest. This is accomplished by using the operator's left thumb to provide downward displacement in the vertical plane after each attempt, until the needle advances under the clavicle.

As the needle is advanced further, the inferior surface of the clavicle should be felt hugging the needle. This ensures that the needle tip is as superior as possible to the pleura. The needle is advanced toward the suprasternal notch during breath holding or expiration, and venipuncture occurs when the needle tip lies beneath the medial end of the clavicle. This may require insertion of the needle to its hub. Blood return may not occur until slow withdrawal of the needle. If venipuncture is not accomplished on the initial thrust, the next attempt should be directed slightly more cephalad. If venipuncture does not occur by the third or fourth attempt, another site should be chosen, as additional attempts are unlikely to be successful and may result in complications.

When blood return is established, the bevel of the needle is rotated 90 degrees toward the heart. The needle is anchored firmly with the left hand while the syringe is detached with the right. Blood return should not be pulsatile, and air embolism prophylaxis is necessary at all times. The guidewire is then advanced through the needle to 15 cm and the needle withdrawn. To increase the success rate of proper placement of the catheter, the J-wire tip should point inferiorly [94]. The remainder of the procedure is as previously described. Triple-lumen catheters should be sutured at 15 to 16 cm on the right and 17 to 18 cm on the left to avoid intracardiac tip placement [31,32,95].

For the supraclavicular approach (Fig. 2.7), the important landmarks are the clavicular insertion of the SCM muscle and the sternoclavicular joint. The operator is positioned at the head of the patient on the side to be cannulated. The site of skin puncture is the claviculosternocleidomastoid angle, just above the clavicle and lateral to the insertion of the clavicular head of the SCM. The needle is advanced toward or just caudal to the contralateral nipple just under the clavicle. This corresponds to a 45-degree angle to the sagittal plane, bisecting a line between the sternoclavicular joint and clavicular insertion of the SCM. The depth of insertion is from just beneath the SCM clavicular head at a 10- to 15-degree angle below the coronal plane. The needle should enter the jugulosubclavian venous bulb after 1 to 4 cm, and the operator may then proceed with catheterization.

Success and Complication Rates

Subclavian vein catheterization is successful in 90% to 95% of cases, generally on the first attempt [96]. The presence of shock does not alter the success rate as significantly as it does during IJV catheterization [97]. Unsuccessful catheterizations are a result of venipuncture failure or inability to advance the guidewire or catheter. Catheter tip malposition occurs in 5% to 20% of cases and tends to be more frequent with the infraclavicular approach. Malposition occurs most commonly to the ipsilateral IJV and contralateral SCV and is usually correctable without repeat venipuncture.

The overall incidence of noninfectious complications varies depending on the operator's experience and the circumstances under which the catheter is inserted. Large series involving several thousand SCV catheters have reported an incidence of major complications of 1% to 3%, with an overall rate of 5%. In smaller, probably more clinically relevant studies, the major complication rate has ranged from 1% to 10% [98–100]. Factors resulting in a higher complication rate are operator inexperience, multiple attempts at venipuncture, emergency conditions, variance from standardized technique, and body mass index. Major noninfectious complications include pneumothorax, arterial puncture, and thromboembolism. There are many

case reports of isolated major complications involving neck structures or the brachial plexus; the reader is referred elsewhere for a complete listing of reported complications [11].

Pneumothorax accounts for one fourth to one half of reported complications, with an incidence of about 1.5%. The incidence varies inversely with the operator's experience and the number of "breaks" in technique. There is no magic figure whereby an operator matures from inexperienced to experienced. Fifty catheterizations are cited frequently as a cutoff number [101], but it is reasonable to expect an operator to be satisfactorily experienced after having performed fewer. For the experienced operator, a pneumothorax incidence of less than 1% is expected. Most pneumothoraces are a result of lung puncture at the time of the procedure, but late-appearing pneumothoraces have been reported.

Most pneumothoraces will require thoracostomy tube drainage with a small chest tube and a Heimlich valve but some can be managed conservatively with 100% oxygen and serial radiographs or needle aspiration only [1]. Rarely, a pneumothorax is complicated by tension, blood, infusion of intravenous fluid (immediately or days to weeks after catheter placement), chyle, or massive subcutaneous emphysema. Bilateral pneumothoraces can occur from unilateral attempts at venipuncture. Pneumothorax can result in death, especially when it goes unrecognized [102].

Subclavian artery puncture occurs in 0.5% to 1.0% of cases, constituting one fourth to one third of all complications. Arterial puncture is usually managed easily by applying pressure above and below the clavicle. Bleeding can be catastrophic in patients with coagulopathy, especially thrombocytopenia. As with other routes, arterial puncture may result in arteriovenous fistula or pseudoaneurysm.

Clinical evidence of central venous thrombosis, including SVC syndrome, development of collaterals around the shoulder girdle, and pulmonary embolism, occurs in 0% to 3% of SCV catheterizations, but routine phlebography performed at catheter removal reveals a much higher incidence of thrombotic phenomena. The importance of the discrepancy between clinical symptoms and radiologic findings is unknown, but upper extremity thrombosis, even if asymptomatic, is not a totally benign condition [46]. Duration of catheterization, catheter material, and patient condition probably impact the frequency of thrombosis, but to an uncertain degree.

In summary, the SCV is an extremely reliable and useful route for CVC, but because of the relatively high rate of pneumothorax and the increased success rate of ultrasound-guided IJV catheterization, its use should be limited to those operators skilled in the technique. Inexperienced operators should use an alternative site. Experienced operators should continue to use this route for certain indications (Table 2.1) but should scrupulously avoid it in patients who cannot tolerate a pneumothorax (severe lung disease, one lung), or in patients with severe coagulopathy, especially platelets <50,000. Ultrasound guidance may be helpful, but requires a higher skill level and a different approach to catheterization.

INFECTIOUS COMPLICATIONS

Tremendous advances in the understanding of the pathophysiology, causes, and prevention of CRI have occurred in recent years and have led to corresponding dramatic improvements in catheter technology, insertion, and management. Table 2.2 summarizes current recommendations or interventions that have been shown to reduce the risk of CRI. This section reviews these recommendations, focusing on the epidemiology, pathogenesis, diagnosis, management, and prevention of central CRI.

Definitions and Epidemiology

Consensus regarding the definition and diagnosis of CRI is a necessary initial step in discussing catheter-related infectious complications. The semiquantitative culture method described by Maki et al. [103] for culturing catheter segments is the most accepted technique for diagnosing CRI. Which catheter segment to culture (the tip or intradermal segment) is still controversial; out of convenience, most centers routinely culture the catheter tip. If semiquantitative methods are used, catheter contamination (probably occurring at time of withdrawal) is defined as less than 15 colony-forming units (CFUs) per culture plate. CRI is a spectrum: growth of greater than or equal to 15 CFUs is identified as significant colonization (all other cultures negative and no clinical symptoms); local or exit-site infection (skin site with erythema, cellulitis, or purulence); catheter-related bacteremia (systemic blood cultures positive for identical organism on catheter segment and no other source); and catheter-related sepsis or septic shock. Alternative methods to diagnose CRI include differential time to positivity [104] and direct Gram [105] or acridine-orange staining [106] of catheters. Using the differential time to positivity, blood

TABLE 2.2

STEPS TO MINIMIZE CENTRAL VENOUS CATHETERIZATION (CVC)-RELATED INFECTION

1. Institution-supported standardized education, with knowledge assessment, of all physicians involved in CVC insertion and care
2. Site preparation with approved chlorhexidine-based preparation
3. Maximal barrier precautions during catheter insertion
4. Use of mobile procedure carts, safety checklist, empowerment of staff
5. Strict protocols for catheter maintenance (including bandage and tubing changes), preferably by dedicated IV catheter team
6. Appropriate site selection, avoiding heavily colonized or anatomically abnormal areas; use of SCV for anticipated CVC of >4 d
7. For anticipated duration of catheterization exceeding 96 hr, use of silver-impregnated cuff, sustained release chlorhexidine gluconate patch, and/or antibiotic/antiseptic-impregnated catheters
8. Prompt removal of any catheter which is no longer required
9. Remove pulmonary artery catheters and introducers after 5 d
10. Replace any catheter not placed with sterile precautions within 48 hr (i.e., catheter placed in emergency)
11. Use multilumen catheters only when indicated; remove when no longer needed
12. Avoid "routine" guidewire exchanges
13. Use surgically implanted catheters or PICCs for long term (i.e., >3 wk) or permanent CVC

CVC, central venous catheterization; PICC, peripherally inserted central catheter; SCV, subclavian vein.

TABLE 2.3

INFECTION RATES FOR VARIOUS INTRAVASCULAR CATHETERS

Device	IVD-related BSIs per 1,000 days (95% CI)
Peripheral IV catheters	0.6 (0.2–0.9)
Midline catheters	0.2 (0.0–0.5)
Arterial catheters	1.4 (0.8–2.0)
PICCs	0.8 (0.4–1.2)
Nontunneled CVCs	
Nonmedicated	2.9 (2.6–3.2)
Medicated; Chlorhexadine–silver sulfadiazine	1.3 (1.0–1.7)
Medicated; minocycline–rifampin	1.2 (0.3–2.1)
Tunneled CVCs	2.1 (1.0–3.2)
Pulmonary artery catheters	3.3 (1.9–4.6)
Nontunneled hemodialysis catheters	6.1 (4.9–7.4)

Adapted from Maki DG, Kluger DM, Crnich CJ: The risk of bloodstream infection in adults with different intravascular devices: a systematic review of 200 published prospective studies. *Mayo Clin Proc* 81:1159–1171, 2006.

cultures are drawn from the catheter and a peripheral vein. If the time to positive culture is greater than 120 minutes longer for the peripheral cultures, a diagnosis of CRI is made. This method has good sensitivity, specificity, and the advantage of faster diagnosis.

The morbidity and economic costs associated with CRI are truly impressive. Estimates vary because the overall incidence of CRI is impacted by so many independent variables, including type of ICU, catheter type and composition, duration of catheterization, and site of insertion. Furthermore, critical care practice is extremely dynamic, and the frequency and type of intravascular catheters used changes over time, rendering much of the data, somewhat out of date. Intravascular devices are now the single most important cause of health-care associated bloodstream infection in the United States and Europe, with an estimated incidence of 250,000 to 500,000 cases annually in the United States alone [107]. More than 5 million CVCs are inserted annually in the United States, accounting for 15 million CVC-days. Approximately 3% to 9% of all CVCs will become infected during clinical use, and the National Healthcare Safety Network reports rates of CVC-associated bloodstream infections varying from 1.2 to 5.5 per 1,000 catheter-days depending on the location of the patient [108]. A recently completed systematic review of the literature reported BSI rates for all intravascular devices [108] (Table 2.3); noncuffed, nontunneled CVCs had an average BSI rate of 2.9 per 1,000 catheter-days. When BSI does occur, often with a resistant organism such as methicillin-resistant *Staphylococcus aureus* (MRSA) and VRE, it increases healthcare costs by as much as $20,000 to 40,000, prolongs ICU and hospital stay by several days, and may increase attributable mortality [109–111]. Importantly, it has been estimated that as many as 50% of CRIs are preventable [112], which should serve as a powerful impetus and render it indefensible for critical care physicians not to implement everything possible to minimize CRI.

Pathophysiology of Catheter Infection

Assuming that they are not contaminated during insertion, catheters can become infected from four potential sources: the skin insertion site, the catheter hub(s), hematogenous seeding, and infusate contamination. Animal and human studies have shown that catheters are most commonly infected by bacteria colonizing the skin site, followed by invasion of the intradermal catheter tract. Once the external surface of the intradermal catheter is infected, bacteria can quickly traverse the entire length and infect the catheter tip, sometimes encasing the catheter in a slime layer known as a biofilm (coagulase-negative staph). From the catheter tip, bacteria may shed into the bloodstream, potentially creating metastatic foci of infection [113]. The pathophysiology of most catheter infections explains why guidewire exchanges are not effective in preventing or treating CRI: the colonized tract and, in many cases, biofilm, remain intact and quickly reinfect the new catheter [114].

The catheter hub(s) also becomes colonized but contributes to catheter-related infectious complications less frequently than the insertion site [115,116]. Hub contamination may be relatively more important as a source of infection for certain types of catheters (hemodialysis) and the longer the catheter remains in place [117]. Hematogenous seeding of catheters from bacteremia is an infrequent cause of CRI.

Site Preparation and Catheter Maintenance

That the majority of CRIs are caused by skin flora highlights the importance of site sterility during insertion and catheter maintenance. Organisms that colonize the insertion site originate from the patient's own skin flora or the hands of operators. Thorough hand washing and scrupulous attention to aseptic technique is mandatory during catheter insertion. A prospective study proved that a nonsterile cap and mask, sterile gown, and a large drape covering the patient's head and body (maximal (triple) sterile barriers, compared to sterile gloves and small drape) reduced the catheter-related bloodstream infection rate sixfold and were highly cost-effective [118]. If a break in sterile technique occurs during insertion, termination of the procedure and replacement of contaminated equipment is mandatory. Use of a mobile catheter cart that can be wheeled to the patient bedside facilitates maintenance of the sterile environment.

Chlorhexidine is a superior disinfectant and should be used instead of iodine-based solutions [119,120]. Proper application includes liberally scrubbing the site using expanding concentric circles. Excessive hair should be clipped with scissors prior to

application of the antiseptic, as shaving can cause minor skin lacerations and disruption of the epidermal barrier to infection.

Care of the catheter after insertion is extremely important in minimizing infection, and all medical personnel should follow standardized protocols [121]. The number of piggyback infusions and medical personnel handling tubing changes and manipulation of the catheter site should be minimized. Replacement of administration sets every 72 to 96 hours is safe and cost-efficient [122], unless there are specific recommendations for the infusate (e.g., propofol). Transparent polyurethane dressings have become more popular than gauze and tape, but have not been found to be superior. It is recommended that the transparent dressing be changed every 7 days or sooner if damp or soiled. Addition of a silver-impregnated cuff or chlorhexidine sponge has been shown to reduce the rate of CRI and is cost-effective [123,124]. Application of iodophor or polymicrobial ointments to the skin site at the time of insertion or during dressing changes does not convincingly reduce the overall incidence of catheter infection, and certain polymicrobial ointments may increase the proportion of *Candida* infections [125].

Frequency of Catheter-Related Infection

Observing the above-mentioned recommendations for catheter insertion and maintenance will minimize catheter-associated infection. Colonization of the insertion site can begin within 24 hours and increases with duration of catheterization; 10% to 40% of catheters may eventually become colonized [126]. Catheter-associated bacteremia occurs in 3% to 8% of catheters [101,127–129], although some studies incorporating newer catheter technologies and procedures have demonstrated rates of catheter-associated bacteremia of 2% or less [130–132]. Overall, catheter-infection rates are best expressed as number of episodes per 1,000 days, and although each ICU should strive for perfection (it is possible to attain and maintain the "holy grail" of zero CRIs over an extended period of time [1]), each ICU should definitely reach or exceed an appropriate benchmark. The NHSN publishes average rates of CRIs for different types of ICUs [109]. Table 2.3 provides national references from published literature that has the added advantage of unique data for each specific catheter type [108].

Type of Catheter

The data presented earlier are derived from large studies and are not necessarily applicable to any given catheter in any specific ICU because of variations in definitions, types of catheters, site of insertion, duration of catheterization, types of fluid infused, and policies regarding routine guidewire changes, all of which have been implicated at some point as important factors in the incidence of CRI. The duration of catheterization in combination with the type of catheter are major factors; the site of insertion is less important. Guidewire changes have an important role in evaluation of the febrile catheterized patient, but routine guidewire changes do not prevent infection. Under ideal conditions, all of these factors are less important. Long-term TPN catheters can be maintained for months with low rates of infection, and there is no cutoff time at which colonization and clinical infection accelerate. Today, when the need for long-term catheterization is anticipated, surgically implanted catheters should be used. These catheters have low infection rates and are never changed routinely [133]. PICCs are also an acceptable option for patients requiring long-term CVC.

Catheters inserted percutaneously in the critical care unit, however, are not subject to ideal conditions and have a finite lifespan. For practical purposes, multilumen catheters have replaced single-lumen catheters for many indications for central venous access. Because catheter hubs are a potential source of infection and triple-lumen catheters can require three times the number of tubing changes, it was widely believed that they would have a higher infection rate. Studies have presented conflicting results, but overall the data support the view that triple-lumen catheters have a modestly higher rate of infection [134–136]. If used efficiently, however, they provide greater intravascular access per device and can decrease the total number of catheter days and exposure to central venipuncture. A slight increase in infection rate per catheter is therefore justifiable from an overall risk–benefit analysis, if multilumen catheters are used only when multiple infusion ports are truly indicated.

Finally, it was hoped that routine subcutaneous tunneling of short-term CVCs, similar to long-term catheters, might be an effective way to minimize CRI. This approach is rational since the long subcutaneous tract acts to stabilize the catheter and perhaps act as a barrier to bacterial invasion, and great technical skill is not required. A meta-analysis did not support the routine practice of tunneling all percutaneously inserted CVCs [137], and it is not a common practice. However, further studies of the tunneling of short-term IJV and FV catheters are warranted, especially hemodialysis catheters, since these sites have a higher infection rate and past studies have generally favored this approach [108,138].

Duration of Catheterization

The length of catheterization should be based solely on the need for continued catheterization of the patient. No catheter should be left in longer than absolutely necessary. Most data suggest that the daily risk of infection remains relatively constant and routine replacement of CVCs without a clinical indication does not reduce the rate of CRI [137,139]. Multiple clinical and experimental studies have also demonstrated that guidewire exchanges neither decrease nor increase infectious risk [140].

The above-mentioned recommendations do not necessarily apply to other special-use catheters, which can be exposed to different clinical situations and risk. Pulmonary artery catheters (PACs) and the introducer should be removed after 96 to 120 hours because of the increased risk of infection after this time [141]. These catheters are at greater risk for infection because patients are sicker, the introducer used for insertion is shorter, and catheter manipulations are frequent.

Catheters inserted for acute temporary hemodialysis historically have had a higher rate of infection than other percutaneously placed catheters. Factors contributing to the increased rate have not been completely elucidated, but logically patient factors probably influence the incidence of infection more than the type of catheter or site of insertion [84]. For acutely ill, hospitalized patients, temporary dialysis catheters should be managed similarly to other multilumen catheters, recognizing that the underlying propensity for infection is distinctly higher [108]. As mentioned earlier, perhaps this is the area that tunneling of catheters should be more thoroughly investigated. For ambulatory outpatients, long-term experience with double-lumen, Dacron-cuffed, silicone CVCs inserted in the IJV has been positive [142].

Site of Insertion

The condition of the site is more important than the location. Whenever possible, sites involved by infection, burns, or other dermatologic processes, or in close proximity to a heavily colonized area (e.g., tracheostomy) should not be used as primary access. Data tends to support that PICC and SCV catheters

are associated with the lowest rate of CRI, and IJV and FV catheters the highest [101].

Guidewire Exchanges

Guidewire exchanges have always been theoretically flawed as a form of infection control, because although a new catheter is placed, the site, specifically the intradermal tract, remains the same. Studies have shown that when the tract and old catheter are colonized, the new catheter invariably also becomes infected. Alternatively, if the initial catheter is not colonized, there is no reason the new catheter will be more resistant to subsequent infection than the original one. In neither situation will a guidewire change prevent infection. However, guidewire changes continue to have a valuable role for replacing defective catheters, exchanging one type of catheter for another, and in the evaluation of a febrile patient with an existing central catheter. In the latter situation, the physician can assess the sterility of the catheter tract without subjecting the patient to a new venipuncture. However one decides to use guidewire exchanges, they must be performed properly. Using maximal barriers, the catheter should be withdrawn until an intravascular segment is exposed, transected sterilely, and the guidewire inserted through the distal lumen. The catheter fragment can then be removed (always culture the tip) and a new catheter threaded over the guidewire. To ensure sterility, most operators should re-prep the site and change gloves before inserting the new catheter or introducer over the guidewire. Insertion of the guidewire through the distal hub of the existing catheter is not appropriate.

NEW CATHETER TECHNOLOGIES

Improvements in catheter technology continue to play an important role in minimizing catheter complications. Catheter material is an important factor in promoting thrombogenesis and adherence of organisms. Most catheters used for CVC are composed of flexible silicone (for surgical implantation) and polyurethane (for percutaneous insertion), because research has shown these materials are less thrombogenic. Knowledge of the pathogenesis of most CRI has stimulated improvements designed to interrupt bacterial colonization of the skin site, catheter, and intradermal tract, and migration to the catheter tip. Antibiotic and antiseptic impregnated catheters represent a major advance in catheter management. Catheters differ from one another by the type of antibiotic or antiseptic with which they are impregnated. Clinical results with these commercially available catheters have been variable [143,144], likely due to varying practices and the baseline infection rate. Good randomized controlled trials comparing the various types of antiseptic catheters with each other are lacking, but we believe that current evidence supports using one of the above catheters if the baseline CRI rate remains high after instituting infection control practices [101,132,133]. The preponderance of data indicates that in real-life practice, these catheters decrease the rate of CRI and improve patient safety, likely at a neutral or favorable cost [129,145]. The emergence of resistant organisms and allergic reactions has not yet been a problem, but ongoing surveillance is needed.

SYSTEMS-BASED MEASURES

Not surprisingly, evidence is pointing to systems-based factors as being more important in reducing the incidence of CRI than any new technology. At Johns Hopkins, the addition of five systems-based changes reduced the CRI rate from 11.3 to 0 per 1,000 catheter days. These simple interventions were: education of physicians and nurses of evidence-based infection control practices, creation of a central catheter insertion cart which contained every item needed for insertion of a catheter, daily questioning of whether catheters could be removed, a bedside checklist for insertion of catheters, and empowering nurses to stop procedures where the infection control guidelines were not being followed [146]. Similar interventions in Pennsylvania reduced their CRI rate from 4.31 to 1.36 per 1,000 catheter days [147]. A statewide initiative in Michigan, the Keystone Project, implemented these strategies on a large scale over the entire state with equally impressive results [1]. Despite the fact that these and other simple systems interventions and implementation require very little capital outlay, many ICUs have yet to adopt them [148,149].

MANAGEMENT OF THE FEBRILE PATIENT

Patients with a CVC frequently develop fever. Removal of the catheter in every febrile patient is neither feasible nor clinically indicated, as the fever is often unrelated to the catheter. Management must be individualized (Fig. 2.7) and depends on type of catheter, duration of catheterization, anticipated need for continued central venous access, risk of establishing new central venous access, and underlying medical condition and prognosis. All critical care units must have protocols for managing the febrile, catheterized patient [150]. Decisions to remove, change over a guidewire, or leave catheters in place must be based on a fundamental knowledge of risks and benefits for catheters inserted at each site.

Catheter sites in the febrile patient should always be examined. Clinical infection of the site mandates removal of the catheter and institution of antibiotics. Surgically implanted catheters are not easily removed or replaced and can often be left in place while the infection is cleared with antibiotics, unless tunnel infection is present. Percutaneously inserted CVCs are relatively easily removed, and the risks of leaving a catheter in place through an infected site outweigh the risk of replacement at a new site, except in very unusual circumstances.

In patients with severe sepsis or septic shock, CVCs should be considered a possible source. If all catheter sites appear normal and a noncatheter source of infection is implicated, appropriate antibiotics are initiated and the catheters left in place. The usual guidelines for subsequent catheter management should be followed, and this rarely results in treatment failure. In contrast, if a noncatheter source cannot be identified, then central catheters in place more than 3 days should be managed individually, with attention to duration of catheterization (Table 2.3). Only for patients with excessive risks for new catheter placement (i.e., severe coagulopathy), guidewire exchange of the catheter is justifiable after obtaining blood cultures through the catheter and a peripheral site and semiquantitative culture of a catheter segment. If within the next 24 hours an alternative source for sepsis is found, or if the catheter segment culture is negative and the patient improves and stabilizes, the guidewire catheter can be left in place and the risk of catheter insertion avoided. Alternatively, if the catheter culture becomes positive, especially if the same organism is identified on peripheral blood cultures, the cutaneous tract is also infected and the guidewire catheter should be removed and alternative access achieved.

The most common situation is the stable febrile patient with a CVC in place (Table 2.4). As mentioned earlier, if a noncatheter source for fever is identified, appropriate antibiotics are given and the catheter is left in place, assuming it is still needed and the site is clinically uninvolved. In the patient

TABLE 2.4

APPROACH TO THE FEBRILE PATIENT WITH A CENTRAL VENOUS CATHETER

1. Catheter no longer needed—remove and culture tip
2. Patient with severe sepsis or septic shock (catheter >72 hr)—promptly remove catheter and culture tip
3. Patient with severe sepsis or septic shock (catheter <72 h)—initiate antibiotics, remove catheter if no improvement in 12–24 h
4. Stable patient (catheter >72 h)—guidewire exchange with tip culture if culture with ≥15 CFU—remove catheter

with no obvious source of fever [1], indications for the CVCs should be reviewed and the catheter withdrawn if it is no longer required. Otherwise, the physician must decide between observation, potential premature withdrawal, and a guidewire change of the catheter. If the catheter is less than 72 hours old, observation is reasonable, as it is very unlikely that the catheter is already infected unless breaks in sterile technique occurred during insertion. For catheters that are at least 72 hours old, guidewire exchanges are rational but, in our opinion, not mandatory. An appropriately performed guidewire change allows comparison of catheter segment cultures to other clinical cultures without subjecting the patient to repeat venipuncture. If within the next 24 hours an alternative source for fever is identified, and/or the initial catheter segment culture is negative, then the guidewire catheter can be left in place.

When catheter-related bacteremia does develop, antibiotic therapy is necessary for a period of 7 to 14 days. Even in patients treated for 14 days, metastatic infection can develop. Catheter-related fever, infection, and septicemia is a complicated disease, and the expertise of an infectious disease consultant may be required to assist with the decision on how long to continue antibiotic therapy.

CHAPTER 3 ■ ARTERIAL LINE PLACEMENT AND CARE

JASON LEE-LLACER AND MICHAEL G. SENEFF

Arterial catheterization remains an extremely important skill for critical care physicians. The most common indications for inserting an arterial catheter remain the need for close blood pressure monitoring and frequent blood gas sampling in unstable and ventilated patients. Newer technologies that necessitate arterial access continue to mature. For example, arterial pulse contour analysis can now be used to predict fluid responsiveness and compute cardiac output more reliably and less invasively in appropriately selected patients [1]. Although it is likely that advancements in current noninvasive technology, such as transcutaneous PCO_2 monitoring and pulse oximetry, will decrease the need for arterial catheter placement, intensivists will always need to be knowledgeable in the setup and interpretation of arterial catheter systems. In this chapter, we review the principles of hemodynamic monitoring and discuss the indications, routes, and management of arterial cannulation.

INDICATIONS FOR ARTERIAL CANNULATION

Arterial catheters should be inserted only when they are specifically required and removed immediately when no longer needed. Too often they are left in place for convenience to allow easy access to blood sampling, which leads to increased laboratory testing and excessive diagnostic blood loss [2,3]. Protocols incorporating guidelines for arterial catheterization and alternative noninvasive monitoring, such as pulse oximetry and end tidal CO_2, have realized significant improvements in resource utilization and cost savings, without impacting the quality of care [4].

The indications for arterial cannulation can be grouped into four broad categories (Table 3.1): (1) hemodynamic monitoring (blood pressure and/or cardiac output/pulse contour analysis); (2) frequent arterial blood gas sampling; (3) diagnostic or therapeutic/interventional radiology procedures, including intra-aortic balloon pump (IABP) use, arterial administration of drugs, vascular stenting and embolization, and (4) continuous cardiac output monitoring.

Noninvasive, indirect blood pressure measurements determined by auscultation of Korotkoff sounds distal to an occluding cuff (Riva–Rocci method) are generally accurate, although systolic readings are consistently lower compared to a simultaneous direct measurement. In hemodynamically unstable patients, however, indirect techniques may significantly underestimate blood pressure. Automated noninvasive blood pressure measurement devices can also be inaccurate, particularly in rapidly changing situations, at the extremes of blood pressure, and in patients with dysrhythmias [5]. For these reasons, direct blood pressure monitoring is usually required for unstable patients. Rapid beat-to-beat changes can easily be monitored and appropriate therapeutic modalities initiated, and variations in individual pressure waveforms may prove diagnostic. Waveform inspection can rapidly diagnose electrocardiogram lead disconnect, indicate the presence of aortic valve disease, help determine the effect of dysrhythmias on perfusion, and reveal the impact of the respiratory cycle on blood pressure (pulsus paradoxus). In addition, in mechanically ventilated patients, responsiveness to fluid boluses may be predicted by calculating the systolic pressure variation (SPV) or pulse pressure variation (PPV) from the arterial waveform, and stroke volume variation (SVV) from the pulse contour analysis. In patients on volume-controlled mechanical ventilation, all of these techniques have been shown to predict, with a high degree of accuracy, patients likely to respond (with an increase in stroke volume) to fluid volume challenge [1].

Recent advances allow continuous CO monitoring using arterial pulse contour analysis. This method relies on the assumption that the contour of the arterial pressure waveform is proportional to the stroke volume [6]. This, however, does not take into consideration the differing impedances among the arteries of individuals and different disease states and therefore requires calibration with another method of determining cardiac output [7]. This is usually done with lithium dilution or transpulmonary thermodilution methods. A different pulse contour analysis device has been introduced which does not require an additional method of determining CO for calibration, but instead estimates impedance based upon a proprietary formula that uses waveform and patient demographic data [7]. This method has significant limitations (i.e., atrial fibrillation) and there is concern that the device may not be accurate in clinical situations with dynamic changes in vascular tone (i.e., sepsis) [8]. Further data and comparison among the methods in authentic and diverse clinical situations are required before definitive recommendations can be made.

Management of complicated patients in critical care units typically requires multiple laboratory and arterial blood gas determinations. In these situations, arterial cannulation permits routine laboratory tests without multiple needle sticks and vessel trauma. In our opinion, an arterial catheter for blood gas determination should be placed when a patient requires two or more measurements daily.

EQUIPMENT, MONITORING, TECHNIQUES, AND SOURCES OF ERROR

The equipment necessary to display and measure an arterial waveform has not changed and includes (a) an appropriate intravascular catheter; (b) fluid-filled noncompliant tubing with stopcocks; (c) transducer; (d) a constant flush device; and (e) electronic monitoring equipment. Using this equipment, intravascular pressure changes are transmitted through the hydraulic (fluid-filled) elements to the transducer, which converts mechanical displacement into a proportional electrical signal.

TABLE 3.1

INDICATIONS FOR ARTERIAL CANNULATION

Hemodynamic monitoring
Acutely hypertensive or hypotensive patients
Use of vasoactive drugs
Multiple blood sampling
Ventilated patients
Limited venous access
Diagnostic or interventional radiology procedures
Intra-arterial drugs
Vascular stenting
Intra-aortic balloon pump use
Arterial embolization
Continuous cardiac output monitoring

The signal is amplified, processed, and displayed as a waveform by the monitor. Undistorted presentation of the arterial waveform is dependent on the performance of each component, and an understanding of potential problems that can interfere with overall fidelity of the system.

The major problems inherent to pressure monitoring with a catheter system are inadequate dynamic response, improper zeroing and zero drift, and improper transducer/monitor calibration. Most physicians are aware of zeroing techniques but do not appreciate the importance of dynamic response in ensuring system fidelity. Catheter-tubing-transducer systems used for pressure monitoring can best be characterized as underdamped second-order dynamic systems with mechanical parameters of elasticity, mass, and friction [9]. Overall, the dynamic response of such a system is determined by its resonant frequency and damping coefficient (zeta). The resonant or natural frequency of a system is the frequency at which it oscillates when stimulated. When the frequency content of an input signal (i.e., pressure waveform) approaches the resonant frequency of a system, progressive amplification of the output signal occurs—a phenomenon known as ringing [10]. To ensure a flat frequency response (accurate recording across a spectrum of frequencies), the resonant frequency of a monitoring system should be at least five times higher than the highest frequency in the input signal [9]. Physiologic peripheral arterial waveforms have a fundamental frequency of 3 to 5 Hz and therefore the resonant frequency of a system used to monitor arterial pressure should ideally be greater than 20 Hz to avoid ringing and systolic overshoot.

The system component most likely to cause amplification of a pressure waveform is the hydraulic element. A good hydraulic system will have a resonant frequency between 10 and 20 Hz, which may overlap with arterial pressure frequencies. Thus amplification can occur, which may require damping to accurately reproduce the waveform [11].

The damping coefficient is a measure of how quickly an oscillating system comes to rest. A system with a high damping coefficient absorbs mechanical energy well (i.e., compliant tubing), causing a diminution in the transmitted waveform. Conversely, a system with a low damping coefficient results in underdamping and systolic overshoot. Damping coefficient and resonant frequency together determine the dynamic response of a recording system. If the resonant frequency of a system is less than 7.5 Hz, the pressure waveform will be distorted no matter what the damping coefficient. On the other hand, a resonant frequency of 24 Hz allows a range in the damping coefficient of 0.15 to 1.1 without resultant distortion of the pressure waveform [9].

Although there are other techniques [12], the easiest method to test the damping coefficient and resonant frequency of a monitoring system is the fast-flush test (also known as the square wave test). This is performed at the bedside by briefly opening and closing the continuous flush device, which produces a square wave displacement on the monitor followed by a return to baseline, usually after a few smaller oscillations (Fig. 3.1). Values for the damping coefficient and resonant frequency can be computed by printing the wave on graph paper [9], but visual inspection is usually adequate to ensure a proper frequency response. An optimum fast-flush test results in one undershoot followed by small overshoot, then settles to the patient's waveform.

For peripheral pulse pressure monitoring, an adequate fast-flush test usually corresponds to a resonant frequency of 10 to 20 Hz coupled with a damping coefficient of 0.5 to 0.7. To ensure the continuing fidelity of a monitoring system, dynamic response validation by fast-flush test should be performed frequently: at least every 8 hours, with every significant change in patient hemodynamic status, after each opening of the system (zeroing, blood sampling, tubing change), and whenever the waveform appears damped [9].

With consideration of the above concepts, components of the monitoring system are designed to optimize the frequency response of the entire system. The 18- and 20-gauge catheters used to gain vascular access are not a major source of distortion but can become kinked or occluded by thrombus, resulting in overdamping of the system. Standard, noncompliant tubing is provided with most disposable transducer kits and should be as short as possible to minimize signal amplification [10]. Air bubbles in the tubing and connecting stopcocks are a notorious source of overdamping of the tracing and can be cleared by flushing through a stopcock. Currently available disposable transducers incorporate microchip technology, are very reliable, and have relatively high resonant frequencies [13]. The transducer is attached to the electronic monitoring equipment by a cable. Modern monitors have internal calibration, filter artifacts, and print the display on request. The digital readout display is usually an average of values over time and therefore does not accurately represent beat-to-beat variability. Monitors provide the capability to freeze a display with on-screen calibration to measure beat-to-beat differences in amplitude

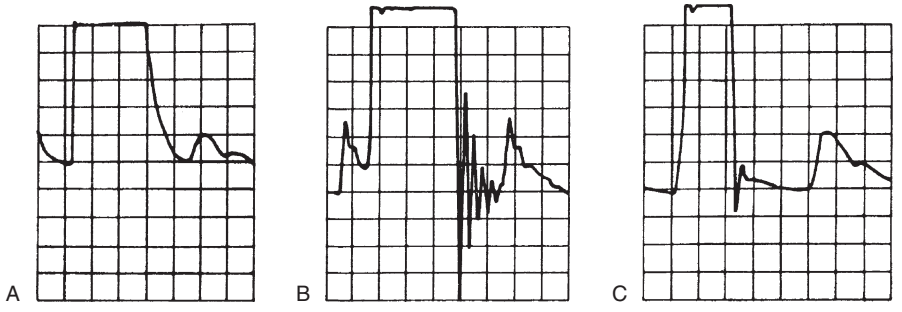

FIGURE 3.1. Fast-flush test. **A:** Overdamped system. **B:** Underdamped system. **C:** Optimal damping.

precisely. This allows measurement of the effect of ectopic beats on blood pressure, PPV, SPV, or assessment of the severity of pulsus paradoxus.

When presented with pressure data or readings believed to be inaccurate, or which are significantly different from indirect readings, a few quick checks can ensure system accuracy. Improper zeroing of the system, because of either change in patient position or zero drift, is the single most important source of error. Zeroing can be checked by opening the transducer stopcock to air and aligning with the midaxillary line, confirming that the monitor displays zero. Zeroing should be repeated with patient position changes, (a transducer that is below the zero reference line will result in falsely high readings and vice versa), when significant changes in blood pressure occur, and routinely every 6 to 8 hours because of zero drift. Disposable pressure transducers incorporate semiconductor technology and are very small, yet rugged and reliable, and due to standardization, calibration of the system is not necessary [13]. Transducers are faulty on occasion, however, and calibration may be checked by attaching a mercury manometer to the stopcock and applying 100, 150, and/or 200 mm Hg pressure. A variation of ±5 mm Hg is acceptable. If calibration is questioned and the variation is out of range, or a manometer is not available for testing, the transducer should be replaced.

If zero referencing and calibration are correct, a fast-flush test will assess the system's dynamic response. Overdamped tracings are usually caused by problems that are correctable, such as air bubbles, kinks, clot formation, overly compliant tubing, loose connections, a deflated pressure bag, or anatomical factors affecting the catheter. An underdamped tracing results in systolic overshoot and can be secondary to excessive tubing length or patient factors such as increased inotropic or chronotropic state. Many monitors can be adjusted to filter out frequencies above a certain limit, which can eliminate frequencies in the input signal causing ringing. However, this may also cause inaccurate readings if important frequencies are excluded.

TECHNIQUE OF ARTERIAL CANNULATION

Site Selection

Several factors are important in selecting the site for arterial cannulation. The ideal artery has extensive collateral circulation that will maintain the viability of distal tissues if thrombosis occurs. The site should be comfortable for the patient, accessible for nursing care and insertion, and close to the monitoring equipment. Sites involved by infection or disruption in the epidermal barrier should be avoided. Certain procedures, such as coronary artery bypass grafting, may dictate preference for one site over another. Larger arteries and catheters provide more accurate (central aortic) pressure measurements. Physicians should also be cognizant of differences in pulse contour recorded at different sites. As the pressure pulse wave travels outward from the aorta, it encounters arteries that are smaller and less elastic, with multiple branch points, causing reflections of the pressure wave. This results in a peripheral pulse contour with increased slope and amplitude, causing recorded values to be artificially elevated. As a result, distal extremity artery recordings yield higher systolic values than central aortic or femoral artery recordings. Diastolic pressures tend to be less affected, and mean arterial pressures measured at the different sites are similar [14].

The most commonly used sites for arterial cannulation in adults are the radial, femoral, axillary, dorsalis pedis, and brachial arteries. Additional sites include the ulnar, axillary and superficial temporal arteries. Peripheral sites are cannulated percutaneously with a 2-inch, 20-gauge, nontapered Teflon catheter-overneedle and larger arteries using the Seldinger technique with a prepackaged kit, typically containing a 6-inch, 18-gauge Teflon catheter, appropriate introducer needles, and guidewire.

Arterial catheterization is performed by physicians from many different specialties and usually the procedure to be performed dictates the site chosen. For example, insertion of an IABP is almost always performed through the femoral artery regardless of the specialty of the physician performing the procedure. Critical care physicians need to be facile with arterial cannulation at all sites, but the radial and femoral arteries are used successfully for more than 90% of all arterial catheterizations performed in the ICU. Although each site has unique complications, available data do not indicate a preference for any one site [15–17]. Radial artery cannulation is usually attempted initially unless the patient is in shock, on high dose vasopressors, and/or pulses are not palpable. If this fails, femoral artery cannulation should be performed. If catheterization at these two sites proves unsuccessful or not appropriate, then the dorsalis pedis, brachial, and axillary artery are the recommended alternative sites. Which of these is chosen depends on the exact clinical situation and the experience and expertise of the operator.

Use of Portable Ultrasound

Bedside ultrasound has not had as great an impact on arterial as it has on venous catheterization because vessel puncture is based on a palpable "landmark" that guides needle placement, and the complication rate during insertion is much lower. However, we have found ultrasound guidance to be very useful and efficient in assisting with brachial and femoral artery catheterizations, and have even used it successfully for selected difficult radial artery procedures. In our experience, ultrasound has the same impact with arterial as it does with venous catheterizations; higher success rate with less procedure time, number of attempts, and complications. Operator technique of ultrasound for arterial is the same as for venous catheterization and the reader is referred to Chapter 2 for a description of ultrasound equipment and technique. Ultrasound images for each of the major arterial routes are shown in Figure 3.2.

Radial Artery Cannulation

A thorough understanding of normal arterial anatomy and common anatomical variants greatly facilitates insertion of catheters and management of unexpected findings at all sites. The radial artery is one of two final branches of the brachial artery. It courses over the flexor digitorum sublimis, flexor pollicis longus, and pronator quadratus muscles and lies just lateral to the flexor carpi radialis in the forearm. As the artery enters the floor of the palm, it ends in the deep volar arterial arch at the level of the metacarpal bones and communicates with the ulnar artery. A second site of collateral flow for the radial artery occurs via the dorsal arch running in the dorsum of the hand (Fig. 3.3).

The ulnar artery runs between the flexor carpi ulnaris and flexor digitorum sublimis in the forearm, with a short course over the ulnar nerve. In the hand the artery runs over the transverse carpal ligament and becomes the superficial volar arch, which forms an anastomosis with a small branch of the radial artery. These three anastomoses provide excellent collateral flow to the hand [18]. A competent superficial or deep palmar arch must be present to ensure adequate collateral flow.

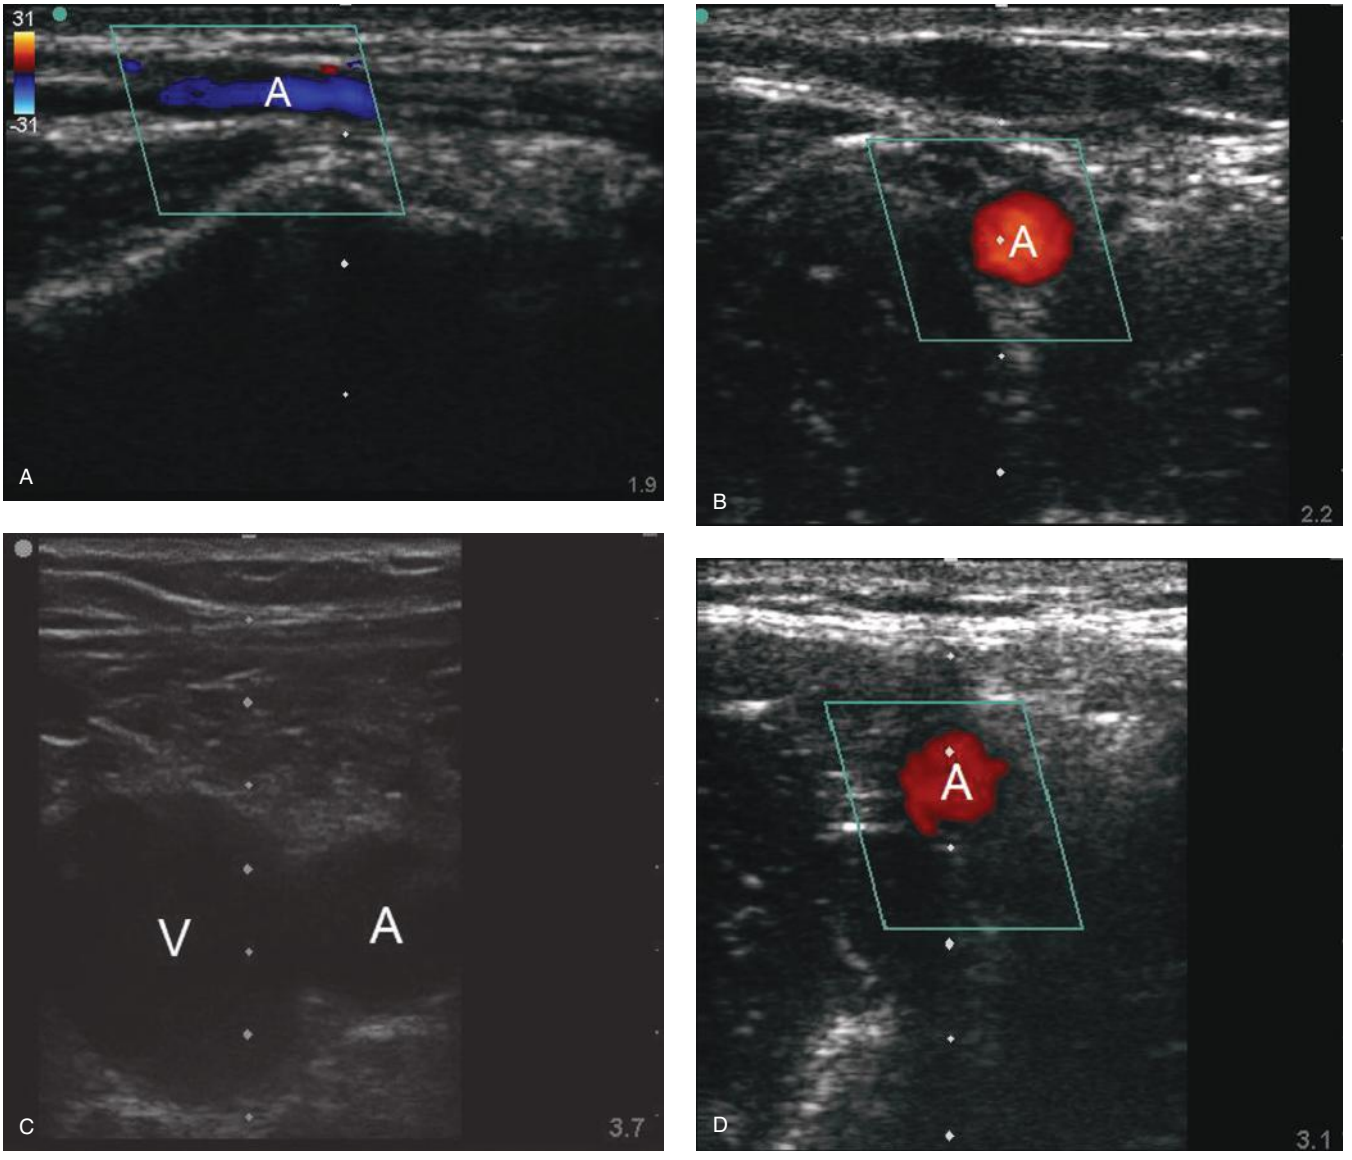

FIGURE 3.2. Portable ultrasound images. **A.** Radial artery longitudinal view. **B.** Brachial artery axial view. **C.** Femoral artery axial view. **D.** Axillary artery axial view. See text for details.

At least one of these arches may be absent in up to 20% of individuals.

Modified Allen's Test

Hand ischemia is a rare but potential devastating complication of radial artery catheterization that may require amputation [19]. Hand ischemia is rare because of the rich collateral circulation described earlier that insures perfusion even if one of the main arteries thrombose. Historically, the modified Allen's test [20], described in previous editions of this text, was used prior to radial catheterization to detect patients' in whom the collateral circulation may not be intact and presumably at increased risk for hand ischemia. However, as a screening tool the Allen's test has never had very good predictive value [21] and our institution, as well as many others, has abandoned its routine use. The best way to prevent hand ischemia is to avoid radial catheterization in patients at increased risk (i.e., high dose vasopressor therapy, scleroderma, vasculopathy) and to perform clinical evaluation of hand perfusion at each nursing shift change. *Any* change in the hand distal to a radial artery catheter that suggests decreased perfusion (color or temperature change, paresthesias, loss of capillary refill) should prompt *immediate* removal of the catheter and further investigation if the changes do not reverse.

Percutaneous Insertion

The hand is positioned in 30 to 60 degrees of dorsiflexion with the aid of a roll of gauze and armband, avoiding hyperabduction of the thumb. The volar aspect of the wrist is prepared (alcoholic chlorhexidine) and draped using sterile technique, and approximately 0.5 mL of lidocaine is infiltrated on both sides of the artery through a 25-gauge or smaller needle. Lidocaine serves to decrease patient discomfort and may decrease the likelihood of arterial vasospasm [22]. The catheter over the needle approach (e.g., radial or brachial site) necessitates cap, mask, sterile gloves and a small fenestrated drape; whereas, the Seldinger technique (i.e., femoral approach) requires maximum barrier precautions. A time out confirming correct patient,

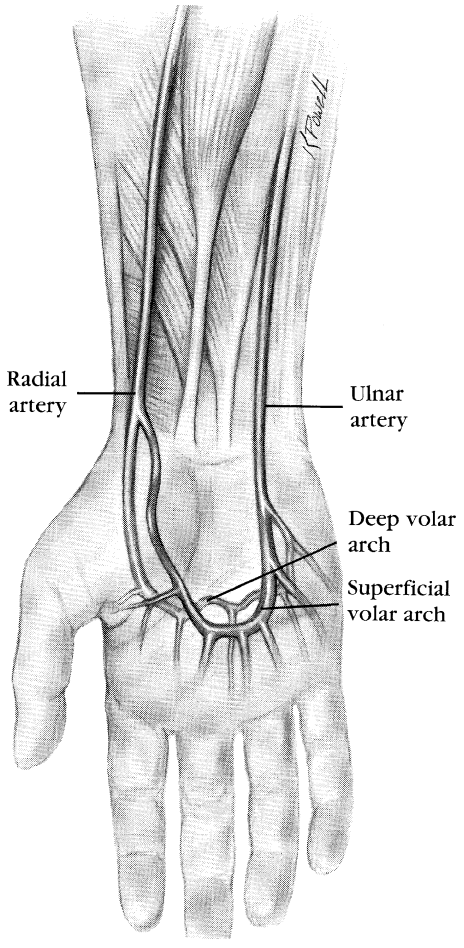

FIGURE 3.3. Anatomy of the radial artery. Note the collateral circulation to the ulnar artery through the deep volar arterial arch and dorsal arch.

correct site, correct equipment and informed consent is necessary before the procedure begins.

A 20-gauge, nontapered, Teflon 1½- or 2-inch catheter-overneedle apparatus is used for puncture. Entry is made at a 30- to 60-degree angle to the skin approximately 3 to 5 cm proximal to the distal wrist crease. Ultrasound image of the radial artery at this position is shown in Figure 3.2A. The needle and cannula are advanced until blood return is noted in the hub, signifying intra-arterial placement of the tip of the needle. A small amount of further advancement is necessary for the cannula to enter the artery as well. With this accomplished, needle and cannula are brought flat to the skin and the cannula advanced to its hub with a firm, steady rotary action. Correct positioning is confirmed by pulsatile blood return on removal of the needle. If the initial attempt is unsuccessful, subsequent attempts should be more proximal, rather than closer to the wrist crease, as the artery is of greater diameter [18], although this may increase the incidence of catheters becoming kinked or occluded [23].

If difficulty is encountered when attempting to pass the catheter, carefully replacing the needle and slightly advancing the whole apparatus may remedy the problem. Alternately, a fixation technique can be attempted (Fig. 3.3). Advancing the needle and catheter through the far wall of the vessel purposely transfixes the artery. The cannula is then pulled back with the needle partially retracted within the catheter until vigorous arterial blood return is noted. The catheter can then be advanced into the arterial lumen, using the needle as a reinforcing stent.

Catheters with self-contained guidewires to facilitate passage of the cannula into the artery are available (Fig. 3.4). Percutaneous puncture is made in the same manner, but when blood return is noted in the catheter hub the guidewire is passed through the needle into the artery, serving as a stent for subsequent catheter advancement. The guidewire and needle are then removed and placement confirmed by pulsatile blood return. The cannula is then secured firmly, attached to transducer tubing, and the site bandaged. Video instruction for the insertion of a radial arterial line is available at www.nejm.org [24].

Dorsalis Pedis Artery Cannulation

Dorsalis pedis artery catheterization is uncommon in most critical care units; compared with the radial artery, the anatomy is less predictable and the success rate is lower [25]. The dorsalis pedis artery is the main blood supply of the dorsum of the foot. The artery runs from the level of the ankle to the great toe. It lies very superficial and just lateral to the tendon of the extensor hallucis longus. The dorsalis pedis anastomoses with branches from the posterior tibial (lateral plantar artery) and, to a lesser extent, peroneal arteries, creating an arterial arch network analogous to that in the hand.

Use of a catheter with self-contained guidewire is recommended for dorsalis pedis catheterization. The foot is placed in plantar flexion and prepared in the usual fashion. Vessel entry is obtained approximately halfway up the dorsum of the foot where the palpable pulse is strongest; advancement is the same as with cannulation of the radial artery. Patients usually find insertion here more painful but less physically limiting. Systolic pressure readings are usually 5 to 20 mm Hg higher with dorsalis pedis catheters than radial artery catheters, but mean pressure values are generally unchanged.

Brachial Artery Cannulation

The brachial artery is cannulated in the bicipital groove proximal to the antecubital fossa at a point where there is no collateral circulation (Fig. 3.2B). In theory, clinical ischemia should be a greater risk, but in most series brachial artery catheters have complication rates comparable to other routes [17,18,26,27]. Even when diminution of distal pulses occurs, because of either proximal obstruction or distal embolization, clinical ischemia is unlikely [26]. An additional anatomic consideration is that the median nerve lies in close proximity to the brachial artery and may be punctured in 1% to 2% of cases [27]. This usually causes only transient paresthesias, but median nerve palsy has been reported. Median nerve palsy is a particular risk in patients with coagulopathy because even minor bleeding into the fascial planes can produce compression of the median nerve [28]. Coagulopathy should be considered a relative contraindication to brachial artery cannulation. Given all these considerations, brachial artery cannulation should only be considered if the radial, femoral, and dorsalis pedis sites are not available or appropriate.

Cannulation of the brachial artery is best performed using a prepackaged kit designed for larger arteries (see femoral artery cannulation). The brachial artery is punctured by extending the arm at the elbow and locating the pulsation a few centimeters proximal to the antecubital fossa, just medial to the bicipital tendon. Once the catheter is established, the elbow must be kept in full extension to avoid kinking or breaking the catheter. Clinical examination of the hand, and Doppler studies if indicated, should be repeated daily while the brachial catheter is in place. The catheter should be promptly removed if diminution of any pulse occurs or there is evidence of embolism. An

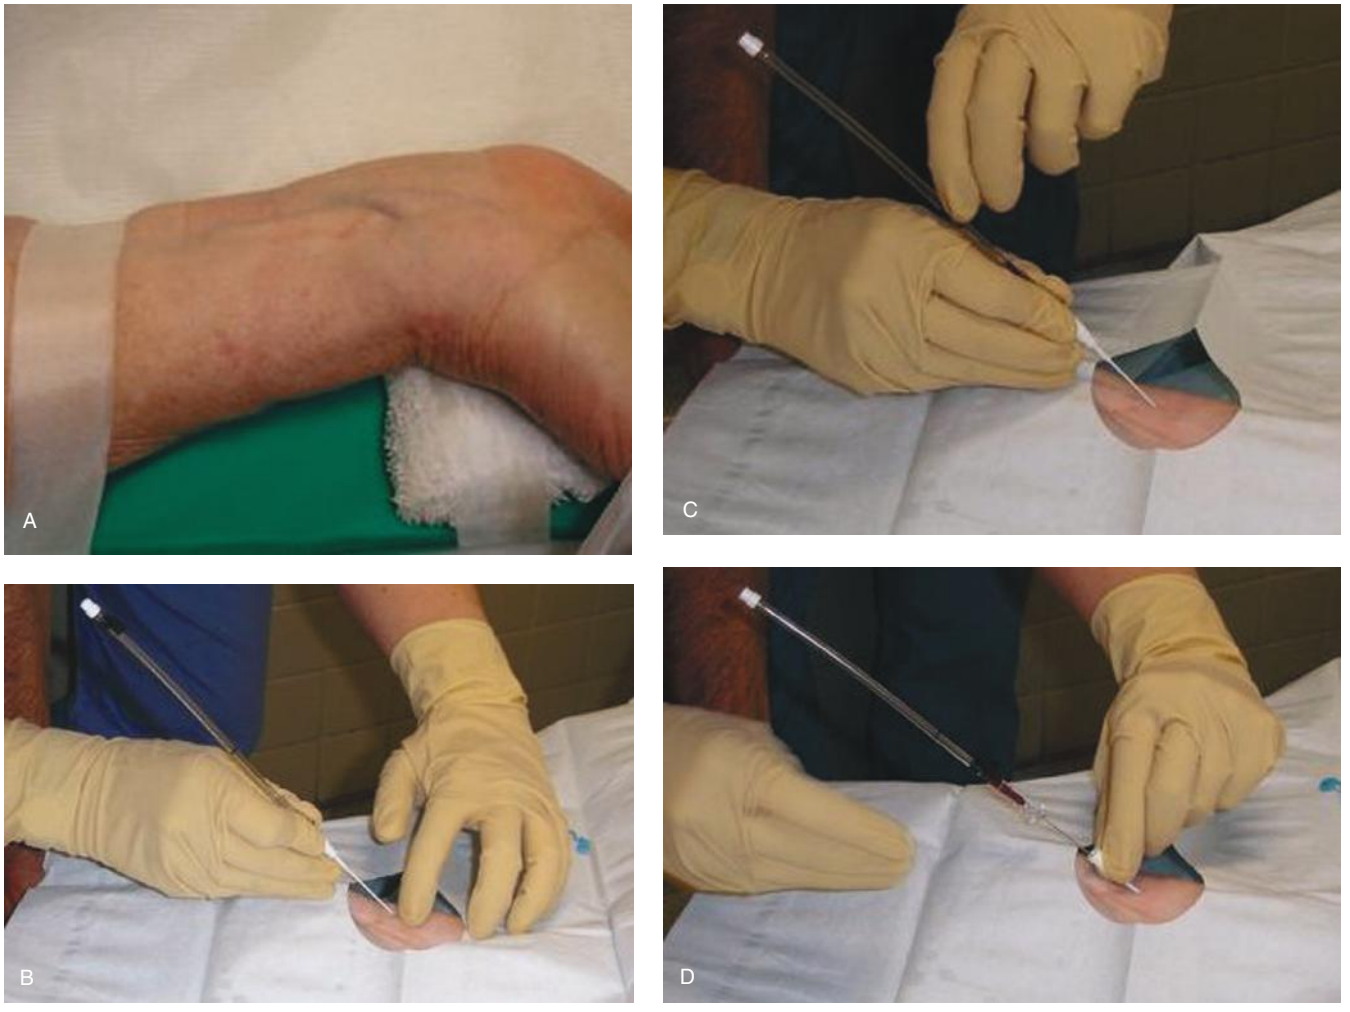

FIGURE 3.4. Cannulation of the radial artery. **A:** A towel is placed behind the wrist, and the hand is immobilized with tape. **B:** The catheter-needle-guidewire apparatus is inserted into the skin at a 30- to 60-degree angle. **C:** The guidewire is advanced into the artery after pulsatile blood flow is obtained. **D:** The catheter is advanced over the guidewire into the artery. [From Irwin RS, Rippe JM: *Manual of Intensive Care Medicine*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006:17, with permission.]

additional concern is air embolism (see later) since placement of a 6-inch catheter puts the tip in the axillary artery.

Femoral Artery Cannulation

The femoral artery is usually the next alternative when radial artery cannulation fails or is inappropriate [15–17]. The femoral artery is large and often palpable when other sites are not, and the technique of cannulation is easy to learn. The most common reason for failure to cannulate is severe atherosclerosis or prior vascular procedures involving both femoral arteries, in which case axillary or brachial artery cannulation is appropriate. Complications unique to this site are rare but include retroperitoneal hemorrhage and intra-abdominal viscus perforation. These complications occur because of poor technique (puncture above the inguinal ligament) or in the presence of anatomical variations (i.e., large inguinal hernia). Ischemic complications from femoral artery catheters are very rare.

The external iliac artery becomes the common femoral artery at the inguinal ligament (Fig. 3.5). The artery courses under the inguinal ligament near the junction of the medial and the middle third of a straight line drawn between the pubis and the anterior superior iliac spine (Fig. 3.2C). The artery is cannulated using the Seldinger technique and any one of several available prepackaged kits. Kits contain the equivalent of a 19-gauge thin-wall needle, appropriate guidewire, and a 6-inch, 18-gauge Teflon catheter. The patient lies supine with the leg extended and slightly abducted. Skin puncture should be 3 to 5 cm caudal to the inguinal ligament to minimize the risk of retroperitoneal hematoma or bowel perforation, which can occur when needle puncture of the vessel is cephalad to the inguinal ligament. The thin-wall needle is directed, bevel up, cephalad at a 45-degree angle. When arterial blood return is confirmed, the needle and syringe may need to be brought down against the skin to facilitate guidewire passage. The guidewire should advance smoothly, but minor manipulation and rotation is sometimes required if the wire meets resistance at the needle tip or after it has advanced into the vessel. Inability to pass the guidewire may be due to an intimal flap over the needle bevel or atherosclerotic plaques in the vessel. In the latter instance, cannulation of that femoral artery may prove impossible. When the guidewire will not pass beyond the needle tip it should be withdrawn and blood return

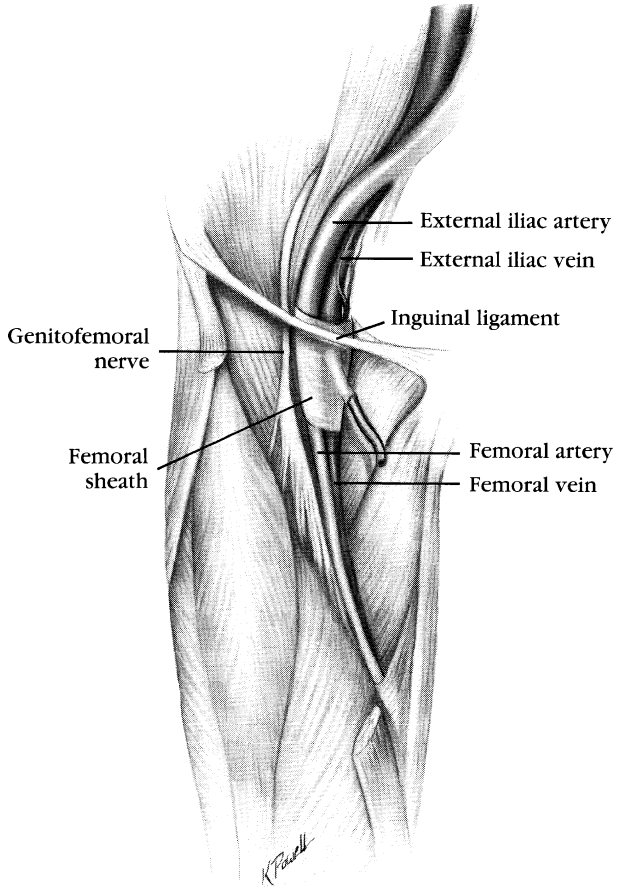

FIGURE 3.5. Anatomy of the femoral artery and adjacent structures. The artery is cannulated below the inguinal ligament.

reestablished by advancing the needle or repeat vascular puncture. The guidewire is then inserted, the needle withdrawn and the catheter threaded over the guidewire to its hub. The guidewire is withdrawn, the catheter sutured securely and connected to the transducer tubing.

Axillary Artery Cannulation

Axillary artery catheterization in the ICU occurs infrequently, but centers experienced with it report a low rate of complications [15,17,29]. The axillary artery is large and frequently palpable when all other sites are not and has a rich collateral circulation. The tip of a 6-inch catheter inserted through an axillary approach lies in the subclavian artery, and thus accurate central pressures are obtained. The central location of the tip makes cerebral air embolism a greater risk, therefore left axillary catheters are preferred for the initial attempt, since air bubbles passing into the right subclavian artery are more likely to traverse the aortic arch. Caution should be exercised in flushing axillary catheters, which is best accomplished manually using low pressures and small volumes.

The axillary artery begins at the lateral border of the first rib as a continuation of the subclavian artery and ends at the inferior margin of the teres major muscle, where it becomes the brachial artery. The optimal site for catheterization is the junction of the middle and lower third of the vessel, which usually corresponds to its highest palpable point in the axilla. At this point, the artery is superficial and is located at the inferior border of the pectoralis major muscle (Fig. 3.2D). The artery is enclosed in a neurovascular bundle, the axillary sheath, with the medial, posterior, and lateral cords of the brachial plexus. Medial to the medial cord is the axillary vein. Not surprisingly, brachial plexus neuropathies have been reported from axillary artery cannulation [30]. Coagulopathy is a relative contraindication, as the axillary sheath can rapidly fill with blood from an uncontrolled arterial puncture, resulting in a compressive neuropathy.

The axillary artery is cannulated using the Seldinger technique and a prepackaged kit. The arm is abducted, externally rotated, and flexed at the elbow by having the patient place the hand under his or her head. The artery is palpated at the lower border of the pectoralis major muscle and fixed against the shaft of the humerus. After site preparation and local infiltration with lidocaine, the thin-wall needle is introduced at a 30- to 45-degree angle to the vertical plane until return of arterial blood. The remainder of the catheterization proceeds as described for femoral artery cannulation.

COMPLICATIONS OF ARTERIAL CANNULATION

Arterial cannulation is a relatively safe invasive procedure. Although estimates of the total complication rate range from 15% to 40%, clinically relevant complications occur in 5% or less (Table 3.2). Risk factors for infectious and noninfectious complications have been identified [31,32] (Table 3.3), but the clinical impact of most of these factors is minimal, given the overall low incidence of complications.

Thrombosis

Thrombosis is the single most common complication of intra-arterial catheters. The incidence of thrombosis varies with the site, method of detection, size of the cannula, and duration of

TABLE 3.2

COMPLICATIONS ASSOCIATED WITH ARTERIAL CANNULATION

Site	Complication
All sites	Pain and swelling
	Thrombosis
	Asymptomatic
	Symptomatic
	Embolization
	Hematoma
	Hemorrhage
	Limb ischemia
	Catheter-related infection including bacteremia
	Diagnostic blood loss
	Pseudoaneurysm
	Heparin-associated thrombocytopenia
Radial artery	Cerebral embolization
	Peripheral neuropathy
Femoral artery	Retroperitoneal hemorrhage
	Bowel perforation
	Arteriovenous fistula
Axillary artery	Cerebral embolization
	Brachial plexopathy
Brachial artery	Median nerve damage
	Cerebral embolization

TABLE 3.3

FACTORS PREDISPOSING TO COMPLICATIONS WITH ARTERIAL CANNULATION

Large tapered cannulas (>20 gauge except at the large artery sites)
Hypotension
Coagulopathy
Low cardiac output
Multiple puncture attempts
Use of vasopressors
Atherosclerosis
Hypercoagulable state
Placement by surgical cutdown
Site inflammation
Intermittent flushing system
Bacteremia

cannulation. Thrombosis is common with radial and dorsalis pedis catheters, but clinical sequelae are rare because of the collateral circulation [31,32]. When a 20-gauge nontapered Teflon catheter with a continuous 3 mL per hour heparinized-saline flush is used to cannulate the radial artery for 3 to 4 days, thrombosis of the vessel can be detected by Doppler study in 5% to 25% of cases [32]. Use of a flush solution containing heparin is no longer standard at our institution because of concern for heparin-induced thrombocytopenia; the incidence of thrombosis does not appear to be significantly higher using saline flush [33,34].

Thrombosis often occurs after catheter removal. Women represent a preponderance of patients who experience flow abnormalities following radial artery cannulation, probably because of smaller arteries and a greater tendency to exhibit vasospasm [23]. Most patients eventually recanalize, generally by 3 weeks after removal of the catheter. Despite the high incidence of Doppler-detected thrombosis, clinical ischemia of the hand is rare and usually resolves following catheter removal. Symptomatic occlusion requiring surgical intervention occurs in fewer than 1% of cases, but can be catastrophic with tissue loss or amputation of the hand [19]. Most patients who develop clinical ischemia have an associated contributory cause, such as prolonged circulatory failure with high-dose vasopressor therapy [31]. We consider the femoral artery the most appropriate first choice in these patients.

Regular inspection of the extremity for unexplained pain or signs of ischemia and immediate removal of the catheter minimize significant ischemic complications. If evidence of ischemia persists after catheter removal, anticoagulation, thrombolytic therapy, embolectomy, surgical bypass, or cervical sympathetic blockade are treatment options and should be pursued aggressively [19,31].

Cerebral Embolization

Continuous flush devices used with arterial catheters are designed to deliver 3 mL per hour of fluid from an infusion bag pressurized to 300 mm Hg. Lowenstein [35] demonstrated that with rapid flushing of radial artery lines with relatively small volumes of radiolabeled solution, traces of the solution could be detected in the central arterial circulation in a time frame representative of retrograde flow. Chang [4,36] demonstrated that injection of greater than 2 mL of air into the radial artery of small primates resulted in retrograde passage of air into the vertebral circulation. Factors that increase the risk for retrograde passage of air are patient size and position (air travels up in a sitting patient), injection site, and flush rate. Air embolism has been cited as a risk mainly for radial arterial catheters but logically could occur with all arterial catheters, especially axillary and brachial artery catheters. The risk is minimized by clearing all air from tubing before flushing, opening the flush valve for no more than 2 to 3 seconds, and avoiding overaggressive manual flushing of the line.

Diagnostic Blood Loss

Diagnostic blood loss (DBL) is patient blood loss that occurs due to frequent blood sampling obtained for laboratory testing. The significance of DBL is underappreciated. It is a particular problem in patients with standard arterial catheter setups that are used as the site for sampling, because 3 to 5 mL of blood is typically wasted (to avoid heparin/saline contamination) every time a sample is obtained. In patients with frequent arterial blood gas determinations, DBL can be substantial and result in a transfusion requirement [37]. There are several ways to minimize DBL, including tubing systems employing a reservoir for blood sampling, continuous intra-arterial blood gas monitoring, point of care microchemistry analysis and the use of pediatric collection tubes. Given the expense and risks of blood component therapy, every ICU should have a blood conservation policy in place that includes minimizing DBL. Protocols that are designed to optimize laboratory utilization have resulted in significant cost savings and reduced transfusion requirements [38].

Other Mechanical and Technical Complications

Other noninfectious complications reported with arterial catheters are pseudoaneurysm formation, hematoma, local tenderness, hemorrhage, neuropathies, and catheter embolization [17]. Heparin-associated thrombocytopenia (HAT) is a risk of any arterial catheter in institutions where heparin is still used as a standard continuous flush solution [39]. Although heparin containing flush solutions may have a slightly reduced rate of vessel thrombosis and catheter occlusions [40] (especially radial), in our opinion the risk of HAT outweighs any benefit. Our institution has used saline-only flush solutions for many years and we have not noticed an increase in thrombotic or other complications.

Infection

Infectious sequelae are the most important clinical complications occurring because of arterial cannulation, and many of the concepts and definitions applied to central venous catheter–related infection (Chapter 2) are also relevant to arterial catheters.

Catheter-associated infection is usually initiated by skin flora that invades the intracutaneous tract, causing colonization of the catheter, and ultimately, bacteremia. An additional source of infection from pressure-monitoring systems is contaminated infusate, which is at greater risk for infection than central venous catheters because (a) the transducer can become colonized because of stagnant flow, (b) the flush solution is infused at a slow rate (3 mL per hour) and may hang for several days, and (c) multiple blood samples are obtained by several different personnel from stopcocks in the system, which can serve as entry sites for bacteria.

Appreciation of the mechanisms responsible for initiating arterial catheter–related infection is important in understanding how to minimize infection. Thorough operator and site

preparation is paramount and triple barrier protection is appropriate for all larger artery insertions. Chlorhexadine should be used for skin preparation [41] and use of a chlorhexidine soaked dressing at the insertion site is excellent practice. Breaks in sterile technique during insertion mandate termination of the procedure and replacement of compromised equipment. Nursing personnel should follow strict guidelines when drawing blood samples or manipulating tubing. Blood withdrawn to clear the tubing prior to drawing samples should not be reinjected unless a specially designed system is in use [42]. Inspection of the site at the start of every nursing shift is mandatory, and the catheter should be removed promptly if abnormalities are noted. Routine change of the pressure monitoring system does not reduce infectious complications and may simply be another opportunity to introduce colonization.

Historically, it was always felt that arterial catheters had a lower risk for infection than central venous catheters, but that is probably no longer true. Impressive reductions in overall Catheter Related Infections (CRI) have occurred as a result of increased research, better technology, and an emphasis on patient safety, leading to a convergence of infectious risks for arterial and central venous catheters [43,44]. Using modern techniques, arterial catheter–related colonization may occurs in up to 5% to 10% of catheters but the incidence of catheter-related bacteremia should be in the range of 0.5 to 2.0 per 1,000 catheter-days [15,16,43–45]. The site of insertion does not appear to be an important factor impacting on the incidence of infection [15–17,25] but duration is likely important [44]. We believe 7 days is an appropriate time to reassess the need for and the location of arterial catheterization [44] but each institution should determine its own catheter-associated infection rate so that rational policies can be formulated based on existing local infection rates.

When arterial catheter infection does occur, *Staphylococcus* species are commonly isolated. Gram-negative organisms are less frequent, but predominate in contaminated infusate or equipment-related infection. Infection with *Candida* species is a greater risk in prolonged catheterization of the glucose-intolerant patient on multiple systemic broad-spectrum antibiotics. Catheter-associated bacteremia should be treated with a 7- to 14-day course of appropriate antibiotics. In complicated cases, longer courses are sometimes necessary.

The optimal evaluation of febrile catheterized patients can be a challenging problem (see Chapter 2). If the site appears abnormal or the patient is in septic shock with no other etiology, the catheter should be removed. More specific guidelines are difficult to recommend, and individual factors should always be considered. In general, arterial catheters in place less than 5 days will not be the source of fever unless insertion was contaminated. Catheters in place 7 days or longer should be changed to a different site given the safety of arterial cannulation and the small but measurable chance of infection. Guidewire exchanges should only be used to change a malfunctioning or damaged catheter.

RECOMMENDATIONS

Either the radial or femoral artery is an appropriate initial site for percutaneous arterial cannulation. Most centers have more experience with radial artery cannulation, but femoral artery catheters are reliable and have a comparable incidence of complication. In our opinion, the femoral artery should be used first in shocked patients, especially when vasopressors are infusing, because of the risk of tissue loss with radial or dorsalis pedis catheters. In more than 90% of patients, the radial or femoral site is adequate to achieve arterial pressure monitoring. When these sites are not appropriate, the dorsalis pedis artery is a good alternative, but cannulation is frequently not possible, especially if radial artery cannulation failed because of poor perfusion. Under these circumstances, the brachial followed by the axillary artery can be safely cannulated; when a coagulopathy is present, ultrasound guidance should be used to avoid complications. Arterial catheters can be left in place until there is clinical indication to remove them, but infection rate increases proportionally. Iatrogenic anemia and overutilization of blood tests are a real phenomenon associated with arterial catheters, which should be discontinued promptly when no longer required for patient management.

CHAPTER 4 ■ PULMONARY ARTERY CATHETERS

HARVEY S. REICH

Since their introduction into clinical practice in 1970 by Swan et al. [1], balloon-tipped, flow-directed pulmonary artery (PA) catheters have found widespread use in the clinical management of critically ill patients. However, in recent years, both the safety and efficacy of these catheters have been brought into question. In this chapter, I review the physiologic basis for their use, some history regarding their development and use, the concerns raised about their use, and suggestions for appropriate use of the catheters and the information obtained from them.

PHYSIOLOGIC RATIONALE FOR USE OF THE PULMONARY ARTERY CATHETER

In unstable situations, during which hemodynamic changes often occur rapidly, clinical evaluation may be misleading [2]. PA catheters allow for direct and indirect measurement of several major determinants and consequences of cardiac performance—preload, afterload, cardiac output (CO)—thereby supplying additional data to aid in clinical decision making [3].

Cardiac function depends on the relationship between muscle length (preload), the load on the muscle (afterload), and the intrinsic property of contractility. Until the development of the flow-directed PA catheter, there was no way to assess all of these by using one instrument in a clinically useful way at bedside. The catheter allows the reflection of right ventricular (RV) preload (right atrial pressure), RV afterload (PA pressure), left ventricular preload—PA occlusion pressure (PAOP) or pulmonary capillary wedge pressure (PCWP)—and contractility (stroke volume or CO). Left ventricular afterload is reflected by the systemic arterial pressure. This information allows the calculation of numerous parameters, including vascular resistances. No other tool allows the gathering of such a large amount of information.

CONTROVERSIES REGARDING USE OF THE PULMONARY ARTERY CATHETER

Despite all of the advantages of the PA catheter, a number of clinical studies have been published in the past decade that have shown either no benefit or an increased risk of morbidity or mortality associated with its use. (See Table 4.1 for a summary of the evidence for its utility.) Consequently, a number of clinicians have elected to minimize the use of this monitoring device.

Furthermore, the relationship of central venous (CV) pressure and PA pressure to predict ventricular filling was studied

TABLE 4.1

TABLE 4.2

GENERAL INDICATIONS FOR PULMONARY ARTERY CATHETERIZATION

Management of complicated myocardial infarction
Hypovolemia versus cardiogenic shock
Ventricular septal rupture versus acute mitral regurgitation
Severe left ventricular failure
Right ventricular infarction
Unstable angina
Refractory ventricular tachycardia
Assessment of respiratory distress
Cardiogenic versus noncardiogenic (e.g., acute respiratory distress syndrome) pulmonary edema
Primary versus secondary pulmonary hypertension
Assessment of shock
Cardiogenic
Hypovolemic
Septic
Pulmonary embolism
Assessment of therapy in selected individuals
Afterload reduction in patients with severe left ventricular function
Inotropic agent
Vasopressors
Beta-blockers
Temporary pacing (ventricular vs. atrioventricular)
Intra-aortic balloon counterpulsation
Mechanical ventilation (e.g., with positive end-expiratory pressure)
Management of postoperative open-heart surgical patients
Assessment of cardiac tamponade/constriction
Assessment of valvular heart disease
Perioperative monitoring of patients with unstable cardiac status during noncardiac surgery
Assessment of fluid requirements in critically ill patients
Gastrointestinal hemorrhage
Sepsis
Acute renal failure
Burns
Decompensated cirrhosis
Advanced peritonitis
Management of severe preeclampsia

in normal volunteers by Kumar et al. [44] who found there was a poor correlation between initial CV pressure and PAOP, with both respective end diastolic ventricular volume and stroke volume indices. Their data call into question the basic tenet of the theoretical benefit of the PA catheter.

INDICATIONS FOR PULMONARY ARTERY CATHETER USE

Clinicians who use a PA catheter for monitoring should understand the fundamentals of the insertion technique, the equipment used, and the data that can be generated. The Pulmonary Artery Catheter Education Program (PACEP) has been developed by seven specialty organizations, along with the NHLBI and the FDA and is available at http://www.pacep.org.

The use of the PA catheter for monitoring has four central objectives: (a) to assess left or right ventricular function, or both, (b) to monitor changes in hemodynamic status, (c) to guide treatment with pharmacologic and nonpharmacologic agents, and (d) to provide prognostic information. The conditions in which PA catheterization may be useful are characterized by a clinically unclear or rapidly changing hemodynamic status. Table 4.2 is a partial listing of the indications. Use of PA catheters in specific disease entities is discussed in other chapters.

CATHETER FEATURES AND CONSTRUCTION

The catheter is constructed from polyvinylchloride and has a pliable shaft that softens further at body temperature. Because polyvinylchloride has a high thrombogenicity, the catheters are generally coated with heparin. Heparin bonding of catheters, introduced in 1981, has been shown to be effective in reducing catheter thrombogenicity [45,46] but can cause heparin-induced thrombocytopenia. The standard catheter length is 110 cm, and the most commonly used external diameter is 5 or 7 French (Fr) (1 Fr = 0.0335 mm). A balloon is fastened 1 to 2 mm from the tip (Fig. 4.1); when inflated, it guides the catheter (by virtue of fluid dynamic drag) from the greater

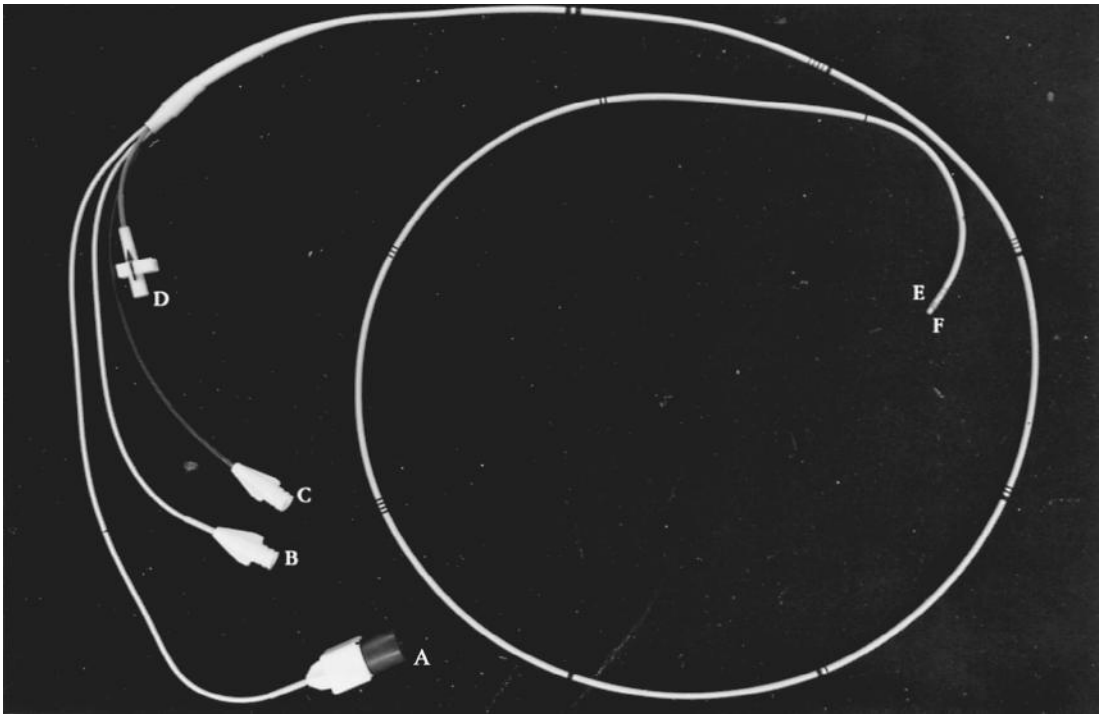

FIGURE 4.1. Quadruple-lumen pulmonary artery catheter. **A:** Connection to thermodilution cardiac output computer. **B:** Connection to distal lumen. **C:** Connection to proximal lumen. **D:** Stopcock connected to balloon at the catheter tip for balloon inflation. **E:** Thermistor. **F:** Balloon. Note that the catheter is marked in 10-cm increments.

intrathoracic veins through the right heart chambers into the PA. When fully inflated in a vessel of sufficiently large caliber, the balloon protrudes above the catheter tip, thus distributing tip forces over a large area and minimizing the chances for endocardial damage or arrhythmia induction during catheter insertion (Fig. 4.2). Progression of the catheter is stopped when it impacts in a PA slightly smaller in diameter than the fully inflated balloon. From this position, the PAOP is obtained. Balloon capacity varies according to catheter size, and the operator must be aware of the individual balloon's maximal inflation volume as recommended by the manufacturer. The balloon is usually inflated with air, but filtered carbon dioxide should be used in any situation in which balloon rupture might result in access of the inflation medium to the arterial system (e.g., if a right-to-left intracardiac shunt or a pulmonary arteriovenous fistula is suspected). If carbon dioxide is used, periodic deflation and reinflation may be necessary, since carbon dioxide diffuses through the latex balloon at a rate of approximately 0.5 cm^3 per minute. Liquids should never be used as the inflation medium.

A variety of catheter constructions is available, each designed for particular clinical applications. Double-lumen catheters allow balloon inflation through one lumen, and a distal opening at the tip of the catheter is used to measure intravascular pressures and sample blood. Triple-lumen catheters have a proximal port terminating 30 cm from the tip of the catheter, allowing simultaneous measurement of right atrial and PA or occlusion pressures. The most commonly used PA catheter in the ICU setting is a quadruple-lumen catheter, which has a lumen containing electrical leads for a thermistor positioned at the catheter surface 4 cm proximal to its tip (Fig. 4.1) [47]. The thermistor measures PA blood temperature and allows thermodilution CO measurements. A five-lumen catheter is also available, with the fifth lumen opening 40 cm from the tip of the catheter. The fifth lumen provides additional central venous access for fluid or medication infusions when peripheral access is limited or when drugs requiring infusion into a large vein (e.g., dopamine, epinephrine) are used. Figure 4.2 shows the balloon on the tip inflated.

Several special-purpose PA catheter designs are available. Pacing PA catheters incorporate two groups of electrodes on the catheter surface, enabling intracardiac electrocardiographic (ECG) recording or temporary cardiac pacing [48]. These catheters are used for emergency cardiac pacing, although it is often difficult to position the catheter for reliable simultaneous cardiac pacing and PA pressure measurements. A five-lumen catheter allows passage of a specially designed 2.4-Fr bipolar pacing electrode (probe) through the additional lumen (located 19 cm from the catheter tip) and allows emergency temporary intracardiac pacing without the need for a separate central venous puncture. The pacing probe is Teflon coated to allow easy introduction through the pacemaker port lumen; the intracavitary part of the probe is heparin impregnated to reduce the risk of thrombus formation. One report demonstrated satisfactory ventricular pacing in 19 of 23 patients using this catheter design (83% success rate) [49]. When a pacing probe is not in use, the fifth lumen may be used for additional central venous access or continuous RV pressure monitoring.

Continuous mixed venous oxygen saturation measurement is clinically available using a fiberoptic five-lumen PA catheter [50]. Segal et al. [51] described a catheter that incorporates Doppler technology for continuous CO determinations. Catheters equipped with a fast-response (95 milliseconds) thermistor and intracardiac ECG-monitoring electrodes are also available. These catheters allow determination of the RV ejection fraction and RV systolic time intervals in critically ill patients [52–55]. The calculated RV ejection fraction has correlated well with simultaneous radionuclide first-pass studies [54].

Aside from the intermittent determination of CO by bolus administration of cold injectate, PA catheters have been adapted to determine near continuous CO by thermal pulses generated by a heating filament on the catheter to produce

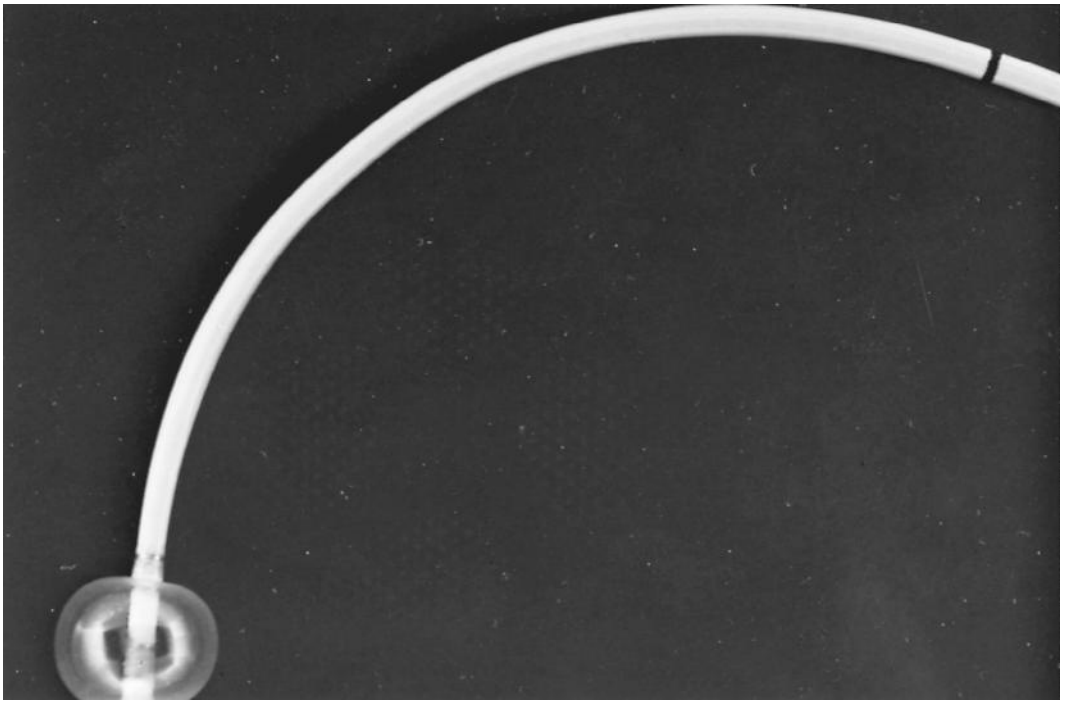

FIGURE 4.2. Balloon properly inflated at the tip of a pulmonary artery catheter. Note that the balloon shields the catheter tip and prevents it from irritating cardiac chambers on its passage to the pulmonary artery.

temperature changes [56]. The accuracy and reliability of CO determination by this heating–cooling cycle have been confirmed by several studies [57–60].

Pressure Transducers

Hemodynamic monitoring requires a system able to convert changes in intravascular pressure into electrical signals suitable for interpretation. The most commonly used hemodynamic monitoring system is a catheter-tubing–transducer system. A fluid-filled intravascular catheter is connected to a transducer by a fluid-filled tubing system. (For more details, see the discussion in Chapters 3 and 26.)

INSERTION TECHNIQUES

General Considerations

Manufacturers' recommendations should be carefully followed. All catheter manufacturers have detailed insertion and training materials.

PA catheterization can be performed in any hospital location where continuous ECG and hemodynamic monitoring are possible and where equipment and supplies needed for cardiopulmonary resuscitation are readily available. Fluoroscopy is not essential, but it can facilitate difficult placements. Properly constructed beds and protective aprons are mandatory for safe use of fluoroscopic equipment. Meticulous attention to sterile technique is of obvious importance; all involved personnel must wear sterile caps, gowns, masks, and gloves, and the patient must be fully covered by sterile drapes.

The catheter should be inserted percutaneously (not by cutdown) into the basilic, brachial, femoral, subclavian, or internal jugular veins by using techniques described in Chapter 2. Threading the catheter into the PA is more difficult from the basilica, brachial, or femoral vein.

Typical Catheter Insertion Procedure

The procedures for typical catheter insertion are as follows:

1. Prepare and connect pressure tubing, manifolds, stopcocks, and transducers. Remove the sterile balloon-tipped catheter from its container. Balloon integrity may be tested by submerging the balloon in a small amount of fluid and checking for air leaks as the balloon is inflated (using the amount of air recommended by the manufacturer). Deflate the balloon.
2. After a time out, insert a central venous cannula or needle into the vein as described in Chapter 2. Using the Seldinger technique, thread the guidewire contained in the catheter kit into the vein and remove the catheter or needle (Figs. 4.3 and 4.4).
3. Make a small incision with a scalpel to enlarge the puncture site (Fig. 4.5). While holding the guidewire stationary, thread a vessel dilator-sheath apparatus (the size should be 8 Fr if a 7-Fr catheter is to be used) over the guidewire and advance it into the vessel, using a twisting motion to get through the puncture site (Fig. 4.6). The dilator and sheath should only be advanced until the tip of the sheath is in the vessel—estimated by the original depth of the cannula or needle required to access the vein. At that point, the dilator and guidewire are held stationary and the sheath is advance off the dilator into the vessel. Advancing the dilator further may cause great vessel or cardiac damage.
4. Remove the guidewire and vessel dilator, leaving the introducer sheath in the vessel (Fig. 4.7). Suture the sheath in place.
5. Pass the proximal portion of the catheter to an assistant and have that person attach the stopcock-pressure tubing-transducer system to the right atrial and PA ports of the

PA catheter. Flush the proximal and distal catheter lumens with normal saline.

6. If a sterile sleeve adapter is to be used, insert the catheter through it and pull the adapter proximally over the catheter to keep it out of the way. Once the catheter is advanced to its desired intravascular location, attach the distal end of the sleeve adapter to the introducer sheath hub.
7. Pass the catheter through the introducer sheath into the vein (Fig. 4.8). Advance it, using the marks on the catheter shaft indicating 10-cm distances from the tip, until the tip is in the right atrium. This requires advancement of

(See text for details.)

approximately 35 to 40 cm from the left antecubital fossa, 10 to 15 cm from the internal jugular vein, 10 cm from the subclavian vein, and 35 to 40 cm from the femoral vein. A right atrial waveform on the monitor, with appropriate fluctuations accompanying respiratory changes or cough, confirms proper intrathoracic location (Fig. 4.9, center). If desired, obtain right atrial blood for oxygen saturation from the distal port. Flush the distal lumen with saline and record the right atrial pressures. (Occasionally, it is necessary to inflate the balloon to keep the tip from adhering to the atrial wall during blood aspiration.)

8. With the catheter tip in the right atrium, inflate the balloon with the recommended amount of air or carbon dioxide (Fig. 4.9A). Inflation of the balloon should be associated with a slight feeling of resistance—if it is not, suspect balloon rupture and do not attempt further inflation or advancement of the catheter before properly reevaluating balloon integrity. If significant resistance to balloon inflation is encountered, suspect malposition of the catheter in a small vessel; withdraw the catheter and readvance it to a new position. Do not use liquids to inflate the balloon, as they might be irretrievable and could prevent balloon deflation.
9. With the balloon inflated, advance the catheter until a RV pressure tracing is seen on the monitor (Fig. 4.9, center). Obtain and record RV pressures. Catheter passage into and through the RV is an especially risky time in terms of arrhythmias. Maintaining the balloon inflated in the RV minimizes ventricular irritation (Fig. 4.9B), but it is important to monitor vital signs and ECG throughout the entire insertion procedure. Elevating the head of the bed to 5 degrees and a right tilt position will facilitate the passage of the catheter through the right ventricle and minimize the generation of arrhythmias [61].
10. Continue advancing the catheter until the diastolic pressure tracing rises above that in the RV (Fig. 4.9, center), indicating PA placement (Fig. 4.9C). If a RV trace still appears after the catheter has been advanced 15 cm beyond the original distance needed to reach the right atrium, suspect curling in the ventricle; deflate the balloon, withdraw it to the right atrium, then reinflate it and try again. Advancement beyond the PA position results in a fall on the pressure tracing from the levels of systolic pressure noted in the RV and PA. When this is noted, record the PAOP (Fig. 4.9, center, D) and deflate the balloon. Phasic PA pressure should reappear on the pressure tracing when the balloon is deflated. If it does not, pull back the catheter with the deflated balloon until the PA tracing appears. With the balloon deflated, blood may be aspirated for oxygen saturation measurement. Watch for intermittent RV tracings indicating slippage of the catheter backward into the ventricle.
11. Carefully record the balloon inflation volume needed to change the PA pressure tracing to the PAOP tracing. If PAOP is recorded with an inflation volume significantly lower than the manufacturer's recommended volume, or if subsequent PAOP determinations require decreasing amounts of balloon inflation volume as compared with an initial appropriate amount, the catheter tip has migrated too far peripherally and should be pulled back immediately.
12. Secure the catheter in the correct PA position by suturing or taping it to the skin to prevent inadvertent advancement. Apply a transparent dressing with a chlorhexidine sponge if indicated.
13. Order a chest radiograph to confirm catheter position; the catheter tip should appear no more than 3 to 5 cm from the midline. To assess whether peripheral catheter migration has occurred, daily chest radiographs are recommended to supplement pressure monitoring and checks on balloon inflation volumes. An initial cross-table lateral radiograph may be obtained in patients on positive end-expiratory pressure (PEEP) to rule out superior placements.

Special Considerations

In certain disease states (right atrial or RV dilatation, severe pulmonary hypertension, severe tricuspid insufficiency, low CO syndromes), it may be difficult to position a flow-directed catheter properly. These settings may require fluoroscopic guidance to aid in catheter positioning. Infusion of 5 to 10 mL of cold saline through the distal lumen may stiffen the catheter and aid in positioning. Alternatively, a 0.025-cm guidewire 145 cm long may be used to stiffen the catheter when placed through the distal lumen of a 7-Fr PA catheter. This manipulation should be performed only under fluoroscopic guidance by an experienced operator. Rarely, nonflow-directed PA catheters (e.g., Cournand catheters) may be required. Because of their rigidity, these catheters have the potential to perforate the right heart and must be placed only under fluoroscopy by a physician experienced in cardiac catheterization techniques.

PHYSIOLOGIC DATA

Measurement of a variety of hemodynamic parameters and oxygen saturations is possible using the PA catheter. A summary of normal values for these parameters is found in Tables 4.3 and 4.4.

Pressures

Right Atrium

With the tip of the PA catheter in the right atrium (Fig. 4.9A), the balloon is deflated and a right atrial waveform recorded (Fig. 4.10). Normal resting right atrial pressure is 0 to 6 mm Hg. Two major positive atrial pressure waves, the a wave and v wave, can usually be recorded. On occasion, a third positive wave, the c wave, can also be seen. The a wave is due to atrial contraction and follows the simultaneously recorded ECG P wave [62,63]. The a wave peak generally follows the peak of

TABLE 4.3

NORMAL RESTING PRESSURES OBTAINED DURING RIGHT HEART CATHETERIZATION

Cardiac chamber	Pressure (mm Hg)
Right atrium	
Range	0–6

the electrical P wave by approximately 80 milliseconds [64]. The v wave represents the pressure generated by venous filling of the right atrium while the tricuspid valve is closed. The peak of the v wave occurs at the end of ventricular systole when the atrium is maximally filled, corresponding to the point near the end of the T wave on the ECG. The c wave is due to the sudden motion of the atrioventricular valve ring toward the right atrium at the onset of ventricular systole. The c wave follows the a wave by a time equal to the ECG P–R interval. The c wave is more readily visible in cases of P–R prolongation [64]. The x descent follows the c wave and reflects atrial relaxation. The y descent is due to rapid emptying of the atrium after opening of the tricuspid valve. The mean right atrial pressure decreases during inspiration with spontaneous respiration (secondary to a decrease in intrathoracic pressure), whereas the a and v waves and the *x* and *y* descents become more prominent. Once a multilumen PA catheter is in position, right atrial blood can be sampled and pressure monitored using the proximal lumen. It should be noted that the pressures obtained via the proximal lumen may not accurately reflect right atrial pressure due to positioning of the lumen against the atrial wall or within the introducer sheath. The latter problem is more frequently encountered in shorter patients [65].

Right Ventricle

The normal resting RV pressure is 17 to 30/0 to 6 mm Hg, recorded when the PA catheter crosses the tricuspid valve (Fig. 4.9B). The RV systolic pressure should equal the PA systolic pressure (except in cases of pulmonic stenosis or RV outflow tract obstruction). The RV diastolic pressure should equal the mean right atrial pressure during diastole when the tricuspid valve is open. Introduction of the catheter with a pacing lumen allows continuous monitoring of RV hemodynamics when the pacing wire is not in place. Using special catheters, RV end-diastolic volume index and RV ejection fraction can be accurately measured [66–69].

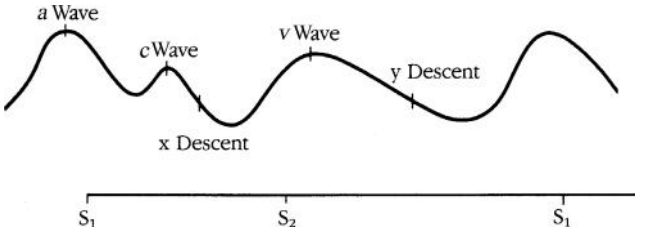

FIGURE 4.10. Stylized representation of a right atrial waveform in relation to heart sounds. (See text for discussion of a, c, and v waves and *x* and *y* descents.) S_1, first heart sound; S_2, second heart sound.

Pulmonary Artery

With the catheter in proper position and the balloon deflated, the distal lumen transmits PA pressure (Fig. 4.9E). Normal resting PA pressure is 15 to 30/5 to 13 mm Hg, with a mean pressure of 10 to 18 mm Hg. The PA waveform is characterized by a systolic peak and diastolic trough with a dicrotic notch due to closure of the pulmonic valve. The peak PA systolic pressure occurs in the T wave of a simultaneously recorded ECG.

Since the pulmonary vasculature is normally a low-resistance circuit, PA diastolic pressure (PADP) is closely related to mean PAOP (PADP is usually 1 to 3 mm Hg higher than mean PAOP) and thus can be used as an index of left ventricle filling pressure in patients in whom an occlusion pressure is unobtainable or in whom PADP and PAOP have been shown to correlate closely. However, if pulmonary vascular resistance is increased, as in pulmonary embolic disease, pulmonary fibrosis, or reactive pulmonary hypertension (see Chapter 56), PADP may markedly exceed mean PAOP and thus become an unreliable index of left heart function [64]. Similar provisos apply when using PA mean pressure as an index of left ventricular function.

Pulmonary Artery Occlusion Pressure

An important application of the balloon flotation catheter is the recording of PAOP. This measurement is obtained when the inflated balloon impacts a slightly smaller branch of the PA (Fig. 4.9D). In this position, the balloon stops the flow, and the catheter tip senses pressure transmitted backward through the static column of blood from the next active circulatory bed—the pulmonary veins. Pulmonary venous pressure is a prime determinant of pulmonary congestion and thus of the tendency for fluid to shift from the pulmonary capillaries into the interstitial tissue and alveoli. Also, pulmonary venous pressure and PAOP closely reflect left atrial pressure (except in rare instances, such as pulmonary veno-occlusive disease, in which there is obstruction in the small pulmonary veins), and serve as indices of left ventricular filling pressure [70,71]. The PAOP is required to assess left ventricular filling pressure, since multiple studies have demonstrated that right atrial (e.g., central venous) pressure correlates poorly with PAOP [72].

The PAOP is a phase-delayed, amplitude-dampened version of the left atrial pressure. The normal resting PAOP is 2 to 12 mm Hg and averages 2 to 7 mm Hg below the mean PA pressure. The PAOP waveform is similar to that of the

right atrium, with a, c, and v waves and *x* and *y* descents (Fig. 4.10). However, in contradistinction to the right atrial waveform, the PAOP waveform demonstrates a v wave that is slightly larger than the a wave [14]. Because of the time required for left atrial mechanical events to be transmitted through the pulmonary vasculature, PAOP waveforms are further delayed when recorded with a simultaneous ECG. The peak of the a wave follows the peak of the ECG P wave by approximately 240 milliseconds, and the peak of the v wave occurs after the ECG T wave has been inscribed. Occlusion position is confirmed by withdrawing a blood specimen from the distal lumen and measuring oxygen saturation. Measured oxygen saturation of 95% or more is satisfactory [71]. The lung segment from which the sample is obtained will be well ventilated if the patient breathes slowly and deeply.

A valid PAOP measurement requires a patent vascular channel between the left atrium and catheter tip. Thus, the PAOP approximates pulmonary venous pressure (and therefore left atrial pressure) only if the catheter tip lies in zone 3 of the lungs [62,73]. (The lung is divided into three physiologic zones, dependent on the relationship of PA, pulmonary venous, and alveolar pressures. In zone 3, the PA and pulmonary venous pressure exceed the alveolar pressure, ensuring an uninterrupted column of blood between the catheter tip and the pulmonary veins.) If, on portable lateral chest radiograph, the catheter tip is below the level of the left atrium (posterior position in supine patients), it can be assumed to be in zone 3. This assumption holds if applied PEEP is less than 15 cm H_2O and the patient is not markedly volume depleted. Whether the catheter is positioned in zone 3 may also be determined by certain physiologic characteristics (Table 4.5). A catheter occlusion outside zone 3 shows marked respiratory variation, an unnaturally smooth vascular waveform, and misleading high pressures.

With a few exceptions [74], estimates of capillary hydrostatic filtration pressure from PAOP are acceptable [75]. It should be noted that measurement of PAOP does not take into account capillary permeability, serum colloid osmotic pressure, interstitial pressure, or actual pulmonary capillary resistance [75,76]. These factors all play roles in the formation of pulmonary edema, and the PAOP should be interpreted in the context of the specific clinical situation.

Mean PAOP correlates well with left ventricular end-diastolic pressure (LVEDP), provided the patient has a normal mitral valve and normal left ventricular function. In myocardial infarction, conditions with decreased left ventricular compliance (e.g., ischemia, left ventricular hypertrophy), and conditions with markedly increased left ventricular filling pressure (e.g., dilated cardiomyopathy), the contribution of atrial contraction to left ventricular filling is increased. Thus, the LVEDP may be significantly higher than the mean left atrial pressure or PAOP [62].

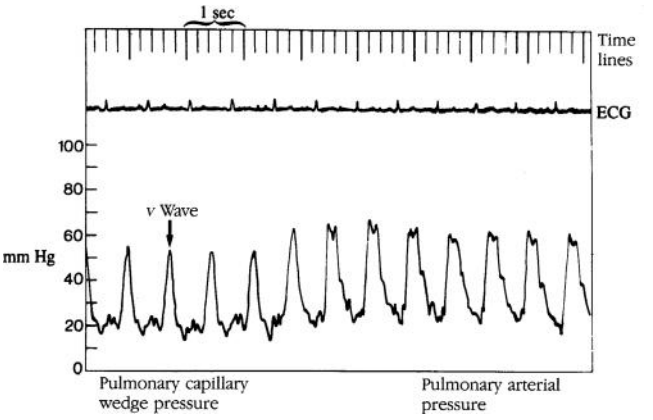

FIGURE 4.11. Pulmonary artery and pulmonary artery occlusion tracings with giant v waves distorting with pulmonary artery recording. ECG, electrocardiogram.

The position of the catheter can be misinterpreted in patients with the presence of giant v waves. The most common cause of these v waves is mitral regurgitation. During this condition, left ventricular blood floods a normal-sized, noncompliant left atrium during ventricular systole, causing giant v waves in the occlusion pressure tracing (Fig. 4.11). The giant v wave of mitral regurgitation may be transmitted to the PA tracing, yielding a bifid PA waveform composed of the PA systolic wave and the v wave. As the catheter is occluded, the PA systolic wave is lost, but the v wave remains. It is important to note that the PA systolic wave occurs earlier in relation to the QRS complex of a simultaneously recorded ECG (between the QRS and T waves) than does the v wave (after the T wave).

Although a large v wave is not diagnostic of mitral regurgitation and is not always present in this circumstance, acute mitral regurgitation remains the most common cause of giant v waves in the PAOP tracing. Prominent v waves may occur whenever the left atrium is distended and noncompliant due to left ventricular failure from any cause (e.g., ischemic heart disease, dilated cardiomyopathy) [77,78] or secondary to the increased pulmonary blood flow in acute ventricular septal defect [79]. Acute mitral regurgitation is the rare instance when the PA end-diastolic pressure may be lower than the computer-measured mean occlusion pressure [64].

End expiration provides a readily identifiable reference point for PAOP interpretation because pleural pressure returns to baseline at the end of passive deflation (approximately equal to atmospheric pressure). Pleural pressure can exceed the normal resting value with active expiratory muscle contraction or

use of PEEP. How much PEEP is transmitted to the pleural space cannot be estimated easily, since it varies depending on lung compliance and other factors. When normal lungs deflate passively, end-expiratory pleural pressure increases by approximately one half of the applied PEEP. In patients with reduced lung compliance (e.g., patients with acute respiratory distress syndrome; ARDS), the transmitted fraction may be one-fourth or less of the PEEP value. In the past, PEEP levels greater than 10 mm Hg were thought to interrupt the column of blood between the left atrium and PA catheter tip, causing the PAOP to reflect alveolar pressure more accurately than left atrial pressure. However, two studies suggest that this may not hold true in all cases. Hasan et al. [80] concluded that the PAOP left atrial fluid column was protected by lung injury, and Teboul et al. [81] could find no significant discrepancy between PAOP and simultaneously measured LVEDP at PEEP levels of 0, 10, and 16 to 20 cm H_2O in patients with ARDS. They hypothesize that (a) a large intrapulmonary right-to-left shunt may provide a number of microvessels shielded from alveolar pressure, allowing free communication from PA to pulmonary veins, or (b) in ARDS, both vascular and lung compliance may decrease, reducing transmission of alveolar pressure to the pulmonary microvasculature and maintaining an uninterrupted blood column from the catheter tip to the left atrium.

Although it is difficult to estimate precisely the true transmural vascular pressure in a patient on PEEP, temporarily disconnecting PEEP to measure PAOP is not recommended. Because the hemodynamics have been destabilized, these measurements will be of questionable value. Venous return increases acutely after discontinuation of PEEP [81], and abrupt removal of PEEP will cause hypoxia, which may not reverse quickly on reinstitution of PEEP [82]. Additional discussion of measurement and interpretation of pulmonary vascular pressures on PEEP is found in Chapter 58.

Cardiac Output

Thermodilution Technique

A catheter equipped with a thermistor 4 cm from its tip allows calculation of CO by using the thermodilution principle [47,83]. The thermodilution principle holds that if a known quantity of cold solution is introduced into the circulation and adequately mixed (passage through two valves and a ventricle is adequate), the resultant cooling curve recorded at a downstream site allows calculation of net blood flow. CO is inversely proportional to the integral of the time-versus-temperature curve.

In practice, a known amount of cold or room temperature solution (typically 10 mL of 0.9% saline in adults and 5 mL of 0.9% saline in children) is injected into the right atrium via the catheter's proximal port. The thermistor allows recording of the baseline PA blood temperature and subsequent temperature change. The resulting curve is usually analyzed by computer, although it can be analyzed manually by simple planimetric methods. Correction factors are added by catheter manufacturers to account for the mixture of cold indicator with warm residual fluid in the catheter injection lumen and the heat transfer from the catheter walls to the cold indicator.

Reported coefficients of variation using triplicate determinations, using 10 mL of cold injectate and a bedside computer, are approximately 4% or less. Variations in the rate of injection can also introduce error into CO determinations, and it is thus important that the solution be injected as rapidly as possible. Careful attention must be paid to the details of this procedure; even then, changes of less than 10% to 15% above or below an initial value may not truly establish directional validity. Thermodilution CO is inaccurate in low-output states, tricuspid regurgitation, and in cases of atrial or ventricular septal defects [84].

Normal values for arterial–venous oxygen content difference, mixed venous oxygen saturation, and CO can be found in Table 4.6.

Analysis of Mixed Venous Blood

CO can be approximated merely by examining mixed venous (PA) oxygen saturation. Theoretically, if CO rises, then the mixed venous oxygen partial pressure will rise, since peripheral tissues need to exact less oxygen per unit of blood. Conversely, if CO falls, peripheral extraction from each unit will increase to meet the needs of metabolizing tissues. Serial determinations of mixed venous oxygen saturation may display trends in CO. Normal mixed venous oxygen saturation is 70% to 75%; values of less than 60% are associated with heart failure and values of less than 40% with shock [85]. Potential sources of error in this determination include extreme low-flow states where poor mixing may occur, contamination of desaturated mixed venous blood by saturated pulmonary capillary blood when the sample is aspirated too quickly through the nonwedged catheter

TABLE 4.6

SELECTED HEMODYNAMIC VARIABLES DERIVED FROM RIGHT HEART CATHETERIZATION

Hemodynamic variable	Normal range
Arterial–venous content difference	3.5–5.5 mL/100 mL
Cardiac index	2.5–4.5 L/min/m^2
Cardiac output	3.0–7.0 L/min
Left ventricular stroke work index	45–60 g/beat/m^2
Mixed venous oxygen content	18.0 mL/100 mL
Mixed venous saturation	75% (approximately)
Oxygen consumption	200–250 mL/min
Pulmonary vascular resistance	120–250 dynes/sec/cm^{-5}
Stroke volume	70–130 mL/contraction
Stroke volume index	40–50 mL/contraction/m^2
Systemic vascular resistance	1,100–1,500 dynes/sec/cm^2

[86] or in certain disease states (e.g., sepsis) where microcirculatory shunting may occur. Fiberoptic reflectance oximetry PA catheters can continuously measure and record mixed venous oxygen saturations in appropriate clinical situations [50,87].

Derived Parameters

Useful hemodynamic parameters that can be derived using data with PA catheters include the following:

1. Cardiac index = CO (L/minute)/BSA (m^2)
2. Stroke volume = CO (L/minute)/heart rate (beats/minute)
3. Stroke index = CO (L/minute)/[heart rate (beats/minute) × BSA (m^2)]
4. Mean arterial pressure (mmHg) = [(2 × diastolic) + systolic]/3
5. Systemic vascular resistance (dyne/second/cm^{-5}) = ([mean arterial pressure − mean right atrial pressure (mm Hg)] × 80)/CO (L/minute)
6. Pulmonary arteriolar resistance (dyne/second/cm^{-5}) = ([mean PA pressure − PAOP (mm Hg)] × 80)/CO (L/minute)
7. Total pulmonary resistance (dyne/second/cm^{-5}) = ([mean PA pressure (mm Hg)] × 80)/CO (L/minute)
8. Left ventricular stroke work index = 1.36 (mean arterial pressure − PAOP) × stroke index/100
9. Do_2 (mL/minute/m^2) = cardiac index × arterial O_2 content × 10

Normal values are listed in Table 4.6.

CLINICAL APPLICATIONS OF THE PULMONARY ARTERY CATHETER

Normal Resting Hemodynamic Profile

The finding of normal CO associated with normal left and right heart filling pressures is useful in establishing a noncardiovascular basis to explain abnormal symptoms or signs and as a baseline to gauge a patient's disease progression or response to therapy. Right atrial pressures of 0 to 6 mm Hg, PA systolic pressures of 15 to 30 mm Hg, PADPs of 5 to 12 mm Hg, PA mean pressures of 9 to 18 mm Hg, PAOP of 5 to 12 mm Hg, and a cardiac index exceeding 2.5 L per minute per m^2 characterize a normal cardiovascular state at rest.

Table 4.7 summarizes specific hemodynamic patterns for a variety of disease entities in which PA catheters have been indicated and provide clinical information that can impact patient care.

COMPLICATIONS

Minor and major complications associated with bedside balloon flotation PA catheterization have been reported (Table 4.8). During the 1970s, in the first 10 years of clinical catheter use, a number of studies reported a relatively high incidence of certain complications. Consequent revision of guidelines for PA catheter use and improved insertion and maintenance techniques resulted in a decreased incidence of these complications

Thrombosis, embolism
Arrhythmias
Intracardiac damage
Infections
Miscellaneous complications

in the 1980s [88]. The majority of complications are avoidable by scrupulous attention to detail in catheter placement and maintenance.

Complications Associated with Central Venous Access

The insertion techniques and complications of central venous cannulation are discussed in Chapter 2. Reported local vascular complications include local arterial or venous hematomas, unintentional entry of the catheter into the carotid system, atrioventricular fistulas, and pseudoaneurysm formation [89–91]. Adjacent structures, such as the thoracic duct, can be damaged, with resultant chylothorax formation. Pneumothorax can be a serious complication of insertion, although the incidence is relatively low (1% to 2%) [64,89,92]. The incidence of pneumothorax is higher with the subclavian approach than with the internal jugular approach in some reports [93], but other studies demonstrate no difference between the two sites [94,95]. The incidence of complications associated with catheter insertion is generally considered to be inversely proportional to the operator's experience.

Balloon Rupture

Balloon rupture occurred more frequently in the early 1970s than it does now and was generally related to exceeding recommended inflation volumes. The main problems posed by balloon rupture are air emboli gaining access to the arterial circulation and balloon fragments embolizing to the distal pulmonary circulation. If rupture occurs during catheter insertion, the loss of the balloon's protective cushioning function can predispose to endocardial damage and attendant thrombotic and arrhythmic complications.

Knotting

Knotting of a catheter around itself is most likely to occur when loops form in the cardiac chambers and the catheter is repeatedly withdrawn and readvanced [96]. Knotting is avoided if care is taken not to advance the catheter significantly beyond the distances at which entrance to the ventricle or PA would ordinarily be anticipated. Knotted catheters usually can be extricated transvenously; guidewire placement [97], venotomy, or more extensive surgical procedures are occasionally necessary.

Knotting of PA catheters around intracardiac structures [98] or other intravascular catheters [99] has been reported. Rarely, entrapment of a PA catheter in cardiac sutures after open-heart surgery has been reported, requiring varying approaches for removal [100].

Pulmonary Infarction

Peripheral migration of the catheter tip (caused by catheter softening and loop tightening over time) with persistent, undetected wedging in small branches of the PA is the most common mechanism underlying pulmonary ischemic lesions attributable to PA catheters [101]. These lesions are usually small and asymptomatic, often diagnosed solely on the basis of changes in the chest radiograph demonstrating an occlusion-shaped pleural-based density with a convex proximal contour [102].

Severe infarctions are usually produced if the balloon is left inflated in the occlusion position for an extended period, thus obstructing more central branches of the PA, or if solutions are injected at relatively high pressure through the catheter lumen in an attempt to restore an apparently damped pressure trace. Pulmonary embolic phenomena resulting from thrombus formation around the catheter or over areas of endothelial damage can also result in pulmonary infarction.

The reported incidence of pulmonary infarction secondary to PA catheters in 1974 was 7.2% [101], but recently reported rates of pulmonary infarction are much lower. Boyd et al. [103] found a 1.3% incidence of pulmonary infarction in a prospective study of 528 PA catheterizations. Sise et al. [104] reported no pulmonary infarctions in a prospective study of 319 PA catheter insertions. Use of continuous saline flush solutions and careful monitoring of PA waveforms are important reasons for the decreased incidence of this complication.

Pulmonary Artery Perforation

A serious and feared complication of PA catheterization is rupture of the PA leading to hemorrhage, which can be massive and sometimes fatal [105–107]. Rupture may occur during insertion or may be delayed a number of days [107]. PA rupture or perforation has been reported in approximately 0.1% to 0.2% of patients [93,108,109], although recent pathologic data suggest the true incidence of PA perforation is somewhat higher [110]. Proposed mechanisms by which PA rupture can occur include (a) an increased pressure gradient between PAOP and PA pressure brought about by balloon inflation and favoring distal catheter migration, where perforation is more likely to occur; (b) an occluded catheter tip position favoring eccentric or distended balloon inflation with a spearing of the tip laterally and through the vessel; (c) cardiac pulsation causing shearing forces and damage as the catheter tip repeatedly contacts the vessel wall; (d) presence of the catheter tip near a distal arterial bifurcation where the integrity of the vessel wall against which the balloon is inflated may be compromised; and (e) simple lateral pressure on vessel walls caused by balloon inflation (this tends to be greater if the catheter tip was occluded before inflation began). Patient risk factors for PA perforation include pulmonary hypertension, mitral valve disease, advanced age, hypothermia, and anticoagulant therapy. In patients with these risk factors and in whom PADP reflects PAOP reasonably well, avoidance of subsequent balloon inflation altogether constitutes prudent prophylaxis.

Another infrequent but life-threatening complication is false aneurysm formation associated with rupture or dissection of the PA [111]. Technique factors related to PA hemorrhage are distal placement or migration of the catheter; failure to remove large catheter loops placed in the cardiac chambers during insertion; excessive catheter manipulation; use of stiffer catheter designs; and multiple overzealous or prolonged balloon inflations. Adherence to strict technique may decrease the incidence of this complication. In a prospective study reported in 1986, no cases of PA rupture occurred in 1,400 patients undergoing PA catheterization for cardiac surgery [94].

PA perforation typically presents with massive hemoptysis. Emergency management includes immediate occlusion arteriogram and bronchoscopy, intubation of the unaffected lung, and consideration of emergency lobectomy or pneumonectomy. PA catheter balloon tamponade resulted in rapid control of bleeding in one case report [112]. Application of PEEP to intubated patients may also tamponade hemorrhage caused by a PA catheter [113,114].

Thromboembolic Complications

Because PA catheters constitute foreign bodies in the cardiovascular system and can potentially damage the endocardium, they are associated with an increased incidence of thrombosis. Thrombi encasing the catheter tip and aseptic thrombotic

vegetations forming at endocardial sites in contact with the catheter have been reported [103,115]. Extensive clotting around the catheter tip can occlude the pulmonary vasculature distal to the catheter, and thrombi anywhere in the venous system or right heart can serve as a source of pulmonary emboli. Subclavian venous thrombosis, presenting with unilateral neck vein distention and upper extremity edema, may occur in up to 2% of subclavian placements [116,117]. Venous thrombosis complicating percutaneous internal jugular vein catheterization is fairly commonly reported, although its clinical importance remains uncertain [118]. Consistently damped pressure tracings without evidence of peripheral catheter migration or pulmonary vascular occlusion should arouse suspicion of thrombi at the catheter tip. A changing relationship of PADP to PAOP over time should raise concern about possible pulmonary emboli.

If an underlying hypercoagulable state is known to exist, if catheter insertion was particularly traumatic, or if prolonged monitoring becomes necessary, one should consider cautiously anticoagulating the patient.

Heparin-bonded catheters reduce thrombogenicity [45] and are commonly used. However, an important complication of heparin-bonded catheters is heparin-induced thrombocytopenia (HIT) [119,120]. Routine platelet counts are recommended for patients with heparin-bonded catheters in place. Because of the risk of HIT, some hospitals have abandoned the use of heparin-bonded catheters.

Rhythm Disturbances

Atrial and ventricular arrhythmias occur commonly during insertion of PA catheters [121]. Premature ventricular contractions occurred during 11% of the catheter insertions originally reported by Swan et al. [1].

Studies have reported advanced ventricular arrhythmias (three or more consecutive ventricular premature beats) in approximately 30% to 60% of patients undergoing right heart catheterization [93,117,122–124]. Most arrhythmias are self-limited and do not require treatment, but sustained ventricular arrhythmias requiring treatment occur in 0% to 3% of patients [103,123,124]. Risk factors associated with increased incidence of advanced ventricular arrhythmias are acute myocardial ischemia or infarction, hypoxia, acidosis, hypocalcemia, and hypokalemia [92,123]. A right lateral tilt position (5-degree angle) during PA catheter insertion is associated with a lower incidence of malignant ventricular arrhythmias than is the Trendelenburg position [61].

Although the majority of arrhythmias occur during catheter insertion, arrhythmias may develop at any time after the catheter has been correctly positioned. These arrhythmias are due to mechanical irritation of the conducting system and may be persistent. Ventricular ectopy may also occur if the catheter tip falls back into the RV outflow tract. Evaluation of catheter-induced ectopy should include a portable chest radiograph to evaluate catheter position and assessment of the distal lumen pressure tracing to ensure that the catheter has not slipped into the RV. Lidocaine may be used but is unlikely to ablate the ectopy because the irritant is not removed [125]. If the arrhythmia persists after lidocaine therapy or is associated with hemodynamic compromise, the catheter should be removed. Catheter removal should be performed by physicians under continuous ECG monitoring, since the ectopy occurs almost as frequently during catheter removal as during insertion [126,127].

Right bundle branch block (usually transient) can also complicate catheter insertion [128]. Patients undergoing anesthesia induction, those in the early stages of acute anteroseptal myocardial infarction, and those with acute pericarditis appear particularly susceptible to this complication. Patients with preexisting left bundle branch block are at risk for developing complete heart block during catheter insertion, and some have advocated the insertion of a temporary transvenous pacing wire, a PA catheter with a pacing lumen, or pacing PA catheter with the pacing leads on the external surface of the catheter [129]. However, use of an external transthoracic pacing device should be sufficient to treat this complication.

Intracardiac Damage

Damage to the right heart chambers, tricuspid valve, pulmonic valve, and their supporting structures as a consequence of PA catheterization has been reported [130–133]. The reported incidence of catheter-induced endocardial disruption detected by pathologic examination varies from 3.4% [115] to 75% [134], but most studies suggest a range of 20% to 30% [117,131,132]. These lesions consist of hemorrhage, sterile thrombus, intimal fibrin deposition, and nonbacterial thrombotic endocarditis. Their clinical significance is not clear, but there is concern that they may serve as a nidus for infectious endocarditis.

Direct damage to the cardiac valves and supporting chordae occurs primarily by withdrawal of the catheters while the balloon is inflated [1]. However, chordal rupture has been reported despite balloon deflation [113]. The incidence of intracardiac and valvular damage discovered on postmortem examination is considerably higher than that of clinically significant valvular dysfunction.

Infections

Catheter-related septicemia (the same pathogen growing from blood and the catheter tip) was reported in up to 2% of patients undergoing bedside catheterization in the 1970s [135]. However, the incidence of septicemia related to the catheter appears to have declined in recent years, with a number of studies suggesting a septicemia rate of 0% to 1% [93,136,137]. In situ time of more than 72 to 96 hours significantly increases the risk of catheter-related sepsis. Right-sided septic endocarditis has been reported [133,138], but the true incidence of this complication is unknown. Becker et al. [130] noted two cases of left ventricular abscess formation in patients with PA catheters and *Staphylococcus aureus* septicemia. Incidence of catheter colonization or contamination varies from 5% to 20%, depending on the duration of catheter placement and the criteria used to define colonization [137–139]. In situ catheter-related bloodstream infection may be diagnosed by either differential time to positivity or quantitative blood cultures [140]. With the former method, paired blood cultures are drawn from a peripheral vein and the catheter. If the catheter blood culture turns positive two or more hours sooner than the peripheral blood culture, the catheter is the likely cause of the bacteremia. With the other method, positive quantitative blood cultures drawn from the catheter are sensitive, specific, and predictive of catheter-related bacteremia [141].

Pressure transducers have also been identified as an occasional source of infection [142]. The chance of introducing infection into a previously sterile system is increased during injections for CO determinations and during blood withdrawal. Approaches to reduce the risk of catheter-related infection include use of a sterile protective sleeve and antibiotic bonding to the catheter [94,143,144]. Scheduled changes of catheters do not reduce the rate of infection [145].

Other Complications

Rare miscellaneous complications that have been reported include (a) hemodynamically significant decreases in pulmonary blood flow caused by balloon inflation in the central PA in

postpneumonectomy patients with pulmonary hypertension in the remaining lung [146], (b) disruption of the catheter's intraluminal septum as a result of injecting contrast medium under pressure [147], (c) artifactual production of a midsystolic click caused by a slapping motion of the catheter against the interventricular septum in a patient with RV strain and paradoxic septal motion [148], (d) thrombocytopenia secondary to heparin-bonded catheters [119,120], and (e) dislodgment of pacing electrodes [149]. Multiple unusual placements of PA catheters have also been reported, including in the left pericardiophrenic vein, via the left superior intercostal vein into the abdominal vasculature, and from the superior vena cava through the left atrium and left ventricle into the aorta after open-heart surgery [150–152].

GUIDELINES FOR SAFE USE OF PULMONARY ARTERY CATHETERS

Multiple revisions and changes in emphasis to the original recommended techniques and guidelines have been published [88,153,154]. These precautions are summarized as follows:

1. Avoiding complications associated with catheter insertion.
   a. Inexperienced personnel performing insertions must be supervised. Many hospitals require that PA catheters be inserted by a fully trained intensivist, cardiologist, or anesthesiologist. Use of ultrasound guidance is recommended.
   b. Keep the patient as still as possible. Restraints or sedation may be required but the patient should be fully monitored with ECG and pulse oximetry.
   c. Strict sterile technique is mandatory. A chlorhexidine skin prep solution and maximum barrier precautions are recommended.
   d. Examine the postprocedure chest radiograph for pneumothorax (especially after subclavian or internal jugular venipuncture) and for catheter tip position.
2. Avoiding balloon rupture.
   a. Always inflate the balloon gradually. Stop inflation if no resistance is felt.
   b. Do not exceed recommended inflation volume. At the recommended volume, excess air will automatically be expelled from a syringe with holes bored in it that is constantly attached to the balloon port. Maintaining recommended volume also helps prevent the accidental injection of liquids.
   c. Keep the number of inflation–deflation cycles to a minimum.
   d. Do not reuse catheters designed for single usage, and do not leave catheters in place for prolonged periods.
   e. Use carbon dioxide as the inflation medium if communication between the right and left sides of the circulation is suspected.
3. Avoiding knotting. Discontinue advancement of the catheter if entrance to right atrium, RV, or PA has not been achieved at distances normally anticipated from a given insertion site. If these distances have already been significantly exceeded, or if the catheter does not withdraw easily, use fluoroscopy before attempting catheter withdrawal. Never pull forcefully on a catheter that does not withdraw easily.
4. Avoiding damage to pulmonary vasculature and parenchyma.
   a. Keep recording time of PAOP to a minimum, particularly in patients with pulmonary hypertension and other risk factors for PA rupture. Be sure the balloon is deflated after each PAOP recording. There is never an indication for continuous PAOP monitoring.
   b. Constant pressure monitoring is required each time the balloon is inflated. It should be inflated slowly, in small increments, and must be stopped as soon as the pressure tracing changes to PAOP or damped.
   c. If an occlusion is recorded with balloon volumes significantly less than the inflation volume recommended on the catheter shaft, withdraw the catheter to a position where full (or nearly full) inflation volume produces the desired trace.
   d. Anticipate catheter tip migration. Softening of the catheter material with time, repeated manipulations, and cardiac motion make distal catheter migration almost inevitable.
      i. Continuous PA pressure monitoring is mandatory, and the trace must be closely watched for changes from characteristic PA pressures to those indicating a PAOP or damped tip position.
      ii. Decreases over time in the balloon inflation volumes necessary to attain occlusion tracings should raise suspicion regarding catheter migration.
      iii. Confirm satisfactory tip position with chest radiographs immediately after insertion and at least daily.
   e. Do not use liquids to inflate the balloon. They may prevent deflation, and their relative incompressibility may increase lateral forces and stress on the walls of pulmonary vessels.
   f. Hemoptysis is an ominous sign and should prompt an urgent diagnostic evaluation and rapid institution of appropriate therapy.
   g. Avoid injecting solutions at high pressure through the catheter lumen on the assumption that clotting is the cause of the damped pressure trace. First, aspirate from the catheter. Then consider problems related to catheter position, stopcock position, transducer dome, transducers, pressure bag, flush system, or trapped air bubbles. Never flush the catheter in the occlusion position.
5. Avoiding thromboembolic complications.
   a. Minimize trauma induced during insertion.
   b. Consider the judicious use of anticoagulants in patients with hypercoagulable states or other risk factors.
   c. Avoid flushing the catheter under high pressure.
   d. Watch for a changing PADP–PAOP relationship, as well as for other clinical indicators of pulmonary embolism.
6. Avoiding arrhythmias.
   a. Constant ECG monitoring during insertion and maintenance, as well as ready accessibility of all supplies for performing cardiopulmonary resuscitation, defibrillation, and temporary pacing, are mandatory.
   b. Use caution when catheterizing patients with an acutely ischemic myocardium or preexisting left bundle branch block.
   c. When the balloon is deflated, do not advance the catheter beyond the right atrium.
   d. Avoid over manipulation of the catheter.
   e. Secure the introducer in place at the insertion site.
   f. Watch for intermittent RV pressure tracings when the catheter is thought to be in the PA position. An unexplained ventricular arrhythmia in a patient with a PA catheter in place indicates the possibility of catheter-provoked ectopy.
7. Avoiding valvular damage.
   a. Avoid prolonged catheterization and excessive manipulation.
   b. Do not withdraw the catheter when the balloon is inflated.
8. Avoiding infections.
   a. Use meticulously sterile technique on insertion.

b. Avoid excessive number of CO determinations and blood withdrawals.
c. Avoid prolonged catheterization.
d. Remove the catheter if signs of phlebitis develop. Culture the tip and use antibiotics as indicated.

SUMMARY

Hemodynamic monitoring enhances the understanding of cardiopulmonary pathophysiology in critically ill patients. Nonetheless, the risk-to-benefit profile of PA catheterization in various clinical circumstances remains uncertain. Recent large trials have concluded that there may be no outcome benefit to patients with PA catheters used as part of clinical decision making. There is increasing concern that PA catheterization may be overused and that the data obtained may not be optimally used, or perhaps in specific groups may increase morbidity and mortality. A recent meta-analysis of 13 randomized clinical trials concludes that the use of the PA catheter neither increased overall mortality or hospital days nor conferred benefit. The authors conclude that despite nearly 20 years of randomized clinical trials involving the PA catheter, there has not been a clear strategy in its use which has lead to improved survival [155].

Although there are open trials involving the PA catheter listed in the clinical trials registry, these are focused on elements of catheter data interpretation or comparisons of hemodynamics obtained from the PA catheter to other methods of obtaining these measurements [156]. There are no further randomized clinical trials looking at the PA catheter and patient outcomes recruiting patients at this time.

Until the results of future studies are available, clinicians using hemodynamic monitoring should carefully assess the risk-to-benefit ratio on an individual patient basis. The operator should understand the indications, insertion techniques, equipment, and data that can be generated before undertaking PA catheter insertion. PA catheterization must not delay or replace bedside clinical evaluation and treatment.

CHAPTER 5 ■ TEMPORARY CARDIAC PACING

SETH T. DAHLBERG

Temporary cardiac pacing may be urgently required for the treatment of cardiac conduction and rhythm disturbances commonly seen in patients treated in the intensive care unit (ICU). Therefore, ICU personnel should be familiar with the indications and techniques for initiating and maintaining temporary cardiac pacing as well as the possible complications of this procedure. Recommendations for training in the performance of transvenous pacing have been published by a Task Force of the American College of Physicians, American Heart Association and American College of Cardiology [1]. Competence in the performance of transvenous pacing also requires the operator to have training in central venous access (Chapter 2) and hemodynamic monitoring (Chapters 4 and 26) [2–5].

INDICATIONS FOR TEMPORARY CARDIAC PACING

As outlined in Table 5.1, temporary pacing is indicated in the diagnosis and management of a number of serious rhythm and conduction disturbances.

Bradyarrhythmias

The most common indication for temporary pacing in the ICU setting is a hemodynamically significant or symptomatic bradyarrhythmia such as sinus bradycardia or high-grade atrioventricular (AV) block.

Sinus bradycardia and AV block are commonly seen in patients with acute coronary syndromes, hyperkalemia, myxedema, or increased intracranial pressure. Infectious processes such as endocarditis or Lyme disease [6] may impair AV conduction. Bradyarrhythmias also result from treatment or intoxication with digitalis, antiarrhythmic, beta-blocker, or calcium channel blocker medications and may also result from exaggerated vasovagal reactions to ICU procedures such as suctioning of the tracheobronchial tree in the intubated patient. Bradycardia-dependent ventricular tachycardia may occur in association with ischemic heart disease.

Tachyarrhythmias

Temporary cardiac pacing is used less often for the prevention and termination of supraventricular and ventricular tachyarrhythmias.

Atrial pacing may be effective in terminating atrial flutter and paroxysmal nodal supraventricular tachycardia [7,8]. Atrial pacing in the ICU setting is most frequently performed when temporary epicardial electrodes have been placed during cardiac surgery. A critical pacing rate (usually 125% to 135% of the flutter rate) and pacing duration (usually about 10 seconds) are important in the successful conversion of atrial flutter to sinus rhythm.

In some clinical situations, pacing termination of atrial flutter may be preferable to synchronized cardioversion, which requires sedation with its attendant risks. Pacing termination is the treatment of choice for atrial flutter in patients with epicardial atrial wires in place after cardiac surgery. It may be preferred as the means to convert atrial flutter in patients on digoxin and those with sick sinus syndrome, as these groups often demonstrate prolonged sinus pauses after DC cardioversion.

Temporary pacing may be required for the prevention of paroxysmal polymorphic ventricular tachycardia in patients with prolonged QT intervals (torsades de pointes), particularly when secondary to drugs [9,10]. Temporary cardiac pacing is the treatment of choice to stabilize the patient while a type I antiarrhythmic agent exacerbating ventricular irritability is metabolized. In this situation, the pacing rate is set to provide a mild tachycardia. The effectiveness of cardiac pacing probably relates to decreasing the dispersion of refractoriness of the ventricular myocardium (shortening the QT interval).

Temporary ventricular pacing may be successful in terminating ventricular tachycardia. If ventricular tachycardia must be terminated urgently, cardioversion is mandated (Chapter 6). However, in less urgent situations, conversion of ventricular tachycardia via rapid ventricular pacing may be useful. The success of this technique depends on the setting in which ventricular tachycardia occurs. "Overdrive" ventricular pacing is often effective in terminating monomorphic ventricular tachycardia in a patient with remote myocardial infarction or in the absence of heart disease. This technique is less effective when ventricular tachycardia complicates acute myocardial infarction or cardiomyopathy. Rapid ventricular pacing is most successful in terminating ventricular tachycardia when the ventricle can be "captured" (asynchronous pacing for 5 to 10 beats at a rate of 50 beats per minute greater than that of the underlying tachycardia). Extreme caution is advised, as pacing may result in acceleration of ventricular tachycardia or degeneration to ventricular fibrillation; a cardiac defibrillator should be immediately available at the bedside.

DIAGNOSIS OF RAPID RHYTHMS

Temporary atrial pacing electrodes may be helpful for the diagnosis of tachyarrhythmias when the morphology of the P wave and its relation to the QRS complexes cannot be determined from the surface electrocardiogram (ECG) [11–13]. A recording of the atrial electrogram is particularly helpful in a rapid, regular, narrow-complex tachycardia in which the differential diagnosis includes atrial flutter with rapid ventricular response, and AV nodal reentrant or other supraventricular

TABLE 5.1

INDICATIONS FOR ACUTE (TEMPORARY) CARDIAC PACING

A. Conduction disturbances
1. Symptomatic persistent third-degree AV block with inferior myocardial infarction
2. Third-degree AV block, new bifascicular block (e.g., right bundle branch block and left anterior hemiblock, left bundle branch block, first-degree AV block), or alternating left and right bundle branch block complicating acute anterior myocardial infarction
3. Symptomatic idiopathic third-degree AV block, or high-degree AV block
B. Rate disturbances
1. Hemodynamically significant or symptomatic sinus bradycardia
2. Bradycardia-dependent ventricular tachycardia
3. AV dissociation with inadequate cardiac output
4. Polymorphic ventricular tachycardia with long QT interval (torsades de pointes)
5. Recurrent ventricular tachycardia unresponsive to medical therapy

AV, atrioventricular.

tachycardia. This technique may also assist in the diagnosis of wide-complex tachycardias in which the differential diagnosis includes supraventricular tachycardia with aberrant conduction, sinus tachycardia with bundle branch block, and ventricular tachycardia.

To record an atrial ECG, the ECG limb leads are connected in the standard fashion and a precordial lead (usually V_1) is connected to the proximal electrode of the atrial pacing catheter or to an epicardial atrial electrode. A multichannel ECG rhythm strip is run at a rapid paper speed, simultaneously demonstrating surface ECG limb leads as well as the atrial electrogram obtained via lead V_1. This rhythm strip should reveal the conduction pattern between atria and ventricles as antegrade, simultaneous, retrograde, or dissociated.

ACUTE MYOCARDIAL INFARCTION

Temporary pacing may be used therapeutically or prophylactically in acute myocardial infarction [14]. Recommendations for temporary cardiac pacing have been provided by a Task Force of the American College of Cardiology and the American Heart Association (Table 5.2) [15]. Bradyarrhythmias unresponsive to medical treatment that result in hemodynamic compromise require urgent treatment. Patients with anterior infarction and bifascicular block or Mobitz type II second-degree AV block, while hemodynamically stable, may require a temporary pacemaker, as they are at risk for sudden development of complete heart block with an unstable escape rhythm.

Prophylactic temporary cardiac pacing has aroused debate for the role it may play in complicated anterior wall myocardial infarction [16]. Thrombolytic therapy or percutaneous coronary intervention, when indicated, should take precedence over placement of prophylactic cardiac pacing, as prophylactic pacing has not been shown to improve mortality. Transthoracic (transcutaneous) cardiac pacing is safe and usually effective [17–20] and would be a reasonable alternative to prophylactic transvenous cardiac pacing, particularly soon after the administration of thrombolytic therapy.

When right ventricular involvement complicates inferior myocardial infarction, cardiac output may be very sensitive to ventricular preload and AV synchrony. Therefore, AV sequential pacing is frequently the pacing modality of choice in patients with right ventricular infarction [21,22].

EQUIPMENT AVAILABLE FOR TEMPORARY PACING

Several methods of temporary pacing are currently available for use in the ICU. Transvenous pacing of the right ventricle or right atrium with a pacing catheter or modified pulmonary artery catheter is the most widely used technique; intraesophageal, transcutaneous, and epicardial pacing are also available.

Transvenous Pacing Catheters

Some of the many transvenous pacing catheters available for use in the critical care setting are illustrated in Figure 5.1. Pacing catheters range in size from 4 Fr (1.2 mm) to 7 Fr (2.1 mm). In urgent situations, or where fluoroscopy is unavailable, a flow-directed flexible balloon-tipped catheter (Fig. 5.1, top) may be placed in the right ventricle using ECG guidance. After gaining access to the central venous circulation, the catheter is passed into the vein and the balloon inflated. After advancing the catheter into the right ventricle, the balloon can be deflated and the catheter tip advanced to the right ventricular apex. Although the balloon-tipped catheter may avoid the need for fluoroscopy, placement may be ineffective in the setting of low blood flow during cardiac arrest or in the presence of severe tricuspid regurgitation. Stiff catheters (Fig. 5.1, middle) are easier to manipulate but require insertion under fluoroscopic guidance.

A flexible J-shaped catheter (Fig. 5.1, bottom), designed for temporary atrial pacing, is also available [23]. This lead is positioned by "hooking" it in the right atrial appendage under fluoroscopic guidance, providing stable contact with the atrial endocardium. Either the subclavian or internal jugular venous approach may be used.

A multilumen pulmonary artery catheter is available with a right ventricular lumen. Placement of a small (2.4 Fr) bipolar pacing lead through the right ventricular lumen allows intracardiac pressure monitoring and pacing through a single catheter [24]. Details on its use and insertion are described in Chapter 4.

Esophageal Electrode

An esophageal "pill" electrode allows atrial pacing and recording of atrial depolarizations without requiring central venous

TABLE 5.2

ACC/AHA RECOMMENDATIONS FOR TREATMENT OF ATRIOVENTRICULAR AND INTRAVENTRICULAR CONDUCTION DISTURBANCES DURING STEMI

Intraventricular conduction	AV conduction

Notes: This table is designed to summarize the atrioventricular (column headings) and intraventricular (row headings) conduction disturbances that may occur during acute anterior or nonanterior STEMI, the possible treatment options, and the indications for each possible therapeutic option.
LAFB, left anterior fascicular block; LPFB, left posterior fascicular block; RBBB, right bundle-branch block; BBB, bundle-branch block; OB, observe; A, atropine; TC, transcutaneous pacing; TV, temporary transvenous pacing; STEMI, ST elevation myocardial infarction; AV, atrioventricular; and MI, myocardial infarction; AMI, anterior myocardial infarction; non-AMI, nonanterior myocardial infarction.
Action: There are four possible actions, or therapeutic options, listed and classified for each bradyarrhythmia or conduction problem:
1. Observe: continued ECG monitoring, no further action planned.
2. A and A*: Atropine administered at 0.6 to 1.0 mg IV every 5 minutes to up to 0.04 mg/kg. In general, because the increase in sinus rate with atropine is unpredictable, this is to be avoided unless there is symptomatic bradycardia that will likely respond to a vagolytic agent, such as sinus bradycardia or Mobitz I, as denoted by the asterisk in the table.
3. TC: Application of transcutaneous pads and standby transcutaneous pacing with no further progression to transvenous pacing imminently planned.
4. TV: Temporary transvenous pacing. It is assumed, but not specified in the table, that at the discretion of the clinician, transcutaneous pads will be applied and standby transcutaneous pacing will be in effect as the patient is transferred to the fluoroscopy unit for temporary transvenous pacing.
Class: Each possible therapeutic option is further classified according to ACC/AHA criteria as Class 1: indicated, Class 2A: probably indicated, 2B: possibly indicated, and Class 3: not indicated.
Level of Evidence: This table was developed from (1) published observational case reports and case series; (2) published summaries, not meta-analyses, of these data; and (3) expert opinion, largely from the prereperfusion era. There are no published randomized trials comparing different strategies of managing conduction disturbances after STEMI. Thus, the level of evidence for the recommendations in this table is C.
How to Use the Table:
Example: 54-year-old man is admitted with an anterior STEMI and a narrow QRS on admission. On day 1, he develops a right bundle-branch block (RBBB), with a PR interval of 0.28 seconds.
1. RBBB is an intraventricular conduction disturbance, so look at row "New bundle-branch block."
2. Find the column for "First-Degree AV Block."
3. Find the "Action" and "Class" cells at the convergence.
4. Note that "Observe" and "Atropine" are class 3, not indicated; transcutaneous pacing (TC) is class 1. Temporary transvenous pacing (TV) is class 2B.

cannulation. As mentioned earlier, detecting atrial depolarization aids in the diagnosis of tachyarrhythmias. Esophageal pacing has also been used to terminate supraventricular tachycardia and atrial flutter [25]. Because the electrode can be uncomfortable and may not give consistent, stable capture, the esophageal electrode is typically limited to short-term use for diagnosis of arrhythmias in pediatric patients.

Transcutaneous External Pacemakers

Transcutaneous external pacemakers have external patch electrodes that deliver a higher current (up to 200 mA) and longer pulse duration (20 to 40 milliseconds) than transvenous pacemakers. External pacing can be implemented immediately and the risks of central venous access avoided. Some patients may require sedation for the discomfort of skeletal muscle stimulation from the high cutaneous current. Transcutaneous external pacemakers have been used to treat brady-asystolic cardiac arrest, symptomatic bradyarrhythmias, and overdrive pacing of tachyarrhythmias and prophylactically for conduction abnormalities during myocardial infarction. They may be particularly useful when transvenous pacing is unavailable, as in the prehospital setting, or relatively contraindicated, as during thrombolytic therapy for acute myocardial infarction [17–19,26–28]. When continued pacing is needed, transvenous pacing is preferable.

Epicardial Pacing

The placement of epicardial electrodes requires open thoracotomy. These electrodes are routinely placed electively during cardiac surgical procedures for use during the postoperative period [12,13]. Typically, both atrial and ventricular electrodes are placed for use in diagnosis of postoperative atrial arrhythmias and for AV pacing. Because ventricular capture is not always reliable, in patients with underlying asystole or an unstable escape rhythm additional prophylactic transvenous pacing should be considered.

Pulse Generators for Temporary Pacing

Newer temporary pulse generators are now capable of ventricular, atrial, and dual chamber sequential pacing with adjustable ventricular and atrial parameters that include pacing modes (synchronous or asynchronous), rates, current outputs (mA), sensing thresholds (mV), and AV pacing interval/delay (milliseconds). Since these generators have atrial sensing/inhibiting capability, they are also set with an upper rate limit (to avoid rapid ventricular pacing while "tracking" an atrial tachycardia); in addition, an atrial pacing refractory period may be programmed (to avoid pacemaker-mediated/endless-loop tachyarrhythmias).

Earlier dual chamber pulse generators may be limited to sensing only ventricular depolarization (DVI mode). Without atrial sensing, if the intrinsic atrial rate exceeds the atrial pacing rate, the atrial pacing stimulus will fail to capture and AV sequential pacing will be lost with AV dissociation. Consequently, with these models, the pacing rate must be set continuously to exceed the intrinsic atrial rate to maintain AV sequential pacing.

CHOICE OF PACING MODE

A pacing mode must be selected when temporary cardiac pacing is initiated. Common modes for cardiac pacing are outlined in Table 5.3. The mode most likely to provide the greatest hemodynamic benefit should be selected. In patients with hemodynamic instability, establishing ventricular pacing is of paramount importance prior to attempts at AV sequential pacing.

TABLE 5.3

COMMON PACEMAKER MODES FOR TEMPORARY CARDIAC PACING

AOO	Atrial pacing: pacing is asynchronous
AAI	Atrial pacing, atrial sensing: pacing is on demand to provide a minimum programmed atrial rate
VOO	Ventricular pacing: pacing is asynchronous
VVI	Ventricular pacing, ventricular sensing: pacing is on demand to provide a minimum programmed ventricular rate
DVI	Dual-chamber pacing, ventricular sensing: atrial pacing is asynchronous, ventricular pacing is on demand following a programmed AV delay
DDD	Dual-chamber pacing and sensing: atrial and ventricular pacing is on demand to provide a minimum rate, ventricular pacing follows a programmed AV delay, and upper-rate pacing limit should be programmed

Ventricular pacing effectively counteracts bradycardia and is most frequently used in ICU patients; however, it cannot restore normal cardiac hemodynamics because it disrupts AV synchrony [29–31]. In patients with noncompliant ventricles (ischemic heart disease, left ventricular hypertrophy, aortic stenosis, and right ventricular infarction), loss of the atrial contribution to ventricular stroke volume (the atrial "kick") during ventricular pacing may result in increased atrial pressure, intermittent mitral and tricuspid regurgitation with reduced cardiac output and blood pressure.

In addition to the hemodynamic benefit of atrial or AV sequential pacing, the risk of atrial fibrillation or flutter may be reduced because of decreased atrial size and/or atrial pressure [32,33]. This suggests that patients with intermittent atrial fibrillation may be better maintained in normal sinus rhythm with atrial or AV sequential pacing, rather than ventricular demand pacing.

PROCEDURE TO ESTABLISH TEMPORARY PACING

After achieving venous access, most often via the internal jugular or subclavian approach (Chapter 2), the pacing catheter is advanced to the central venous circulation and then positioned in the right heart using fluoroscopic or ECG guidance [34]. To position the electrode using ECG guidance, the patient is connected to the limb leads of the ECG machine, and the distal (negative) electrode of the balloon-tipped pacing catheter is connected to lead V_1 with an alligator clip or a special adaptor supplied with the lead. Lead V_1 is then used to continuously monitor a unipolar intracardiac electrogram. The morphology of the recorded electrogram indicates the position of the catheter tip (Fig. 5.2). The balloon is inflated in the superior vena cava, and the catheter is advanced while observing the recorded intracardiac electrogram. When the tip of the catheter reaches the right ventricle, the balloon is deflated and the catheter advanced to the right ventricular apex. ST segment elevation of the intracardiac electrogram due to a current of injury indicates contact of the catheter tip with the ventricular endocardium.

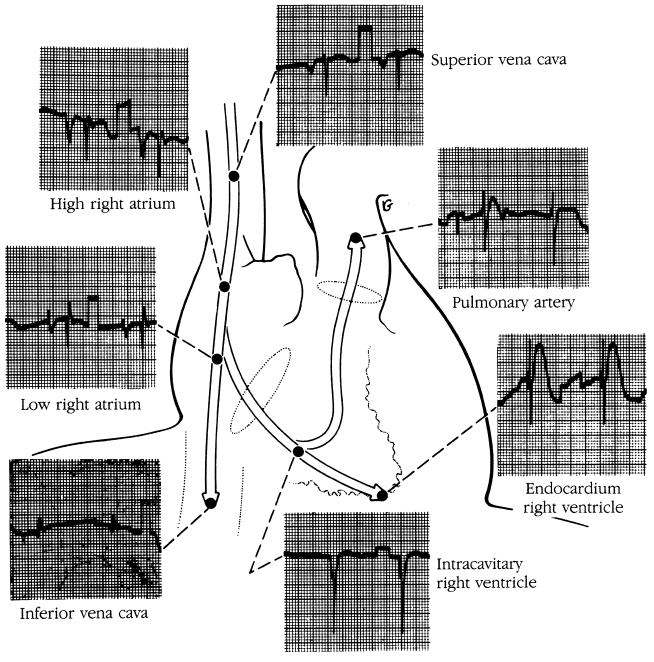

FIGURE 5.2. Pattern of recorded electrogram at various locations in the venous circulation. (From Harthorne JW, McDermott J, Poulin FK: Cardiac pacing, in Johnson RA, Haber E, Austen WG (eds): *The Practice of Cardiology: The Medical and Surgical Cardiac Units at the Massachusetts General Hospital*. Boston, Little, Brown, 1980, with permission.)

After the tip of the pacing catheter is satisfactorily inserted in the right ventricular apex, the leads are connected to the ventricular output connectors of the pulse generator, with the pacemaker box in the off position. The pacemaker is then set to asynchronous mode (VOO) and the ventricular rate set to exceed the patient's intrinsic ventricular rate by 10 to 20 beats per minute. The threshold current for ventricular pacing is set at 5 to 10 mA. Then the pacemaker is switched on. Satisfactory ventricular pacing is evidenced by a wide QRS complex, with ST segment depression and T wave inversion immediately preceded by a pacemaker depolarization (spike). With pacing from the apex of the right ventricle, the paced rhythm usually demonstrates a pattern of left bundle branch block on the surface ECG [35].

Ventricular pacing is maintained as the output current for ventricular pacing is slowly reduced. The pacing threshold is defined as the lowest current at which consistent ventricular capture occurs. With the ventricular electrode appropriately positioned at or near the apex of the right ventricle, a pacing threshold of less than 0.5 to 1.0 mA should be achieved. If the output current for continuous ventricular pacing is consistently greater than 1 to 1.5 mA, the pacing threshold is too high. Possible causes of a high pacing threshold include relatively refractory endomyocardial tissue (fibrosis) or, most commonly, unsatisfactory positioning of the pacing electrode. The tip of the pacing electrode should be repositioned in the region of the ventricular apex until satisfactory ventricular capture at a current of less than 1.0 mA is consistently maintained. After the threshold current for ventricular pacing has been established at a satisfactory level, the ventricular output is set to exceed the threshold current at least threefold. This guarantees uninterrupted ventricular capture despite any modest increase in the pacing threshold.

The pacemaker is now in VOO mode. However, the pacing generator generally should be set in the VVI ("demand") mode, as this prevents pacemaker discharge soon after an intrinsic or spontaneous premature depolarization, while the heart lies in the electrically vulnerable period for induction of sustained ventricular arrhythmias [36]. To set the pacemaker in VVI mode, the pacing rate is set at 10 beats per minute less than the intrinsic rate and the sensitivity control is moved from asynchronous to the minimum sensitivity level. The sensitivity is gradually increased until pacing spikes appear. This level is the sensing threshold. The sensitivity is then set at a level slightly below the determined threshold and the pacing rate reset to the minimum desired ventricular rate.

If AV sequential pacing is desired, the atrial J-shaped pacing catheter should be advanced into the right atrium and rotated anteromedially to achieve a stable position in the right atrial appendage; however, positioning the atrial catheter usually requires fluoroscopy [34,37]. The leads are then connected to the atrial output of the pulse generator. The atrial current is set to 20 mA and the atrial pacing rate adjusted to at least 10 beats per minute greater than the intrinsic atrial rate. The AV interval is adjusted at 100 to 200 milliseconds (shorter intervals usually provide better hemodynamics), and the surface ECG is inspected for evidence of atrial pacing (electrode depolarization and capture of the atrium at the pacing rate).

Atrial capture on ECG is indicated by atrial depolarization (P waves) immediately following the atrial pacing spikes. In patients with intact AV conduction, satisfactory atrial capture can be verified by shutting off the ventricular portion of the pacemaker and demonstrating AV synchrony during atrial pacing.

As long as the atrial pacing rate continually exceeds the intrinsic sinus rate, the atrial P wave activity should track with the atrial pacing spike.

The dual-chamber temporary pacemaker may not have atrial sensing capability. If not, the pacemaker will function in a DVI mode (Table 5.3). Should the intrinsic atrial rate equal or exceed the atrial pacing rate, the atrial stimulus will fail to capture and AV sequential pacing will be lost. If the pacemaker has atrial sensing capability, the atrial sensing threshold should be determined and an appropriate level set. The pacer will then function in the DDD mode. The DDD mode is usually preferred, as it provides optimum cardiac hemodynamics through a range of intrinsic atrial rates. In this mode, an upper-rate limit must be set to prevent rapid ventricular pacing in response to a paroxysmal supraventricular tachycardia.

COMPLICATIONS OF TEMPORARY PACING

Transvenous pacing in the ICU setting is most often performed via the internal jugular or subclavian approach. Appropriate selection of the optimal route requires an understanding of the results and complications of each technique [38,39].

Complications of temporary pacing from any venous access route include pericardial friction rub, arrhythmia, right ventricular perforation, cardiac tamponade, infection, unintentional arterial injury, diaphragmatic stimulation, phlebitis, and pneumothorax. Using predominantly the subclavian or internal jugular approaches, Donovan and Lee reported a 7% rate of serious complications related to temporary cardiac pacing [40]. The Mayo Clinic experience revealed that percutaneous cannulation of the right internal jugular vein provided the simplest, most direct route to the right-sided cardiac chambers [41].

Complications of internal jugular venous cannulation may include pneumothorax, carotid arterial injury, venous thrombosis, and pulmonary embolism (Chapter 2) [42]. These risks are minimized by knowledge of anatomic landmarks, adherence to proved techniques, use of a small-caliber needle to localize the vein before insertion of the large-caliber needle and use of ultrasound assistance (for full discussion see Chapter 2). Full-dose systemic anticoagulation, thrombolytic therapy, and prior neck surgical procedures are relative contraindications to routine internal jugular vein cannulation [43].

Percutaneous subclavian venipuncture is also frequently used for insertion of temporary pacemakers [36,44]. This approach should be avoided in patients with severe obstructive lung disease or a bleeding diathesis (including thrombolytic therapy), in whom the risk of pneumothorax or bleeding is increased.

Although insertion of a pacing lead via the brachial vein may reduce the risk of central arterial injury or hematoma formation in the patient receiving thrombolytic therapy or full-dose anticoagulation, motion of the patient's arm relative to the torso may result in an unstable position of the pacing electrode [41]. The risk of infection may also be increased with this approach. The femoral venous approach is used for electrophysiologic studies or during cardiac catheterization when the catheter is left in place for only a few hours. This approach is less desirable when long-term cardiac pacing is required, since there is a risk of deep venous thrombosis or infection around the catheter approach [45]. Central venous access by the subclavian or internal jugular route provides more stable long-term positioning of the pacing lead.

CHAPTER 6 ■ CARDIOVERSION AND DEFIBRILLATION

MARK S. LINK AND NAOMI F. BOTKIN

The use of electric shock to terminate arrhythmia is one of the critical findings of the last century and underlies much of the modern treatment of arrhythmias. Thanks to the pioneering work of Zoll et al. [1] and Lown et al. [2] in the second half of the twentieth century, the use of electric shock gained widespread acceptance. Although incorporating the same mechanism and physics, *Cardioversion* refers to the use of direct-current electric shock to terminate arrhythmias other than ventricular fibrillation, while *Defibrillation* refers to the termination of ventricular fibrillation. Cardioversion shocks are synchronized to the QRS to avoid the initiation of ventricular fibrillation which may result from shocks on the T-wave while defibrillation occurs with unsynchronized shocks.

PHYSIOLOGY OF ARRHYTHMIA AND SHOCK

Arrhythmias may be due to reentry, increased automaticity, or triggered activity. Reentry refers to the phenomenon in which a wave of excitation travels repeatedly over a closed pathway or circuit of conduction tissue. Reentry requires slow conduction in a portion of myocardium so that by the time the impulse exits the slowly conducting portion the remaining myocardium has repolarized and is hence able to be depolarized again.

Many of the commonly encountered arrhythmias are due to a fixed reentrant mechanism, including atrial flutter, atrioventricular (AV) nodal reentrant tachycardia (AVNRT), AV reentrant tachycardia (AVRT), and most ventricular tachycardias. Atrial fibrillation, once thought exclusively reentrant, has been shown to be caused by foci in the pulmonary veins in many individuals [3]. Atrial fibrillation may also be secondary to functional reentry. Ventricular fibrillation is also due to functional reentry. Cardioversion and defibrillation terminate these arrhythmias by simultaneously depolarizing all excitable tissue, disrupting the process of reentry.

Arrhythmias may also be due to disorders of impulse formation (increased automaticity or triggered activity). These include sinus tachycardia, focal atrial tachycardia, and idiopathic ventricular tachycardias. Sinus tachycardia is a physiologic response and not a pathologic tachycardia; thus, sinus tachycardia will not respond to cardioversion, but atrial tachycardias and ventricular tachycardias generally will terminate.

Insight into the effect of shock on fibrillating myocardial cells has grown in the past few decades. Although it was initially thought that all activation fronts had to be terminated simultaneously to stop atrial and ventricular fibrillation [4], it is now believed that if the vast majority of myocardium is silenced, the remaining mass is insufficient to perpetuate the arrhythmia [5]. The effect of shock on fibrillating myocardium is complex and is dependent on multiple factors including energy, waveform, and myocardial refractory state [6]. Electric shocks at low energy levels may fail to terminate atrial and ventricular fibrillation [7]. Atrial and ventricular arrhythmias may also be terminated by the shock and then reinitiated shortly thereafter. And finally, ventricular fibrillation can be triggered in patients not already in this rhythm if shock occurs on the vulnerable portion of the T wave. Thus, synchronization of shocks with the R wave will minimize the risk.

INDICATIONS AND CONTRAINDICATIONS

Cardioversion and defibrillation are performed for a variety of reasons in the intensive care setting. In the case of hemodynamic instability due to tachyarrhythmia of nearly any type, the urgent use of shock is strongly indicated. One must be careful,

however, not to shock sinus tachycardia, which is commonly present in patients who are hypotensive for noncardiac reasons. Acute congestive heart failure and angina that are secondary to an acute tachyarrhythmia are also indications for urgent cardioversion; however, there is usually sufficient time to provide some sedation. Care must be taken not to shock tachycardias that are secondary to the heart failure or chest pain. In the absence of hemodynamic instability or significant symptoms, cardioversion is usually considered elective and the risks and benefits of the procedure must be carefully weighed.

Extreme caution should be exercised in patients with digitalis toxicity or electrolyte imbalance because of the increased risk of ventricular tachycardia or fibrillation after being shocked. Patients with severe sinus node disease may exhibit significant bradyarrhythmia after cardioversion from atrial fibrillation. In addition, patients who have been in atrial fibrillation for greater than 48 hours are at risk for thromboembolism after cardioversion; appropriate measures should be taken to minimize this risk (see later).

CLINICAL COMPETENCE

A clinical competence statement by the American College of Cardiology and American Heart Association outlines the cognitive and technical skills required for the successful and safe performance of elective external cardioversion (Table 6.1). A minimum of eight cardioversions should be supervised before a physician is considered competent to perform the procedure independently. In addition, a minimum of four procedures should be performed annually to maintain competence [8].

Methods

Patient Preparation

In the case of unconsciousness due to tachyarrhythmia, the shock must be performed urgently. In more elective settings, patient safety and comfort become paramount. As with any procedure, informed consent should be obtained. Patients should refrain from eating and drinking for several hours to decrease the risk of regurgitation and aspiration. Constant heart rhythm monitoring should be used throughout the procedure and a 12-lead electrocardiogram should be obtained before and after the shock.

Medications with rapid onset and short half-life are favored for achieving analgesia, sedation, and amnesia. The combination of a benzodiazepine, such as midazolam, and a narcotic, such as fentanyl, is a common choice in the absence of anesthesiology assistance. Propofol is often used when an anesthesiologist is present to assist with airway management and sedation. Existing hospital policies for monitoring during moderate sedation should be followed, including frequent assessment of blood pressure and pulse oximetry. Supplemental oxygen is delivered via nasal cannula or face mask.

Shock Waveforms

Defibrillators that employ biphasic waveforms have largely replaced those using monophasic waveforms. Advantages of biphasic waveforms are lower defibrillation thresholds, meaning shocks using biphasic waveforms require less energy to achieve defibrillation [6], and they are less likely to cause skin burns and myocardial damage. Both biphasic truncated exponential waveform and biphasic rectilinear waveform are commercially available, with the former being more common. Randomized trials comparing the two types of biphasic waveforms in the cardioversion of atrial fibrillation have failed to show any significant difference in efficacy [9–11].

The efficacy of biphasic shocks in the termination of ventricular fibrillation has been well established [12,13]. Furthermore, clinical studies of atrial fibrillation cardioversion have established the superiority of biphasic over monophasic waveform shocks [14,15]. For instance, one study demonstrated the equivalent efficacy of a 120 to 200 J biphasic sequence with a 200 to 360 J monophasic sequence [15]. Biphasic waveforms allow fewer shocks to be given and a lower total energy delivery

TABLE 6.1

COGNITIVE AND TECHNICAL SKILLS NECESSARY FOR PERFORMING EXTERNAL CARDIOVERSION

Physicians should have knowledge of the following:
- Electrophysiologic principles of cardioversion
- Indications for the procedure
- Anticoagulation management
- Proper use of antiarrhythmic therapy
- Use of sedation and the management of overdose
- Direct current cardioversion equipment, including the selection of appropriate energy and synchronization.
- Treatment of possible complications, including advanced cardiac life support (ACLS), defibrillation, and pacing
- Proper placement of paddles or pads
- Appropriate monitor display and recognition of arrhythmias
- Ability to differentiate failure to convert atrial fibrillation from an immediate recurrence of atrial fibrillation
- Baseline 12-lead electrocardiogram reading, recognition of acute changes, drug toxicity, and contraindications

Physicians should have the following technical skills:
- Proper preparation of skin and electrode placement, including application of saline jelly or saline soaked gauze
- Achievement of artifact-free monitored strips and synchronization signal/marker
- Technically acceptable 12-lead electrocardiograms before and after cardioversion
- Temporary pacing and defibrillation capabilities
- Ability to perform advanced cardiac life support, including proper airway management

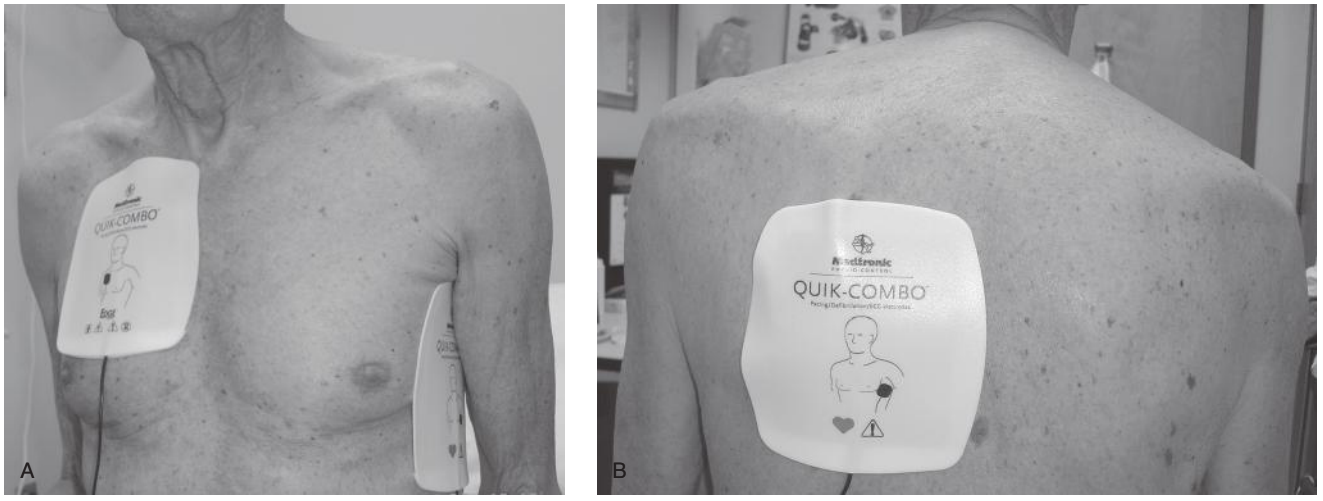

FIGURE 6.1. A: Self-adhesive defibrillator pads in the anterior and lateral positions. **B:** Self-adhesive defibrillator pad in the posterior position. When posterior positioning is used, the second pad is placed anteriorly.

[14]. Whether or not this translates into a significant clinical advantage remains to be demonstrated. However, there is evidence that biphasic shocks result in less dermal injury [14]. Although an animal model suggested better maintenance of cardiac function after biphasic shocks [16], human data on myocardial function are unavailable.

Electrodes

Until recently, hand-held paddles were the only available means of cardioversion or defibrillation. Self-adhesive pads have become more common in the past few years, although paddles may still be used. Limited data are available comparing the two modalities, but one study suggested the superiority of paddles over pads in cardioverting atrial fibrillation [17]). This phenomenon might be explained by the lower transthoracic impedance achieved with paddles [18]. Whichever modality is used, impedance can be minimized by avoiding positioning over breast tissue, by clipping body hair when it is excessive [19], by delivering the shock during expiration, and by firm pressure on the pads or paddles.

The optimal anatomic placement of pads and paddles is controversial; however, the general principal holds that the heart must lie between the two electrodes [6]. Both anterior–lateral and anterior–posterior placements are acceptable (Fig. 6.1). The anterior paddle is placed on the right infraclavicular chest. In anterior–lateral placement, the lateral paddle should be located lateral to the left breast and should have a longitudinal orientation, since this results in a lower transthoracic impedance than horizontal orientation [20]. When anterior–posterior positioning is used, the posterior pad is commonly located to the left of the spine at the level of the lower scapula, although some physicians favor placement to the right of, or directly over, the spine. There are data to suggest that anterior–posterior placement is more successful in the cardioversion of atrial fibrillation than anterior–lateral positioning when monophasic waveforms are used [21]. It is thought that anterior–posterior positioning directs more of the delivered energy to the atria than anterior–lateral placement. However, a study employing biphasic waveforms failed to show any difference of success with anterior–lateral compared with anterior–posterior pad positions [22].

Using the Defibrillator

External defibrillators are designed for easy operation. After the patient is adequately prepared and the electrodes are applied, attention may be turned to the device itself. If the QRS amplitude on the rhythm tracing is small and difficult to see, a different lead should be selected. If cardioversion—rather than defibrillation—is to be performed, the synchronization function should be selected. Many defibrillators require that external leads be applied for synchronization. The appropriate initial energy is selected. Finally, the capacitor is charged, the area is cleared, and the shock is delivered. One should be aware that the synchronization function is automatically deselected after each shock in most devices, meaning that it must be manually reselected prior to any further shock delivery if another synchronized shock is desired.

Table 6.2 provides a checklist for physicians involved in cardioversion. Table 6.3 gives recommendations for the initial energy selection for defibrillation and cardioversion of various arrhythmias. Recommendations specific to each device are available in the manufacturers' manuals and should be consulted by physicians unfamiliar with their particular device.

TABLE 6.2

CHECKLIST FOR PERFORMING CARDIOVERSION

Preparing the patient:
1. Ensure NPO status
2. Obtain informed consent
3. Apply self-adhesive pads (clip hair if needed)
4. Apply external lead
5. Achieve adequate sedation and analgesia
6. Monitor vital signs and cardiac rhythm throughout

Performing the cardioversion:
1. Select initial energy appropriate for specific device
2. Select the synchronization function
3. Confirm that arrhythmia is still present
4. Charge, clear, and deliver shock
5. If no change in rhythm, escalate energy as appropriate

NPO, nil per os.

TABLE 6.3

SUGGESTED INITIAL ENERGY FOR CARDIOVERSION AND DEFIBRILLATION

Rhythm	Monophasic (J)	Biphasic (J)
Ventricular fibrillation, pulseless ventricular tachycardia	360	120–200
Ventricular tachycardia with pulse	100	100
Atrial fibrillation	200	100–200
Atrial flutter	50–100	50

Treatment of Ventricular Fibrillation and Pulseless Ventricular Tachycardia

The algorithm for the treatment of pulseless ventricular tachycardia and ventricular fibrillation in the most recently published American Heart Association guidelines contains some important changes from the previous guidelines [23]. Rather than beginning with three sequential shocks, the guidelines recommend only one shock followed by five cycles of cardiopulmonary resuscitation (CPR) before the rhythm is reassessed [6]. This change was prompted by new data demonstrating that a single biphasic shock was more efficacious than three monophasic shocks in termination of ventricular fibrillation. In addition, three sequential shocks involve a substantial interruption in CPR, which has been shown to be associated with a decreased odds of survival [24]. In the 2010 algorithm, vasopressors (epinephrine or vasopressin) may be given before or after the second shock, and antiarrhythmics such as amiodarone and lidocaine may be considered before or after the second shock (Table 6.4). Both ventricular fibrillation and pulseless ventricular tachycardia are treated with unsynchronized, high-energy shocks of 120 to 200 J with biphasic defibrillators (or 360 J in the case of devices that use monophasic waveforms). If there is any confusion regarding which energy should be used it is best to shock with the highest available energy.

TABLE 6.4

TREATMENT OF VENTRICULAR FIBRILLATION AND PULSELESS VENTRICULAR TACHYCARDIA

- Assess airway, breathing, and circulation
- Assess rhythm
- Deliver 1 shock
  - Monophasic: 360 J
  - Biphasic: use device specific energy; if unknown, maximum energy
- Resume compressions immediately and perform five cycles of CPR
- Check rhythm—if still VT/VF, shock again
  - Monophasic: 360 J
  - Biphasic: same as first shock or higher dose
- Resume compressions immediately and perform five cycles of CPR
- Give a vasopressor during CPR, either before or after the second shock
  - Epinephrine 1 mg IV/IO, repeat every 3–5 min, OR
  - Vasopressin 40 U IV/IO may replace First or second dose of epinephrine
- Check rhythm—if still VT/VF, shock again
- Consider an antiarrhythmic before or after second shock:
  - Amiodarone 300 mg IV/IO once, then consider additional 150 mg once OR
  - Lidocaine 1 to 1.5 mg/kg first dose, then 0.5 to 0.75 mg/kg IV/IO, maximum three doses.

IO, intraosseous; IV, intravenous; VF, ventricular fibrillation; VT, ventricular tachycardia.

Treatment of Wide Complex Tachycardia with a Pulse

When a pulse is present, a regular, wide complex tachycardia may be ventricular tachycardia, supraventricular tachycardia with aberrant conduction, or a supraventricular tachycardia with preexcitation. If signs of instability are present (such as chest pressure, altered mental status, hypotension, or heart failure) and are thought to be secondary to the tachycardia, urgent cardioversion is indicated. A starting energy of 100 J is recommended when a monophasic shock waveform is being used. The optimal initial energy with biphasic devices is unknown but it would seem reasonable to begin at 100 J. The energy should be escalated with each successive shock, such as 200, 300, and 360 J [25].

If the patient is stable, however, one might consider enlisting the assistance of an expert in distinguishing between ventricular and supraventricular arrhythmia. If this is not possible, it is generally safest to assume a ventricular etiology. Stable ventricular tachycardia may be treated initially with antiarrhythmic agents such as amiodarone, lidocaine, or procainamide. Elective cardioversion can be performed if necessary, once sedation and analgesia are assured.

Wide complex tachycardia that appears irregular is usually atrial fibrillation with aberrant conduction but may also be polymorphic ventricular tachycardia or torsades de pointes. If the arrhythmia is atrial fibrillation, treatment should follow the recommendations for atrial fibrillation (see later). However, if the Wolff–Parkinson–White Syndrome is suspected, AV nodal blocking agents are contraindicated and procainamide or ibutilide should be used. If the patient is hypotensive or in shock or if the rhythm is thought to be polymorphic ventricular tachycardia then an unsynchronized shock is advised.

Treatment of Supraventricular Tachycardia

The most common narrow complex tachycardia is sinus tachycardia, which is an appropriate cardiac response to some other physiologic condition. Atrial fibrillation and atrial flutter are the next most common, followed by AVNRT, AV-reciprocating tachycardia (AVRT) and atrial tachycardia. Supraventricular tachycardia—defined as a nonventricular tachycardia other than sinus tachycardia—should be suspected when the arrhythmia starts suddenly, when it is more rapid than maximal sinus rates (220-age), and when P waves are absent or closely follow the QRS. Initial therapy involves vagal maneuvers and adenosine. If these fail, nondihydropyridine calcium channel antagonists or beta-blockers may terminate the

arrhythmia. Cardioversion is indicated only rarely for clinical instability, usually in patients with underlying heart disease in whom the initial therapies fail.

Treatment of Atrial Fibrillation and Flutter

Rate Control

Although the majority of patients with atrial fibrillation and flutter remain hemodynamically stable, many develop bothersome symptoms such as palpitations, chest pressure, and, occasionally, pulmonary edema. However, a rapid ventricular response is usually secondary to—rather than the cause of heart failure and ischemia. Beta-blockers and nondihydropyridine calcium channel antagonists are used to slow the ventricular response rate by slowing AV nodal conduction. Many patients become asymptomatic or minimally symptomatic with adequate rate control, allowing the decision about cardioversion to be made electively.

Electrical Cardioversion

Cardioversion for atrial fibrillation or flutter is usually performed electively. The risk of thromboembolism dictates a thoughtful decision about treatment options. When cardioversion is performed, an appropriate initial starting dose is 100 to 200 J for monophasic waveform shock and 120 to 200 J for biphasic shock. Atrial flutter responds to lower energy, so a starting dose of 50 to 100 J is recommended with a monophasic waveform. The ideal starting energy for biphasic devices is unknown, so 50 to 100 J is reasonable. If atrial fibrillation or flutter fails to terminate, shock energy should be escalated. For most defibrillators, the synchronization function must be selected after each shock.

Anticoagulation

Patients with atrial fibrillation or flutter may develop thrombus in the left atrial appendage or left atrial cavity, leading to thromboembolism during or after cardioversion. One study demonstrated a risk of pericardioversion thromboembolism of 5.3% in patients who were not anticoagulated and 0.8% in those who were [26].

There is general agreement that cardioversion of patients who have been in atrial fibrillation for less than 24 to 48 hours is very unlikely to cause thromboembolism. Current guidelines indicate that pericardioversion anticoagulation with heparin or low molecular weight heparin is optional in these patients [27]. Individuals in atrial fibrillation or flutter for greater than 48 hours are at risk for thromboembolism. In these individuals, a transesophageal echocardiogram is necessary to exclude left atrial thrombus in all but the most emergent cases [28,29]. Alternatively, one can therapeutically anticoagulate for at least 3 weeks prior to cardioversion. Most physicians will anticoagulate for a few weeks after cardioversion, as the risk of thromboembolism still exists during this period.

Pharmacologic Cardioversion

Cardioversion can be achieved not only electrically but also pharmacologically. Pharmacologic cardioversion is used mainly for atrial fibrillation and flutter of relatively short duration. Although electrical cardioversion is quicker and has a higher probability of success, pharmacologic cardioversion does not require sedation. The risk of thromboembolism with pharmacologic cardioversion has not been well established but is thought to be similar to that of electric shock because it is the return of sinus rhythm rather than the shock itself that is believed to precipitate thromboembolism [30,31].

Dofetilide, flecainide, ibutilide, propafenone, amiodarone, and quinidine have been demonstrated to have some degree of efficacy in restoring sinus rhythm [27]. Each of these medications has potential toxicities including malignant arrhythmias and hypotension. The risks and benefits should be carefully weighed when selecting a pharmacologic agent. Although beta-blockers and calcium channel antagonists are often believed to facilitate cardioversion, their efficacy has not been established in controlled trials.

Management of Resistant Atrial Fibrillation

Electrical cardioversion is unsuccessful in up to 10% of atrial fibrillation and atrial flutter, most often because of early recurrences of arrhythmia. The duration of atrial fibrillation is inversely related to the probability of successful cardioversion.

When cardioversion fails to even temporarily terminate the arrhythmia, the operator's technique should be reviewed and modified. Electrode position may be altered, from anterior–posterior to anterior–lateral or vice versa. Firmer pressure may be employed via the paddles or pads. If a device that delivers monophasic waveform shocks is being employed, it may be exchanged for one that delivers biphasic waveform shocks. Ibutilide may be initiated prior to another attempt at cardioversion [32]. Other antiarrhythmic agents may reduce the recurrence of arrhythmia.

Complications of Defibrillation and Cardioversion

Burns

Shock can cause first-degree burns and pain at the paddle or pad site. One study documented moderate to severe pain in nearly one quarter of patients undergoing cardioversion. Pain was directly related to total energy delivered and number of shocks [33]. Another study showed a lower rate of dermal injury with biphasic rather than monophasic shocks, probably due to the lower energy necessary with biphasic shocks [14]. The lowest effective energy should be used to minimize skin injury. In addition, saline-soaked gauzes between the skin and the paddles, rather than conductive gel, will minimize burns.

Thromboembolism

Cardioversion of atrial fibrillation and atrial flutter carries a risk of thromboembolism. Up to 7% of patients in atrial fibrillation who undergo cardioversion without receiving anticoagulation may experience this complication [26], and anticoagulation is standard of care for those in atrial fibrillation or flutter for those in arrhythmias more than 48 hours [27].

Arrhythmia

Bradyarrhythmias such as sinus arrest and sinus bradycardia are common immediately after shock and are almost always short lived. Patients who have atrial fibrillation may have concomitant sinus node dysfunction that is masked by the atrial fibrillation and unmasked by cardioversion.

Ventricular tachycardia and ventricular fibrillation can occasionally be precipitated by shock, particularly in patients with digitalis toxicity or hypokalemia [34,35]. Elective cardioversion should therefore be avoided in patients with these conditions. If cardioversion or defibrillation must be performed urgently, one should anticipate the ventricular arrhythmias to be more refractory to shock than usual.

Myocardial Damage

Occasionally, one may see transient ST segment elevations on postshock electrocardiograms [36]. This is unlikely to signify

myocardial injury. Although a study of cardioversion using higher-than-usual energy levels demonstrated an increase in creatine-kinase–MB levels above that expected from skeletal muscle damage in 10% of patients, there was no elevation in troponin-T or -I seen [37]. This observation suggests that clinically significant myocardial damage from cardioversion or defibrillation is unlikely. Nonetheless, it has been suggested that any two consecutive shocks be delivered no less than 1 minute apart to minimize the chance of myocardial damage [38]. Of course, this recommendation applies only to nonemergent situations.

Miscellaneous Topics

Patients with Implanted Pacemakers and Defibrillators

Patients with implanted pacemakers and defibrillators may undergo external cardioversion and defibrillation safely. However, one must be aware of the possibility that external energy delivery may alter the programming of the internal device. Furthermore, energy may be conducted down an internal lead, causing local myocardial injury and a resultant change in the pacing or defibrillation threshold. The paddles or pads used for external electric shock should never be placed over the device. In addition, interrogation of the device immediately after any external shock delivery is recommended.

Chest Thump

The use of a manual "thump" on the chest to successfully terminate ventricular tachycardia was described in several patients in 1970 [39]. Unfortunately, this technique may inadvertently trigger ventricular fibrillation if the blow happens to fall during the vulnerable period of the ventricle [40]. A chest thump is extremely unlikely to terminate ventricular fibrillation [41,42]. For these reasons, chest thump is considered a therapy of last resort, administered only to a pulseless patient when a defibrillator is unavailable and unlikely to become available soon. It should not be administered when a pulse is present unless a defibrillator is immediately available.

Cardioversion and Defibrillation in Pregnancy

Cardioversion and defibrillation have been performed in all trimesters of pregnancy without obvious adverse fetal effects or premature labor [43]. It has been suggested that the fetal heart rhythm be monitored during cardioversion [44].

CHAPTER 7 ■ PERICARDIOCENTESIS

CRAIG S. SMITH AND RICHARD C. BECKER

Pericardiocentesis is a potentially life-saving procedure performed in the critical care setting. In contrast to other cardiac conditions, however, there is a paucity of randomized clinical data to help guide physicians in the diagnosis and management of pericardial diseases. This chapter reviews the indications for emergent and urgent pericardiocentesis, summarizes the pathobiology of pericardial effusions, and provides a step-by-step approach to pericardiocentesis, including management of patients following the procedure.

INDICATIONS FOR PERICARDIOCENTESIS

The initial management of patients with a known or suspected pericardial effusion is largely determined by clinical status. In the absence of hemodynamic instability or suspected purulent bacterial pericarditis, there is no need for emergent or urgent pericardiocentesis. Diagnostic pericardiocentesis may be performed to establish the etiology of an effusion, although only after thorough noninvasive workup is completed before consideration of an invasive procedure [1]. While the etiology of effusions varies widely in the literature depending upon patient population, a diagnosis based on initial examination alone was highly predictive of effusion etiology in one study [2]. In another large series of patients, between 50% and 60% of moderate to large effusions were due to a previously established medical condition [3]. In addition, the clinical context in which diagnostic pericardiocentesis is performed affects its predictive value, with greater diagnostic yield for large effusions than for acute pericarditis [4–6]. Primarily due to the routine use of echocardiographic guidance, the major (1.2%) and minor (3.5%) complications of pericardiocentesis have significantly decreased over the past several decades, with successful single needle passage rates approaching 90% and relief of tamponade in over 97% [7]. As a result, the 2004 European Society of Cardiology (ESC) recommends pericardiocentesis as the method of choice for pericardial fluid removal/sampling [8]. Surgical intervention is recommended for recurring large effusions for which repeated pericardiocentesis has not been effective, loculated or posterior effusions of hemodynamic consequence, purulent pericarditis, traumatic hemopericardium, constrictive pericarditis, and effusions due to aortic dissection [8]. Whenever possible, elective pericardiocentesis should be performed by an experienced operator using echocardiographic guidance. While generally safe, it should be performed in a location with adequate physiologic monitoring to assess any hemodynamic sequelae from complications and to aid in the diagnosis of effusive-constrictive pericarditis.

In contrast to diagnostic pericardiocentesis, the management of hemodynamically compromised patients requires emergent removal of pericardial fluid to restore adequate ventricular filling (preload) and hasten clinical stabilization. Aggressive fluid resuscitation and inotropic agents have been the mainstay of medical management for cardiac tamponade. These measures are largely ineffective and should be used only as a bridge to pericardial drainage [9,10]. The exact method and timing of pericardiocentesis is ultimately dictated by the patient's overall degree of instability. While echocardiographic and fluoroscopic guidance is preferred, unguided (or blind) pericardiocentesis may be required in patients with severe hypotension not responsive to temporizing measures. In this setting, there are no absolute contraindications to the procedure, and it should be performed without delay at the patient's bedside.

Urgent pericardiocentesis is indicated for patients with an established effusion who are initially hypotensive but respond quickly to hemodynamic support. Unlike acute tamponade, subacute tamponade is more likely to present with protean

symptoms such as dyspnea and fatigue. Patients with preexisting hypertension may not demonstrate severe hypotension due to a persistent sympathetic response. Echocardiographic assessment of effusion size, hemodynamic impact, and optimal percutaneous approach are of paramount importance [11]. The procedure should be performed within several hours of presentation while careful monitoring and support continue. As in elective circumstances, pericardiocentesis in these patients should be undertaken with appropriate visual guidance, the method of which depends on the physician's expertise and resources.

Three additional points must be stressed regarding patients undergoing expedited pericardiocentesis. First, coagulation parameters—prothrombin time, partial thromboplastin time, and platelet count (>50,000 per μL)—should be checked and, when possible, quickly normalized prior to the procedure. If clinically feasible, the procedure should be postponed until the international normalized ratio is less than 1.4. An anti-Xa level is recommended for patients receiving low-molecular-weight heparin. For emergent pericardiocentesis performed on anticoagulant therapy, prolonged and continuous drainage is recommended. Second, many critical care specialists and cardiologists advocate performance of all pericardiocentesis procedures in the catheterization laboratory with concomitant right heart pressure monitoring to document efficacy of the procedure and to exclude a constrictive element of pericardial disease, although excessive delays must be avoided (see Chapter 34). Finally, efforts to ensure a cooperative and stationary patient during the procedure greatly facilitate the performance, safety, and success of pericardiocentesis.

The clinical presentation of hemodynamically significant pericardial effusions varies widely among patients. A comprehensive understanding requires knowledge of normal pericardial anatomy and physiology.

ANATOMY

The pericardium is a membranous structure with two layers: the visceral and parietal pericardium. The visceral pericardium is a monolayer of mesothelial cells adherent to the epicardial surface by a loose collection of small blood vessels, lymphatics, and connective tissue. The parietal pericardium is a relatively inelastic 2 mm dense outer network of collagen and elastin with an inner surface of mesothelial cells. It is invested around the great vessels and defines the shape of the pericardium, with attachments to the sternum, diaphragm, and anterior mediastinum while anchoring the heart in the thorax [12]. Posteriorly, the visceral epicardium is absent, with the parietal epicardium attached directly to the heart at the level of the vena cavae [13]. The potential space between the visceral and parietal mesothelial cell layers normally contains 15 to 50 mL of serous fluid, which is chemically similar to plasma ultrafiltrate, in the atrioventricular (AV) and interventricular grooves [14]. The pericardium is relatively avascular, but is well innervated and may produce significant pain with vagal responses during procedural manipulation or inflammation [15].

Because of the inelastic physical properties of the pericardium, the major determinant of when and how pericardial effusions come to clinical attention is directly related to the speed of accumulation. Effusions that collect rapidly (over minutes to hours) may cause hemodynamic compromise with volumes of 250 mL or less. These effusions are usually located posteriorly and are often difficult to detect without echocardiography or other imaging modalities such as multislice computed tomography or cardiac magnetic resonance imaging . In contrast, effusions developing slowly (over days to weeks) allow for dilation of the fibrous parietal membrane. Volumes of 2,000 mL or greater may accumulate without significant hemodynamic compromise. As a result, chronic effusions may present with symptoms such as cough, dyspnea, dysphagia, or early satiety owing to compression of adjacent thoracic structures. Conversely, intravascular hypovolemia, impaired ventricular systolic function, and ventricular hypertrophy with decreased elasticity of the myocardium (diastolic dysfunction) may exacerbate hemodynamic compromise without significant effusions present.

PROCEDURE

Since the first blind (or closed) pericardiocentesis performed in 1840 [16], numerous approaches to the pericardial space have been described. Marfan [17] performed the subcostal approach in 1911, which then became the standard approach for unguided pericardiocentesis as it is extrapleural and avoids the coronary and internal mammary arteries.

The advent of clinically applicable ultrasonography has opened a new chapter in diagnostic and therapeutic approaches to pericardial disease, allowing clinicians to quantitate and localize pericardial effusions quickly and noninvasively [18,19]. Callahan et al. [20,21] at the Mayo Clinic established the efficacy and safety of two-dimensional echocardiography to guide pericardiocentesis. While direct quantification of total fluid accumulation with echo is not yet possible, circumferential effusions of more than 10 mm are considered large (500 mL), and the ESC recommends pericardiocentesis of effusions of more than 20 mm, regardless of the presence of hemodynamic compromise (class IIa indication) [8]. Typically, at least 250 mL of fluid is required for safe pericardiocentesis. The routine use of echocardiography has resulted in two major trends in clinical practice: First, two-dimensional echocardiography is commonly used to guide pericardiocentesis, with success rates comparable to those of traditionally fluoroscopic-guided procedures [22–24]. Second, approaches other than the traditional subxiphoid method have been investigated owing to the ability to clearly define the anatomy (location and volume) of each patient's effusion [20,21]. In one series of postsurgical patients, the subxiphoid approach was the most direct route in only 12% of effusions [25]. With the use of echo guidance, apical pericardiocentesis and parasternal pericardiocentesis are increasingly performed with success rates comparable to those of the subxiphoid approach. In the apical approach, the needle is directed parallel to the long axis of the heart toward the aortic valve. Parasternal pericardiocentesis is performed with needle insertion 1 cm lateral to the sternal edge to avoid internal mammary laceration. All approaches employ a Seldinger technique of over-the-wire catheter insertion. As the subxiphoid approach remains the standard of practice and is the preferred approach for unguided emergent pericardiocentesis, it will be described later.

Regardless of the approach used, confirmation of appropriate positioning is mandatory and preferably performed before a dilation catheter is advanced over the wire. Direct visualization of the needle with either echocardiography or fluoroscopy and injection of agitated saline (echo guided) or a small amount of contrast (fluoroscopy guided) should be performed to confirm the correct position. Contrast layering inferiorly and not entering circulation or causing a myocardial stain confirms correct positioning.

In addition to two large-bore peripheral intravenous lines for aggressive resuscitative efforts, standard electrocardiographic monitoring is mandatory. Historically, an electrocardiographic (ECG) lead directly attached to the puncture needle has been used to detect contact with the myocardium via the appearance of a large "injury current" (ST elevation).

TABLE 7.1

MATERIALS FOR PERCUTANEOUS PERICARDIOCENTESIS

Site preparation
Antiseptic
Gauze
Sterile drapes and towels
Sterile gloves, masks, gowns, caps
5-mL or 10-mL syringe with 25-gauge needle
1% lidocaine (without epinephrine)
Code cart
Atropine (1-mg dose vial)
Procedure
No. 11 blade
20-mL syringe with 10 mL of 1% lidocaine (without epinephrine)
18-gauge, 8-cm, thin-walled needle with blunt tip
Multiple 20- and 40-mL syringes
Hemostat
Electrocardiogram machine
Three red-top tubes
Two purple-top (heparinized) tubes
Culture bottles
Postprocedure
Suture material
Scissors
Sterile gauze and bandage

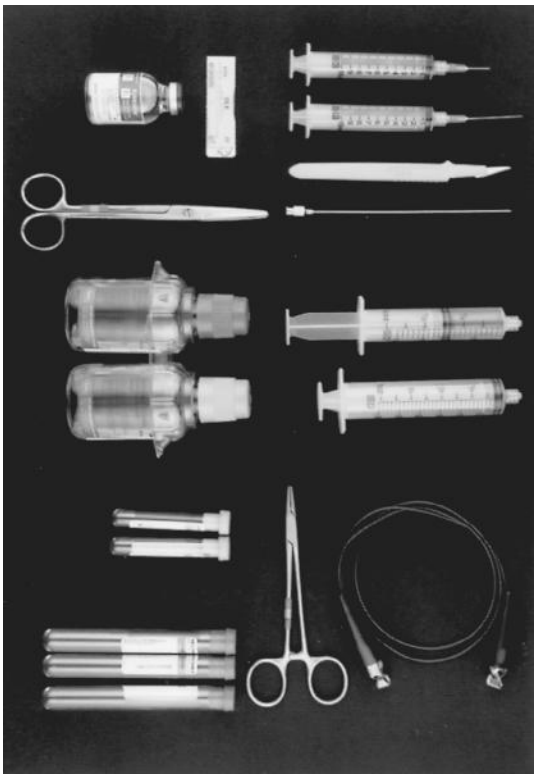

FIGURE 7.1. Materials required for pericardiocentesis (*clockwise from upper left*): 1% lidocaine solution, suture material, 10-mL syringe with 25-gauge needle, 10-mL syringe with 22-gauge needle, no. 11 blade, 18-gauge 8-cm thin-walled needle, 20-mL syringe, 30-mL syringe, alligator clip, hemostat, three red-top tubes, two purple-top tubes, culture bottles, scissors.

Because a suboptimally grounded needle could fibrillate the heart (and the widespread availability of echocardiography), many cardiologists have abandoned this practice and the 2004 ESC guidelines consider it an inadequate safeguard [8,26].

The materials required for bedside pericardiocentesis are listed in Table 7.1 (Fig. 7.1). Table 7.2 (Fig. 7.2) lists the materials required for simultaneous placement of an intrapericardial drainage catheter. The materials are available in prepackaged kits or individually.

The subxiphoid approach for pericardiocentesis is as follows:

1. *Patient preparation*. Assist the patient in assuming a comfortable supine position with the head of the bed elevated to approximately 45 degree from the horizontal plane. Extremely dyspneic patients may need to be positioned fully upright, with a wedge if necessary. Elevation of the thorax allows free-flowing effusions to collect inferiorly and anteriorly, sites that are safest and easiest to access using the subxiphoid approach.
2. *Needle entry site selection*. Locate the patient's xiphoid process and the border of the left costal margin using inspection and careful palpation. The needle entry site should be 0.5 cm to the (patient's) left of the xiphoid process and 0.5 to 1.0 cm inferior to the costal margin (Fig. 7.3). It is helpful to estimate (by palpation) the distance between the skin surface and the posterior margin of the bony thorax: This helps guide subsequent needle insertion. The usual distance is 1.0 to 2.5 cm, increasing with obesity or protuberance of the abdomen.
3. *Site preparation*. Strict sterile techniques must be maintained at all times in preparation of the needle entry site. Prepare a wide area in the subxiphoid region and lower thorax with a chlorhexidine solution. Use maximum barrier precautions and use a large fenestrated drape to cover the field. After performing a time out, raise a 1- to 2-cm subcutaneous wheal by infiltrating the needle entry site with 1% lidocaine solution (without epinephrine). To facilitate needle entry, incise the skin with a no. 11 blade at the selected site after achieving adequate local anesthesia.
4. *Insertion of the needle apparatus*. The angle of entry with respect to the skin should be approximately 45 degree in the subxiphoid area. Direct the needle tip superiorly, aiming for the patient's left shoulder. Continue to advance the needle posteriorly while alternating between aspiration and

TABLE 7.2

MATERIALS FOR INTRAPERICARDIAL CATHETER

Catheter placement
Teflon-coated flexible J-curved guidewire
6 Fr dilator
8 Fr dilator
8 Fr, 35-cm flexible pigtail catheter with multiple fenestrations (end and side holes)
Drainage system[a]
Three-way stopcock
Sterile intravenous tubing
500-mL sterile collecting bag (or bottle)
Sterile gauze and adhesive bag (or bottle)
Suture material

[a]System described allows continuous drainage.

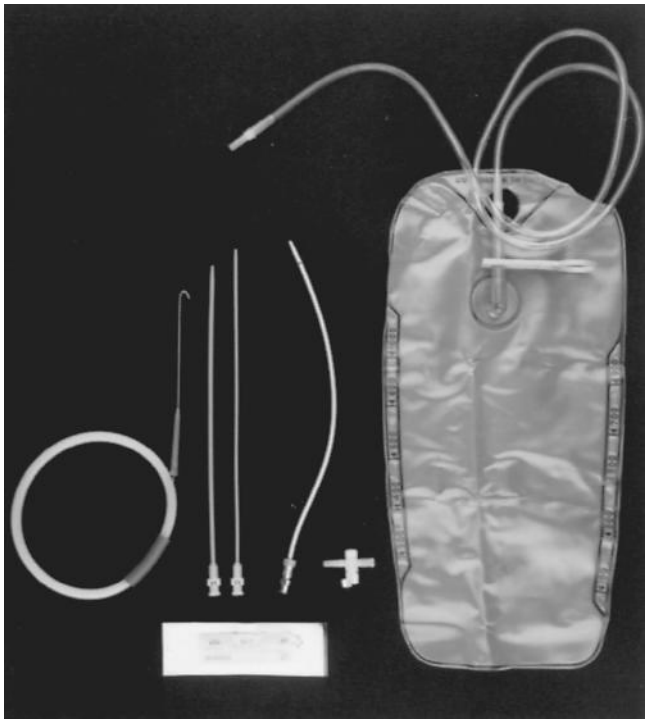

FIGURE 7.2. Materials required for intrapericardial catheter placement and drainage (*clockwise from lower left*): Teflon-coated flexible 0.035-in J-curved guidewire, 8 Fr dilator, 6.3 Fr dilator, 8 Fr catheter with end and side holes (35-cm flexible pigtail catheter not shown), three-way stopcock, 500-mL sterile collecting bag and tubing, suture material.

injection of lidocaine (with a half-filled 20-mL syringe of 1% lidocaine), until the tip has passed just beyond the posterior border of the bony thorax (Fig. 7.3). The posterior border usually lies within 2.5 cm of the skin surface. If the needle tip contacts the bony thorax, inject lidocaine after aspirating to clear the needle tip and anesthetize the periosteum. Then, walk the needle behind the posterior (costal) margin.

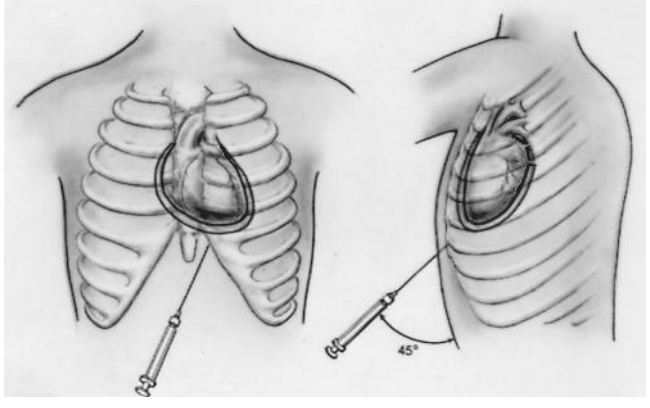

FIGURE 7.3. Insertion of the needle apparatus. After the subxiphoid region and lower thorax are prepared and adequate local anesthesia is given, the pericardiocentesis needle is inserted in the subxiphoid incision. The angle of entry (with the skin) should be approximately 45 degree. The needle tip should be directed superiorly, toward the patient's left shoulder.

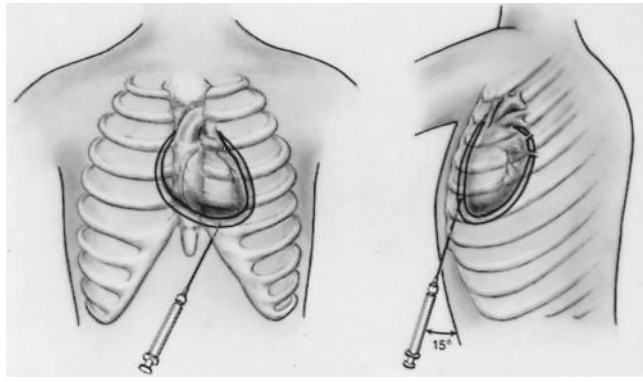

FIGURE 7.4. Needle direction. The needle tip should be reduced to 15 degree once the posterior margin of the bony thorax has been passed. Needle advancement: The needle is advanced toward the left shoulder slowly while alternating between aspiration and injection. A "give" is felt, and fluid is aspirated when the pericardial space is entered.

5. *Needle direction*. Once under the costal margin, reduce the angle of contact between the needle and skin to 15 degree: This will be the angle of approach to the pericardium; the needle tip, however, should still be directed toward the patient's left shoulder. A 15-degree angle is used regardless of the height of the patient's thorax (whether at 45 degree or sitting upright) (Fig. 7.4).
6. *Needle advancement*. Advance the needle slowly while alternating between aspiration of the syringe and injection of 1% lidocaine solution. Obtain a baseline lead V tracing and monitor a continuous ECG tracing for the presence of ST-segment elevation or premature ventricular contractions (evidence of epicardial contact) as the needle is advanced. Advance the needle along this extrapleural path until either
   a. a "give" is felt, and fluid is aspirated from the pericardial space (usually 6.0 to 7.5 cm from the skin) (Fig. 7.4). Some patients may experience a vasovagal response at this point and require atropine intravenously to increase their blood pressure and heart rate or
   b. ST-segment elevation or premature ventricular contractions are observed on the electrocardiographic lead V tracing when the needle tip contacts the epicardium. If ST-segment elevation or premature ventricular complexes occur, immediately (and carefully) withdraw the needle toward the skin surface while aspirating. Avoid any lateral motion, which could damage the epicardial vessels. Completely withdraw the needle if no fluid is obtained during the initial repositioning.

   If sanguineous fluid is aspirated, the differentiation between blood and effusion must be made immediately. In addition to confirming catheter position by saline or contrast as described above (or pressure transduction), several milliliters of fluid can be placed on a gauze and observed for clotting. Intrinsic fibrinolytic activity in the pericardium prevents subacute/chronic effusions from clotting, where frank hemorrhage or intraventricular blood will overwhelm fibrinolysis.

   The patient's hemodynamic status should improve promptly with removal of sufficient fluid. Successful relief of tamponade is supported by (a) a fall in intrapericardial pressure to levels between −3 and +3 mm Hg, (b) a fall in right atrial pressure and a separation between right and left ventricular diastolic pressures, (c) augmentation of cardiac output, (d) increased systemic blood pressure, and (e) reduced

TABLE 7.3

DIAGNOSTIC STUDIES PERFORMED ON PERICARDIAL FLUID

Hematocrit

Antinuclear antibody
Rheumatoid factor
Total complement, C3

pulsus paradoxus to physiologic levels (10 mm Hg or less). An improvement may be observed after removal of the first 50 to 100 mL of fluid. If the right atrial pressure remains elevated after fluid removal, an effusive-constrictive process should be considered. The diagnostic studies performed on pericardial fluid are outlined in Table 7.3. Several options exist for continued drainage of the pericardial space. The simplest approach is to use large-volume syringes and aspirate the fluid by hand. This approach is not always practical (i.e., in large-volume effusions), however, and manipulation of the needle apparatus may cause myocardial trauma. Alternatively, most pericardiocentesis kits include materials and instructions for a catheter-over-needle technique for inserting an indwelling pericardial drain via the Seldinger technique.

7. *Pericardial drain Placement (Fig. 7.5)*. Create a track for the catheter by passing a 6 French (Fr) dilator over a firmly held guidewire. After removing the dilator, use the same technique to pass an 8 Fr dilator. Then advance an 8 Fr flexible pigtail (or side hole) catheter over the guidewire into the pericardial space. Remove the guidewire. Passage of the dilators is facilitated by use of a torquing (clockwise/counterclockwise) motion. Proper positioning of the catheter using radiography, fluoroscopy, or bedside echocardiography can be used to facilitate fluid drainage.
8. *Drainage system* [27,28]. Attach a three-way stopcock to the intrapericardial catheter and close the system by attaching the stopcock to the sterile collecting bag with the connecting tubing. The catheter may also be connected to a transducer, allowing intrapericardial pressure monitoring. The system may be secured as follows:
   a. Suture the pigtail catheter to the skin, making sure the lumen is not compressed. Cover the entry site with a sterile gauze and dressing.
   b. Secure the drainage bag (or bottle) using tape at a level approximately 35 to 50 cm below the level of the heart. Echocardiography or fluoroscopic guidance may be used to reposition the pigtail catheter, facilitating complete drainage of existing pericardial fluid.

It is recommended to drain fluid in sequential steps of less than 1,000 mL to avoid acute right-ventricular dilation—a rare but serious complication [8,29]. Drainage is recommended until pericardial pressure is subatmospheric with inspiration. The catheter should be flushed manually every 4 to 6 hours using 10 to 15 cc of normal saline solution until volume of aspiration falls to less than 25 mL per day [30].

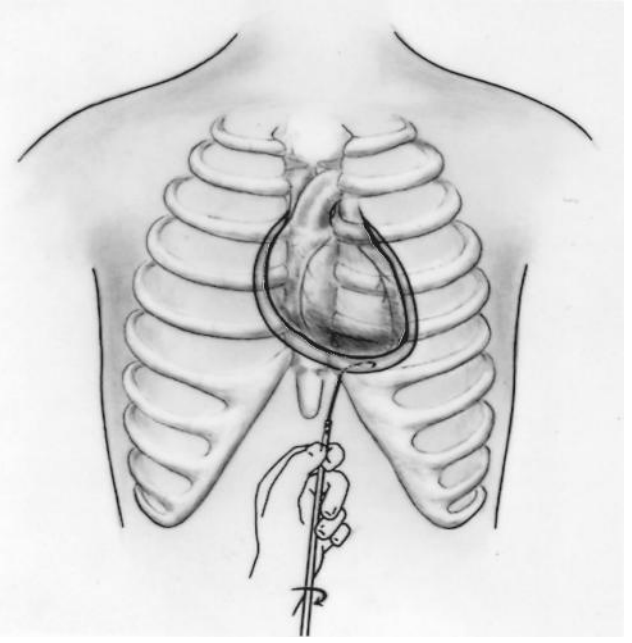

FIGURE 7.5. Placement technique. Holding the needle in place, a Teflon-coated, 0.035-in guidewire is advanced into the pericardial space. The needle is then removed. After a series of skin dilations, an 8Fr, 35-cm flexible pigtail catheter is placed over the guidewire into the pericardial space. Passage of dilators and the pigtail catheter is facilitated by a gentle clockwise/counterclockwise motion.

SHORT-TERM AND LONG-TERM MANAGEMENT

After pericardiocentesis, close monitoring is required to detect evidence of recurrent tamponade and procedure-related complications. Table 7.4 lists the most common serious complications associated with pericardiocentesis [1,8,31,32]. Factors associated with an increased risk of complications include (a) small effusion (less than 250 mL), (b) posterior effusion, (c) loculated effusion, (d) maximum anterior clear space (by echocardiography) less than 10 mm, and (e) unguided percutaneous approach. All patients undergoing pericardiocentesis should have a portable chest radiograph performed immediately after the procedure to exclude the presence of pneumothorax. A transthoracic two-dimensional echocardiogram should be obtained within several hours to evaluate the adequacy of pericardial drainage and confirm catheter placement. As pericardiocentesis typically does not remove all of the effusion (and active bleeding or secretion may occur), the pericardial catheter is typically left in for 24 to 72 hours or until drainage subsides. Extended catheter drainage is safe and is associated with a trend toward lower recurrence rates over a 4-year follow-up [30]. Catheter drainage of more than 100 mL per day after 3 days may need to be considered for surgical intervention, sclerosing agents, or percutaneous balloon pericardotomy.

The long-term management of patients with significant pericardial fluid collections is beyond the scope of this chapter

TABLE 7.4

COMPLICATIONS OF PERICARDIOCENTESIS

Cardiac puncture with hemopericardium
Coronary artery laceration (hemopericardium or myocardial infarction)
Pneumothorax
Hemothorax
Arrhythmias
Bradycardia
Ventricular tachycardia/ventricular fibrillation
Trauma to abdominal organs (liver, gastrointestinal tract)
Hemorrhagic peritonitis
Cardiac arrest (predominantly pulseless electrical activity from myocardial perforation, but occasionally tachyarrhythmia or bradyarrhythmia)[a]
Transient biventricular dysfunction
Infection
Fistula formation
Pulmonary edema

[a]Incidence has varied from 0% to 5% in studies and was less common in guided procedures, more common in "blind" procedures.

Viral (including HIV)
Bacterial
Fungal
Tuberculosis
Aortic dissection
Complication of cardiac catheterization, percutaneous coronary intervention, or pacemaker insertion
Myxedema
Postirradiation

(see Chapter 34); however, the indications for surgical intervention have been reviewed briefly earlier in the chapter. The etiology of the pericardial effusion (Table 7.5) and the patient's functional status are of central importance for determining the preferred treatment. Aggressive attempts at nonsurgical management of chronically debilitated patients or those with metastatic disease involving the pericardium may be appropriate [33,34]. Percutaneous balloon pericardotomy or pericardial sclerosis with tetracycline, cisplatin, and other agents has benefited carefully selected patients with malignant pericardial disease [35–37]. Patients with a guarded prognosis who fail aggressive medical therapy should be offered the least invasive procedure.

CHAPTER 8 ■ CHEST TUBE INSERTION AND CARE

ULISES TORRES AND ROBERT A. LANCY

Chest tube insertion involves placement of a sterile tube into the pleural space to evacuate air or fluid into a closed collection system to restore negative intrathoracic pressure, promote lung expansion, and prevent potentially lethal levels of pressure from developing in the thorax. In order to avoid all the potential life-threatening complications that can result from the insertion of a chest tube, a clear concept of physiopathology and anatomy has to be established, followed by a visualization of the different steps in order to proceed with a safe practice [1].

PLEURAL ANATOMY AND PHYSIOLOGY

The pleural space is a potential space that separates the visceral and parietal pleura with a thin layer of lubricating fluid. Although up to 500 mL per day may enter the pleural space, 0.1 to 0.2 mL per kg surrounds each lung in the pleural space at any given time. These two layers are lined by an extensive lymphatic network that ultimately drains into the thoracic duct via the mediastinal and intercostal lymph nodes. These lymphatics prevent the accumulation of this pleural fluid. It is estimated that this mechanism allows clearance of up to 20 mL per hour per hemithorax of pleural fluid in a 70-kg human. The elastic recoil of the chest wall and lung creates a subatmospheric pressure in the space, between −5 and −10 cm H_2O, which binds the lung to the chest wall [2,3].

Drainage of the pleural space is necessary when the normal physiologic processes are disrupted by increased fluid entry into the space due to alterations in hydrostatic pressures (e.g., congestive heart failure) or oncotic pressures or by changes in the parietal pleura itself (e.g., inflammatory diseases). A derangement in lymphatic drainage, as with lymphatic obstruction by malignancy, may also result in excess fluid accumulation and disruption of the pleural and lung parenchymal anatomy, creating accumulation of air and/or blood.

CHEST TUBE PLACEMENT

Indications

The indications for closed intercostal drainage include a variety of disease processes in the hospital setting (Table 8.1). The procedure may be performed to palliate a chronic disease process or to relieve an acute, life-threatening process. Chest tubes also may provide a vehicle for pharmacologic interventions, as when used with antibiotic therapy for treatment of an empyema or instillation of sclerosing agents to prevent recurrence of malignant effusions.

Pneumothorax

Accumulation of air in the pleural space is the most common indication for chest tube placement. Symptoms include tachypnea, dyspnea, and pleuritic pain, although some patients (in particular, those with a small spontaneous pneumothorax) may be asymptomatic. Physical findings include diminished breath sounds and hyperresonance to percussion on the affected side.

Diagnosis is often confirmed by chest radiography. The size of a pneumothorax may be estimated, but this is at best a rough approximation of a three-dimensional space using a two-dimensional view. Although the gold standard for the identification of a pneumothorax (independent of location within the thorax) is a computed tomography (CT) scan of the chest, ultrasound (US) identification has been shown to have the same sensitivity as that of a CT scan. Furthermore, US estimates of the extension of the pneumothorax correlate well with CT scan [4]. The sensitivity of detecting a pneumothorax with US ranges from 86% to 89%, compared to a range of 28% to 75% with a supine chest X-ray [4–6].

The decision to insert a chest tube for a pneumothorax is based on the patient's overall clinical status and may be aided by serial chest radiographs. Tube decompression is indicated in those who are symptomatic, who have a large or expanding

TABLE 8.1

INDICATIONS FOR CHEST TUBE INSERTION

- Pneumothorax
  - Primary or spontaneous
  - Secondary
    - Chronic obstructive pulmonary disease
    - Pneumonia
    - Abscess/empyema
    - Malignancy
  - Traumatic
  - Iatrogenic
    - Central line placement
    - Positive-pressure ventilation
  - Thoracentesis
    - Lung biopsy
- Hemothorax
  - Traumatic
    - Blunt
    - Penetrating (trauma or biopsy)
  - Iatrogenic
  - Malignancy
  - Pulmonary arteriovenous malformation
  - Blood dyscrasias
  - Ruptured thoracic aortic aneurysm
- Empyema
  - Parapneumonic
  - Posttraumatic
  - Postoperative
  - Septic emboli
  - Intra-abdominal infection
- Chylothorax
  - Traumatic
  - Surgical
  - Congenital
  - Malignancy
- Pleural effusion
  - Transudate
  - Exudate (malignancy, inflammatory)

pneumothorax, who are being mechanically ventilated (the latter of whom may present acutely with deteriorating oxygenation and an increase in airway pressures, necessitating immediate decompression), or in patients where there is no capability for serial chest radiographs or the absence of trained personnel (off-hour shifts and geographic location) for the emergency placement of a chest tube [3].

A small, stable, asymptomatic pneumothorax can be followed with serial chest radiographs. Reexpansion occurs at the rate of approximately 1.25% of lung volume per day [7].

Persistent leaking of air into the pleural space with no route of escape will ultimately collapse the affected lung, flatten the diaphragm, and eventually produce contralateral shift of the mediastinum. Compression of the contralateral lung and compromise of venous return result in progressive hypoxemia and hypotension. Emergency decompression with a 14- or 16-gauge catheter in the midclavicular line of the second intercostal space may be lifesaving while preparations for chest tube insertion are being made.

Hemothorax

Accumulation of blood in the pleural space can be classified as spontaneous, iatrogenic, or traumatic. Attempted thoracentesis or tube placement may result in injury to the intercostal or internal mammary arteries or to the pulmonary parenchyma. Up to a third of patients with traumatic rib fractures may have an accompanying pneumothorax or hemothorax [8]. Pulmonary parenchymal bleeding from chest trauma is often self-limited due to the low pressure of the pulmonary vascular system. However, systemic sources (intercostal, internal mammary or subclavian arteries, aorta, or heart) may persist and become life threatening.

Indications for open thoracotomy in the setting of traumatic hemothorax include initial blood loss greater than 1,500 mL or continued blood loss exceeding 500 mL over the first hour, 200 mL per hour after 2 to 4 hours, or 100 mL per hour after 6 to 8 hours, or in an unstable patient who does not respond to volume resuscitation [9–11]. Placement of large-bore [36 to 40 French (Fr)] drainage tubes encourages evacuation of blood and helps determine the need for immediate thoracotomy.

Spontaneous pneumothoraces may result from necrotizing pulmonary infections, pulmonary arteriovenous malformations, pulmonary infarctions, primary and metastatic malignancies of the lung and pleura, and tearing of adhesions between the visceral and parietal pleurae.

Empyema

Empyemas are pyogenic infections of the pleural space that may result from numerous clinical conditions, including necrotizing pneumonia, septic pulmonary emboli, spread of intra-abdominal infections, or inadequate drainage of a traumatic hemothorax. Pyothorax as a complication of pneumonia is less common now than in the preantibiotic era, with the common organisms now being *Staphylococcus aureus* and anaerobic and gram-negative microbes.

Definitive management includes evacuation of the collection and antibiotic therapy. Large-bore drainage tubes (36 to 40 Fr) are used, and success is evidenced by resolving fever and leukocytosis, improving clinical status, and eventual resolving drainage. The tube can then be removed slowly over several days, allowing a fibrous tract to form. If no improvement is seen, rib resection and open drainage may be indicated. Chronic empyema may require decortication or, in more debilitated patients, open-flap drainage (Eloesser procedure). Fibrinolytic enzymes (urokinase or streptokinase) can also be instilled through the tube to facilitate drainage of persistent purulent collections or for hemothorax or malignant effusions [12–14].

Chylothorax

A collection of lymphatic fluid in the pleural space is termed *chylothorax*. Because of the immunologic properties of lymph, the collection is almost always sterile. As much as 1,500 mL per day may accumulate and may result in hemodynamic compromise or adverse metabolic sequelae as a result of loss of protein, fat, and fat-soluble vitamins. The diagnosis is confirmed by a fluid triglyceride level greater than 110 mg per dL or a cholesterol–triglyceride ratio of less than 1 [15,16]. Primary causes of chylothorax include trauma, surgery, malignancy, and congenital abnormalities [17].

Treatment involves tube drainage along with aggressive maintenance of volume and nutrition. With central parenteral nutrition and intestinal rest (to limit flow through the thoracic duct), approximately 50% will resolve without surgery [18]. Open thoracotomy may be necessary to ligate the duct and close the fistula; in the cases when the abdominal lymphatics are patent, percutaneous catheterization and embolization of the thoracic duct can be perform with good results [19].

Pleural Effusion

Management of a pleural effusion often begins with thoracentesis to identify the collection as either a transudative or

exudative process. Treatment of *transudative* pleural effusions is aimed at controlling the underlying cause (e.g., congestive heart failure, nephrotic syndrome, and cirrhosis). Tube thoracostomy may be helpful in controlling a temporary ventilatory or compliance-related issue, but it is not usually the solution. *Exudative* pleural effusions, however, often require tube drainage.

Sometimes it is necessary to perform chemical pleurodesis in order to develop apposition of pleural surfaces. Agents that can be used include bleomycin, doxycycline, and talc [20–22].

CONTRAINDICATIONS

Large bullous disease of the lung may be mistaken for a pneumothorax, a circumstance in which attempted pleural tube placement may result in significant morbidity. CT scanning is indicated in these instances to clearly analyze the anatomy. Likewise, an apparent pleural effusion may be a lung abscess or consolidated pulmonary parenchyma (e.g., pneumonia and atelectasis). Again, CT scanning or ultrasonography may prove to be helpful in delineating the pathology before tube placement.

History of a process that will promote pleural symphysis (such as a sclerosing procedure, pleurodesis, pleurectomy, or previous thoracotomy on the affected side) should raise caution and prompt evaluation with CT scanning to help identify the exact area of pathology and to direct tube placement away from areas where the lung is adherent to the chest wall. In a postpneumonectomy patient, the pleural tube should be placed above the original incision, as the diaphragm frequently rises to this height.

The possibility of herniation of abdominal contents through the diaphragm in patients with severe blunt abdominal trauma or stab wounds in the vicinity of the diaphragm requires more extensive evaluation before tube placement. In addition, coagulopathies should be corrected before tube insertion in a nonemergent setting. A clinical study showed that placement of chest tubes under emergency conditions (e.g., trauma) using the lateral approach results in more tube misplacements than using the anterior approach. Although no clinical or functional consequences were observed after the misplaced tubes were repositioned, the risk of malpositioning should be considered if the patient is obese, has large breasts, or has a clear history of cardiomegaly [23].

TECHNIQUE

Chest tube insertion requires knowledge not only of the anatomy of the chest wall and intrathoracic and intra-abdominal structures, but also of general aseptic technique. The procedure should be performed or supervised only by experienced personnel, because the complications of an improperly placed tube may have immediate life-threatening results. Before tube placement, the patient must be evaluated thoroughly by physical examination and chest films to avoid insertion of the tube into a bulla or lung abscess, into the abdomen, or even into the wrong side. Particular care must be taken before and during the procedure to avoid intubation of the pulmonary parenchyma.

The necessary equipment is provided in Table 8.2. Sterile technique is mandatory whether the procedure is performed in the operating room, in the intensive care unit, in the emergency room, or on the ward. Detailed informed consent is obtained, and a time-out is performed to make sure all the equipment is ready and available and that the procedure is being done on the correct side and correct patient.

TABLE 8.2

CHEST TUBE INSERTION EQUIPMENT

Chlorhexidine or povidone–iodine solution
Sterile towels and drapes with full body cover
Sterile sponges
1% lidocaine without epinephrine (40 mL)
10-mL syringe
18-, 21-, and 25-gauge needles
2 Kelly clamps, one large and one medium
Mayo scissors
Standard tissue forceps
Towel forceps
Needle holder
0-Silk suture with cutting needle
Scalpel handle and no. 10 blade
Chest tubes (24, 28, 32, and 36 Fr)
Chest tube drainage system (filled appropriately)
Petrolatum gauze
2-in. nonelastic adhesive tape
Sterile gowns and gloves, masks, caps

Careful titration of parenteral narcotics or benzodiazepines and careful, generous administration of local anesthetic agents provide for a relatively painless procedure. Standard, large-bore drainage tubes are made from either Silastic or rubber. Silastic tubes are either right angled or straight, have multiple drainage holes, and contain a radiopaque stripe with a gap to mark the most proximal drainage hole. They are available in sizes ranging from 6 to 40 Fr, with size selection dependent on the patient population (6 to 24 Fr for infants and children) and the collection being drained (24 to 28 Fr for air, 32 to 36 Fr for pleural effusions, and 36 to 40 Fr for blood or pus). Small-caliber Silastic tubes have been increasingly employed for chest drainage, particularly after open-heart surgery, to decrease pain and encourage earlier ambulation [24].

Before performing the procedure, it is important to review the steps to be taken and to ensure that all necessary equipment is available. Patient comfort and safety are paramount. There are three techniques for insertion of a thoracostomy tube. The first two direct techniques require a surgical incision and are (i) blunt dissection and (ii) trocar puncture. Only the former technique has been discussed as the latter is not commonly employed. The third technique is the percutaneous method, which can also be done at the bedside with US guidance.

1. With the patient supine and the head of the bed adjusted for comfort, the involved side is elevated slightly with the ipsilateral arm brought up over the head (Fig. 8.1). Supplemental oxygen is administered as needed. Localize the borders of the triangle of safety whenever possible (A: below level of axillary vessels; B: above fifth intercostal space at the anterior border of the latissimus dorsi; C: lateral border of pectoralis major) [25].
2. The tube is usually inserted through the fourth or fifth intercostal space in the anterior axillary line. An alternative entry site (for decompression of a pneumothorax) is the second intercostal space in the midclavicular line, but for cosmetic reasons and to avoid the thick pectoral muscles, the former site is preferable in adults.
3. Under sterile conditions, the area is prepared with 2% chlorhexidine in 70% isopropyl alcohol, and after allowing it to dry, it is draped to include the nipple, which serves as a landmark, as well as the axilla. A 2- to 3-cm area is infiltrated with 1% lidocaine to raise a wheal two fingerbreadths below the intercostal space to be penetrated. (This

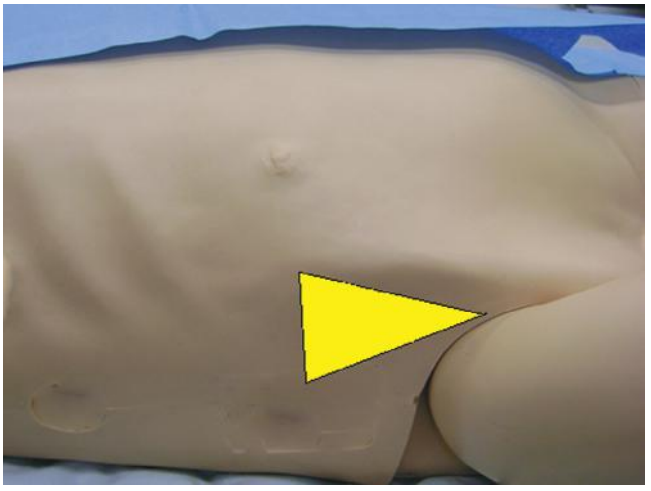

FIGURE 8.1. Positioning of the patient with the arm flexed over the head. Identification of the triangle of safety.

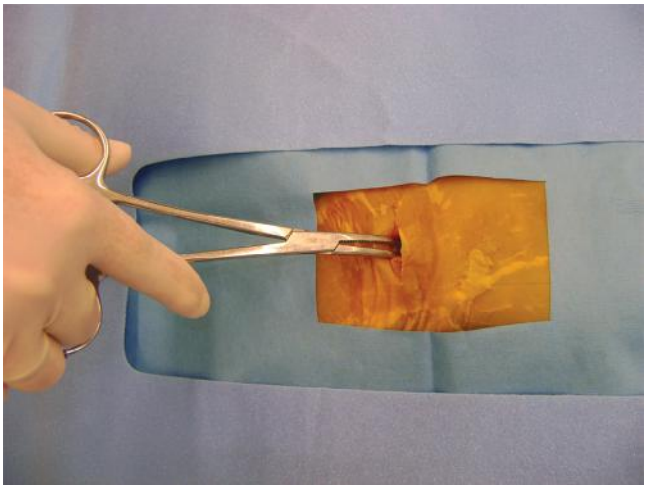

FIGURE 8.2. Dissection with Kelly clamp.

allows for a subcutaneous tunnel to be developed, through which the tube will travel, and discourages air entry into the chest following removal of the tube.)

4. A 2-cm transverse incision is made at the wheal, and additional lidocaine is administered to infiltrate the tissues through which the tube will pass, including a generous area in the intercostal space (especially the periosteum of the ribs above and below the targeted interspace). Care should be taken to anesthetize the parietal pleura fully, as it (unlike the visceral pleura) contains pain fibers. Each injection of lidocaine should be preceded by aspiration of the syringe to prevent injection into the intercostal vessels. Up to 30 to 40 mL of 1% lidocaine may be needed to achieve adequate local anesthesia.
5. To confirm the location of air or fluid, a thoracentesis is then performed at the proposed site of tube insertion. If air or fluid is not aspirated, the anatomy should be reassessed and chest radiographs and CT scans reexamined before proceeding.
6. A short tunnel is created to the chosen intercostal space using Kelly clamps and the intercostal muscles are bluntly divided (Fig. 8.2).
7. The closed clamp is carefully inserted through the parietal pleura, hugging the superior portion of the lower rib to prevent injury to the intercostal bundle of the rib above. The clamp is placed to a depth of less than 1 cm to prevent injury to the intrathoracic structures and is spread open approximately 2 cm.
8. A finger is inserted into the pleural space to explore the anatomy and confirm proper location and lack of pleural symphysis. Only easily disrupted adhesions should be broken. Bluntly dissecting strong adhesions may tear the lung and initiate bleeding.
9. The end of the chest tube is grasped with the clamp and guided with the finger through the tunnel into the pleural space. Once the tip of the tube is in the pleural space, the clamp is removed and the chest tube is advanced and positioned apically for a pneumothorax and dependently for fluid removal (Fig. 8.3A, B). All holes must be confirmed to be within the pleural space. The use of undue pressure or force to insert the tube should be avoided (Fig. 8.4A, B).
10. The location of the tube should be confirmed by observing the flow of air (seen as condensation within the tube) or

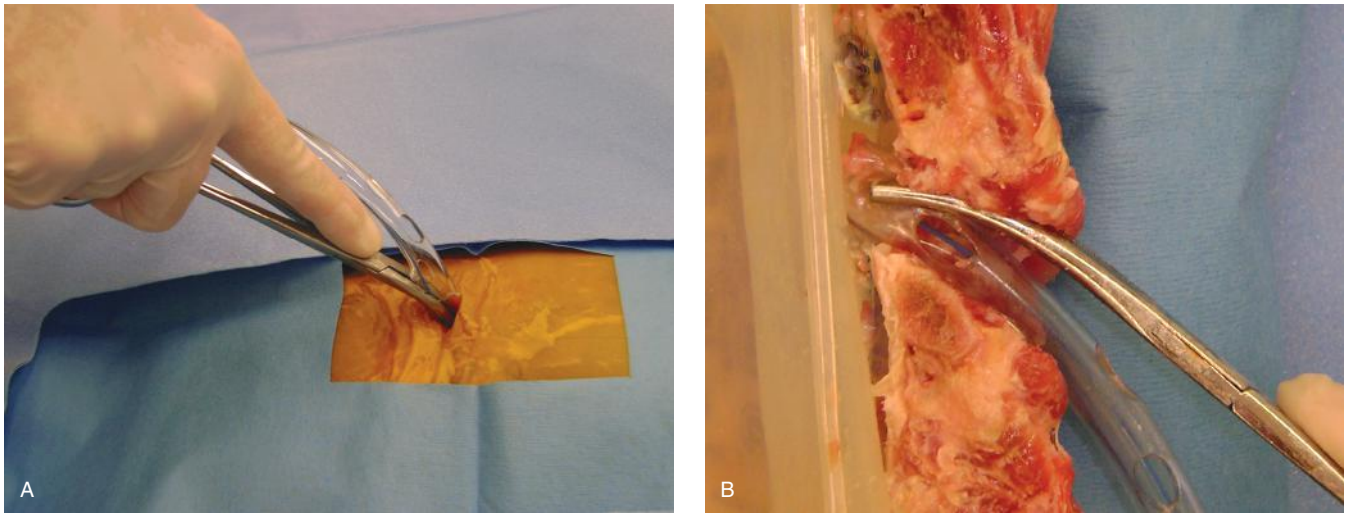

FIGURE 8.3. A, B: The clamp penetrates the intercostal muscle. The end of the chest tube is grasped with a Kelly clamp and guided with a finger through the chest incision. The clamp can be placed above or bellow the tube.

FIGURE 8.4. A, B: Advance the tube once the clamp has been removed.

fluid from the tube. It is then sutured to the skin securely to prevent slippage (Fig. 8.5). A simple suture to anchor the tube can be used or a horizontal mattress suture can be used to allow the hole to be tied closed when the tube is removed. An occlusive petrolatum gauze dressing is applied, and the tube is connected to a drainage apparatus and securely taped to the dressing and to the patient. All connections between the patient and the drainage apparatus must also be tight and securely taped.

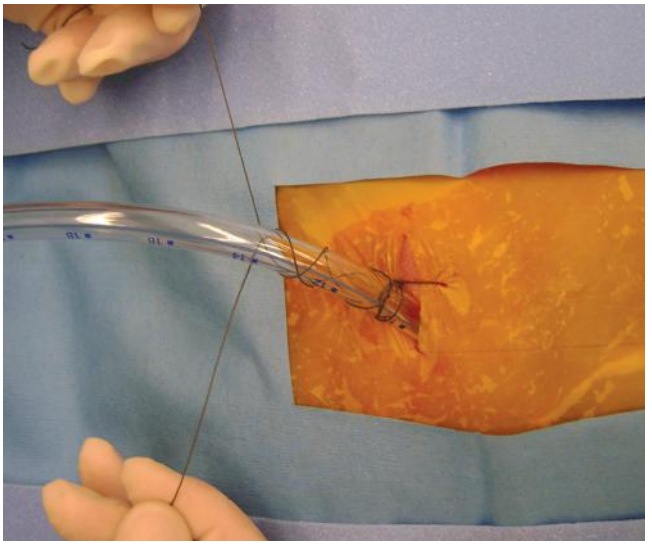

FIGURE 8.5. The tube is securely sutured to the skin with a 1–0 or 2–0 silk suture. This suture is left long, wrapped around the tube, and secured with tape. To seal the tunnel, the suture is tied when the tube is pulled out.

COMPLICATIONS

Chest tube insertion may be accompanied by significant complications. In one series, insertion and management of pleural tubes in patients with blunt chest trauma carried a 9% incidence of complications. Insertion alone is usually accompanied by a 1% to 2% incidence of complications even when performed by experienced personnel [26] (Table 8.3). The use of small-caliber, less rigid, Silastic drains has been found to be safe and efficacious as the more rigid, conventional chest tubes [27], and they allow both more mobility and earlier discharge when used in open-heart surgery patients [28].

CHEST TUBE MANAGEMENT AND CARE

While a chest tube is in place, the tube and drainage system must be checked daily for adequate functioning. Most institutions use a three-chambered system that contains a calibrated collection trap for fluid, an underwater seal unit to allow escape of air while maintaining negative pleural pressure, and

TABLE 8.3

COMPLICATIONS OF CHEST TUBE INSERTION

Unintentional tube placement into vital structures (lung, liver, spleen, etc.)
Bleeding
Reexpansion pulmonary edema

Residual hemothorax
Empyema

a suction regulator. Suction is routinely established at 15 to 20 cm water, controlled by the height of the column in the suction regulator unit, and maintained as long as an air leak is present. The drainage system is examined daily to ensure that appropriate levels are maintained in the underwater seal and suction regulator chambers. If suction is desired, bubbling should be noted in the suction regulator unit. Connections between the chest tube and the drainage system should be tightly fitted and securely taped. For continuous drainage, the chest tube and the tubing to the drainage system should remain free of kinks, should not be left in a dependent position, and should never be clamped. If problems are encountered with repetitive kinking, a corrugated tubing splint can be used around the chest tube to improve the resistance [29]. The tube can be milked and gently stripped, although with caution, as this may generate negative pressures of up to 1,500 mm Hg and can injure adjacent tissues [30]. Irrigation of the tube is discouraged. Dressing changes should be performed every 2 or 3 days and as needed. Adequate pain control is mandatory to encourage coughing and ambulation to facilitate lung reexpansion.

Chest films can be obtained to evaluate the progress of drainage and to ensure that the most proximal drainage hole has not migrated from the pleural space (a situation that may result in pneumothorax or subcutaneous emphysema). If this occurs and the pathologic process is not corrected, replacement of the tube is usually indicated, especially if subcutaneous emphysema is developing. Mandatory routine daily chest X-rays are not indicated to monitor chest tubes in the intensive care unit unless there is a clinical necessity [31]. A tube should never be readvanced into the pleural space, and if a tube is to be replaced, it should always be at a different site rather than the same hole. If a pneumothorax persists, increasing the suction level may be beneficial, but an additional tube may be required if no improvement results; other etiologies should be considered after this point and further evaluation with a CT scan of the chest. Proper positioning may also be confirmed by chest CT scanning [32].

CHEST TUBE REMOVAL

Indications for removal of chest tubes include resolution of the pneumothorax or fluid accumulation in the pleural space, or both. For a pneumothorax, the drainage system is left on suction until the air leak stops. If an air leak persists, brief clamping of the chest tube can be performed to confirm that the leak is from the patient and not the system. If, after several days, an air leak persists, placement of an additional tube may be indicated. When the leak has ceased for more than 24 to 48 hours (or if no fluctuation is seen in the underwater seal chamber), the drainage system is placed on water seal by disconnecting the wall suction, followed by a chest film several hours later. If no pneumothorax is present and no air leak appears in the system with coughing, deep breathing, and reestablishment of suction, the tube can be removed. For fluid collections, the tube can be removed when drainage is less than 200 cc per 24 hours or lesser [33], unless sclerotherapy is planned.

Tube removal is often preceded by oral or parenteral analgesia at an appropriate time interval [34]. The suture holding the tube to the skin is cut. At end-inspiration, the tube is pulled out and the hole simultaneously covered with occlusive petrolatum gauze dressing at peak inspiration or end expiration the chest tube is pulled [35]. A chest radiograph is performed immediately to check for a pneumothorax if there are clinical signs and symptoms or if the patient is at high risk for reaccumulation; otherwise, a nonurgent chest radiograph can be ordered and repeated 24 hours later to rule out reaccumulation of air or fluid [36].

RELATED SYSTEMS

Percutaneous aspiration of the pleural space to relieve a pneumothorax without an active air leak has been reported. Although successful in up to 75% cases of needle-induced or traumatic pneumothoraces, the success rate is less for those with a spontaneous pneumothorax [37,38]. Small-bore catheters placed via Seldinger technique or using a trocar have been successful for treatment of spontaneous and iatrogenic pneumothoraces [39–41].

Heimlich valves (one-way flutter valves that allow egress of air from pleural tubes or catheters) have also gained popularity because ambulation is facilitated and outpatient care can be provided to those with persistent air leaks [42,43].

CHAPTER 9 ■ BRONCHOSCOPY

STEPHEN J. KRINZMAN, PAULO J. OLIVEIRA AND RICHARD S. IRWIN

Since its commercial introduction for clinical use in 1968, flexible bronchoscopy has had a dramatic impact on the approach and management of patients with a wide variety of respiratory problems [1]. Because of its safety, low complication rate [2], and comfort [3], flexible bronchoscopy has largely replaced rigid bronchoscopy as the procedure of choice for most endoscopic evaluations of the airway. However, rigid bronchoscopy is indicated for (a) brisk hemoptysis (200 mL per 24 hours); (b) extraction of foreign bodies; (c) endobronchial resection of granulation tissue that might occur after traumatic and/or prolonged intubation; (d) biopsy of vascular tumors (e.g., bronchial carcinoid), in which brisk and excessive bleeding can be controlled by packing; (e) endoscopic laser surgery; and (f) dilation of tracheobronchial strictures and placement of airway stents [1,4]. In the last two decades, there has been renewed interest in the use of rigid bronchoscopy by pulmonologists, driven by the advent of dedicated endobronchial prostheses (airway stents) in the early 1990s and the application of advanced bronchoscopic modalities (laser photoresection, electrocautery, and cryotherapy) for the management of both malignant and benign central airway obstructions [5,6]. These advances in bronchoscopy have fused older techniques and instruments, such as rigid bronchoscopy, with novel applications of flexible bronchoscopy, spurring the development of the field of interventional pulmonology. In an attempt to establish uniformity in the training and performance of bronchoscopy and advanced interventions, the American College of Chest Physicians recently published comprehensive guidelines for interventional pulmonary procedures [7].

DIAGNOSTIC INDICATIONS

General Considerations

Because flexible bronchoscopy can be performed easily even in intubated patients, the same general indications apply to critically ill patients on ventilators and noncritically ill patients; however, only the indications most commonly encountered in critically ill patients are discussed here. Where relevant, the potential application of advanced bronchoscopic diagnostic and therapeutic interventions in the intensive care unit (ICU) setting are also discussed.

Common Indications

Hemoptysis

Hemoptysis is one of the most common clinical problems for which bronchoscopy is indicated [8,9] (see Chapter 53 for a detailed discussion). Whether the patient complains of blood streaking or massive hemoptysis (expectoration of greater than 600 mL in 48 hours), bronchoscopy should be considered to localize the site of bleeding and diagnose the cause. Localization of the site of bleeding is crucial if definitive therapy, such as surgery, becomes necessary, and it is also useful to guide angiographic procedures. Bronchoscopy performed within 48 hours of the time when bleeding stops is more likely to

localize the site of bleeding (34% to 91%) compared with delayed bronchoscopy (11% to 52%) [10]. Bronchoscopy is more likely to identify a bleeding source in patients with moderate or severe hemoptysis [11]. Whenever patients have an endotracheal or tracheostomy tube in place, hemoptysis should always be evaluated, because it may indicate potentially life-threatening tracheal damage. Unless the bleeding is massive, a flexible bronchoscope, rather than a rigid bronchoscope, is the instrument of choice for evaluating hemoptysis. In the setting of massive hemoptysis, the patient is at risk for imminent decompensation and death due to asphyxiation. Stabilization of the patient, focusing on establishment of a secure airway, and timely communication with pulmonology, thoracic surgery, anesthesiology, and interventional radiology is of utmost importance. This coordinated, multidisciplinary effort should focus on rapid transfer to the operation room (OR) suite for rigid bronchoscopy. The rigid bronchoscope is ideal in this situation because it provides a secure route for ventilation, serves as a larger conduit for adequate suctioning, and can quickly isolate the lung in the case of a lateralized bleeding source. In most situations, once an adequate airway has been established and initial suctioning of excessive blood has been performed, the flexible bronchoscope can be inserted through the rigid bronchoscope to more accurately assess and localize the source of bleeding beyond the main bronchi [12].

Diffuse Parenchymal Disease

The clinical setting influences the choice of procedure. When diffuse pulmonary infiltrates suggest sarcoidosis, carcinomatosis, or eosinophilic pneumonia, transbronchoscopic lung forceps biopsy should be considered initially because it has an extremely high yield in these situations (see Chapter 69). Transbronchial lung biopsy has a low yield for the definitive diagnosis of inorganic pneumoconiosis and pulmonary vasculitides [13]; when these disorders are suspected, surgical lung biopsy is the procedure of choice. In the case of pulmonary fibrosis and acute interstitial pneumonitis, transbronchial biopsy usually does not provide adequate tissue for a specific histologic diagnosis, although by excluding infection the procedure may provide sufficient information to guide therapy.

Ventilator-Associated Pneumonia

The ability to determine the probability of ventilator-associated pneumonia (VAP) is very limited, with a sensitivity of only 50% and a specificity of 58% [14]. Quantitative cultures obtained via bronchoscopy may thus play an important role in the diagnostic strategy. Quantitative cultures of bronchoalveolar lavage (BAL) fluid and protected specimen brush (PSB), with thresholds of 10^4 colony-forming units (CFU) per mL and 10^3 CFU per mL, respectively, are most commonly employed prior to initiation of antimicrobial therapy. Cultures of bronchial washings do not add to the diagnostic yield of quantitative BAL culture alone [15]. For a brief description of how to perform BAL and obtain PSB cultures, see the "Procedure" section, given later in the chapter.

For BAL, an evidence-based analysis of 23 prior investigations yields a sensitivity of 73% and a specificity of 82%, indicating that BAL cultures fail to diagnose VAP in almost one-fourth of all cases [16]. A similar analysis of PSB cultures indicates a very wide range of results, with a sensitivity of 33% to greater than 95% and a median of 67%, and a specificity of 50% to 100% with a median of 95% [17,18]. PSB is thus more specific than it is sensitive, and negative results may not be sufficient to exclude the presence of VAP [19]. Blind protected telescoping catheter specimens yield similar results to bronchoscopically directed PSB cultures [20,21]. It is critical to note that colony counts change very quickly with antibiotic therapy. Within 12 hours of starting antibiotic therapy, 50% of all significant bacterial species initially identified in significant numbers had colony counts reduced to below the "pathogenic" threshold level. After 48 hours of therapy, only 14% of isolates are still present above threshold values [22]. It is therefore essential to obtain quantitative cultures before starting or changing antibiotics.

Despite the greater accuracy of quantitative bronchoscopic cultures, prospective randomized trials of early invasive diagnostic strategies employing bronchoscopy and quantitative lower respiratory tract cultures for VAP have not demonstrated significant advantages in mortality or other major clinical end points [23,24] over simpler methods. The largest such trial [24] found that compared to therapy based on nonquantitative endotracheal aspirates, patients randomized to bronchoscopy with quantitative cultures had no improvement in mortality, duration of mechanical ventilation, or length of ICU or hospital stay. On the basis of these findings, routine use of bronchoscopy in immunocompetent adults with suspected VAP cannot be recommended.

Pulmonary Infiltrates in Immunocompromised Patients

When an infectious process is suspected, the diagnostic yield depends on the organism and the immune status of the patient. In immunocompetent patients, BAL has a sensitivity of 87% for detecting respiratory pathogens [19], and a negative BAL quantitative culture has a specificity of 96% in predicting sterile lung parenchyma. Numerous recent investigations have examined the utility of bronchoscopy in immunocompromised patients. Most of these investigations have found that the diagnostic yield of BAL in such patients is approximately 50% and that the results of BAL lead to a change in treatment in 17% to 38% of patients. In one prospective multicenter trial [25], BAL was the only conclusive diagnostic study in 33% of patients. Although it is difficult to distinguish respiratory decompensation caused by bronchoscopy from the natural history of the patients' underlying disease, the same study found that 48% of patients developed deterioration in respiratory status after bronchoscopy and 27% of patients were intubated. Transbronchial biopsy may add little to the diagnostic yield of BAL in immunocompromised patients, with an incremental yield of 7% to 12% [26–29]. In some series, the major complication rate of transbronchial biopsy was greater than the diagnostic utility, including a 14% incidence of major bleeding requiring intubation [29]. BAL has a relatively poor sensitivity for detecting fungal infections in this population (40%) [26]. In AIDS patients, the sensitivity of lavage or transbronchial lung biopsy for identifying all opportunistic organisms can be as high as 87% [30,31]. Transbronchial biopsy adds significantly to the diagnostic yield in AIDS patients and may be the sole means of making a diagnosis in up to 24% of patients, including diagnoses of *Pneumocystis jirovecii, Cryptococcus neoformans*, *Mycobacterium tuberculosis,* and nonspecific interstitial pneumonitis [32]. Lavage alone may have a sensitivity of up to 97% for the diagnosis of *P. jirovecii* pneumonia [33]. However, because induced sputum samples can also be positive for *P. jirovecii* in up to 79% of cases [33], induced expectorated sputum, when available, should be evaluated first for this organism before resorting to bronchoscopy.

Acute Inhalation Injury

In patients exposed to smoke inhalation, flexible nasopharyngoscopy, laryngoscopy, and bronchoscopy are indicated to identify the anatomic level and severity of injury. Prophylactic intubation should be considered if considerable upper airway mucosal injury is noted early; acute respiratory failure is more likely in patients with mucosal changes seen at segmental or lower levels [34]. Upper airway obstruction is a life-threatening problem that usually develops during the initial 24 hours

after inhalation injury. It correlates significantly with increased size of cutaneous burns, burns of the face and neck, and rapid intravenous fluid administration, and also portends a greater mortality [35].

Blunt Chest Trauma

Patients may present with atelectasis, pulmonary contusion, hemothorax, pneumothorax, pneumomediastinum, or hemoptysis. Prompt bronchoscopic evaluation of such patients has a diagnostic yield of 53%; findings may include tracheal or bronchial laceration or transection (14%), aspirated material (6%), supraglottic tear with glottic obstruction (2%), mucus plugging (15%), and distal hemorrhage (13%) [36]. Many of these diagnoses may not be clinically evident and require surgical intervention.

Postresectional Surgery

Flexible bronchoscopy can identify a disrupted suture line causing bleeding and pneumothorax following surgery and an exposed endobronchial suture causing cough. In these postpneumonectomy situations, the location of dehiscence and the subsequent bronchopleural fistula (BPF) is easily identified visually via flexible bronchoscopy at the stump site. However, when the BPF occurs in the setting of acute respiratory distress syndrome (ARDS) or necrotizing pneumonia, localization at the segmental and subsegmental level can be more challenging. Readers are referred to Chapter 57, which comprehensively covers this topic.

Assessment of Intubation Damage

When a nasotracheal or orotracheal tube of the proper size is in place, the balloon can be routinely deflated and the tube withdrawn over the bronchoscope to look for subglottic damage. The tube is withdrawn up through the vocal cords and over the flexible bronchoscope and glottic and supraglottic damage sought. This technique may by useful after reintubation for stridor, or when deflation of the endotracheal tube cuff does not produce a significant air leak, suggesting the potential for life-threatening upper airway obstruction when extubation takes place. The flexible bronchoscope may readily identify mechanical problems such as increased airway granulation tissue leading to airway obstruction, tracheal stenosis at pressure points along the artificial airway–tracheal interface, and tracheobronchomalacia.

THERAPEUTIC INDICATIONS

Atelectasis

When atelectasis occurs in critically ill patients who had a normal chest film on admission, mucus plugging is the most likely cause [37]. Bronchoscopy has a success rate of up to 89% in cases of lobar atelectasis, but only produced clinical improvement in 44% of patients when performed for retained secretions [38]. One randomized trial found no advantage of bronchoscopy over a very aggressive regimen of frequent chest physiotherapy, recruitment maneuvers, saline nebulization, and postural drainage [39]. This study also found that the presence of air bronchograms on the initial chest X-ray predicted relative failure of either intervention to resolve the atelectasis. Occasionally, the direct instillation of acetylcysteine (Mucomyst) through the bronchoscope may be necessary to liquefy the thick, tenacious inspissated mucus [40]. Because acetylcysteine may induce bronchospasm in patients with asthma, these patients must be pretreated with a bronchodilator.

Foreign Bodies

Although the rigid bronchoscope is considered by many to be the instrument of choice for removing foreign bodies, devices with which to grasp objects are available for use with the flexible bronchoscope [41]. A review of flexible bronchoscopy in the management of tracheobronchial foreign bodies in adults from the Mayo Clinic demonstrated a success rate of 89% [42]. The success of flexible bronchoscopy in foreign body removal can be enhanced by rigorous preprocedure preparation, assuring the availability of appropriate ancillary grasping equipment, practicing a "dry run," and ensuring that a bronchoscopist with experience in foreign body removal is involved. It is also important to have an appreciation for situations in which rigid bronchoscopy with added ancillary interventions, such as laser therapy or cryotherapy, might be useful (e.g., an embedded foreign body with significant granulation tissue reaction at risk for bleeding) [43].

Endotracheal Intubation

In patients with ankylosing spondylitis and other mechanical problems of the neck, the flexible bronchoscope may be used as an obturator for endotracheal intubation. The bronchoscope with an endotracheal tube passed over it can be passed transnasally (after proper local anesthesia) or transorally. The tube can then be advanced over the scope.

Hemoptysis

On rare occasions where brisk bleeding threatens asphyxiation, endobronchial tamponade may stabilize the patient before definitive therapy is performed (see Chapter 53). With the use of the flexible bronchoscope, usually passed through a rigid bronchoscope or endotracheal tube, a Fogarty catheter with balloon is passed into the bleeding lobar orifice. When the balloon is inflated and wedged tightly, the patient may be transferred to surgery or angiography for bronchial arteriography and bronchial artery embolization [44]. Other bronchial blocking and lung separation techniques have been described and reviewed in the literature [45]. The wire-guided endobronchial blocker (Arndt blocker) is a dedicated bronchial blocker that has a wire loop at its distal end, which—when looped around the distal end of the flexible bronchoscope—can be guided to the bleeding airway, inflated, and its position adjusted under direct visualization. More simple techniques that take advantage of the flexible bronchoscope's ability to act as a stylet for a single-lumen endotracheal tube can be used to separate the lung. One can use the bronchoscope to preferentially intubate the right main or left main bronchus in an acute, emergent situation. Hemostasis may also be achieved by using flexible bronchoscopy to apply oxidized regenerated cellulose mesh to the bleeding site, instill thrombin/thrombin–fibrinogen preparations, and more traditionally, perform iced saline lavage or apply topical epinephrine (1:20,000) to temporize the bleeding [10,46]. There have also been reports of treating hemoptysis by instilling cyanoacrylate through a catheter in the working channel of the flexible bronchoscope [47]. In the case of a visibly bleeding endobronchial tumor, hemostasis can be attained with laser photocoagulation (Nd-YAG laser), electrocautery, or argon plasma coagulation.

Central Obstructing Airway Lesions

Some patients with cancer and others with benign lesions that obstruct the larynx, trachea, and major bronchi can be treated by electrocautery, laser photoresection, argon plasma coagulation, cryotherapy, or photodynamic therapy applied through the bronchoscope (rigid or flexible) [48–55]. Flexible bronchoscopy can also be used to place catheters that facilitate endobronchial delivery of radiation (brachytherapy). Metal or silicone endobronchial stents can be placed bronchoscopically to relieve stenosis of large central airways. Adequate insertion of stents and relief of stenosis (especially due to extrinsic compression) is typically accompanied by dilation of the airway via rigid bronchoscopy or with balloon dilation applied with the aid of flexible bronchoscopy. Several issues regarding airway stents should be noted: silicone stents can only be placed via rigid bronchoscopy and metal stents should generally not be used in the setting of a nonmalignant central airway obstruction because they are associated with excessive growth of granulation tissue with subsequent worsening of airway obstruction and can be very challenging to remove once this complication occurs [51]. The primary goal of the interventions described earlier for the management of malignant central airway obstruction is palliative. Multiple case reports have confirmed that these interventions improve quality of life by relieving symptoms of dyspnea almost immediately [52–55]. In many instances, these procedures also facilitate liberation from mechanical ventilation and downgrading of the level of care from the ICU. It appears that in intubated ICU patients, flexible bronchoscopy performed at the bedside with stent deployment and resective interventions, when necessary, is just as effective as rigid bronchoscopic interventions in the appropriately selected patient [54].

Closure of Bronchopleural Fistula

After placement of a chest tube, drainage of the pleural space, and stabilization of the patient (e.g., infection and cardiovascular and respiratory systems), bronchoscopy can be used to visualize a proximal BPF or localize a distal BPF; it can also be used in attempts to close the BPF [56]. Please see Chapter 57, which comprehensively covers this topic.

Percutaneous Dilatational Tracheostomy

Flexible bronchoscopic guidance is extremely helpful during bedside percutaneous tracheostomy [57,58]. Please see Chapter 12, which comprehensively covers this topic.

COMPLICATIONS

When performed by a trained specialist, *routine* flexible bronchoscopy is extremely safe. Mortality should not exceed 0.1%, and overall complications should not exceed 8.1% [2]. The rare deaths have been due to excessive premedication or topical anesthesia, respiratory arrest from hemorrhage, laryngospasm or bronchospasm, and cardiac arrest from acute myocardial infarction [59,60]. Nonfatal complications occurring within 24 hours of the procedure include fever (1.2% to 24%) [2,61], pneumonia (0.6% to 6%) [2], vasovagal reactions (2.4%) [2], laryngospasm or bronchospasm (0.1% to 0.4%) [2], cardiac arrhythmias (0.9% to 4%) [2,62], pneumothorax, anesthesia-related problems (0.1%) [2], and aphonia (0.1%) [2]. Fever may occur in up to 24% of patients after bronchoscopy and appears to be cytokine mediated and uncommonly indicative of a true infection or bacteremia [61]. Transient bacteremias often occur (15.4% to 33%) after rigid bronchoscopy [63], probably due to trauma to the teeth and airways. Most investigations have found that the incidence of bacteremia after transoral flexible bronchoscopy is much lower (0.7%) [64]. Current guidelines by the American Heart Association for respiratory tract procedures recommend prophylactic antibiotics only when incision or biopsy of the respiratory tract mucosa is anticipated. Prophylaxis is further restricted to patients with high-risk cardiac conditions (prosthetic valves, prior history of infective endocarditis, congenital heart disease, and cardiac transplantation with valvulopathy) only and no distinction is made between rigid and flexible bronchoscopy [65].

Although routine bronchoscopy is extremely safe, critically ill patients appear to be at higher risk of complications. Patients with asthma are prone to develop laryngospasm and bronchospasm. Bone marrow and stem cell transplant recipients are more likely to develop major bleeding during bronchoscopy (0% to 14%) [28,66], particularly if PSB or transbronchial lung biopsy is performed (7% to 14% vs. 1.5% for BAL alone) [29,66]. Patients with uremia are at increased risk of bleeding [67]. One investigation found that aspirin use did not increase bleeding risk after transbronchial biopsy [68]. In critically ill, mechanically ventilated patents, bronchoscopy causes a transient decrease in PaO_2 (partial arterial oxygen pressure) of approximately 25% [69], and transbronchial lung biopsy is more likely to result in pneumothorax (7% to 23%) [70], particularly in patients with ARDS (up to 36%) [71]. Patients with ARDS also have more pronounced declines in oxygenation, with a mean decrease of more than 50% in the PaO_2 [69].

CONTRAINDICATIONS

Bronchoscopy should not be performed (a) unless an experienced bronchoscopist is available; (b) when the patient will not or cannot cooperate; (c) when adequate oxygenation cannot be maintained during the procedure; (d) in unstable cardiac patients [72–74]; and (e) in untreated symptomatic patients with asthma [75]. The impact of coagulation parameters and antiplatelet agents on bleeding risk during transbronchial biopsy remains controversial [68,76]. In patients with recent cardiac ischemia, the major complication rate is low (3% to 5%) and is similar to that of other critically ill populations [77,78]. Although patients with stable carbon dioxide retention can safely undergo bronchoscopy with a flexible instrument [79], premedication, sedation during the procedure, and supplemental oxygen must be used with caution. The major contraindications to rigid bronchoscopy include inability to tolerate general anesthesia, an unstable cervical spine, limited range of motion at the spine, any condition that inhibits opening of the jaw, and an inexperienced operator and staff [5].

Consideration of bronchoscopy in neurologic and neurosurgical patients requires attention to the effects of bronchoscopy on intracranial pressure (ICP) and cerebral perfusion pressure (CPP). In patients with head trauma, bronchoscopy causes the ICP to increase by at least 50% in 88% of patients and by at least 100% in 69% of patients despite the use of deep sedation and paralysis [80]. Because mean arterial pressure tends to rise in parallel with ICP, there is often no change in CPP. No significant neurologic complications have been noted in patients with severe head trauma [80,81] or with space-occupying intracranial lesions with computed tomographic evidence of elevated ICP [82]. Bronchoscopy in such patients should be accompanied by deep sedation, paralysis, and medications for cerebral protection (thiopental and lidocaine). Cerebral hemodynamics should be continuously monitored to ensure that ICP and CPP are within acceptable levels. Caution is warranted in patients with markedly elevated baseline ICP or with borderline CPP.

PROCEDURE

Airway and Intubation

In nonintubated patients, flexible bronchoscopy can be performed by the transnasal or transoral route with a bite block [1]. There has also been a relatively recent interest in performing noninvasive ventilation-assisted flexible bronchoscopy via face mask, first described in eight immunocompromised patients with infiltrates and severe hypoxemia (PaO_2/FIO_2 <100) [83]. The procedure was well tolerated with either maintenance of or an improvement in oxygenation noted throughout, and none of the patients required intubation. Since then, multiple case reports and small randomized controlled trials using similar applications of noninvasive ventilation during bronchoscopy in expanded patient populations with severe hypoxemia (PaO_2/FIO_2 <200) have been described with similar outcomes [84,85]. Thus, it appears that this technique, augmented by BAL, appears to be a safe, effective, and viable option of obtaining an early and accurate diagnosis of pneumonia in nonintubated, otherwise marginal, patients with severe hypoxemia. In intubated and mechanically ventilated patients, the flexible bronchoscope can be passed into the tube through a swivel adapter with a rubber diaphragm that will prevent loss of the delivered respiratory gases [86]. To prevent dramatic increases in airway resistance and an unacceptable loss of tidal volumes, the lumen of the endotracheal tube should be at least 2 mm larger than the outer diameter of the bronchoscope [87,88]. Thus, flexible bronchoscopy with an average adult-sized instrument (outside diameter of scope 4.8 to 5.9 mm) can be performed in a ventilated patient if there is an endotracheal tube in place that is 8 mm or larger in internal diameter. If the endotracheal tube is smaller, a pediatric bronchoscope (outside diameter 3.5 mm) or intubation endoscope (outside diameter 3.8 mm) must be used. Both diagnostic and therapeutic interventions via flexible bronchoscopy have also been performed more frequently in the last decade through laryngeal mask airways used to secure the airway in spontaneously breathing and generally anesthetized individuals [89].

Premedication

Topical anesthesia may be achieved by hand-nebulized lidocaine and lidocaine jelly as a lubricant [1] and by instilling approximately 3 mL of 1% or 2% lidocaine at the main carina and, if needed, into the lower airways. Lidocaine is absorbed through the mucus membranes, producing peak serum concentrations that are nearly as high as that when the equivalent dose is administered intravenously, although toxicity is rare if the total dose does not exceed 6 to 7 mg per kg. In 2000, a study performed in otherwise healthy patients with asthma demonstrated the safety of topical lidocaine doses up to 8.2 mg per kg in this population [90] and subsequently led to this upper limit being recommended by the British Thoracic Society in their guidelines for diagnostic flexible bronchoscopy [91]. In patients with hepatic or cardiac insufficiency, lidocaine clearance is reduced, and the dose should be decreased to a maximum of 4 to 5 mg per kg [92,93]. Administering nebulized lidocaine prior to the procedure substantially increases the total lidocaine dose without improving cough or patient comfort [94]. Moderate sedation with incremental doses of midazolam, titrated to produce light sleep, produces amnesia in more than 95% of patients, but adequate sedation may require a total of greater than 20 mg in some subjects [95]. Cough suppression is more effective when narcotics are added to benzodiazepine premedication regimens [95]. Premedication with intravenous atropine has not been found to reduce secretions, decrease coughing, or prevent bradycardia [96,97] and has been associated with greater hemodynamic fluctuations when compared to placebo [98]. Propofol [99] and fospropofol [100] have also been used with success during moderate sedation for bronchoscopy, and may have the advantage of more rapid onset and shorter recovery time.

Mechanical Ventilation

Maintaining adequate oxygenation and ventilation while preventing breath stacking and positive end expiratory pressure (auto-PEEP) may be challenging when insertion of the bronchoscope reduces the effective lumen of the endotracheal tube by more than 50%. PEEP caused by standard scopes and tubes will approach 20 cm H_2O with the potential for barotrauma [87]. The inspired oxygen concentration must be temporarily increased to 100% prior to starting the procedure [87]. Expired volumes should be constantly monitored to ensure that they are adequate [88]. Meeting these ventilatory goals may require increasing the high-pressure limit in volume-cycled ventilation to near its maximal value, allowing the ventilator to overcome the added resistance caused by the bronchoscope. Although this increases the measured peak airway pressure, the alveolar pressure is not likely to change significantly because the lung is protected by the resistance of the bronchoscope [88]. Alternatively, decreasing the inspiratory flow rate in an attempt to decrease measured peak pressures may paradoxically increase alveolar pressures by decreasing expiratory time and thus increasing auto-PEEP. Suctioning should be kept to a minimum and for short periods of time because it will decrease the tidal volumes being delivered [87].

Quantitative Cultures

BAL is performed by advancing the bronchoscope until the tip wedges tightly in a distal bronchus from the area of greatest clinical interest. If the disease process is diffuse, perform the procedure in the right middle lobe because this is the area from which the best returns are most consistently obtained. Three aliquots of saline, typically 35 to 50 mL, are then instilled and withdrawn; in some protocols, the first aliquot is discarded to prevent contamination with more proximal secretions. A total instilled volume of 100 mL with at least 5% to 10% retrieved constitutes an adequate specimen [101]. PSB may be performed through a bronchoscope by advancing the plugged catheter assembly until it projects from the bronchoscope. When the area of interest is reached (e.g., purulent secretions can be seen), the distal plug is ejected and the brush is then fully advanced beyond the protective sheath. After the specimen is obtained, the brush is pulled back into the sheath and only then is the catheter assembly removed from the bronchoscope.

CHAPTER 10 ■ THORACENTESIS

MARK M. WILSON AND RICHARD S. IRWIN

Thoracentesis is an invasive procedure that involves the introduction of a needle, cannula, or trocar into the pleural space to remove accumulated fluid or air. Although a few prospective studies have critically evaluated the clinical value and complications associated with it [1–3], most studies concerning thoracentesis have dealt with the interpretation of the pleural fluid analyses [4,5].

INDICATIONS

Although history (cough, dyspnea, or pleuritic chest pain) and physical findings (dullness to percussion, decreased breath sounds, and decreased vocal fremitus) suggest that an effusion is present, chest radiography or ultrasonic examination is essential to confirm the clinical suspicion. Thoracentesis can be performed for diagnostic or therapeutic reasons. When done for diagnostic reasons, the procedure should be performed whenever possible before any treatment has been given to avoid confusion in interpretation [5]. Analysis of pleural fluid has been shown to yield clinically useful information in more than 90% of cases [2]. The four most common diagnoses for symptomatic and asymptomatic pleural effusions are malignancy, congestive heart failure, parapneumonia, and postoperative sympathetic effusions. A diagnostic algorithm for evaluation of a pleural effusion of unknown etiology is presented in Figure 10.1. In patients whose pleural effusion remains undiagnosed after thoracentesis and closed pleural biopsy, thoracoscopy should be considered for visualization of the pleura and directed biopsy. Thoracoscopy has provided a positive diagnosis in more than 80% of patients with recurrent pleural effusions that are not diagnosed by repeated thoracentesis, pleural biopsy, or bronchoscopy.

Therapeutic thoracentesis is indicated to remove fluid or air that is causing cardiopulmonary embarrassment or to relieve severe symptoms. Definitive drainage of the pleural space with a thoracostomy tube must be done for a tension pneumothorax (PTX) and should be considered for a PTX that is slowly enlarging, any size PTX in the mechanically ventilated patient, hemothorax, or the instillation of a sclerosing agent after drainage of a recurrent malignant pleural effusion.

CONTRAINDICATIONS

Absolute contraindications to performing a thoracentesis are an uncooperative patient, the inability to identify the top of the rib clearly under the percutaneous puncture site, a lack of expertise in performing the procedure, and the presence of a coagulation abnormality that cannot be corrected. Relative

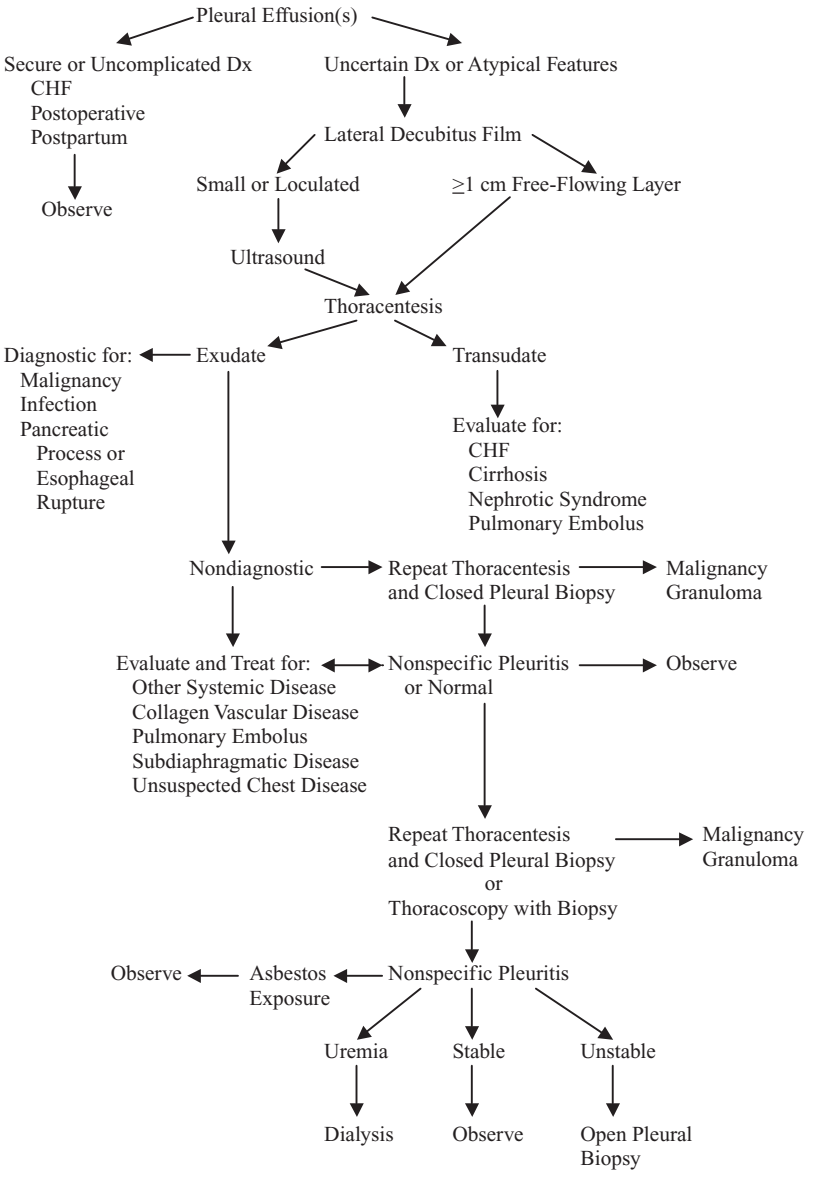

FIGURE 10.1. Diagnostic algorithm for evaluation of pleural effusion. CHF, congestive heart failure; Dx, diagnosis. [Adapted from Smyrnios NA, Jederlinic PJ, Irwin RS: Pleural effusion in an asymptomatic patient. Spectrum and frequency of causes and management considerations. *Chest* 97:192, 1990.]

contraindications to a thoracentesis include entry into an area where known bullous lung disease exists, a patient who is on positive end-expiratory pressure, and a patient who has only one "functioning" lung (the other having been surgically removed or that has severe disease limiting its gas exchange function). In these settings, it may be safest to perform the thoracentesis under ultrasonic guidance.

COMPLICATIONS

A number of prospective studies have documented that complications associated with the procedure are not infrequent [1,2]. The overall complication rate has been reported to be as high as 50% to 78%, and can be further categorized as major (15% to 19%) or minor (31% to 63%) [2,3]. Complication rates appear to be inversely related to experience level of the operator; the more experienced, the fewer the complications [6]. Although death due to the procedure is infrequently reported, complications may be life threatening [1].

Major complications include PTX, hemopneumothorax, hemorrhage, hypotension, and reexpansion pulmonary edema. The reported incidence of PTX varies between 3% and 30% [1–3,6,7], with up to one-third to one-half of those with demonstrated PTX requiring subsequent intervention. Various investigators have reported associations between PTX and underlying lung disease (chronic obstructive pulmonary disease, prior thoracic radiation, prior thoracic surgery, or lung cancer) [8,9], needle size and technique [3,8], number of passes required to obtain a sample [8], aspiration of air during the procedure, experience level of the operator [1,3,6], use of a vacuum bottle [9], size of the effusion [2,8], and mechanical ventilation versus spontaneously breathing patients. Some of the above-mentioned studies report directly contradictory findings compared to other similar studies. This is most apparent in the reported association between PTX and therapeutic thoracentesis [3,8], which was not supported by subsequent large prospective trials [8,9]. The most likely explanation for this discrepancy in the literature concerning the presumed increased risk for PTX for therapeutic over diagnostic procedures is the generally lower experience level of the operator in the first group. Small sample sizes also limit the generalization of reported findings to allow for the delineation of a clear risk profile for the development of a PTX due to thoracentesis. The presence of

baseline lung disease, low experience level of the operator with the procedure, and the use of positive-pressure mechanical ventilation appear for now to be the best-established risk factors in the literature. Further research involving more patients is needed.

Although PTX is most commonly due to laceration of lung parenchyma, room air may enter the pleural space if the thoracentesis needle is open to room air when a spontaneously breathing patient takes a deep breath. (Intrapleural pressure is subatmospheric.) The PTX may be small and asymptomatic, resolving spontaneously, or large and associated with respiratory compromise, requiring chest tube drainage. Hemorrhage can occur from laceration of an intercostal artery or inadvertent puncture of the liver or spleen even if coagulation studies are normal. The risk of intercostal artery laceration is greatest in the elderly because of increased tortuosity of their vessels. This last complication is potentially lethal, and open thoracotomy may be required to control the bleeding.

Hypotension may occur during the procedure (as part of a vasovagal reaction or tension PTX) or hours after the procedure (most likely due to reaccumulation of fluid into the pleural space or the pulmonary parenchyma from the intravascular space). Hypotension in the latter settings responds to volume expansion; it can usually be prevented by limiting pleural fluid drainage to 1.5 L or less. Other major complications are rare, and include implantation of tumor along the needle tract of a previously performed thoracentesis, venous and cerebral air embolism (so-called pleural shock) [10,11], and inadvertent placement of a sheared-off catheter into the pleural space [1].

Minor complications include dry tap or insufficient fluid, pain, subcutaneous hematoma or seroma, anxiety, dyspnea, and cough [2]. Reported rates for these minor complications range from 16% to 63% and depend on the method used to perform the procedure, with higher rates associated with the catheter-through-needle technique [2,3]. Dry tap and insufficient fluid are technical problems, and they expose the patient to increased risk of morbidity because of the need to perform a repeat thoracentesis. Under these circumstances, it is recommended that the procedure be repeated under direct sonographic guidance. Pain may originate from parietal pleural nerve endings from inadequate local anesthesia, inadvertent scraping of rib periosteum, or piercing an intercostal nerve during a misdirected needle thrust.

PROCEDURES

General Considerations

The most common techniques for performing thoracentesis are catheter-over-needle, needle-only, and needle under direct sonographic guidance. The catheter-through-needle technique has been used much less frequently over the past decade.

Technique for Diagnostic (Needle-Only or Catheter-Over-Needle) Removal of Freely Flowing Fluid

The technique for diagnostic removal of freely flowing fluid is as follows:

1. Obtain a lateral decubitus chest radiograph to confirm a free-flowing pleural effusion.
2. Describe the procedure to the patient and obtain written informed consent. Operators should be thoroughly familiar with the procedure they will be performing and should receive appropriate supervision from an experienced operator before performing thoracentesis on their own.
3. With the patient sitting, arms at sides, mark the inferior tip of the scapula on the side to be tapped. This approximates the eighth intercostal space and should be the lowest interspace punctured, unless it has been previously determined by sonography that a lower interspace can be safely entered or chest radiographs and sonography show the diaphragm to be higher than the eighth intercostal space.
4. Position the patient sitting at the edge of the bed, comfortably leaning forward over a pillow-draped, height-adjusted, bedside table (Fig. 10.2). The patient's arms should be crossed in front to elevate and spread the scapulae. An assistant should stand in front of the patient to prevent any unexpected movements.
5. Percuss the patient's posterior chest to determine the highest point of the effusion. The interspace below this point should be entered in the posterior axillary line, unless it is below the eighth intercostal space. Gently mark the superior aspect of the rib in the chosen interspace with your fingernail. (The inferior portion of each rib contains an intercostal artery and should be avoided.)
6. Cleanse the area with 2% chlorhexidine in 70% isopropyl alcohol and allow it to dry. Using sterile technique, drape the area surrounding the puncture site.
7. Anesthetize the superficial skin with 2% lidocaine using a 25-gauge needle. Change to an 18- to 22-gauge, 2-in.-long needle and generously anesthetize the deeper soft tissues, aiming for the top of the rib. Always aspirate through the syringe as the needle is advanced and before instilling lidocaine to ensure that the needle is not in a vessel or the pleural space. Carefully aspirate through the syringe as the pleura is approached. (The rib is 1 to 2 cm thick.) Fluid enters the syringe on reaching the pleural space. The patient may experience discomfort as the needle penetrates the well-innervated parietal pleura. Be careful not to instill anesthetic into the pleural space; it is bactericidal for most organisms, including *Mycobacterium tuberculosis*. Place a gloved finger at the point on the needle where it exits the skin (to estimate the required depth of insertion) and remove the needle.
8. Attach a three-way stopcock to a 20-gauge, 1.5-in.-long needle and to a 50-mL syringe. The valve on the stopcock should be open to the needle to allow aspiration of fluid during needle insertion.
9. Insert the 20-gauge needle (or the catheter-over-needle apparatus) into the anesthetized tract with the bevel of the needle down and always aspirate through the syringe as the needle/catheter-over-needle apparatus is slowly advanced. When pleural fluid is obtained using the needle-only technique, stabilize the needle by attaching a clamp to the needle where it exits the skin to prevent further advancement of the needle into the pleural space. Once pleural fluid is obtained with the catheter-over-needle technique, direct the needle-catheter apparatus downward to ensure that the catheter descends to the most dependent area of the pleural space. Advance the catheter forward in a single smooth motion as the inner needle is simultaneously pulled back out of the chest.
10. Once pleural fluid can easily be obtained, fill a heparinized blood gas syringe from the side port of the three-way stopcock for measurement of fluid pH [12]. Express all air bubbles from the sample, cap it, and place it in a bag containing iced slush for immediate transport to the laboratory.
11. Fill the 50-mL syringe and transfer its contents into the appropriate collection tubes and containers [12]. Always maintain a closed system during the procedure to prevent room air from entering the pleural space. For most diagnostic studies, 50 to 100 mL should be ample fluid [13–15].

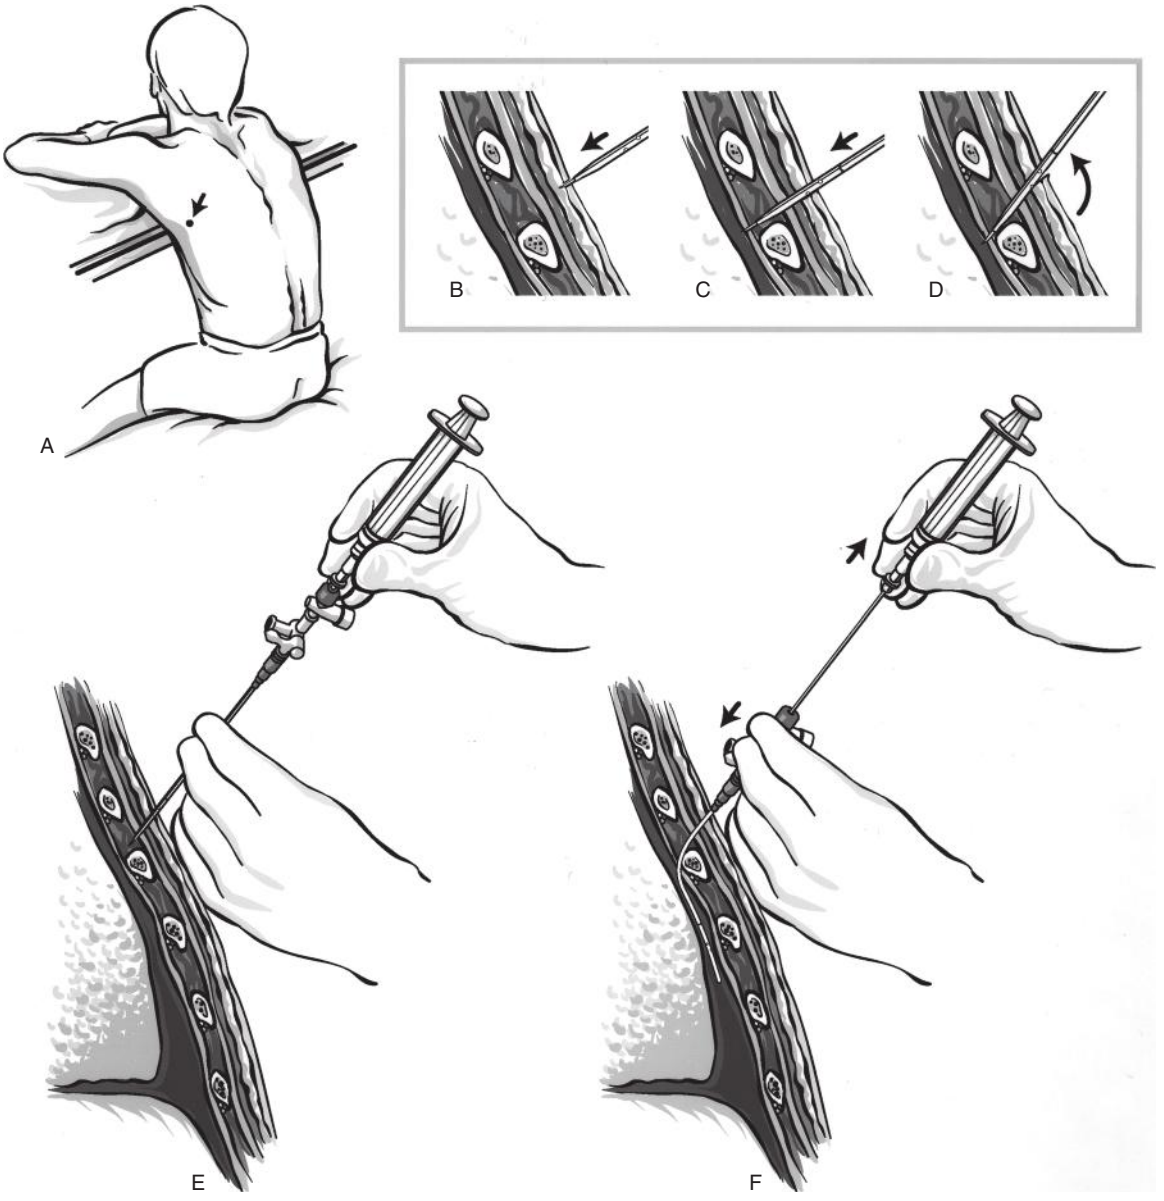

FIGURE 10.2. Catheter-over-needle technique for thoracentesis of freely flowing pleural field. **A:** The patient is comfortably positioned, sitting up and leaning forward over a pillow-draped, height-adjusted, bedside table. The arms are crossed in front of the patient to elevate and spread the scapulae. The preferred entry site is along the posterior axillary line. **B:** The catheter apparatus is gently advanced through the skin and across the upper surface of the rib. The needle is advanced several millimeters at a time while continuously aspirating through the syringe. **C:** As soon as the parietal pleura has been punctured, fluid will appear in the syringe. **D:** Before the catheter is advanced any farther, the apparatus is directed downward. **E, F:** In rapid sequence, the catheter is advanced fully to the chest wall and the needle withdrawn from the apparatus. The one-way valve in the apparatus maintains a closed system until the operator manually changes the position of the stopcock to allow drainage of the pleural fluid.

Always ensure that the three-way stopcock has the valve closed toward the patient when changing syringes.

12. When the thoracentesis is completed, remove the needle (or catheter) from the patient's chest as he or she hums or performs a Valsalva maneuver. Apply pressure to the wound for several minutes and then apply a sterile bandage.
13. A routine chest radiograph after thoracentesis is generally not indicated for most asymptomatic, nonventilated patients. Obtain a postprocedure upright end-expiratory chest radiograph if air was aspirated during the procedure, PTX is suspected by developing signs or symptoms, or multiple needle passes were required [16–19].

Technique for Therapeutic Removal of Freely Flowing Fluid

To perform the technique for therapeutic removal of freely flowing fluid, steps 1 to 7 should be followed as described

previously. Removal of more than 100 mL pleural fluid generally involves placement of a catheter into the pleural space to minimize the risk of PTX from a needle during this longer procedure. Commercially available kits generally use a catheter-over-needle system, although catheter-through-needle systems are still available in some locations. Each kit should have a specific set of instructions for performing this procedure. Operators should be thoroughly familiar with the recommended procedure for the catheter system that they will be using and should receive appropriate supervision from an experienced operator before performing thoracentesis on their own.

Technique for Thoracentesis by Directed Guidance

Ultrasound guidance has long been used to assist thoracentesis for loculated or small-volume pleural effusions. In recent years, dynamic (real-time) sonographic scanners have become more readily available, and coupled with brief physician training time, ultrasound-assisted thoracentesis is rapidly becoming standard of practice for free-flowing effusions as well [20–23]. The protocol is similar to that described for the needle-only technique, but the needle can be inserted under direct guidance after localization of the effusion. The use of a catheter is optional in this setting. Of important note is that mandatory use of ultrasound for choosing the thoracentesis site and/or for guiding the procedure, the rate of PTX in one study decreased from 8.6% to 1.1% [21].

Technique for Removal of Freely Moving Pneumothorax

The technique for removal of freely moving PTX is as follows:

1. Follow the same catheter-over-needle protocol described for removing freely moving fluid, but position the patient supine with the head of the bed elevated to 30 to 45 degrees.
2. Prepare the second or third intercostal space in the anterior midclavicular line (which avoids hitting the more medial internal mammary artery) for the needle and catheter insertion.
3. Have the bevel of the needle facing up and direct the needle upward so that the catheter can be guided toward the superior aspect of the hemithorax.
4. Air can be actively withdrawn by syringe or pushed out when intrapleural pressure is supra-atmospheric (e.g., during a cough) as long as the catheter is intermittently open to the atmosphere. In the latter setting, air can leave but not reenter if the catheter is attached to a one-way check-valve apparatus (Heimlich valve) or if it is put to underwater seal.
5. When local anesthesia and skin cleansing are not possible because a tension PTX is life threatening, perform the procedure without them. If a tension PTX is known or suspected to be present and a chest tube is not readily available, quickly insert a 14-gauge needle and 16-gauge catheter according to the above technique to avoid puncturing the lung. If a tension PTX is present, air escapes under pressure. When the situation has stabilized and the tension PTX has been diagnosed, leave the catheter in place until a sterile chest tube can be inserted.

INTERPRETATION OF PLEURAL FLUID ANALYSIS

To determine the etiology of a pleural effusion, a number of tests on pleural fluid are helpful. The initial determination should be to classify the effusion as a transudate or an exudate, using the criteria discussed later. Additional studies can then be ordered to help establish a final diagnosis for the etiology of the pleural effusion, especially in the setting of an exudate.

Transudates Versus Exudates

A transudate is biochemically defined by meeting all of the following classic (Light's) criteria [24]: pleural fluid–serum total protein ratio of less than 0.5, pleural fluid–serum lactate dehydrogenase (LDH) ratio of less than 0.6, and pleural fluid LDH of less than two-thirds the normal serum level. Transudates are generally caused by hydrostatic or oncotic pressure imbalances or from migration of fluid from peritoneal or retroperitoneal spaces to the pleural space. An exudate is present when any of the foregoing criteria for transudates is not met. Exudates arise through a variety of mechanisms that result primarily from inflammation of the lung or pleura, impaired lymphatic drainage, or migration of fluid from the peritoneal space.

A wide variety of alternative diagnostic criteria have been studied since Light's original work was published. Abbreviated criteria with similar diagnostic accuracy, but without the need for concurrent serum measurements, have been proposed [4,25]. Meta-analysis indicates that a classic transudate can be identified with equal accuracy by the combination of both pleural fluid cholesterol of less than 45 mg per dL and a pleural fluid LDH less than 0.45 times the upper limit of normal for serum LDH.

If a transudate is present, generally no further tests on pleural fluid are indicated (Table 10.1). One exception to this is the transudative pleural effusion due to urinothorax [26]. An acidotic transudate is characteristic of a urinothorax, and elevated pleural fluid creatinine confirms the diagnosis. If an exudate is identified, further laboratory evaluation is generally warranted (Fig. 10.1). If subsequent testing does not narrow the differential diagnosis and tuberculous pleuritis is a diagnostic consideration, a percutaneous pleural biopsy should be considered [27]. Thoracoscopy-guided pleural biopsy should be considered in patients with pleural effusion of unknown etiology despite the above-listed evaluation.

Selected Tests That Are Potentially Helpful to Establish Etiology for a Pleural Effusion

pH

Pleural fluid pH determinations may have diagnostic and therapeutic implications [28–30]. For instance, the differential diagnosis associated with a pleural fluid pH of less than 7.2 is consistent with systemic acidemia, bacterially infected effusion (empyema), malignant effusion, rheumatoid or lupus effusion, tuberculous effusion, ruptured esophagus, noninfected parapneumonic effusion that needs drainage, and urinothorax. Pleural effusions with a pH of less than 7.2 are potentially sclerotic and require consideration for chest tube drainage to aid resolution [31,32].

Amylase

A pleural fluid amylase level that is twice the normal serum level or with an absolute value of greater than 160 Somogyi units may be seen in patients with acute and chronic pancreatitis, pancreatic pseudocyst that has dissected or ruptured into the pleural space, primary and metastatic cancer, and esophageal rupture. Salivary isoenzymes predominate with malignancy and esophageal rupture, whereas intrinsic pancreatic disease is characterized by the presence of pancreatic isoenzymes.

TABLE 10.1

CAUSES OF PLEURAL EFFUSIONS

ETIOLOGIES OF EFFUSIONS THAT ARE VIRTUALLY ALWAYS TRANSUDATES

Congestive heart failure
Nephrotic syndrome
Hypoalbuminemia
Urinothorax
Trapped lung
Cirrhosis
Atelectasis
Peritoneal dialysis
Constrictive pericarditis
Superior vena caval obstruction

ETIOLOGIES OF EFFUSIONS THAT ARE TYPICALLY EXUDATES

Infections
Parapneumonic
Tuberculous pleurisy
Parasites (amebiasis, paragonimiasis, and echinococcosis)
Fungal disease
Atypical pneumonias (virus, *Mycoplasma*, Q fever, and *Legionella*)
Nocardia and *Actinomyces*
Subphrenic abscess
Hepatic abscess
Splenic abscess
Hepatitis
Spontaneous esophageal rupture

Noninfectious Inflammations
Pancreatitis
Benign asbestos pleural effusion
Pulmonary embolism[a]
Radiation therapy
Uremic pleurisy
Sarcoidosis
Postcardiac injury syndrome
Hemothorax
Acute respiratory distress syndrome

Malignancies[b]
Carcinoma
Lymphoma
Mesothelioma
Leukemia
Chylothorax

Chronically Increased Negative Intrapleural Pressure
Atelectasis
Trapped lung
Cholesterol effusion

Iatrogenic
Drug-induced (nitrofurantoin and methotrexate)
Esophageal perforation
Esophageal sclerotherapy
Central venous catheter misplacement or migration
Enteral feeding tube in space

Connective Tissue Disease
Lupus pleuritis
Rheumatoid pleurisy
Mixed connective tissue disease
Churg–Strauss syndrome
Wegener's granulomatosis
Familial Mediterranean fever

Endocrine Disorders
Hypothyroidism[c]
Ovarian hyperstimulation syndrome

Lymphatic Disorders
Malignancy
Yellow nail syndrome
Lymphangioleiomyomatosis

Movement of Fluid from Abdomen to Pleural Space
Pancreatitis
Pancreatic pseudocyst
Meigs' syndrome
Carcinoma
Chylous ascites

[a] 10% to 20% may be transudates.
[b] More than 20% are transudates.
[c] Occasional transudates.
Adapted from Sahn SA: The pleura. *Am Rev Respir Dis* 138:184, 1988.

Glucose

A low pleural fluid glucose value is defined as less than 50% of the normal serum value. In this situation, the differential diagnosis includes rheumatoid and lupus effusion, bacterial empyema, malignancy, tuberculosis, and esophageal rupture [32].

Triglyceride and Cholesterol

Chylous pleural effusions are biochemically defined by a triglyceride level greater than 110 mg per dL and the presence of chylomicrons on a pleural fluid lipoprotein electrophoresis [32]. The usual appearance of a chylous effusion is milky, but an effusion with elevated triglycerides may also appear serous. The measurement of a triglyceride level is therefore important. Chylous effusions occur when the thoracic duct has been disrupted somewhere along its course. The most common causes are trauma and malignancy (e.g., lymphoma). A pseudochylous effusion appears grossly milky because of an elevated cholesterol level, but the triglyceride level is normal. Chronic effusions, especially those associated with rheumatoid and tuberculous pleuritis, are characteristically pseudochylous.

Cell Counts and Differential

Although pleural fluid white blood cell count and differential are never diagnostic of any disease, it would be distinctly unusual for an effusion other than one associated with bacterial pneumonia to have a white blood cell count exceeding 50,000 per μL. In an exudative pleural effusion of acute origin, polymorphonuclear leukocytes predominate early, whereas mononuclear cells predominate in chronic exudative effusions. Although pleural fluid lymphocytosis is nonspecific, severe lymphocytosis (>80% of cells) is suggestive of tuberculosis or malignancy. Finally, pleural fluid eosinophilia is nonspecific and most commonly associated with either blood or air in the pleural space.

A red blood cell count of 5,000 to 10,000 cells per μL must be present for fluid to appear pinkish. Grossly bloody

effusions containing more than 100,000 red blood cells per mm^3 are most consistent with trauma, malignancy, or pulmonary infarction. To distinguish a traumatic thoracentesis from a preexisting hemothorax, several observations are helpful. First, because a preexisting hemothorax has been defibrinated, it does not form a clot on standing. Second, a hemothorax is suggested when a pleural fluid hematocrit value is 30% or more of the serum hematocrit value.

Cultures and Stains

To maximize the yield from pleural fluid cultures, anaerobic and aerobic cultures should be obtained. Because acid-fast stains may be positive in up to 20% of tuberculous effusions, they should always be performed in addition to Gram-stained smears. By submitting pleural biopsy pieces to pathology and microbiology laboratories, it is possible to diagnose up to 90% of tuberculous effusions percutaneously [24].

Cytology

Malignancies can produce pleural effusions by implantation of malignant cells on the pleura or impairment of lymphatic drainage secondary to tumor obstruction. The tumors that most commonly cause pleural effusions are lung, breast, and lymphoma. Pleural fluid cytology should be performed for an exudative effusion of unknown etiology, using at least 60 to 150 mL fluid [13,14,33]. If initial cytology results are negative and strong clinical suspicion exists, additional samples of fluid can increase the chance of a positive result to approximately 60% to 70%. The addition of a pleural biopsy increases the yield to approximately 80%. In addition to malignancy, cytologic examination can definitively diagnose rheumatoid pleuritis, whose pathognomonic picture consists of slender, elongated macrophages and giant, round, multinucleated macrophages, accompanied by amorphous granular background material.

CHAPTER 11 ■ ARTERIAL PUNCTURE FOR BLOOD GAS ANALYSIS

KIMBERLY A. ROBINSON AND RICHARD S. IRWIN

Analysis of a sample of arterial blood for pH_a, partial arterial carbon dioxide pressure ($PaCO_2$), partial arterial oxygen pressure (PaO_2), bicarbonate, and percentage oxyhemoglobin saturation is performed with an arterial blood gas (ABG) analysis. Because an ABG can be safely and easily obtained and furnishes rapid and accurate information on how well the lungs and kidneys are working, it is the single most useful laboratory test in managing patients with respiratory and metabolic disorders. One should not rely on oximetry alone to evaluate arterial oxygen saturation (SaO_2) fully. Given the shape of the oxyhemoglobin saturation curve, there must be a substantial fall in PaO_2 before SaO_2 is altered to any appreciable degree, and it is not possible to predict the level of PaO_2 and $PaCO_2$ reliably using physical signs such as cyanosis [1] and depth of breathing [2]. In addition, a discrepancy between SaO_2 measured by pulse oximetry and that calculated by the ABG can aid in the diagnosis of carboxyhemoglobinemia and methemoglobinemia.

Unsuspected hypoxemia or hypercapnia (acidemia) can cause a constellation of central nervous system and cardiovascular signs and symptoms. The clinician should have a high index of suspicion that a respiratory or metabolic disorder, or both, is present in patients with these findings and is most appropriately evaluated by obtaining an ABG. Although acute hypercapnia to 70 mm Hg (pH 7.16) and hypoxemia to less than 30 mm Hg may lead to coma and circulatory collapse, chronic exposures permit adaptation with more subtle effects [3]. Thus, the ABG provides the most important way of making a diagnostic assessment regarding the nature and severity of a respiratory or metabolic disturbance and of following its course over time.

Normal range of values for pH_a is 7.35 to 7.45 and for $PaCO_2$, 35 to 45 mm Hg [4]. For PaO_2, the accepted predictive regression equation in nonsmoking, upright, normal individuals aged 40 to 74 years is as follows [5]: $PaO_2 = 108.75 - (0.39 \times \text{age in years})$.

DRAWING THE ARTERIAL BLOOD GAS SPECIMEN

Percutaneous Arterial Puncture

The conventional technique of sampling arterial blood using a glass syringe is described in detail, because it is the standard to which all other methods are compared. The pulsatile arterial vessel is easily palpated in most cases. If a large enough needle is used, entry is apparent as the syringe fills spontaneously by the pressurized arterial flow of blood, without the need for applying a vacuum or using a vacuum-sealed collecting tube. It is logical to preferentially enter arteries that have the best collateral circulation so that if spasm or clotting occurs, the distal tissue is not deprived of perfusion. Logic also dictates that puncture of a site where the artery is superficial is preferable, because entry is easiest and pain is minimized. The radial artery best fulfills the criteria discussed earlier in the chapter; it is very superficial at the wrist, and the collateral circulation to the hand by the ulnar artery provides sufficient collateral blood flow in approximately 92% of normal adults in the event of total occlusion of the radial artery [6].

The absence of a report of total occlusion of the radial artery after puncture for ABG in an adult with normal hemostasis and the absence of significant peripheral vascular disease attest to the safety of the percutaneous arterial puncture. It also suggests that determining the adequacy of collateral flow to the superficial palmar arch by Allen's test [7], a modification of Allen's test [8] (see Chapter 3), or Doppler ultrasound [6] before puncture is not routinely necessary in patients with normal hemostasis and the absence of significant peripheral vascular disease. If radial artery sites are not accessible, dorsalis pedis, posterior tibial, superficial temporal (in infants), brachial, and femoral arteries are alternatives (see Chapter 3).

Contraindications

Brachial and especially femoral artery punctures are not advised in patients with abnormal hemostatic mechanisms because adequate vessel tamponade may not be possible in that these vessels are not located superficially, risking greater chance of complications [9]. If frequent sampling of superficial arteries in the same situation becomes necessary, arterial cannulation is recommended (see Chapter 3). Moreover, any vessel that has been reconstructed surgically should not be punctured for fear of forming a pseudoaneurysm, compromising the integrity of an artificial graft site or seeding the foreign body that could become a nidus for infection. This should also include avoidance of a femoral arterial puncture on the same side as a transplanted kidney.

The conventional recommended radial artery technique is as follows:

1. Put on protective gloves and sit in a comfortable position facing the patient.
2. With the patient's hand supinated and the wrist slightly hyperextended, palpate the radial artery. Severe hyperextension may obliterate the pulse.
3. Cleanse the skin with an alcohol swab.
4. With a 25-gauge needle, inject enough 1% lidocaine intradermally to raise a small wheal at the point where the skin puncture is to be made. The local anesthetic makes subsequent needle puncture with a 22-gauge needle less painful and often painless [10]. If local anesthesia is not given, however, the potential pain and anxiety, if associated with breath holding, may cause substantial blood gas changes. Thirty-five seconds of breath holding in normal subjects has been associated with a fall in PaO_2 of 50 mm Hg and a pH of 0.07 and a rise in $PaCO_2$ of 10 mm Hg [11].

5. Attach a needle no smaller than 22 gauge to a glass syringe that can accept 5 mL blood.
6. Wet the needle and syringe with a sodium heparin solution (1,000 units per mL). Express all excess solution.
7. With the needle, enter the artery at an angle of approximately 30 degrees to the long axis of the vessel. This insertion angle minimizes the pain associated with unintentional contact with the periosteum below the artery.
8. As soon as the artery is entered, blood appears in the syringe. Allow the arterial pressure to fill the syringe with at least 3 mL of blood. Do not apply suction by pulling on the syringe plunger.
9. Immediately after obtaining the specimen, expel any tiny air bubbles to ensure that the specimen will be anaerobic and then cap the syringe.
10. Roll the blood sample between both palms for 5 to 15 seconds to mix the heparin and blood. Apply pressure to the puncture site for 5 minutes or longer, depending on the presence of a coagulopathy. If the arterial sample was obtained from the brachial artery, compress this vessel so that the radial pulse cannot be palpated.
11. Immerse the capped sample in a bag of ice and water (slush) and immediately transport it to the blood gas laboratory.
12. Write on the ABG slip the time of drawing and the conditions under which it was drawn (e.g., fraction of inspired oxygen, ventilator settings, and the patient's position and temperature).

Deviations from these recommended techniques may introduce the following errors:

1. The syringe material may influence the results of PaO_2 [12–14]. The most accurate results have been consistently obtained using a glass syringe. If plastic is used, the following errors may occur: (a) falsely low PaO_2 values may be obtained because plastic allows oxygen to diffuse to the atmosphere from the sample whenever the PO_2 exceeds 221 mm Hg; (b) plastic syringes with high surface area to volume ratios (e.g., 1-mL tuberculin syringes) worsen gas permeability errors as compared to standard 3-mL syringes. For this reason, butterfly infusion kits with their long, thin tubing should not be used [15]; (c) plastic syringes tenaciously retain air bubbles, and extra effort is necessary to remove them [13]; (d) plastic impedes smooth movement of the plunger that can have an impact on the clinician's confidence that arterial rather than venous blood has been sampled.
2. If suction is applied for plunger assistance, gas bubbles may be pulled out of the solution. If they are expelled, measured PaO_2 and $PaCO_2$ tensions may be falsely lowered [16].
3. Although liquid heparin is a weak acid, plasma pH is not altered because it is well buffered by hemoglobin. Mixing liquid heparin with blood dilutes dissolved gasses, shifting their concentration to that of heparin (PO_2 approximately 150 mm Hg and PCO_2 less than 0.3 mm Hg at sea level and room temperature). The degree of alteration depends on the amount of heparin relative to blood and the hemoglobin concentration [16–19]. The dilutional error is no greater than 4% if a glass syringe and 22-gauge needle are only wetted with approximately 0.2 mL heparin and 3 to 5 mL blood collected. Any less heparin risks a clotted and unusable sample. Dilutional errors are avoided with the use of crystalline heparin, but this preparation is difficult to mix and increases the risk of clotting the specimen.
4. If an ABG specimen is not analyzed within 1 minute of being drawn or not immediately cooled to 2°C, the PO_2 and pH fall and PCO_2 rises because of cellular respiration and consumption of oxygen by leukocytes, platelets, and reticulocytes [20]. This is of particular concern in patients with leukemia (leukocytes greater than 40×10^9 per L) or thrombocytosis ($1{,}000 \times 10^9$ per L) [21].
5. Unintentional sampling of a vein normally causes a falsely low PaO_2. A venous PO_2 greater than 50 mm Hg can be obtained if the sampling area is warmed. The PO_2 of "arterialized" venous blood can approximate PaO_2 when blood flow is greatly increased by warming, compromising the time for peripheral oxygen extraction.

Complications

Using the conventional radial artery technique described earlier in the chapter, complications are unusual. They include a rare vasovagal episode, local pain, and limited hematomas. An expanding aneurysm of the radial artery and reflex sympathetic dystrophy [22] have been reported even more rarely after frequent punctures [23].

MEASUREMENTS FROM THE ARTERIAL BLOOD GAS SPECIMEN

Although pH, PCO_2, PO_2, bicarbonate, and SaO_2 are all usually reported, it is important to understand that the bicarbonate and SaO_2 are calculated, not directly measured. Although the calculated bicarbonate value is as reliable as the measured pH and PCO_2 values, given their immutable relationship through the Henderson–Hasselbalch equation, the calculated SaO_2 is often inaccurate because of the many variables that cannot be corrected (e.g., 2,3-diphosphoglycerate and binding characteristics of hemoglobin).

The patient in the intensive care unit often requires serial ABG measurements to follow the progression of critical illness and guide therapy. Although it is understandable to interpret fluctuations in the ABG data as a sign of the patient's condition worsening or improving, depending on the trend, it is also important to appreciate that modest fluctuations may be due to deviations in the collection of the ABG specimen. Therefore, routine monitoring of ABGs without an associated change in patient status may not be warranted and may lead to an unproductive, lengthy, and expensive search for the cause.

When electrolytes and other blood values are measured from the unused portion of an ABG sample, clinicians should be aware of the following: Traditional liquid and crystalline heparins for ABG sampling are sodium-heparin salts that artificially increase plasma sodium concentrations. Calcium and potassium bind to the negatively charged heparins, spuriously lowering their values. Lithium or electrolyte-balanced heparin is now available that contains physiologic concentrations of sodium and potassium that should be used whenever sodium, potassium, ionized magnesium, ionized calcium, chloride, glucose, and lactate are measured in an ABG specimen [24–26]. Although lithium or electrolyte-balanced heparin minimizes the errors in electrolyte concentrations, dilutional error may still exist if excessive amounts are used for anticoagulation.

By convention, ABG specimens are analyzed at 37°C. Although no studies have demonstrated that correction for the patient's temperature is clinically necessary, blood gases drawn at temperatures greater than 39°C should probably be corrected for temperature [27]. Because the solubility of oxygen and carbon dioxide increases as blood is cooled to 37°C, the hyperthermic patient is more acidotic and less hypoxemic than uncorrected values indicate. Therefore, for each 1°C that the patient's temperature is greater than 37°C, PaO_2 should be increased 7.2%, $PaCO_2$ increased 4.4%, and pH decreased 0.015. Temperature correction for pH and $PaCO_2$ in the hypothermic patient is controversial. Although correction back to the patient's temperature may result in better preservation of cerebral blood flow, intracranial pressure can be adversely affected in selected

populations. The reader is referred elsewhere for more information [28]. However, PaO_2 values must be corrected for temperature lest significant hypoxemia be overlooked. The PaO_2 at 37°C is decreased by 7.2% for each degree that the patient's temperature is less than 37°C.

It should also be noted that transport of an ABG specimen to the laboratory via a pneumatic tube system can result in alterations in PaO_2 secondary to contamination with room air. This effect is presumed to be due to pressure changes within the pneumatic tube system because the use of pressure-tight transport containers obliterates the effect [29]. If a pneumatic tube system is to be used, one must be sure that all air bubbles are carefully expelled from the ABG specimen and that a pressure-tight transport container is used. Otherwise, it may be best to hand-carry samples to the laboratory [29–31].

PHYSICIAN RESPONSIBILITY

Even when the ABG values of pH, PCO_2, PO_2, and bicarbonate appear consistently reliable, the clinician should periodically check the accuracy of the blood gas samples because the bicarbonate is calculated, not directly measured. Aliquots of arterial blood can be sent simultaneously for ABG analysis and to the chemistry laboratory for a total (T) CO_2 content. Accuracy of the blood gas laboratory's values can be checked using Henderson's simple mathematical equation that is a rearrangement of the Henderson–Hasselbalch equation: $[H^+] = 25 \times PaCO_2/HCO_3^-$. $[H^+]$ is solved by using the pH measured in the blood gas laboratory (Table 11.1). Measured arterial TCO_2 should be close to the calculated bicarbonate value. Venous TCO_2 should not be used in this exercise because it is often and normally up to 5 mEq per L greater than arterial TCO_2.

ALTERNATIVES

Many situations may arise whereby arterial blood samples are not available. For example, severe peripheral vascular disease makes radial arterial puncture difficult, or the patient refuses arterial blood sampling or cannulation. In general, in the absence of circulatory failure or limb ischemia, central and peripheral venous blood may substitute for arterial when monitoring acid–base and ventilatory status. In hemodynamically stable patients, pH_a is, on average, 0.03 units higher than central venous pH (pH_{cv}) and $PaCO_2$ is lower than central venous carbon dioxide ($P_{cv}CO_2$) by 5 mm Hg [32], and changes in each are tightly correlated [33]. Regression analysis reveals $pH_a = (1.027 \times pH_{cv}) - 0.156$ and $PaCO_2 = (0.754 \times P_{cv}CO_2) + 2.75$. In shock, the accentuated discrepancy may be due to increased carbon dioxide generated by the buffering of acids in conditions characterized by increased lactic acid production.

It must be made clear that in the absence of warming a sampling area to collect "arterialized" venous blood, an arterial sample is still necessary for evaluation of accurate oxygenation status for precise measurements of PO_2 and alveolar–arterial oxygen gradient determination. Once the oxygenation and acid–base status have been identified, pulse oximetry can be used to follow trends in SaO_2 in stable or improving patients because serial ABGs are costly and risk vessel injury with repeated arterial punctures.

Some progress has been made in the area of noninvasive measurement of gas exchange. This includes oximetry, transcutaneous PO_2 and PCO_2 ($P_{tc}CO_2$) measurement, end-tidal CO_2, and indwelling intravascular electrode systems. Measurement of end-tidal CO_2 requires a closed system of gas collection (i.e., ventilator circuit or noninvasive mask ventilation) that is not always possible. Thus, there has been increased focus on transcutaneous measurement of carbon dioxide tension. These systems require localized heating of the skin by a heating element to increase local perfusion. Studies have suggested improvement in the ability of transcutaneous systems to accurately assess SpO_2 and $P_{tc}CO_2$ in critically ill patients as long as the $PaCO_2$ is less than 56 mm Hg [34,35].

TABLE 11.1

RELATION BETWEEN $[H^+]$ AND PH OVER A NORMAL RANGE OF PH VALUES[a]

pH	$[H^+]$ (nM/L)
7.36	44
7.37	43
7.38	42
7.39	41
7.40	40
—	—
7.41	39
7.42	38
7.43	37
7.44	36

[a]Note that pH 7.40 corresponds to hydrogen ion concentration of 40 nM/L and that, over the small range shown, each deviation in pH of 0.01 units corresponds to opposite deviation in $[H^+]$ of 1 nM/L. For pH values between 7.28 and 7.45, $[H^+]$ calculated empirically in this fashion agrees with the actual value obtained by means of logarithms to the nearest nM/L (nearest 0.01 pH unit). However, in the extremes of pH values, less than pH 7.28 and greater than pH 7.45, the estimated $[H^+]$ is always lower than the actual value, with the discrepancy reaching 11% at pH 7.10 and 5% at pH 7.50. Modified from Kassirer J, Bleich H: Rapid estimation of plasma carbon dioxide tension from pH and total carbon dioxide content. *N Engl J Med* 171:1067, 1965.

POINT-OF-CARE TESTING

Blood gas analysis is now routinely performed at the bedside with point-of-care testing (POCT) devices. Advantages of POCT include convenience and rapid turnaround time, theoretically improving the quality of patient care. With regard to pH, PO_2, and PCO_2, several studies have verified a high correlation between POCT results and conventional analysis methods [36,37].

CHAPTER 12 ■ TRACHEOSTOMY

SCOTT E. KOPEC AND TIMOTHY A. EMHOFF

Although reports of performing tracheostomy date back to the first century BC [1], it was not performed regularly until the 1800s when used by Trousseau and Bretonneau in the management of diphtheria. In the early 1900s, this procedure was used to treat difficult cases of respiratory paralysis from poliomyelitis. Largely because of improvements in tubes and advances in clinical care, endotracheal intubation has become the treatment of choice for short-term airway management.

Although tracheostomy is occasionally required in critically ill and injured patients who cannot be intubated for various reasons (e.g., cervical spine injury, upper airway obstruction, laryngeal injury, and anatomic considerations), the most common use of this procedure today is to provide long-term access to the airway in patients who are dependent on mechanical ventilation. With improvements in critical care medicine over the past 30 years, more patients are surviving the initial episodes of acute respiratory failure, trauma, and extensive surgeries and are requiring prolonged periods of mechanical ventilation. It is now common practice to expeditiously convert these patients from translaryngeal intubation to tracheostomy. Tracheostomy is becoming a very common procedure in the intensive care unit (ICU). The prevalence of tracheostomies in ICU patients ranges from 8% to more than 30% [2,3].

In this chapter we review the indications, contraindications, complications, and techniques associated with tracheostomy. We also discuss the timing of converting an orally intubated patient to tracheostomy.

INDICATIONS

The indications for tracheostomy can be divided into three general categories: (i) to bypass obstruction of the upper airway, (ii) to provide an avenue for tracheal toilet and removal of retained secretions, and (iii) to provide a means for ventilatory support. These indications are summarized in Table 12.1 [4–10].

Anticipated prolonged ventilatory support, especially patients receiving mechanical ventilation via translaryngeal intubation, is the most common indication for placing a tracheostomy in the ICU. There are several advantages and disadvantages of both translaryngeal intubation and tracheostomy in patients requiring prolonged ventilator support,

TABLE 12.1

INDICATIONS FOR TRACHEOSTOMY [4–10]

Upper airway obstruction
Laryngeal dysfunction: Vocal cord paralysis
Trauma: Upper airway obstruction due to hemorrhage, edema, or crush injury; unstable mandibular fractures; injury to the larynx; cervical spine injuries
Burns and corrosives: Hot smoke, caustic gases, corrosives
Foreign bodies
Congenital anomalies: Stenosis of the glottic or subglottic area
Infections: Croup, epiglottitis, Ludwig's angina, deep neck space infections
Neoplasms: Laryngeal cancer
Postoperative: Surgeries of the base of the tongue and hypopharynx; rigid fixation of the mandibular
Obstructive sleep apnea
Tracheal toilet
Inability to clear secretions: Generalized weakness, altered mental status, excess secretions
Neuromuscular disease
Ventilatory support: Prolonged or chronic

and these are summarized in Table 12.2 [11–13]. Most authors feel that when the procedure is performed by a skilled surgical group, the potential benefits of tracheostomy over translaryngeal intubation for most patients justify the application despite its potential risks. However, there are no detailed clinical trials consistently confirming the advantages of tracheostomy in patients requiring prolonged mechanical ventilation. In a retrospective and a nonrandomized study, there were conflicting data regarding mortality in patients with respiratory failure of more than 1 week with regard to receiving a tracheostomy or continuing with an endotracheal tube [2,3].

CONTRAINDICATIONS

There are no absolute contraindications to tracheostomy. Relative complications include uncorrected coagulopathy, high levels of ventilator support (i.e., high levels of positive

TABLE 12.2

ADVANTAGES AND DISADVANTAGES OF INTUBATION AND TRACHEOSTOMY [11–13]

Translaryngeal intubation	
Advantages	**Disadvantages**
Reliable airway during urgent intubation	Bacterial airway colonization
Avoidance of surgical complications	Inadvertent extubation
Lower initial cost	Laryngeal injury
	Tracheal stenosis
	Purulent sinusitis (nasotracheal intubations)
	Patient discomfort
Tracheostomies	
Advantages	**Disadvantages**
Avoids direct injury to the larynx	Complications (see Table 12.3)
Facilitates nursing care	Bacterial airway colonization
Enhances patient mobility	Cost
More secure airway	Surgical scar
Improved patient comfort	Tracheal and stomal stenosis
Permits speech	
Provides psychologic benefit	
More rapid weaning from mechanical ventilation	
Better oral hygiene	
Decreased risk of nosocomial pneumonia	

end-expiratory pressure [PEEP]), and abnormal anatomy of the upper airway. However, a prospective cohort study has demonstrated that percutaneous tracheostomy can be safely preformed in patients with refractory coagulopathy from liver disease [14]. Morbidly obese patients with body mass index greater than 30 kg per m^2 also appear to be at higher risk for complications with both open tracheostomy [15] and percutaneous tracheostomy [16]. In patients with severe brain injury, percutaneous tracheostomy can be safely performed without significantly further increasing intracranial pressure [17].

Certain conditions warrant special attention before anesthesia and surgery. In patients undergoing conversion from translaryngeal intubation to a tracheostomy for prolonged ventilatory support, the procedure should be viewed as an elective or semielective procedure. Therefore, the patient should be as medically stable as possible, and all attempts should be made to correct the existing coagulopathies, including uremia. Ventilator settings should be reduced to where tube exchange during the tracheostomy is safe because during the exchange positive pressure is temporarily lost for some period of time. If not already on 5 cm H_2O of PEEP, placing the patient supine and using 5 or 7.5 cm H_2O of PEEP temporarily is a good test to decide if the patient will tolerate the exchange. For obvious reasons, emergent tracheostomies for upper airway obstruction may need to be preformed when the patient is unstable or has a coagulopathy.

TIMING OF TRACHEOSTOMY

When to perform a tracheostomy on an intubated, critically ill patient has continued to remain very controversial. Older recommendations range from performing a tracheostomy after just 3 days of translaryngeal intubation due to the risk of mucosal damage to the larynx and vocal cords [18] to more than 21 days on the basis of reported high complication rates of open tracheostomies [19]. In 2003, Heffner recommended a more up-to-date approach regarding the timing of converting an intubated patient to a tracheostomy [11]. This recommendation takes into account the very low mortality and morbidity associated with placing a tracheostomy, plus the advantages and disadvantages of both translaryngeal intubation and tracheostomy. In summary, if a patient remains ventilator dependent after a week of translaryngeal intubation, a tracheostomy can be considered. Whether to perform the procedure or not should depend on the anticipated duration of ventilatory support and the benefits of a tracheostomy in that specific patient. If the patient appears to have minimal barriers to weaning and appears likely to be successfully weaned and extubated within 7 days, tracheostomy should be avoided. In those patients whom it appears unlikely that they will successfully be weaned and extubated in 7 days, tracheostomy should be strongly considered. For those patients whose ability to wean and be extubated is unclear, the patient's status should be readdressed daily [11].

Over the past several years there has been momentum to perform a tracheostomy early, that is, after 1 week of mechanical ventilation. Fueling this was a meta-analysis [20], which suggested advantages to "early tracheostomy," performed within 7 days of translaryngeal intubation over a "late tracheostomy" (>7 days) in critically ill patients requiring mechanical ventilation. The meta-analysis combined five prospective studies and included 406 patients and suggested that early tracheostomy resulted in a decrease in length of ICU stay by an average of 15.3 days and a decrease in duration of mechanical ventilation by an average of 8.5 days [20]. Potential reasons for the decrease in duration of mechanical ventilation include easier weaning due to less dead space, less resistance, and less obstruction due to mucus plugging in patients with tracheostomies. There was no significant increase in hospital mortality or risk of hospital-acquired pneumonia. However, there are obvious limitations to the meta-analysis. Since this meta-analysis, several other studies have revealed conflicting data. Table 12.3 summarizes several studies comparing early versus late tracheostomy [20–28]. In summary, it remains unclear if early tracheostomy has any impact on mortality, length of ICU stay, days on mechanical ventilation, or ventilatory-associated pneumonia. Until more definitive data are available, Heffner's 2003 recommendations [11] appear to make the most sense for most medical and surgical patients on prolonged mechanical ventilation.

TABLE 12.3

STUDIES EVALUATING EARLY (≤7 DAYS) VERSUS LATE (>7 DAYS) TRACHEOSTOMY

Study	No. of patients	Study type	Patient type	Results
Rodriquez et al., 1990	106	Prospective Randomized	Surg	Decreased ICU LOS and MV days with early tracheostomy
Sugarman et al., 1997	127	Prospective Randomized	Surg, Trauma	No difference in mortality, VAP rate, or ICU LOS
Brook et al., 2000	90	Prospective Observational	Med, Surg	Decreased MV days and hospital costs
Rumbak et al., 2004	120	Prospective	Med	Decreased mortality, VAP 2004 rate, ICU LOS, and MV days with early trach
Griffiths et al., 2005		Meta-analysis	Med, Surg	Decreased MV days and ICU LOS with early trach, no difference in mortality or VAP rate
Scales et al., 2008	10,927	Retrospective Cohort	Med, Surg	Decreased mortality, MV days, ICU LOS with early trach
Blot et al., 2008	123	Prospective Randomized	Med, Surg	No difference in mortality, VAP rate, or ICU LOS
Durbin et al., 2010	641	Meta-analysis	Med, Surg	No difference in mortality, VAP rate, or MV days
Terragni et al., 2010	419	Prospective Randomized	Med, Surg	No difference in VAP rate ICU LOS or mortality, but decreased MV days

LOS, length of stay; Med, medicine patients; MV, mechanical ventilation; Surg, surgery patients; VAP, ventilator-associated pneumonia.

Early tracheostomy may be beneficial in some specific instances. Patients with blunt, multiple-organ trauma have a shorter duration of mechanical ventilation, fewer episodes of nosocomial pneumonia [29], and a significant reduction in hospital costs [30] when the tracheostomy is performed within 1 week of their injuries. Similar benefits have been reported in patients with head trauma and poor Glasgow Coma Score [31–33], acute spine trauma [34,35], and thermal injury [36] if a tracheostomy is performed within a week after the injury. Also, patients with facial injuries may require early tracheostomy to allow or facilitate facial fracture surgery, fixation, and immobilization.

PROCEDURES

Emergency Tracheostomy

Emergency tracheostomy is a moderately difficult procedure requiring training and skill, experience, adequate assistance, time, lighting, and proper equipment and instrumentation. When time is short, the patient is uncooperative, anatomy is distorted, and the aforementioned requirements are not met, tracheostomy can be very hazardous. Emergency tracheostomy comprises significant risks to nearby neurovascular structures, particularly in small children in whom the trachea is small and not well defined. The risk of complications from emergency tracheostomy is two to five times higher than for elective tracheostomy [37,38]. Nonetheless, there are occasional indications for emergency tracheostomy [39], including transected trachea, anterior neck trauma with crushed larynx [40], severe facial trauma, acute laryngeal obstruction or near-impending obstruction, and pediatric (younger than 12 years) patients requiring an emergency surgical airway in whom an cricothyrotomy is generally not advised. In emergency situations when there is inadequate time or personnel to perform an emergency tracheostomy, a cricothyrotomy may be a more efficient and expedient manner to provide an airway.

Cricothyrotomy

Cricothyrotomy (cricothyroidotomy) was condemned in Jackson's [41] 1921 article on high tracheostomies because of excessive complications, particularly subglottic stenoses [42]. He emphasized the importance of the cricoid cartilage as an encircling support for the larynx and trachea. However, a favorable report of 655 cricothyrotomies, with complication rates of only 6.1% and no cases of subglottic stenoses [43], prompted reevaluation of cricothyrotomy for elective and emergency airway access. Further reports emphasized the advantages of cricothyrotomy over tracheostomy. These include technical simplicity, speed of performance, low complication rate [43–47], suitability as a bedside procedure, usefulness for isolation of the airway for median sternotomy [46,48], radical neck dissection [49], lack of need to hyperextend the neck, and formation of a smaller scar. Also, because cricothyrotomy results in less encroachment on the mediastinum, there is less chance of esophageal injury and virtually no chance of pneumothorax or tracheal arterial fistula [47]. Despite these considerations, many authorities currently recommend that cricothyrotomy should be used as an elective long-term method of airway access only in highly selective patients [41,43,49–51]. Use of cricothyrotomy in the emergency setting, particularly for managing trauma, is not controversial [52–54]. Emergency cricothyrotomy is useful because it requires a small number of instruments and less training than tracheostomy and can be performed quickly as indicated as a means of controlling the airway in an emergency when oral or nasotracheal intubation is nonsuccessful or contraindicated. The cricothyroid membrane is higher in the neck than the tracheal rings and therefore closer to the surface and more accessible. In emergency situations, translaryngeal intubations fail because of massive oral or nasal hemorrhage or regurgitation, structural deformities of the upper airway, muscle spasm and clenched teeth, and obstruction by foreign body through the upper airway [52]. Cricothyrotomy finds its greatest use in trauma management, axial or suspected cervical spine injury, alone or in combination with severe facial trauma, where nasotracheal and orotracheal intubation is both difficult and hazardous. Thus cricothyrotomy has an important role in emergency airway management [53].

Use and Contraindications

Cricothyrotomy should not be used to manage airway obstruction that occurred immediately after endotracheal extubation because the obstruction may be found below the larynx [41,43,53]; likewise, with primary laryngeal trauma or diseases such as tumor or an infection, cricothyrotomy may prove to be useless. It is contraindicated in infants and children younger than 10 to 12 years under all circumstances because stenosis and even transection are possible [53]. In this age group, percutaneous transtracheal ventilation may be a temporizing procedure until the tracheostomy can be performed.

Anatomy

The cricothyroid space is no larger than 7 to 9 mm in its vertical dimension, smaller than the outside diameter of most tracheostomy tubes (outside diameter 10 mm). The cricothyroid artery runs across the midline in the upper portion, and the membrane is vertically in the midline. The anterior superior edge of the thyroid cartilage is the laryngeal prominence. The cricothyroid membrane is approximately 2 to 3 cm below the laryngeal prominence and can be identified as an indentation immediately below the thyroid cartilage. The lower border of the cricothyroid membrane is the cricoid cartilage [47,48,52,55]. A description of the cricothyrotomy procedure is contained in standard surgical texts.

Complications

The report of incidents of short- and long-term complications of cricothyrotomy ranges from 6.1% [43] for procedures performed in elective, well-controlled, carefully selected cases to greater than 50% [53,56] for procedures performed under emergency or other suboptimal conditions. The incidence of subglottic stenosis after cricothyrotomy is 2% to 3% [42,44]. This major complication occurs at the tracheostomy or cricothyrotomy site, but not at the cuff site [57]. Necrosis of cartilage due to iatrogenic injury to the cricoid cartilage or pressure from the tube on the cartilage may play a role [54]. Possible reasons that subglottic stenoses may occur more commonly with cricothyrotomy than with tracheostomy are as follows: the larynx is the narrowest part of the laryngotracheal airway; subglottic tissues, especially in children, are intolerant of contact; and division of the cricothyroid membrane and cricoid cartilage destroy the only complete rings supporting the airway [42]. Furthermore, the range of tube sizes is limited due to the rigidity of the surrounding structures (cricoid and thyroid cartilage), and the curvature of the tracheostomy tube at this level may obstruct the airway due to potential posterior membrane impingement [58]. Prior laryngotracheal injury, as with prolonged translaryngeal intubation, is a major risk factor for the development of subglottic stenosis after cricothyrotomy [42,44].

The association of cricothyrotomy with these possible complications leads most authorities to consider replacing a

cricothyrotomy within 48 to 72 hours with a standardized tracheostomy procedure. This is commonly done by an open surgical tracheostomy (OST), which occurs between the second and third tracheal rings, as compared to a percutaneous dilational tracheostomy (PDT), which usually occurs between the cricoid cartilage and the first ring or the first and second rings [58].

TRACHEOSTOMY PROCEDURES IN THE INTENSIVE CARE UNIT

Tracheostomy is one of the most common surgical ICU procedures and is commonly performed for weaning purposes and for airway protection for patients requiring prolonged ventilation. There are two major techniques for tracheostomy, open and percutaneous, with various modifications of each. The different surgical tracheostomy techniques are well described in the references for this chapter [59–62].

Open Surgical Tracheostomy

In OST the patient's neck is extended and the surgical field is exposed from the chin to several inches below the clavicle. This area is prepped and draped, and prophylactic antibiotics are administered at the discretion of the surgeon. A vertical or horizontal incision may be used; however, a horizontal incision will provide a better cosmetic result. The platysma muscle is divided in line with the incision and the strap muscles are separated in the midline. The thyroid isthmus is then mobilized superiorly or divided as needed to access the trachea. In the event of a low-lying cricoid cartilage, dissection on the anterior wall of the trachea helps to mobilize the trachea out of the mediastinum, and also the use of a cricoid hook will elevate the trachea to expose the second or third tracheal ring. Following identification of the second or third tracheal ring, a vertical tracheostomy is created or a tracheal flap (Bjork flap) is fashioned to create a fistulous tract by suturing the tracheal mucosal flap to the skin in the incision.

Variations on this technique include the use of retention sutures through the lateral aspect of the tracheal walls for retraction purposes during tracheostomy tube insertion and for expeditious reinsertion of a tracheostomy tube in the event of accidental tube decannulation [61,63].

Percutaneous Dilational Techniques

The PDT are divided into several techniques; however, all are alike in that they depend on the basic technique of guidewire placement through the anterior tracheal wall, followed by dilation over this guidewire to create a tracheal stoma. This is all accomplished with provision of adequate monitoring of O_2 saturations as well as adequate monitoring of cardiac rhythm and blood pressure. To be assured of early successful tracheal cannulation within the operating room, use end-tidal CO_2 monitoring via the fresh tracheostomy tube and in the ICU by capnography [64]. There are several different modifications from the original technique that was described by Ciaglia et al. [65] in 1988. There modifications are described in details elsewhere [62].

Both techniques, PDT and OST, can be performed in either the ICU or the operating room. There have been several meta-analyses comparing OST with PDT, most showing no significant difference in mortality or major complications between the two methods of performing the tracheostomy. Freeman et al. [66] reviewed multiple prospective controlled studies published between 1991 and 1999 totaling 236 patients and concluded that there is no difference in mortality between PDT and OST, and PDT was associated with less bleeding and stomal infections and was performed quicker. Delancy et al. [67] also concluded that there was no significant difference in mortality and major complications between PDT and OST in a meta-analysis consisting of 17 randomized trials and a total of 1,212 patients. They also showed a decrease in stomal infections in the PDT group, but no difference in bleeding complications. Similar findings were demonstrated by meta-analysis studies by Higgins and Punthakee [68] and Oliver et al. [69]. However, Dulguerov et al. [70] reviewed 3,512 patients from 48 studies performed between 1960 and 1996 and concluded that OST was more favorable than PDT. Subsequent critiques of these papers indicate the inherent weakness of heterogeneous patient populations and the use of case series and nonrandomized studies in meta-analyses [71–73]. It is likely that experience and technical modifications allow both the techniques to be performed in appropriate patients with the same degree of safety and efficiency (<1% procedure-related mortality) [74].

Other factors have been used to justify the use of one procedure over the other such as cost efficiency [75,76], bleeding, infection, procedural time, and estimated time from the decision to proceed to successful completion of the procedure [74]. Each factor can be used to justify one procedure over another, but it is likely that institutional practice variations and operator experience are more important in the selection of one procedure over another. This is particularly relevant with respect to the target population where ICU daily expenses far outweigh the procedural costs of either technique [77], and the expected patient mortality can reach as high as 35% [78].

It is probably more important to judiciously use the institutional resources and the operator experience in providing the "best" tracheal technique for these compromised patients. It is possible that the target population may vary from one institution to another (cardiac vs. trauma vs. neurosurgical vs. medical ICU patients), which may influence the decision to perform one technique over another. Patient body habitus also plays a large role in selection: difficulty palpating tracheal rings in a short, thick-necked patient makes percutaneous tracheostomy not only difficult but dangerous. This patient is better served in an operating room setting where optimum sedation/paralysis (if needed) and positioning can be accomplished while directly exposing the anterior trachea, mobilizing it if necessary to access the airway with an appropriately sized, sometimes custom-made, tube.

Nonetheless, there are certain distinct advantages of PDT that can be outlined as follows: (a) easier access for timing of the procedure; (b) reduced operating room and manpower utilization; (c) less expensive than OST (even if both the procedures are performed in the ICU); (d) no requirement for transportation of critically ill patients to an operating room; (e) improved cosmetic result; and (f) possibly reduced stomal infection, bleeding, and reduced tracheal secretions in the parastomal area due to the tight fitting of the stoma around the tracheostomy tube.

We do recommend considering performing OST instead of PST in the following patients: (a) patients with more severe respiratory distress (FIO_2 >0.60, positive end-expiratory pressure >10, and complicated translaryngeal intubation or a nonpalpable cricoid cartilage or a cricoid cartilage <3 cm above the sternal notch [75]); (b) obese patients with abundant pretracheal subcutaneous fat; (c) patients with large goiters; (d) abnormal airways secondary to congenital-acquired conditions; (e) the need for the constant attendance of a second physician to monitor ventilation or circulatory abnormalities; (f) abnormal bleeding diathesis that cannot be adequately corrected by coagulation factors [79].

TUBES AND CANNULAS

Characteristics of a good tracheostomy tube are flexibility to accommodate varying patient anatomies, inert material, wide internal diameter, the smallest external diameter possible, a smooth surface to allow easy insertion and removal, and sufficient length to be secured once placed, but not so long as to impinge the carina or other tracheal parts [80]. Until the late 1960s, when surgeons began to experiment with silicone and other synthetic materials, tracheostomy tubes and cannulas were made of metal. At present, almost all tracheostomy tubes are made of synthetic material. One disadvantage of a silicone tube over a metal one is the increased thickness of the tube wall, resulting in a larger outer diameter. Silicone tubes are available with or without a cuff. The cuff allows occlusion of the airway around the tube, which is necessary for positive-pressure ventilation. It may also minimize aspiration. In the past, cuffs were associated with a fairly high incidence of tracheal stenosis caused by ischemia and necrosis of the mucus membrane and subsequent cicatricial contracture at the cuff site [81,82]. High-volume, low-pressure cuffs diminish pressure on the wall of the trachea, thereby minimizing (but not eliminating) problems due to focal areas of pressure necrosis [83]. Cuff pressures should always be maintained at less than 30 cm H_2O, as higher pressures impair mucosal capillary blood flow leading to ischemic injury to the trachea [84]. Cuff pressures should be checked with a manometer daily in critically ill patients. Once the patient is weaned from mechanical ventilation, the cuff should be deflated or consideration should be given to placing an uncuffed tracheostomy tube until the patient can be decannulated. If the only purpose of the tube is to secure the airway (sleep apnea) or provide access for suctioning secretions, a tube without a cuff can be placed. A comprehensive review of tracheostomy tubes can be found elsewhere [85].

POSTOPERATIVE CARE

The care of a tracheostomy tube after surgery is important. Highlighted below are some specific issues that all intensivists need to know when caring for patients with tracheostomies.

Wound and Dressing Care

Daily examinations of the stoma are important in identifying infections or excoriations of the skin at the tracheostomy site [86]. In addition, keeping the wound clean and free of blood and secretions is very important, especially in the immediate posttracheostomy period. Dressing changes should be preformed at least twice a day and when the dressings are soiled. Some authors recommend cleaning the stoma with 1:1 mixture of hydrogen peroxide and sterile saline [86]. When changing dressings and tapes, special care is needed to avoid accidental dislodging of the tracheostomy tube. Sutures, placed either for fixation and/or through the rings themselves for exposure, should be removed as soon as practical, usually after 1 week when an adequate stoma has formed, to facilitate cleaning the stomal area. Malodorous tracheal "stomatitis" that can lead to an enlarging stoma around the tube should be treated with topical antimicrobial dressings such as 0.25% Dakin's solution to facilitate resolution.

Inner Cannulas

The inner cannulas should be used at all times in most tracheostomy tubes in the ICU. Bivona now makes a tracheostomy tube that is lined with silicone and does not require an inner cannula. In other tracheotomy tubes, inner cannulas serve to extend the life of the tracheostomy tubes by preventing the buildup secretions within the tracheostomy. The inner cannulas can be easily removed and either cleaned or replaced with a sterile, disposable one. Disposable inner cannulas have the advantage of quick and efficient changing, a decrease in nursing time, decreased risk of cross-contamination, and guaranteed sterility [87]. The obturator should be kept at the bedside at all times in the event that reinsertion of the tracheostomy is necessary.

Humidification

One of the functions of the upper airway is to moisten and humidify inspired air. Because tracheostomies bypass the upper airway, it is vital to provide patients who have tracheostomies with warm, humidified air. Humidification of inspired gases prevents complications in patients with tracheostomies. Failure to humidify the inspired gases can obstruct the tube by inspissated secretions, impair mucociliary clearance, and decrease cough [88].

Suctioning

Patients with tracheostomies frequently have increased amounts of airway secretions coupled with decreased ability to clear them effectively. Keeping the airways clear of excess secretions is important in decreasing the risk of lung infection and airway plugging [86]. Suctioning is frequently required in patients with poor or ineffective cough. Suction techniques should remove the maximal amount of secretions while causing the least amount of airway trauma [89]. Routine suctioning, however, is not recommended [90]. In the patient who requires frequent suctioning because of secretions, who otherwise appears well, without infection and without tracheitis, the tube itself may be the culprit. Downsizing the tube or even a short trial (while being monitored) with the tube removed may result in significantly less secretions, obviating the need for the tube.

Tracheostomy Tube Changes

Tracheostomy tubes do not require routine changing. In fact, there may be significant risks associated with routine tracheostomy tube changes, especially if this is performed within a week of the initial procedure and by inexperienced caregivers. A survey of accredited otolaryngology training programs suggested a significant incidence of loss of airway and deaths associated with routine changing of tracheostomy tubes within 7 days of initial placement, especially if they are changed by inexperienced physicians [91]. In general, the tube needs to be changed only under the following conditions: (a) there is a functional problem with it, such as an air leak in the balloon; (b) when the lumen is narrowed due to the buildup of dried secretions; (c) when switching to a new type of tube; or (d) when downsizing the tube prior to decannulation. Ideally, a tracheostomy tube should not be changed until 7 to 10 days after its initial placement. The reason for this is to allow the tracheal stoma and the tract to mature. Patients who have their tracheostomy tube changed before the tract is fully mature risk having the tube misplaced into the soft tissue of the neck. If the tracheostomy tube needs to be replaced before the tract has had time to mature, the tube should be changed over a guide, such as a suction catheter or tube changer [92].

Oral Feeding and Swallowing Dysfunction Associated with Tracheostomies

Great caution should be exercised before initiating oral feedings in patients with tracheostomy. Numerous studies have demonstrated that patients are at a significantly increased risk for aspiration when a tracheostomy is in place.

Physiologically, patients with tracheostomies are more likely to aspirate because the tracheostomy tube tethers the larynx, preventing its normal upward movement needed to assist in glottic closure and cricopharyngeal relaxation [93]. Tracheostomy tubes also disrupt normal swallowing by compressing the esophagus and interfering with deglutition [94], decreasing duration of vocal cord closure [95], and resulting in uncoordinated laryngeal closure [96]. In addition, prolonged orotracheal intubation can result in prolonged swallowing disorders even after the endotracheal tube is converted to a tracheostomy [97]. It is therefore not surprising that more than 65% of patients with tracheostomies aspirate when swallowing [98,99]. It is felt that 77% of the episodes are clinically silent [100,101].

Before attempting oral feedings in a patient with a tracheostomy, several objective criteria must be met. Obviously, the patient must be consistently alert, appropriate, and able to follow complex commands. The patient should also have adequate cough and swallowing reflexes, adequate oral motor strength, and a significant respiratory reserve [102]. These criteria are probably best assessed by a certified speech therapist. However, bedside clinical assessment may only identify 34% of the patients at high risk for aspiration [103]. Augmenting the bedside swallowing evaluation by coloring feedings or measuring the glucose in tracheal secretions does not appear to increase the sensitivity in detecting the risk of aspiration [104,105]. A video barium swallow may identify between 50% and 80% of patients with tracheostomies, who are at a high risk, to aspirate oral feeding [101,103]. A laryngoscopy to observe directly a patient's swallowing mechanics, coupled with a video barium swallow, may be more sensitive in predicting which patients are at risk for aspiration [103]. Scintigraphic studies may be the most sensitive test to determining which patients are aspirating [106], and it is much easier to perform than endoscopy. Plugging of the tracheostomy [106] or using a Passy–Muir valve [107] may reduce aspiration in patients with tracheostomies who are taking oral feedings, but this is not a universal finding [108].

Because of the high risk for aspiration and the difficulty assessing which patients are at high risk to aspirate, we do not institute oral feedings in our patients with tracheostomy in the ICU. We believe that the potential risks of a percutaneous endoscopically placed gastrostomy feeding tube or maintaining a nasogastric feeding tube are much less than the risk of aspiration of oral feedings and its complications (i.e., recurrent pneumonia, acute respiratory distress syndrome, and prolonged weaning).

Discharging Patients with Tracheotomies from the ICU to the General Ward

Two relatively recent studies have raised concern about the safety of patients, who have been weaned from mechanical ventilation, who are transferred from the ICU to the general hospital ward with the tracheostomy in place [109,110]. Fernandez et al. retrospectively showed an increased mortality in patients with tracheostomy tubes versus those decannulated prior to transfer out of the ICU, especially among patients with a poorer overall prognosis [109]. Martinez et al. prospectively studied 73 patients who received tracheostomies, who were without neurologic injury, and who were transferred from the ICU to the general ward [110]. Thirty-five of these patients were decannulated prior to transfer to the wards. The decannulated group had a significantly lower mortality. Factors found to be associated with increased mortality in patients not decannulated prior to transfer include body mass index greater than 30 kg per m^2 and tenacious secretions.

Patients with tracheostomies who are transferred to the general medical wards do need special attention. We suggest that these patients be safely cared for on the general ward, provided there is a multidisciplinary team approach between physicians, nurses, and respiratory therapist.

COMPLICATIONS

Tracheostomies, whether inserted by percutaneous dilatation or open surgical procedure, are associated with a variety of complications. These complications are best grouped by the time of occurrence after the placement and are divided into immediate, intermediate, and late complications (Table 12.4). The reported incidence of complications varies from as low

TABLE 12.4

COMPLICATIONS OF TRACHEOSTOMIES [13]

Immediate complications (0–24 h)
Tube displacement
Arrhythmia
Hypotension
Hypoxia/hypercapnia
Loss of airway control
Pneumothorax
Pneumomediastinum
Acute surgical emphysema
Major hemorrhage
Bacteremia
Esophageal injury (*uncommon*)
Cardiorespiratory arrest (*uncommon*)
Tracheolaryngeal injury (*uncommon*)
Crushed airway from dilational tracheostomy (*uncommon*)
Intermediate complications (from day 1 to day 7)
Persistent bleeding
Tube displacement
Tube obstruction (mucus, blood)
Major atelectasis
Wound infection/cellulitis
Late complications (>day 7)
Tracheoinnominate artery fistula
Tracheomalacia
Tracheal stenosis
Necrosis and loss of anterior tracheal cartilage
Tracheoesophageal fistula
Major aspiration
Chronic speech and swallowing deficits
Tracheocutaneous fistula

as 4% [111] to as high as 39% [28], with reported mortality rates from 0.03% to 0.6% [70,112]. Complication rates appear to decrease with increasing experience of the physician performing the procedure [113]. Posttracheostomy mortality and morbidity is usually due to iatrogenic tracheal laceration [114], hemorrhage, tube dislodgment, infection, or obstruction. Neurosurgical patients have a higher posttracheostomy complication rate than other patients [115,116]. Tracheostomy is more hazardous in children than in adults, and carries special risks in the very young, often related to the experience of the surgeon [117]. A comprehensive understanding of immediate, intermediate, and late complications of tracheostomy and their management is essential for the intensivist.

Obstruction

Obstruction of the tracheostomy tube is a potentially life-threatening complication. The tube may become plugged with clotted blood or inspissated secretions. In this case, the inner cannula should be removed immediately and the patient suctioned. Should that fail, it may be necessary to remove the outer cannula also, a decision that must take into consideration the reason the tube was placed and the length of time it has been in place. Obstruction may also be due to angulation of the distal end of the tube against the anterior or posterior tracheal wall. An undivided thyroid isthmus pressing against the angled tracheostomy tube can force the tip against the anterior tracheal wall, whereas a low superior transverse skin edge can force the tip of the tracheostomy tube against the posterior tracheal wall. An indication of this type of obstruction is an expiratory wheeze. Division of the thyroid isthmus and proper placement of transverse skin incisions prevent anterior or posterior tube angulation and obstruction [118].

Tube Displacement/Dislodgment

Dislodgment of a tracheostomy tube that has been in place for 2 weeks or longer is managed simply by replacing the tube. If it cannot be immediately replaced or if it is replaced and the patient cannot be ventilated (indicating that the tube is not in the trachea), orotracheal intubation should be performed. Immediate postoperative displacement can be fatal if the tube cannot be promptly replaced and the patient cannot be reintubated.

Dislodgment in the early postoperative period is usually caused by one of several technical problems. Failure to divide the thyroid isthmus may permit the intact isthmus to ride up against the tracheostomy tube and thus displace it [118]. Excessively low placement of the stoma (i.e., below the second and third rings) can occur when the thoracic trachea is brought into the neck by overextending the neck or by excessive traction on the trachea. When the normal anatomic relationships are restored, the trachea recedes below the suprasternal notch, causing the tube to be dislodged from the trachea [118,119]. The risk of dislodgment of the tracheostomy tube, a potentially lethal complication, can be minimized by (a) transection of the thyroid isthmus at surgery, if indicated; (b) proper placement of the stoma; (c) avoidance of excessive neck hyperextension and/or tracheal traction; (d) application of sufficiently tight tracheostomy tube retention tapes; and (e) suture of the tracheostomy tube flange to the skin in patients with short necks. Some surgeons apply retaining sutures to the trachea for use in the early postoperative period in case the tube becomes dislodged, allowing the trachea to be pulled into the wound for reintubation. Making a Bjork flap involves suturing the inferior edge of the trachea stoma to the skin, thus allowing a sure pathway for tube placement. Bjork flaps, however, tend to interfere with swallowing and promote aspiration [120]. Reintubation of a tracheostomy can be accomplished by using a smaller, beveled endotracheal tube and then applying a tracheostomy tube over the smaller tube, using the Seldinger technique [121]. Using a nasogastric tube as a guidewire has also been described [92].

If a tracheostomy becomes dislodged within 7 to 10 days of surgery, we recommend translaryngeal endotracheal intubation to establish a safe airway. The tracheostomy tube can then be replaced under less urgent conditions, with fiberoptic guidance if needed.

Subcutaneous Emphysema

Approximately 5% of patients develop subcutaneous emphysema after tracheostomy [121]. It is most likely to occur when dissection is extensive and/or the wound is closed tightly. Partial closure of the skin wound is appropriate, but the underlying tissues should be allowed to approximate naturally. Subcutaneous emphysema generally resolves over the 48 hours after tracheostomy, but when the wound is closed tightly and the patient is coughing or on positive-pressure ventilation, pneumomediastinum, pneumopericardium, and/or tension pneumothorax may occur [118].

Pneumothorax and Pneumomediastinum

The cupola of the pleura extends well into the neck, especially in patients with emphysema; thus, the pleura can be damaged during tracheostomy. This complication is more common in the pediatric age group because the pleural dome extends more cephalad in children [1]. The incidence of pneumothorax after tracheostomy ranges from 0% to 5% [1,111,121]. Many surgeons routinely obtain a postoperative chest radiograph.

Hemorrhage

Minor postoperative fresh tracheostomy bleeding occurs in up to 37% of cases [1] and is probably the most common complication of this procedure. Postoperative coughing and straining can cause venous bleeding by dislodging a clot or ligature. Elevating the head of the bed, packing the wound, and/or using homeostatic materials usually controls minor bleeding. Major bleeding can occur in up to 5% of tracheotomies and is due to hemorrhage from the isthmus of the thyroid gland, loss of a ligature from one of the anterior jugular veins, or injury to the transverse jugular vein that crosses the midline just above the jugular notch [122]. Persistent bleeding may require a return to the operating room for management. Techniques to decrease the likelihood of early posttracheostomy hemorrhage include (a) use of a vertical incision; (b) careful dissection in the midline, with care to pick up each layer of tissue with instruments rather than simply spread tissues apart; (c) liberal use of ligatures rather than electrocautery; and (d) careful division and suture ligation of the thyroid isthmus. Late hemorrhage after tracheostomy is usually due to bleeding granulation tissue or another relatively minor cause. However, in these late cases, a tracheoinnominate artery fistula needs to be ruled out.

Tracheoinnominate Artery Fistula

At one point, it had been reported that 50% of all tracheostomy bleeding occurring more than 48 hours after the procedure was due to an often fatal complication of rupture of the innominate

artery caused by erosion of the tracheostomy tube at its tip or cuff into the vessel [121]. However, because the advent of the low-pressure cuff, the incidence of this complication has decreased considerably and occurs less than 1% of the time [123].

Eighty-five percent of tracheoinnominate fistulas occur within the first month after tracheostomy [124], although they have been reported as late as 7 months after operation. Other sites of delayed exsanguinating posttracheostomy hemorrhage include the common carotid artery, superior and inferior thyroid arteries, aortic arch, and innominate vein [124]. Rupture and fistula formation are caused by erosion through the trachea into the artery due to excessive cuff pressure or by angulation of the tube tip against the anterior trachea. Infection and other factors that weaken local tissues, such as malnourishment and steroids, also seem to play a role [125]. The innominate artery rises to about the level of the sixth ring anterior to the trachea, and low placement of the stoma can also create close proximity of the tube tip or cuff to the innominate artery. Rarely, an anomaly of the innominate, occurring with an incidence of 1% to 2% [124], is responsible for this disastrous complication. Pulsation of the tracheostomy tube is an indication of potentially fatal positioning [124]. Initially, hemorrhage from a tracheoinnominate fistula is usually not exsanguinating. Herald bleeds must be investigated promptly using fiberoptic tracheoscopy. If a tracheoinnominate fistula seems probable (minimal tracheitis, anterior pulsating erosions), the patient should be taken to the operating room for evaluation. Definitive management involves resection of the artery [126]. The mortality rate approaches 100%, even with emergent surgical intervention [127]. Sudden exsanguinating hemorrhage may be managed by hyperinflation of the tracheostomy cuff tube or reintubation with an endotracheal tube through the stoma, attempting to place the cuff at the level of the fistula. A lower neck incision with blind digital compression on the artery may be part of a critical resuscitative effort [128]. If a tracheoinnominate artery fistula is suspected, the patient should be evaluated in the operating room and preparations should be made for a possible sternotomy.

Misplacement of Tube

Misplacement of the tube error occurs at the time of surgery or when the tube is changed or replaced through a fresh stoma. If not recognized, associated mediastinal emphysema and tension pneumothorax can occur, along with alveolar hypoventilation. Injury to neurovascular structures, including the recurrent laryngeal nerve, is possible [119]. The patient must be orally intubated or the tracheostoma recannulated. Some advise placing retaining sutures in the trachea at the time of surgery. The availability of a tracheostomy set at the bedside after tracheostomy facilitates emergency reintubation.

Stomal Infections

An 8% to 12% incidence of cellulitis or purulent exudate is reported with tracheostomy [1,121]. The risk of serious infection is less than 0.5% [111]. Attention to the details of good stoma care and early use of antibiotics are advised. However, prophylactic antibiotics are not recommended [129].

Tracheoesophageal Fistula

Tracheoesophageal fistula caused by injury to the posterior tracheal wall and cervical esophagus occurs in less than 1% of patients, more commonly in the pediatric age group. Early postoperative fistula is a result of iatrogenic injury during the procedure [121,128]. The chances of creating a fistula can be minimized by entering the trachea initially with a horizontal incision between two tracheal rings (the second and third), thereby eliminating the initial cut into a hard cartilaginous ring [118]. A late tracheoesophageal fistula may be due to tracheal necrosis caused by tube movement or angulation, as in neck hyperflexion, or excessive cuff pressure [119,121,128]. A tracheoesophageal fistula should be suspected in patients with cuff leaks, abdominal distention, recurrent aspiration pneumonia, and reflux of gastric fluids through the tracheostomy site. It may be demonstrated on endoscopy and contrast studies. Tracheoesophageal fistulas require surgical repair. For patients who could not tolerate a major surgical procedure, placement of an esophageal and a tracheal stent may be used [130–132].

Tracheal Stenosis

Some degree of tracheal stenosis is seen in 40% to 60% of patients with tracheostomies [112,133]. However, 3% to 12% of these stenoses are clinically significant enough to require intervention [134]. Stenosis most commonly occurs at the level of the stoma or just above the stoma, but distal to the vocal cords [127]. The stenosis typically results from bacterial infection or chondritis of the anterior and lateral tracheal walls. Granulation tissue usually develops first. Ultimately the granulation tissue matures, becoming fibrous and covered with a layer of epithelium. The granulation tissue itself can also result in other complications, such as obstructing the airway at the level of the stoma, making changing the tracheostomy tube difficult, and occluding tube fenestrations. Identified risk factors for developing tracheal stenosis include sepsis, stomal infections, hypotension, advanced age, male gender, corticosteroid use, excess motion of the tracheostomy tube, oversized tube, prolonged placement, elevated cuff pressures, and excessive excision of the anterior trachea cartilage [127,135]. Using properly sized tracheostomy tubes, inflating cuffs only when indicated, and maintaining intracuff pressures to less than 15 to 20 mm Hg may decrease the incidence of tracheal stenosis [136]. Tracheal stenosis, as well as other long-term complications, appears to be less with the percutaneous procedure [137–139].

Treatment options for granulation tissue include topical strategies (such as topical antibiotic or steroids, silver nitrate, and polyurethane form dressings) or surgical strategies (laser excision, electrocautery, and surgical removal) [127]. Treatment options for symptomatic tracheal stenosis include dilatation with a rigid bronchoscopy with coring, intralumen laser excision, or surgical resection with end-to-end tracheal anastomosis [140].

Tracheomalacia

Tracheomalacia is a weakening of the tracheal wall resulting from ischemic injury to the trachea, followed by chondritis, then destruction, and necrosis of the tracheal cartilage [127]. Consequently, there is collapse of the affected portion of the trachea with expiration, resulting in airflow limitation, air trapping, and retention of airway secretions. Tracheomalacia may ultimately result in the patient failing to wean from mechanical ventilation. A short-term therapeutic approach to tracheomalacia is to place a longer tracheostomy tube to bypass the area of malacia. Long-term treatment options include stenting, tracheal resection, or tracheoplasty [127].

Dysphagia and Aspiration

The major swallowing disorder associated with tracheostomy is aspiration (see the section Oral Feeding and Swallowing Dysfunction). Because of the high risk for aspiration, we do not recommend oral feeding in ICU patients with tracheostomies.

Tracheocutaneous Fistula

Although the tracheostoma generally closes rapidly after decannulation, a persistent fistula may occasionally remain, particularly when the tracheostomy tube is present for a prolonged period. If this complication occurs, the fistula tract can be excised and the wound closed primarily under local anesthesia [141].

CONCLUSION

Tracheostomy is one of the most common surgical procedures preformed in the ICU and appears to be the airway of choice for patients requiring mechanical ventilation for more than 1 to 2 weeks. The exact timing for converting patients to tracheostomy is not entirely clear, so the physician must weight the risks and benefits of tracheostomy versus translaryngeal intubation and estimate the expected duration of mechanical ventilation for each individual patient. The physician performing the tracheostomy procedure needs to assess each patient to determine the best technique (whether it be performed bedside percutaneously or open in the operating room) for that specific patient. The patient's medical condition, the physician's experience with the various techniques, and the hospital's resources all need to be considered in determining the type of procedure performed.

CHAPTER 13 ■ GASTROINTESTINAL ENDOSCOPY

ANUPAM SINGH, RANDALL S. PELLISH AND WAHID Y. WASSEF

Gastrointestinal (GI) endoscopy has evolved into an essential diagnostic and therapeutic tool for the treatment of critically ill patients in the new millennium. Innovations in the field continue to emerge. This chapter reviews general aspects of current indications and contraindications, provides an update of emerging technologies, and concludes by discussing potential future directions in the field.

INDICATIONS

The indications for GI endoscopy in the intensive care unit (ICU) are summarized in Table 13.1 and are divided into those for (a) evaluation of the upper GI tract (esophagus, stomach, and duodenum); (b) evaluation of the pancreaticobiliary tract; (c) evaluation of the mid-GI tract (jejunum and ileum); and (d) evaluation of the lower GI tract (colon and rectum).

Evaluation of the Upper Gastrointestinal Tract

Common indications for evaluation of the upper GI tract in the ICU include, but are not limited to, upper GI bleeding (UGIB), caustic or foreign body ingestion, and placement of feeding tubes. Evaluation of the GI tract in ICU patients with clinically insignificant bleeding or chronic GI complaints should generally be postponed until their medical/surgical illnesses improve. One exception in this group of patients is if anticoagulation or thrombolytic therapy is being contemplated.

Upper Gastrointestinal Bleeding

With an estimated 300,000 admissions annually, acute UGIB is one of the most common medical emergencies [1]. It is defined as the presence of melena, hematemesis, or blood in the nasogastric (NG) aspirate. Studies have shown improved outcomes with urgent endoscopic management in critically ill patients with hemodynamic instability or continuing transfusion requirements [2,3]. Urgent evaluation allows differentiation between nonvariceal (peptic ulcer, esophagitis, Mallory–Weiss tear, and angiodysplasia) and variceal lesions (esophageal or gastric varices), therefore promoting targeted therapy [4,5]. Furthermore, urgent evaluation allows the identification and stratification of stigmata of bleeding, promoting appropriate triage and risk stratification. Finally, urgent evaluation allows the early identification of patients who may require surgical or radiologic intervention [6,7].

Foreign Body Ingestions

Foreign body ingestions (FBI) can be divided into two groups: (i) food impactions and (ii) caustic ingestion. Food impactions constitute the majority of FBI. Although most will pass spontaneously, endoscopic removal will be needed for 10% to 20% of cases, and 1% of patients will ultimately require surgery [8]. Evaluation is crucial to determine the underlying cause of the obstruction (strictures, rings, and carcinoma). Although caustic ingestions constitute only a small number of FBI, they are frequently life threatening, especially when they occur intentionally in adults, and warrant endoscopic evaluation to prognosticate and triage this group of patients [9].

Feeding Tubes

Enteral nutrition improves outcomes in critically ill patients and is preferred over parenteral nutrition in patients with a functional GI tract [10]. Although nasoenteric and oroenteric feeding tubes may be used for short-term enteral nutrition, these tubes are felt to carry a higher risk of aspiration, displacement, and sinus infections than endoscopically placed percutaneous tubes. Percutaneous endoscopic gastrostomy (PEG) [11] is appropriate for most patients in the ICU when there is a reversible disease process likely to require more than 4 weeks of enteral nutrition (e.g., neurologic injury,

TABLE 13.1

INDICATIONS FOR GASTROINTESTINAL (GI) ENDOSCOPY

Upper GI endoscopy
Upper GI bleeding (variceal or nonvariceal)
Caustic or foreign body ingestion
Placement of feeding or drainage tubes
Endoscopic retrograde cholangiopancreatography
Severe gallstone pancreatitis
Severe cholangitis
Bile leak
Lower GI endoscopy
Lower GI bleeding
Decompression of nontoxic megacolon or sigmoid volvulus
Unexplained diarrhea in the immunocompromised (graft vs. host disease and cytomegalovirus infection)

tracheostomy, and neoplasms of the upper aerodigestive tract) [12]. PEG with jejunostomy tube and direct percutaneous endoscopic jejunostomy (PEJ) tubes are appropriate for select patients in the ICU with high risk of aspiration. This includes patients with severe gastroesophageal reflux disease and those with gastroparesis. Enteral feeding beyond the ligament of Treitz with a nasojejunal tube or a jejunostomy tube has been demonstrated to be beneficial in patients with necrotizing pancreatitis. Occasionally, endoscopic gastrostomies or jejunostomies may be indicated for decompression in patients with GI obstruction [13]. Although these procedures are technically simple and can be performed at the bedside under moderate sedation, the risks and benefits should always be weighed carefully in this critically ill group of patients [14].

Evaluation of the Pancreaticobiliary Tract

The indications for evaluation of the pancreaticobiliary tract by endoscopic retrograde cholangiopancreatography (ERCP) in critically ill patients are described in detail in Chapter 97 and only briefly discussed here. Indications include biliary tract obstruction by gallstones [15–17], pancreatic duct leaks, and bile duct leaks (generally a postoperative or traumatic complication) [18–20]. ERCP with sphincterotomy and/or stenting is the treatment of choice. When conventional ERCP is unsuccessful, the recent introduction of miniature endoscopes (cholangioscopes or pancreatic scopes) with direct endoscopic visualization into these ductal systems has proved to be beneficial through the use of advanced techniques such as electrohydraulic lithotripsy (EHL), laser lithotripsy, and glue [21]. Unfortunately, this technique is limited by its lack of availability at all centers and the great deal of experience that is needed for its proper use.

FIGURE 13.1. Normal jejunal image as seen by video capsule endoscope (VCE).

FIGURE 13.2. Tumor seen in proximal jejunum during double-balloon enteroscopy (DBE). (Courtesy: David Cave, MD: Professor of Medicine, University of Massachusetts Medical School.)

Evaluation of the Mid-Gastrointestinal Tract (Jejunum and Ileum)

Persistent, obscure GI bleeding is the most common indication for evaluation of this portion of the GI tract. Although this area of the GI tract had been difficult to evaluate in the past, this is no longer the case. The advent of the wireless video capsule endoscope (VCE), the double-balloon endoscope (DBE), and the spiral endoscope has made this area of the GI tract easily accessible. VCE is usually the first test performed to look for possible sites of bleeding in the jejunum and ileum (Fig. 13.1). If bleeding or lesions are identified, the DBE (Fig. 13.2) or the spiral endoscope (Fig. 13.3) would be used to implement therapy.

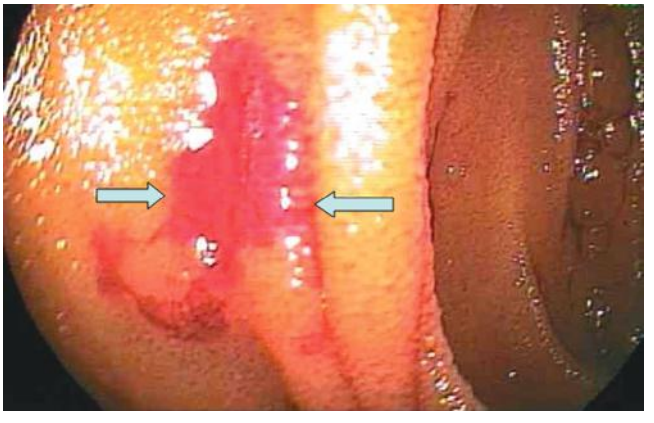

FIGURE 13.3. Bleeding seen in jejunum during spiral endoscopy. (Courtesy: David Cave, MD: Professor of Medicine, University of Massachusetts Medical School.)

Evaluation of the Lower Gastrointestinal Tract

Colonoscopic evaluation is urgently needed in ICU patients in cases of severe lower GI bleeding (LGIB), acute colonic distention, and at times for the evaluation of infection (*Cytomegalovirus* [CMV] and *Clostridium difficile*) in the immunocompromised patients [22,23].

Severe LGIB is predominantly a disease of the elderly. It is defined as bleeding from a source distal to the ligament of Treitz for less than 3 days [24]. Common causes include, but are not limited to, diverticular bleeding, ischemic colitis, and vascular abnormalities (arteriovenous malformations, AVMs). However, as many as 11% of patients initially suspected to have an LGIB are ultimately found to have a UGIB [25]. Therefore, UGIB sources should always be considered first in patients with LGIB, particularly in patients with unstable hemodynamics. Once an upper GI source has been excluded, colonoscopy should be performed to evaluate the lower GI tract and administer appropriate therapy. Although urgent colonoscopy within 24 to 48 hours has shown to decrease the length of hospital stay [26] and endoscopic intervention is often successful, 80% to 85% of LGIBs stop spontaneously [27]. If the bleeding is severe or a source cannot be identified at colonoscopy, a technetium (TC)-99m red blood cell scan with or without angiography should be considered [28].

Acute Colonic Distention

This condition can be caused by acute colonic obstruction or acute colonic pseudo-obstruction. Acute colonic obstruction can be caused by neoplasms, diverticular disease, and volvulus [29]. Volvulus (Fig. 13.4A and B) is a "closed-loop obstruction" and is considered an emergency because unlike the other causes of colonic obstruction, it can rapidly deteriorate from obstruction to ischemia, perforation, and death. However, if identified and treated early, it can be reversed. Acute colonic pseudo-obstruction is a syndrome of massive dilation of the colon without mechanical obstruction that develops in hospitalized patients with serious underlying medical and surgical conditions due to impaired colonic motility. Increasing age, cecal diameter, delay in decompression, and status of the bowel significantly influence mortality, which is approximately 40% when ischemia or perforation is present. Evaluation of the markedly distended colon in the ICU setting involves excluding mechanical obstruction and other causes of toxic megacolon, such as *C. difficile* infection, and assessing for signs of ischemia and perforation. The risk of colonic perforation in acute colonic pseudo-obstruction increases when cecal diameter exceeds 12 cm and when the distention has been present for greater than 6 days [30].

CONTRAINDICATIONS

Absolute and relative contraindications for endoscopic procedures are outlined in Table 13.2. In general, endoscopy is contraindicated when the patient is hemodynamically unstable, when there is suspected perforation, or when adequate patient cooperation or consent cannot be obtained [31]. However, there are exceptions to these rules. In these cases, resuscitation and endoscopic intervention would need to go on simultaneously.

TABLE 13.2

CONTRAINDICATIONS TO ENDOSCOPY

Absolute contraindications
Suspected or impending perforated viscus
Risks to the patient outweigh benefits of the procedure
Relative contraindications
Adequate patient cooperation or consent cannot be obtained
Hemodynamic instability or myocardial infarction
Inadequate airway protection or hypoxemia
Severe coagulopathy or thrombocytopenia
Inflammatory changes with increased risk of perforation (e.g., diverticulitis or severe inflammatory bowel disease)

PERIPROCEDURAL CARE

Key elements of planning interventional endoscopic procedures include appropriate resuscitation and reversal of coagulopathies [32]. Proper sedation may simply involve light sedation in some patients [33]. However, in uncooperative, confused, or hypoxemic patients, it may require endotracheal intubation with deep sedation or general anesthesia. Although endotracheal intubation does not significantly alter the risk of acquired pneumonia or cardiovascular events [33,34], it does generate controlled conditions during the procedure and may help prevent massive aspiration (especially in patients with variceal bleeding). Antibiotics need to be considered in patients with ascites and those with a history of endocarditis [35].

Upper Gastrointestinal Endoscopy

Upper Gastrointestinal Bleeding

In all patients with upper GI bleeding, an empty stomach is crucial for thorough evaluation and identification of the bleeding lesion. Through proper identification and treatment, studies have shown a reduction in the risk of rebleeding and in the need for surgical intervention [36]. Gastric lavage with an NG tube or through use of the endoscope can clear the stomach of blood and clot partially. At times, the use of the prokinetic agents such as erythromycin (250 mg in 50 mL of normal saline IV, 20 minutes prior to the procedure) may also be helpful. Studies have in fact shown that this approach may improve the endoscopic visualization, improve the outcome, and decrease the need for "second-look" endoscopy [37]. Although metoclopramide may theoretically have a similar effect, the use of this agent has not been studied extensively. If a variceal hemorrhage is suspected, on the basis of a clinical history or physical examination suggesting portal hypertension, adjunctive therapy should be initiated immediately in the absence of contraindications. Both somatostatin analogues (octreotide) or vasopressin and its analogues have been used intravenously (IV) to reduce portal pressures and prevent recurrent bleeding. A recent meta-analysis slightly favored octreotide over terlipressin/vasopressin in the control of esophageal variceal bleeding [38]. Octreotide is usually given as a onetime bolus of 50 to 100 μg IV, followed by 25 to 50 μg IV per hour for 3 to 5 days. In addition, prophylactic antibiotics should be given to patients with active esophageal variceal bleeding for the prevention of bacterial infections [39]. In contrast to nonvariceal hemorrhage, volume resuscitation should be performed judiciously in variceal bleeding as volume repletion can theoretically increase portal pressures.

If the bleeding source is found to be a peptic ulcer, the intervention will depend on the specific endoscopic findings [7]. If an actively bleeding or a nonbleeding visible vessel is identified in the crater of the ulcer, endoscopic hemostatic techniques are recommended. If the ulcer has a clean base with no signs of active bleeding, endoscopic intervention is not indicated. A number of endoscopic methods have been developed for hemostasis, including injection therapy, thermal cautery therapy, and mechanical hemostasis with clips (Table 13.3). The combination of injection therapy with thermal coaptive therapy is superior to either alone [1,40]. Although no single solution for endoscopic injection therapy appears superior to another, an epinephrine–saline solution is usually injected in four quadrants surrounding the lesion. Heater probe and multipolar electrocoagulation instruments are subsequently applied with firm pressure to achieve optimal coaptation. Mechanical hemostasis, with hemoclips, has been a more recent addition for hemostasis therapy (Fig. 13.5A and B). Controlled trials comparing clipping alone with other endoscopic hemostatic techniques for nonvariceal UGIB are limited. Current evidence suggests that the hemoclip is not superior to other endoscopic modalities in terms of initial hemostasis, rebleeding rate, emergency surgery, and the mortality rate for treatment of peptic ulcer bleed [41]. However, they may be especially useful in the treatment of critically ill patients [42] and patients with coagulopathy. Argon plasma coagulation (APC) is a noncoaptive technique that provides cautery to tissues by means of ionized argon gas. This method is most commonly used in the treatment of AVMs. The YAG laser has fallen out of favor in the acute management of high-risk patients because of its poor portability and associated high cost.

TABLE 13.3

ENDOSCOPIC METHODS FOR HEMOSTATIS

Thermal methods of hemostasis
Heater probe
Multipolar electrocoagulation (bicap)
Neodymium yttrium-aluminium-garnet (YAG) laser
Argon plasma coagulation
Injection therapy for hemostasis
Distilled water or saline
Epinephrine (adrenaline)
Sclerosants (Cyanoacrylate, polidocanol, ethanol, ethanolamine oleare, sodium tetradecyl sulfate, sodium morrhuate)
Thrombin Fibrin-glue
Mechanical methods
Clips
Band ligation
Detachable loops

Whatever method of hemostasis is used, patients with nonvariceal UGIB need to be placed on antisecretory therapy with a proton pump inhibitor (PPI) following endoscopic hemostasis [2,40]. IV administration of a PPI is a faster way to achieve gastric acid suppression than is oral administration of the same agent. Peak suppression after IV administration occurs within hours, compared with several days later after oral administration. This is crucial because it can reduce the risk of rebleeding and the need for surgery [43,44]. The PPIs currently approved for IV use in the United States include pantoprazole, lansoprazole, and esomeprazole [45].

If the bleeding is found to be caused by esophageal varices, endoscopic variceal ligation (EVL) has become the procedure of choice [46]. With this technique, the varix is suctioned into a banding device attached to the tip of the endoscope and a rubber band is then deployed at its base to obliterate the varix. In contrast, endoscopic sclerotherapy (EST) causes obliteration by injection of a sclerosing agent (e.g., sodium morrhuate) in or around the bleeding varix. A meta-analysis by Laine and Cook [47] suggested that EVL was superior to EST in all major outcomes (recurrent bleeding, local complications such as ulcers or strictures, time to variceal obliteration, and survival). However, EST is effective in controlling active bleeding in more than 90% of cases and can be injected even with poor visualization during an active bleed.

Endoscopic methods (EST, EVL, and injection of fibrin glue) have also been used for the treatment of bleeding gastric varices in small and mostly uncontrolled studies. However, these methods carry a considerable risk of rebleeding and mortality. Patients with bleeding gastric varices generally require urgent

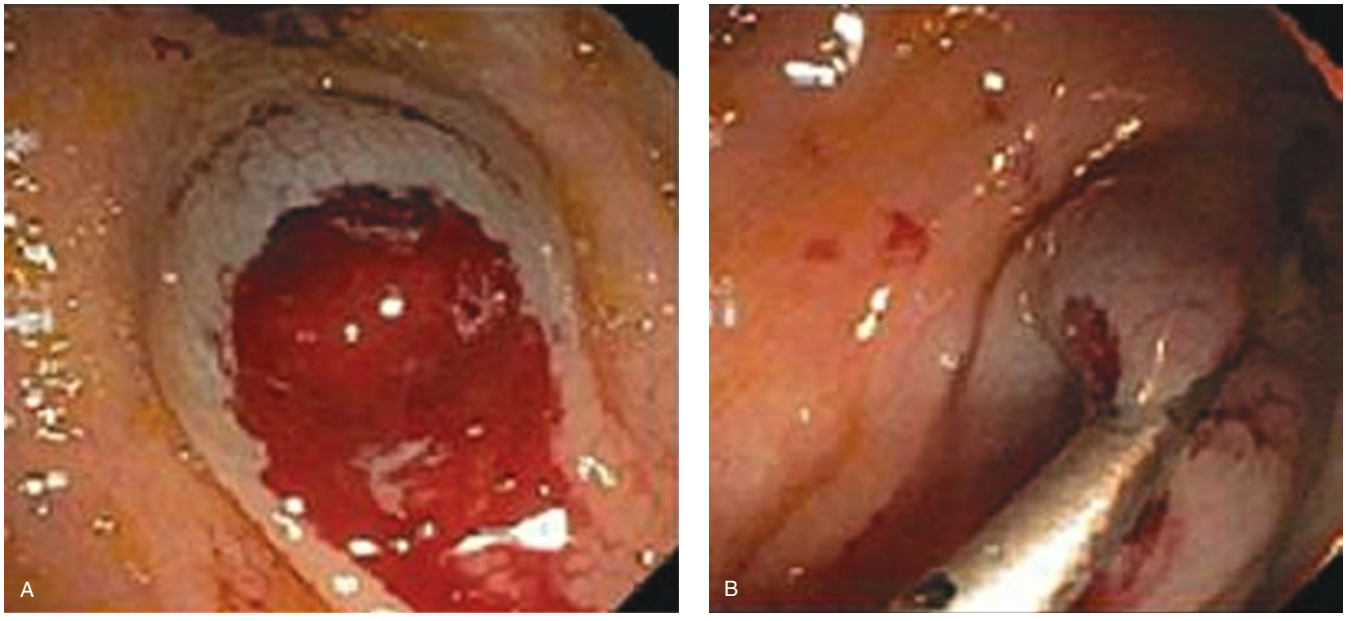

FIGURE 13.5. A: Postpolypectomy bleeding. **B:** Hemostasis by hemoclip for postpolypectomy bleeding.

placement of a transjugular intrahepatic portosystemic shunt (TIPS) [48].

Enteric Feeding Tubes

Please see Chapter 16 for more detail on the placement of enteric feeding tubes.

Pancreaticobiliary Endoscopy (Refer to Chapter 97)

Small Bowel Endoscopy

The techniques are essentially the same as those for upper GI endoscopy. Please refer to that section for details.

Lower Gastrointestinal Endoscopy

Unlike any of the other types of endoscopies previously discussed, this is the only one requiring a preprocedure bowel preparation. In urgent situations, this can be done through a technique known as a rapid purge. This technique is usually achieved by drinking 4 L or more polyethylene glycol–based solutions over a 2- to 3-hour period. Approximately one-third of hospitalized patients require an NGT for this type of preparation [49]. Metoclopramide (10 mg IV × 1), administered prior to starting the preparation, may help to control nausea and promote gastric emptying [25].

Lower Gastrointestinal Bleeding

The endoscopic treatment options for LGIB are similar to those for UGIB (see earlier in the chapter) and should be based on the stigmata of bleeding that are identified. Hemostasis is usually approached through a combination approach of injection therapy with clipping or coagulation therapy.

Decompressive Endoscopy

A water-soluble contrast enema or computed tomography (CT) should be the initial procedure to perform in patients with acute colon distention. This will establish the presence or absence of mechanical obstruction. Subsequently, the patient should undergo resuscitation with IV fluids (IVF), frequent repositioning, NG and rectal tube placement, correction of metabolic imbalances, and discontinuation of medications known to slow intestinal transit [50]. If conservative measures are unsuccessful, decompressive endoscopy with minimal inflation of air resolves acute obstruction of the colon in the majority of cases (81%) [51]. Despite a high recurrence rate (23% to 57%), colonoscopy is often considered the initial procedure of choice in the absence of intestinal ischemia [52,53]. This may be reduced with the placement of a decompression tube beyond the splenic flexure [54]. In patients with mechanical obstruction, self-expanding metallic stents (SEMS) can be placed with good outcome [55]. In patients with nonmechanical obstruction, medical therapy with the parasympathomimetic agent neostigmine should be considered. On the basis of a double-blind, placebo-controlled, randomized trial, the parasympathomimetic agent neostigmine has been shown to reduce colonic distention significantly, reduce recurrence, and cause minimal risk [56]. This agent should only be given in the absence of contraindications and under close cardiorespiratory monitoring with atropine at the bedside. Percutaneous, endoscopic, or surgical cecostomy presents another alternative if the aforementioned interventions are unsuccessful.

COMPLICATIONS

Although major complications of endoscopic procedures are infrequent, critically ill patients may be particularly sensitive to adverse outcomes due to multiple comorbidities. Complications can be divided into two groups: (i) general complications and (ii) specific complications (Table 13.4).

FUTURE DIRECTIONS

With the start of the new millennium, rapid advances have been made in the development of new techniques [57]. Natural orifice transluminal endoscopic surgery (NOTES) is such

TABLE 13.4

COMPLICATIONS OF ENDOSCOPY

General complications
Complications of conscious sedation (cardiopulmonary, allergic, paradoxical reactions)
Bleeding (e.g., treatment of lesions, sphincterotomy)
Perforation (caused by endoscope, accessories, or air insufflation)
Aspiration
Myocardial ischemia
Specific complications (examples)
Endoscopic retrograde cholangiopancreatography: Pancreatitis, cholangitis, perforation
Sclerotherapy: Ulceration, mediastinitis
Stenting procedures: Stent migration

a technique. It involves the use of a natural orifice (such as stomach, rectum, vagina, or urethra) for intraperitoneal access to perform a variety of procedures in the retroperitoneum, such as liver biopsy, cystogastrostomy, appendectomy, cholecystectomy, nephrectomy, and tubal ligation. In the ICU setting, this type of a procedure is being evaluated for a number of potential scenarios: (i) the evaluation of suspected abdominal sepsis and ischemia at the bedside [58]; (ii) the feasibility of transgastric mapping of the diaphragm and implantation of a percutaneous electrode for therapeutic diaphragmatic stimulation in difficult-to-wean ICU patients [59]; and (iii) direct J-tube placement in selected patients without the need for surgery. Whatever role NOTES will have in the future of the critical care population, it is already changing how we approach a number of GI problems and will be a part of the ever-evolving management of the critically ill population in the future to expedite and improve their care.

CHAPTER 14 ■ PARACENTESIS AND DIAGNOSTIC PERITONEAL LAVAGE

LENA M. NAPOLITANO

ABDOMINAL PARACENTESIS

Indications

Abdominal paracentesis is a simple procedure that can be easily performed at the bedside in the intensive care unit and may provide important diagnostic information or therapy in critically ill patients with ascites. As a *diagnostic* intervention, abdominal paracentesis with removal of 20 mL of peritoneal fluid is performed to determine the etiology of the ascites or to ascertain whether infection is present, as in spontaneous bacterial peritonitis [1]. It can also be used in any clinical situation in which the analysis of a sample of peritoneal fluid might be useful in ascertaining a diagnosis and guiding therapy. The evaluation of ascites should therefore include a diagnostic paracentesis with ascitic fluid analysis.

As a *therapeutic* intervention, abdominal paracentesis is usually performed to drain large volumes of abdominal ascites, termed large-volume paracentesis (LVP), with removal of more than 5 L of ascitic fluid [2]. Ascites is the most common presentation of decompensated cirrhosis, and its development heralds a poor prognosis, with a 50% 2-year survival rate. Effective first-line therapy for ascites includes sodium restriction (2 g per day), use of diuretics, and LVP. When tense or refractory ascites is present, LVP is safe and effective, and has the advantage of producing immediate relief from ascites and its associated symptoms [3]. LVP can be palliative by diminishing abdominal pain from distention or improving pulmonary function by allowing better diaphragmatic excursion in patients who have ascites refractory to aggressive medical management. LVP is also used for percutaneous decompression of resuscitation-induced abdominal compartment syndrome related to the development of acute tense ascites [4].

Refractory ascites occurs in 10% of patients with cirrhosis and is associated with substantial morbidity and a 1-year survival of less than 50% [5,6]. For patients with refractory ascites, transjugular intrahepatic portosystemic shunt (TIPS) is superior to LVP for long-term control of ascites, but it is associated with greater encephalopathy risk and does not affect mortality [7,8].

Techniques

Before abdominal paracentesis is initiated, a catheter must be inserted to drain the urinary bladder, and correction of any underlying coagulopathy or thrombocytopenia should be considered. A consensus statement from the International Ascites Club states that "there are no data to support the correction of mild coagulopathy with blood products prior to therapeutic paracentesis, but caution is needed when severe thrombocytopenia is present" [3]. The practice guideline from the American Association for the Study of Liver Diseases states that routine correction of prolonged prothrombin time or thrombocytopenia is not required when experienced personnel perform paracentesis [9]. This has been confirmed in a study of 1,100 LVPs in 628 patients [10]. But in critically ill patients, there is still uncertainty as to the optimal platelet count and prothrombin time for the safe conduct of paracentesis.

The patient must next be positioned correctly. In critically ill patients, the procedure is performed in the supine position with the head of the bed elevated at 30 to 45 degrees. If the patient is clinically stable and therapeutic LVP is being performed, the patient can be placed in the sitting position, leaning slightly forward, to increase the total volume of ascites removed.

The site for paracentesis on the anterior abdominal wall is then chosen (Fig. 14.1). The preferred site is in the lower

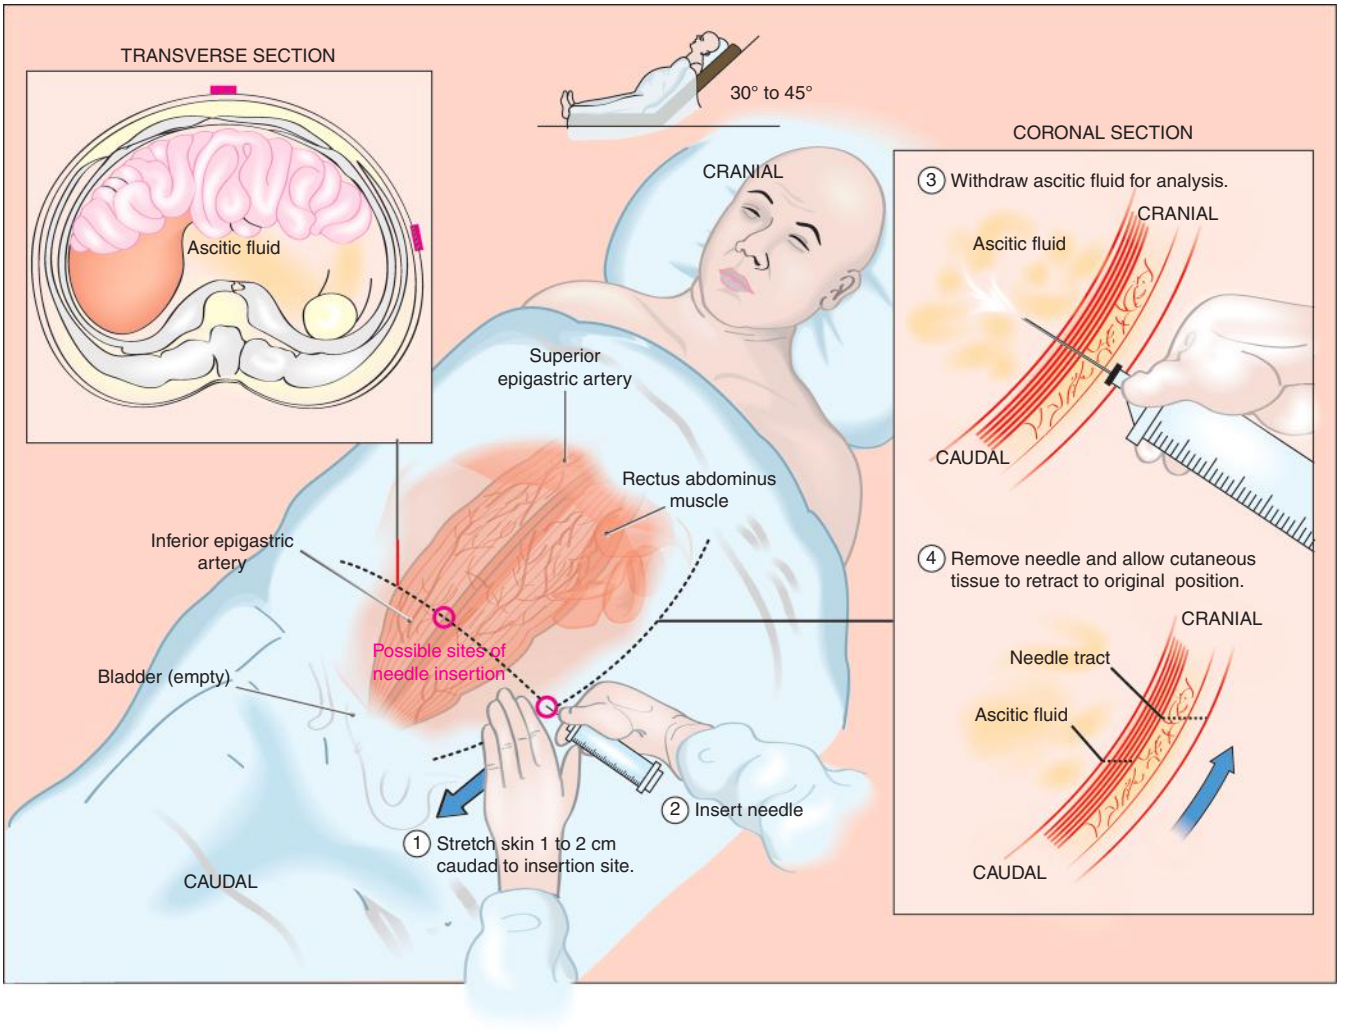

FIGURE 14.1. Suggested sites for paracentesis.

abdomen, just lateral to the rectus abdominis muscle and inferior to the umbilicus. It is important to stay lateral to the rectus abdominis muscle to avoid injury to the inferior epigastric artery and vein. In patients with chronic cirrhosis and caput medusae (engorged anterior abdominal wall veins), these visible vascular structures must be avoided. Injury to these veins can cause significant bleeding because of the underlying portal hypertension and may result in hemoperitoneum. The left lower quadrant of the abdominal wall is preferred over the right lower quadrant for abdominal paracentesis because critically ill patients often have cecal distention. The ideal site is therefore in the left lower quadrant of the abdomen, lateral to the rectus abdominis muscle in the midclavicular line and inferior to the umbilicus. It has also been determined that the left lower quadrant is significantly thinner and the depth of ascites greater compared with the infraumbilical midline position, confirming the left lower quadrant as the preferred location for paracentesis [11].

If the patient had previous abdominal surgery limited to the lower abdomen, it may be difficult to perform a paracentesis in the lower abdomen and the upper abdomen may be chosen. The point of entry, however, remains lateral to the rectus abdominis muscle in the midclavicular line. If there is concern that the ascites is loculated because of a previous abdominal surgery or peritonitis, abdominal paracentesis should be performed under ultrasound guidance to prevent iatrogenic complications.

Abdominal paracentesis can be performed by the needle technique, by the catheter technique, or with ultrasound guidance. Diagnostic paracentesis usually requires 20 to 50 mL peritoneal fluid and is commonly performed using the needle technique. However, if large volumes of peritoneal fluid are required, the catheter technique is used because it is associated with a lower incidence of complications. LVP should always be performed with the catheter technique. Ultrasound guidance can be helpful in diagnostic paracentesis using the needle technique or in LVP using the catheter technique.

Needle Technique

With the patient in the appropriate position and the access site for paracentesis determined, the patient's abdomen is prepared with 2% chlorhexidine and sterile aseptic technique is used. If necessary, intravenous sedation is administered to prevent the patient from moving excessively during the procedure (see Chapter 20). Local anesthesia, using 1% or 2% lidocaine with 1:200,000 epinephrine, is infiltrated into the site. A skin wheal is created with the local anesthetic, using a short 25- or 27-gauge needle. Then, using a 22-gauge, 1.5-in. needle, the local anesthetic is infiltrated into the subcutaneous tissues and anterior abdominal wall, with the needle perpendicular to the skin. Before the anterior abdominal wall and peritoneum are infiltrated, the skin is pulled taut inferiorly, allowing the peritoneal cavity to be entered at a different location than the skin entrance site, thereby decreasing the chance of ascitic leak. This is known as the *Z-track technique*. While tension is maintained inferiorly on the abdominal skin, the needle is advanced

through the abdominal wall fascia and peritoneum, and local anesthetic is injected. Intermittent aspiration identifies when the peritoneal cavity is entered, with return of ascitic fluid into the syringe. The needle is held securely in this position with the left hand, and the right hand is used to withdraw approximately 20 to 50 mL ascitic fluid into the syringe for a diagnostic paracentesis.

Once adequate fluid is withdrawn, the needle and syringe are withdrawn from the anterior abdominal wall and the paracentesis site is covered with a sterile dressing. The needle is removed from the syringe, because it may be contaminated with skin organisms. A small amount of peritoneal fluid is sent in a sterile container for Gram stain and 10 mL is inoculated into blood culture bottles immediately at bedside for culture and sensitivity. The remainder of the fluid is sent for appropriate studies, which may include cytology, cell count and differential, protein, specific gravity, amylase, pH, lactate dehydrogenase, bilirubin, triglycerides, and albumin. A serum to ascites albumin gradient (SAAG) greater than 1.1 g per dL is indicative of portal hypertension and cirrhosis (Table 14.1) [12]. Peritoneal fluid can be sent for smear and culture for acid-fast bacilli if tuberculous peritonitis is in the differential diagnosis.

TABLE 14.1

ETIOLOGIES OF ASCITES BASED ON NORMAL OR DISEASED PERITONEUM AND SERUM TO ASCITES ALBUMIN GRADIENT (SAAG)

Normal peritoneum	
Portal hypertension (SAAG > 1.1 g/dL)	
Hepatic congestion	
	Congestive heart failure
	Constrictive pericarditis
	Tricuspid insufficiency
	Budd–Chiari syndrome
Liver disease	
	Cirrhosis
	Alcoholic hepatitis
	Fulminant hepatic failure
	Massive hepatic metastases
Hypoalbuminemia (SAAG < 1.1 g/dL)	
	Nephrotic syndrome
	Protein-losing enteropathy
	Severe malnutrition with anasarca
Miscellaneous conditions (SAAG < 1.1 g/dL)	
	Chylous ascites
	Pancreatic ascites
	Bile ascites
	Nephrogenic ascites
	Urine ascites
	Ovarian disease
Diseased peritoneum infections (SAAG < 1.1 g/dL)	
	Bacterial peritonitis
	Tuberculous peritonitis
	Fungal peritonitis
	HIV-associated peritonitis
Malignant conditions	
	Peritoneal carcinomatosis
	Primary mesothelioma
	Pseudomyxoma peritonei
	Hepatocellular carcinoma
Other rare conditions	
	Familial Mediterranean fever
	Vasculitis
	Granulomatous peritonitis
	Eosinophilic peritonitis

Catheter Technique

Positioning, use of aseptic technique, and local anesthetic infiltration are the same as for the needle technique. A 22-gauge, 1.5-in. needle attached to a 10-mL syringe is used to document the free return of peritoneal fluid into the syringe at the chosen site. This needle is removed from the peritoneal cavity and a catheter-over-needle assembly is used to gain access to the peritoneal cavity. If the anterior abdominal wall is thin, an 18- or 20-gauge Angiocath can be used as the catheter-over-needle assembly. If the anterior abdominal wall is quite thick, as in obese patients, it may be necessary to use a long (5.25-in., 18- or 20-gauge) catheter-over-needle assembly or a percutaneous single- or multiple-lumen central venous catheter (18- or 20-gauge) and gain access to the peritoneal cavity using the Seldinger technique.

The peritoneal cavity is entered as for the needle technique. The catheter-over-needle assembly is inserted perpendicular to the anterior abdominal wall using the Z-track technique; once peritoneal fluid returns into the syringe barrel, the catheter is advanced over the needle, the needle is removed, and a 20- or 50-mL syringe is connected to the catheter. The tip of the catheter is now in the peritoneal cavity and can be left in place until the appropriate amount of peritoneal fluid is removed. This technique, rather than the needle technique, should be used when LVP is performed, because complications (e.g., intestinal perforation) may occur if a needle is left in the peritoneal space for an extended period.

When the Seldinger technique is used in patients with a large anterior abdominal wall, access to the peritoneal cavity is initially gained with a needle or catheter-over-needle assembly. A guidewire is then inserted through the needle and an 18- or 20-gauge single- or multiple-lumen central venous catheter is threaded over the guidewire. It is very important to use the Z-track method for the catheter technique to prevent development of an ascitic leak, which may be difficult to control and may predispose the patient to peritoneal infection.

Ultrasound Guidance Technique

Patients who have had previous abdominal surgery or peritonitis are predisposed to abdominal adhesions, and it may be quite difficult to gain free access into the peritoneal cavity for diagnostic or therapeutic paracentesis. Ultrasound-guided paracentesis can be very helpful in this population, and in patients where the traditional technique fails, by providing accurate localization of the peritoneal fluid collection and determining the best abdominal access site. This procedure can be performed using the needle or catheter technique as described earlier in the chapter, depending on the volume of peritoneal fluid to be drained. Once the fluid collection is localized by the ultrasound probe, the abdomen is prepared and draped in the usual sterile fashion. A sterile sleeve can be placed over the ultrasound probe so that there is direct real-time ultrasound visualization of the needle or catheter as it enters the peritoneal cavity. The needle or catheter is thus directed to the area to be drained, and the appropriate amount of peritoneal or ascitic fluid is removed. If continued drainage of a loculated peritoneal fluid collection is desired, the radiologist can place a chronic indwelling peritoneal catheter using a percutaneous guidewire technique (see Chapter 22).

The use of ultrasound guidance for drainage of loculated peritoneal fluid collections has markedly decreased the incidence of iatrogenic complications related to abdominal paracentesis. If the radiologist does not identify loculated ascites on the initial ultrasound evaluation and documents a large amount of peritoneal fluid that is free in the abdominal cavity, he or she can then indicate the best access site by marking the anterior

abdominal wall with an indelible marker. The paracentesis can then be performed by the clinician and repeated whenever necessary. This study can be performed at the bedside in the intensive care unit with a portable ultrasound unit. A video for the correct procedural technique for paracentesis is available for review [13].

Complications

The most common complications related to abdominal paracentesis are bleeding and persistent ascitic leak. Because most patients in whom ascites have developed also have some component of chronic liver disease with associated coagulopathy and thrombocytopenia, it is very important to consider correction of any underlying coagulopathy before proceeding with abdominal paracentesis. In addition, it is very important to select an avascular access site on the anterior abdominal wall. The Z-track technique is very helpful in minimizing persistent ascitic leak and should always be used. Another complication associated with abdominal paracentesis is intestinal or urinary bladder perforation, with associated peritonitis and infection. Intestinal injury is more common when the needle technique is used. Because the needle is free in the peritoneal cavity, iatrogenic intestinal perforation may occur if the patient moves or if intra-abdominal pressure increases with Valsalva maneuver or coughing. Urinary bladder injury is less common and underscores the importance of draining the urinary bladder with a catheter before the procedure. This injury is more common when the abdominal access site is in the suprapubic location; therefore, this access site is not recommended. Careful adherence to proper technique of paracentesis minimizes associated complications.

In patients who have large-volume chronic abdominal ascites, such as that secondary to hepatic cirrhosis or ovarian carcinoma, transient hypotension and paracentesis-induced circulatory dysfunction (PICD) may develop during LVP. PICD is characterized by worsening hypotension and arterial vasodilation, hyponatremia, azotemia, and an increase in plasma renin activity. Evidence is accumulating that PICD is secondary to an accentuation of an already established arteriolar vasodilation with multiple etiologies, including the dynamics of paracentesis (the rate of ascitic fluid extraction), release of nitric oxide from the vascular endothelium, and mechanical modifications due to abdominal decompression [14].

PICD is associated with increased mortality and may be prevented with the administration of plasma expanders. It is very important to obtain reliable peripheral or central venous access in these patients so that fluid resuscitation can be performed if PICD develops during the procedure. A study randomized 72 patients to receive albumin or saline after total paracentesis [15]. The incidence of PICD was significantly higher in the saline group compared with the albumin group (33.3% vs. 11.4%, $p = 0.03$). However, no significant differences were found when less than 6 L of ascitic fluid was evacuated (6.7% vs. 5.6%, $p = 0.9$). Significant increases in plasma renin activity were found 24 hours and 6 days after paracentesis when saline was used, whereas no changes were observed with albumin. Albumin was more effective than saline in the prevention of PICD, but it is not required when less than 6 L of ascitic fluid is evacuated. Therefore, the administration of albumin intravenously (6 to 8 g per L of ascites removed) is recommended with LVP (>6 L).

There have been nine prospective randomized controlled trials ($n = 806$) on the use of plasma expanders for therapeutic paracentesis [1]. In a recent systematic review, there was no significant difference between therapeutic paracentesis with or without volume expansion with albumin, nor with nonalbumin plasma expanders compared with albumin for hyponatremia, renal impairment, encephalopathy, or death. However, these studies did not specifically examine prevention of PICD (defined by an increase in plasma renin activity or aldosterone concentration), and some studies have determined that albumin prevented PCID more effectively than synthetic plasma expanders [15,16].

Randomized trials comparing terlipressin (a vasoconstrictor) with albumin in PICD in cirrhosis documented that both terlipressin and albumin prevented paracentesis-induced renal impairment in these patients [17,18]. Terlipressin may be as effective as intravenous albumin in preventing PICD in patients with cirrhosis. Midodrine and octreotide in combination or alone have shown conflicting results for improving systemic and renal hemodynamics and renal function in patients with cirrhosis-related complications, including the prevention of PICD, and additional studies are warranted [19].

LVP is only transiently therapeutic; the underlying chronic disease induces reaccumulation of the ascites. Percutaneous placement of a tunneled catheter is a viable and safe technique to consider in patients who have symptomatic malignant ascites that require frequent therapeutic paracentesis for relief of symptoms [20].

DIAGNOSTIC PERITONEAL LAVAGE

Before the introduction of diagnostic peritoneal lavage (DPL) by Root et al. [21] in 1965, nonoperative evaluation of the injured abdomen was limited to standard four-quadrant abdominal paracentesis. Abdominal paracentesis for the evaluation of hemoperitoneum was associated with a high false-negative rate. This clinical suspicion was confirmed by Giacobine and Siler [22] in an experimental animal model of hemoperitoneum documenting that a 500-mL blood volume in the peritoneal cavity yielded a positive paracentesis rate of only 78%. The initial study by Root et al. [21] reported 100% accuracy in the identification of hemoperitoneum using 1-L peritoneal lavage fluid. Many subsequent clinical studies confirmed these findings, with the largest series reported by Fischer et al. [23] in 1978. They reviewed 2,586 cases of DPL and reported a false-positive rate of 0.2%, false-negative rate of 1.2%, and overall accuracy of 98.5%. Since its introduction in 1965, DPL has been a cornerstone in the evaluation of hemoperitoneum due to blunt and penetrating abdominal injuries. However, it is nonspecific for determination of the type or extent of organ injury.

Recent advances have led to the use of ultrasound (focused assessment with sonography in trauma [FAST]; Fig. 14.2) and rapid helical computed tomography (CT) in the emergent evaluation of abdominal trauma and have significantly decreased the use of DPL in the evaluation of abdominal trauma to less than 1% [24–26]. FAST has replaced DPL as the initial screening modality of choice for severe abdominal trauma in more than 80% of North American centers surveyed [27] and FAST is now taught in the Advanced Trauma Life Support course [28]. Practice management guidelines from the Eastern Association for the Surgery of Trauma recommend FAST be considered the initial diagnostic modality to exclude hemoperitoneum [29]. DPL remains a valuable adjunct to modern imaging techniques in early trauma assessment, particularly in hemodynamically unstable patients with initial FAST examination that is negative or equivocal and in the assessment of potential hollow visceral injury in blunt abdominal trauma [30]. Diagnostic peritoneal aspiration, without a full lavage, has also been utilized successfully in these circumstances [31].

Indications

The primary indication for DPL is evaluation of blunt abdominal trauma in patients with associated hypotension. If the initial

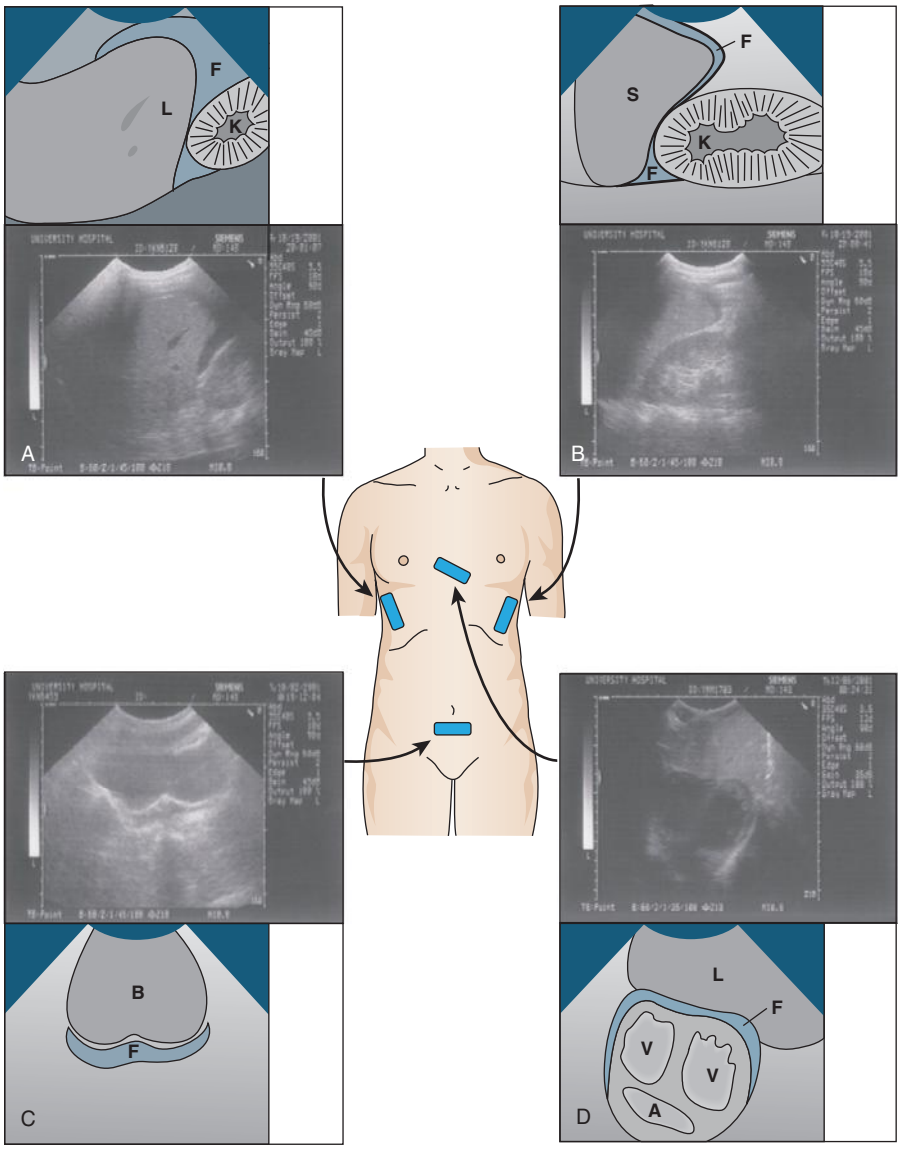

FIGURE 14.2. The FAST examination.

FAST examination is positive for hemoperitoneum, surgical intervention (laparotomy) is required. If the FAST examination is negative or equivocal, DPL should be considered. If the patient is hemodynamically stable and can be transported safely, CT scan of the abdomen and pelvis is the diagnostic method of choice. If the patient is hemodynamically unstable or requires emergent surgical intervention for a craniotomy, thoracotomy, or vascular procedure, it is imperative to determine whether there is a coexisting intraperitoneal source of hemorrhage to prioritize treatment of life-threatening injuries. FAST or DPL can be used to diagnose hemoperitoneum in patients with multisystem injury, who require general anesthesia for the treatment of associated traumatic injuries. Patients with associated thoracic or pelvic injuries should also have definitive evaluation for abdominal trauma, and DPL can be used in these individuals. DPL can also be used to evaluate for traumatic hollow viscus injury, and a cell count ratio (defined as the ratio between white blood cell (WBC) and red blood cell (RBC) count in the lavage fluid divided by the ratio of the same parameters in the peripheral blood) less than or equal to 1 has a specificity of 97% and sensitivity of 100% [32].

DPL can also be used to evaluate penetrating abdominal trauma; however, its role differs from that in blunt abdominal trauma [33]. A hemodynamically unstable patient with abdominal penetrating injury requires no further investigation and immediate laparotomy should be undertaken. Instead, the role of DPL in the *hemodynamically stable* patient with penetrating abdominal injury is to identify hemoperitoneum and hollow viscus or diaphragmatic injury. DPL has also been recommended as the initial diagnostic study in stable patients with penetrating trauma to the back and flank, defining an RBC count greater than 1,000 per μL as a positive test [34]. Implementation of this protocol decreased the total celiotomy rate from 100% to 24%, and the therapeutic celiotomy rate increased from 15% to 80%.

DPL may prove to be useful in evaluation for possible peritonitis or ruptured viscus in patients with an altered level of consciousness but no evidence of traumatic injury. DPL can be considered in critically ill patients with sepsis to determine if intra-abdominal infection is the underlying source. When DPL is used to evaluate intra-abdominal infection, a WBC count greater than 500 per μL of lavage fluid is considered positive. DPL can also serve a therapeutic role. It is very effective in rewarming patients with significant hypothermia. It may potentially be used therapeutically in pancreatitis, fecal peritonitis, and bile pancreatitis, but multiple clinical studies have not documented its efficacy in these cases.

DPL should not be performed in patients with clear signs of significant abdominal trauma and hemoperitoneum associated with hemodynamic instability. These patients should undergo emergent celiotomy. Pregnancy is a relative contraindication to DPL; it may be technically difficult to perform because of the gravid uterus and is associated with a higher risk of complications. Bedside ultrasound evaluation of the abdomen in the pregnant trauma patient is associated with least risk to the woman and to the fetus. An additional relative contraindication to DPL is multiple previous abdominal surgeries. These patients commonly have multiple abdominal adhesions, and it may be very difficult to gain access to the free peritoneal cavity. If DPL is indicated, it must be performed by the open technique to prevent iatrogenic complications such as intestinal injury.

Techniques

Three techniques can be used to perform DPL: (i) the closed percutaneous technique, (ii) the semiclosed technique, and (iii) the open technique. The closed percutaneous technique, introduced by Lazarus and Nelson [35] in 1979, is easy to perform, can be done rapidly, is associated with a low complication rate, and is as accurate as the open technique. It should not be used in patients who have had previous abdominal surgery or a history of abdominal adhesions. The open technique entails the placement of the peritoneal lavage catheter into the peritoneal cavity under direct visualization. It is more time consuming than the closed percutaneous technique. The semiclosed technique requires a smaller incision than does the open technique and uses a peritoneal lavage catheter with a metal stylet to gain entrance into the peritoneal cavity. It has become less popular as clinicians have become more familiar and skilled with the Lazarus–Nelson closed technique.

The patient is placed in the supine position for all three techniques. A catheter is placed into the urinary bladder and a nasogastric tube is inserted into the stomach to prevent iatrogenic bladder or gastric injury. The nasogastric tube is placed on continuous suction for gastric decompression. The skin of the anterior abdominal wall is prepared with 2% chlorhexidine solution and sterilely draped, leaving the periumbilical area exposed. Standard aseptic technique is used throughout the procedure. Local anesthesia with 1% or 2% lidocaine with 1:200,000 epinephrine is used as necessary throughout the procedure. The infraumbilical site is used unless there is clinical concern of possible pelvic fracture and retroperitoneal or pelvic hematoma, in which case the supraumbilical site is optimal.

Closed Percutaneous Technique

With the closed percutaneous technique, local anesthesia is infiltrated inferior to the umbilicus and a 5-mm skin incision is made just at the inferior umbilical edge. An 18-gauge needle is inserted through this incision and into the peritoneal cavity, angled toward the pelvis at approximately a 45-degree angle with the skin. The penetration through the linea alba and then through the peritoneum is felt as two separate "pops." A J-tipped guidewire is passed through the needle and into the peritoneal cavity, again directing the wire toward the pelvis by maintaining the needle at a 45-degree angle to the skin. The 18-gauge needle is then removed and the DPL catheter inserted over the guidewire into the peritoneal cavity, using a twisting motion and guided inferiorly toward the pelvis. The guidewire is then removed, and a 10-mL syringe is attached to the catheter for aspiration. If free blood returns from the DPL catheter before the syringe is attached or if gross blood returns in the syringe barrel, hemoperitoneum has been documented, the catheter is removed, and the patient is quickly transported to the operating room for emergent celiotomy. If no gross blood returns on aspiration through the catheter, peritoneal lavage is performed using 1 L Ringer's lactate solution or normal saline that has been previously warmed to prevent hypothermia. The fluid is instilled into the peritoneal cavity through the DPL catheter; afterward, the peritoneal fluid is allowed to drain out of the peritoneal cavity by gravity until the fluid return slows. A minimum of 250 mL lavage fluid is considered a representative sample of the peritoneal fluid [36]. A sample is sent to the laboratory for determination of RBC count, WBC count, amylase concentration, and presence of bile, bacteria, or particulate matter. When the lavage is completed, the catheter is removed and a sterile dressing applied over the site. Suture approximation of the skin edges is not necessary when the closed technique is used for DPL.

Semiclosed Technique

Local anesthetic is infiltrated in the area of the planned incision and a 2- to 3-cm vertical incision made in the infraumbilical or supraumbilical area. The incision is continued sharply down through the subcutaneous tissue and linea alba, and the peritoneum is then visualized. Forceps, hemostats, or Allis clamps are used to grasp the edges of the linea alba and elevate the fascial edges to prevent injury to the underlying abdominal structures. The DPL lavage catheter with a metal inner stylet is inserted through the closed peritoneum into the peritoneal cavity at a 45-degree angle to the anterior abdominal wall, directed toward the pelvis. When the catheter–metal stylet assembly is in the peritoneal cavity, the DPL catheter is advanced into the pelvis and the metal stylet removed. A 10-mL syringe is attached to the catheter, and aspiration is conducted as previously described. When the lavage is completed, the fascia must be reapproximated with sutures, the skin closed, and a sterile dressing applied.

Open Technique

After the administration of appropriate local anesthetic, a vertical midline incision approximately 3 to 5 cm long is made. This incision is commonly made in the infraumbilical location, but in patients with presumed pelvic fractures or retroperitoneal hematomas or in pregnant patients, a supraumbilical location is preferred. The vertical midline incision is carried down through the skin, subcutaneous tissue, and linea alba under direct vision. The linea alba is grasped on either side using forceps, hemostats, or Allis clamps, and the fascia is elevated to prevent injury to the underlying abdominal structures. The peritoneum is identified, and a small vertical peritoneal incision is made to gain entrance into the peritoneal cavity. The DPL catheter is then inserted into the peritoneal cavity under direct visualization and advanced inferiorly toward the pelvis. It is inserted without the stylet or metal trocar. When in position, a 10-mL syringe is attached for aspiration. If aspiration of the peritoneal cavity is negative (i.e., no gross blood returns), peritoneal lavage is performed, as described earlier in the chapter. As in the semiclosed technique, the fascia and skin must be reapproximated to prevent dehiscence or evisceration, or both.

A prospective randomized study documented that the Lazarus–Nelson technique of closed percutaneous DPL can be performed faster than the open procedure [37]. The procedure times with the closed technique varied from 1 to 3 minutes, compared with 5 to 24 minutes for the open technique. It was documented that the closed percutaneous technique was as accurate as the open procedure and was associated with a lower incidence of wound infections and complications. The closed percutaneous technique, using the Seldinger technique, should therefore be used initially in all patients except those who have had previous abdominal surgery or in pregnant patients. This has been confirmed in a study of 2,501 DPLs performed over a 75-month period for blunt or penetrating

abdominal trauma [38]. The majority (2,409, or 96%) were performed using the closed percutaneous technique, and 92 (4%) were done open because of pelvic fractures, previous scars, or pregnancy. Open DPL was less sensitive than closed DPL in patients who sustained blunt trauma (90% vs. 95%), but slightly more sensitive in determining penetration (100% vs. 96%). Overall, there were few (21, or 0.8%) complications, and the overall sensitivity, specificity, and accuracy were 95%, 99%, and 98%, respectively, using an RBC count of 100,000 per μL in blunt trauma and 10,000 per μL in penetrating trauma as the positive threshold. A meta-analysis concluded that the closed DPL technique is comparable to the standard open DPL technique in terms of accuracy and major complications, with the advantage of reduced performance time with closed DPL, which is offset by increased technical difficulties and failures [39].

A DPL modification [40] that resulted in more rapid infusion and drainage of lavage fluid used cystoscopy irrigation tubing for instillation and drainage of the lavage fluid, saving an average of 19 minutes per patient for the DPL completion. This modification can be applied to the closed percutaneous or open DPL technique to decrease the procedure time in critically ill patients.

Interpretation of Results

The current guidelines for interpretation of positive and negative results of DPL are provided in Table 14.2. A positive result can be estimated by the inability to read newsprint or typewritten print through the lavage fluid as it returns through clear plastic tubing. This test is not reliable, however, and a quantitative RBC count in a sample of the peritoneal lavage fluid must be performed [41]. For patients with nonpenetrating abdominal trauma, an RBC count greater than 100,000 per μL of lavage fluid is considered positive and requires emergent celiotomy. Fewer than 50,000 RBCs per μL is considered negative and RBC counts of 50,000 to 100,000 per μL are considered indeterminate. The guidelines for patients with penetrating abdominal trauma are much less clear with clinical studies using an RBC count of greater than 1,000 or 10,000 per μL to greater than 100,000 per μL as the criterion for a positive DPL in patients with penetrating thoracic or abdominal trauma. The lower the threshold the more sensitive the test, but the higher the nontherapeutic laparotomy rate.

Determination of hollow viscus injury by DPL is much more difficult. A WBC count greater than 500 per μL of lavage fluid or an amylase concentration greater than 175 units per dL of lavage fluid is usually considered positive. These studies, however, are not as accurate as the use of RBC count in the lavage fluid to determine the presence of hemoperitoneum. One study in patients with blunt abdominal trauma determined that the WBC count in lavage fluid has a positive predictive value of only 23% and probably should not be used as an indicator of a positive DPL [42]. Other studies analyzed alkaline phosphatase levels in DPL fluid to determine if this assay is helpful in the diagnosis of hollow viscus injuries [43,44], but the results have been variable. A prospective study used a diagnostic algorithm of initial abdominal ultrasound, followed by helical CT and subsequent DPL (if CT was suggestive of blunt bowel or mesenteric injury) using a cell count ratio (defined as the ratio between WBC and RBC count in the lavage fluid divided by the ratio of the same parameters in the peripheral blood) greater than or equal to 1 to determine the need for laparotomy in patients with blunt abdominal injuries [45]. This proposed algorithm had a high accuracy (100%) while requiring the performance of DPL in only a few (2%) patients.

It must be stressed that DPL is not accurate for determination of retroperitoneal visceral injuries or diaphragmatic injuries [46]. The incidence of false-negative DPL results is approximately 30% in patients who sustained traumatic diaphragmatic rupture. In addition, DPL is insensitive in detecting subcapsular hematomas of the spleen or liver that are contained, with no evidence of hemoperitoneum. Although DPL is now used in the evaluation of nontraumatic intra-abdominal pathology, the criteria for positive lavage in these patients have not yet been established. Additional clinical studies are needed.

TABLE 14.2

INTERPRETATION OF DIAGNOSTIC PERITONEAL LAVAGE RESULTS

POSITIVE
Nonpenetrating abdominal trauma
Immediate gross blood return via catheter
Immediate return of intestinal contents or food particles
Aspiration of 10 mL blood via catheter
Return of lavage fluid via chest tube or urinary catheter
Red blood cell (RBC) count >100,000/μL
White blood cell (WBC) count >500/μL
Cell count ratio (defined as the ratio between WBC and RBC count in the lavage fluid divided by the ratio of the same parameters in the peripheral blood) ≥1
Amylase >175 U/100 mL
Penetrating abdominal trauma
Immediate gross blood return via catheter
Immediate return of intestinal contents or food particles
Aspiration of 10 mL blood via catheter
Return of lavage fluid via chest tube or Foley catheter
RBC count used is variable, from >1,000/μL to >100,000/μL
WBC count >500/μL
Amylase >175 U/100 mL
NEGATIVE
Nonpenetrating abdominal trauma
RBC count <50,000/μL
WBC count <100/μL
Cell count ratio (defined as the ratio between WBC and RBC count in the lavage fluid divided by the ratio of the same parameters in the peripheral blood) <1
Amylase <75 U/100 mL
Penetrating abdominal trauma
RBC count used is variable, from <1,000/μL to <50,000/μL
WBC count <100/μL
Amylase <75 U/100 mL

Complications

Complications of DPL by the techniques described here include malposition of the lavage catheter, injury to the intra-abdominal organs or vessels, iatrogenic hemoperitoneum, wound infection or dehiscence, evisceration, and possible unnecessary laparotomy. DPL is a very valuable technique, however, and if it is performed carefully, with attention to detail, these complications are minimized. In the largest series published to date, with more than 2,500 DPLs performed, the complications rate was 0.8% [38]. Wound infection, dehiscence, and evisceration are more common with the open technique; therefore, the closed percutaneous technique is recommended in all patients who do not have a contraindication to this technique. Knowledge of all techniques is necessary, however, because the choice of technique should be based on the individual patient's presentation.

CHAPTER 15 ■ GASTROESOPHAGEAL BALLOON TAMPONADE FOR ACUTE VARICEAL HEMORRHAGE

MARIE T. PAVINI AND JUAN CARLOS PUYANA

Gastroesophageal variceal hemorrhage is an acute and catastrophic complication that occurs in one-third to one-half of patients with portal pressures greater than 12 mm Hg [1]. Because proximal gastric varices and varices in the distal 5 cm of the esophagus lie in the superficial lamina propria, they are more likely to bleed and respond to endoscopic treatment [2]. Variceal rupture is likely a factor of size, wall thickness, and portal pressure, and may be predicted by Child-Pugh class, red wale markings indicating epithelial thickness, and variceal size [1]. Although urgent endoscopy, sclerotherapy, and band ligations are considered first-line treatments, balloon tamponade remains a valuable intervention in the treatment of bleeding esophageal varices. Balloon tamponade is accomplished using a multilumen tube, approximately 1 m in length, with esophageal and gastric cuffs that can be inflated to compress esophageal varices and gastric submucosal veins, thereby providing hemostasis through tamponade, while incorporating aspiration ports for diagnostic and therapeutic usage.

HISTORICAL DEVELOPMENT

In 1930, Westphal described the use of an esophageal sound as a means of controlling variceal hemorrhage. In 1947, successful control of hemorrhage by balloon tamponade was achieved by attaching an inflatable latex bag to the end of a Miller–Abbot tube. In 1949, a two-balloon tube was described by Patton and Johnson. A triple-lumen tube with gastric and esophageal balloons, as well as a port for gastric aspiration, was described by Sengstaken and Blakemore in 1950. In 1955, Linton and Nachlas engineered a tube with a larger gastric balloon capable of compressing the submucosal veins in the cardia, thereby minimizing flow to the esophageal veins, with suction ports above and below the balloon. The Minnesota tube was described in 1968 as a modification of the Sengstaken–Blakemore tube, incorporating the esophageal suction port, which will be described later. Several studies have published combined experience with tubes such as the Linton–Nachlas tube; however, the techniques described here are limited to the use of the Minnesota and Sengstaken–Blakemore tubes.

ROLE OF BALLOON TAMPONADE IN THE MANAGEMENT OF BLEEDING ESOPHAGEAL VARICES

Treatment of portal hypertension to prevent variceal rupture includes primary and secondary prophylaxis. Primary prophylaxis consists of beta-blockers, band ligation, and endoscopic surveillance, whereas secondary prophylaxis includes nitrates, transjugular intrahepatic portosystemic shunt (TIPS), and surgical shunt [3]. Management of acute variceal bleeding involves multiple simultaneous and sequential modalities. Balloon tamponade is considered a temporary bridge within these modalities. Self-expanding metal stents as an alternative to balloon tamponade are currently under investigation [4].

Splanchnic vasoconstrictors such as somatostatin, octreotide, terlipressin (the only agent shown to decrease mortality), or vasopressin (with nitrates to reduce cardiac side effects) decrease portal blood flow and pressure, and should be administered as soon as possible [5–7]. In fact, Pourriat et al. [8] advocate administration of octreotide by emergency medical personnel before patient transfer to the hospital. Recombinant activated factor VII has been reported to achieve hemostasis in bleeding esophageal varices unresponsive to standard treatment, and may also be considered [9]. Emergent therapeutic endoscopy in conjunction with pharmacotherapy is more effective than pharmacotherapy alone and is also performed as soon as possible. Band ligation has a lower rate of rebleeding and complications when compared with sclerotherapy, and should be performed preferentially, provided visualization is adequate to ligate varices successfully [3,10]. Tissue adhesives such as polidocanol and cyanoacrylate delivered through an endoscope are being used and studied outside the United States.

Balloon tamponade is performed to control massive variceal hemorrhage, with the hope that band ligation or sclerotherapy and secondary prophylaxis will then be possible (Fig. 15.1). If bleeding continues beyond these measures, TIPS [11] is considered. Shunt surgery [12] may be considered if TIPS is contraindicated. Other alternatives include percutaneous transhepatic embolization, emergent esophageal transection with stapling [13], esophagogastric devascularization with esophageal transection and splenectomy, and hepatic transplantation. If gastric varices are noted, therapeutic options include endoscopic administration of the tissue adhesive cyanoacrylate, TIPS, balloon-occluded retrograde transvenous obliteration [14], balloon-occluded endoscopic injection therapy [15], and devascularization with splenectomy, shunt surgery, and liver transplantation.

INDICATIONS AND CONTRAINDICATIONS

A Minnesota or Sengstaken–Blakemore tube is indicated in patients with a diagnosis of esophageal variceal hemorrhage, in which neither band ligation nor sclerotherapy is technically possible, readily available, or has failed [16]. If at all possible, making an adequate anatomic diagnosis is critical before

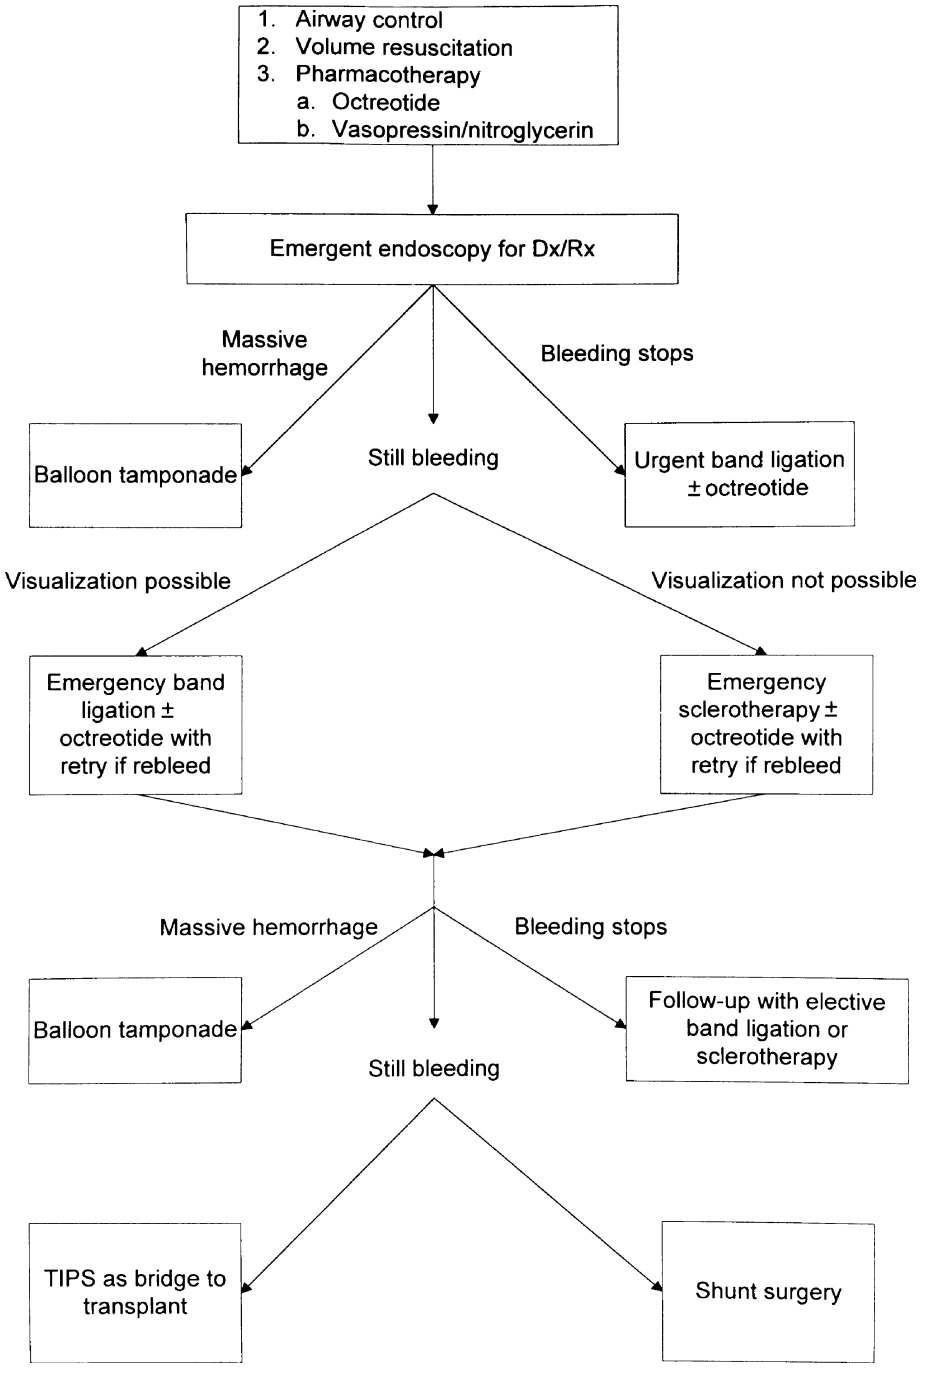

FIGURE 15.1. Management of esophageal variceal hemorrhage. Dx, diagnosis; Rx, therapy; TIPS, transjugular intrahepatic portosystemic shunt.

any of these balloon tubes are inserted. Severe upper gastrointestinal bleeding attributed to esophageal varices in patients with clinical evidence of chronic liver disease results from other causes in up to 40% of cases. The observation of a white nipple sign (platelet plug) is indicative of a recent variceal bleed. A balloon tube is contraindicated in patients with recent esophageal surgery or esophageal stricture [17]. Some authors do not recommend balloon tamponade when a hiatal hernia is present, but there are reports of successful hemorrhage control in some of these patients [18]. If there is no other option, it may be practical to titrate to the lowest effective balloon pressures especially if repeated endoscopic sclerotherapy has been performed as there is increased risk of esophageal perforation [19].

TECHNICAL AND PRACTICAL CONSIDERATIONS

Airway Control

Endotracheal intubation (see Chapter 1) is imperative in patients with upper gastrointestinal bleeding and hemodynamic compromise, encephalopathy, or both. The incidence of aspiration pneumonia is directly related to the presence of encephalopathy or impaired mental status [20]. Suctioning of pulmonary secretions and blood that accumulates in the hypopharynx is facilitated in patients who have been intubated.

Sedatives and analgesics are more readily administered in intubated patients, and may be required often because balloon tamponade is poorly tolerated in most patients and retching or vomiting may lead to esophageal rupture [21]. The incidence of pulmonary complications is significantly lower when endotracheal intubation is routinely used [22].

Hypovolemia, Shock, and Coagulopathy

Adequate intravenous access should be obtained with large-bore venous catheters for blood product administration and fluid resuscitation with crystalloids and colloids. A central venous catheter or pulmonary artery catheter may be required to monitor intravascular filling pressures, especially in patients with severe cirrhosis, advanced age, or underlying cardiac and pulmonary disease. Packed red blood cells should be administered keeping four to six units available in case of severe recurrent bleeding, which commonly occurs in these patients. Coagulopathies, thrombocytopenia, or qualitative platelet disorders should be treated emergently. Octreotide and other vasoconstrictive therapies should be initiated as indicated.

Clots and Gastric Decompression

If time permits, placement of an Ewald tube and aggressive lavage and suctioning of the stomach and duodenum facilitates endoscopy, diminishes the risk of aspiration, and may help control hemorrhage from causes other than esophageal varices. It should be removed prior to balloon tamponade.

Infection and Ulceration

Mortality is increased if infection is present in bleeding cirrhotic patients. The rate of early rebleeding is also increased in the presence of infection [23]. Prophylactic antibiotic use reduces the incidence of early rebleeding and increases survival [24]. Intravenous proton pump inhibitors are more efficacious than histamine-2-receptor antagonists in maintaining gastric pH at a goal of 7. Ulcers can form from sclerotherapy, banding, or direct cuff pressure during balloon tamponade. Shaheen et al. [25] found that the postbanding ulcers in patients receiving a proton pump inhibitor were two times smaller than those in patients who had not received a proton pump inhibitor.

Balloons, Ports, and Preparation

All lumens should be flushed to assure patency and the balloons inflated underwater to check for leaks. Two clean 100-mL (or larger) Foley-tip syringes and two to four rubber-shod hemostats should be readied for inflation of the balloons. To ensure that the gastric balloon will not be positioned in the esophagus, preinsertion compliance should be tested by placing 100-mL aliquots of air up to the listed maximum recommended volumes into the gastric inflation port while recording the corresponding pressures using a manometer attached to the gastric pressure port. In this way, postinsertion pressures can be compared. A portable handheld manometer allows for simpler continuous monitoring as well as patient transport and repositioning. If possible, a second manometer should be attached to the esophageal pressure port to facilitate inflation and continuous monitoring. Place a plug or hemostat on the other arm of the esophageal inflation port instead of a 100-mL syringe as the manometer may also be used for inflation, rendering the syringe superfluous [26,27]. Both balloons are then completely deflated using suction and clamped with rubber hemostats or plugged before lubrication. The Minnesota tube (Fig. 15.2) enjoys a fourth lumen that allows for suctioning above the esophageal balloon [18], whereas the Sengstaken–Blakemore tube (Fig. 15.3) must have a 14 to 18 French nasogastric tube

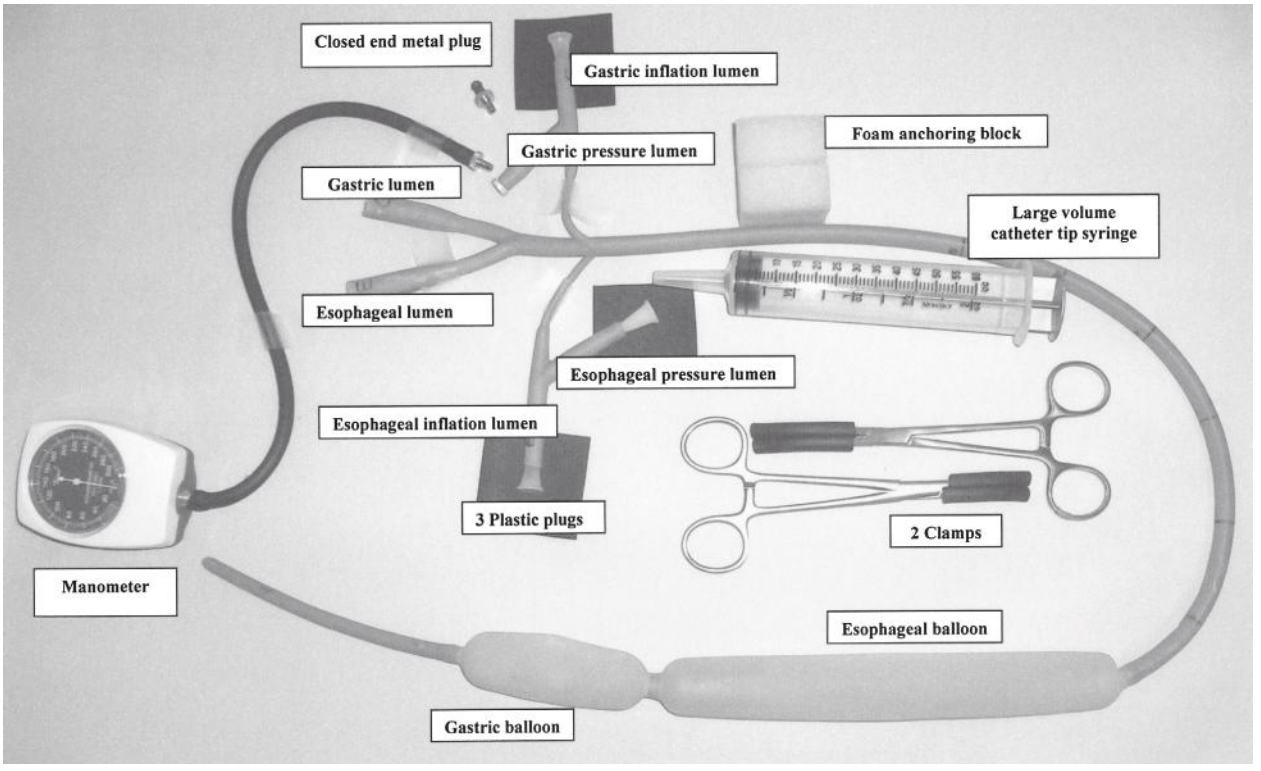

FIGURE 15.2. Minnesota tube.

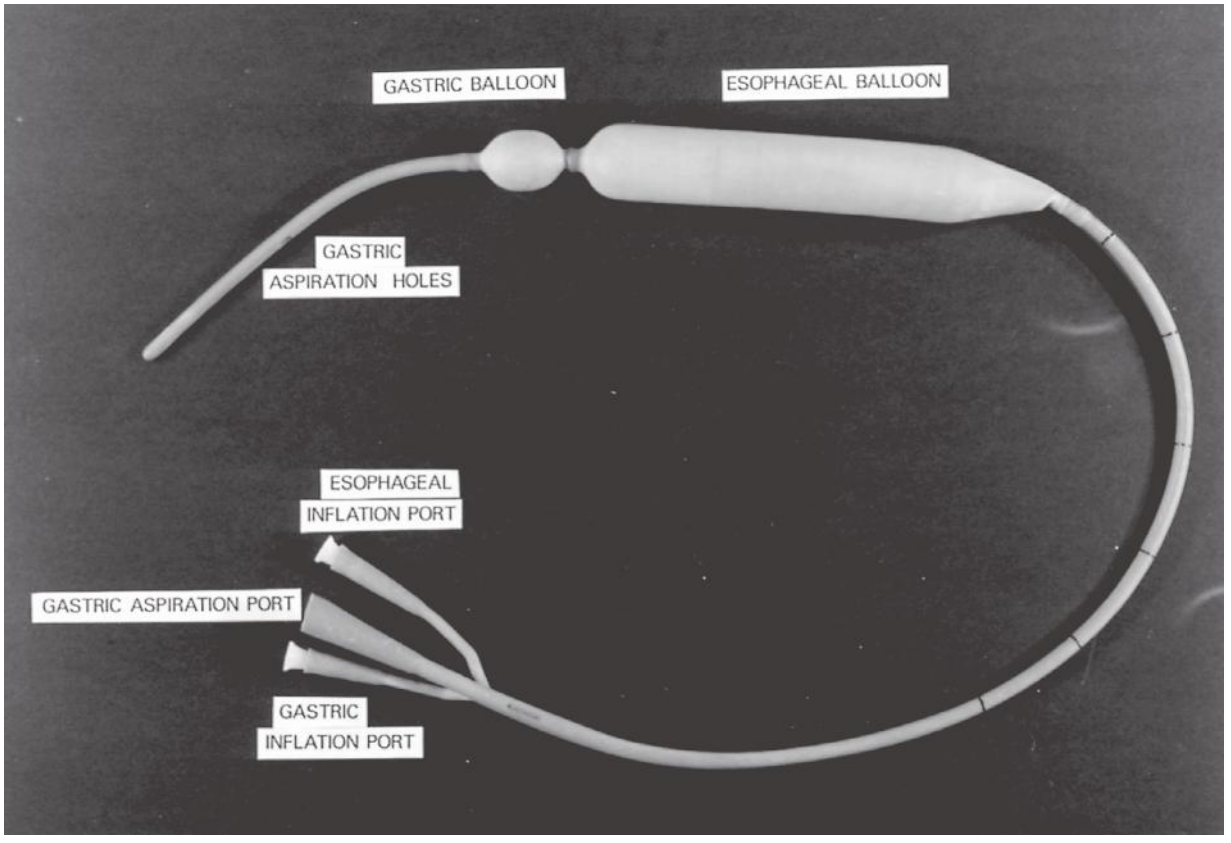

FIGURE 15.3. Sengstaken–Blakemore tube.

secured a few centimeters proximal to the esophageal balloon to be used for esophageal decompression. The nasogastric tube should be used even if the esophageal balloon is not inflated because inflation of the gastric balloon precludes proper drainage of esophageal secretions [28]. If the patient is to be placed in an aircraft (i.e., for evacuation), water should be instilled into balloon(s) instead of air [29].

Insertion and Placement of the Tube

The head of the bed should be elevated to reduce the risk of aspiration. Oral suction should be readied and the correct length of the tube to reach the patient's stomach should be selected (usually 45 to 60 cm orally). If the patient is not intubated, head down with left lateral positioning should be attained to minimize the risk of aspiration [17]. If using a Minnesota tube, the esophageal aspiration port should be set to continuous suction and the tube generously lubricated with lidocaine jelly prior to inserting it through the nose or mouth into the stomach. However, the nasal route is not recommended in patients with coagulopathy or thrombocytopenia. In the difficult insertion, the tube may be placed endoscopically [30] or with a guidewire [31]. Duarte described a technique of placing the tube in a longitudinally split Ewald tube [32]. Auscultation in the epigastrium while air is injected through the gastric lumen verifies the position of the tube, but the position of the gastric balloon must be confirmed at this time radiologically or by ultrasound if it is more expedient [33] as high placement can lead to esophageal rupture and low placement to duodenal rupture [34]. The manometer is then connected to the gastric pressure port and the gastric balloon is inflated with no more than 80 mL of air. A pressure of greater than 15 mm Hg at this stage suggests esophageal placement [27,35]. A (portable) radiograph must be obtained that includes the upper abdomen and lower chest (Figs. 15.4 and 15.5). When it is documented that the gastric balloon is below the diaphragm, it should be further inflated with air in 100 mL aliquots to a volume of 250 to 300 mL. The gastric balloon of the Minnesota tube can be inflated to 450 to 500 mL. If the change in manometric pressure for an aliquot is more than 15 mm Hg of the preinsertion pressure or if the gastric balloon is underinflated causing upward migration, erroneous esophageal placement should be considered. Record tube insertion depth (i.e., at the teeth). Tube balloon inlets should be clamped with rubber-shod hemostats after insufflation. Hemorrhage is frequently controlled with insufflation of the gastric balloon alone without applying traction, but in patients with torrential hemorrhage, it is necessary to apply traction (vide infra). If the bleeding continues, the manometer attached to the esophageal pressure port is used to inflate the esophageal balloon to a pressure of approximately 45 mm Hg. Some authors inflate the esophageal balloon in all patients immediately after insertion. If there is still bleeding, deflate the esophageal balloon, apply more traction, and reinflate in the event that it is a gastric variceal bleed. Pressures should be monitored and maintained.

Fixation and Traction Techniques

Fixation and traction on the tube depend on the route of insertion. When the nasal route is used, attachment of a sponge rubber cuff around the tube at the nostril prevents skin and cartilage necrosis. When traction is required, the tube should be attached to a cord that is passed over a catcher's mask for

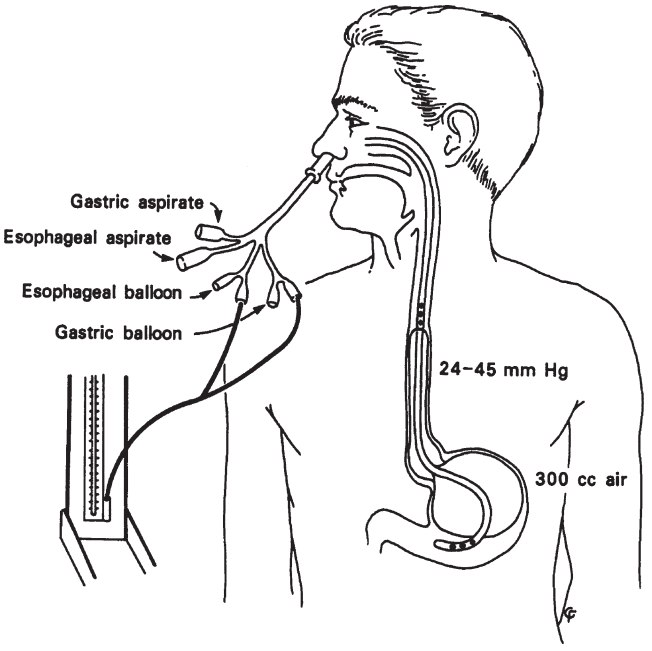

FIGURE 15.4. Proper positioning of the Minnesota tube.

maximum transportability [36] or a pulley in a bed with an overhead orthopedic frame and aligned directly as it comes out of the nose to avoid contact with the nostril. This type of system allows maintenance of traction with a known weight of 500 to 1,500 g either temporarily with IV fluid bags [17] or more permanently with block weights. When the tube is inserted through the mouth, traction is better applied by placing a football helmet on the patient and attaching the tube to the face mask of the helmet after a similar weight is applied for tension. Pressure sores can occur on the head and forehead if the helmet does not fit properly or if it is used for a prolonged period. Several authors recommend overhead traction for either oral or nasal insertion [37].

Maintenance, Monitoring, and Care

Periodically flush ports to ensure patency. To reduce encephalopathy, the gastric aspiration port should be used to thoroughly lavage the stomach before being set to low intermittent suction. It may be used later for medication administration. The esophageal port may be set to intermittent or continuous suction, depending on the extent of bleeding and drainage [35]. Tautness and inflation should be checked often and at least 1 hour after insertion, allowing for only transient fluctuations of as much as 30 mm Hg with respirations and esophageal spasm. Sedation or a pressure decrease may be necessary if large pressure fluctuations persist. If repositioning of the tube is required, assure that the esophageal balloon is deflated. Soft restraints should also be in use and the head of the bed elevated. The tube is left in place a minimum of 24 hours with gastric balloon tamponade maintained continuously for up to 48 hours. The esophageal balloon should be deflated for 5 minutes every 6 hours to help prevent mucosal ischemia and esophageal necrosis. Radiographic assurance of correct placement should be obtained every 24 hours and when dislodgement is suspected (Fig. 15.5). Watch for localized cervical edema, which may signal obstruction or malpositioning [38]. A pair of scissors should be kept with the apparatus in case rapid decompression becomes necessary as balloon migration can acutely obstruct the airway or rupture the esophagus. It is advisable to take care not to utilize bare hemostats and to clamp at the thicker portion of the ports as it is possible for the lumen to become obliterated and the tube thus impacted [39].

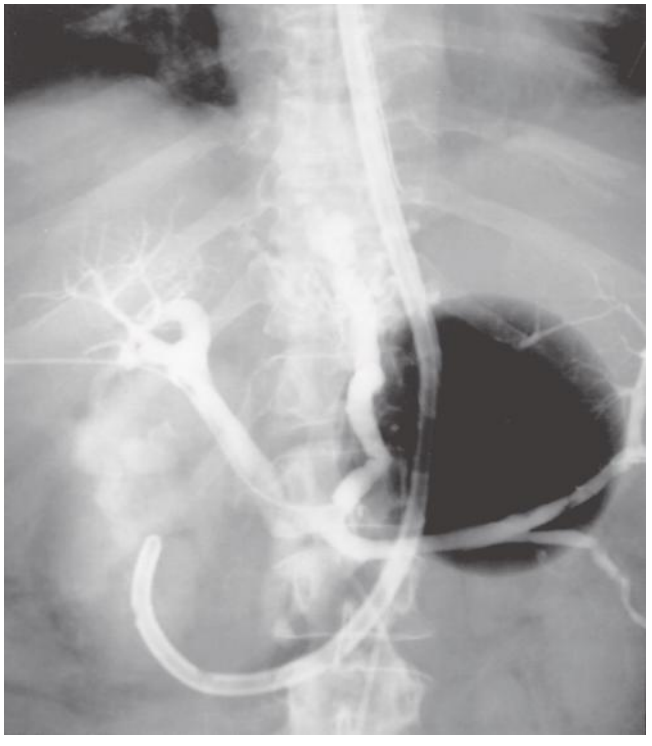

FIGURE 15.5. Radiograph showing correct position of the tube; the gastric balloon is seen below the diaphragm. Note the Salem sump above the gastric balloon and adjacent to the tube. (Courtesy: Ashley Davidoff, MD.)

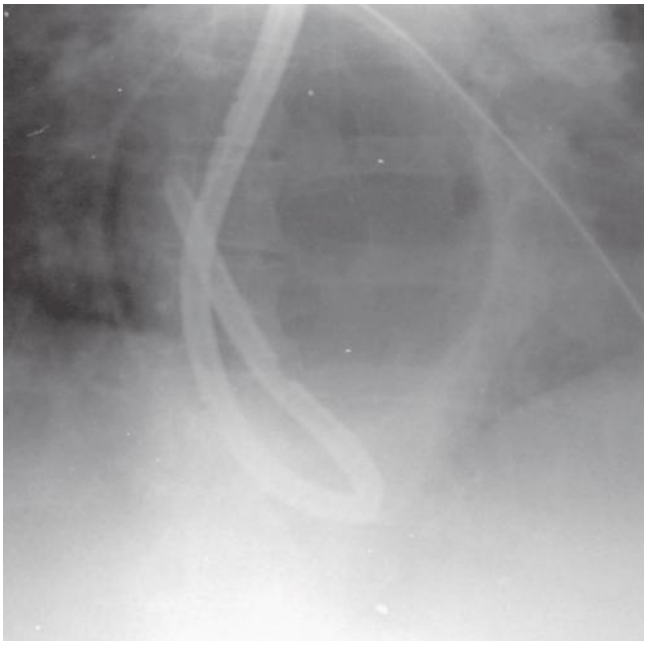

FIGURE 15.6. Chest radiograph showing distal segment of the tube coiled in the chest and the gastric balloon inflated above the diaphragm in the esophagus. (Courtesy: Ashley Davidoff, MD.)

Removal of the Tube

Once hemorrhage is controlled, the esophageal balloon is deflated first. This may be done incrementally over time if desired. The gastric balloon is left inflated for an additional 24 to 48 hours and may be deflated if there is no evidence of bleeding. The tube is left in place 24 hours longer. If bleeding recurs, the balloon is reinflated. The tube is removed if no further bleeding occurs. Primary therapy and secondary prophylaxis, as described previously, should be considered because balloon tamponade is a bridge intervention and rebleeding can occur in up to two thirds of patients within 3 months without therapy [3].

COMPLICATIONS

Rebleeding when the cuff(s) is deflated should be anticipated. The highest risk of rebleeding is in the first few days after balloon deflation. By 6 weeks, the risk of rebleeding returns to premorbid risk level. Independent predictors of mortality in patients undergoing balloon tamponade, described by Lee et al. [40], include blood transfusion greater than 10 units, coagulopathy, presence of shock, Glasgow Coma Score, and total volume of sclerosing agent (ethanolamine).

Aspiration pneumonia is the most common complication of balloon tamponade. The severity and fatality rate is related to the presence of impaired mental status and encephalopathy in patients with poor control of the airway. The incidence ranges from 0% to 12%. Acute laryngeal obstruction and tracheal rupture are the most severe of all complications and the worst examples of tube migration or malpositioning. Migration of the tube occurs when the gastric balloon is not inflated properly after adequate positioning in the stomach or when excessive traction (>1.5 kg) is used, causing migration cephalad to the esophagus or hypopharynx. Mucosal ulceration of the gastroesophageal junction is common and is directly related to prolonged traction time (>36 hours). Perforation of the esophagus is reported as a result of misplacing the gastric balloon above the diaphragm (Fig. 15.6). The incidence of complications that are a direct cause of death ranges from 0% to 20%.

CHAPTER 16 ■ ENDOSCOPIC PLACEMENT OF FEEDING TUBES

LENA M. NAPOLITANO

INDICATIONS FOR ENTERAL FEEDING

Nutritional support is an essential component of intensive care medicine (see Chapters 190–192). It has become increasingly evident that nutritional support administered via the enteral route is far superior to total parenteral nutrition [1–11]. The Society of Critical Care Medicine/American Society for Parenteral and Enteral Nutrition Guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient [1], the Canadian Clinical Practice Guidelines for Nutrition Support in Critically Ill Adults [2], the European Society for Clinical Nutrition and Metabolism (ESPEN) Guidelines on Enteral Nutrition for Intensive Care [3], and the Practice Management Guidelines for Nutritional Support of the Trauma Patient [4] all strongly recommend that enteral nutrition be used in preference to parenteral nutrition.

Provision of nutrition through the enteral route aids in prevention of gastrointestinal mucosal atrophy, thereby maintaining the integrity of the gastrointestinal mucosal barrier. Other advantages of enteral nutrition are preservation of immunologic gut function and normal gut flora, improved use of nutrients, and reduced cost. Some studies suggest that clinical outcome is improved and infectious complications are decreased in patients who receive enteral nutrition compared with parenteral nutrition.

An evidence-based consensus statement on the management of critically ill patients with severe acute pancreatitis also recommended that enteral nutrition be used in preference to parenteral nutrition [12]. A systematic review also concluded that patients with severe acute pancreatitis should begin enteral nutrition early because such therapy modulates the stress response, promotes more rapid resolution of the disease process, and improves outcome [13].

Although there are absolute or relative contraindications to enteral feeding in selected cases, most critically ill patients can receive some or all of their nutritional requirements via the gastrointestinal tract. Even when some component of nutritional support must be provided intravenously (IV), feeding via the gut is desirable.

Several developments—including new techniques for placement of feeding tubes, availability of smaller caliber, minimally reactive tubes, and an increasing range of enteral formulas—have expanded the ability to provide enteral nutritional support to critically ill patients. Enteral feeding at a site proximal to the pylorus may be absolutely or relatively contraindicated in patients with increased risk of pulmonary aspiration, but feeding more distally (particularly distal to the ligament of Treitz) decreases the likelihood of aspiration. Other relative or absolute contraindications to enteral feeding include fistulas, intestinal obstruction, upper gastrointestinal hemorrhage, and severe inflammatory bowel disease or intestinal ischemia. Enteral feeding is not recommended in patients with severe malabsorption or early in the course of severe short-gut syndrome.

ACCESS TO THE GASTROINTESTINAL TRACT

After deciding to provide enteral nutrition, the clinician must decide whether to deliver the formula into the stomach, duodenum, or jejunum, and determine the optimal method for accessing the site, which is based on the function of the patient's gastrointestinal tract, duration of enteral nutritional support required, and risk of pulmonary aspiration. Gastric feeding provides the most normal route for enteral nutrition, but it is commonly poorly tolerated in the critically ill patient because of gastric dysmotility with delayed emptying [14]. Enteral nutrition infusion into the duodenum or jejunum may decrease the incidence of aspiration because of the protection afforded by a competent pyloric sphincter; however, the risk of aspiration is not completely eliminated by feeding distal to the pylorus [15–17]. Infusion into the jejunum is associated with the lowest risk of pulmonary aspiration. An advantage of this site of administration is that enteral feeding can be initiated early in the postoperative period, because postoperative ileus primarily affects the colon and stomach and only rarely involves the small intestine. However, the early use of postpyloric feeding instead of gastric feeding in critically ill adult patients with no evidence of impaired gastric emptying was not associated with significant clinical benefits [18,19].

TECHNIQUES

Enteral feeding tubes can be placed via the transnasal, transoral, or percutaneous transgastric or transjejunal routes. If these procedures are contraindicated or unsuccessful, the tube may be placed by endoscopy, using endoscopic and laparoscopic technique, or surgically via a laparotomy [20].

Nasoenteric Route

Nasoenteric tubes are the most commonly used means of providing enteral nutritional support in critically ill patients. This route is preferred for short- to intermediate-term enteral support when eventual resumption of oral feeding is anticipated. It is possible to infuse enteral formulas into the stomach using a conventional 16- or 18-French (Fr) polyvinyl chloride nasogastric tube, but patients are usually much more comfortable if a small-diameter silicone or polyurethane feeding tube is used. Nasoenteric tubes vary in luminal diameter (6 to 14 Fr) and length, depending on the desired location of the distal

orifice: stomach, 30 to 36 in.; duodenum, 43 in.; jejunum, at least 48 in. Some tubes have tungsten-weighted tips designed to facilitate passage into the duodenum via normal peristalsis; others have a stylet. Most are radiopaque. Some tubes permit gastric decompression while delivering formula into the jejunum.

Nasoenteric feeding tubes should be placed with the patient in a semi-Fowler's or sitting position. The tip of the tube should be lubricated, placed in the patient's nose, and advanced to the posterior pharynx. If the patient is alert and can follow instructions, the patient should be permitted to sip water as the tube is slowly advanced into the stomach. To avoid unintentional airway placement and serious complications, position of the tube should be ascertained after it has been inserted to 30 cm. Acceptable means of documenting intraesophageal location of the tube include a chest radiograph or lack of CO_2 detection through the lumen of the tube by capnography or colorimetry. If the tube is in the airway, CO_2 will be detected and the tube must be removed. Alternatively, commercial systems are now available to track tube progression from the esophagus through the stomach to the duodenum by electromagnetic means. Proper final placement of the tube in the stomach must be confirmed by chest or upper abdominal radiograph before tube feeding is begun. The following methods to assess final tube placement are unreliable and do not assess tube misdirection into the lower respiratory tract: auscultation over the left upper quadrant with air insufflation through the tube, assessment of pH with gastric content aspiration, and easy passage of the tube to its full length with the absence of gagging and coughing [21,22]. The tube should be securely taped to the nose, forehead, or cheek without tension.

Delayed gastric emptying has been confirmed in critically ill patients and may contribute to gastric feeding intolerance. One study randomized 80 critically ill patients to gastric feeding with erythromycin (200 mg IV every 8 hours as a prokinetic agent) or through a transpyloric feeding tube and identified that the two were equivalent in achieving goal caloric requirements [23]. Spontaneous transpyloric passage of enteral feeding tubes in critically ill patients is commonly unsuccessful secondary to the preponderance of gastric atony. The addition of a tungsten weight to the end of enteral feeding tubes and the development of wire or metal stylets in enteral feeding tubes are aimed at improving the success rate for spontaneous transpyloric passage. Once the tube is documented to be in the stomach, various bedside techniques including air insufflation, pH-assisted, magnet-guided [24], and spontaneous passage with [25] or without motility agents may help to facilitate transpyloric feeding tube passage.

IV metoclopramide and erythromycin have been recommended as prokinetic agents. But a Cochrane Database Systematic Review concluded that doses of 10 or 20 mg of IV metoclopramide were equally ineffective in facilitating transpyloric feeding tube placement [26]. No matter which techniques are used to facilitate transpyloric passage of enteral feeding tubes, these tubes must be inserted by skilled practitioners using defined techniques [27,28].

If the tube does not pass into the duodenum on the first attempt, placement can be attempted under endoscopic assistance or fluoroscopic or electromagnetic guidance. The latter method requires specialized equipment. Endoscopic placement of nasoenteral feeding tubes is easily accomplished in the critically ill patient and can be performed at the bedside using portable equipment [29–33]. Transnasal or transoral endoscopy can be used for placement of nasoenteral feeding tubes in critically ill patients [33]. The patient is sedated appropriately (see Chapter 20), and topical anesthetic is applied to the posterior pharynx with lidocaine or benzocaine spray. A 43- to 48-in.-long nasoenteric feeding tube with an inner wire stylet is passed transnasally into the stomach. The endoscope is inserted and advanced through the esophagus into the gastric lumen. An endoscopy forceps is passed through the biopsy channel of the endoscope and used to grasp the tip of the enteral feeding tube. The endoscope, along with the enteral feeding tube, is advanced distally into the duodenum as far as possible (Fig. 16.1).

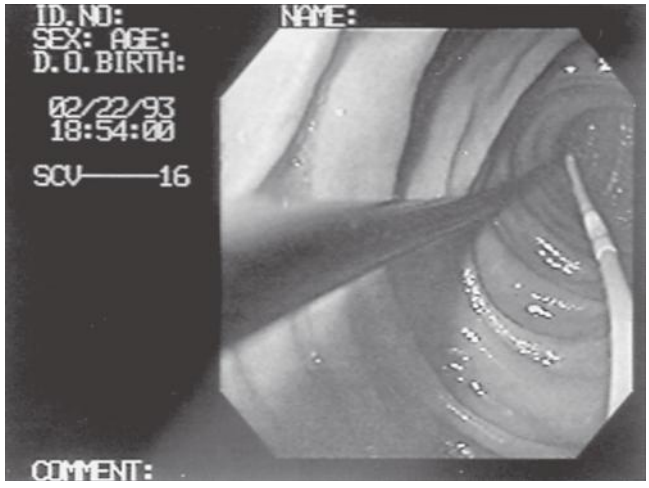

FIGURE 16.1. Endoscopic placement of nasoenteral feeding tube. Endoscopy forceps and gastroscope advance the feeding tube in the duodenum.

The endoscopy forceps and feeding tube remain in position in the distal duodenum as the endoscope is withdrawn back into the gastric lumen. The endoscopy forceps are opened, the feeding tube released, and the endoscopy forceps withdrawn carefully back into the stomach. On first pass, the feeding tube is usually lodged in the second portion of the duodenum. The portion of the feeding tube that is redundant in the stomach is advanced slowly into the duodenum using the endoscopy forceps to achieve a final position distal to the ligament of Treitz (Fig. 16.2). An abdominal radiograph is obtained at the completion of the procedure to document the final position of the nasoenteral feeding tube. Endoscopic placement of postpyloric enteral feeding tubes is highly successful, eliminates the risk of transporting the patient to the radiology department for fluoroscopic placement, and allows prompt achievement of nutritional goals because enteral feeding can be initiated immediately after the procedure.

The recent development of ultrathin endoscopes (outer diameter 5.1 to 5.9 mm vs. 9.8 mm in standard gastroscope) has enabled nasoenteric feeding tube placement via transnasal endoscopy using an over-the-wire technique. A 90% success rate was documented with endoscopic procedure duration of approximately 13 minutes, shorter than fluoroscopic procedure duration and without the need for additional sedation [34]. Unsedated transnasal ultrathin endoscopy can also be used for feeding tube or percutaneous endoscopic gastrostomy (PEG) placement in patients who are unable to undergo transoral endoscopy, that is, those who have partial or complete occlusion of the mouth [35].

Electromagnetic guidance employs a feeding tube with a guidewire that emits electromagnetic waves. A box with three receivers that is placed on the patient's xiphoid process triangulates the position of the tube. The clinician is able to "view" the tip on a monitor as it passes down the esophagus through the stomach and into the duodenum. Although the manufacturer asserts an x-ray after the procedure is not necessary, the practice at many institutions is to obtain an x-ray to confirm placement of the tube.

FIGURE 16.2. Abdominal radiograph documenting the optimal position of an endoscopically placed nasoenteral feeding tube, past the ligament of Treitz.

Percutaneous Route

PEG tube placement, introduced by Ponsky et al. [36] in 1990, has become the procedure of choice for patients requiring prolonged enteral nutritional support. PEG tubes range in size from 20 to 28 Fr. PEG rapidly replaced open gastrostomy as the method of choice for enteral nutrition. Unlike surgical gastrostomy, PEG does not require general anesthesia and laparotomy and eliminates the discomfort associated with chronic nasoenteric tubes. This procedure can be considered for patients who have normal gastric emptying and low risk for pulmonary aspiration, and can be performed in the operating room, in an endoscopy unit, or at the bedside in the intensive care unit with portable endoscopy equipment.

PEG should not be performed in patients with near or total obstruction of the pharynx or esophagus, in the presence of coagulopathy, or when transillumination is inadequate. Relative contraindications are ascites, gastric cancer, and gastric ulcer. Previous abdominal surgery is not a contraindication. The original method for PEG was the pull technique; more recent modifications are the push and introducer techniques.

Pull Technique

The pull technique is performed with the patient in the supine position. The abdomen is prepared and draped. The posterior pharynx is anesthetized with a topical spray or solution (e.g., benzocaine spray or viscous lidocaine), and IV sedation (e.g., 1 to 2 mg of midazolam; see Chapter 20) is administered. A prophylactic antibiotic, usually a first-generation cephalosporin, is administered before the procedure. The fiberoptic gastroscope is inserted into the stomach, which is then insufflated with air. The lights are dimmed, and the assistant applies digital pressure to the anterior abdominal wall in the left subcostal area approximately 2 cm below the costal margin, looking for the brightest transillumination (light reflex). The endoscopist should be able to clearly identify the indentation in the stomach created by the assistant's digital pressure on the anterior abdominal wall (digital reflex); otherwise, another site should be chosen.

When the correct spot has been identified, the assistant anesthetizes the anterior abdominal wall. The endoscopist then introduces a polypectomy snare through the endoscope. A small incision is made in the skin, and the assistant introduces a large-bore catheter–needle stylet assembly into the stomach and through the snare. The snare is then tightened securely around the catheter. The inner stylet is removed, and a looped insertion wire is introduced through the catheter and into the stomach. The cannula is slowly withdrawn so that the snare grasps the wire. The gastroscope is then pulled out of the patient's mouth with the wire firmly grasped by the snare. The end of the transgastric wire exiting the patient's mouth is then tied to a prepared gastrostomy tube. The assistant pulls on the end of the wire exiting from the abdominal wall while the endoscopist guides the lubricated gastrostomy tube into the posterior pharynx and the esophagus. With continued traction, the gastrostomy tube is pulled into the stomach so that it exits on the anterior abdominal wall. The gastroscope is reinserted into the stomach to confirm adequate placement of the gastrostomy tube against the gastric mucosa and to document that no bleeding has occurred. The intraluminal portion of the tube should contact the mucosa, but excessive tension on the tube should be avoided because this can lead to ischemic necrosis of the gastric wall. The tube is secured to the abdominal wall using sutures. Feedings may be initiated immediately after the procedure or 24 hours later.

Push Technique

The push technique is similar to the pull technique. The gastroscope is inserted and a point on the anterior abdominal wall localized, as for the pull technique. Rather than introducing a looped insertion wire, however, a straight guidewire is snared and brought out through the patient's mouth by withdrawing the endoscope and snare together. A commercially developed gastrostomy tube (Sachs–Vine) with a tapered end is then passed in an aboral direction over the wire, which is held taut. The tube is grasped and pulled out the rest of the way. The gastroscope is reinserted to check the position and tension on the tube.

Introducer Technique

The introducer technique uses a peel-away introducer technique originally developed for the placement of cardiac pacemakers and central venous catheters. The gastroscope is inserted into the stomach and an appropriate position for placement of the tube is identified. After infiltration of the skin with local anesthetic, a 16- or 18-gauge needle is introduced into the stomach. A J-tipped guidewire is inserted through the needle into the stomach and the needle is withdrawn. Using a twisting motion, a 16-Fr introducer with a peel-away sheath is passed over the guidewire into the gastric lumen [37,38]. The guidewire and introducer are removed, leaving in place the sheath that allows placement of a 14-Fr Foley catheter. The sheath is peeled away after the balloon is inflated with 10 mL of normal saline. Some advocate this as the optimal method for PEG in patients with head and neck cancer, related to an overall lower rate of complications in this patient population [39].

Percutaneous Endoscopic Gastrostomy/Jejunostomy

If postpyloric feeding is desired (especially in patients at high risk for pulmonary aspiration), a PEG/jejunostomy may be performed. The tube allows simultaneous gastric decompression and duodenal/jejunal enteral feeding [40]. A second, smaller feeding tube can be attached and passed through the gastrostomy tube and advanced endoscopically into the duodenum or jejunum. When the PEG is in position, a guidewire is passed through it and grasped using endoscopy forceps. The guidewire and endoscope are passed into the duodenum as distally as possible. The jejunal tube is then passed over the guidewire through the PEG into the distal duodenum, advanced into the jejunum, and the endoscope is withdrawn. An alternative method is to grasp a suture at the tip of the feeding tube or the distal tip of the tube itself and pass the tube into the duodenum, using forceps advanced through the biopsy channel of the endoscope. This obviates the need to pass the gastroscope into the duodenum, which may result in dislodgment of the tube when the endoscope is withdrawn.

Direct Percutaneous Endoscopic Jejunostomy

Jejunostomy tubes can be placed endoscopically by means of a PEG with jejunal extension (PEG-J) or by direct percutaneous jejunostomy (PEJ) [41,42]. Because the size of the jejunal extension of the PEG-J tube is significantly smaller than that of the direct PEJ, some have suggested that the PEJ provides more stable jejunal access for those who require long-term jejunal feeding. Unfortunately, a low success rate (68%) and a high adverse event rate (22.5%) have been documented in the largest series to date [43].

Fluoroscopic Technique

Percutaneous gastrostomy and gastrojejunostomy can also be performed using fluoroscopy [44–46]. The stomach is insufflated with air using a nasogastric tube or a skinny needle if the patient is obstructed proximally. Once the stomach is distended and position is checked again with fluoroscopy, the stomach is punctured with an 18-gauge needle. A heavy-duty wire is passed and the tract is dilated to 7 Fr. A gastrostomy tube may then be inserted into the stomach. An angiographic catheter is introduced and manipulated through the pylorus. The percutaneous tract is then further dilated and the gastrojejunostomy tube is advanced as far as possible.

Complications

The most common complication after percutaneous placement of enteral feeding tubes is infection, usually involving the cutaneous exit site and surrounding tissue [47]. Gastrointestinal hemorrhage has been reported, but it is usually due to excessive tension on the tube, leading to necrosis of the stomach wall. Gastrocolic fistulas, which develop if the colon is interposed between the anterior abdominal wall and the stomach when the needle is introduced, have been reported. Adequate transillumination aids in avoiding this complication. Separation of the stomach from the anterior abdominal wall can occur, resulting in peritonitis when enteral feeding is initiated. In most instances, this complication is caused by excessive tension on the gastrostomy tube. Another potential complication is pneumoperitoneum, secondary to air escaping after puncture of the stomach during the procedure, and is usually clinically insignificant. If the patient develops fever and abdominal tenderness, a Gastrografin study should be obtained to exclude the presence of a leak.

All percutaneous gastrostomy and jejunostomy procedures described here have been established as safe and effective. The method is selected on the basis of the endoscopist's experience and training and the patient's nutritional needs.

SURGICAL PROCEDURES

Since the advent of PEG, surgical placement of enteral feeding tubes is usually performed as a concomitant procedure as the last phase of a laparotomy performed for another indication. Occasionally, an operation solely for tube placement is performed in patients requiring permanent tube feedings when a percutaneous approach is contraindicated or unsuccessful. In these cases, the laparoscopic approach to enteral access should be considered [48]. Laparoscopic gastrostomy was introduced in 2000, 10 years after the PEG. Patients who are not candidates for PEG, due to head and neck cancer, esophageal obstruction, large hiatal hernia, gastric volvulus, or overlying intestine or liver, should be considered for laparoscopic gastrostomy or jejunostomy.

Gastrostomy

Gastrostomy is a simple procedure when performed as part of another intra-abdominal operation. It should be considered when prolonged enteral nutritional support is anticipated after surgery.

Complications are quite common after surgical gastrostomy. This may reflect the poor nutritional status and associated medical problems in many patients who undergo this procedure. Potential complications include wound infection, dehiscence, gastrostomy disruption, internal or external leakage, gastric hemorrhage, and tube migration.

Needle–Catheter Jejunostomy

The needle–catheter jejunostomy procedure consists of the insertion of a small (5-Fr) polyethylene catheter into the small intestine at the time of laparotomy for another indication. Kits containing the necessary equipment for the procedure are available from commercial suppliers. A needle is used to create a submucosal tunnel from the serosa to the mucosa on the antimesenteric border of the jejunum. A catheter is inserted through the needle and then the needle is removed. The catheter is brought out through the anterior abdominal wall and the limb of the jejunum is secured to the anterior abdominal wall with sutures. The tube can be used for feeding immediately after the operation. The potential complications are similar to those associated with gastrostomy, but patients may have a higher incidence of diarrhea. Occlusion of the needle–catheter jejunostomy is common because of its small luminal diameter, and elemental nutritional formulas are preferentially used.

Transgastric Jejunostomy

Critically ill patients who undergo laparotomy commonly require gastric decompression and a surgically placed tube for enteral nutritional support. Routine placement of separate gastrostomy and jejunostomy tubes is common in this patient population and achieves the objective of chronic gastric decompression and early initiation of enteral nutritional support through the jejunostomy. Technical advances in surgically placed enteral feeding tubes led to the development of transgastric jejunostomy [49] and duodenostomy tubes, which allow simultaneous decompression of the stomach and distal feeding into the

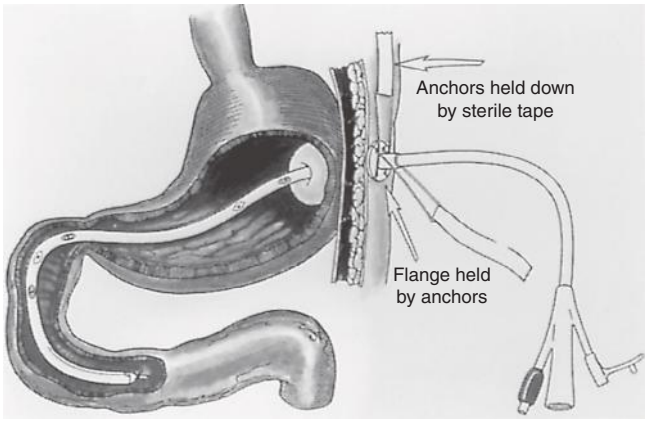

FIGURE 16.3. Transgastric duodenal feeding tube, which allows simultaneous gastric decompression and duodenal feeding, can be placed percutaneously (with endoscopic or fluoroscopic assistance) or surgically.

duodenum or jejunum. The advantage of these tubes is that only one enterotomy into the stomach is needed, eliminating the possible complications associated with open jejunostomy tube placement. In addition, only one tube is necessary for gastric decompression and jejunal feeding, eliminating the potential complications of two separate tubes for this purpose.

The transgastric jejunostomy tube is placed surgically in the same manner as a gastrostomy tube, and the distal portion of the tube is advanced manually through the pylorus into the duodenum, with its final tip resting as far distally as possible in the duodenum or jejunum (Fig. 16.3). The transgastric jejunostomy tube is preferred to transgastric duodenostomy tube because it is associated with less reflux of feedings into the stomach and a decreased risk of aspiration pneumonia. Surgical placement of transgastric jejunostomy tubes at the time of laparotomy is recommended for patients who likely require prolonged gastric decompression and enteral feeding.

DELIVERING THE TUBE-FEEDING FORMULA

The enteral formula can be delivered by intermittent bolus feeding, gravity infusion, or continuous pump infusion. In the intermittent bolus method, the patient receives 300 to 400 mL of formula every 4 to 6 hours. The bolus is usually delivered with the aid of a catheter-tipped, large-volume (60-mL) syringe. The main advantage of bolus feeding is simplicity. This approach is often used for patients requiring prolonged supplemental enteral nutritional support after discharge from the hospital. Bolus feeding can be associated with serious side effects, however. Bolus enteral feeding into the stomach can cause gastric distention, nausea, cramping, and aspiration. The intermittent bolus method should not be used when feeding into the duodenum or jejunum because boluses of formula can cause distention, cramping, and diarrhea.

Gravity-infusion systems allow the formula to drip continuously during 16 to 24 hours or intermittently during 20 to 30 minutes, four to six times per day. This method requires constant monitoring because the flow rate can be extremely irregular. The main advantages of this approach are simplicity, low cost, and close simulation of a normal feeding pattern.

Continuous pump infusion is the preferred method for the delivery of enteral nutrition in the critically ill patient. A peristaltic pump can be used to provide a continuous infusion of formula at a precisely controlled flow rate, which decreases problems with distention and diarrhea. Gastric residuals tend to be smaller with continuous pump-fed infusions, and the risk of aspiration may be decreased. In adult burn and trauma patients, continuous feedings are associated with less stool frequency and shorter time to achieve nutritional goals [50,51].

MEDICATIONS

When medications are administered via an enteric feeding tube, it is important to be certain that the drugs are compatible with each other and with the enteral formula. In general, medications should be delivered separately rather than as a combined bolus. For medications that are better absorbed in an empty stomach, tube feedings should be suspended for 30 to 60 minutes before administration.

Medications should be administered in an elixir formulation via enteral feeding tubes whenever possible to prevent occlusion of the tube. Enteral tubes should always be flushed with 20 mL of saline after medications are administered. To use an enteral feeding tube to administer medications dispensed in tablet form, often the pills must be crushed and delivered as slurry mixed with water. This is inappropriate for some medications, however, such as those absorbed sublingually or formulated as a sustained-released tablet or capsule.

COMPLICATIONS

Enteral tube placement is associated with few complications if practitioners adhere to appropriate protocols and pay close attention to the details of the procedures [52].

Nasopulmonary Intubation

Passage of an enteral feeding tube into the tracheobronchial tree most commonly occurs in patients with diminished cough or gag reflexes due to obtundation, altered mental status, or other causes such as the presence of endotracheal intubation. The presence of a tracheostomy or endotracheal tube does not guarantee proper placement. A chest (or upper abdominal) radiograph should always be obtained before initiating tube feedings with a new tube to ensure that the tube is properly positioned. Endotracheal or transpulmonary placement of a feeding tube can be associated with pneumothorax, hydrothorax, pneumonia, pulmonary hemorrhage, abscess formation, or death. A chest radiograph or a means of detecting CO_2 through the tube after it has been inserted 30 cm should be obtained to prevent inadvertent placement of small-bore feeding tubes into the lungs.

Aspiration

Pulmonary aspiration is a serious and potentially fatal complication of enteral nutritional support [53]. The incidence of this complication is variable and depends on the patient population studied. The two most common bedside tests for detecting aspiration in tube-fed patients include adding dye to the formula and observing for its appearance in tracheobronchial secretions, and using glucose oxidase reagent strips to test tracheobronchial secretions for glucose-containing enteral formula [54]. No large prospective clinical trials have validated the use and safety of bedside monitors for aspiration, and their use should be abandoned. Nonrecumbent positioning is an evidence-based method for aspiration prevention that needs to be initiated in all patients receiving enteral nutrition.

Major risk factors for aspiration include obtundation or altered mental status, absence of cough or gag reflexes, delayed gastric emptying, gastroesophageal reflux, and feeding in the supine position. The risk of pulmonary aspiration is minimized when the enteral feeding tube is positioned in the jejunum past the ligament of Treitz.

Gastrointestinal Intolerance

Delayed gastric emptying is sometimes improved by administering the prokinetic agents metoclopramide (10 to 20 mg IV) or erythromycin (200 mg IV). Dumping syndrome (i.e., diarrhea, distention, and abdominal cramping) can limit the use of enteral feeding. Dumping may be caused by delivering a hyperosmotic load into the small intestine.

Diarrhea in critically ill patients should not be attributed to intolerance of enteral feeding until other causes are excluded. Other possible etiologies for diarrhea include medications (e.g., magnesium-containing antacids and quinidine), alterations in gut microflora due to prolonged antibiotic therapy, antibiotic-associated colitis, ischemic colitis, viral or bacterial enteric infection, electrolyte abnormalities, and excessive delivery of bile salts into the colon. Diarrhea can also be a manifestation of intestinal malabsorption because of enzyme deficiencies or villous atrophy [55].

Even if diarrhea is caused by enteral feeding, it can be controlled in nearly 50% of cases by instituting a continuous infusion of formula (if bolus feedings are used), slowing the rate of infusion, changing the formula, adding fiber to the enteral formula, or adding antidiarrheal agents (e.g., tincture of opium).

Metabolic Complications

Prerenal azotemia and hypernatremia can develop in patients fed with hyperosmolar solutions. The administration of free water, either added to the formula or as separate boluses to replace obligatory losses, can avert this situation. Deficiencies of essential fatty acids and fat-soluble vitamins can develop after prolonged support with enteral solutions that contain minimal amounts of fat. Periodic enteral supplementation with linoleic acid or IV supplementation with emulsified fat can prevent this [56]. The amount of linoleic acid necessary to prevent chemical and clinical fatty acid deficiency has been estimated to be 2.5 to 20.0 g per day.

Bacterial Contamination

Bacterial contamination of enteral solutions [57–59] occurs when commercial packages are opened and mixed with other substances, and more commonly, it occurs with hospital-formulated and powdered feeds that require preparation compared to commercially prepared, ready-to-feed enteral formulas supplied in cans. The risk of contamination also depends on the duration of feeding. Contaminated formula may also play a significant role in the etiology of diarrhea in patients receiving enteral nutrition.

Occluded Feeding Tubes

Precipitation of certain proteins when exposed to an acid pH may be an important factor leading to the solidifying of formulas. Most premixed intact protein formulas solidify when acidified to a pH less than 5. To prevent occlusion of feeding tubes, the tube should be flushed with saline before and after checking residuals. Small-caliber nasoenteric feeding tubes should be flushed with 20 mL of saline every 4 to 6 hours to prevent tube occlusion, even when enteral feedings are administered by continuous infusion.

Medications are a frequent cause of clogging. When administering medications enterally, liquid elixirs should be used, if available, because even tiny particles of crushed tablets can occlude the distal orifice of small-caliber feeding tubes. If tablets are used, it is important to crush them to a fine powder and solubilize them in liquid before administration. In addition, tubes should be flushed with saline before and after the administration of any medications.

Several maneuvers are useful for clearing a clogged feeding tube. The tube can be irrigated with warm saline, a carbonated liquid, cranberry juice, or a pancreatic enzyme solution (e.g., Viokase). Commonly, a mixture of lipase, amylase, and protease (Pancrease) dissolved in sodium bicarbonate solution (for enzyme activation) is instilled into the tube with a syringe and the tube clamped for approximately 30 minutes to allow enzymatic degradation of precipitated enteral feedings. The tube is then vigorously flushed with saline. The pancreatic enzyme solution was successful in restoring tube patency in 96% of cases where formula clotting was the likely cause of occlusion and use of cola or water had failed [60,61]. Prevention of tube clogging with flushes and pancreatic enzyme are therefore the methods of choice in maintenance of chronic enteral feeding tubes.

CHAPTER 17 ■ CEREBROSPINAL FLUID ASPIRATION

JOHN P. WEAVER

This chapter presents guidelines for safe cerebrospinal fluid (CSF) aspiration for the emergency department or the intensive care physician, and provides a basic understanding of the indications, techniques, and potential complications of these procedures.

Physicians and supervised physician extenders routinely and safely perform CSF aspiration procedures with necessary equipment and sterile supplies readily accessible in most acute hospital patient care units. Most CSF aspirations are performed using local anesthesia alone, without sedation. Because it may be a painful and anxiety-provoking procedure, sedation may be required for an uncooperative patient or for the pediatric population [1,2]. Radiographic imaging (fluoroscopy or ultrasound) is needed in situations in which external anatomic landmarks provide inadequate guidance for safe needle placement or when needle placement using external landmarks alone has proved to be unsuccessful due to anatomic variations caused by trauma, operative scar, congenital defects, or degenerative changes. Fluoroscopy may be used for complicated lumbar puncture, C1–2 puncture, and myelography. Computed tomography (CT) or magnetic resonance imaging (MRI) may be used for stereotactic placement of ventricular catheters. Clinicians should recognize the need for specialized equipment and training in certain cases.

CEREBROSPINAL FLUID ACCESS

Diagnostic Objectives

CSF analysis continues to be a major diagnostic tool in many diseases. The most common indication for CSF sampling is the suspicion of a cerebral nervous system (CNS) infection. CSF is also analyzed for the diagnosis of subarachnoid hemorrhage (SAH), demyelinating diseases, CNS spread of neoplasm, and CNS degenerative conditions. CSF access is necessary for neurodiagnostic procedures, such as myelography and cisternography, and studies for device patencies (tube studies) that require injection of contrast agents. CSF access for pressure recording is also important in the diagnosis of normal-pressure hydrocephalus, benign intracranial hypertension, and head injury.

CSF is an ultrafiltrate of plasma and is normally clear and colorless. Its analysis is a sample of the fluid surrounding the brain and spinal cord. Abnormalities of color and clarity can reflect the presence of cells, protein, hemosiderin, or bilirubin that indicates pathologic processes. The diagnostic tests performed on the aspirated CSF depend on the patient's age, history, and differential diagnosis. A basic profile includes glucose and protein values, a blood cell count, Gram stain, and aerobic and anaerobic cultures. CSF glucose depends on blood glucose levels and is usually equivalent to two-thirds of the serum glucose. It is slightly higher in neonates. Glucose is transported into the CSF via carrier-facilitated diffusion, and changes in spinal fluid glucose concentration lag blood levels by about 2 hours. Increased CSF glucose is nonspecific and usually reflects hyperglycemia. Hypoglycorrhachia can be the result of any inflammatory or neoplastic meningeal disorder, and it reflects increased glucose use by nervous tissue or leukocytes and inhibited transport mechanisms. Elevated lactate levels caused by anaerobic glycolysis in bacterial and fungal meningitis usually accompany lower glucose concentrations.

CSF protein content is usually less than 0.5% of that in plasma with an intact blood–brain barrier. Albumin constitutes up to 75% of CSF protein, and immunoglobulin G (IgG) is the major component of the γ-globulin fraction. IgG freely traverses a damaged blood–brain barrier. Although often nonspecific, elevated CSF protein is an indicator of CNS pathology. There is a gradient of total protein content in the spinal CSF column, with the highest level normally found in the lumbar subarachnoid space at 20 to 50 mg per dL. This is followed by the cisterna magna at 15 to 25 mg per dL and the ventricles at 6 to 12 mg per dL. A value exceeding 500 mg per dL is compatible with an intraspinal tumor or spinal compression causing a complete subarachnoid block, meningitis, or bloody CSF [3]. Low protein levels are seen in healthy children younger than 2 years, pseudotumor cerebri, acute water intoxication, and leukemic patients.

A normal CSF cell count includes no erythrocytes and a maximum of five leukocytes per milliliter. A greater number of white blood cells (WBCs) are normally found in children (up to 10 per milliliter, mostly lymphocytes). Pathologically, increased WBCs are present in infection, leukemia, Guillian–Barré syndrome, hemorrhage, encephalitis, and multiple sclerosis (MS).

Hemorrhage

A *nontraumatic* SAH in the adult population may be due to a ruptured aneurysm. A paroxysmal severe headache is the classic symptom of aneurysm rupture, but atypical headaches reminiscent of migraine are not uncommon. Warning leaks or a sentinel headache occurring at least 4 weeks prior to the diagnosis of SAH was reported by Beck et al. [4] in 17.3% of patients with subsequent diagnosis of SAH.

Leblanc [5] reported that up to 50% of patients with a warning "leak" headache are undiagnosed after evaluation by their physician and 55% of patients with premonitory warning headaches had normal CT findings, but all had a positive finding of SAH on lumbar puncture. Lumbar puncture is indicated with such presenting headache if the head CT is normal and if the clinical history and presentation are typical for aneurysm rupture.

A lumbar puncture should not be performed without prior CT if the patient has any focal neurologic deficit. The neurologic abnormality might indicate the presence of an intracranial mass lesion, and lumbar puncture can increase the likelihood of downward transtentorial herniation. SAH can also cause acute obstructive hydrocephalus by intraventricular extension or

obstruction to CSF resorptive mechanisms at the arachnoid granulations. The CT scan would demonstrate ventriculomegaly, which is best treated by CSF access and diversion using a ventricular catheter.

A traumatic lumbar puncture presents a diagnostic dilemma, especially in the context of diagnosing suspected SAH. Differentiating characteristics include a decreasing red blood cell count in tubes collected serially during the procedure, the presence of a fibrinous clot in the sample, and a typical ratio of about 1 leukocyte per 700 red blood cells. Xanthochromia is more indicative of SAH and is quickly evaluated by spinning a fresh CSF sample and comparing the color of the supernatant to that of water. In performing this test, the use of a spectrophotometer is much more sensitive than by visual inspection. Spinal fluid accelerates red blood cell hemolysis, and hemoglobin products are released within 2 hours of the initial hemorrhage, creating the xanthochromia. Associated findings, such as a slightly depressed glucose level, increased protein, and an elevated opening pressure, are also more suggestive of the presence of an SAH.

Infection

CSF evaluation is the single most important aspect of the laboratory diagnosis of meningitis. The analysis usually includes a Gram stain, blood cell count with white cell differential, protein and glucose levels, and aerobic and anaerobic cultures with antibiotic sensitivities. With suspicion of tuberculosis or fungal meningitis, the fluid is analyzed by acid-fast stain, India ink preparation, cryptococcal antigen, and culture in appropriate media. More extensive cultures may be performed in the immunocompromised patient.

Immunoprecipitation tests to identify bacterial antigens for *Streptococcus pneumoniae*, streptococcus group B, *Haemophilus influenzae*, and *Neisseria meningitidis* (meningococcus) allow rapid diagnosis and early specific treatment. Polymerase chain reaction testing can be performed on CSF for rapid identification of several viruses, particularly those commonly responsible for CNS infections in patients with acquired immunodeficiency syndrome. Polymerase chain reaction testing exists for herpes, varicella zoster, cytomegalovirus, and Epstein–Barr virus, as well as toxoplasmosis and *Mycobacterium tuberculosis* [6]. If the clinical suspicion is high for meningitis, administration of broad-spectrum antibiotic therapy should be initiated without delay following CSF collection [7].

Shunt Malfunction

A ventriculoperitoneal shunt is the most commonly encountered implanted system for CSF diversion. The system consists of a ventricular catheter connected to a reservoir and valve mechanism at the skull and a catheter that passes in the subcutaneous soft tissue in the neck and anterior chest wall to the peritoneum. The distal tubing can be alternatively inserted in the jugular vein, the pleura, or even the urinary bladder. Proximal shunt failure of the ventricular catheter may occur due to choroid plexus obstruction or cellular debris from CSF infection. Valve or distal tubing obstruction occurs also from cellular debris, from disconnection, poor CSF absorption, or formation of an intra-abdominal pseudocyst.

The clinical presentation of an obstructed shunt is variable. It may be slowly progressive and intermittent, or there may be a rapid decline in mentation progressing into a coma. A CT scan should be performed immediately to determine ventricular size. Ventriculomegaly is a reliable indicator of a malfunctioning shunt; however, the CT scan should be compared with previous studies because the ventricular system in a shunted patient is often congenitally or chronically abnormal.

Aspiration from the reservoir or valve system of a shunt can be performed to determine patency and collect CSF to diagnose an infectious process. The necessity of and procedure for a shunt tap is best left to a neurosurgeon. Shunt aspiration is an invasive procedure that carries a risk of contaminating the system with skin flora, and the resultant shunt infection requires a lengthy hospitalization for shunt externalization, antibiotic treatment, and replacement of all hardware. Therefore, CSF collection by shunt tap should be performed very selectively and after other potential sources of infection have been evaluated. When shunt failure is due to distal obstruction, aspiration of CSF may temper neurologic impairment and even be lifesaving until surgical revision can be performed.

Normal-Pressure Hydrocephalus

Serial lumbar punctures or continuous CSF drainage via a lumbar subarachnoid catheter can be used as provocative diagnostic tests to select patients who would benefit from a shunt for CSF diversion. The results have a positive predictive value if the patient's gait improves. Lumbar CSF access may also be used for infusion tests, measurement of CSF production rate, pressure–volume index, and outflow resistance or absorption. Some studies suggest that these values are also predictive of therapeutic CSF diversion [8–10].

Benign Intracranial Hypertension (Pseudotumor Cerebri)

Benign intracranial hypertension occurs in young persons, often obese young women. Intracranial pressure (ICP) is elevated without focal deficits and in the absence of ventriculomegaly or intracranial mass lesions [11]. The condition causes blindness, and most patients demonstrate some visual loss. Etiologic factors for childhood presentation include chronic middle ear infection, dural sinus thrombosis, head injury, vitamin A overdosage, tetracycline exposure, internal jugular venous thrombosis, and idiopathic causes. Some authors have proposed a broader definition of the "pseudotumor cerebri syndrome" on the basis of the underlying pathophysiologic mechanism of the presumed CSF circulation disorder [12].

Lumbar puncture demonstrates an elevated ICP (up to 40 cm H_2O), and CSF dynamics demonstrates an increase in outflow resistance. Serial daily punctures can be therapeutic, with CSF aspirated until closing pressure is within normal limits (<20 cm H_2O). In some cases, this can restore the balance between CSF formation and absorption; other cases require medical therapy, such as weight loss, steroids, acetazolamide, diuretics, and glycerol. If all these therapeutic interventions fail, placement of a permanent shunting system may be necessary.

Neoplasms

The subarachnoid space can be infiltrated by various primary or secondary tumors, giving rise to symptoms of meningeal irritation. CSF cytology can determine the presence of neoplastic cells, although their complete identification is not always possible. Systemic neoplasms, such as melanoma or breast cancer, have a greater propensity to metastasize into the CSF spaces than do primary CNS tumors and may even present primarily as meningeal carcinomatosis. Ependymoma, medulloblastoma or primitive neuroectodermal tumor, germinoma, and high-grade glioma are the most commonly disseminated primary tumors. Hematopoietic cancers such as leukemia and lymphoma also frequently infiltrate the subarachnoid spaces with little or no parenchymal involvement. CSF sampling is useful for an initial diagnostic and screening tool in the neurologically intact patient who harbors a tumor type with high risk of CNS relapse. Lymphoma cells in primary CNS lymphoma

are present in increased number and pleocytosis correlates with positive cytology [13]. A generous amount of CSF or multiple samples may be required for diagnosis and cisternal puncture may enhance the diagnosis if the lumbar CSF is nondiagnostic. Acute leukemias that tend to invade the CNS include acute lymphocytic leukemia, acute nonlymphocytic leukemia, acute myelogenous leukemia, acute myelomonocytic leukemia, and acute undifferentiated leukemia [14].

Myelography

Lumbar puncture is the most common means of access for lumbar and cervical myelography because the density of contrast material is higher than CSF and may be directed by gravity to the area of interest. Cervical C1–2 puncture had been a usual access route for cervical myelography, but now, it is often reserved for patients in whom a successful lumbar puncture is not possible due to extensive arachnoiditis, epidural tumor, severe spinal stenosis, or CSF block.

Other Neurologic Disorders

There is extensive literature on CSF changes in demyelinating diseases, including MS. Typical lumbar puncture findings are normal ICP, normal glucose levels, mononuclear pleocytosis, and elevated protein levels due to increased endothelial permeability. Immunoelectrophoresis reveals elevated IgG and oligoclonal bands that suggest inflammation in the CNS and may be a sign of MS [15,16].

CSF findings described in other disease states include elevated tau protein and decreased β-amyloid precursor protein in Alzheimer's disease and the presence of anti-GM1 antibodies and cytoalbumin dissociation in Guillain–Barré syndrome [17].

Therapeutic Intervention

Fistulas

CSF leaks occur due to a variety of nontraumatic and traumatic etiologies. Orthostatic headaches are a characteristic symptom of CSF leak, and rhinorrhea may be evident. Iatrogenic postoperative CSF leaks may occur following surgery at the skull base as a result of dural or bony defects. CSF fistulas following middle cranial fossa or cerebellopontine angle surgery occur infrequently, and CSF usually leaks through the auditory tube to the nasopharynx. Dural closure in the posterior fossa following suboccipital craniectomy is often difficult and not watertight. A fistula in that area usually results in a pseudomeningocele, which is clinically apparent as subcutaneous swelling at the incision site. Leaks following lumbar surgery are unusual, but they may occur as a result of recent myelography, dural tear, or inadequate dural closure [18]. In pediatric patients, repair of meningoceles or other spina bifida defects are more likely to present with a CSF leak because of dural or fascial defects.

The most common presentation of a CSF fistula follows trauma. Basilar skull fractures that traverse the ethmoid or frontal sinuses can cause CSF rhinorrhea. Fractures along the long axis of the petrous bone usually involve the middle ear, causing the hemotympanum noted on examination and CSF otorrhea if the tympanic membrane is ruptured. Most CSF leaks present within 48 hours, but delayed leaks are not uncommon because the fistula can be occluded with adhesions, hematoma, or herniated brain tissue, which temporarily tamponades the defect.

The diagnosis of a leak may be easily made on clinical examination; however, at times, the nature of a "drainage fluid" is uncertain and laboratory characterization is necessary. Dipping the fluid for glucose is misleading because nasal secretions are positive for glucose. A chloride level often shows a higher value than in peripheral blood, but identification of β_2-transferrin is the most accurate diagnostic for CSF. This protein is produced by neuraminidase in the brain and is uniquely found in the spinal and perilymph fluids [19].

Elevation of the patient's head is the primary treatment of CSF leak. Placement of a lumbar drainage catheter or daily lumbar punctures should be used if conservative therapy fails. The use of a continuous lumbar drainage by a catheter is somewhat controversial because of the potential for intracranial contamination from the sinuses if the ICP is lowered. To help prevent such complications, the lumbar drain collection bag can be maintained no lower than the patient's shoulder level and the duration of drainage should not exceed 5 days.

Intracranial Hypertension

Intracranial hypertension can cause significant neurologic morbidity or even death. Access to the intracranial CSF space is useful for diagnosis and treatment [20]. A ventriculostomy is commonly used both as an ICP monitor and as a means to treat intracranial hypertension by CSF drainage. An ICP-measuring device should be placed following traumatic brain injury for patients who exhibit a Glasgow Coma Scale score less than 8, a motor score less than 6 (not aphasic), and with initial CT findings of diffuse brain edema, intercranial hematoma, cortical contusions, or absent or compressed basal cisterns [21]. ICP monitoring can also be indicated in cerebrovascular diseases, including aneurysmal SAH, spontaneous cerebral hematoma, ischemic and hypoxic cerebral insults, and intraventricular hemorrhage. Obstructive hydrocephalus is another major indication for placement of a ventricular catheter for drainage and monitoring. ICP may be elevated due to cerebral edema that surrounds tumors, intracranial hematomas, stroke, and traumatic contusions, or that occurs postoperatively or following cranial radiation therapy. Diffuse brain swelling also occurs in the setting of inflammatory and infectious disorders such as Reye's syndrome or meningitis, or as a result of hyperthermia, carbon dioxide retention, or intravascular congestion.

Drug Therapy

The CSF can be a route of administration for medications such as chemotherapeutic agents and antibiotics. Treatment of lymphoma and leukemia often involves intrathecal injections of various agents, which may be infused through a lumbar route or an intraventricular injection via an implanted reservoir. Meningeal carcinomatosis is treated by intrathecal chemotherapy (e.g., methotrexate). Serial injections of small amounts are performed in an attempt to minimize neurotoxicity, and the use of a ventricular reservoir may be less traumatic for the patient than that of multiple lumbar punctures. Treatment of meningitis and ventriculitis may include intrathecal antibiotics in addition to systemic therapy. Careful dosage and administration are recommended, especially if the ventricular route is used, as many antibiotics can cause seizures or an inflammatory ventriculitis when given intrathecally.

TECHNIQUES OF CEREBROSPINAL FLUID ACCESS

There are several techniques for CSF aspiration. All procedures should be performed using sterile technique (including sterile gloves and a mask), and the skin is prepared with antiseptic solution and draped with sterile towels.

Lumbar Puncture

Lumbar puncture is a common procedure that is readily performed by the general practitioner at the bedside and can be performed in any hospital or outpatient setting where commercially prepared lumbar puncture trays are available. In patients with advanced spinal degeneration, extensive previous lumbar surgery for congenital defects and the assistance of a radiologist for needle placement using fluoroscopy or ultrasonography may be required. Contraindications to lumbar puncture include skin infection at the entry site, anticoagulation or blood dyscrasias, papilledema in the presence of supratentorial masses, posterior fossa lesions, and known spinal subarachnoid block or spinal cord arteriovenous malformations.

In adults, CSF aspirations are adequately performed under local anesthesia using 1% lidocaine without premedication. In the pediatric population, however, sedation is often required and allows for a smoother procedure. This is also true in the case of anxious, confused, or combative adult patients.

Oral or rectal chloral hydrate may be used in small children, and moderate sedation using intravenous midazolam and fentanyl or dexmedetomidine can be highly successful in appropriately monitored adults and children when performed in a monitored setting by an experienced individual. The application of a topical anesthetic, such as EMLA cream (2.5% lidocaine and 2.5% prilocaine), preceding injection can also be useful. Conversely, it has been demonstrated in a controlled clinical trial that in the neonatal population, injection of a local anesthetic for lumbar puncture is probably not required and does not reduce perceived stress or discomfort [22].

Figures 17.1 and 17.2 depict some of the steps for lumbar puncture. The patient is placed in the lateral knee-chest position or with the patient sitting leaning forward over a bedside table. The sitting position may be preferred for obese patients in whom adipose tissue can obscure the midline or in elderly patients with significant lumbar degenerative disease. Following a time-out (correct patient, procedure, site, and equipment), the local anesthetic is injected subcutaneously using a 25- or 27-gauge needle. A 1.5-in. needle is then inserted through the skin wheal and additional local anesthetic is injected along the midline, thus anesthetizing the interspinous ligaments and muscles. This small anesthetic volume is usually adequate; however, a more extensive field block is accomplished by additional injections on each side of the interspinous space near the lamina [23].

The point of skin entry is midline at the level of the superior iliac crests, which is usually between the spinous processes of L3 to L4. Lower needle placement at L4 to L5 or L5 to S1 is required in children and neonates to avoid injury to the conus medullaris, which lies more caudal than in adults. The needle is advanced with the stylet or obturator in place to maintain needle patency and prevent iatrogenic intraspinal epidermoid tumors. The bevel of the needle should be parallel to the longitudinal fibers of the dura and spinal column. The needle should be oriented rostrally at an angle of about 30 degrees to the skin and virtually aimed toward the umbilicus. When properly oriented, the needle passes through the following structures before entering the subarachnoid space: skin, superficial fascia, supraspinous ligament, interspinous ligament, ligamentum flavum, epidural space with its fatty areolar tissue and internal vertebral plexus, dura, and arachnoid membrane (Fig. 17.3). The total depth varies from less than 1 in. in the very young patient to as deep as 4 in. in the obese adult. The kinesthetic sensations of passing through the ligaments into the epidural

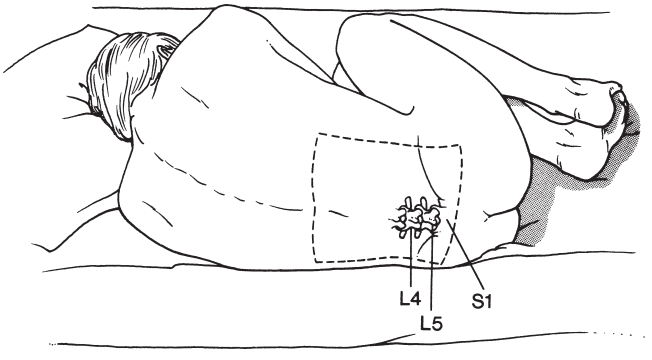

FIGURE 17.1. Patient in the lateral decubitus position with back on the edge of the bed and knees, hips, back, and neck flexed. [From Davidson RI: Lumbar puncture, in VanderSalm TJ (ed): *Atlas of Bedside Procedures*. 2nd ed. Boston, Little, Brown, 1988, with permission.]

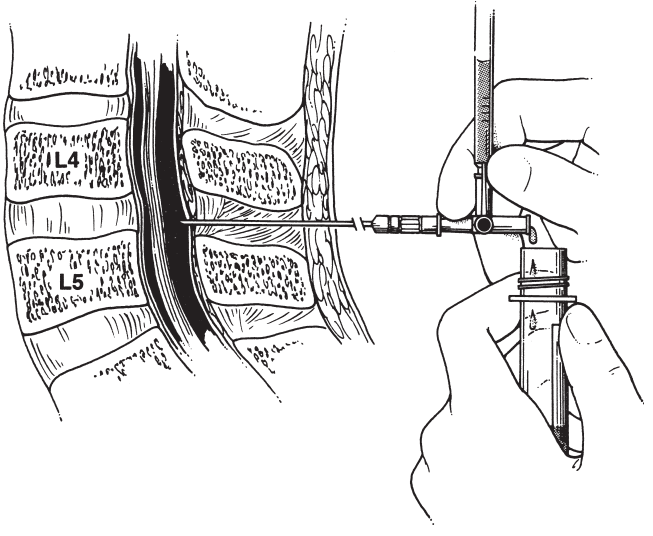

FIGURE 17.3. The spinal needle is advanced to the spinal subarachnoid space and cerebrospinal fluid samples collected after opening pressure is measured. [From Davidson RI: Lumbar puncture, in VanderSalm TJ (ed): *Atlas of Bedside Procedures*. 2nd ed. Boston, Little, Brown, 1988, with permission.]

space followed by dural puncture are quite consistent and recognized with practice. Once intradural, the bevel of the needle is redirected in a cephalad direction in order to improve CSF flow. A spinal needle no smaller than 22 gauge should be used for pressure measurement. The opening pressure is best measured with the patient's legs relaxed and extended partly from the knee-chest position. Pressure measurements may be difficult in children and may be estimated using CSF flow rate [24].

Once CSF is collected, the closing pressure is measured prior to needle withdrawal. It is best to replace the stylet in the needle prior to exiting the subarachnoid space. CSF pressure measurements are not accurate if performed in the sitting position due to the hydrostatic pressure of the CSF column above the entry point or if a significant amount of CSF was lost when the stylet is first withdrawn. If necessary, the pressure could be measured by reclining the patient to the lateral position once entry in the CSF space has been secured.

Although a lumbar puncture is typically safe, there are a number of potential complications and risks involved. Hemorrhage is uncommon but can be seen in association with bleeding disorders and anticoagulation therapy. Spinal SAH has been reported in such conditions, resulting in blockage of CSF outflow with subsequent back and radicular pain, sphincter disturbances, and even paraparesis [25]. Spinal subdural hematoma is likewise very infrequent, but it is associated with significant morbidity that may require prompt surgical intervention. Infection by introduction of the patient's skin flora or the operator's mouth or nose flora into the subarachnoid spaces, causing meningitis, is uncommon and preventable if aseptic techniques (including mask) are used. Risks of infection are increased in serial taps or placement of lumbar catheters for the treatment of CSF fistulas.

Postural headache is the most common complication following lumbar puncture. Its reported frequency varies from 1% to 70% [26]. It is thought to be due to excessive leakage of CSF into the paraspinous spaces, resulting in intracranial hypotension with stretching and expansion of the pain-sensitive intracerebral veins. MRI has demonstrated a reduced CSF volume following lumbar puncture, but with no significant brain displacement and no correlation with headache [27]. Psychologic factors and previous history of headaches seem to strongly influence the patient's risk of and tolerance to headache [28]. A smaller needle size, parallel orientation to the dural fibers, a paramedian approach, and stylet reinsertion prior to withdrawal of the spinal needle have also been reported to decrease the risk of headache after lumbar puncture [29].

The choice of needle type has been the subject of literature debate. Several needle tip designs are available, including the traditional Quincke needle with a beveled cutting tip, the Sprotte needle with a pencil point and side hole, and the Whitacre needle, which is similar to the Sprotte needle but with a smaller side hole. The use of an atraumatic needle seems to be adequate for the performance of a diagnostic lumbar puncture and is probably associated with a lower risk of a postpuncture headache [30,31].

Postdural puncture headache typically develops within 72 hours and lasts 3 to 5 days. Conservative treatment consists of bed rest, hydration, and analgesics. Non-phenothiazine antiemetics are administered if the headache is associated with nausea. If the symptoms are more severe, methylxanthines (caffeine or theophylline) are prescribed orally or parenterally. These agents are successful in up to 85% of patients [32]. Several other pharmacologic agents are discussed in the literature, but none seems to be as effective as caffeine. If the headache persists or is unaffected, an epidural blood patch is then recommended because it is one of the most effective treatments for this condition [33]. Epidural injection of other agents, such as saline, dextran, or adenocorticotropic hormone, has also been described and may be valuable under certain conditions (e.g., sepsis or acquired immunodeficiency syndrome) [34].

An uncommon sequela of lumbar puncture or continuous CSF drainage is hearing loss. Drainage decreases ICP, which is transmitted to the perilymph via the cochlear aqueduct and can cause hearing impairment [35]. The rate of occurrence of this complication is reported to be 0.4%, but is probably higher because it goes unrecognized and seems reversible. There are a few documented cases of irreversible hearing loss [36].

Transient sixth-nerve palsy has also been reported, probably due to nerve traction following significant CSF removal. Neurovascular injury can occur uncommonly in the setting of a subarachnoid block due to spinal tumors. In this situation, CSF drainage leads to significant traction and spinal coning with subsequent neurologic impairment [37,38].

Lateral Cervical (C1–2) Puncture

The C1–2 or lateral cervical puncture was originally developed for percutaneous cordotomy. It may be used for myelography or aspiration of CSF if the lumbar route is inaccessible. It is most safely performed with fluoroscopic guidance with the patient supine, the head and neck flexed, and the lateral neck draped. The skin entry point is 1 cm caudal and 1 cm dorsal to the tip of the mastoid process. The site is infiltrated with a local anesthetic, and the spinal needle is introduced and directed toward the junction of the middle and posterior thirds of the bony canal to avoid an anomalous vertebral or posterior inferior cerebellar artery that may lie in the anterior half of the canal. The stylet should be removed frequently to check for CSF egress. When the procedure is performed under fluoroscopy, the needle is seen to be perpendicular to the neck and just under the posterior ring of C1. The same sensation is recognized when piercing the dura as in a lumbar puncture and the bevel is then directed cephalad in a similar fashion. Complications of the lateral cervical puncture include injury to the spinal cord or the vertebral artery and irritation of a nerve root, causing local pain and headache.

Cisternal Puncture

A cisternal puncture provides CSF access via the cisterna magna when other routes are not possible. A preoperative lateral skull radiograph is performed to ensure normal anatomy. The patient is positioned sitting with the head slightly flexed. The hair is removed in the occipital region and the area prepared, draped, and infiltrated with lidocaine. The entry point is in the midline between the external occipital protuberance in the upper margin of the spinous process of C2 or via an imaginary line through both external auditory meati. The spinal needle is directed through a slightly cephalad course and usually strikes the occipital bone. It is then redirected more caudally in a stepwise fashion until it passes through the atlanto-occipital membrane and dura, producing a "popping" sensation. The cisterna magna usually lies 4 to 6 cm deep to the skin; the needle should not be introduced beyond 7.0 to 7.5 cm from the skin to prevent injury to the medulla or the vertebral arteries. The procedure can be performed relatively safely in a cooperative patient as the cisterna magna is a large CSF space; however, it is rarely practiced due to the greater potential morbidity.

Aspiration of Reservoirs and Shunts

An implanted reservoir or shunt system should not be accessed without prior consultation with a neurosurgeon, despite the apparent simplicity of the procedure itself. Violating implanted systems carries several risks, including infection, which can result in a lengthy hospitalization, prolonged antibiotic course,

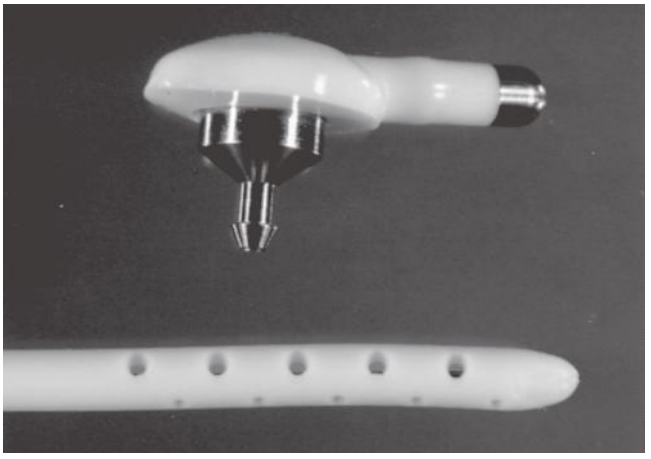

FIGURE 17.4. Close-up view of ventricular reservoir in the calvarial burr hole, the funneled base connected directly to the proximal end of the ventricular catheter. The distal perforated end is shown.

and several operative procedures for shunt externalization, hardware removal, and insertion of a new shunt system.

Subcutaneous reservoirs in ventriculoatrial or ventriculoperitoneal shunting systems are located proximal to the unidirectional valve and can be accessed percutaneously. The reservoirs are usually button-sized, measuring approximately 7 to 10 mm in diameter and 2 mm in height. They can be located in the burr hole directly connected to the ventricular catheter (Fig. 17.4) or as an integral part of the valve system (Fig. 17.5). Indications for reservoir taps have been previously discussed.

The procedure can be performed in any hospital or outpatient setting. Gloves, mask, antiseptic solution, razor, sterile drapes, 23- or 25-gauge needle (short hub or butterfly), tuberculin syringe, and sterile collection tubes are readied. The patient can be in any comfortable position that allows access to the reservoir. Sedation may be required for toddlers, but is otherwise unnecessary. Reference to a skull radiograph may be helpful in localization. The reservoir is palpated, overlying hair is removed preferably with a clipper rather than a razor and the skin cleansed. Local anesthesia is usually not required and the use of topical anesthetic creams is occasionally considered. The needle is inserted perpendicular to the skin and into the reservoir, to a total depth of 3 to 5 mm. A manometer is then connected to the needle or butterfly tubing for pressure measurement. CSF collection is performed and drug injection is performed only if CSF flow is demonstrated. A "dry tap" usually indicates faulty placement or catheter obstruction. Occasionally, an old reservoir may have retracted into the burr hole and not be palpable or may be too calcified for needle penetration and some older shunting systems may not even have a reservoir. Risks and complications of shunt aspiration include improper insertion, contamination with skin flora, introduction of blood in the shunt system, and choroid plexus hemorrhage due to vigorous aspiration.

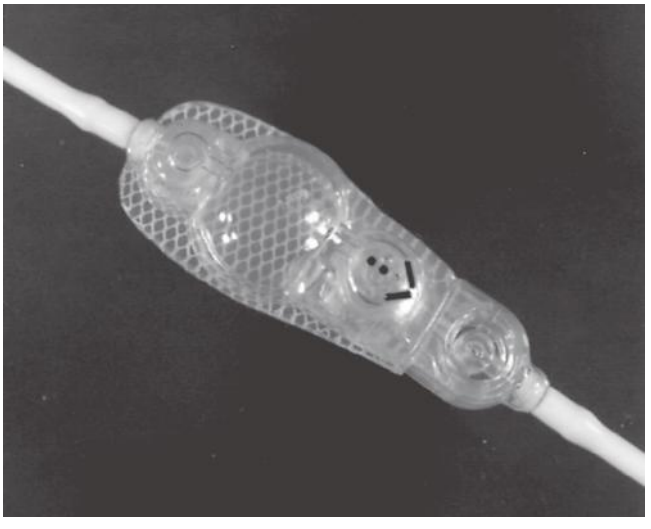

FIGURE 17.5. A domed reservoir in series in one type of shunt valve. The large, clear-domed area for puncture lies immediately proximal to the one-way valve.

Lumboperitoneal Shunt

Lumboperitoneal shunts are placed via percutaneous insertion of a lumbar subarachnoid catheter or through a small skin incision. They are tunneled subcutaneously around the patient's flank to the abdomen, where the distal catheter enters the peritoneal cavity through a separate abdominal incision. A reservoir or valve or both may be used and are located on the lateral aspect of the flank. Careful palpation between the two incisions usually reveals the tubing path and reservoir placement in the nonobese patient. The patient is placed in lateral decubitus position and a pillow under the dependent flank may be of assistance. The same technique as described for a ventricular shunt is then performed. Fluid aspiration should be particularly gentle as an additional risk of this procedure is nerve root irritation.

Ventricular Reservoirs

Ventricular reservoirs are inserted as part of a blind system consisting of a catheter located in a CSF space, usually the lateral ventricle, and without distal runoff. Such systems are placed for CSF access purposes only, such as for instillation of antibiotics or chemotherapeutic agents, or CSF aspiration for treatment and monitoring. Ommaya reservoirs are dome-shaped structures (Fig. 17.6) with a diameter of 1 to 2 cm and have a connecting port placed at their base or side. They are placed subcutaneously and attached to a ventricular

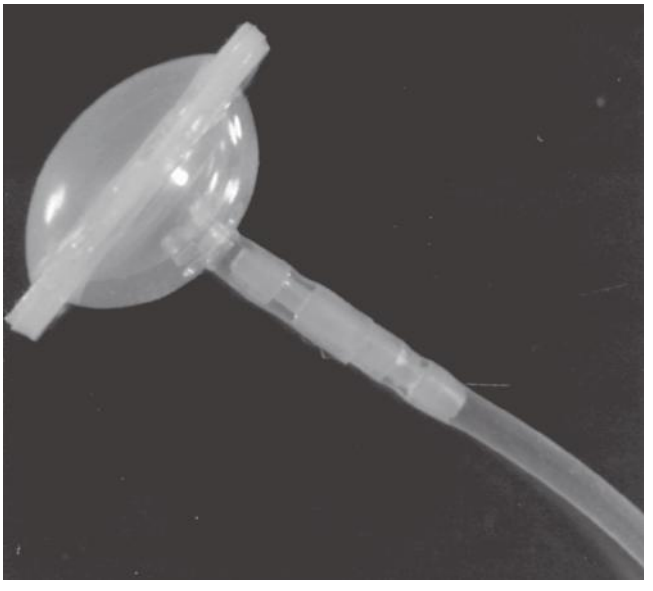

FIGURE 17.6. Close-up view of a ventricular (Ommaya) double-domed reservoir, the caudal half of which is designed to lie within the burr hole.

FIGURE 17.7. Coronal section through the brain at the level of the frontal horns, illustrating the subgaleal/epicalvarial location at the reservoir, with the distal perforated part of the catheter lying within the ventricle.

subarachnoid catheter (Fig. 17.7). Aspiration technique is essentially the same as from a shunt reservoir; however, the Ommaya reservoir is often larger and differs in shape from many shunt reservoirs. It is accessed, preferably, with a 25-gauge needle or butterfly. CSF is allowed to flow by gravity if possible; a volume equal to that to be instilled is removed and held for analysis or reinjection. The antibiotic or chemotherapeutic agent is injected; 1 mL of CSF or sterile saline can be used to flush the dose into the ventricle, or gentle barbotage of the reservoir may be performed to achieve the same goal. Risks and complications are essentially the same as in shunt aspirations (i.e., infection, bleeding, and improper insertion), with the addition of chemical ventriculitis or arachnoiditis.

Ventriculostomy

A ventriculostomy is a catheter placed in the lateral ventricle for CSF drainage or ICP monitoring and treatment. It is performed by a neurosurgeon in the operating room or at the bedside in the intensive care unit or emergency department. It is usually performed through the nondominant hemisphere and into the frontal horn of the lateral ventricle. An alternate approach is to cannulate the occipital horn or trigone through an occipital entry point located 6 cm superior to the inion and 4 cm from the midline. Premedication is not necessary unless the patient is very anxious or combative. Radiographic guidance is typically not required unless the procedure is being performed stereotactically. CT or MRI stereotaxy is needed if the ventricles are very small, as in diffuse brain swelling or slit ventricle syndrome. Complications of ventriculostomy placement include meningitis or ventriculitis, scalp wound infection, intracranial hematoma or cortical injury, and failure to cannulate the ventricle.

Lumbar Drainage

Continuous CSF drainage via a lumbar catheter is useful in the treatment of CSF fistulas and as a provocative test to demonstrate the potential effects of shunting in normal-pressure hydrocephalus or ventriculomegaly of various etiologies. Commercially available lumbar drainage kits are closed sterile systems that drain into a replaceable collection bag. Catheter placement is performed just as in lumbar puncture; however, a large-bore Tuohy needle is used, through which the catheter is threaded once CSF return has been confirmed. Needle orientation follows the same guidelines as discussed for a lumbar puncture and is even more important in the case of this large-gauge needle. Epidural catheter kits could also be used, although the catheters tend to be slightly stiffer and have a narrower diameter. Complications include hemorrhage in the epidural or subarachnoid space, infection, inability to aspirate CSF, CSF leak, nerve root irritation, and, most ominously, a supratentorial subdural hematoma secondary to overdrainage. This complication tends to be more common in elderly individuals. The potential for overdrainage is significant because of the large diameter of the catheter and because the amount of drainage depends on the cooperation of the patient and the nursing staff.

SUMMARY

Of the various techniques available for CSF access, lumbar puncture is the procedure most commonly and safely performed by the general practitioner. Other techniques are described that may require the assistance of a radiologist, neurologist, anesthesiologist, or neurosurgeon.

CHAPTER 18 ■ PERCUTANEOUS SUPRAPUBIC CYSTOSTOMY

SATYA ALLAPARTHI, K.C. BALAJI AND PHILIP J. AYVAZIAN

Percutaneous suprapubic cystostomy was described four centuries ago; safety of the procedure was first demonstrated by Garson and Peterson in 1888. The first modern method was the Campbell trocar set, described in 1951 [1]. It is used to divert urine from the bladder when standard urethral catheterization is impossible or undesirable [2]. In emergency situations, the majority of these patients are men with urethral stricture or complex prostatic disease or patients with trauma with urethral disruption. Complete urethral transection associated with a pelvic fracture is an absolute indication for emergent suprapubic cystostomy. The procedure for placement of a small-diameter catheter is rapid, safe, and easily accomplished at the bedside under local anesthesia. This chapter first addresses methods for urethral catheterization before discussing the percutaneous approach.

URETHRAL CATHETERIZATION

Urethral catheterization remains the principal method for bladder drainage. The indications for the catheter should be clarified because they influence the type and size of catheter to be used [3]. A history and physical examination with particular attention to the patient's genitourinary system are important.

Catheterization may be difficult with male patients in several instances. Patients with lower urinary tract symptoms (e.g., urinary urgency, frequency, nocturia, decreased stream, and hesitancy) may have benign prostatic hypertrophy. These patients may require a larger bore catheter, such as 20 or 22 French (Fr). When dealing with urethral strictures, a smaller bore catheter should be used, such as 12 or 14 Fr. Patients with a history of prior prostatic surgery such as transurethral resection of the prostate, open prostatectomy, or radical prostatectomy may have an irregular bladder neck as a result of contracture after surgery. The use of a coudé-tip catheter, which has an upper deflected tip, may help in negotiating the altered anatomy after prostate surgery. The presence of a high-riding prostate or blood at the urethral meatus suggests urethral trauma. In this situation, urethral integrity must be demonstrated by retrograde urethrogram before urethral catheterization is attempted.

Urethral catheterization for gross hematuria requires large catheters, such as 22 or 24 Fr, which have larger holes for irrigation and removal of clots. Alternatively, a three-way urethral catheter may be used to provide continuous bladder irrigation to prevent clotting. Large catheters impede excretion of urethral secretions, however, and can lead to urethritis or epididymitis if used for prolonged periods.

Technique

In male patients, after the patient is prepared and draped, 10 mL of a 2% lidocaine hydrochloride jelly is injected retrograde into the urethra. Anesthesia of the urethral mucosa requires 5 to 10 minutes after occluding the urethral meatus either with a penile clamp or manually to prevent loss of the

jelly [4]. The balloon of the catheter is tested, and the catheter tip is covered with a water-soluble lubricant. After stretching the penis upward and perpendicular to the body, the catheter is inserted into the urethral meatus. The catheter is advanced up to the hub to ensure its entrance into the bladder. To prevent urethral trauma, the balloon is not inflated until urine is observed draining from the catheter. Irrigation of the catheter with normal saline helps verify the position. A common site of resistance to catheter passage is the external urinary sphincter within the membranous urethra, which may contract voluntarily. Any other resistance may represent a stricture, necessitating urologic consultation. In patients with prior prostate surgery, an assistant's finger placed in the rectum may elevate the urethra and allow the catheter to pass into the bladder.

In female patients, short, straight catheters are preferred. Typically, a smaller amount of local anesthesia is used. Difficulties in catheter placement occur after urethral surgery or vulvectomy, or with vaginal atrophy or morbid obesity. In these cases, the meatus is not visible and may be retracted under the symphysis pubis. Blind catheter placement over a finger located in the vagina at the palpated site of the urethral meatus may be successful.

When urologic consultation is obtained, other techniques for urethral catheterization can be used. Flexible cystoscopy may be performed to ascertain the reason for difficult catheter placement and for insertion of a guidewire. A urethral catheter can then be placed over the guidewire by the Seldinger technique. Filiforms and followers are useful for urethral strictures.

Indications

On occasion, despite proper technique (as outlined previously), urethral catheterization is unsuccessful. These are the instances when percutaneous suprapubic cystotomy is necessary. Undoubtedly, the most common indication for percutaneous suprapubic cystotomy is for the management of acute urinary retention in men. Other indications for a percutaneous suprapubic cystotomy in the intensive care unit are provided in Table 18.1.

Contraindications

The contraindications to percutaneous suprapubic cystotomy are provided in Table 18.2. An inability to palpate the bladder or distortion of the pelvic anatomy from previous surgery or trauma makes percutaneous entry of the bladder difficult. In these situations, the risks of penetrating the peritoneal cavity become substantial. The bladder may not be palpable if the patient is in acute renal failure with oliguria or anuria, has a small contracted neurogenic bladder, or is incontinent. When the bladder is not palpable, it can be filled in a retrograde manner with saline to distend it. In men, a 14-Fr catheter is placed in the fossa navicularis just inside the urethral meatus and the balloon is filled with 2 to 3 mL of sterile water to occlude the urethra. Saline is injected slowly into the catheter until the bladder is palpable and then the suprapubic tube may be placed. In patients with a contracted neurogenic bladder, it is impossible to adequately distend the bladder by this approach. For these patients, ultrasonography is used to locate the bladder and allow the insertion of a 22-gauge spinal needle. Saline is instilled into the bladder via the needle to distend the bladder enough for suprapubic tube placement (Fig. 18.1).

In patients with previous lower abdominal surgery, ultrasonographic guidance is often necessary before a percutaneous cystotomy can be performed safely. Previous surgery can lead to adhesions that can hold a loop of intestine in the area of insertion. Other relative contraindications include patients with coagulopathy, a known history of bladder tumors, or active hematuria and retained clots. In patients with bladder tumors, percutaneous bladder access should be avoided because tumor cell seeding can occur along the percutaneous tract. Suprapubic cystotomy tubes are small in caliber and therefore do not function effectively with severe hematuria and retained clots. Instead, open surgical placement of a large-caliber tube is necessary if urethral catheterization is impossible.

TABLE 18.1

COMMON INDICATIONS FOR PERCUTANEOUS CYSTOTOMY

Unsuccessful urethral catheterization in the setting of acute urinary retention
History of prostate surgery
Presence or suspected urethral trauma
Urethral stricture
Severe hypospadias
Periurethral abscess
Presence of severe urethral, epididymal, or prostate infection

TABLE 18.2

RELATIVE CONTRAINDICATIONS TO PERCUTANEOUS SUPRAPUBIC CYSTOTOMY

Nonpalpable bladder
Previous lower abdominal surgery
Coagulopathy
Known bladder tumor
Clot retention

Technique

There are two general types of percutaneous cystotomy tubes that range in size from 8 to 14 Fr [5,6]. The first type uses an obturator with a preloaded catheter. Examples include the Stamey catheter (Cook Urological, Spencer, IN) and the Bonanno catheter (Beckton Dickinson and Co, Franklin Lakes, NJ) [7]. The Stamey device is a polyethylene Malecot catheter with a luer lock hub that fits over a hollow needle obturator (Fig. 18.2A). When the obturator is locked to the hub of the catheter, the Malecot flanges are pulled inward (closed) and the system is ready for use. The Bonanno catheter uses a flexible 14-Fr Teflon tube, which is inserted over a hollow 18-gauge obturator (Fig. 18.2B). The obturator locks into the catheter hub and extends beyond the catheter tip. When the obturator is withdrawn, the tube pigtails in the bladder. One advantage to the Stamey catheter is that the flanges provide a secure retaining system. The Bonanno catheter generally induces fewer bladder spasms, however, and is better tolerated.

The second type of percutaneous cystotomy tube consists of a trocar and sheath, which are used to penetrate the abdominal wall and bladder [8,9]. One of the most popular systems is the Lawrence suprapubic catheter (Rusch, Duluth, GA). This system allows a standard Foley catheter to be placed after removal of the trocar (Fig. 18.2C).

The patient is placed in the supine position; a towel roll may be placed under the hips to extend the pelvis. Trendelenburg position may help to move the abdominal contents away from the bladder. The bladder is palpated to ensure that it is distended. The suprapubic region is prepared with 2%

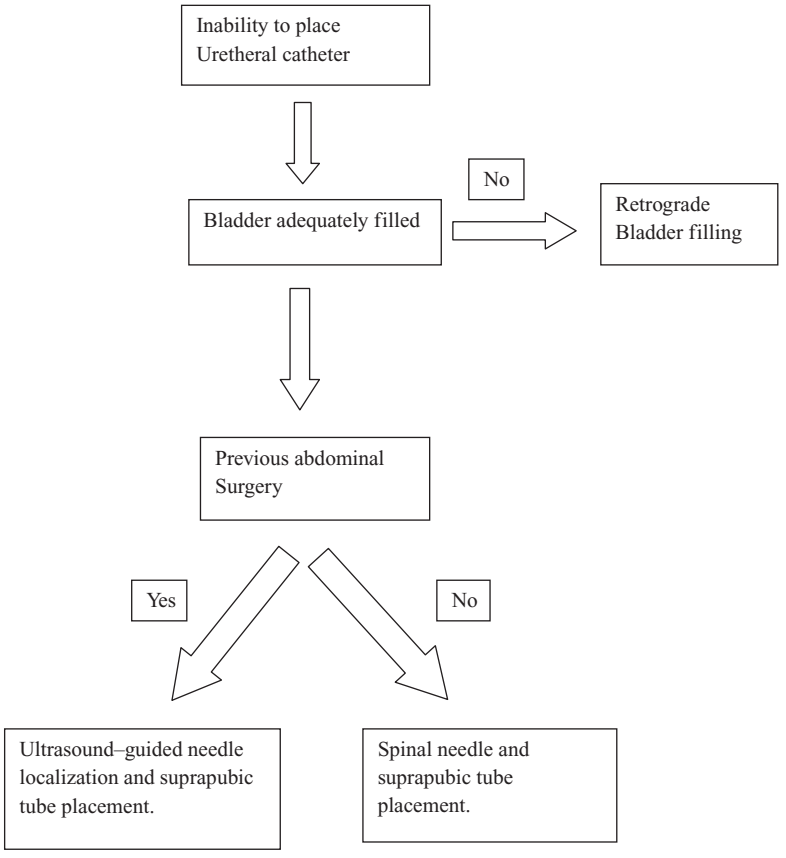

FIGURE 18.1. Algorithm for percutaneous suprapubic tube placement.

chlorhexidine/10% povidone–iodine solution and draped with sterile towels. The insertion site is several centimeters above the symphysis pubis in the midline: this approach avoids the epigastric vessels. In obese patients with a large abdominal fat pad, the fold is elevated. The needle should be introduced into the suprapubic crease, where the fat thickness is minimal. One percent lidocaine is used to anesthetize the skin, subcutaneous tissues, rectus fascia, and retropubic space. A 22-gauge spinal needle with a 5-mL syringe is directed vertically and advanced until urine is aspirated. If the bladder is smaller or the patient had previous pelvic surgery, the needle is directed at a 60-degree caudal angle. Insertion of the cystotomy tube is predicated on the feasibility of bladder puncture and after the angle and depth of insertion are established with the spinal needle (Fig. 18.3).

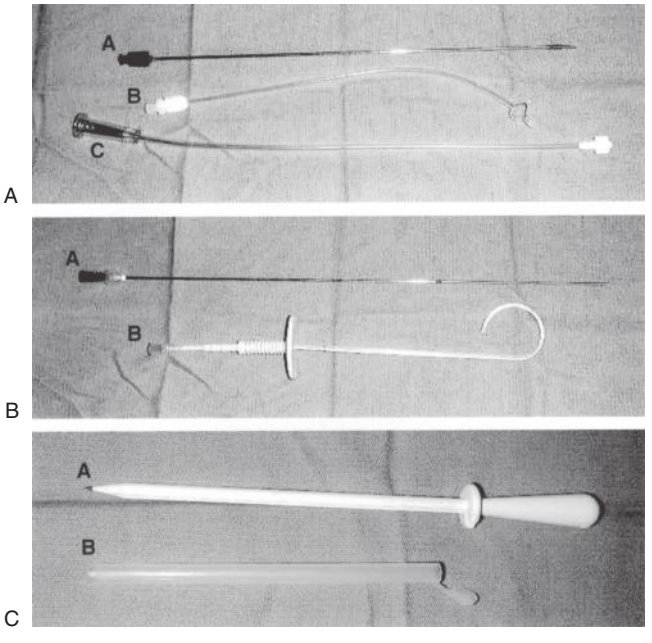

FIGURE 18.2. A: Stamey suprapubic cystostomy trocar set (A is the obturator, B is the Malecot catheter, and C is the drainage tube). **B:** Bonanno catheter set (A is the obturator and B is the catheter). **C:** Lawrence suprapubic catheter (A is the trocar and B is the sheath).

At the site of bladder puncture, a small 2-mm incision is made with a no. 11 blade. The catheter mounted on the obturator is advanced into the bladder. Two hands are used to grasp the system to provide a forceful, but controlled, thrust through the abdominal wall. One hand can be positioned on the obturator at a site marking the depth of the bladder. A syringe attached to the end of the obturator is used to aspirate urine and confirm obturator placement. Once the bladder is penetrated, the entire system is advanced 2 to 3 cm. This prevents the catheter tip from withdrawing into the retropubic space when the bladder decompresses. After unlocking the obturator from the catheter, the obturator acts as a guide while the catheter is advanced into the bladder. When using a Stamey catheter, the catheter can be gently withdrawn until the Malecot flanges meet resistance against the anterior bladder wall. The Stamey catheter is then advanced 2 cm back into the bladder to allow for movement. This maneuver pulls the catheter away from the bladder trigone and helps reduce bladder spasms.

The same general technique applies to placement of the Lawrence suprapubic catheter system. After the bladder is penetrated, urine appears at the hub of the suprapubic catheter introducer (trocar plus sheath). The trocar is then removed and a Foley catheter is inserted. The Foley catheter balloon is inflated to secure it in the bladder. Pulling the tab at the top of the peel-away sheath allows the remaining portion of the sheath to be removed away from the catheter.

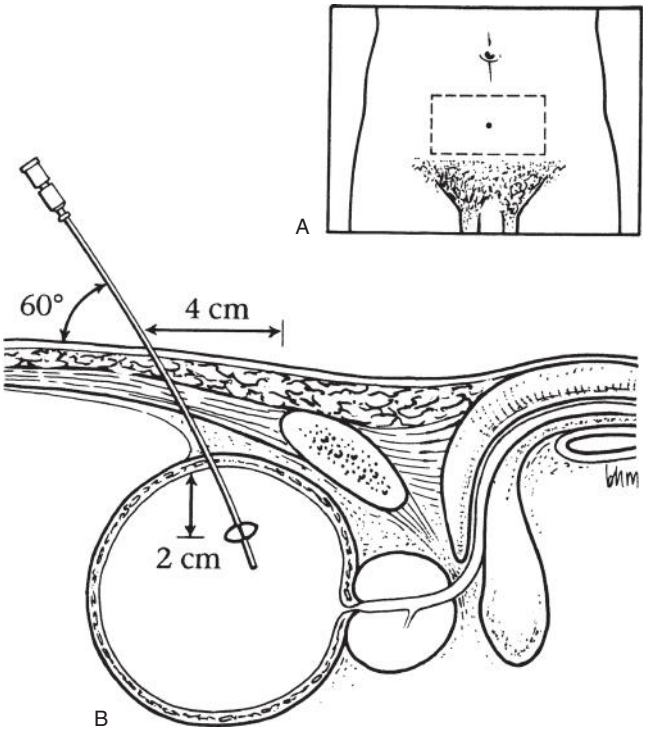

FIGURE 18.3. Technique of suprapubic trocar placement. **A:** Area to be shaved, prepared, and draped before trocar placement. **B:** Position of the Stamey trocar in the bladder. The angle, distance from the pubis, and position of the catheter in relation to the bladder wall are demonstrated.

The patency of the catheter is assessed by irrigating the bladder after decompression. The catheter can be fixed with a simple nylon suture and sterile dressing. The Bonanno catheter contains a suture disk. The Lawrence suprapubic catheter does not require extra fixation because the balloon on the Foley catheter secures it in place.

IMAGE-GUIDED PERCUTANEOUS SUPRAPUBIC CYSTOSTOMY

Ultrasound provides physicians with a twofold increase in success rates for suprapubic bladder needle aspiration and was sensitive in evaluating and confirming bladder distention [10]. It is readily available, can be performed at the bedside, is easy to perform, and poses no additional risk to the patient [11,12]. Ultrasound visualization of a full bladder is easy to learn and provides a well-defined image of the bladder (Fig. 18.4). The bladder is located beneath the abdominal muscles in the lower midline position, anterior to the uterus in females. A full bladder is easy to visualize as a midline symmetrical hypoechoic image under the abdominal rectus muscles in the suprapubic abdominal region. The bladder is best visualized when it is distended, using 3.5-, 5.0-, or 7.5-MHz transducer probes on transabdominal transverse and longitudinal axial planes. Ultrasound can establish the presence of fluid in and surrounding the bladder, as well as provide dimensions of depth and size of the bladder itself. Tenting of the bladder wall can be seen by ultrasound as the needle pushes against the bladder before penetration occurs and the catheter can be seen within the bladder once the cystostomy tube placement has been performed.

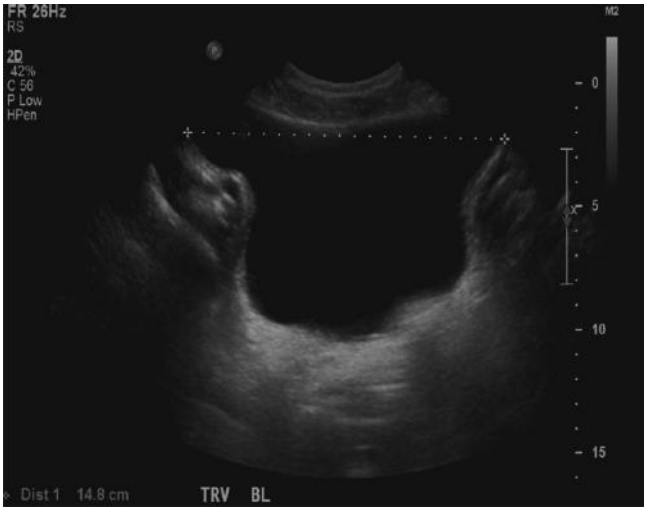

FIGURE 18.4. Ultrasound image of full bladder.

SUPRAPUBIC CATHETER CARE

Bladder spasms occur commonly after suprapubic catheter placement. When using a Stamey catheter or a Foley catheter, bladder spasms can be prevented by withdrawing the tube until it meets the anterior bladder wall and then advancing 2 cm back into the bladder. Persistent bladder spasms can be treated with anticholinergic therapy (e.g., oxybutynin and hyoscyamine). This medication should be discontinued before removing the suprapubic tube to prevent urinary retention.

A suprapubic tube that ceases to drain is usually caused by kinking of the catheter or displacement of the catheter tip into the retropubic space. If necessary, suprapubic catheters may be replaced either by using an exchange set (available for Stamey catheters) or by dilating the cystotomy tract. Closure of the percutaneous cystotomy tract is generally prompt after the tube is removed. Prolonged suprapubic tube use can lead to a mature tract, which may take several days to close. If the tract remains open, bladder decompression via a urethral catheter may be required.

COMPLICATIONS

Placement of suprapubic cystotomy tubes is generally safe with infrequent complications. Possible complications are provided in Table 18.3 [13]. Bowel complications are severe, but rare, with this procedure [14]. Penetration of the peritoneal cavity or bowel perforation produces peritoneal or intestinal symptoms and signs. This complication may be avoided by attempting the procedure on well-distended bladders, using a midline

TABLE 18.3

COMPLICATIONS OF PERCUTANEOUS CYSTOTOMY

Hypotension
Bladder perforation and infection of space of Retzius

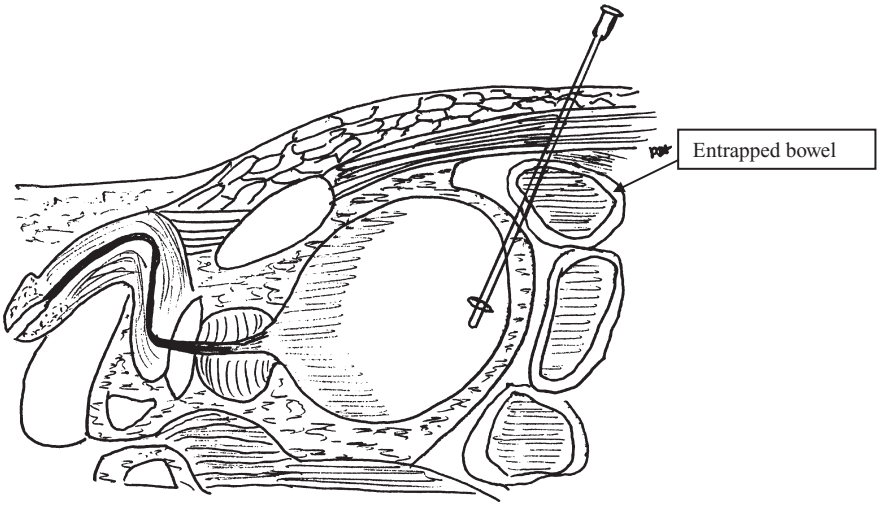

FIGURE 18.5. Placement of the suprapubic tube can perforate entrapped bowel.

approach no more than 4 cm above the pubis or under image guidance.

In patients who have had previous lower abdominal or pelvic surgery, an ultrasound may be used to properly place the suprapubic tube and rule out entrapped bowel (Fig. 18.5). Patients who develop peritoneal symptoms and signs require a full evaluation of the location of not only the suprapubic tube (by a cystogram) but also the cystotomy tract. A kidney–ureter–bladder radiograph and computed tomography scans may be helpful.

Hematuria is the most common complication after suprapubic tube placement. Rarely, this requires open cystotomy for placement of a large-caliber tube for irrigation. Hematuria can result secondary to laceration of blood vessels or rapid decompression of a chronically distended bladder, and the risk of hematuria may be reduced by gradual bladder decompression. Another risk with decompression of chronically distend bladder is postobstructive diuresis.

Complications associated with the catheter include loss of a portion of the catheter in the bladder, calcification of the catheter, or bladder stone formation. These complications may be avoided by preventing prolonged catheter use. Beyond 4 weeks, evaluation and replacement or removal of catheter is advisable.

When chronically distended bladders are decompressed, patients are at risk for postobstructive diuresis [15]. Patients who are at greatest risk include those with azotemia, peripheral edema, congestive heart failure, and mental status changes. Patients with postobstructive diuresis (i.e., urine outputs >200 mL per hour) require frequent monitoring of vital signs and intravenous fluid replacement.

Hypotension rarely occurs after suprapubic tube placement. It may be caused by a vasovagal response or bleeding, alleviated by fluid administration. Another rare, but possible, complication is a through-and-through bladder perforation that is treated conservatively with bladder decompression.

CHAPTER 19 ■ ASPIRATION OF THE KNEE AND SYNOVIAL FLUID ANALYSIS

BONNIE J. BIDINGER AND ERIC W. JACOBSON

Arthrocentesis is a safe and relatively simple procedure that involves the introduction of a needle into a joint space to remove synovial fluid. It constitutes an essential part of the evaluation of arthritis of unknown cause, frequently with the intent to rule out a septic process [1–3].

Ropes and Bauer [4] first categorized synovial fluid as *inflammatory* or *noninflammatory* in 1953. In 1961, Hollander et al. [5] and Gatter and McCarty [6] coined the term *synovianalysis* to describe the process of joint fluid analysis and were instrumental in establishing its critical role in the diagnosis of certain forms of arthritis. Septic arthritis and crystalline arthritis can be diagnosed by synovial fluid analysis alone. They may present similarly but require markedly different treatments, thus necessitating early arthrocentesis and prompt synovial fluid analysis.

INDICATIONS

Arthrocentesis is performed for diagnostic and therapeutic purposes. The main indication for arthrocentesis is to assist in the evaluation of arthritis of unknown cause. In the intensive care unit, it is most commonly performed to rule out septic arthritis. As many types of inflammatory arthritis mimic septic arthritis, synovial fluid analysis is essential in differentiating the various causes of inflammatory arthritis [4,7] (Table 19.1). Therefore, patients presenting with acute monoarthritis or oligoarthritis require prompt arthrocentesis with subsequent synovial fluid analysis, preferably before initiation of treatment.

Arthrocentesis is also used for therapeutic purposes. In a septic joint, serial joint aspirations are required to remove accumulated inflammatory or purulent fluid. This accomplishes complete drainage of a closed space and allows serial monitoring of the total white blood cell count, Gram stain, and culture to assess treatment response. Inflammatory fluid contains many destructive enzymes that contribute to cartilage and bony degradation; removal of the fluid may slow this destructive process [8,9]. Additionally, arthrocentesis allows for injection of long-acting corticosteroid preparations into the joint space, which may be a useful treatment for various inflammatory and noninflammatory forms of arthritis [10].

Before performing arthrocentesis, it must be ascertained that the true joint is inflamed and an effusion is present. This requires a meticulous physical examination to differentiate arthritis from periarticular inflammation. Bursitis, tendinitis, and cellulitis all may mimic arthritis. In the knee, the examination begins with assessment of swelling. A true effusion may cause bulging of the parapatellar gutters and the suprapatellar pouch [11]. The swelling should be confined to the joint space. To check for small effusions, the bulge test is performed [12]. Fluid is stroked from the medial joint line into the suprapatellar pouch and then from the suprapatellar pouch down along the lateral joint line. If a bulge of fluid is noted at the medial joint line, a small effusion is present (Fig. 19.1). If a large effusion is present, one can detect a ballotable patella by pushing it against the femur with the right index finger while applying pressure to the suprapatellar pouch with the left hand [13]. Comparison with the opposite joint is helpful. Many texts describe joint examination and assessment for fluid in the knee and other joints [11–13].

CONTRAINDICATIONS

Absolute contraindications to arthrocentesis include local infection of the overlying skin or other periarticular structures and severe coagulopathy [1–3,10]. If coagulopathy is present and septic arthritis is suspected, every effort should be made to correct the coagulopathy (with fresh-frozen plasma or alternate factors) before joint aspiration. Therapeutic anticoagulation is not an absolute contraindication, but every effort should be made to avoid excessive trauma during aspiration in this circumstance. Known bacteremia is a contraindication because inserting a needle into the joint space disrupts capillary integrity, allowing joint space seeding [14]. However, if septic arthritis is strongly suspected, joint aspiration is indicated. The presence of articular instability (e.g., that seen with badly damaged joints) is a relative contraindication, although the presence of a large presumed inflammatory fluid may still warrant joint aspiration.

COMPLICATIONS

The major complications of arthrocentesis are iatrogenically induced infection and bleeding, both of which are extremely rare [1]. The risk of infection after arthrocentesis has been estimated to be less than 1 in 10,000 [15]. Hollander [16] reported an incidence of less than 0.005% in 400,000 injections. Strict adherence to aseptic technique reduces the risk of postarthrocentesis infection. Significant hemorrhage is also extremely rare. Correction of prominent coagulopathy before arthrocentesis reduces this risk.

Another potential complication of arthrocentesis is direct injury to the articular cartilage by the needle. This is not quantifiable, but any injury to the cartilage could be associated with degenerative change over time. To avoid cartilaginous damage, the needle should be pushed in only as far as necessary to obtain fluid and excessive movement of the needle during the procedure should be avoided.

Other complications include discomfort from the procedure itself, allergic reactions to the skin preparation or local anesthetic, and in the case of steroid injection, postinjection flare and local soft-tissue atrophy from the glucocorticoid [17].

TABLE 19.1

COMMON CAUSES OF NONINFLAMMATORY AND INFLAMMATORY ARTHRITIDES

Noninflammatory	Inflammatory
Osteoarthritis	Rheumatoid arthritis
Trauma/internal derangement	Spondyloarthropathies
Avascular necrosis	Psoriatic arthritis
Hemarthrosis	Reiter's syndrome/reactive arthritis
Malignancy	Ankylosing spondylitis
Benign tumors	Ulcerative colitis/regional enteritis
Osteochondroma	Crystal-induced arthritis
Pigmented villonodular synovitis	Monosodium urate (gout)
	Calcium pyrophosphate dihydrate (pseudogout)
	Hydroxyapatite
	Infectious arthritis
	Bacterial
	Mycobacterial
	Fungal
	Connective tissue diseases
	Systemic lupus erythematosus
	Vasculitis
	Scleroderma
	Polymyositis
	Hypersensitivity
	Serum sickness

ARTHROCENTESIS EQUIPMENT

Procedure	Equipment
Skin preparation and local anesthesia	2% chlorhexidine in 70% isopropyl alcohol Ethyl chloride spray For local anesthesia—1% lidocaine; 25-gauge, 1.5-in needle; 22-gauge, 1.5-in. needle; 5-mL syringe Sterile sponge/cloth
Arthrocentesis	Gloves 20- to 60-mL syringe (depending on size of effusion) 18- to 22-gauge, 1.5-in. needle Sterile sponge/cloth Sterile clamp Sterile bandage
Collection	15-mL anticoagulated tube (with sodium heparin or ethylene-diaminetetraacetic acid) Sterile tubes for routine cultures Slide, cover slip

TECHNIQUE

Joint aspiration is easily learned. A sound knowledge of the joint anatomy, including the bony and soft-tissue landmarks used for joint entry, is needed. Strict aseptic technique must be followed to minimize risk of infection, and relaxation of the muscles surrounding the joint should be encouraged because muscular contraction can impede the needle's entry into the joint.

Most physicians in the intensive care unit can aspirate the knee because it is one of the most accessible joints. Other joints should probably be aspirated by an appropriate specialist, such as a rheumatologist or an orthopedic surgeon. Certain joints are quite difficult to enter blindly and are more appropriately entered using radiologic guidance, such as with fluoroscopy or computed tomography; these include the hip, sacroiliac, and temporomandibular joints. Many texts describe in detail the aspiration technique of other joints [3,16–18]. The technique for knee aspiration is as follows:

1. Describe the procedure to the patient, including the possible complications, and obtain written informed consent.
2. Collect all items needed for the procedure (Table 19.2).
3. With the patient supine and the knee fully extended, examine the knee to confirm the presence of an effusion, as described previously.
4. Identify landmarks for needle entry. The knee may be aspirated from a medial or lateral approach. The medial approach is more commonly used and is preferred when small effusions are present. Identify the superior and inferior borders of the patella. Entry should be halfway between the borders, just inferior to the undersurface of the patella (Fig. 19.2). The entry site may be marked with pressure from

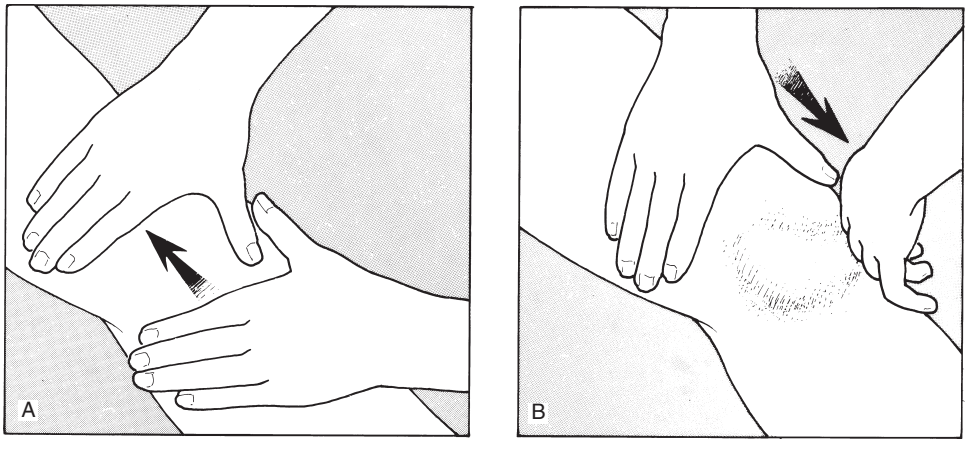

FIGURE 19.1. The bulge test. **A:** Milk fluid from the suprapatellar pouch into the joint. **B:** Slide the hand down the lateral aspect of the joint line and watch for a bulge medial to the joint.

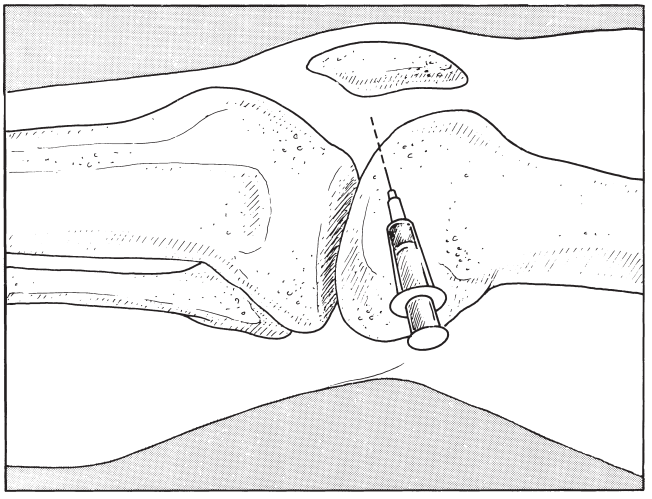

FIGURE 19.2. Technique of aspirating the knee joint. The needle enters halfway between the superior and inferior borders of the patella and is directed just inferior to the patella.

the end of a ballpoint pen with the writing tip retracted. An indentation mark should be visible.

5. Cleanse the area with 2% chlorhexidine in 70% isopropyl alcohol and allow the area to dry. Practice universal precautions: wear gloves at all times while handling any body fluid, although they need not be sterile for routine knee aspiration. Do not touch the targeted area once it has been cleaned.
6. Apply local anesthesia. A local anesthetic (1% lidocaine) may be instilled subcutaneously with a 25-gauge, 1.5-in. needle. Once numbing has occurred, deeper instillation of the local anesthetic to the joint capsule can be performed. Some physicians may use ethyl chloride as an alternative anesthetic. However, this agent provides only superficial anesthesia of the skin. To use, spray ethyl chloride directly onto the designated area and stop when the first signs of freezing are evident in order to limit potential for skin damage.
7. To enter the knee joint, use an 18- to 22-gauge, 1.5-in. needle with a 20- to 60-mL syringe. Use a larger gauge needle particularly if septic arthritis is suspected as the aspirated fluid may be purulent and more difficult to aspirate. Use a quick thrust through the skin and on through the capsule to minimize pain. Avoid hitting periosteal bone, which causes significant pain, or cartilage, which causes cartilaginous damage. Aspirate fluid to fill the syringe. If the fluid appears purulent or hemorrhagic, try to tap the joint dry, which will remove mediators of inflammation that may perpetuate an inflammatory or destructive process. If the syringe is full and more fluid remains, a sterile hemostat may be used to clamp the needle, thus stabilizing it, while switching syringes. When the syringes have been switched, more fluid can be withdrawn. The syringes must be sterile.
8. On occasion, effusions can be difficult to aspirate. Reasons for this include increased fluid viscosity, fibrin and other debris impeding flow through the needle, loculated fluid, and use of a needle with an inappropriately small gauge. Additionally, the fluid may not be accessible by the approach being used [19]. At times, one can obtain a small drop of joint fluid by using continuous suction as the needle is withdrawn from the joint space [17]. This small specimen can then be sent for Gram stain, culture, and if possible, crystal analysis.
9. When the fluid has been obtained, quickly remove the needle and apply pressure to the needle site with a piece of sterile gauze. When bleeding has stopped, remove the gauze, clean the area with alcohol, and apply an adhesive bandage. If the patient is receiving anticoagulation therapy or has a bleeding diathesis, apply prolonged pressure.
10. Document the amount of fluid obtained and perform gross examination, noting the color and clarity. A string sign may be performed at the bedside to assess fluid viscosity (see the following section). Send fluid for cell count with differential count, Gram stain, routine culture, specialized cultures for *Gonococcus*, *Mycobacterium*, and fungus, if indicated, and polarized microscopic examination for crystal analysis. Other tests, such as glucose and complement determinations, are generally not helpful. Use an anticoagulated tube to send fluid for cell count and crystal analysis. Sodium heparin and ethylenediaminetetraacetic acid are appropriate anticoagulants. Lithium heparin and calcium oxalate should be avoided because they can precipitate out of solution to form crystals, thus potentially giving a false-positive assessment for crystals [6,20]. Fluid may be sent for Gram stain and culture in the syringe capped with a blunt tip or in a sterile redtop tube.

SYNOVIAL FLUID ANALYSIS

Synovial fluid analysis is identical for all joints and begins with bedside observation of the fluid. The color, clarity, and viscosity of the fluid are characterized. Synovial fluid is divided into noninflammatory and inflammatory types on the basis of the total nucleated cell count. A white blood cell count less than or equal to 2,000 per μL indicates a *noninflammatory fluid* and a count greater than 2,000 per μL indicates an *inflammatory fluid*. Table 19.3 shows how fluid is divided into major categories on the basis of appearance and cell count.

TABLE 19.3

JOINT FLUID CHARACTERISTICS

Characteristic	Normal	Noninflammatory	Inflammatory	Septic
Color	Clear	Yellow	Yellow or opalescent	Variable—may be purulent
Clarity	Transparent	Transparent	Translucent	Opaque
Viscosity	Very high	High	Low	Typically low
Mucin clot	Firm	Firm	Friable	Friable
White blood cell count per μL	200	200–2,000	2,000–100,000	>50,000, usually >100,000
Polymorphonuclear cells (%)	<25	<25	>50	>75
Culture	Negative	Negative	Negative	Usually positive

GROSS EXAMINATION

Color

Color and clarity should be tested using a clear glass tube. Translucent plastic, as used in most disposable syringes, interferes with proper assessment [1]. Normal synovial fluid is colorless. Noninflammatory and inflammatory synovial fluid appears yellow or straw colored. Septic effusions frequently appear purulent and whitish. Depending on the number of white blood cells present, pure pus may be extracted from a septic joint. Hemorrhagic effusions appear red or brown. If the fluid looks like pure blood, the tap may have aspirated venous blood. The needle is removed, pressure is applied, and the joint is reentered from an alternate site. If the same bloody appearance is noted, the fluid is a hemorrhagic effusion and probably not related to the trauma of the aspiration. If any question remains, the hematocrit of the effusion is compared with that of peripheral blood. The hematocrit in a hemorrhagic effusion is typically lower than that of peripheral blood. In the case of a traumatic tap, the hematocrit of the fluid should be equal to that of peripheral blood. For causes of a hemorrhagic effusion, refer to Table 19.4.

Clarity

The clarity of synovial fluid depends on the number and types of cells or particles present. Clarity is tested by reading black print on a white background through a glass tube filled with the synovial fluid. If the print is easily read, the fluid is transparent. This is typical of normal and noninflammatory synovial fluid. If the black print can be distinguished from the white background, but is not clear, the fluid is translucent. This is typical of inflammatory effusions. If nothing can be seen through the fluid, it is opaque. This occurs with grossly inflammatory, septic, and hemorrhagic fluids.

Viscosity

The viscosity of synovial fluid is a measure of the hyaluronic acid content. Degradative enzymes such as hyaluronidase are released in inflammatory conditions, thus destroying hyaluronic acid and other proteinaceous material, resulting in a thinner, less viscous fluid. Highly viscous fluid, on the other hand, can be seen in myxedematous or hypothyroid effusions.

Viscosity can be assessed at the bedside using the string sign [1]. A drop of fluid is allowed to fall from the end of the needle or syringe and the length of the continuous string that forms is estimated. Normal fluid typically forms at least a 6-cm continuous string. Inflammatory fluid does not form a string; instead, it drops off the end of the needle or syringe like water dropping from a faucet.

The mucin clot, another measure of viscosity, estimates the presence of intact hyaluronic acid and hyaluronic acid–protein interactions. This test is performed by placing several drops of synovial fluid in 5% acetic acid and then mixing with a stirring stick. A good mucin clot forms in normal, noninflammatory fluid. The fluid remains condensed in a clot resembling chewed gum. A poor mucin clot is seen with inflammatory fluid; the fluid disperses diffusely within the acetic acid.

Scurvy

CELL COUNT AND DIFFERENTIAL

The cell count should be obtained as soon as possible after arthrocentesis, as a delay of even several hours may cause an artificially low white blood cell count [21]. The total white blood cell count of synovial fluid differentiates noninflammatory from inflammatory fluid, as noted previously. In general, the higher the total white blood cell count, the more likely the joint is to be infected. This is not absolute, however, and there is considerable overlap. For instance, a total white cell count greater than 100,000 per μL may be seen in conditions other than infection, whereas a total white blood cell count of 50,000 per μL may be due to infection, crystalline disease, or systemic inflammatory arthropathy [28]. The technique for the cell count is identical to that used with peripheral blood. The fluid may be diluted with normal saline for a manual count, or an automated counter may be used. Viscous fluid with excessive debris may clog a counter or give falsely elevated results, thus making the manual procedure somewhat more accurate.

The differential white blood cell count is also performed using the technique used for peripheral blood, typically using Wright's stain. The differential is calculated on the basis of direct visualization. The differential count includes cells typically seen in peripheral blood, such as polymorphonuclear cells, monocytes, and lymphocytes, as well as cells localized to the synovial space. In general, the total white blood cell count and the polymorphonuclear cell count increase with inflammation and infection. Septic fluid typically has a differential of greater than 75% polymorphonuclear cells (see Table 19.3).

In addition to distinguishing polymorphonuclear cells from monocytes and lymphocytes, Wright's stain can detect other cells in synovial fluid that can be useful in establishing a diagnosis. For instance, iron-laden chondrocytes, which are seen in hemochromatosis, may be picked up by Wright's stain, as may be fat droplets and bone marrow spicules, which are suggestive of trauma or a fracture into the joint [19].

CRYSTALS

All fluid should be assessed for the presence of crystals. As with cell count, crystal analysis should be performed as soon as possible after arthrocentesis. A delay is associated with a decreased yield [21]. One drop of fluid is placed on a slide and covered with a coverslip; this is examined for crystals using a compensated polarized light microscope. The presence of intracellular monosodium urate (MSU) or calcium pyrophosphate dihydrate (CPPD) crystals confirms a diagnosis of gout or pseudogout, respectively. MSU crystals are typically long and needle shaped: they may appear to pierce through a white blood cell. The crystals are strongly negatively birefringent, appearing yellow when parallel to the plane of reference. Typically, CPPD crystals are small and rhomboid. The crystals are weakly positively birefringent, appearing blue when oriented parallel to the plane of reference. Rotating the stage of the microscope by 90 degrees and thereby the orientation of the crystals (now perpendicular to the plane of reference) changes their color:

TABLE 19.5

CLASSIFICATION OF HYPERURICEMIA

- Primary hyperuricemia
  - Idiopathic
  - Enzymatic defects (e.g., hypoxanthine guanine phosphoribosyl- transferase deficiency)
- Secondary hyperuricemia
  - Increased production of uric acid
    - Increased de novo purine synthesis
    - Excessive dietary purine intake
    - Increased nucleic acid turnover (myeloproliferative/lymphoproliferative disorders, psoriasis, hemolytic anemia, ethyl alcohol abuse)
- Decreased renal excretion of uric acid
  - Medications
    - Diuretics
    - Low-dose salicylates
    - Pyrazinamide
    - Ethambutol
    - Cyclosporine
- Chronic renal failure
- Hyperacidemia (lactic acidosis, ketoacidosis, starvation, ethyl alchohol abuse)
- Lead nephropathy

MSU crystals turn blue and CPPD crystals turn yellow. Refer to Tables 19.5 and 19.6 for a classification of hyperuricemia and conditions associated with CPPD deposition disease.

In addition to MSU and CPPD crystals, other less common crystals may induce an inflammatory arthropathy. Basic calcium crystals (e.g., hydroxyapatite) and oxalate crystals are two such types. Much like MSU crystals in gout, hydroxyapatite crystals can incite acute articular and periarticular inflammation, which can be difficult to distinguish clinically from septic arthritis and cellulitis, respectively [22]. On light microscopy, however, crystals appear as clumps of shiny nonbirefringent globules, and with alizarin red S stain, the clumps appear red-orange [22,23]. If hydroxyapatite is suspected, alizarin red S stain must be requested specifically from the laboratory as it is not a routine component of the crystal analysis. Calcium oxalate crystals can also induce an inflammatory arthritis. This is generally seen in patients on long-term hemodialysis [24–26], but may also be seen in young patients with primary oxalosis [22]. Synovial fluid typically reveals characteristic bipyramidal crystals as well as polymorphic forms [22].

TABLE 19.6

CONDITIONS ASSOCIATED WITH CALCIUM PYROPHOSPHATE DIHYDRATE DEPOSITION DISEASE

- Hereditary

The yield for all crystals can be increased by spinning the specimen and examining the sediment. If the fluid cannot be examined immediately, it should be refrigerated to preserve the crystals. It is important to note that even in the presence of crystals, infection must be considered because crystals can be seen concomitantly with a septic joint.

Other crystals include cryoimmunoglobulins in patients with multiple myeloma and essential cryoglobulinemia [27], and cholesterol crystals in patients with chronic inflammatory arthropathies, such as rheumatoid arthritis. Cholesterol crystals are a nonspecific finding and appear as platelike structures with a notched corner.

GRAM STAIN AND CULTURE

The Gram stain is performed as with other body fluids. It should be performed as soon as possible to screen for the presence of bacteria. It has been reported that the sensitivity of synovial fluid Gram stain in septic arthritis ranges between 50% and 75% for nongonococcal infection and less than 10% for gonococcal infection [28]. Specificity is much higher; this suggests that a positive Gram stain, despite a negative culture, should be considered evidence of infection. In fact, it is not uncommon for only the Gram stain to be positive in the setting of infection [28]. However, the absence of bacteria by the Gram stain does not rule out a septic process.

Synovial fluid in general should be cultured routinely for aerobic and anaerobic bacterial organisms. A positive culture confirms septic arthritis. In certain circumstances (e.g., in chronic monoarticular arthritis), fluid may be cultured for the presence of mycobacteria, fungus, and spirochetes. If disseminated gonorrhea is suspected, the laboratory must be notified because the fluid should be plated directly onto chocolate agar or Thayer–Martin medium. Just as Gram stain of synovial fluid in gonococcal infection is often negative, so too is synovial fluid culture. Synovial fluid culture is positive approximately 10% to 50% of the time, versus 75% to 95% of the time for nongonococcal infection [28]. However, cultures of genitourinary sites and mucosal sites in gonococcal infection are positive approximately 80% of the time [29]. Therefore, when suspicion of gonococcal arthritis is high (e.g., in a young, healthy, sexually active individual with a dermatitis-arthritis syndrome), the diagnosis must often be confirmed by a positive culture from the urethra, cervix, rectum, or pharynx.

In addition to documenting infection and identifying a specific organism, synovial fluid culture can be useful in determining antibiotic sensitivities and subsequent treatment. Furthermore, serial synovial fluid cultures can help in assessing response to therapy. For example, a negative follow-up culture associated with a decrease in synovial fluid polymorphonuclear cell count is highly suggestive of improvement.

Other studies on synovial fluid (e.g., glucose, protein, lactate dehydrogenase, complement, and immune complexes) are generally not helpful. Specifically, in a study by Shmerling et al. [30], the investigators observed that synovial fluid glucose and protein were "highly inaccurate." The synovial fluid glucose and protein misclassified effusions as inflammatory versus noninflammatory 50% of the time. By contrast, synovial fluid cell count and differential were found to be reliable and complementary; sensitivity and specificity of cell count was 84% for both and for the differential was 75% and 92%, respectively [30]. Although synovial fluid lactate dehydrogenase was also found to be accurate, it did not offer any additional information above and beyond the cell count

and differential. A more recent critical appraisal of synovial fluid analysis was conducted by Swan et al. [31] in 2002. Through a detailed survey of the literature, the authors confirmed the diagnostic value of synovial fluid analysis in cases of acute arthritis when an infectious or crystalline etiology is suspected, as well as in cases of intercritical gout. The usefulness of other synovial fluid assays was not supported by the literature.

Of note, there are special stains for synovial fluid that can be helpful as the clinical picture warrants; these include Congo red staining for amyloid arthropathy. Amyloid deposits display an apple-green birefringence with polarized light [32]. Prussian blue stain for iron deposition may reveal iron in synovial lining cells in hemochromatosis [19]. However, neither of these studies should be considered a routine component of synovial fluid analysis.

CHAPTER 20 ■ ANESTHESIA FOR BEDSIDE PROCEDURES

MARK DERSHWITZ

When a patient in an intensive care unit (ICU) requires a bedside procedure, it is usually the attending intensivist, as opposed to a consultant anesthesiologist, who directs the administration of the necessary hypnotic, analgesic, and/or paralytic drugs. Furthermore, unlike in the operating room, the ICU usually has no equipment for the administration of gaseous (e.g., nitrous oxide) or volatile (e.g., isoflurane) anesthetics. Anesthesia for bedside procedures in the ICU is thus accomplished via a technique involving total intravenous anesthesia (TIVA).

COMMON PAIN MANAGEMENT PROBLEMS IN ICU PATIENTS

Dosing of Agent

Selecting the proper dose of an analgesic to administer is problematic for several reasons, including difficulty in assessing the effectiveness of pain relief, pharmacokinetic (PK) differences

between the critically ill and other patients, and normal physiologic changes associated with aging.

Assessing the Effectiveness of Pain Relief

Critically ill patients are often incapable of communicating their feelings because of delirium, obtundation, or endotracheal intubation. This makes psychologic evaluation quite difficult because surrogate markers of pain intensity (e.g., tachycardia, hypertension, and diaphoresis) are inherent in the host response to critical illness.

Pharmacokinetic Considerations

Most of the pressors and vasodilators administered in the ICU by continuous intravenous (IV) infusion have a relatively straightforward PK behavior: they are water-soluble molecules that are bound very little to plasma proteins. In contrast, the hypnotics and opioids used in TIVA have high lipid solubility and most are extensively bound to plasma proteins, causing their PK behavior to be far more complex. Figure 20.1 shows the disappearance curves of fentanyl and nitroprusside after bolus injection. The fentanyl curve has three phases: (i) a very rapid phase (with a half-life of 0.82 minutes) lasting about 10 minutes, during which the plasma concentration decreases more than 90% from its peak value; (ii) an intermediate phase (with a half-life of 17 minutes) lasting from about 10 minutes to an hour; and (iii) finally a terminal, very slow phase (with a half-life of 465 minutes) beginning about an hour after bolus injection. After a single bolus injection of fentanyl, the terminal phase occurs at plasma concentrations below which there is a pharmacologic effect. However, after multiple bolus injections or a continuous infusion, this latter phase occurs at therapeutic plasma concentrations. Thus, fentanyl behaves as a short-acting drug after a single bolus injection, but as a very long-lasting drug after a continuous infusion of more than an hour in duration (i.e., fentanyl accumulates). Thus, it is inappropriate to speak of the half-life of fentanyl.

The disappearance curve of nitroprusside has two phases: (i) a very rapid phase (with a half-life of 0.89 minute) lasting about 10 minutes, during which the plasma concentration decreases more than 85% from its peak value, and (ii) a terminal phase (with a half-life of 14 minutes). It may be slightly slower in offset as compared with fentanyl during the initial 10 minutes after a bolus injection, but it does not accumulate at all even after a prolonged infusion.

The PK behavior of the lipid-soluble hypnotics and analgesics given by infusion may be described by their context-sensitive half-times (CSHTs). This concept may be defined as follows: when a drug is given as an IV bolus followed by an IV infusion designed to maintain a constant plasma drug concentration, the time required for the plasma concentration to fall by 50% after termination of the infusion is the CSHT [3]. Figure 20.2 depicts the CSHT curves for the medications most likely to be used for TIVA in ICU patients.

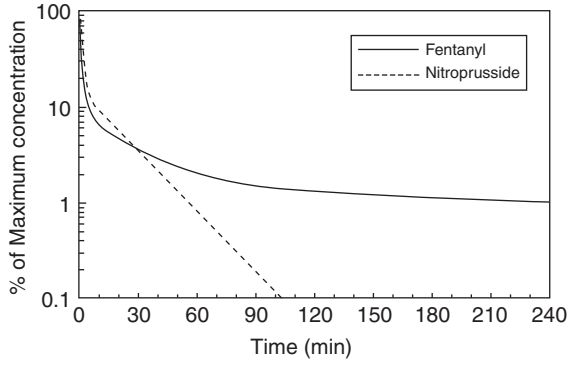

FIGURE 20.1. The time courses, on a semilogarithmic scale, of the plasma concentrations of fentanyl [1] and nitroprusside [2] following a bolus injection. Each concentration is expressed as the percentage of the peak plasma concentration. The fentanyl curve has three phases with half-lives of 0.82, 17, and 465 minutes. The nitroprusside curve has two phases with half-lives of 0.89 and 14 minutes.

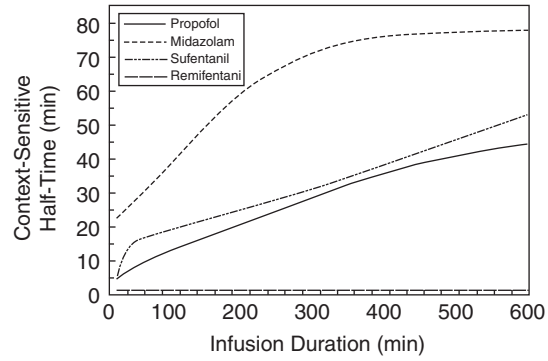

FIGURE 20.2. The context-sensitive half-times for propofol [4], midazolam [5], sufentanil [6], and remifentanil [7] as a function of infusion duration.

PK behavior in critically ill patients is unlike that in normal subjects for several reasons. Because ICU patients frequently have renal and/or hepatic dysfunction, drug excretion is significantly impaired. Hypoalbuminemia, common in critical illness, decreases protein binding and increases free drug concentration [8]. Because free drug is the only moiety available to tissue receptors, decreased protein binding increases the pharmacologic effect for a given plasma concentration. It is therefore more important in ICU patients that the doses of medications used for TIVA are individualized for a particular patient.

Physiologic Changes Associated with Aging

People 65 years of age and older comprise the fastest growing segment of the population and constitute the majority of patients in many ICUs. Aging leads to (a) a decrease in total body water and lean body mass; (b) an increase in body fat and, hence, an increase in the volume of distribution of lipid-soluble drugs; and (c) a decrease in drug clearance rates, due to reductions in liver mass, hepatic enzyme activity, liver blood flow, and renal excretory function. There is a progressive, age-dependent increase in pain relief and electroencephalographic suppression among elderly patients receiving the same dose of opioid as younger patients. There is also an increase in central nervous system (CNS) depression in elderly patients following administration of identical doses of benzodiazepines.

Selection of Agent

Procedures performed in ICUs today (Table 20.1) span a spectrum that extends from those associated with mild discomfort (e.g., esophagogastroscopy) to those that are quite painful (e.g., orthopedic manipulations, wound debridement, and tracheostomy). Depending on their technical difficulty, these procedures can last from minutes to hours. To provide a proper anesthetic, medications should be selected according to the nature of the procedure and titrated according to the patient's response to surgical stimulus. In addition, specific disease states should be considered in order to maximize safety and effectiveness.

TABLE 20.1

BEDSIDE PROCEDURES AND ASSOCIATED LEVELS OF DISCOMFORT

Mildly to moderately uncomfortable
Transesophageal echocardiography[a]
Transtracheal aspiration
Thoracentesis[a]
Paracentesis[a]
Moderately to severely uncomfortable
Endotracheal intubation[a]
Flexible bronchoscopy[a]
Thoracostomy[a]
Bone marrow biopsy
Colonoscopy
Peritoneal dialysis catheter insertion[a]
Peritoneal lavage[a]
Percutaneous gastrostomy[a]
Percutaneous intra-aortic balloon insertion[a]
Extremely painful
Rigid bronchoscopy
Debridement of open wounds
Dressing changes
Orthopedic manipulations
Tracheostomy[a]
Pericardiocentesis/pericardial window[a]
Open lung biopsy
Ventriculostomy[a]

[a]Procedures in which the level of discomfort may be significantly mitigated by the use of local anesthesia.

Head Trauma

Head-injured patients require a technique that provides effective, yet brief, anesthesia so that the capacity to assess neurologic status is not lost for extended periods of time. In addition, the technique must not adversely affect cerebral perfusion pressure. If the effects of the anesthetics dissipate too rapidly, episodes of agitation and increased intracranial pressure (ICP) may occur that jeopardize cerebral perfusion. In contrast, if the medications last too long, there may be difficulty in making an adequate neurologic assessment following the procedure.

Coronary Artery Disease

Postoperative myocardial ischemia following cardiac and noncardiac surgery strongly predicts adverse outcome [9]. Accordingly, sufficient analgesia should be provided during and after invasive procedures to reduce plasma catecholamine and stress hormone levels.

Renal and/or Hepatic Failure

Risk of an adverse drug reaction is at least three times higher in patients with azotemia than in those with normal renal function. This risk is magnified by excessive unbound drug or drug metabolite(s) in the circulation and changes in the target tissue(s) induced by the uremic state.

Liver failure alters many drug volumes of distribution by impairing synthesis of the two major plasma-binding proteins: albumin and α_1-acid glycoprotein. In addition, reductions in hepatic blood flow and hepatic enzymatic activity decrease drug clearance rates.

CHARACTERISTICS OF SPECIFIC AGENTS USED FOR BEDSIDE PROCEDURES

Hypnotics

The characteristics of the hypnotics are provided in Table 20.2, whereas their recommended doses are provided in Table 20.3. When rapid awakening is desired, propofol and etomidate are the hypnotic agents of choice. Ketamine may be useful when a longer duration of anesthesia is needed. Midazolam is rarely used alone as a hypnotic; however, its profound anxiolytic and amnestic effects render it useful in combination with other agents.

Propofol

Description. Propofol is a hypnotic agent associated with pleasant emergence and little hangover. It has essentially replaced thiopental for induction of anesthesia, especially in outpatients. It is extremely popular because it is readily titratable and has more rapid onset and offset kinetics than midazolam. Thus, patients emerge from anesthesia more rapidly after propofol than after midazolam, a factor that may make propofol the preferred agent for sedation and hypnosis in general and for patients with altered level of consciousness in particular.

The CSHT for propofol is about 10 minutes following a 1-hour infusion, and the CSHT increases about 5 minutes for each additional hour of infusion for the first several hours, as shown in Figure 20.2. Thus, the CSHT is about 20 minutes after a 3-hour infusion. The CSHT rises much more slowly for infusions longer than a day; a patient who is sedated (but not rendered unconscious) with propofol for 2 weeks recovers in approximately 3 hours [10]. This rapid recovery of neurologic status makes propofol a good sedative in ICU patients,

TABLE 20.2

CHARACTERISTICS OF INTRAVENOUS HYPNOTIC AGENTS[a]

	Propofol	Etomidate	Ketamine	Midazolam	Fospropofol
Onset	Fast	Fast	Fast	**Intermediate**	**Intermediate**
Duration	Short	Short	Intermediate	Intermediate	Short
Cardiovascular effects	↓	**None**	↑	Minimal	↓
Respiratory effects	↓	↓	**Minimal**	↓	↓
Analgesia	None	None	**Profound**	None	None
Amnesia	Mild	Mild	**Profound**	**Profound**	Mild

[a]The listed doses should be reduced 50% in elderly patients. Entries in bold type indicate noteworthy differences among the drugs.

TABLE 20.3

USUAL DOSES OF INTRAVENOUS ANESTHETIC AGENTS GIVEN BY CONTINUOUS INFUSION[a]

	Propofol	Etomidate	Ketamine	Midazolam	Sufentanil	Remifentanil
Bolus dose (mg/kg)	1–2	0.2–0.3	1–2	0.05–0.15	0.5–1.5	0.5–1.5
Infusion rate (μg/kg/min)	100–200	NR[b]	25–100	0.25–1.5	0.01–0.03	0.05–0.5

[a]The "usual doses" are for patients without preexisting tolerance and significant cardiovascular disease. The required doses will be higher in patients with tolerance, and should be reduced in elderly patients and in patients with decreased cardiovascular function. In all cases, the medications should be titrated to specific endpoints as described in the text.
[b]Not recommended due to the possibility of prolonged adrenal suppression.

especially those with head trauma, who may not tolerate mechanical ventilation without pharmacologic sedation.

Even though recovery following termination of a continuous infusion is faster with propofol than with midazolam, a comparative trial showed that the two drugs were roughly equivalent in effectiveness for overnight sedation of ICU patients [11]. For long-term sedation (e.g., more than 1 day), however, recovery is significantly faster in patients given propofol.

In spontaneously breathing patients sedated with propofol, respiratory rate appears to be a more predictable sign of adequate sedation than hemodynamic changes. The ventilatory response to rebreathing carbon dioxide during a maintenance propofol infusion is similar to that induced by other sedative drugs (i.e., propofol significantly decreases the slope of the carbon dioxide response curve). Nevertheless, spontaneously breathing patients anesthetized with propofol are able to maintain normal end-tidal carbon dioxide values during minor surgical procedures.

Bolus doses of propofol in the range of 1 to 2 mg per kg induce loss of consciousness within 30 seconds. Maintenance infusion rates of 100 to 200 μg per kg per minute are adequate in younger subjects to maintain general anesthesia, whereas doses should be reduced by 20% to 50% in elderly individuals.

Adverse Effects

Cardiovascular. Propofol depresses ventricular systolic function and lowers afterload, but has no effect on diastolic function [12,13]. Vasodilation results from calcium channel blockade. In patients undergoing coronary artery bypass surgery, propofol (2 mg per kg IV bolus) produced a 23% fall in mean arterial blood pressure, a 20% increase in heart rate, and a 26% decrease in stroke volume. In pigs, propofol caused a dose-related depression of sinus node and His-Purkinje system functions, but had no effect on atrioventricular node function or on the conduction properties of atrial and ventricular tissues. In patients with coronary artery disease, propofol administration may be associated with a reduction in coronary perfusion pressure and increased myocardial lactate production [14].

Neurologic. Propofol may improve neurologic outcome and reduce neuronal damage by depressing cerebral metabolism. Propofol decreases cerebral oxygen consumption, cerebral blood flow, and cerebral glucose utilization in humans and animals to the same degree as that reported for thiopental and etomidate [15]. Propofol frequently causes pain when injected into a peripheral vein. Injection pain is less likely if the injection site is located proximally on the arm or if the injection is made via a central venous catheter.

Metabolic. The emulsion used as the vehicle for propofol contains soybean oil and lecithin and supports bacterial growth; iatrogenic contamination leading to septic shock is possible. Currently available propofol preparations contain ethylenediaminetetraacetic acid (EDTA), metabisulfite, or benzyl alcohol as a bacteriostatic agent. Because EDTA chelates trace metals, particularly zinc, serum zinc levels should be measured daily during continuous propofol infusions. Hyperlipidemia may occur, particularly in infants and small children. Accordingly, triglyceride levels should be monitored daily in this population whenever propofol is administered continuously for more than 24 hours.

Fospropofol

Fospropofol is a water-soluble prodrug of propofol. Fospropofol is metabolized to propofol by the action of alkaline phosphatase. The peak hypnotic effect occurs in about 10 minutes following a bolus injection. The kinetic disposition of liberated propofol differs from that of injected propofol emulsion, with the former being slower for reasons that are as yet unexplained [16,17]. Apparent advantages of an aqueous solution of fospropofol are the reduced risk of bacterial contamination as compared to propofol emulsion and the absence of a lipid load that has been associated with organ toxicity during long-term infusions of propofol emulsion. Although fospropofol does not usually cause pain at the site of injection, it commonly causes a burning sensation distant to the site of injection, typically in the perineum or buttocks. Although it is currently approved for procedural sedation only, it may find utility for sedation or anesthesia in the ICU.

Because the molecular weight of fospropofol is higher than that of propofol, its administered dose is necessarily higher. The package label is unfortunately written in terms of dosing in volume units; because virtually every other medication used in the ICU is dosed in terms of an infusion rate that is a function of the body mass, such doses will be used here. The marketed preparation contains 3.5% fospropofol (35 mg per mL). The manufacturer recommends a bolus dose of 6.5 mg per kg followed by repeat injections of 1.6 mg per kg no more often than every 4 minutes; an infusion rate of 400 μg per kg per minute following the bolus dose would be equivalent. Furthermore, the manufacturer recommends that the doses be decreased by 25% in persons older than 65 years or with severe systemic disease. These dose recommendations are designed to achieve procedural sedation and not general anesthesia. As with propofol, the dose will likely need to be increased two- to threefold to induce and maintain general anesthesia; however, no such study in human beings has yet been published.

Etomidate

Description. Etomidate has onset and offset PK characteristics similar to propofol and an unrivaled cardiovascular profile, even in the setting of cardiomyopathy [18]. Not only does etomidate lack significant effects on myocardial contractility, but baseline sympathetic output and baroreflex regulation of

sympathetic activity are well preserved. Etomidate depresses in a dose-related manner cerebral oxygen metabolism and blood flow without changing the intracranial volume–pressure relationship.

Etomidate is particularly useful (rather than thiopental or propofol) in certain patient subsets: patients with hypovolemia, those with multiple trauma with closed-head injury, and those with low ejection fraction, severe aortic stenosis, left main coronary artery disease, or severe cerebral vascular disease. Etomidate may be contraindicated in patients with established or evolving septic shock because of its inhibition of cortisol synthesis (see later).

Adverse Effects

Metabolic. Etomidate, when given by prolonged infusion, may increase mortality associated with low plasma cortisol levels [19]. Even single doses of etomidate can produce adrenal cortical suppression lasting 24 hours or more in normal patients undergoing elective surgery [20]. These effects are more pronounced as the dose is increased or if continuous infusions are used for sedation. Etomidate-induced adrenocortical suppression occurs because the drug blocks the 11β-hydroxylase that catalyzes the final step in the synthesis of cortisol. It is also noteworthy that etomidate causes the highest incidence of postoperative nausea and vomiting of any of the IV anesthetic agents.

In 2005, Jackson warned against the use of etomidate in patients with septic shock [21]. Since then, there have been several studies that have attempted to confirm or refute the safety of etomidate in critically ill patients, including those with sepsis. Unfortunately, some of these studies purportedly confirmed the danger of etomidate [22–25], whereas others support its continued use in patients with sepsis [26–30].

Ketamine

Description. Ketamine induces a state of sedation, amnesia, and marked analgesia in which the patient experiences a strong feeling of dissociation from the environment. It is unique among the hypnotics in that it reliably induces unconsciousness by the intramuscular route. Ketamine is rapidly metabolized by the liver to norketamine, which is pharmacologically active. Ketamine is both slower in onset and offset as compared with propofol or etomidate following IV infusion.

Many clinicians consider ketamine to be the analgesic of choice in patients with a history of bronchospasm. In the usual dosage, it decreases airway resistance, probably by blocking norepinephrine uptake, which in turn stimulates β-adrenergic receptors in the lungs. In contrast to many β-agonist bronchodilators, ketamine is not arrhythmogenic when given to patients with asthma receiving aminophylline.

Ketamine may be safer than other hypnotics or opioids in unintubated patients because it depresses airway reflexes and respiratory drive to a lesser degree. It may be particularly useful for procedures near the airway, where physical access and ability to secure an airway are limited (e.g., gunshot wounds to the face). Because ketamine increases salivary and tracheobronchial secretions, an anticholinergic (e.g., 0.2 mg glycopyrrolate) should be given prior to its administration. In patients with borderline hypoxemia despite maximal therapy, ketamine may be the drug of choice because it does not inhibit hypoxic pulmonary vasoconstriction.

Another major feature that distinguishes ketamine from most other IV anesthetics is that it stimulates the cardiovascular system (i.e., raises heart rate and blood pressure). This action appears to result from both direct stimulation of the CNS with increased sympathetic nervous system outflow and blockade of norepinephrine reuptake in adrenergic nerves.

Because pulmonary hypertension is a characteristic feature of acute respiratory distress syndrome (ARDS), drugs that increase right ventricular afterload should be avoided. In infants with either normal or elevated pulmonary vascular resistance, ketamine does not affect pulmonary vascular resistance as long as constant ventilation is maintained, a finding also confirmed in adults.

Cerebral blood flow does not change when ketamine is injected into cerebral vessels. In mechanically ventilated pigs with artificially produced intracranial hypertension in which ICP is on the shoulder of the compliance curve, 0.5 to 2.0 mg per kg IV ketamine does not raise ICP; likewise, in mechanically ventilated preterm infants, 2 mg per kg IV ketamine does not increase anterior fontanelle pressure, an indirect monitor of ICP [31,32]. Unlike propofol and etomidate however, ketamine does not lower cerebral metabolic rate. It is relatively contraindicated in patients with an intracranial mass, with increased ICP, or who have suffered recent head trauma.

Adverse Effects

Psychologic. Emergence phenomena following ketamine anesthesia have been described as floating sensations, vivid dreams (pleasant or unpleasant), hallucinations, and delirium. These effects are more common in patients older than 16 years, in females, after short operative procedures, after large doses (>2 mg per kg IV), and after rapid administration (>40 mg per minute). Pre- or concurrent treatment with benzodiazepines or propofol usually minimizes or prevents these phenomena [33].

Cardiovascular. Because ketamine increases myocardial oxygen consumption, there is risk of precipitating myocardial ischemia in patients with coronary artery disease if ketamine is used alone. On the other hand, combinations of ketamine plus diazepam, ketamine plus midazolam, or ketamine plus sufentanil are well tolerated for induction in patients undergoing coronary artery bypass surgery. Repeated bolus doses are often associated with tachycardia. This can be reduced by administering ketamine as a constant infusion.

Ketamine produces myocardial depression in the isolated animal heart. Hypotension has been reported following ketamine administration in hemodynamically compromised patients with chronic catecholamine depletion.

Neurologic. Ketamine does not lower the minimal electroshock seizure threshold in mice. When administered with aminophylline, however, a clinically apparent reduction in seizure threshold is observed.

Midazolam

Description. Although capable of inducing unconsciousness in high doses, midazolam is more commonly used as a sedative. Along with its sedating effects, midazolam produces anxiolysis, amnesia, and relaxation of skeletal muscle.

Anterograde amnesia following midazolam (5 mg IV) peaks 2 to 5 minutes after IV injection and lasts 20 to 40 minutes. Because midazolam is highly (95%) protein bound (to albumin), drug effect is likely to be exaggerated in ICU patients. Recovery from midazolam is prolonged in obese and elderly patients and following continuous infusion because it accumulates to a significant degree. In patients with renal failure, active conjugated metabolites of midazolam may accumulate and delay recovery. Although flumazenil may be used to reverse excessive sedation or respiratory depression from midazolam, its duration of action is only 15 to 20 minutes. In addition, flumazenil may precipitate acute anxiety reactions or seizures, particularly in patients receiving chronic benzodiazepine therapy.

Midazolam causes dose-dependent reductions in cerebral metabolic rate and cerebral blood flow, suggesting that it may be beneficial in patients with cerebral ischemia.

Because of its combined sedative, anxiolytic, and amnestic properties, midazolam is ideally suited for both brief, relatively painless procedures (e.g., endoscopy) and prolonged sedation (e.g., during mechanical ventilation).

Adverse Effects

Respiratory. Midazolam (0.15 mg per kg IV) depresses the slope of the carbon dioxide response curve and increases the dead space–tidal volume ratio and arterial P_{CO_2}. Respiratory depression is even more marked and prolonged in patients with chronic obstructive pulmonary disease (COPD). Midazolam also blunts the ventilatory response to hypoxia.

Cardiovascular. Small (<10%) increases in heart rate and small decreases in systemic vascular resistance are frequently observed after administration of midazolam. It has no significant effects on coronary vascular resistance or autoregulation.

Neurologic. Because recovery of cognitive and psychomotor function may be delayed for up to 24 hours, midazolam as the sole hypnotic may not be appropriate in situations where rapid return of consciousness and psychomotor function are a high priority.

Opioids

Morphine

Description. Pain relief by morphine and its surrogates is relatively selective in that other sensory modalities (touch, vibration, vision, and hearing) are not obtunded. Opioids blunt pain by (i) inhibiting pain processing by the dorsal horn of the spinal cord, (ii) decreasing transmission of pain by activating descending inhibitory pathways in the brain stem, and (iii) altering the emotional response to pain by actions on the limbic cortex.

Various types of opioid receptors (denoted by Greek letters) have been discovered in the CNS. The classical pharmacologic effects of morphine such as analgesia and ventilatory depression are mediated by μ-receptors. Other μ-effects include sedation, euphoria, tolerance and physical dependence, decreased gastrointestinal motility, biliary spasm, and miosis. The κ-receptor shares a number of effects with the μ-receptor, including analgesia, sedation, and ventilatory depression. The δ-receptor is responsible for mediating some of the analgesic effects of the endogenous opioid peptides, especially in the spinal cord. Few of the clinically used opioids have significant activity at δ-receptors at the usual analgesic doses.

Morphine is a substrate for the P-glycoprotein, a protein responsible for the transport of many molecules out of cells. The combination of slow CNS penetration due to lower lipid solubility and rapid efflux accounts for the slow onset of morphine's CNS effects. Peak analgesic effects may not occur for more than an hour after IV injection; hence, the plasma profile of morphine does not parallel its clinical effects [34].

Morphine is unique among the opioids in causing significant histamine release after IV injection that occurs almost immediately. The beneficial effect of giving morphine to a patient with acute pulmonary edema is far more related to this hemodynamic effect rather than to its analgesic and sedating effects.

Adverse Effects

Gastrointestinal. Constipation, nausea, and/or vomiting are well-described side effects of morphine administration. Reduced gastric emptying and bowel motility (both small and large intestines), often leading to adynamic ileus, appear to be mediated both peripherally (by opioid receptors located in the gut) and centrally (by the vagus nerve).

Cardiovascular. Hypotension is not unusual following morphine administration, especially if it is given rapidly (i.e., 5 to 10 mg per minute). In patients pretreated with both H_1- and H_2-antagonists, the hypotensive response following morphine administration is significantly attenuated, despite comparable increases in plasma histamine concentrations. These data strongly implicate histamine as the mediator of these changes.

Respiratory. Morphine administration is followed by a dose-dependent reduction in responsiveness of brain stem respiratory centers to carbon dioxide. Key features of this phenomenon include a reduction in the slope of the ventilatory and occlusion pressure responses to carbon dioxide, a rightward shift of the minute ventilatory response to hypercarbia, and an increase in resting end-tidal carbon dioxide and the apneic threshold (i.e., the P_{CO_2} value below which spontaneous ventilation is not initiated without hypoxemia). The duration of these effects often exceeds the time course of analgesia. In addition to blunting the carbon dioxide response, morphine decreases hypoxic ventilatory drive. Morphine administration in patients with renal failure has been associated with prolonged respiratory depression secondary to persistence of its active metabolite, morphine-6-glucuronide [35].

The administration of small doses of IV naloxone (40 μg) to patients in order to reverse the ventilatory depressant effect of morphine may produce some adverse effects. Anecdotal reports describe the precipitation of vomiting, delirium, arrhythmias, pulmonary edema, cardiac arrest, and sudden death subsequent to naloxone administration in otherwise healthy patients after surgery. Furthermore, the duration of action of naloxone is shorter than any of the opioids it may be used to antagonize (except remifentanil). Recurring ventilatory depression therefore remains a distinct possibility, and in the spontaneously breathing patient, it is a source of potential morbidity.

Reversal with a mixed opioid agonist–antagonist agent such as nalbuphine or butorphanol appears to be safer than with naloxone. Mixed opioid agonist–antagonist agents may either increase or decrease the opioid effect, depending on the dose administered, the particular agonist already present, and the amount of agonist remaining.

For bedside procedures in the ICU, many of these problems can be obviated by using a shorter acting opioid.

Neurologic. Morphine has little effect on cerebral metabolic rate or cerebral blood flow when ventilation is controlled. Morphine may affect cerebral perfusion pressure adversely by lowering mean arterial pressure.

Fentanyl and Its Congeners

Description. Fentanyl, sufentanil, and remifentanil enter and leave the CNS much more rapidly than does morphine, thereby causing a much faster onset of effect after IV administration. The only significant difference among these agents is their PK behavior.

Fentanyl may be useful when given by intermittent bolus injection (50 to 100 μg), but when given by infusion, its duration becomes prolonged [36]. For TIVA in ICU patients in whom rapid emergence is desirable, sufentanil or remifentanil is the preferred choice for continuous infusion. When the procedure is expected to be followed by postoperative pain, sufentanil is preferred. Figure 20.2 shows that its CSHT is similar to that of propofol for infusions of up to 10 hours. When the procedure is expected to be followed by minimal postoperative pain

(e.g., bronchoscopy), remifentanil is preferred. Its CSHT is about 4 minutes regardless of the duration of the infusion.

Remifentanil owes its extremely short duration to rapid metabolism by tissue esterases, primarily in skeletal muscle [37]. Its PK behavior is unchanged in the presence of severe hepatic [38] or renal [39] failure.

Sufentanil infusion for TIVA may be initiated with a 0.5 to 1.5 μg per kg bolus followed by an infusion at 0.01 to 0.03 μg per kg per minute. If given with a propofol infusion, the two infusions may be stopped simultaneously as governed by the curves in Figure 20.2. Remifentanil infusion for TIVA may be initiated with a 0.5 to 1.5 μg per kg bolus followed by an infusion at 0.05 to 0.5 μg per kg per minute. The remifentanil infusion should be continued until after the procedure is completed; if the patient is expected to have postoperative pain, another opioid should be given because the remifentanil effect will dissipate within a few minutes.

Adverse Effects

Cardiovascular. Although fentanyl, sufentanil, and remifentanil do not affect plasma histamine concentrations, bolus doses can be associated with hypotension, especially when infused rapidly (i.e., <1 minute). This action is related to medullary vasomotor center depression and vagal nucleus stimulation.

Neurologic. Fentanyl and sufentanil have been reported to increase ICP in ventilated patients following head trauma. They may adversely affect cerebral perfusion pressure by lowering mean arterial pressure. All of the fentanyl derivatives may cause chest wall rigidity when a large bolus is given rapidly. This effect may be mitigated by neuromuscular blocking (NMB) agents as well as by coadministration of a hypnotic agent.

NEUROMUSCULAR BLOCKING AGENTS

There are two pharmacologic classes of NMB agents (see Chapter 25): depolarizing agents (e.g., succinylcholine) and nondepolarizing agents (e.g., vecuronium and cisatracurium). Succinylcholine is an agonist at the nicotinic acetylcholine receptor of the neuromuscular junction. Administration of succinylcholine causes an initial intense stimulation of skeletal muscle, manifested as fasciculations, followed by paralysis due to continuing depolarization. Nondepolarizing agents are competitive antagonists of acetylcholine at the neuromuscular junction; they prevent acetylcholine, released in response to motor nerve impulses, from binding to its receptor and initiating muscle contraction. Distinctions among the nondepolarizing agents are made on the basis of PK differences as well as by their cardiovascular effects.

NMB agents are used to facilitate endotracheal intubation and improve surgical conditions by decreasing skeletal muscle tone. Prior to intubation, the administration of an NMB agent results in paralysis of the vocal cords, increasing the ease with which the endotracheal tube may be inserted and decreasing the risk of vocal cord trauma. During surgery, the decrease in skeletal muscle tone may aid in surgical exposure (as during abdominal surgery), decrease the insufflation pressure needed during laparoscopic procedures, and make joint manipulation easier during orthopedic surgery. NMB agents should *not* be used to prevent patient movement, which is indicative of inadequate anesthesia. Dosing of NMB agents should be based on monitoring evoked twitch response; ablation of two to three twitches of the train-of-four is sufficient for the majority of surgical procedures and permits easy reversal.

PRACTICAL CONSIDERATIONS FOR TIVA

Electing to perform common procedures (e.g., tracheostomy and percutaneous gastrostomy) in the ICU instead of the operating room represents a potential cost saving of tremendous scope. Not only does this strategy eradicate costly operating room time and support resources, it eliminates misadventures that sometimes occur in hallways and on elevators. Cost analyses estimate an average overall cost reduction of 50% or more compared with traditional operative procedures [40]. TIVA represents the most cost-effective method of facilitating this.

In most patients, safe and effective TIVA may be achieved via the infusions of propofol plus sufentanil or propofol plus remifentanil. Premedication with midazolam decreases the required propofol doses and decreases the likelihood of recall for intraoperative events. Bolus doses should not be used in hemodynamically unstable patients, and lower bolus doses should be used in elderly individuals. NMB agents are also given if needed.

The opioid infusion rate is titrated to minimize signs of inadequate analgesia (e.g., tachycardia, tachypnea, hypertension, sweating, and mydriasis), although differentiation of pain from the sympathetic responses to critical illness is difficult. The propofol infusion rate is titrated to the endpoint of loss of consciousness; the depth of anesthesia monitors that are based on analysis of the electroencephalogram waveform (bispectral index (BIS), patient state index (PSI), or spectral entropy) facilitate locating this endpoint more accurately. Loss of consciousness should be achieved prior to the initiation of muscle paralysis. It is possible for patients to be completely aware of intraoperative events at times when there is no change in hemodynamics or any manifestation of increased sympathetic activity [41,42]. Hence, administering an opioid to blunt incisional pain without inducing loss of consciousness with a hypnotic is inappropriate.

The following additional points deserve consideration in this context:

1. In subhypnotic doses, propofol is less effective than midazolam in producing amnesia. In the absence of coadministration of a benzodiazepine, propofol must cause unconsciousness in order to reliably prevent recall. Prompt treatment of patient responses (movement, tachycardia, and hypertension) is important.
2. Medications infused for TIVA should be given via a carrier IV fluid running continuously at a rate of at least 50 mL per hour. This method not only helps deliver medication into the circulation, but also serves as another monitor of occlusion of the drug delivery system. Occlusion of the infusion line for more than a few minutes may lead to patient awareness.
3. To take advantage of the known CSHT values for the TIVA agents, communication with the surgeon during the procedure is important in order to anticipate the optimum time for stopping the infusions. The sufentanil and propofol infusions are stopped in advance of the end of the procedure, whereas remifentanil is infused until the procedure is complete.
4. To maintain reasonably constant propofol and sufentanil blood concentrations, the maintenance infusion rates should be decreased during the procedure because the plasma concentrations increase over time at constant infusion rates. An approximate guideline is a 10% reduction in infusion rate every 30 minutes.
5. Strict aseptic technique is important especially during the handling of propofol.

CHAPTER 21 ■ INTERVENTIONAL ULTRASOUND

GISELA I. BANAUCH AND PAUL H. MAYO

INTRODUCTION

Ultrasonography has major applications in critical care medicine. When used at the bedside by the intensivist who is in charge of the clinical management of the case, it allows for immediate diagnosis and management decisions to be made at the point of care. Bedside, intensivist-performed ultrasound differs substantially from standard radiology or cardiology performed ultrasonography in that the intensivist acquires the image, interprets the image, and promptly applies the results to the clinical situation. This avoids the time delay and clinical disassociation implicit to ultrasonography that is performed on a consultative basis by radiology or cardiology services.

The scope of practice of critical care ultrasonography encompasses those aspects of the discipline that have utility to diagnosis and management of the critically ill patient. A summary of the important elements that are required for competence in the field have been presented in a recent consensus statement [1]. Ultrasonography may be divided into two general categories of application in critical care management: (i) to guide diagnosis and management and (ii) for purposes of procedural guidance. The two are often related. For example, ultrasonography may be used to diagnose a pleural effusion. Ultrasonography is then used to guide thoracentesis, which in turn is useful in identifying the cause of the pleural effusion and therefore its management. This chapter reviews the use of ultrasonography for procedural guidance in the intensive care unit (ICU). For detailed review of critical care ultrasonography, the reader is referred to comprehensive texts on the subject [2,3].

A major responsibility of the intensivist is to safely perform a wide variety of invasive procedures that may be associated with significant complications. The proceduralist has a specific target, such as a vascular structure or body compartment (e.g., pleural, peritoneal, or pericardial), and seeks to avoid injury to adjacent structures while assuring accurate placement of the needle. Inaccurate placement of the needle may injure adjacent structures with potential major morbidity or even life-threatening complication, as well as lead to failure of either diagnostic effort or essential vascular or body cavity access.

This discussion assumes that the reader is fully trained in physical tasks of the procedure (proper sterile technique, needle manipulation, wire insertion, dilation etc.). These are reviewed in other chapters of this text specific to each procedure. Ultrasonography is used to augment the safety and success rate of the operator who is fully competent in the mechanical aspects of the procedure.

The use of ultrasonography for procedural guidance is based on a simple principle. The safety and success of needle insertion is augmented by the ability to image the target; to identify and therefore avoid adjacent structures; and if required, to guide real-time needle insertion. The alternative is to rely on off-line analysis of standard radiography images and/or on landmark technique. Intuitively, ultrasound guidance is an attractive alternative to traditional technique. It is now in widespread use in the critical care community. This chapter reviews the use of ultrasonography for the guidance of a variety of procedures that are commonly performed by the intensivist.

GENERAL PRINCIPLES

1. To maximize the utility of ultrasonography, the operator should have basic knowledge of ultrasound physics, machine control, transducer manipulation, image acquisition, ultrasound anatomy, image orientation, and image interpretation. In addition, the intensivist must have full capability in all the mechanical aspects of the procedure.
2. The machine should be carefully positioned such that the operator may view the screen and the procedure site without untoward head movement; this often requires rearrangement of cluttered equipment that typically surrounds the patient bed in the critical care unit. Machine position for ergonomic efficiency is particularly important when using ultrasonography for real-time image-guided needle insertion. Room lighting and angle of the ultrasound machine's screen should be adjusted to minimize screen glare. Before starting the procedure, machine settings should be set for optimal image quality with attention to gain, depth, and image orientation. Many modern machines are designed such that the structure of interest is best visualized if it is placed in the center of the screen. Some machines have automated image optimization software so that the operator does not need to adjust controls beyond pushing a single control button. The resulting image may not, in fact, be optimal, and it may need further readjustment.
3. In situations where real-time guidance is required (e.g., vascular access) or when there is need for scanning while maintaining a sterile field, ultrasound procedure guidance requires that the operator use a purpose-designed sterile probe cover. The use of covers made from sterile gloves or sterile intravenous skin covers is strongly discouraged. They frequently fail during the procedure, while the operator's attention is focused on the sonographic image or on needle direction and insertion on the sterile field. Well-designed sterile transducer covers are low cost and come with sterile ultrasound coupling medium.
4. By standard convention, guidance of thoracic, abdominal, and vascular procedures requires that the screen orientation marker be placed on the left of the screen. Guidance of procedures related to the heart, such as pericardiocentesis or transvenous pacemaker insertion, is performed with the screen orientation marker placed on the right of the screen. This convention relates purely to common usage patterns. When scanning from the head of the patient, as with internal jugular venous (IJV) access, the operator needs to decide on how to orient the screen marker in reference to the transducer. We suggest that the orientation marker be

on the left of the screen and that the corresponding marker on the transducer always be held such that it is pointed toward the left side of the examiner (unless scanning the vessel in longitudinal axis when the transducer marker is directed cephalad). It is important to understand and standardize orientation and transducer marker position so that the operator can direct the needle in predictable fashion during real-time guidance of needle insertion.

5. Whenever planning an ultrasound-guided procedure, the operator should explore the structure of interest before prepping and draping the patient. This allows for optimal site selection before site preparation. If the procedure aims to cannulate a vessel (e.g., central venous or arterial catheterization), the potential target should be evaluated on both sides of the body unless absolute contraindications exist on one side (e.g., arteriovenous fistula in the upper extremity would preclude radial arterial catheterization on that side). Multiple studies have documented significant anatomic variability in vascular lumina, positioning, and location with respect to adjacent structures for both venous and arterial targets [4–9].
6. Initially, vascular structures should be imaged in their transverse axis, as this approach is best to differentiate the artery and the vein [10]. Features such as compressibility, pulsation, luminal variation with respiratory effort, and/or respiratory maneuvers can all be used to help distinguish arterial from venous vessels. The cross-sectional ultrasonographic view usually displays the vein in close proximity to its accompanying artery, thus facilitating comparison of vessel changes with dynamic maneuvers, such as compression and Valsalva. Detection of vessel pulsatility requires a steady imaging plane for at least a few seconds. Pulsatility is sometimes diminished with hypotension. Differentiation of arterial from venous structures is challenging especially when the patient's perfusion is maintained with a nonpulsatile ventricular assist device (impeller device). The much less compressible, thicker arterial walls, as well as the lack of vessel lumen variability with respiratory effort and/or respiratory maneuvers, provide the most reliable features that differentiate arterial from venous structures in this situation. Color and spectral Doppler analysis may occasionally be required to distinguish the vein from the artery in situations of difficult anatomy or in the subclavian position.
7. For pleural or abdominal access, initial orientation should always be achieved in the longitudinal image plane. The variable position of the diaphragm in the critically ill patient makes is easiest to differentiate intrathoracic from intraabdominal fluid collections using longitudinal image planes.
8. Whenever possible, the operator should document relevant ultrasound images during the procedure. This may be as simple as capturing a frozen video image that can be placed in the chart. Depending on system capability, video clips may be captured and stored off line. Image documentation is important for quality review and billing purposes. However, it may not be practical in all situations, particularly during hectic resuscitation efforts.
9. Ultrasound guidance of procedures requires specific training. The cognitive aspects of the field are straightforward, and can be easily learned from books, audiovisual sources, courses, or via e-learning program. Image interpretation and acquisition require a component of hands-on scanning under the supervision of a skilled bedside instructor. Real-time guidance of needle insertion is a complex psychomotor skill that requires practice. Unfortunately, this is often achieved with the experiential approach; that is, the inexperienced operator is expected to perform the procedure the first time on an actual patient. To avoid this, we strongly recommend that training in real-time needle insertion take place on an ultrasound manikin. Ultrasound-capable vascular access manikins of excellent design are now commercially available [11]. Trainees may practice ultrasound control of the needle and targeted vascular access multiple times before their first effort at the patient bedside. This is imperative for patient safety and comfort as well as for operator confidence.

Ultrasound Guidance of Vascular Access

Vascular access is a major responsibility of the intensivist. Insertion of catheters of varying size and function requires central venous cannulation, accurate ongoing measurement of arterial pressure and waveform requires arterial line insertion, whereas peripheral venous (PV) access is a routine requirement of patient care. Considerations such as obesity or unusual body habitus (e.g., kyphoscoliosis or genetic disease) and coagulopathy may present special challenges. PV access may be difficult in patients due to obesity, intravenous drug use, or chemotherapy. Ultrasound is uniquely useful for guidance of all forms of vascular access.

A benefit of ultrasound guidance of vascular access is that it allows the operator to identify contraindications to vascular access that are not apparent by simple physical examination. For example, marked respiratory effort may completely obliterate internal jugular and subclavian vein lumina during inspiration in the volume-depleted patient. Such intermittent luminal collapse precludes successful vascular access and cannot be identified, except with ultrasonography. The presence of a thrombus in the femoral vein (FV) frequently cannot be detected by physical examination, but it is readily identified ultrasonographically and contraindicates cannulation at that site. Ultrasonography thus warns the operator to redirect attention to less complication-prone sites.

SPECIFIC PROCEDURES

Internal Jugular Venous Access

Several studies report that ultrasound guidance of IJV access is superior to landmark technique, with lower complication and higher success rate [12]. The reasons for this are obvious. Landmark technique may be straightforward in a slender subject, but much less so in an obese subject. Asymmetric IJV size and variation in IJV position relative to the carotid occur in up to 30% of the normal population and cannot be appreciated by surface physical examination [13,14]. A national quality organization has stated that ultrasound guidance of IJV access is required for patient safety purposes [15]. The Residency Review Committee has stated that training in this technique is highly recommended during critical care fellowship training; this will likely be followed by it becoming a mandatory requirement.

In guiding IJV access, ultrasonography should be used in a methodical fashion in order to maximize its utility as follows:

1. Vascular access requires the use of a linear ultrasound transducer typically of 7.5 MHz frequency. This allows for adequate resolution of structures that are relatively near the surface of the body. Lower frequency transducers, which penetrate more deeply at the cost of reduced resolution, are not suitable for guidance of vascular access. The patient should be placed in Trendelenburg in order to distend the vein as much as possible.
2. The operator should perform a preliminary scan of both sides of the neck before the sterile preparation. This allows for identification of aberrant anatomy and/or thrombus, and determination of the best site, angle, and depth of needle penetration. The IJV is usually lateral to the carotid

artery when scanning the anterior neck, and is differentiated from the carotid artery by its larger size, thin wall, and lack of characteristic pulsation, easy compressibility, size fluctuation with respiration or respiratory maneuvers, and the presence of thin mobile venous valves. Color Doppler may be used to confirm, but it is not generally required. The examination of the vein starts with a two-dimensional (2-D) study to examine the anatomy and observe for visible echogenic thrombus. The 2-D examination is followed by compression of the vessel to exclude isoechoic thrombus not visible on 2-D imaging. A fully compressible IJV indicates that there is no thrombus at the site of the examination. In order to ensure patency of the vessel along the length that will be traversed by the central venous catheter, several sites along the course of the vessel must be examined and then compressed. The presence of an ipsilateral thrombus contraindicates line insertion, whereas the presence of a contralateral thrombus is of concern, as the proposed IJV insertion may itself predispose to thrombus. This may yield bilateral IJV thrombus, which is undesirable.

3. The preprocedure scan should include examination of the anterior lung (with the patient in supine position) in order to rule out pneumothorax *before* the procedure. The transducer is held perpendicular to the chest wall in order to examine the rib interspaces of the upper anterior chest. The pleural interface is identified between the rib shadows. Presence of lung sliding, lung pulse, or B-lines rules out pneumothorax with a high level of certainty [16]. The examination may be accomplished with similar result, using a low-frequency abdominal or cardiac transducer, or using a high-frequency vascular transducer that is used to guide vascular access. Following the procedure, the operator again examines the anterior chest for pneumothorax. The finding of pneumothorax following the procedure, when none existed before, is strong evidence for procedural mishap. The preprocedure chest examination should include both lungs to cover the very rare eventuality that the patient has a contralateral pneumothorax before the procedure.
4. Before the sterile field is established, the ultrasound machine must be positioned to allow optimal hand–eye coordination for the operator. Because the operator normally stands on the side of the IJV to be cannulated, next to the patient's head and facing the patient's feet, the optimal position for the ultrasound machine is on the operator's side of the patient, immediately adjacent to the patient's lower chest or upper abdomen. Inadequate placement of the ultrasound screen makes efficient hand–eye coordination very difficult. With an inappropriately placed ultrasound screen, the operator needs to rotate his or her head in order to compare changes in the ultrasound image with changes in needle insertion depth and angle. With a well-placed ultrasound screen, the operator needs to only move his or her head up or down in order to compare ultrasonographic image changes with changes in needle angle and insertion depth on the sterile field. The chance of accidentally changing the ultrasonographic imaging plane (thus losing the ultrasound image essential for real-time guidance) during head rotation is much greater than the chance of an inadvertent change in scanning plane during a simple up-and-down movement of the head.
5. Following preliminary scanning and appropriate placement of the ultrasound unit, the patient is prepared with standard sterile technique. The transducer is covered with a purpose-designed sterile transducer cover. The operator has a choice at this point. A helper may hold the transducer while the operator introduces the needle, or the operator may hold the transducer in one hand while guiding the needle with the other. The latter is the preferred technique. The ability to manipulate the transducer and needle in tandem is advantageous. A variation of ultrasound guidance of vascular access is the "mark-and-stick" technique wherein the operator identifies the vessel and marks an appropriate site for line insertion. The needle is introduced without the benefit of real-time guidance. Although this yields higher success rate than traditional landmark method, it is inferior to real-time guidance [12] and so is not discussed further.
6. The operator needs to decide whether to use transverse or longitudinal scanning plane for real-time needle guidance. This is based on personal preference and training background. Some skilled operators prefer longitudinal approach, as they maintain that it is easier to identify the needle in long axis and therefore to guide it into the vessel. Many operators prefer the transverse plane. In either case, maximal safety is achieved by maintaining clear identification of the needle tip throughout the procedure [17].
7. There are two general approaches to real-time guidance in the transverse scanning plane. The first, which is conceptually easier, is to insert the needle very close to the transducer and angle down toward the vessel, with the goal of identifying the needle tip as it enters the scanning plane and the vessel. This technique results in a very acute angle at which the vessel is accessed, which sometimes makes it difficult to thread the guidewire. Alternatively, the needle may be introduced at some distance from the target vessel. The transducer is then moved toward the needle until the needle tip is identified. The transducer and needle tip are then moved forward in tandem, with the needle tip adjusted at the appropriate angle. In this manner, visual control of the needle tip is maintained throughout its forward movement. In addition, the angle at which the vessel is accessed tends to be less acute, making it easier to thread the guidewire. With the longitudinal scanning method, the transducer is used to obtain a longitudinal image of the target vessel. The needle is introduced along the longitudinal midline of the transducer and kept in full view while it is moved toward the vessel wall. The longitudinal approach tends to result in the least acute angle at which the vessel is accessed, making it easiest to thread the guidewire into the vessel successfully even when the vessel is located relatively far from the skin surface, for example, in the obese patient.
8. A vexing problem with IJV access is vessel compression. Under ultrasound guidance, the advancing needle may compress the anterior wall of the IJV, often to the extent that the vascular lumen is effaced. With further forward movement of the needle, it passes through the posterior wall of the vessel. Frequently, as the needle is slowly withdrawn, the vessel lumen opens up, blood enters the needle and syringe, and the wire is passed without problem. Whether minor needle insertion through the posterior wall has any clinical implication or not has not been determined. It may be avoided by downward orientation of the bevel and careful attention to angulation of the needle, as well as positioning the patient in Trendelenburg. Extensive head rotation or head extension and the presence of a laryngeal mask airway all reduce IJV diameter and move the vein into a position anterior to the carotid artery, thus increasing the risk of inadvertent arterial puncture [18–20].
9. Following wire insertion and before dilation of the vessel, the location of the wire in a venous vessel should be documented. This is best achieved in a longitudinal view of the vessel. If the wire is found to be in the artery (an occasional event, particularly with a less experienced operator), it may be removed without great consequence to the patient. However, inadvertent dilation of the carotid artery may have catastrophic effect. Positive identification of the wire within the vein adds only a short additional time to the procedure and avoids a rare, but dangerous, complication.

10. Generally, a postprocedure chest radiograph is used to document proper position of the venous catheter. Ultrasonography may be used as an alternative method [21]. Identification of suboptimal line position with ultrasonography allows repositioning while the sterile field is still in place, unlike a delayed chest radiograph. However, identification of line position with ultrasonography adds several minutes to the procedure and requires a high level of ultrasound training.
11. Following the procedure, the operator should examine the anterior chest in order to rule out procedure-related pneumothorax. The presence of sliding lung, lung pulse, and/or B-lines excludes pneumothorax. This underlines the importance of performing ultrasonography both *before* and *after* the procedure. The loss of lung sliding, lung pulse, and/or B-lines *following* IJV central venous access, when they were present immediately before the procedure, is strong evidence for a procedure-related pneumothorax. Ultrasonography is more accurate than standard supine chest radiography for the detection of pneumothorax, and has similar accuracy as chest computerized tomography [22].

Subclavian Venous Access

Ultrasonography may be used to guide SCV access [23,24]. The authors' opinion is that ultrasound guidance of SCV access may not augment safety or success in patients with normal anatomy. However, it does have utility in patients with challenging anatomy or coagulopathy. It also requires a higher skill level than IJV or FV access. It should only be used by the operator who has a high level of competence in real-time needle guidance. The pleural surface is in close proximity to the SCV and so accurate identification and precise control of the needle tip are required in order to avoid a pneumothorax. Many of the principles described for IJV insertion apply to the SCV. What follows are concerns that are specific to this site:

1. The SCV is more difficult to locate than the IJV. One strategy is to scan the upper chest with the transducer in longitudinal scanning plane in order to locate the clavicle. Once this is done, the transducer is moved laterally along the clavicle until the vessel is seen to appear from under the clavicle. Further lateral movement of the transducer will image the SCV independent of the clavicle. At this point, the transducer is rotated 90 degrees to obtain a long axis view of the vein. This is the appropriate orientation for real-time guidance of needle insertion. The subclavian artery is located immediately adjacent to the vein, and most often deep to it. Unfortunately, the vein may not be compressible due to anatomic constraint, so it may be challenging to differentiate the artery from the vein. Observation of respirophasic changes, venous valves, and the use of color and pulse wave Doppler all have utility in making the critical distinction between the two structures. It is difficult to visualize SCV thrombus, as compression study is often not possible. Lack of respirophasic changes and/or lack of color Doppler flow augmentation on compression of the ipsilateral arm suggest the possibility of thrombus.
2. In order to minimize operator head movement during the insertion, the ultrasound machine should be positioned immediately adjacent to the patient's axilla on the side that is contralateral to the side at which access will be attempted (e.g., adjacent to the patient's right axilla if the left SCV has been chosen for venous access).
3. Ultrasound guidance of SCV access should be performed with the vein imaged in its long axis so that the entire needle and its tip can be visualized real time throughout the insertion. Any loss of needle tip control runs the risk of pleural or arterial puncture. For the experienced landmark operator, ultrasound guidance of SCV access presents a psychologic challenge. The operator is so used to relying on the clavicle as a definitive structural guide during insertion that it is difficult to perform the access at a lateral site that ignores the clavicle landmark completely. More lateral puncture sites, however, are anatomically less risky for both arterial and pleural puncture, whereas vessel lumen is reduced only by 25% [25].
4. Because the puncture site of the subclavian vein is considerably more lateral for ultrasound-guided punctures compared to landmark-guided punctures, the tip of the central venous catheter may not reach to the superior vena cava when a short catheter is used. This is especially true when the left subclavian vein is used for access.
5. For safety purposes, the operator should use the same precautions as with the IJV insertion by checking for pneumothorax before and after the procedure and by documenting that the wire is within the vein before dilation. Unlike the IJV and FV, where wire identification is straightforward, identification of the wire in the subclavian vein may be difficult, as the clavicle may block easy identification. A useful technique is to image the ipsilateral IJV and follow it down to the medial supraclavicular area. Downward rotation of the probe reveals the confluence of the IJV and the SCV with wire identification.

Femoral Venous Access

Ultrasonography may be used to guide FV access [26], and has the same rationale as for the IJV. It reduces complication rate and improves success rate. It has particular utility in emergency situations that mandate immediate venous access. A trained operator can safely establish venous access very rapidly using ultrasound guidance. Many of the principles described for IJV insertion apply to the FV site. What follows are concerns that are specific to this site:

1. The safe site for FV access should be at the common femoral vein (CVF) level. Immediately below the inguinal crease, the FV rotates so that it is posterior to the artery (then becoming the superficial FV). Attempts at access at this level risk arterial injury. In the worst-case scenario, the needle passes through the artery into the vein. Following dilation, the catheter is passed through the artery and rests, as a fully functional venous line, in the vein. Subsequently, it is removed with no special precaution as the operator believes that it was a well-placed venous line. Major arterial bleeding ensues. Ultrasonography allows identification of the CFV in a position that is medial to the vein at a site close to the inguinal ligament. This is the appropriate site for needle puncture. The position of the vein remains side by side with the artery for a longer distance caudally if the leg is rotated externally (similar to optimal positioning for insertion using the landmark technique [27]).
2. Identification of the vein and artery is straightforward and is based on methods outlined in the discussion on IJV access. The vessel should be imaged in transverse plane and the needle guided into it under real-time ultrasound control. The wire should be documented within the vein before dilation.

Peripheral Venous Access

Ultrasound guidance for PV access improves success rates and reduces complications [28]. Site-specific considerations for ultrasound-guided PV insertion follow:

1. The operator must have knowledge of the complex venous anatomy of the upper extremity. Accessing PVs may be

performed using both cross-sectional and longitudinal scanning techniques. The advantage of the latter is that the needle is visualized along its entire length so that it may be guided accurately into a small venous structure.

Arterial Access

Principles for ultrasound guidance of arterial access are similar to those for ultrasound guidance of venous access. Particular points of importance for each arterial access site follow.

Radial Artery

Ultrasound-guided radial arterial cannulation has been shown to significantly increase success on the first attempt [29], and is especially valuable in hypotensive and grossly edematous patients. In the patient without edema, the artery is located quite superficially at the wrist. Color Doppler imaging can help in its identification. The artery is accompanied by two easily collapsible venous structures, the venae comitantes. Wrist extension beyond 60 degrees reduces vessel diameter, thus making cannulation more difficult [8].

Femoral Artery

Ultrasound guidance for femoral arterial access has been proved valuable in obese and hypotensive patients [30]. The technique is also of benefit in coagulopathic patients. In addition, ultrasound allows selection of a vessel site that is less affected by atherosclerotic changes, as well as permits prompt detection of complications due to catheterization, such as pseudoaneurysm, hematoma, or arteriovenous fistula [31,32].

Ultrasound Guidance of Pleural Access

Pleural fluid collections are frequently encountered in critically ill patients. Ultrasound guidance of thoracentesis reduces the risk of pneumothorax [33]. Ultrasound-guided thoracentesis is safe for patients on mechanical ventilatory support [34,35]. Ultrasound guidance for pleural access and device insertion should incorporate the following points:

1. Prior to establishing the sterile field, a comprehensive scan of the hemithorax should be undertaken with the aim of identifying a safe site, angle, and depth for needle insertion. It is of paramount importance that the operator's first action be a differentiation between peritoneal and retroperitoneal structures and pleural structures. This requires unequivocal identification of the diaphragm. In the intubated, sedated patient, the diaphragm is often located more cranially than in the awake, upright patient. The prudent operator first proceeds with identification of the kidney and the adjacent liver or spleen in the longitudinal axis. The operator then scans more cranially, identifying the curvilinear diaphragm with its characteristic respiratory movement. Positive identification of the diaphragm avoids inadvertent subdiaphragmatic needle insertion with its potentially lethal effect. Pleural fluid, unless loculated, assumes a dependent position in the hemithorax. In the supine patient, the fluid is posterior in location. Ultrasonographically, pleural fluid appears as a hypoechoic space that is subtended by typical anatomic boundaries (inside of chest wall and diaphragm) and associated with typical dynamic findings (lung flapping, diaphragmatic movement, plankton sign, and mobile elements within the fluid, such as septations). Complex effusions, such as empyema or hemothorax, may be difficult to identify by the inexperienced ultrasonographer. Before proceeding with thoracentesis, operators must be completely confident in their identification of fluid within the thorax.
2. It is important that the patient maintain the same position between ultrasonographic site localization and actual device insertion. If the patient changes position between ultrasonographic site localization and actual device insertion, free-flowing fluid may redistribute to a different area in the hemithorax. A large pleural effusion is easy to locate by scanning in the midaxillary line. It may be more difficult to identify a safe access site in patients with smaller effusions, as the mattress blocks appropriate transducer position in the supine patient. In this situation, the operator may need to reposition the patient for better access.
3. When localizing a safe access site and angle, the operator should explore its extent in all three dimensions. This requires imaging the collection in two orthogonal planes (typically, a longitudinal and a coronal plane). A moderate-sized collection that tracks into an interlobar fissure may appear to have a considerable extent, with a wide separation between parietal and visceral pleural surface, if its long axis is imaged; however, an orthogonal scan in a coronal plane will quickly reveal the small lateral extent of such a collection. When determining where to insert the device, the operator must take into consideration not only the optimal point on the thoracic skin, but also the angle with the thorax in which the ultrasound transducer provides the image of the collection's largest extent. This optimal transducer angle for imaging of the collection must then be reproduced without continuous ultrasonographic guidance during insertion of the device. Reproduction of the optimal imaging angle assures that the largest extent of the fluid collection is accessed during device insertion. In this manner, fluid collections with a separation between visceral and parietal pleural surfaces of 15 mm or more can be accessed safely [34].
4. The hypoechoic space between parietal and visceral pleura is usually presumed to contain fluid; however, gelatinous contents can occasionally present with a similar ultrasonographic image [36]. If sterile transducer sheaths are available during the procedure, the operator can image the intrathoracic device position if no fluid return is achieved, thus assuring access to the intended space. If color Doppler signals are imaged in the hypoechoic space on preinsertion scanning, this also assures liquid rather than gelatinous intrathoracic contents [37].

If a pleural device is inserted in order to perform medical pleurodesis, the extent of pleurodesis can be assessed in follow-up pleural ultrasound 1 to 2 days later and repeat ultrasound-guided local pleurodesis can then be performed in locules with persistent fluid content [38].

Ultrasound Guidance of Pericardiocentesis

Pericardiocentesis may be performed safely with ultrasound guidance [39]. The intensivist performs pericardiocentesis for diagnostic purposes. Alternatively, pericardiocentesis may be a lifesaving procedure if the patient has pericardial tamponade. The skills required for performance of ultrasound-guided pericardiocentesis are similar to those required for thoracentesis and paracentesis. The operator must identify a safe site, angle, and depth for needle insertion that avoids injury to structures adjacent to the pericardial fluid. This requires that the operator examine the heart from multiple windows: parasternal, apical, and subcostal. Using ultrasonography, the operator identifies the largest area of fluid collection. This is often at the apical four-chamber view, or in large effusions, from a parasternal view. The subcostal approach is frequently prohibited by the presence of the liver in a blocking position, a feature that is

easily recognized with ultrasonography. The use of fluoroscopy to guide pericardiocentesis is typically limited to the subcostal approach. The liver is not easily identified using fluoroscopy, so hepatic laceration is a hazard that is not readily apparent when using fluoroscopy. In addition, the apical or parasternal windows frequently reveal a larger fluid collection target than does the subcostal approach. Some concerns specific to pericardiocentesis are as follows:

1. Lacerations of the myocardium or a coronary artery are specific potentially lethal complications of pericardiocentesis. Site selection requires that there be sufficient fluid to allow safe needle insertion. In making this determination, the operator must observe for cardiac movement that occurs during contractile cycle, which is respirophasic or results from cardiac swinging within the effusion. A minimum of 10 mm of space within the effusion is required for safe needle insertion. Large effusions may allow the operator to select an angle of approach that is free of any cardiac structure. The presence of interposed liver may preclude a subcostal approach. Aerated lung does not permit transmission of ultrasound so that the ultrasonographic visualization of the heart precludes injury to interposed aerated lung. Consolidated lung has a specific ultrasonographic appearance, and must not be interposed in the planned needle track. A coexisting pleural effusion may be interposed between the pericardial effusion and the needle insertion site. The pleural effusion should be removed before the pericardial fluid is accessed.
2. Once the site is selected, it should be marked without placing traction on the skin that may cause inadvertent site movement on release of the traction. The depth of needle penetration is a critical measurement. Compression artifact caused by firm pressure of the transducer in the obese or edematous patient may cause an underestimation of the depth of needle penetration. This needs to be factored into the depth estimate; otherwise the operator will not be able to access the pericardial fluid, out of mistaken concern that the needle has been inserted too far. Angle selection is determined by the location of the fluid. Whenever possible, it should be perpendicular to the skin surface, as this is the easiest angle to duplicate with the needle and syringe assembly.
3. Unlike thoracentesis and paracentesis, it is important to include the transducer with full sterile cover into the set up of the sterile field. The intensivist should be prepared to rescan the target site just before needle insertion in order to document the correct angle for needle insertion, recheck depth in case of initial failure due to compression artifact, and check for proper device position immediately following catheter insertion.
4. Real-time guidance of needle insertion is not necessary for safe performance of pericardiocentesis, similar to thoracentesis and paracentesis. A final confirmatory scan is performed immediately before needle insertion and the needle is placed with free-hand technique duplicating the angle defined by the transducer. Aspiration of fluid is followed by wire insertion and device insertion via Seldinger technique. Correct catheter position may be verified by injection of agitated saline solution.

Ultrasound Guidance of Paracentesis

Peritoneal fluid collections commonly occur in the critically ill. Ultrasound guidance improves the safety of peritoneal access, especially in patients with peritoneal adhesions or difficult anatomy (e.g., morbid obesity and massive subcutaneous edema [40]). Many of the principles described for ultrasound-guided pleural access also apply to ultrasound-guided peritoneal access. Specifically, a comprehensive scan of the abdomen should first ascertain the area of maximal intraperitoneal fluid, and the patient should maintain the same position between the ultrasonographic site localization and the actual procedure so as to avoid fluid redistribution. The operator should explore the extent of the peritoneal fluid collection using two orthogonal planes. In addition, the operator who accesses the peritoneal space under ultrasound guidance should bear in mind the following:

1. The best site, angle, and depth for needle penetration are determined at the bedside. The needle–syringe assembly must duplicate the angle at which the transducer was held when determining the best angle of attack. Normally, an area superior to and medial to the left anterosuperior iliac spine contains some of the free intra-abdominal fluid in the left paracolic gutter (similar to the area identified with the landmark technique). Because the sigmoid colon courses retroperitoneally at this location, the risk of large bowel injury is less than that on the contralateral side, which contains the intraperitoneal cecum. Perihepatic and perisplenic fluid collections also occur in patients with ascites, but the risk of solid organ injury is higher in these locations, and the operator should have experience prior to attempting puncture at these subdiaphragmatic sites.
2. In the edematous patient, compression of the subcutaneous tissue leads to an underestimation of the soft-tissue distance that needs to be traversed prior to entering the peritoneal space (so-called compression artifact). Any ultrasonographic measurement of the distance between the skin and the peritoneal cavity should thus be performed from an image acquired while the transducer is applied to the skin with minimal pressure.

Other Ultrasound-Guided Procedures

Beyond vascular access, thoracentesis, paracentesis, and pericardiocentesis, ultrasonography may be used to guide other procedures of interest to the intensivist as follows:

1. Aspiration and biopsy of solid and fluid-filled structures. Ultrasonography allows the intensivist to identify a fluid-filled structure such as an abscess [41]. With knowledge of surrounding anatomy, a safe site, angle, and depth of needle penetration may be identified for access. Similarly, solid lesions may be accessed for aspiration and biopsy [42].
2. Airway management. Ultrasonography may be used to document endotracheal tube placement and diagnose inadvertent main stem bronchial intubation [43]. Ultrasonography is useful in performing percutaneous tracheostomy to screen for dangerous vascular aberrancy and guide tracheal access.
3. Transvenous pacemaker insertion. Ultrasonography may be used to guide transvenous pacemaker insertion. The subcostal window permits visualization of the IVC, right atrium, and right ventricle. The pacemaker wire may be manipulated into position under real-time guidance.
4. Lumbar puncture. Ultrasonography may be used to guide lumbar puncture [44]. This has application in the patients with difficult anatomy.

CONCLUSION

Ultrasonography is a useful technique in guiding a variety of procedures that are routine to critical care medicine. These include vascular access, thoracentesis, paracentesis, and pericardiocentesis. Competence in ultrasonographic guidance is a useful skill for the intensivist as it improves the safety, comfort, and efficiency of these common procedures.

CHAPTER 22 ■ INTERVENTIONAL RADIOLOGY: PERCUTANEOUS DRAINAGE TECHNIQUES

BRIAN T. CALLAHAN, SALOMAO FAINTUCH AND FELIPE B. COLLARES

Over the past decade, image-guided percutaneous drainage procedures have become accepted as safe and effective alternatives to surgery for the first-line treatment of symptomatic fluid collections in the body. Image guidance typically provided by sonography or computed tomography (CT) allows for precise localization of fluid collections, improved drainage techniques, and faster patient recovery. Rapid imaging localization and percutaneous treatment has played a major role in decreasing the morbidity and mortality associated with surgical exploration [1–4].

GENERAL AIMS

The aim of the interventional radiologist is to detect and localize symptomatic fluid collections, ascertain if additional imaging or laboratory tests are needed, and determine what, if any, intervention is required. Close communication between interventional and critical care staff is essential to accomplish these goals. Image-guided aspiration or drainage procedures can alleviate symptoms due to mass effect or inflammation, provide fluid samples for laboratory characterization, and cause reduction in sepsis [5]. A list of fluid collections amenable to image-guided procedures is provided in Table 22.1.

DIAGNOSTIC IMAGING

CT and ultrasound are the two main imaging modalities used for percutaneous image guidance. Magnetic resonance imaging (MRI)-guided drainage is available at some academic institutions, but limited by availability, cost, and paucity of MRI-compatible devices. The choice between CT and ultrasound is ultimately determined by operator experience, availability of equipment, and nature of the collection such as size, location, and presence of septations. Advantages of ultrasound include portability, lack of radiation, low cost, and real-time visualization of needle placement into a collection. Ultrasound can also be readily combined with fluoroscopic guidance techniques. Limitations of ultrasound include poor visualization of deep collections secondary to large body habitus, bone, overlying bowel gas, or surgical dressings. CT provides excellent visualization of the fluid collection and its relation to vital structures, allowing for the safest percutaneous access route to be chosen. For deep collections such as those located in the pelvis or retroperitoneal space, CT is particularly well suited [6]. There is typically a shorter learning curve to master CT-guided procedures, especially given the availability of commercially produced skin grids to help aid needle placement. The main limitations of CT include radiation exposure, cost, and lack of real-time visualization of needle placement. The recent advent of CT fluoroscopy allowing the operator to obtain rapid sequential images of needle position without having to leave the patient is a major step forward for helping to resolve some of these technical issues [5]. Table 22.2 is a summary of the advantages and limitations of CT versus sonography [7].

TABLE 22.1

FLUID COLLECTIONS SUCCESSFULLY TREATED WITH PERCUTANEOUS DRAINAGE

Sterile	Nonsterile
Ascites	
Hematoma	Enteric abscess
Lymphocele	Lung abscess and empyema
Pancreatic pseudocyst	Ruptured appendicitis
Postsurgical seroma	Pancreatic abscess
Urinoma	Tubo-ovarian abscess
Multilocular fluid collections	Cholecystitis

INDICATIONS

The indications for image-guided drainage and aspiration include, but are not limited to, fluid sampling to assess infected versus sterile collections, reduction of microorganism burden due to extraction of contaminated material, and relief of pressure symptoms secondary to excess fluid accumulation. In the critically ill patient, catheter drainage may stabilize the patient's condition so that a more definitive surgical procedure can be performed at a later time [8,9]. Abscess size is an important determinant of the need for percutaneous drainage. Many patients with abscesses smaller than 4 cm in diameter can be treated conservatively with broad-spectrum antibiotics, hydration, and bowel rest [10]. If a small collection is unresponsive to initial antibiotic therapy, a drainage procedure should be considered. In patients with abscesses larger than 4 cm, studies have shown that percutaneous catheter placement is beneficial and less invasive than surgical intervention [10].

CONTRAINDICATIONS

Contraindications are divided into absolute and relative. Absolute contraindications for percutaneous drainage include absence of a safe access route or uncorrectable coagulopathy. An uncooperative or unwilling patient may also cause termination of a procedure. Often, the study may be rescheduled

TABLE 22.2

ADVANTAGES AND LIMITATIONS OF COMPUTED TOMOGRAPHY (CT) AND ULTRASOUND

	Advantages	Limitations
CT	Excellent 2-D and 3-D (with reformatting) spatial resolution Images not obscured by overlying structures	Radiation exposure Lack of real-time image guidance Procedures take longer Higher cost
US	No radiation required, real time visualization of anatomy and needle placement Portability allows bedside procedures Low cost	Overlying structures (i.e., bowel gas, real-time visualization of bone) may obscure target More difficult to master Need cooperative patient

to allow for general anesthesia or deep sedation to be provided for patient safety. The utmost care should be taken to avoid transgression of major blood vessels, pleura, pancreas, and spleen. One should also avoid prolonged drainage of sterile collections due to the risk of secondary infection [11]. In patients with relative contraindications, procedures may require more planning or additional time, but are usually amenable to treatment. For example, a transenteric (small bowel) route may allow for needle aspiration of a collection previously thought to be inaccessible [12]. If no direct route is available, the liver, kidney, and stomach may be safely transgressed during needle aspiration or catheter placement. Recent advances in technique such as transgluteal, transvaginal, or transrectal sampling provide more options for draining difficult-to-reach collections [13–15].

RISKS, BENEFITS, AND ALTERNATIVES

Overall complications associated with percutaneous drainage are reported to be less than 15% [16]. These include damage to vital structures, bleeding, and infection among others. Mortality (ranging from 1% to 6%) is frequently secondary to sepsis or multiorgan failure rather than the drainage procedure itself. Depending on the location and physical properties of an infected or sterile collection, percutaneous drainage is curative in 75% to 90% of cases [6,16,17]. In approximately 10% of cases, percutaneous drainage can serve as a temporizing measure allowing surgery to be postponed or performed in a single step [10]. Patients whose drainage collections contain feculent material or a fistulous communication tend to respond poorly, and further surgical intervention may be required. Indications for surgery also include visceral perforation, peritonitis, uncontrolled sepsis, and lack of improvement or deterioration of clinical status following several days of medical treatment [18].

PREPROCEDURE PREPARATION

Regardless of the study to be performed, certain basic principals apply to all patients about to undergo a drainage procedure. After review of the risks, benefits, and alternatives to the procedure, informed consent should be obtained from the patient or health care proxy. The radiologist should review the case with the referring physician to determine if the procedure is medically indicated or if other treatment alternatives exist. A comprehensive history and physical examination is taken, including review of previous and current imaging studies to evaluate fluid collection size, location, and complexity. Determination of the imaging modality used to characterize the fluid collection depends on location and operator preference. Once the collection has been localized, the access route is planned. The basic tenets of surgical drainage are followed using established surgical routes to find the shortest and least invasive path while avoiding lung, pleura, bowel, and other vital structures. Prior to the procedure, the patient should stop all anticoagulant medications, given the benefits of the drainage procedure outweigh the risk to the patient from thrombosis. For example, clopidogrel (Plavix), an antiplatelet agent, should be held for 7 to 10 days before the procedure [19]. For patients receiving vitamin K antagonists such as Coumadin, guidelines recommend bridging anticoagulation with therapeutic dose low-molecular-weight heparin (given subcutaneously) or intravenous unfractionated heparin (given intravenously) [19,20]. The goal is to maintain the international normalized ratio (INR) less than 1.5. It is believed that anticoagulants can be safely restarted 6 to 8 hours following the procedure. Coagulation parameters should also be obtained within a few days before the procedure and corrected if necessary. In a nonemergent situation, the prothrombin time (PT) should be less than 15 seconds, the partial thromboplastin time less than 35 seconds, platelet count greater than 75,000 per mL and INR less than 1.5. In emergent situations where the PT is elevated, fresh-frozen plasma should be given. Platelet transfusions can be administered just prior to the procedure to raise levels to an acceptable value.

The patient should have nothing to eat for 4 to 6 hours prior to the study to reduce the risk of aspiration during moderate sedation. Transient bacteremia associated with percutaneous drainage of an infected collection may require prophylactic treatment with antibiotics. Initial coverage should utilize a broad-spectrum antibiotic before more selective therapy can be deduced from fluid Gram stain and culture. If intravenous contrast is required to visualize a collection, the patient's renal function (blood urea nitrogen [BUN] and creatinine) should be evaluated. If elevated (serum creatinine >1.5 mg per dL), the patient may require hydration and pretreatment with sodium bicarbonate and oral or intravenous *N*-acetylcysteine (Mucomyst) [21]. Low osmolality contrast agents may also be used to help reduce the risk of contrast-induced nephrotoxicity. In patients with a history of prior "contrast reaction," the incident should be discussed to determine if symptoms were truly an anaphylactic reaction. In the setting of a validated contrast reaction, the risks and benefits of the study should be weighed and discussed with both the patient and the referring physician. If a decision is made to precede with intravenous contrast administration, these patients are usually pretreated with a combination of a steroid and an antihistamine. Oral contrast may be given to patients prior to CT to better delineate bowel loops. Reports of unopacified bowel mistaken for an abscess collection are not uncommon.

EQUIPMENT

With the advent of portable, high-resolution ultrasound machines, diagnostic or therapeutic procedures may now be performed at the bedside. Drainage of ascites, pleural effusions, and placement of cholecystostomy tubes are just some of procedures performed at our institution when the patient is too unstable to transport. All procedures must be performed under sterile conditions, with patient monitoring and sedation performed by a qualified nurse. For most procedures, convenient premade sterile kits are available, containing drapes, skin preparation, lidocaine, blades, sharps containers, and additional instruments tailored to the intervention to be performed. A variety of different-size and -configuration needles, guidewires, and catheters should be available to the radiologist during the procedure.

PATIENT CONSENT AND PREPROCEDURE REVIEW

After a thorough explanation of the risks, benefits, and alternatives of the procedure, informed consent should be obtained from the patient or a health care proxy [22].

A careful review of the procedure "time-out" should be held just prior to gaining access to confirm patient identity, site, review allergies and to verify the procedure to be performed.

ANESTHESIA AND MONITORING

Most image-guided drainage procedures can be performed with local anesthesia alone or in combination with moderate sedation. Typically, local anesthesia is achieved using subcutaneous infiltration with 1% to 2% lidocaine using a thin 25-gauge needle. At our institution, we have found that addition of sodium bicarbonate (75 mg per mL mixed in a 1:10 ratio) to lidocaine reduces the pain perception of an intradermal injection [23]. Longer acting agents such as tetracaine gel or bupivacaine (lasting 4 to 8 hours) are available for procedures lasting more than a couple hours. For moderate sedation, the procedure is typically performed using a combination of intravenous fentanyl and midazolam (Versed). The interventional radiologist should be familiar with these drug protocols and their reactions, and conscious sedation certification is recommended. In procedures where balloon dilation is performed or if patients are unable to hold still for long periods of time, general anesthesia may be required. The patient should be well hydrated, and vital signs must be continuously monitored during the procedure as well as during the patient's recovery. It is imperative that the interventional suite is equipped with basic monitoring equipment, including pulse oximetry, blood pressure monitoring devices, and electrocardiography. For the infrequent event of cardiopulmonary resuscitation, a defibrillator, backboard, and code cart supplied with the necessary medications for advanced life support should always be available.

STERILE TECHNIQUE

Regardless of known risk factors, universal precautions against contact exposure should be applied to all patients, including wearing of sterile gloves, impermeable gowns, and a face mask with shield. Hands should be washed with an antibacterial surgical scrub before starting the procedure. All equipment should be placed on a sterile field within easy reach, such as a bedside table. Proper preparation of the patient's skin using an antimicrobial product is essential in reducing the number of microorganisms present. Preferred antiseptics include 70% alcohol, 10% povidone–iodine, or a chlorhexidine-containing product [24]. Skin preparation should be performed in a way that preserves skin integrity and prevents injury to the skin. Shaving is no longer recommended because it may create breaks in the skin where bacteria can multiply and grow. The skin prep should be large enough to allow for extension of the incision or placement of adjacent drainage sites. Creating and maintaining a sterile field by placing sterile surgical drapes around the patient's incision large enough to prevent inadvertent contamination is essential.

PROCEDURES

General Considerations

In principle, a unilocular collection with a well-developed cavity wall is best suited for percutaneous drainage. After localization of the collection with either CT or ultrasound, the patient is placed on the imaging table in the optimal position that affords the shortest and safest approach to the collection being entered. For multiloculated or semisolid collections, multiple drain placements may be required. If possible, drains should be inserted into the most dependent portion of the collection.

Diagnostic or Therapeutic Aspiration

CT and ultrasound used alone or with fluoroscopic guidance can be used to localize the collection. After appropriate patient positioning and selection of the skin insertion site, local anesthesia with 1% lidocaine is administered and a small incision made with a no. 11 scalpel. After the skin entrance site is widened with a surgical forceps, a 22- or 20-gauge needle can be advanced into the collection under image guidance. For a hematoma or viscous collection, 16- or 18-gauge large-bore needles can be used [2,25]. Aspiration of fluid confirms position, and can be sent for culture, Gram stain, and cytology if needed. Additional laboratory tests can be added such as in the case of evaluating fluid for amylase in a peripancreatic collection or creatinine in suspected urinomas. The aspiration needle may be left in place to serve as a guide for parallel catheter placement or a conduit for introduction of a guidewire.

Catheter Selection

Multiple types of drainage catheters are available on the market. These come in different sizes, configurations, and materials. Selection of the appropriate catheter is largely governed by the size, location, and physical properties of the collection to be drained. The two major catheter designs include sump and nonsump varieties. A sump catheter is well suited for abscess drainage and ranges in size from 8 to 14 French (Fr). The catheter contains a small lumen that allows ingress of irrigant or air for drainage and a larger outer lumen designed to prevent side-hole blockage when the catheter is apposed against an abscess cavity wall [26]. Smaller bore nonsump catheters are usually more flexible than sump catheters allowing for guidewire placement into difficult-to-reach fluid collections. Limitations of nonsump catheters include smaller side holes and internal bores, limiting their effectiveness in draining viscous collections, such as pus or hematoma. The largest caliber catheter that can be safely and comfortably inserted should be used to help drain viscous fluid and prevent blockage from debris.

Therapeutic Catheter Drainage

Broadly, catheter drainage systems can be introduced using the trocar or Seldinger technique. The trocar system consists of an 8- to 16-Fr pigtail catheter coaxially loaded over a hollow metal stiffener with a sharp inner stylet. Under image guidance, the trocar system is advanced together into the fluid collection. Once the catheter has reached the desired location, the inner stylet is removed and aspiration performed confirming position within the collection. Next, the catheter is advanced off the cannula into the cavity, assuming its pigtail configuration. Most CT drainages are performed using this system. Advantages of the trocar technique include a single pass and less chance of access loss. The trocar technique is well suited to large, easily accessible collections, and can be performed quickly and safely at the bedside under ultrasound guidance. Given the rigidity of the system, the trocar system is not recommended for drainage procedures where the collection is small or difficult to access.

An alternative to the trocar system for drain placement is the use of the Seldinger technique (Fig. 22.1). The Seldinger system involves two steps starting with insertion of an 18- to 20-gauge sheathed needle into a collection under image guidance. Following aspiration of fluid to confirm position, the needle is removed and a 0.035-in. guidewire is advanced through the sheath into the cavity [27]. The guidewire is subsequently used for tract dilatation and placement of 8- to 12-Fr drainage catheters. This technique is best performed under continuous image guidance such a fluoroscopy as guidewire access can easily be lost in inexperienced hands. If this occurs, cavity decompression may make guidewire reentry nearly impossible. It is recommended not to evacuate the cavity before the catheter has been secured in position.

Fixing the Catheter

A wide variety of catheters containing various types of self-locking detention devices are available on the market. The most frequently used self-locking mechanism consists of a string that when pulled, forms a pigtail at the catheter's internal end. The string can then be locked in position fixing the pigtail in place to prevent accidental dislodgement. A second type of locking device, a Malecot or "mushroom" catheter can be deployed when the abscess cavity does not contain enough room for pigtail formation. For drainage, the catheter should be connected to a bag with intervening stopcock to allow for irrigation. Further security can be achieved by fixing the catheter to the skin with tape and sutures or a commercially available external fixation device. We have found adhesive external devices to be particularly well suited to catheter fixation without the need for additional skin suturing.

Management of the Catheter

The patient with a percutaneous drainage catheter requires regular monitoring. A team approach requiring communication

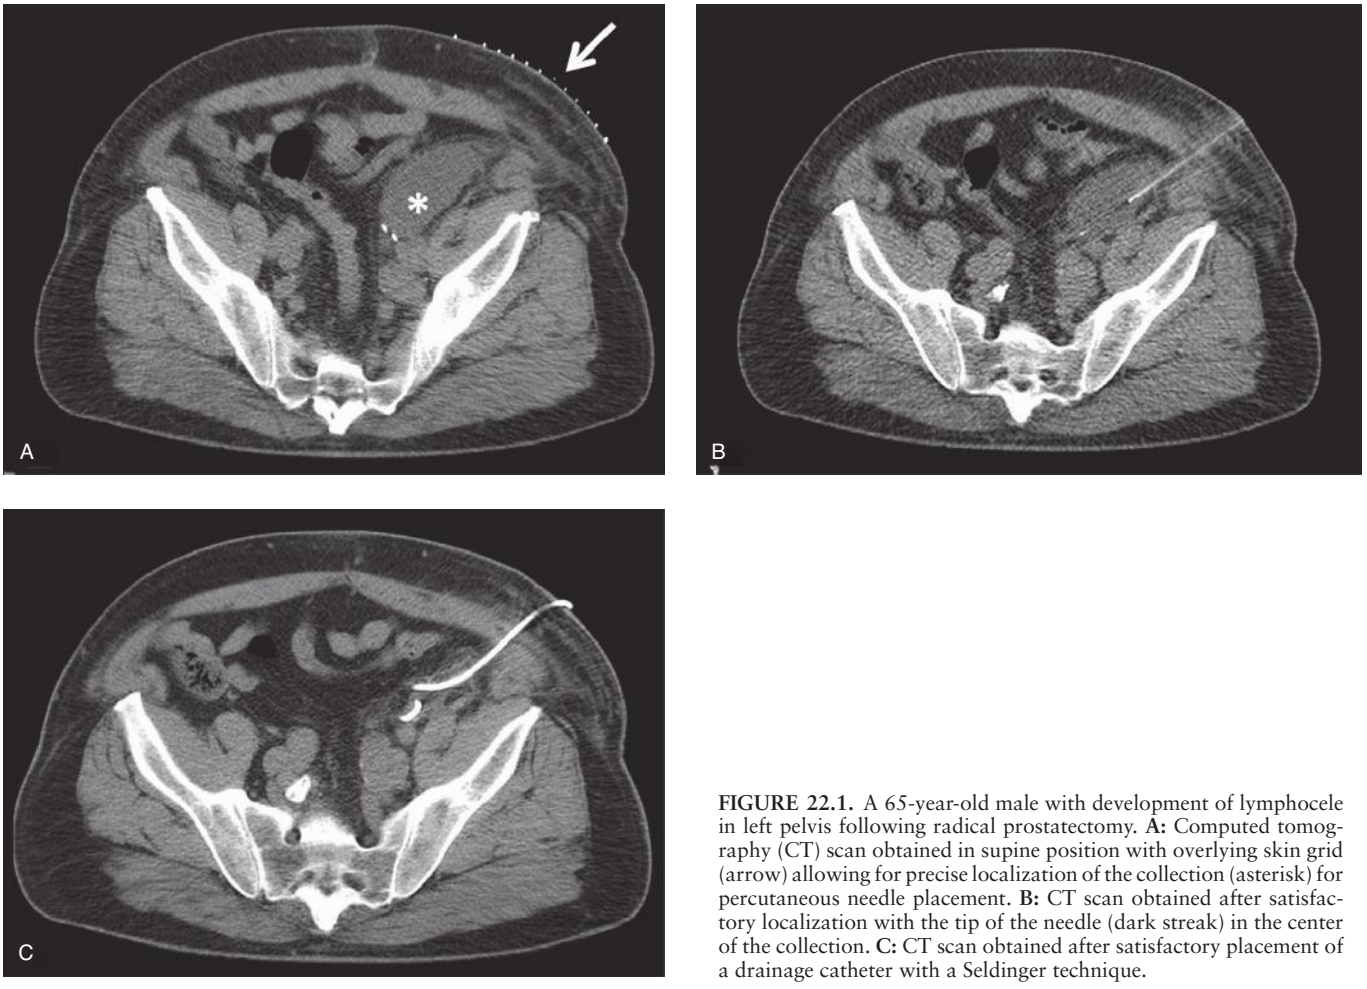

FIGURE 22.1. A 65-year-old male with development of lymphocele in left pelvis following radical prostatectomy. **A:** Computed tomography (CT) scan obtained in supine position with overlying skin grid (arrow) allowing for precise localization of the collection (asterisk) for percutaneous needle placement. **B:** CT scan obtained after satisfactory localization with the tip of the needle (dark streak) in the center of the collection. **C:** CT scan obtained after satisfactory placement of a drainage catheter with a Seldinger technique.

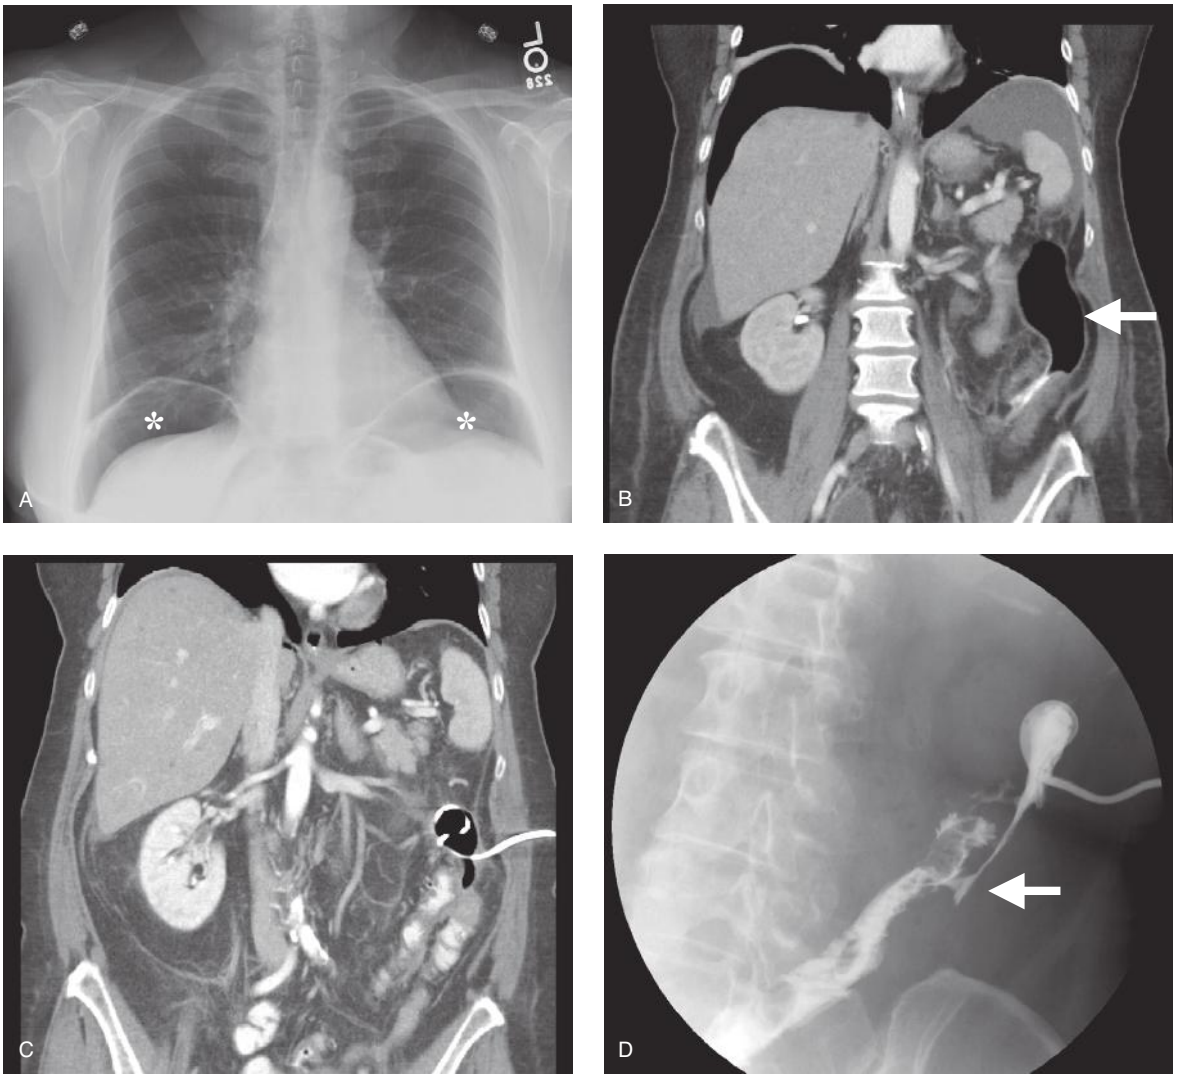

FIGURE 22.2. A 63-year-old female status post–recent sigmoid resection presenting with abdominal pain. **A:** Chest x-ray showing large amount of free intraperitoneal air (asterisks) concerning for bowel perforation. **B:** Computed tomography (CT) scan obtained with oral contrast shows large gas and fluid containing collection (arrow) from leak at the surgical anastomosis. **C:** CT scan performed after satisfactory position of drainage catheter into the collection. **D:** Due to high drainage output (>50 cc per day), abscessogram was performed demonstrating a fistulous communication (arrow) with the descending colon.

between interventional and critical care staff is critical to prevent catheter malfunction. Daily rounds should be conducted to ensure the catheter is draining and not kinked or dislodged. During rounds, the skin insertion site, catheter tubing, amount of drainage, and body temperature should be evaluated. It is useful to mark the level of the skin insertion on the catheter during initial placement to allow for easy assessment of catheter dislodgement. Most catheters are connected to a bag for external drainage, allowing for evaluation of fluid volume and consistency. Gentle irrigation of the abscess cavity with 10 to 20 mL of sterile saline is recommended three to four times daily to ensure patency. Vigorous irrigation is not recommended as expansion of the abscess cavity may lead to transient bacteremia [28]. Dressing changes should also be performed daily. In anticipation of the patient's discharge from the hospital, family members are instructed in catheter care or a visiting nursing service is arranged. The patient and his or her family should be instructed in catheter care and to how to recognize any potential or existing malfunction. The patient is advised to return to the department in the event of abdominal pain, leakage from the catheter entry site, fever, or chills. When long-term drainage is anticipated, catheters should be exchanged approximately every 3 months to avoid blockage from encrustation or debris.

Patient Response

Following complete evacuation of purulent material from an infected cavity, improved clinical response should be seen in a matter of hours to several days [8,12]. Parameters of improving clinical status include defervescence, reduction in pain, and resolution of leukocytosis. If there is no improvement after 2 to 3 days, suspicion should be raised for an undrained collection, catheter malfunction, or fistula formation. In such

cases, follow-up imaging using CT, ultrasound, or fluoroscopy with contrast injection into the collection is recommended. Abscesses containing loculations are more difficult to drain than are unilocular collections. Several techniques have been employed to treat multiloculated collections including placement of additional drains or use of guidewires or fibrinolytic agents (such as urokinase) to break up septations [29]. Semisolid collections such as necrotic tumors, infected hematomas, or pancreatic abscesses are also more resistant to drainage and may require surgical debridement.

Removal of the Catheter

Early removal of the drainage catheter is one of the more common causes of postprocedural morbidity and mortality. Therefore, it is essential for the interventional radiologist to be familiar with guidelines for catheter removal. The most important factor to consider prior to drain removal is the clinical status of the patient. The patient's condition should improve significantly within 24 to 48 hours after catheter removal [3,6,10]. The percutaneous drainage catheter should remain in place until the cavity is undetectable on imaging and the volume of drainage is less than 10 cc on two consecutive days. Daily rounds by the interventional staff should carefully assess the patient for resolution of fever, absence of elevated white blood cell count, or other signs of clinical improvement. If the patient fails to respond to treatment, the catheter should be examined to rule out displacement or kinking. Continuous high drainage (>50 mL per day) should alert the radiologist for a possible fistulous tract to bowel, pancreas, or biliary tree, and the appropriate imaging modality should be used for further evaluation [8,30]. Catheter removal is achieved by cutting or untying the string that fixates the locking device in place.

Follow-up imaging on simple collections is typically not required; however, enteric or complex collections should be evaluated with CT or an abscessogram (Fig. 22.2) prior to discharge to document resolution or decreased size of the abscess cavity.

Clinical Outcome and Complications

Depending on the location and makeup of an infected or sterile collection, image-guided percutaneous drainage is successful in 70% to 90% of cases. Overall complications are reported to be less than 15% [1–4], but most are minor. Major complications (5% to 7% complication rate) include infection, bleeding, septicemia, injury to adjacent structures such as bowel and death. Inadvertent contamination of a previously sterile collection is also a possibility with prolonged catheter drainage [11]. Enteric transgression can usually be treated conservatively with delayed catheter removal to allow for a mature fistulous tract to develop. Minor complications (3% to 5% complication rate) include pain, infection of the skin insertion site, transient bacteremia, and malfunction of the catheter secondary to kinking, dislodgement, or clogging with debris, such as blood clots. Pain can be minimized by judicious use of analgesics. Daily catheter evaluation by the interventional staff can serve to reduce catheter malfunction. Mortality from the procedure, usually related to sepsis or organ failure, compares favorably with the surgical literature rates of 10% to 20% [31]. The recurrence rate following abscess drainage has been estimated to be between 5% and 10%. Recurrence may be due to early catheter removal, failure to completely drain a loculated collection or fistulous communication with the bowel, pancreatic duct, or biliary system. Fistulas should be suspected if there is high output from the catheter (>50 mL per day) or the drainage fluid contains feculent material. When the patient fails to respond to treatment or sepsis is not resolving, repeat imaging with CT or ultrasound should be performed to determine the cause. Repeat drainage of these cavities has been shown to be successful in 50% of patients with the need for surgical drainage reduced by half [3,32].

In conclusion, image-guided percutaneous drainage has been established as the first-line treatment for sterile or infected fluid collections in the abdomen and pelvis. Awareness of the advantages and limitations of the procedure together with an integrated management approach between interventional and critical care staff will serve to benefit the patient and improve clinical outcomes.

CHAPTER 23 ■ CARDIOPULMONARY RESUSCITATION

BRUCE GREENBERG AND JOHN A. PARASKOS

HISTORY

Since the introduction of cardiopulmonary resuscitation (CPR), we have been forced to rethink our definitions of life and death. Although sporadic accounts of attempted resuscitations are recorded from antiquity, until recently no rational quarrel could be found with the sixth-century BC poetic fragment of Ibycus, "You cannot find a medicine for life once a man is dead" [1]. Until 1960, successful resuscitation was largely limited to artificial ventilation for persons who had undergone respiratory arrest due to causes such as near-drowning, smoke inhalation, and aspiration. Such attempts were likely to succeed if performed before cardiac arrest had resulted from hypoxia and acidosis. Emergency thoracotomy with "open heart massage" was rarely resorted to and was occasionally successful if definitive therapy was readily available [2]. Electric reversal of ventricular fibrillation (VF) by externally applied electrodes was described in 1956 by Zoll et al. [3]. This ability to reverse a fatal arrhythmia without opening the chest challenged the medical community to develop a method of sustaining adequate ventilation and circulation long enough to bring the electric defibrillator to the patient's aid. By 1958, adequate rescue ventilation became possible with the development of the mouth-to-mouth technique described by Safar et al. [4] and Elam et al. [5]. In 1960, Kouwenhoven et al. [6] described "closed chest cardiac massage," thus introducing the modern era of CPR. The simplicity of this technique—"all that is needed are two hands"—has led to its widespread dissemination. The interaction of this technique of sternal compression with mouth-to-mouth ventilation was developed as basic CPR. The first national conference on CPR was sponsored by the National Academy of Sciences in 1966 [7]. Instruction in CPR for both professionals and the public soon followed through community programs in basic life support (BLS) and advanced cardiac life support (ACLS). Standards for both BLS and ACLS were set in 1973 [8] and have been updated periodically.

For individuals with adequately preserved cardiopulmonary and neurologic systems, the cessation of breathing and cardiac contraction may be reversed if CPR and definitive care are quickly available. The short period during which the loss of vital signs may be reversed is often referred to as *clinical death*. If ventilation and circulation are not restored before irreversible damage to vital structures occurs, then irreversible death occurs. This is referred to as *biologic death*. In difficult circumstances, the best single criterion (medical and legal) for the ultimate death of the functioning integrated human individual (i.e., the person) is brain death [9,10]. By this criterion, we can make decisions as to the appropriateness of continuing "life-sustaining" techniques.

EFFICACY

The value of standardized CPR continues to undergo considerable scrutiny. Unfortunately, it appears that its efficacy is limited (Table 23.1). CPR does not seem to go beyond short-term sustenance of viability until definitive therapy can be administered. This was the stated goal of Kouwenhoven et al. [6]. The benefit of rapid initiation of CPR has been demonstrated in numerous studies [11–14]. Data from prehospital care systems in Seattle showed that 43% of patients found in VF were discharged from the hospital if CPR (i.e., BLS) was applied within 4 minutes and defibrillation (i.e., ACLS) within 8 minutes. If the onset of CPR is delayed, or if the time to defibrillation is longer than 10 minutes, the probability is greater that the patient will be in asystole or in *fine* VF and will convert to asystole. Survival decreases as each minute passes without return of spontaneous circulation (ROSC).

Even though patients experiencing cardiac arrest in the hospital can be expected to receive CPR and definitive therapy well within the 4- and 8-minute time frames, the outcomes of in-hospital cardiac arrests are poor (Table 23.1).

Recognizing the importance of early defibrillation, it is imperative that all first-response systems provide defibrillation, by either using emergency medical technicians capable of performing defibrillation or equipping and training emergency personnel with automatic or semiautomatic defibrillators [26]. The development of inexpensive, small, lightweight, easy-to-use, voice-prompted defibrillators allows early access to defibrillation, before the arrival of emergency medical services (EMS). Where these have been made available, and where first

EXPERIMENTAL AND ALTERNATE TECHNIQUES OF CARDIOPULMONARY RESUSCITATION (CPR)

Researcher [Reference]	Technique	Notes
Taylor et al. [15]	Longer compression	Proposed use of longer duration to 40%–50% of the duration compression–relaxation cycle
Chandra et al. [14,16]	Simultaneous chest compression and lung inflation	High airway pressures of 60–110 mm Hg are used to augment carotid flow, requiring intubation and a mechanical ventilator. Its use has not met with universal success
Harris et al. [17] Redding [18] Koehler et al. [19] Chandra et al. [20]	Abdominal binding	Abdominal binding increases intrathoracic pressure by redistributing blood into the thorax during CPR. Studies have demonstrated adverse effects on coronary perfusion, cerebral oxygenation, and canine resuscitation
Ralston et al. [21]	Interposed abdominal	Abdominal compression is released when the sternum is compressed. Higher oxygen delivery and cerebral and myocardial blood flows are reported. One study suggests an improved survival and neurologic outcome
Barranco et al. [22]	Simultaneous chest	Simultaneous chest and abdominal compression provided higher intrathoracic pressures in compression in humans
Maier et al. [23]	High-impulse CPR	At compression rates of 150/min (with moderate force and brief duration), cardiac output in dogs increased as the coronary flow remained as high as 75% of prearrest values. High impulse and high compression rates can result in rescuer fatigue and increased injury
Cohen et al. [24]	Active compression	Forceful rebound using a plunger-like device resulted in improved hemodynamics. Clinical results are equivocal
Halperin et al. [25]	Vest inflation	Circumferential chest pressure with an inflatable vest showed improved hemodynamics and survival in dogs

responders have been trained in their use, survival rates have been dramatically improved [27].

Although the current approach is modestly successful for VF, CPR techniques have most likely not yet been optimized, and further improvement is greatly needed. Cardiac output has been measured at no better than 25% of normal during conventional CPR in humans [28]. In animal models, myocardial perfusion and coronary flow have been measured at 1% to 5% of normal [29]. Cerebral blood flow has been estimated to be 3% to 15% of normal when CPR is begun immediately [30], but it decreases progressively as CPR continues [31] and intracranial pressures rise. Despite these pessimistic findings, complete neurologic recovery has been reported in humans even after prolonged administration of CPR [32].

Researchers continue to evaluate new approaches and techniques, and further refinements in the delivery of CPR can be expected. Although research in improved CPR techniques and devices should be encouraged, research in this field is difficult. Animal models vary, and animal data may not be valid in humans. Before new CPR techniques can be adopted, they must have been demonstrated, ideally in humans, to improve either survival or neurologic outcome.

MECHANISMS OF BLOOD FLOW DURING RESUSCITATION

Any significant improvement in CPR technique would seem to require an understanding of the mechanism by which blood flows during CPR. However, there is no unanimity among researchers in this area. It is of interest that significant advances seem to have been made by research groups holding very different ideas concerning the basic mechanism of blood flow during CPR. Indeed, it is possible that several mechanisms are operative, which of these is most important may vary according to a patient's size and chest configuration.

Cardiac Compression Theory

In 1960, when Kouwenhoven et al. [6] reported on the efficacy of closed chest cardiac massage, most researchers accepted the theory that blood is propelled by compressing the heart trapped between the sternum and the vertebral columns. According to this theory, during sternal compression, the intraventricular pressures would be expected to rise higher than the pressures elsewhere in the chest. With each sternal compression, the semilunar valves would be expected to open and the atrioventricular (AV) valves to close. With sternal release, the pressure in the ventricles would be expected to fall and the AV valves to open, allowing the heart to fill from the lungs and systemic veins. Indeed, a transesophageal echocardiographic study in humans also supports this theory [33]. If the cardiac compression mechanism were operative, ventilation would best be interposed between sternal compressions so as not to interfere with cardiac compression. Also, the faster the sternal compression, the higher the volume of blood flow, assuming that the ventricles could fill adequately. The theory of cardiac compression was first brought into question in 1962, when Weale and Rothwell-Jackson [34] demonstrated that during chest compression, there is a rise in venous pressure almost equal to that of the arterial pressure. The following year, Wilder et al. [35] showed that ventilating synchronously with chest compression produced higher arterial pressures than alternating ventilation and compression. It was more than a decade, however, before more data confirmed these initial findings.

Thoracic Pump Theory

In 1976, Criley et al. [36] reported that during cardiac arrest, repeated forceful coughing is capable of generating systolic pressures comparable with those of normal cardiac activity. This finding strongly suggested that high intrathoracic pressures are capable of sustaining blood flow, independent of sternal compression. Subsequently, Niemann et al. [37,39] proposed that the propulsion of blood during sternal compression is due to the same mechanism of increased intrathoracic pressure. Studies using pressure measurements [13] and angiography [39] support this hypothesis, as do most echocardiographic studies [40]. According to this theory, the heart serves as a conduit only during CPR. Forward flow is generated by a pressure gradient between intrathoracic and extrathoracic vascular structures. Flow to the arterial side is favored by functional venous valves and greater compressibility of veins, compared to arteries, at their exit points from the thorax. The thoracic pump theory provides the rationale for experimental attempts at augmenting forward flow by increasing intrathoracic pressure.

EXPERIMENTAL AND ALTERNATIVE TECHNIQUES OF CPR

Several experimental and alternate techniques of CPR are presented in Table 23.2 [14,19–25].

Interposed Abdominal Compression CPR

Interposed abdominal compression CPR was developed by Ralston et al. [21] and Babbs et al. [41]. This technique includes manual compression of the abdomen by an extra rescuer during the relaxation phase of chest compression (Fig. 23.1). The mid-abdomen is compressed at a point halfway between the xiphoid process and the umbilicus with a force of approximately 100 mm Hg of external pressure. This pressure is estimated to be equivalent to that required to palpate the aortic pulse in a subject with a normal pulse. Two randomized clinical trials

TABLE 23.2

SUMMARY OF BASIC LIFE SUPPORT ABCD MANEUVERS FOR INFANTS, CHILDREN, AND ADULTS (NEWBORN INFORMATION NOT INCLUDED)

	Adult	Child	Infant
Maneuver	Lay rescuer: 8 y HCP: adolescent and older	Lay rescuers: 1–8 y HCP: 1 y–adolescent	Younger than 1 y of age
Airway	Head tilt–chin lift (HCP: suspected trauma, use jaw thrust)		
Breathing: initial	2 breaths at 1 s/breath	2 effective breaths at 1 s/breath	
HCP: rescue breathing without chest compressions	10–12 breaths/min (approximate)	12–20 breaths/min (approximate)	
HCP: rescue breaths for CPR with advanced airway		8–10 breaths/min (approximate)	
Foreign body airway obstruction	Conscious: abdominal thrusts		Infant conscious: back slaps and chest thrusts
	Unconscious: CPR		Infant unconscious: CPR
Circulation HCP: pulse check (≤10 s)	Carotid		Brachial or femoral
Compression landmarks	Lower half of the sternum, between nipples		Just below the nipple line (lower half of the sternum)
Compression method: Push hard and fast	Heel of one hand, other hand on top	Heel of one hand or as for adults	Two or three fingers
Allow complete recoil			HCP (two rescuers): two thumb–encircling hands
Compression depth	1½–2 in	Approximately one-third to one-half the depth of the chest	
Compression rate	Approximately 100/min		
Compression-to-ventilation ratio	30:2 (one or two rescuers)	30:2 (single rescuer) HCP: 15:2 (two rescuers)	
Defibrillation: AED	Use adult pads Do not use child pads	Use AED after 5 cycles of CPR (out of hospital) Use pediatric system for children 1–8 y if available HCP: for sudden collapse (out of hospital) or in-hospital arrest use AED as soon as available	No recommendation for infants <1 y of age

Note: Maneuvers used by only health care providers are indicated by "HCP." AED, automatic external defibrillator.
Adapted from ECC Committee, Subcommittees and Task Forces of the American Heart Association: 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 112[24, Suppl]:IV1–203, 2005.

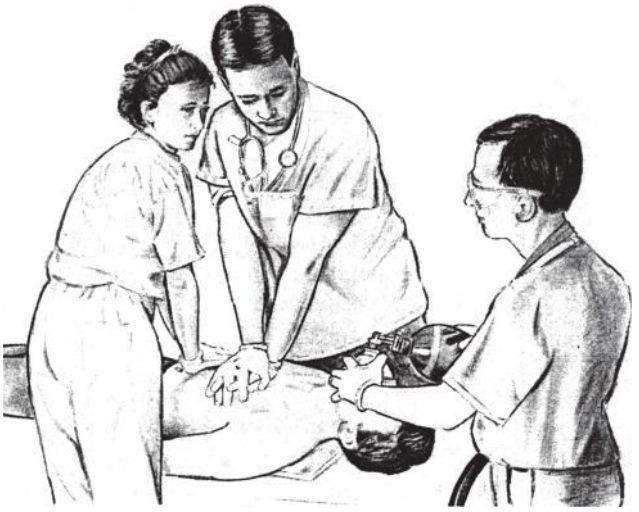

FIGURE 23.1. Interposed abdominal compression cardiopulmonary resuscitation. It is more convenient when the interposed chest and abdominal compressions are performed from opposite sides of the patient. [From Guidelines 2000 for cardiopulmonary resuscitation and emergency cardiovascular care. *Circulation* 102[Suppl 8]:I-1, 2000, with permission. Copyright 2000, American Heart Association.]

have demonstrated a statistically significant improvement in outcome measures for in-hospital cardiac arrest [42,43], but no improvement has been shown for out-of-hospital arrest [44]. On the basis of these findings, interposed abdominal compression CPR is recommended as an option for in-hospital cardiac arrest when sufficient personnel trained in the technique are available. However, it should be emphasized that the safety and efficacy of interposed abdominal compression CPR in patients with recent abdominal surgery, pregnancy, or aortic aneurysm has not been studied.

Open-Chest CPR

One of the first forms of successful CPR was open-chest CPR. It was shown to be effective when definitive care was rapidly available and is associated with survival rates, largely in operating room arrests, ranging from 16% to 37% [2]. Mechanistically, open-chest CPR clearly involves cardiac compression without use of a thoracic gradient. Weale and Rothwell-Jackson [34] demonstrated lower venous pressures and higher arterial pressures than with closed-chest compression. There is considerable evidence that open-chest CPR may be more efficacious than closed-chest CPR in terms of cardiac output and cerebral and myocardial preservation. One study has suggested increased ROSC with open-chest CPR [45]. Clearly, some patients with penetrating chest trauma are not likely to respond to chest compression and are candidates for open-chest CPR. Several studies suggest a benefit from thoracotomy in these patients [46]. If open-chest CPR is to be used, it should be used early in the sequence. Patients with blunt chest and abdominal trauma may also be candidates for open-chest CPR. Obviously, this technique should not be attempted unless adequate facilities and trained personnel are available.

Cardiopulmonary Bypass for Unresponsive Arrest

Cardiopulmonary bypass is certainly not a form of routine life support; however, it has been considered as a possible adjunct to artificial circulation. It is an indispensable adjunct to cardiac surgery and is being used more frequently for invasive procedures as a standby in case of sudden cardiac collapse. In dog models, bypass has been shown capable of providing near-normal end-organ blood flow with improved ability to resuscitate and neurologic status [47]. Emergency bypass can be instituted with femoral artery and vein access, without thoracotomy [48]. Lack of study in humans, timely access, and cost are issues to consider before bypass can be recommended for wider use in cardiac arrest.

INFECTIOUS DISEASES AND CPR

The fear provoked by the spread of human immunodeficiency virus (HIV) may lead to excessive caution when dealing with strangers. The effect of this fear on CPR is serious and must be addressed at some length [49].

The public's fear can be counteracted only by continued education and by stressing the facts. Health care workers have more opportunities for exposure to patients with HIV and their concerns must be adequately addressed [50].

Saliva has not been implicated in the transmission of HIV even after bites, percutaneous inoculation, or contamination of open wounds with saliva from HIV-infected patients [51,52]. Hepatitis B–positive saliva has also not been demonstrated to be infectious when applied to oral mucus membranes or through contamination of shared musical instruments or CPR training manikins used by hepatitis B carriers. However, it is not impossible that the mouth-to-mouth technique may result in the exchange of blood between the patient and the rescuer if there are open lesions or trauma to the buccal mucosa or lips. Diseases such as tuberculosis, herpes, and respiratory viral infections are potentially spread during mouth-to-mouth ventilation. Infections thought to have been transmitted by CPR include *Helicobacter pylori*, *Mycobacterium tuberculosis*, meningococcus, herpes simplex, *Shigella*, *Streptococcus*, *Salmonella*, and *Neisseria gonorrhoeae*. There have been no cases reported of transmission of HIV, hepatitis B virus, hepatitis C virus, or cytomegalovirus. The impact of these facts is different for lay people and health care professionals, and different for those carrying infection and for those at risk of infection [53].

Implications for Rescuers With Known or Potential Infection

Potential rescuers who know or highly suspect that they are infected with a serious pathogenic organism should not perform mouth-to-mouth ventilation if another rescuer is available who is less likely to be infectious or if the circumstances allow for any other immediate and effective method of ventilation, such as using mechanical ventilation devices.

Implications for Health Care Professionals

Although the probability of a rescuer becoming infected with HIV during CPR seems minimal, all those called on to provide CPR in the course of their employment should have ready access to mechanical ventilation devices. Bag–valve–mask devices should be available as initial ventilation equipment, and early endotracheal intubation should be encouraged when possible. Masks with one-way valves and plastic mouth and nose covers with filtered openings are available and provide some protection from transfer of oral fluids and aerosols. S-shaped mouthpieces, masks without one-way valves, and handkerchiefs

provide little, if any, barrier protection and should not be considered for routine use. With these guidelines in mind, health care professionals are reminded that they have a special moral and ethical, and in some instances legal, obligation to provide CPR, especially in the setting of their occupational duties.

Implications for Manikin Training in Cardiopulmonary Resuscitation

The guidelines of the American Heart Association (AHA) specify that students or instructors should not actively participate in CPR training sessions with manikins if they have dermatologic lesions on their hands or in oral or circumoral areas, if they are known to be infected with hepatitis or HIV, or if they have reasons to believe that they are in the active stage of any infectious process. In routine ventilation training, instructors should not allow participants to exchange saliva by performing mouth-to-mouth ventilation in sequence without barrier mouthpieces. Special plastic mouthpieces and specialized manikins protect against such interchange of mucus.

Training in CPR for People With Chronic Infections

If a potentially infectious person is to be trained in CPR, commonsense precautions should be taken to protect other participants from any risk of infection. The chronically infected individual should be given a separate manikin for practice that is adequately disinfected before anyone else uses it. The chronically infected trainee should be made aware of the preceding guidelines for potential rescuers with infections. In addition, the potential risk of infection for the immunocompromised rescuer should not be ignored.

An agency that requires successful completion of a CPR course as a prerequisite for employment must decide whether to waive its requirement for an employee who is unable to complete a CPR course for whatever reason. That agency must also determine whether a chronically infected person should continue to work in a situation in which CPR administration is a duty of employment.

STANDARD PROCEDURES AND TEAM EFFORT

The distinctive function of the intensive care unit (ICU) is to serve as a locus of concentrated expertise in medical and nursing care, life-sustaining technologies, and treatment of complex multiorgan system derangement. Historically, it was the development of effective treatment for otherwise rapidly fatal arrhythmias during acute myocardial infarction that impelled the medical community to establish ICUs [54]. Rapid response by medical personnel has been facilitated by constant professional attendance and the development of widely accepted guidelines for resuscitation. Each member of the professional team is expected to respond in accordance with these guidelines.

Avoiding the need for CPR and ACLS by early intervention is a goal of rapid response teams (RRT). RRT, also called medical evaluation teams (MET), have been consistently shown to decrease hospital code rates [55]. Some studies have found a decrease in hospital mortality with the use of RRT, though this has not been found in all studies. How RRT can best be organized and implemented, as well as which hospitals benefit most, is yet to be determined [56].

The skills necessary to perform adequately during a cardiac or respiratory arrest and to interface smoothly with ACLS techniques cannot be learned from reading texts and manuals. CPR courses taught according to AHA guidelines allow hands-on experience that approximates the real situation and tests the psychomotor skills needed in an emergency. All those who engage in patient care should be trained in BLS. Those whose duties require a higher level of performance should be trained in ACLS as well. As these skills deteriorate with disuse, they need to be updated. It is worth noting that there is no "certification" in BLS or ACLS. Issuance of a "card" is neither a license to perform these techniques nor a guarantee of skill, but simply an acknowledgment that an individual attended a specific course and passed the required tests. If employers or government agencies require such a card of their health workers, it is by their own mandate.

The ensuing discussion of BLS and ACLS techniques follows the recommendations and guidelines established by the AHA and presented in a supplement to volume 112 of *Circulation* [57].

BASIC LIFE SUPPORT FOR ADULTS WITH AN UNOBSTRUCTED AIRWAY

BLS is meant to support the circulation and respiration of those who have experienced cardiac or respiratory arrest. After recognizing and ascertaining its need, definitive help is summoned without delay and CPR is initiated.

Respiratory Arrest

Respiratory arrest may result from airway obstruction, near-drowning, stroke, smoke inhalation, drug overdose, electrocution, or physical trauma. In the ICU, pulmonary congestion, respiratory distress syndrome, and mucus plugs are frequent causes of primary respiratory arrests. The heart usually continues to circulate blood for several minutes, and the residual oxygen in the lungs and blood may keep the brain viable. Early intervention by opening the airway and providing ventilation may prevent cardiac arrest and may be all that is required to restore spontaneous respiration. In the intubated patient, careful suctioning of the airway and attention to the ventilator settings are required.

Cardiac Arrest

Cardiac arrest results in rapid depletion of oxygen in vital organs. After 6 minutes, brain damage is expected to occur, except in cases of hypothermia (e.g., near-drowning in cold water). Therefore, early bystander CPR (within 4 minutes) and rapid ACLS with attempted defibrillation (within 8 minutes) are essential in improving survival and neurologic recovery rates [58].

The sequence of steps in CPR may be summarized as the ABCs of CPR: *a*irway, *b*reathing, and *c*irculation. This mnemonic is useful in teaching the public, but it should be remembered that each step is preceded by *assessment* of the need for intervention: before opening the airway, the rescuer determines unresponsiveness; before breathing, the rescuer determines breathlessness; before circulation, the rescuer determines pulselessness (Table 23.2).

Assessment and Determination of Unresponsiveness and Alerting of Emergency Medical Services

A person who has undergone cardiac arrest may be found in an apparently unconscious state (i.e., an unwitnessed arrest) or may be observed to suddenly lapse into apparent unconsciousness (i.e., a witnessed arrest). In either case, the rescuer must react promptly to assess the person's responsiveness by attempting to wake and communicate with the person by tapping or gently shaking and shouting. The rescuer should summon the nearby staff for help. If no other person is immediately available, the rescuer should call the hospital emergency line for the resuscitation team to respond (e.g., "code blue").

In the ICU, nearly all arrests should be witnessed. Early recognition of cardiac and respiratory arrests is facilitated by electronic and video monitoring. Unfortunately, it is quite possible for a patient to become lost behind this profusion of electronic signals, the dependability of which varies widely. For several precious minutes, a heart with pulseless electric activity (PEA) continues to provide a comforting electronic signal, while the brain suffers hypoxic damage. A high frequency of false alarms due to loose electrodes or other artifacts may dangerously raise the threshold of awareness and prolong the response time of the ICU team. The overall efficacy of the monitoring devices, therefore, depends highly on meticulous skin preparation and care of electrodes, transducers, pressure cables, and the like.

Sudden apparent loss of consciousness, occasionally with seizures, may be the first signal of arrest and requires prompt reaction. After determining unresponsiveness, the pulse is assessed. If the carotid pulse cannot be palpated in 5 to 10 seconds and a defibrillator is not immediately available, a precordial thump can be considered and is performed by striking the lower third of the sternum with the fist, from a height of approximately 8 in (or the span of the stretched fingers of one hand). However, there is a lack of evidence supporting its use. The thump should not be performed by BLS providers and the AHA has not recommended for or against its use [57]. If the pulse does not return and a defibrillator is not immediately available, the rescuer should proceed with establishing the airway (see the next section).

Opening the Airway and Determining Breathlessness

After establishing unresponsiveness and positioning the individual on his or her back (Fig. 23.2), the next step is to open the airway and check for spontaneous breathing (see Chapter 1). In a monitored arrest with VF or tachycardia, this step is taken after initial attempts to defibrillate. Meticulous attention to establishing an airway and supplying adequate ventilation is essential to any further resuscitative effort. The team leader must carefully monitor the adequacy of ventilation, as well as direct the resuscitative effort. The leadership role is best accomplished if the leader does not directly perform procedures.

FIGURE 23.2. The patient must be supine on a firm, flat surface. [From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. *JAMA* 268:2171, 1992, with permission. Copyright 1992, American Medical Association.]

The head tilt–chin lift maneuver (Figs. 23.3 and 23.4) is usually successful in opening the airway. The head is tilted backward by a hand placed on the forehead. The fingers of the other hand are positioned under the mandible and the chin is lifted upward. The teeth are almost approximated, but the mouth is not allowed to close. Because considerable cervical hyperextension occurs, this method should be avoided in patients with cervical injuries or suspected cervical injuries. The jaw-thrust maneuver (Fig. 23.5) provides the safest initial approach to opening the airway of a patient with a cervical spine injury; it usually allows excellent airway opening with a minimum of cervical extension. The angles of the mandible are grasped using both hands and lifting upward, thus tilting the head gently backward.

After opening the airway, the rescuer should take 3 to 5 seconds to determine if there is spontaneous air exchange. This is accomplished by placing an ear over the patient's mouth and nose while watching to see if the patient's chest and abdomen rise and fall ("look, listen, and feel"; see Fig. 23.4). If

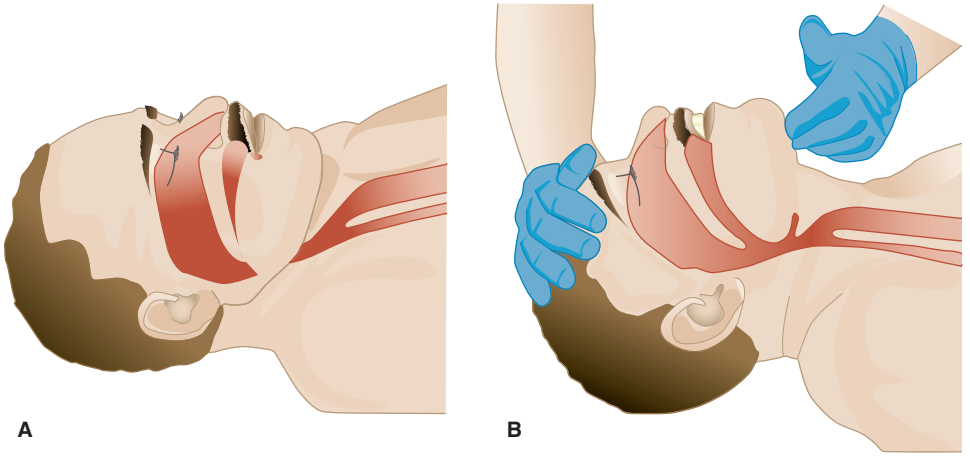

FIGURE 23.3. Opening the airway. **A:** Airway obstruction caused by tongue and epiglottis. **B:** Opening the airway with the head tilt–chin lift maneuver. [From *BLS for Healthcare Providers*, American Heart Association, 2006, with permission. Copyright 2006, American Heart Association.]

the rescuer fails to see movement, hear respiration, or feel the rush of air against the ear and cheek, rescue breathing should be initiated.

Rescue Breathing

If spontaneous breathing is absent, rescue breathing with an airway–mask–bag unit must be initiated (see Chapter 1). If equipment is immediately available and the rescuer is trained, intubation and ventilatory adjuncts should be used initially. Each breath should be delivered during 1 second, allowing the patient's lungs to deflate between breaths. Thereafter, the rate of 10 to 12 breaths per minute is maintained for as long as necessary, with tidal volumes of approximately 700 mL. Delivering the breath during 1 second helps to prevent gastric insufflation compared with faster delivery. Melker et al. [59] demonstrated airway pressures well in excess of those required to open the lower esophageal sphincter when quick breaths are used to ventilate patients. If the patient wears dentures, they are usually best left in place to assist in forming an adequate seal.

If air cannot be passed into the patient's lungs, another attempt at opening the airway should be made. The jaw-thrust maneuver may be necessary. If subsequent attempts at ventilation are still unsuccessful, the patient should be considered to have an obstructed airway and attempts should be made to dislodge a potential foreign body obstruction.

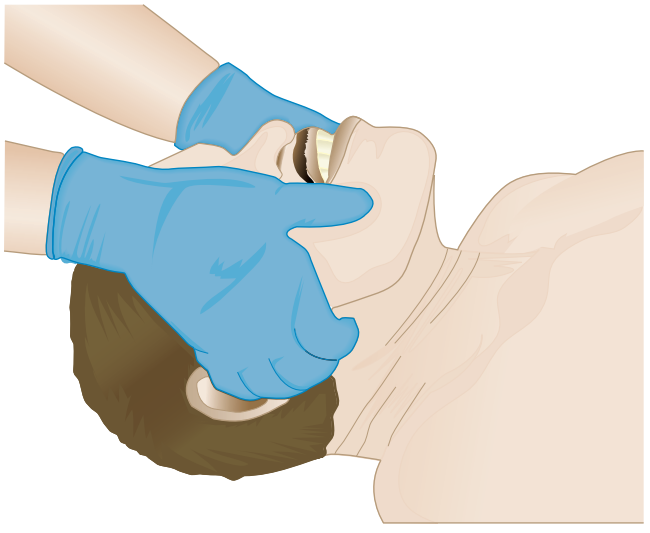

FIGURE 23.5. Jaw-thrust maneuver: opening the airway with minimal extension of the neck. [From *BLS for Healthcare Providers*, American Heart Association, 2006, with permission. Copyright 2006, American Heart Association.]

Determining Pulselessness

In the adult, the absence of a central pulse is best determined by palpating the carotid artery (Fig. 23.6), although rarely the carotid pulse may be absent because of localized obstruction. If a pulse is not felt after 10 seconds of careful searching, chest compression is initiated, unless electric countershock for ventricular arrhythmia or artificial pacing for asystole is immediately available. Although lay rescuers are no longer expected to perform a pulse check because it has been shown that checking the carotid pulse by a lay person is an inaccurate method of confirming the presence or absence of circulation, it is the position of the AHA that *health care providers* should continue to be taught and to perform a pulse check. Therefore, rescuers should start CPR if the victim is unconscious (unresponsive), not moving and not breathing [60].

Chest Compression

Artificial circulation depends on adequate chest compression through sternal depression. Recent recommendations of CPR

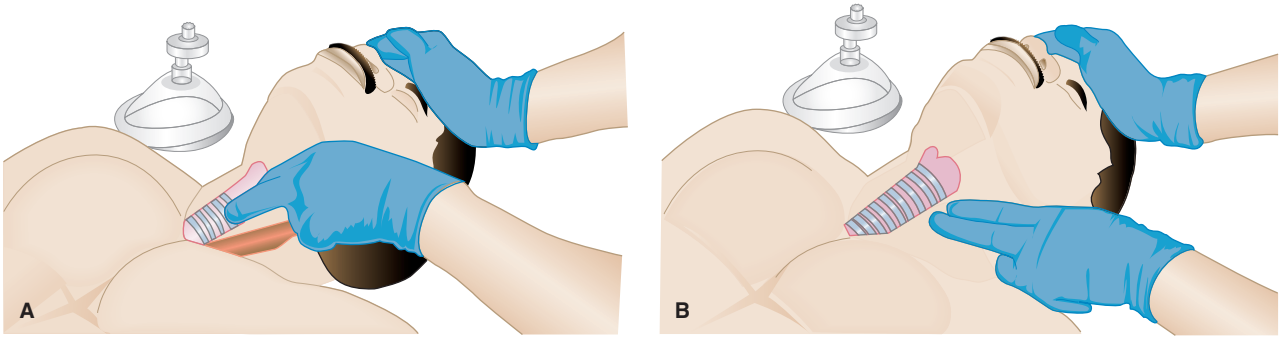

FIGURE 23.6. Determining pulselessness. **A:** Feeling the laryngeal cartilage. **B:** Fingers slide into groove between trachea and sternocleidomastoid muscle, searching for carotid pulse. are "push hard at a rate of 100 compressions per minute, allow full chest recoil, and minimize interruptions in chest compressions" [60]. The safest manner of depressing the sternum is with the heel of the rescuer's hand at the nipple line, with the fingers kept off the rib cage (Fig. 23.7). It is usually most effective to cover the heel of one hand with the heel of the other, the heels being parallel to the long axis of the sternum. If the rescuer's hands are placed either too high or too low on the sternum, or if the fingers are allowed to lie flat against the rib cage, broken ribs and organ laceration can result. Although it is important to allow the chest to recoil to its normal position after each compression, it is not advisable to lift the hands from the chest or change their position.

The rescuer's elbows should be kept locked and the arms straight, with the shoulders directly over the patient's sternum (Fig. 23.7). This position allows the rescuer's upper body to provide a perpendicularly directed force for sternal depression. The sternum is depressed 1.5 to 2.0 in (4 to 5 cm) at a rate of approximately 100 compressions per minute. In large patients, a slightly greater depth of sternal compression may be needed to generate a palpable carotid or femoral pulse. At the end of each compression, pressure is released and the sternum is allowed to return to its normal position. Equal time should be allotted to compression and relaxation with smooth movements, avoiding jerking or bouncing the sternum. Manual and automatic chest compressors are available for fatigue-free sternal compression and are used by some EMS crews and emergency room and ICU personnel. Whether using hinged manually operated devices or compressed air-powered plungers, the rescuer must be constantly vigilant about proper placement and adequacy of sternal compression. An experimental device using a plunger-like suction device may improve flow by facilitating sternal rebound and thoracic vascular filling; this has been referred to as *active compression–decompression CPR*.

Ventilation and sternal compression should not be interrupted except under special circumstances. Warranted interruptions include execution of ACLS procedures (e.g., endotracheal intubation and placement of central venous lines) or an absolute need to move the patient. Even in these limited circumstances, interruption of CPR should be minimized. In a retrospective analysis of the VF waveform, interruption of CPR was associated with a decreased probability of conversion of VF to another rhythm [61].

New data suggest that chest compression-only CPR is as effective as standard CPR (chest compression plus rescue breathing) for out-of-hospital arrest [62,63]. Subgroup analysis in one study suggested a trend for increased survival to hospital discharge for chest compression-only CPR if the cause of the arrest was cardiac in origin or the rhythm was shockable [62].

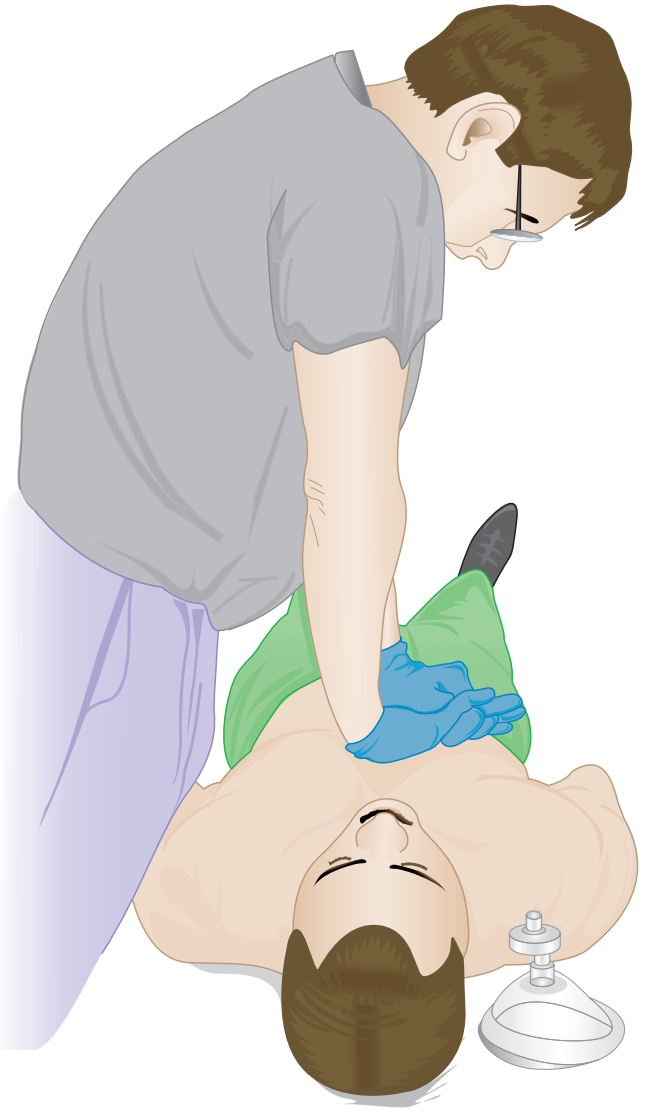

FIGURE 23.7. External chest compression. Proper position of the rescuer: place heel of the hand on the breast bone at the nipple line with shoulders directly over the patient's sternum and elbows locked. [From *BLS for Healthcare Providers*, American Heart Association, 2006, with permission. Copyright 2006, American Heart Association.]

Whether chest compression-only therapy supplants standard therapy will require further research.

Two-Rescuer CPR

The combination of artificial ventilation and circulation can be delivered more efficiently and with less fatigue by two rescuers. One rescuer, positioned at the patient's side, performs sternal compressions, while the other, positioned at the patient's head, maintains an open airway and performs ventilation. This technique should be mastered by all health care workers called on to perform CPR. Lay people have not been routinely taught this method in the interest of improving retention of basic skills. The compression rate for two-rescuer CPR, as for one-rescuer CPR, is approximately 100 compressions per minute. The new recommendation of the compression-to-ventilation ratio is 30 to 2. In an animal model of cardiac arrest, a compression-to-ventilation ratio of 30 to 2 was associated with significantly shorter time to ROSC [64]. The only exception to this recommendation is when two health care workers are providing CPR to a child or infant (except newborns); in this instance, a 15 to 2 compression-to-ventilation ratio should be used [60]. When the rescuer performing compressions is tired, the two rescuers should switch responsibilities with the minimum possible delay.

Complications of BLS Procedures

Proper application of CPR should minimize serious complications, but serious risks are inherent in BLS procedures and should be accepted in the context of cardiac arrest. Awareness of these potential complications is important to the postresuscitative care of the arrest patient.

Gastric distention and regurgitation are common complications of artificial ventilation without endotracheal intubation. These complications are more likely to occur when ventilation pressures exceed the opening pressure of the lower esophageal sphincter. In mask ventilation, 1 second should be allowed for air delivery. Although an esophageal obturator airway may decrease the threat of distention and regurgitation during its use, the risk is increased at the time of its removal. To obviate this risk, the trachea should be intubated and protected with an inflated cuff before the esophageal cuff is deflated and the esophageal obturator removed.

Complications of sternal compression and manual thrusts include rib and sternal fractures, costochondral separation, flail chest, pneumothorax, hemothorax, hemopericardium, subcutaneous emphysema, mediastinal emphysema, pulmonary contusions, bone marrow and fat embolism, and lacerations of the esophagus, stomach, inferior vena cava, liver, or spleen [65]. Although rib fractures are common during CPR, especially in the elderly, no serious sequelae are likely unless tension pneumothorax occurs and is not recognized. The more serious complications are unlikely to occur in CPR if proper hand position is maintained and exaggerated depth of sternal compression is avoided. Overzealous or repeated abdominal or chest thrusts for relief of airway obstruction are more likely to cause fractures or lacerations. For this reason, abdominal thrust is not recommended for the infant younger than 1 year.

Monitoring the Effectiveness of Basic Life Support

The effectiveness of rescue effort is assessed regularly by the ventilating rescuer, who notes the chest motion and the escape of expired air. Unintentional hyperventilation is frequent during CPR, with studies in clinical situations showing that patients are commonly ventilated at a rate of 18 to 30, far faster than recommended. The adequacy of circulation is assessed by noting an adequate carotid pulse with sternal compressions.

Animal and clinical studies suggest that the best guides to the efficacy of ongoing CPR efforts are aortic diastolic pressure and myocardial perfusion pressure (aortic diastolic minus right atrial diastolic) [66–68]. In instrumented patients for whom systemic arterial pressure (with or without central venous pressure) is available, attempts should be made to optimize myocardial perfusion pressure during CPR.

Pupillary response, if present, is a good indicator of cerebral circulation. However, fixed and dilated pupils should not be accepted as evidence of irreversible or biologic death. Ocular diseases, such as cataracts, and a variety of drugs (e.g., atropine and ganglion-blocking agents) interfere with the pupillary light reflex. The decision to cease BLS should be made only by the physician in charge of the resuscitation effort; this decision should not be made until it is obvious that the patient's cardiovascular system will not respond with ROSC to adequate administration of ACLS, including electric and pharmacologic interventions. Remediable problems such as airway obstruction, severe hypovolemia, and pericardial tamponade should also have been reasonably excluded by careful attention to ACLS protocols. Published guidelines in the literature suggest that BLS can be stopped if all of the following are present: the event was not witnessed by EMS personnel, no AED has been used, and there is no ROSC in the prehospital setting [57].

PEDIATRIC RESUSCITATION

Most infants and children who require resuscitation have had a primary respiratory arrest. Cardiac arrest results from the ensuing hypoxia and acidosis; therefore, the focus of pediatric resuscitation is airway maintenance and ventilation. The outcomes for CPR in children with cardiac arrest are poor because the cessation of cardiac activity is usually the manifestation of prolonged hypoxia. Brain damage is, therefore, all too common. Respiratory arrest, if treated before cessation of cardiac activity has supervened, carries a much better prognosis [69]. It is for this reason that it is recommended to provide the initial steps of CPR for infants and children before taking the time to telephone for emergency assistance. The first minute of CPR will allow opening of the airway and the beginning of artificial ventilation. If an obstructed airway is found, attempts at dislodging a foreign body should not be delayed. In children with a history of cardiac disease or arrhythmias, or in previously healthy children who are witnessed to have a sudden collapse, a primary arrhythmic event is more likely and immediate activation of the EMS system may be beneficial.

Effective techniques for ventilation and chest compression vary with the child's size. Infant procedures are applicable to patients who are smaller than an average child of 1 year. Child techniques are applicable to patients who are of a size similar to the average child of 1 to 8 years. Adult techniques are appropriate for patients who appear larger than the typical child of 8 years of age.

If the child is found to be apneic, he or she is placed in the supine position and the head tilt–chin lift maneuver is used to open the airway (Fig. 23.8). Overextension of the neck is unnecessary and is best avoided. Some believe that overextension of the child's flexible neck may obstruct the trachea; however, there are no data to support this. The jaw-thrust maneuver should be used if an adequate airway is not obtained with the head tilt–chin lift maneuver or if neck injury is suspected.

Artificial ventilation of the infant requires the rescuer's mouth to cover both the mouth and the nose to make an effective seal. If the child's face is too large to allow a tight seal to

FIGURE 23.8. Head tilt–chin lift in the infant: opening the airway. [From *BLS for Healthcare Providers*, American Heart Association, 2006, with permission. Copyright 2006, American Heart Association.]

FIGURE 23.9. Locating finger position for sternal compression in the infant, using an imaginary line between the nipples. be made over both the mouth and the nose, the mouth alone is covered, as for the adult.

The lung volume of the pediatric patient is small enough that a "puff" of air from the airway–mask–bag unit apparatus might be adequate to inflate the lungs. However, the smaller diameter of the tracheobronchial tree and any pulmonary disease that may be contributing to the arrest usually provide considerable resistance to airflow. Therefore, a surprising amount of inspiratory pressure may be needed to move adequate air into the lungs. This is especially true for the child who may have edematous respiratory passages. Accordingly, adequacy of ventilation must be monitored by observing the rising and falling of the chest and feeling and listening for the exhaled air from the child's mouth and nose. Excessive ventilatory volumes may exceed esophageal opening pressure and cause gastric distention.

Gastric decompression is dangerous and should be avoided until the patient has been intubated and the cuff inflated to protect the respiratory tract from aspiration. If the gastric distention is so severe that ventilation is greatly compromised, the child's body should be turned to one side before pressure on the abdomen is applied. It is preferable to use a gastric tube with suction whenever possible.

The ventilation rate for infants is approximately 20 breaths per minute (one every 3 seconds), whereas the rate for children can be 12 to 20 breaths per minute (one every 3 to 5 seconds). Adolescents are ventilated at the adult rate of 10 to 12 breaths per minute (one every 5 seconds). If artificial circulation is not necessary, more rapid ventilatory rates are acceptable.

Artificial circulation is instituted in the absence of a palpable pulse. The pulse of the larger child can easily be detected at the carotid artery, as in the adult. The neck of the infant, however, is too short and fat for reliable palpation of the carotid artery. Palpation of the precordium is also unreliable; some infants have no precordial impulse in spite of adequate cardiac output. It is recommended, therefore, that the presence of an infant's pulse be determined by palpating the brachial artery between the elbow and the shoulder.

To apply chest compression in an infant, the rescuer's index finger is placed on the sternum, just below the intermammary line. The proper area for compression is one fingerbreadth below the intermammary line on the lower sternum, at the location of the middle and ring fingers (Fig. 23.9). Using two or three fingers, the sternum is compressed approximately one-third to one-half the depth of the thorax. Alternatively, for chest compressions in the infant, the *two thumb–encircling hands* technique may be used when two rescuers are available (Fig. 23.10). The frequency of sternal compressions for infants and children is 100 per minute. During one-rescuer support, the ratio of compression to ventilation is 30 to 2 for infants and children [60].

OBSTRUCTED AIRWAY

An unconscious patient can experience airway obstruction when the tongue falls backward into the pharynx. Alternatively, the epiglottis may block the airway when the pharyngeal muscles are lax. In the sedated or ill patient, regurgitation of stomach contents into the pharynx is a frequent cause of respiratory arrest. Blood clots from head and facial injuries are another source of pharyngeal and upper airway obstruction. Even otherwise healthy people may have foreign body obstruction from poorly chewed food, large wads of gum, and so forth. The combination of attempting to swallow inadequately chewed food, drinking alcohol, and laughing is particularly conducive to pharyngeal obstruction. Children's smaller airways are likely to obstruct with small nuts or candies.

FIGURE 23.10. Chest compression in the infant using the two thumb–encircling hands technique. (Two rescuers are required.) [From Guidelines 2000 for cardiopulmonary resuscitation and emergency cardiovascular care. *Circulation* 102[Suppl 8]:I-1, 2000, with permission. Copyright 2000, American Heart Association.]

Children are also prone to airway obstruction by placing toys or objects such as marbles or beads in their mouths.

Patients who experience partial obstruction with reasonable gas exchange should be encouraged to continue breathing efforts with attempts at coughing. A patient whose obstruction is so severe that air exchange is obviously markedly impaired (cyanosis with lapsing consciousness) should be treated as having complete obstruction.

Patients who experience complete obstruction may still be conscious. They are unable to cough or vocalize. A subdiaphragmatic abdominal thrust may force air from the lungs in sufficient quantity to expel a foreign body from the airway [70].

If the person is still standing, the rescuer stands behind the person and wraps his or her arms around the person's waist. The fist of one hand is placed with the thumb side against the person's abdomen in the midline, slightly above the umbilicus and well below the xiphoid process (Fig. 23.11). The fist is grasped with the other hand and quickly thrust inward and upward. It may be necessary to repeat the thrust six to ten times to clear the airway. Each thrust should be a separate and distinct movement.

If the patient is responsive and lying down, he or she should be positioned face up in the supine position. The rescuer kneels beside or astride the person's thighs and places the heel of one hand against the person's abdomen, slightly above the navel and well below the xiphoid process. The other hand is placed directly on top of the first and pressed inward and upward with a quick forceful thrust. If the patient is unresponsive, CPR should be initiated.

FIGURE 23.11. Abdominal thrust with conscious patient standing: rescuer standing behind individual with foreign body airway obstruction. [From *BLS for Healthcare Providers*, American Heart Association, 2006, with permission. Copyright 2006, American Heart Association.]

If attempted rescue breathing in an arrested patient fails to move air into the lungs, an obstructed airway must be presumed to be present. It may simply be due to the tongue or epiglottis, rather than a foreign body. If the airway remains closed after repositioning the head, other maneuvers to open the airway, including the jaw-thrust and tongue-jaw lift, must be used. Chest thrusts may be substituted for abdominal thrusts in patients in advanced stages of pregnancy, in patients with severe ascites, or in the markedly obese. The fist is placed in midsternum for the erect and conscious patient. For the supine patient, the hand is positioned on the lower sternum, as for external cardiac compression. Each thrust is delivered slowly and distinctly.

If attempts at dislodging a foreign body or relieving airway obstruction fail, special advanced procedures are necessary to provide oxygenation until direct visualization, intubation, or tracheostomy is accomplished.

ADVANCED CARDIAC LIFE SUPPORT IN ADULTS

The use of adjunctive equipment, more specialized techniques, and pharmacologic and electric therapy in the treatment of a person who has experienced cardiac or respiratory arrest is generally referred to as *ACLS*. These techniques and their interface with BLS and the EMS are considered in the AHA's ACLS teaching program. An improvement in survival after in-hospital cardiac arrest has been demonstrated after medical house officers were trained in ACLS [71]. An in-depth discussion is available in the ACLS text published by the AHA.

The focus of the following sections is on the techniques and medications used in the initial resuscitative efforts. The demarcation from therapies more commonly reserved for the ICU is often indistinct; indeed, it is expected to vary with the experience of the prehospital team and the degree of physician supervision. In general, most ACLS measures should be applied by trained personnel operating within an EMS system in the community, in transport, or in the hospital setting.

Airway and Ventilatory Support

Oxygenation and optimal ventilation are prerequisites for successful resuscitation (see Chapter 1). Supplemental oxygen should be administered as soon as it becomes available, beginning with 100%. In the postresuscitation period, the amount of administered oxygen may be decreased as guided by the arterial blood partial pressure of oxygen.

Emergency ventilation commonly begins with the combined use of a mask and oral airway. Mouth-to-mask ventilation is very effective as long as an adequate seal is maintained between the mask and the face. Most masks are best fitted by flaring the top and molding it over the bridge of the nose. The inflated rim is then carefully molded to the cheeks as the mask is allowed to recoil. Relatively firm pressure is required to maintain the seal. Masks with one-way valves also provide a measure of isolation from the patient's saliva and breath aerosol. Bag–valve–mask ventilation requires strong hands and a self-inflating bag. The bag should be connected to a gas reservoir and to oxygen so that 100% oxygen delivery can be approximated. It cannot

be overemphasized that the success of this method depends on airway patency and an adequate seal between the mask and the face. Equally important is adequate compression of the bag to deliver the required tidal volume. It is advisable that everyone who uses this technique practice on a recording ventilating manikin to assess the adequacy of the method in his or her hands. Many people will discover that their hands are not large enough or strong enough to deliver 700 mL air. Some may have to squeeze the bag between their elbow and chest wall to supply adequate ventilation. If two people are available to ventilate, one should secure the mask while the other uses both hands to attend to the bag.

The mask design should include the following features:

- The use of transparent material, which allows the rescuer to assess lip color and to observe vomitus, mucus, or other obstructing material in the patient's airway.
- A cushioned rim around the mask's perimeter to conform to the patient's face and to facilitate a tight seal.
- A standard 15- to 22-mm connector, which allows the use of additional airway equipment.
- A comfortable fit to the rescuer's hand.
- An oxygen insufflation inlet, which allows oxygen supplementation during mouth-to-mask ventilation.
- A one-way valve, which allows some protection during mouth-to-mask ventilation.
- Availability in appropriate sizes and shapes, for various-sized faces. Most adults will be accommodated by a standard medium-sized (no. 4) oval-shaped mask.

Ventilating bags must be designed to include the following features:

- A self-refilling bag, which allows operation independent of a fresh gas source.
- A fresh gas inlet, which allows ambient air or supplemental oxygen to flow into the reservoir bag through a valve inlet.
- A nipple for oxygen connection, located near the gas inlet valve.
- An oxygen reservoir bag.
- Availability in pediatric and adult sizes.
- A nonrebreathing valve directing flow to the patient during inhalation and to the atmosphere during exhalation. The valve casing should be transparent to allow visual inspection of its function. A pop-off feature is often present to prevent high airway pressures; however, such valves should have provision to override the pop-off feature because higher airway pressures are sometimes required to ventilate lungs with unusually high resistances, especially in children.
- Reservoir tubing that can be attached to the fresh gas inlet valve, which allows an accumulation of oxygen to refill the reservoir bag during the refill cycle. Such a reservoir allows delivered oxygen to approach 100%; without it, the self-refilling bag can deliver only 40% to 50% oxygen.

Oxygen-powered resuscitators allow the pressure of compressed oxygen tanks at 50 psi to drive lung inflation. They are usually triggered by a manual control button, and the oxygen can be delivered through a mask or tube for ease of ventilation. These devices deliver oxygen at a flow rate of 100 L per minute and allow airway pressures of 60 cm H_2O. However, when used with masks and unprotected airways (not separated from the esophagus by an inflated cuff), these devices are likely to cause gastric distention and poor ventilation. They are not as reliable as mouth-to-mask or valve–bag–mask ventilation. When used in adults, they should be recalibrated to deliver flows of no more than 40 L per minute to avoid opening the lower esophageal sphincter. A relief valve that opens at approximately 60 cm H_2O and vents any excess volume into the atmosphere should be present. In addition, an alarm that sounds whenever the relief valve pressure is exceeded should be present. This alarm warns the rescuer that the patient requires higher inspiratory pressures and may not be adequately ventilated. Barotrauma is likely to occur in infants and children. Children often have high airway resistances and are difficult to ventilate with these resuscitators. These devices should be avoided in general and should not be used with infants or children.

Endotracheal intubation is required if the patient cannot be rapidly resuscitated or when adequate spontaneous ventilation does not resume quickly. Experienced personnel should attempt intubation. Resuscitative efforts should not be interrupted for more than 30 seconds with each attempt. Cricoid pressure should be applied, when possible, by a second person during endotracheal intubation to protect against regurgitation of gastric contents. The prominence inferior to that of the thyroid cartilage is the cricoid cartilage. Downward pressure should be applied with the thumb and index finger (Fig. 23.12) until the cuff of the endotracheal tube is inflated.

Once the patient is intubated and the trachea is protected from regurgitation, faster inspiratory flow rates are possible. However, hyperventilation should be avoided. Checking arterial blood gases will assist in the determination of an adequate minute ventilation. Increasing the respiratory rate may be detrimental [72].

The laryngeal mask airway (LMA) has been effective for maintaining airway patency during anesthesia since 1988 and has been accepted as one of the adjuncts for airway control and ventilation during CPR. The LMA provides a more stable and consistent means of ventilation than bag–mask ventilation [73]. The current research concludes that regurgitation is less common with LMA than with the bag-mask, and although it cannot provide complete protection from aspiration, it is less frequent when used as the first-line airway device [73,74]. Multiple studies have documented the advantages of LMA for its relative ease with insertion and ease of use by a variety of personnel: nurses, medical students, respiratory therapists, and EMS, many with little prior experience using the device. Studies have shown that inexperienced personnel achieved an 80% to 94% success rate on first placement attempts and achieved 98% and 94% on subsequent attempts of adult and pediatric cases, respectively. The LMA provides adequate and effective ventilation when measured against endotracheal intubation [75]. Additionally, less equipment and training are needed to insert the device successfully. It may also have advantages over the endotracheal tube when patient airway access is obstructed, when the patient has an unstable neck

FIGURE 23.12. Cricoid pressure: application of downward pressure over the cricoid with neck extended. [From Sellick BA: Cricoid pressure to control regurgitation of stomach contents during induction of anaesthesia. *Lancet* 2:404, 1961, with permission.]

injury, or when suitable positioning of the patient for endotracheal intubation is unattainable. LMA insertion has been successful when attempts at endotracheal intubation by experts were unsuccessful [75]. Endotracheal tubes can be fiberoptically inserted through an established LMA.

Relative contraindications for LMA use include the patient with an increased risk of aspiration pneumonitis. Examples of such situations include morbid obesity, pregnancy, recent food ingestion, gastrointestinal obstruction, and hiatal hernia. Despite these considerations, oxygenation and ventilation during cardiac arrest receive top priority and the LMA should be used if it is the fastest and efficient means of providing airway patency.

If attempts at relieving an obstructed airway have failed, several advanced techniques may be used to secure the airway until intubation or tracheostomy is successfully performed. In transtracheal catheter ventilation, a catheter is inserted over a needle through the cricothyroid membrane (Fig. 23.13). The needle is removed and intermittent jet ventilation initiated (see Chapter 1). In cricothyrotomy, an opening is made in the cricothyroid membrane with a knife (see Chapter 12). Tracheostomy, if still necessary, is best performed in the operating room by a skilled surgeon after the airway has already been secured by one of the aforementioned techniques.

Circulatory Support

Chest compression should not be unduly interrupted while adjunctive procedures are instituted. The rescuer coordinating the resuscitation effort must ensure that adequate pulses are generated by the compressor. The carotid or femoral pulse should be evaluated every few minutes.

Mechanical chest compressors seem useful in the hands of experienced resuscitators. It is important that such devices be correctly calibrated to provide a stroke of 1.5 to 2.0 in. The position of the press on the sternum must be checked frequently to ensure adequate compression with a minimum of damage. The press may be a manually operated hinged device or may be powered by compressed gas (usually 100% oxygen). The plunger is mounted on a backboard and is associated with a time–pressure-cycled ventilator. This device is programmed to deliver CPR using a compression duration that is 50% of the cycle length. Such units allow the patient to be harnessed to the backboard, fixing the location of the plunger. When used properly, with careful monitoring of patient position, this device facilitates CPR during transport. An acceptable electrocardiogram (ECG) can often be recorded with the compressor in operation, and defibrillation can be delivered during the downstroke of chest compression, without delays in CPR.

ECG monitoring is necessary during resuscitation to guide appropriate electric and pharmacologic therapy. Until ECG monitoring allows diagnosis of the rhythm, the patient should be assumed to be in VF (see the section "Ventricular Fibrillation and Pulseless Ventricular Tachycardia").

Most defibrillators currently marketed have built-in monitoring circuitry in the paddles or pads (quick look). On application of the defibrillator paddles, the patient's ECG is displayed on the monitor screen. This facilitates appropriate initial therapy. For continuous monitoring beyond the first few minutes, a standard ECG monitoring unit should be used.

ECG monitoring must never be relied on without frequent reference to the patient's pulse and clinical condition. What appears on the monitor screen to be VF or asystole must not be treated as such unless the patient is found to be without a pulse. An apparently satisfactory rhythm on the monitor must be accompanied by an adequate pulse and blood pressure.

Defibrillation

Electric defibrillation is the definitive treatment for most cardiac arrests. It should be delivered as early as possible and repeated frequently until VF or pulseless VT has been terminated.

Electric defibrillation involves passing an electric current through the heart and causing synchronous depolarization of the myofibrils. As the myofibrils repolarize, the opportunity arises for the emergence of organized pacemaker activity.

Proper use of the defibrillator requires special attention to the following:

1. *Selection of proper energy levels* (see the section "Clinical Settings"). This lessens myocardial damage and arrhythmias occasioned by unnecessarily high energies. For biphasic defibrillators, the energy should be 120 to 200 J. For the monophasic defibrillators, the energy should be 360 J [57].
2. *Proper asynchronous mode.* The proper mode must be selected if the rhythm is VF. The synchronizing switch must be deactivated or the defibrillator will dutifully await the R wave that will never come. For rapid pulseless VT (approximately 150 to 200 beats per minute), it is best not to attempt synchronization with the R wave because this increases the likelihood of delivering the shock on the T wave. If the countershock should fall on the T wave and induce VF, another unsynchronized countershock must be delivered promptly after confirming pulselessness.
3. *Proper position of the paddles or pads.* This allows the major energy of the electric arc to traverse the myocardium. The anterolateral position requires that one paddle or pad be placed to the right of the upper sternum, just below the clavicle. The other paddle or pad is positioned to the left of the nipple in the left midaxillary line. In the anteroposterior position, one paddle or pad is positioned under the left scapula with the patient lying on it. The anterior paddle or pad is positioned just to the left of the lower sternal border.
4. *Adequate contact between paddles or pads and skin.* This should be ensured, using just enough electrode paste to cover the paddle face without spilling over the surrounding skin. The rescuer should hold the paddles with firm pressure (approximately 25 lb). The pressure should be delivered using the forearms; leaning into the paddles should be avoided for fear that the rescuer may slip. If defibrillator electrode paddles are used, the skin must be carefully prepared according to the manufacturer's directions.

5. *No contact with anyone other than the patient.* The rescuer must be sturdily balanced on both feet and not standing on a wet floor. CPR must be discontinued with no one remaining in contact with the patient. It is the responsibility of the person defibrillating to check the patient's surroundings, ensure the safety of all participants, loudly announce the intention to countershock, and depress both buttons. The use of an automatic or semiautomatic defibrillator does not decrease the operator's need for diligence.
6. If no skeletal muscle twitch or spasm has occurred, the equipment, contacts, and synchronizer switch used for elective cardioversions should be rechecked.

Electric energy delivered in a biphasic waveform is clearly superior to monophasic waveforms for implantable defibrillators (see Chapter 6), but there is a paucity of evidence to show that one waveform is superior over another with regard to ROSC or survival to hospital discharge. External defibrillators are now available with biphasic waveforms.

Electronic Pacemaker

Pacemaker therapy requiring positioning of transvenous or transthoracic electrodes is time consuming, technically demanding, and usually interferes with adequate performance of CPR. External pacing equipment often allows myocardial capture with some discomfort and skeletal muscle contraction [76]. Obviously, this is unimportant during asystole or bradycardic cardiac arrest. Unfortunately, pacing does not produce a perfusing rhythm in most cases of cardiac arrest. Patients who respond to emergency pacing are those with severe bradycardias or conduction block who have reasonably well-preserved myocardial function [77].

Venous Access

Venous access with a reliable intravenous (IV) route must be established early in the course of the resuscitative effort to allow for the administration of necessary drugs and fluids. However, initial defibrillation attempts and CPR should not be delayed for the placement of an IV line. Peripheral venous access through antecubital veins is often more convenient because it is less likely to interfere with other rescue procedures. Cannulation of such veins may be difficult, however, because of venous collapse or constriction. A large-bore catheter system should be used because needles in the vein are apt to become dislodged during CPR. A long catheter may be threaded into the central circulation. Alternatively, the extremity may be elevated for 10 to 20 seconds and 20 mL of flush solution used to help entry of the drug into the central circulation [78]. Lower extremity peripheral veins should be avoided because it is questionable whether drugs enter into the central circulation from such veins during CPR [79].

Central venous access offers a more secure route for drug administration and should be attempted if initial resuscitative efforts are not successful. Femoral vein cannulation is apparently difficult to achieve during CPR, and flow into the thorax is slower than with upper torso access. If the femoral vein is successfully cannulated, a long line should be placed into the vena cava above the level of the diaphragm. Internal jugular or subclavian routes are preferable, but central venous catheterization at these sites should not be allowed to delay defibrillation attempts or interfere with CPR. They should be placed by experienced operators.

Although central lines may be associated with an increased incidence of complications for patients receiving fibrinolytic therapy, they are not an absolute contraindication to its use.

In infants and children as well as adults, the intraosseous (IO) route is easy to achieve and very effective for venous access. Special kits to achieve IO access in the adult are now available.

Drugs such as epinephrine, atropine, and lidocaine can be administered via the endotracheal tube if there is delay in achieving venous access. However, this route requires a higher dose to achieve an equivalent blood level [38], and a sustained duration of action (a "depot effect") can be expected if there is a return in spontaneous circulation [38]. It is suggested that 2.0 to 2.5 times the IV dose be administered when using the endotracheal route. Delivery of the drug to the circulation is facilitated by diluting the drug in 10 mL of normal saline or distilled water and delivering it through a catheter positioned beyond the tip of the endotracheal tube. Stop chest compressions, spray the solution quickly down the endotracheal tube, and give several quick insufflations before reinitiating chest compressions. Intracardiac injection of epinephrine is to be avoided.

Correction of Hypoxia

Hypoxia should be corrected early during CPR with administration of the highest possible oxygen concentration. Inadequate perfusion, decreased pulmonary blood flow, pulmonary edema, atelectasis, and ventilation–perfusion mismatch all contribute to the difficulty in maintaining adequate tissue oxygenation. Inadequate tissue oxygenation results in anaerobic metabolism, the generation of lactic acid, and the development of metabolic acidosis.

Correction of Acidosis

Correction of acidosis must be considered when the arrest has lasted for more than several minutes. *Metabolic acidosis* develops because of tissue hypoxia and conversion to anaerobic metabolism. *Respiratory acidosis* occurs because of apnea or hypoventilation with intrapulmonary ventilation–perfusion abnormalities; the marked decrease in pulmonary blood flow that exists even with well-performed CPR also contributes.

Sodium bicarbonate reacts with hydrogen ions to buffer metabolic acidosis by forming carbonic acid and then carbon dioxide and water. Each 50 mEq sodium bicarbonate generates 260 to 280 mm Hg carbon dioxide, which can be eliminated only through the expired air. Because carbon dioxide of exhaled gas during CPR is decreased, the carbonic acid generated by sodium bicarbonate cannot be effectively eliminated. Paradoxic intracellular acidosis is likely to result, and arterial blood gases may not correctly reflect the state of tissue acidosis. The sodium and osmolar load of bicarbonate is high; excessive administration results in hyperosmolarity, hypernatremia, and worsened cellular acidosis. With these concerns in mind, the AHA guidelines suggest that sodium bicarbonate be avoided until successful resuscitation has reestablished a perfusing rhythm [80]. In the postresuscitative state, the degree of acidosis can be better estimated from blood gases and the acidemia corrected with hyperventilation and possibly bicarbonate administration. Sodium bicarbonate is of questionable value in treating the metabolic acidosis during cardiac arrest; it has not been shown to facilitate ventricular defibrillation or survival in cardiac arrest [81,82]. In any case, bicarbonate should not be used during cardiac arrest until at least 10 minutes have passed, the patient is intubated, and the patient has not responded to initial defibrillation and drug intervention. An exception is the patient with known preexisting hyperkalemia in whom administration of bicarbonate is recommended. The use of bicarbonate may also be of value in patients who have a known preexisting bicarbonate-responsive acidosis or a tricyclic antidepressant overdosage, or to alkalinize the urine in

drug overdosage. When bicarbonate is used, 1 mEq per kg may be given as the initial dose. When possible, further therapy should be guided by the calculated base deficit. To avoid iatrogenically induced alkalosis, complete correction of the calculated base deficit should be avoided.

Volume Replacement

Increased central volume is often required during CPR, especially if the initial attempts at defibrillation have failed. PEA is particularly likely to be caused either by acute severe hypovolemia (e.g., exsanguination) or by a cardiovascular process for which volume expansion may be a lifesaving temporizing measure (e.g., pericardial tamponade, pulmonary embolism, and septic shock). The usual clues for hypovolemia, such as collapsed jugular and peripheral veins and evidence of peripheral vasoconstriction, are unavailable during cardiac arrest; furthermore, dry mucus membranes and absence of normal secretions (tears and saliva) are unreliable in acute hypovolemia. Most physical findings of tamponade, pulmonary embolism, or septic shock are absent during arrest. Therefore, one must be guided by an appropriate clinical history and have a low threshold to administer volume during CPR.

Simple crystalloids, such as 5% dextrose in water (D_5W), are inappropriate for rapid expansion of the circulatory blood volume. Isotonic crystalloids (0.9% saline and Ringer's lactate), colloids, or blood are necessary for satisfactory volume expansion. Crystalloids are more readily available, easier to administer, and less expensive than colloids. They are also free of the potential to cause allergic reactions or infections. Colloids are more likely to sustain intravascular volume and oncotic pressure.

If the patient has a weak pulse, simple elevation of the legs may help by promoting venous return to the central circulation. Volume challenges should be given as needed until pulse and blood pressure have been restored or until there is evidence of volume overload.

DRUG THERAPY

Sympathomimetic Drugs and Vasopressors

Sympathomimetic drugs act either directly on adrenergic receptors or indirectly by releasing catecholamines from nerve endings. Most useful during cardiac emergencies are the adrenergic agents, which include the endogenous biogenic amines epinephrine, norepinephrine, and dopamine, and the synthetic agent isoproterenol and its derivative dobutamine [57]. Of note, none of the sympathomimetics can be administered in a line with an alkaline infusion. Extravasation of any agent with α-adrenergic activity can result in tissue necrosis, so they should be infused via a central venous catheter if possible. If extravasation does occur, 5 to 10 mg phentolamine in 10 to 15 mL saline should be infiltrated as soon as possible into the area of extravasation.

Epinephrine

Epinephrine is a naturally occurring catecholamine that has both α- and β-activities. Although epinephrine is the pressor agent used most frequently during CPR, the evidence that it improves the outcome in humans is scant.

Indications for the use of epinephrine include all forms of cardiac arrest because its α-vasoconstrictive activity is important in raising the perfusion pressure of the myocardium and brain. The importance of α-adrenergic activity during resuscitation has been noted in several studies [83], whereas administration of pure β-agonists (e.g., isoproterenol or dobutamine) has been shown to be ineffective [84]. The β-action of epinephrine is theoretically useful in asystole and bradycardic arrests by increasing heart rate. The β-effect has also been touted to convert asystole to VF or to convert "fine" VF to "coarse." Coarse or wide-amplitude VF is easier to convert to a perfusing rhythm than fine or small-amplitude VF. However, this may be primarily due to the shorter time course of the arrest in patients still manifesting wide-amplitude rather than small-amplitude VF.

Epinephrine is best administered IV. As soon as possible after failed ventricular defibrillation attempts (or if defibrillation is not an option), an adult in cardiac arrest should be given a 1-mg dose at a 1 to 10,000 dilution (10 mL). It should be given in the upper extremity or centrally (see the earlier discussion in the section "Venous Access"), and may be repeated every 5 minutes. If a peripheral line is used, the drug should be administered rapidly and followed by a 20-mL bolus of IV fluid and elevation of the extremity. It should not be administered in the same IV line as an alkaline solution. If an IV line has not been established, the endotracheal route may be used, but the intracardiac route should be avoided because it is prone to serious complications such as intramyocardial injection, coronary laceration, and pneumothorax. An IV infusion of 1 to 10 μg per minute can also be given for inotropic and pressor support. Two multicenter trials evaluating the effectiveness of high-dose epinephrine in cardiac arrest failed to demonstrate an improvement in survival or neurologic outcome [85,86].

Risks in the use of epinephrine and other α-agonists include tissue necrosis from extravasation and inactivation from admixture with bicarbonate.

Norepinephrine

Norepinephrine is a potent α-agonist with β-activity. Its salutary α-effects during CPR are similar to those of epinephrine [87]. However, there are no data to support the belief that it is superior to epinephrine during an arrest.

The major effect of norepinephrine is on the blood vessels. Initial coronary vasoconstriction usually gives way to coronary vasodilatation, probably as a result of increased myocardial metabolic activity. In a heart with compromised coronary reserve, this may cause further ischemia. During cardiac arrest, its usefulness, like that of epinephrine, is most likely due to peripheral vasoconstriction with an increase in perfusion pressure. In patients with spontaneous circulation who are in cardiogenic shock (when peripheral vasoconstriction is often already extreme), its effect is more difficult to predict. Norepinephrine also causes considerable renal and mesenteric vasoconstriction, whereas dopamine at low infusion rates causes vasodilatation in these vascular beds.

Indications for the use of norepinephrine during cardiac arrest are similar to those for epinephrine, although there does not appear to be any reason to prefer it to epinephrine. Norepinephrine appears to be most useful in the treatment of shock caused by inappropriate decline in peripheral vascular resistance, such as septic shock and neurogenic shock. It is administered by IV infusion and titrated to an adequate perfusion pressure. Bitartrate, 4 to 8 mg (2 to 4 mg of the base), should be diluted in 500 mL D_5W or 5% dextrose in normal saline. A typical starting infusion rate is 0.5 μg per minute and most adults respond to 2 to 12 μg per minute, but some require rates up to 30 μg per minute. Abrupt termination of the infusion (as may occur in transport) may lead to sudden severe hypotension.

Precautions to the use of norepinephrine include its inappropriate use in hypovolemic shock and in patients with already severe vasoconstriction. Intra-arterial pressure monitoring

is strongly recommended when using norepinephrine because indirect blood pressure measurement is often incorrect in patients with severe vasoconstriction. In patients with myocardial ischemia or infarction, the myocardial oxygen requirements are increased by all catecholamines, but especially by norepinephrine because of its marked afterload-increasing properties. Unless the increased oxygen delivery occasioned by the rise in perfusion pressure outweighs the increase in myocardial oxygen requirement caused by the afterload increase, norepinephrine is likely to have deleterious effects. Heart rate, rhythm, ECG evidence for ischemia, direct systemic and pulmonary pressures, urine output, and cardiac output should be closely monitored when using this drug in patients with myocardial ischemia or infarction.

Isoproterenol

This synthetic catecholamine has almost pure β-adrenergic activity. Its cardiac activity includes potent inotropic and chronotropic effects, both of which will increase the myocardium's oxygen demand. In addition to bronchodilatation, the arterial beds of the skeletal muscles, kidneys, and gut dilate, resulting in a marked drop in systemic vascular resistance. Cardiac output can be expected to increase markedly unless the increased myocardial oxygen demand results in substantial myocardial ischemia. Systolic blood pressure is usually maintained because of the rise in cardiac output, but the diastolic and mean pressures usually decrease. As a result, coronary perfusion pressure drops at the same time that the myocardial oxygen requirement is increased. This combination can be expected to have deleterious effects in patients with ischemic heart disease, especially during cardiac arrest. The main clinical usefulness of isoproterenol is in its ability to stimulate pacemakers within the heart.

Indications for isoproterenol are primarily in the setting of atropine-resistant, hemodynamically significant bradyarrhythmias, including profound sinus and junctional bradycardia, as well as various forms of high-degree AV block. It should be used only as an interim measure, until effective transcutaneous or IV pacing can be instituted. If the aortic diastolic pressure is already low, epinephrine is likely to be better tolerated as a stimulus to pacemakers. *Under no circumstances should isoproterenol be used during cardiac arrest.*

Isoproterenol is administered by titration of an IV solution. One mg isoproterenol (Isuprel) is diluted with either 250 mL D_5W (4 mg per mL) or 500 mL D_5W (2 mg per mL). The infusion rate should be only rapid enough to effect an adequate perfusing heart rate (2 to 20 μg per minute, or 0.05 to 0.5 μg per kg per minute). Depending on the adequacy of cardiac reserve, a target heart rate as low as 50 to 55 beats per minute may be satisfactory. Occasionally, more rapid rates are necessary.

Precautions in the use of isoproterenol are largely due to the increase in myocardial oxygen requirement, with its potential for provoking ischemia; *this effect, coupled with the possibility of dropping the coronary perfusion pressure, makes isoproterenol a dangerous selection in the coronary patient.* The marked chronotropic effects may cause tachycardia and provoke serious ventricular arrhythmias, including VF. Isoproterenol is usually contraindicated if tachycardia is already present, especially if the arrhythmia may be secondary to digitalis toxicity. If significant hypotension develops with its use, it may be combined with another β-agonist with α-activity. However, switching to dopamine or epinephrine is usually preferable; better yet is the use of pacing for rate control.

Dopamine

This naturally occurring precursor of norepinephrine has α-, β-, and dopamine-receptor–stimulating activities. The dopamine-receptor activity dilates renal and mesenteric arterial beds at low doses (1 to 2 μg per kg per minute). β-adrenergic activity is more prominent with doses from 2 to 10 μg per kg per minute, whereas α-adrenergic activity is predominant at doses greater than 10 μg per kg per minuteα It has not been shown that these dose ranges have relevance in the clinical setting. Indications for the use of dopamine are primarily significant hypotension and cardiogenic shock.

Dopamine is administered by IV titration in the range of 2 to 20 μg per kg per minute. Rarely, a patient may need in excess of 20 μg per kg per minute. A 200-mg ampule is diluted to 250 or 500 mL in D_5W or 5% dextrose in normal saline for a concentration of 800 or 400 mg per mL. As with all catecholamine infusions, the lowest infusion rate that results in satisfactory perfusion should be the goal of therapy.

Precautions for dopamine are similar to those for other catecholamines. Tachycardia or ventricular arrhythmias may require reduction in dosage or discontinuation of the drug. If significant hypotension occurs from the dilating activity of dopaminergic or β-active doses, small amounts of an α-active drug may be added. Dopamine may increase myocardial ischemia.

Dobutamine

Dobutamine is a potent synthetic β-adrenergic agent that differs from isoproterenol in that tachycardia is less problematic. Unless ischemia supervenes, cardiac output will increase, as will renal and mesenteric blood flow.

Dobutamine is indicated primarily for the short-term enhancement of ventricular contractility in the patient with heart failure. It may be used for stabilization of the patient after resuscitation or for the patient with heart failure refractory to other drugs. It may also be used in combination with IV nitroprusside, which lowers peripheral vascular resistance and thereby left ventricular afterload. Although nitroprusside lowers peripheral resistance, dobutamine maintains the perfusion pressure by augmenting the cardiac output.

Dobutamine is administered by slow-titrated IV infusion. A dose as low as 0.5 μg per kg per minute may prove to be effective, but the usual dose range is 2.5 to 10.0 μg per kg per minute. A 250-mg vial is dissolved in 10 mL of sterile water and then to 250 or 500 mL D_5W for a concentration of 1.0 or 0.5 μg per mL.

Precautions for dobutamine are similar to those for other β-agonists. Dobutamine may cause tachycardia, ventricular arrhythmias, myocardial ischemia, and extension of infarction. It must be used with caution in patients with coronary artery disease.

Vasopressin

Vasopressin is not a catecholamine, but a naturally occurring antidiuretic hormone. In high doses, it is a powerful constrictor of smooth muscles and as such has been studied as an adjunctive therapy for cardiac arrest in an attempt to improve perfusion pressures and organ flows. Vasopressin may be especially useful in prolonged cardiac arrest as it remains effective as a vasopressor even in severe acidosis [88]. It may be used as a first agent in arrest in lieu of epinephrine or as the second agent if the first dose of epinephrine failed to cause a return in pulse. The dose of vasopressin is 40 units IV or IO.

Antiarrhythmic Agents

Antiarrhythmic agents have been thought to play an important role in stabilizing the rhythm in many resuscitation situations; however, the data in support of their value are scanty. Although lidocaine, bretylium, and procainamide had been considered

useful in counteracting the tendency to ventricular arrhythmias, convincing evidence of benefit to their use for pulseless VT and VF is wanting. On the basis of recent studies, amiodarone has gained considerable acceptance for the emergency treatment of refractory VT and VF.

Amiodarone

Amiodarone is a benzofuran derivative that is structurally similar to thyroxine and contains a considerable level of iodine. Gastrointestinal absorption is slow; therefore, when given orally, the onset of action is delayed while the drug slowly accumulates in adipose tissue. The mean elimination half-life is 64 days (range, 24 to 160 days). IV administration allows rapid onset of action, with therapeutic blood levels achieved with 600 mg given over 24 hours.

Amiodarone decreases myocardial contractility, and it also causes vasodilatation, which counterbalances the decrease in contractility. In general, it is therefore well tolerated even by those with myocardial dysfunction.

Amiodarone given IV has been successful in terminating a variety of reentrant and other types of supraventricular and ventricular rhythms. In a major study of out-of-hospital cardiac arrest due to ventricular arrhythmias refractory to shock, patients were initially treated with either amiodarone (246 patients) or placebo (258 patients). Patients given amiodarone had a higher incidence of bradycardia (41% vs. 25%) and hypotension (59% vs. 48%), but also a higher rate of survival to hospital admission (44% vs. 34%) [89]. This study did not demonstrate an increase in survival to hospital discharge or in neurologic status. On the basis of this study, amiodarone has been given status as an option for use after defibrillation attempts and epinephrine in refractory ventricular arrhythmias during cardiac arrest. It is also an option for ventricular rate control in rapid atrial arrhythmias in patients with impaired left ventricular function when digitalis has proved ineffective. Other optional uses are for control of hemodynamically stable VT, polymorphic VT, preexcited atrial arrhythmias, and wide-complex tachycardia of uncertain origin. It may also be useful for chemical cardioversion of atrial fibrillation or as an adjunct to electric cardioversion of refractory paroxysmal supraventricular tachycardia (PSVT) and atrial fibrillation or flutter.

Administration in cardiac arrest (pulseless VT or VF) is by rapid IV infusion of 300 mg diluted in 20 to 30 mL of saline or D_5W. Supplementary infusions of 150 mg may be used for recurrent or refractory VT or VF.

Administration for rhythms with a pulse is by IV infusion of 150 mg given during 10 minutes, followed by infusion of 1 mg per minute for 6 hours and then 0.5 mg per minute. Supplemental infusions of 150 mg may be given for recurrent or resistant arrhythmias to a total maximum dose of 2 g during 24 hours.

Lidocaine

This antiarrhythmic agent has been used for ventricular arrhythmias, such as premature ventricular complexes and VT. Premature ventricular complexes are not unusual in apparently healthy people and most often are benign. Even in the patient with chronic heart disease, premature ventricular complexes and nonsustained VT are usually asymptomatic, and controversy exists concerning the need to treat under these circumstances. The situation is different for patients with myocardial ischemia or recent myocardial infarction, who are much more likely to progress from premature ventricular complexes to sustained VT or VF. There is some evidence for the efficacy of prophylactic lidocaine in reducing primary VF in patients with acute myocardial infarction. However, the toxic-to-therapeutic ratio is not favorable enough to warrant its routine use in patients with suspected acute myocardial infarction [90].

Administration of lidocaine begins with an IV bolus. The onset of action is rapid. Its duration of action is brief, but may be prolonged by continuous infusion. A solution of lidocaine, typically 20 mg per mL (2%), should be prepared for IV administration. Prefilled syringes are available for bolus injection (see the section "Ventricular Fibrillation and Pulseless Ventricular Tachycardia" for current dosing recommendations). If the patient has suffered an acute myocardial infarction and has had ventricular arrhythmias, the infusion is continued for hours to days and tapered slowly. If the cause of the arrhythmia has been corrected, the infusion may be tapered more rapidly.

Precautions should be taken against excessive accumulation of lidocaine. The dosage should be reduced in patients with low cardiac output, congestive failure, hepatic failure, and age older than 70 years because of the decreased liver metabolism of the drug. Toxic manifestations are usually neurologic, and can vary from slurred speech, tinnitus, sleepiness, and dysphoria to localizing neurologic symptoms. Frank seizures may occur with or without preceding neurologic symptoms and may be controlled with short-acting barbiturates or benzodiazepines. Conscious patients should be warned about possible symptoms of neurologic toxicity and asked to report them immediately if they occur. Enlisting the patient's aid may also allay the fear that could otherwise develop from unexpected neurologic symptoms. Excessive blood levels can significantly depress myocardial contractility.

Procainamide

Procainamide hydrochloride is an antiarrhythmic agent with quinidine-like activity. Like quinidine, it is useful in suppressing a wide variety of ventricular and supraventricular arrhythmias. It is effective against reentrant as well as ectopic arrhythmogenic mechanisms. It has somewhat less vagolytic effect than quinidine and does not cause the rise in digoxin level seen with quinidine. Procainamide is sometimes of use in the critical care setting for the suppression of ventricular arrhythmias not effectively treated by amiodarone or lidocaine or in patients who cannot be treated with either of these two agents. It may also be used in patients with supraventricular arrhythmias causing hemodynamic compromise or worsening ischemia.

Procainamide is administered either orally or by IV injection. For serious arrhythmias in the critical care setting, IV injection is preferable. An infusion of 20 mg per minute (0.3 mg per kg per minute) is given up to a loading dose of 17 mg per kg (1.2 g for a 70-kg patient) or until the arrhythmia is suppressed, hypotension develops, or the QRS widens by 50% of its original width. A maintenance infusion may then be started at 1 to 4 mg per minute. The dosage should be lowered in the presence of renal failure. Blood levels of procainamide and its metabolite *N*-acetylprocainamide should be monitored in patients with renal failure or patients who are receiving more than 3 mg per minute for more than 24 hours. Infusions as low as 1.4 mg per kg per hour may be needed in patients with renal insufficiency.

Precautions in the use of procainamide include its production of systemic hypotension, disturbance in AV conduction, and decreased ventricular contractility. IV infusion must be carefully monitored, with frequent blood pressure determinations and measurement of ECG intervals PR, QRS, and QT. Hypotension usually responds to slowing the infusion rate. If the QRS interval increases by more than 50% of its initial width, procainamide infusion should be discontinued. Widened QRS signifies toxic blood levels and may herald serious AV conduction abnormalities and asystole. This is particularly true of patients with digitalis intoxication and those with antecedent AV conduction abnormalities. A marked increase in QT interval may predispose a patient to torsades de pointes. Patients who have ventricular arrhythmias of the torsades variety or

ventricular arrhythmias associated with bradycardias should not be treated with procainamide.

Adenosine

Adenosine is an endogenous purine nucleoside that depresses AV nodal conduction and sinoatrial nodal activity. Because of the delay in AV nodal conduction, adenosine is effective in terminating arrhythmias that use the AV node in a reentrant circuit (e.g., PSVT) [91]. In supraventricular tachycardias, such as atrial flutter or atrial fibrillation, or atrial tachycardias that do not use the AV node in a reentrant circuit, blocking transmission through the AV node may prove helpful in clarifying the diagnosis [92,93]. However, the use of adenosine in wide-complex tachycardia of uncertain origin to discriminate between VT and supraventricular tachycardia with aberrancy is discouraged. The half-life of adenosine is less than 5 seconds because it is rapidly metabolized.

Administration is by IV bolus of 6 mg given during 1 to 3 seconds, followed by a 20-mL saline flush. An additional dose of 12 mg may be given if no effect is seen within 1 to 2 minutes. Patients taking theophylline may need higher doses.

Side effects caused by adenosine are transient and may include flushing, dyspnea, and angina-like chest pain (even in the absence of coronary disease). Sinus bradycardia and ventricular ectopy are common after terminating PSVT with adenosine, but the arrhythmias are typically short lived so as to be clinically unimportant. The reentrant tachycardia may recur after the effect of adenosine has dissipated and may require additional doses of adenosine or a longer acting drug, such as verapamil or diltiazem.

Theophylline and other methylxanthines, such as theobromine and caffeine, block the receptor responsible for adenosine's electrophysiologic effect; therefore, higher doses may be required in their presence. Dipyridamole and carbamazepine, on the other hand, potentiate and may prolong the effect of adenosine; therefore, other forms of therapy may be advisable.

Verapamil and Diltiazem

Unlike other calcium channel–blocking agents, verapamil and diltiazem increase refractoriness in the AV node and significantly slow conduction. This action may terminate reentrant tachycardias that use the AV node in the reentrant circuit (e.g., PSVT). These drugs may also slow the ventricular response in patients with atrial flutter or fibrillation and even in patients with multifocal atrial tachycardia. They should be used only in patients in whom the tachycardia is known to be supraventricular in origin.

Administration of verapamil is by IV bolus of 2.5 to 5.0 mg during 2 minutes. In the absence of a response, additional doses of 5 to 10 mg may be given at 15- to 30-minute intervals to a maximum of 20 mg. The maximum cumulative dose is 20 mg. Diltiazem may be given as an initial dose of 0.25 mg per kg with a follow-up dose of 0.35 mg per kg, if needed. A maintenance infusion of 5 to 15 mg per hour may be used to control the rate of ventricular response in atrial fibrillation.

Verapamil and diltiazem should be used for arrhythmias known to be supraventricular in origin and in the absence of preexcitation. Both verapamil and diltiazem may decrease myocardial contractility and worsen congestive heart failure or even provoke cardiogenic shock in patients with significant left ventricular dysfunction. They should, therefore, be used with caution in patients with known cardiac failure or suspected diminished cardiac reserve and in the elderly. If worsened failure or hypotension develops after the use of these agents, calcium should be administered, as described in the section "Other Agents."

Magnesium

Cardiac arrhythmias and even sudden cardiac death have been associated with magnesium deficiency [91]. Hypomagnesemia decreases the uptake of intracellular potassium and may precipitate VT or fibrillation. Routine use of magnesium in cardiac arrest or after myocardial infarction is not recommended. Magnesium may be of value for patients with torsades de pointes, even in the absence of hypomagnesemia.

Magnesium is administered IV. For rapid administration during VT or VF with suspected or documented hypomagnesemia, 1 to 2 g may be diluted in 100 mL of D_5W and given during 1 to 2 minutes. A 24-hour infusion of magnesium may be used for peri-infarction patients with documented hypomagnesemia. A loading dose of 1 to 2 g is diluted in 100 mL D_5W and slowly given during 5 minutes to 1 hour, followed by an infusion of 0.5 to 1 g per hour during the ensuing 24 hours. Clinical circumstances and the serum magnesium level dictate the rate and duration of the infusion. Hypotension or asystole may occur with rapid administration.

Other Agents

Additional drugs occasionally found useful or necessary during resuscitation or in the immediate postresuscitation period include atropine, calcium, nitroprusside, and nitroglycerine; these agents are discussed in the following sections. Many other drugs may be required in particular circumstances and are discussed in other parts of this text. An incomplete list of these drugs includes beta-blockers, ibutilide, propafenone, flecainide, sotalol, digoxin, antibiotics, thiamine, thyroxine, morphine, naloxone, adrenocorticoids, fibrinolytic agents, anticoagulants, antiplatelet agents, and dextrose.

Atropine Sulfate

Atropine is an anticholinergic drug that increases heart rate by stimulating pacers and facilitating AV conduction that is suppressed by excessive vagal tone.

Atropine is indicated primarily in bradycardias causing hemodynamic difficulty or associated with ventricular arrhythmias (see Fig. 23.17). Atropine may be useful in AV block at the nodal level. It is also used in asystole and bradycardic arrests in the hope that decreased vagal tone will allow the emergence of an effective pacemaker [57].

Atropine is administered by IV bolus. If a rapid, full vagolytic response is desired, as in asystole or bradycardic arrest, 1 mg should be administered IV at once. If a satisfactory response has not occurred within several (3 to 5) minutes, additional 1-mg doses should be given in a bolus, to a maximum dose of 3 mg (0.04 mg per kg). For bradycardia with a pulse, the initial dose should be 0.5 mg repeated every 5 minutes until the desired effect is obtained, to a maximum dose of 3 mg (0.04 mg per kg). Atropine may be given by the endotracheal route at doses 2.5 times the IV dose.

Precautions for atropine include the requirement that an inordinately rapid heart rate not be produced. Patients with ischemic heart disease are likely to have worsened ischemia or ventricular arrhythmias if the rate is too rapid. Uncommonly, a patient will have a paradoxic slowing of rate with atropine; this is more likely to occur with smaller first doses and is caused by a central vagal effect. This effect is rapidly counteracted by additional atropine. In this situation, the next dose of atropine should be given immediately. If additional atropine does not correct the problem, the patient may require judicious use of isoproterenol or pacemaker therapy.

Calcium

Calcium's positive inotropic effect has led to its use in cardiac arrest. The contractile state of the myocardium depends in part on the intracellular concentration of the calcium ion. Transmembrane calcium flux serves an important regulatory function in both active contraction and active relaxation. The use of calcium in cardiac arrest is based on an early report by Kay and Blalock [94] in which several pediatric cardiac surgical patients were successfully resuscitated, apparently with the aid of calcium. However, several field studies have failed to demonstrate an improvement in survival or neurologic outcome with the use of calcium versus a control [95]. In addition, after standard doses of calcium administered during cardiac arrest, many patients are found to have very high calcium blood levels [96]. This is apparently due to the markedly contracted volume of distribution of the ion in the arrested organism. In addition, calcium has the theoretic disadvantage of facilitating postanoxic tissue damage, especially in the brain and heart. Digitalis toxicity may be exacerbated by the administration of calcium.

Calcium is indicated only in those circumstances in which calcium has been shown to be of benefit [57]: calcium channel blocker toxicity, severe hyperkalemia, severe hypocalcemia, arrest after multiple transfusions with citrated blood, fluoride toxicity, and while coming off heart–lung bypass after cardioplegic arrest.

Calcium is available as calcium chloride, calcium gluceptate, and calcium gluconate. The gluconate salt is unstable and less frequently available. The chloride salt provides the most direct source of calcium ion and produces the most rapid effect. The gluceptate and gluconate salts require hepatic degradation to release the free calcium ion. Calcium chloride is, therefore, the best choice. It is highly irritating to tissues and must be injected into a large vein with precautions to avoid extravasation. Calcium chloride is available in a 10% solution. An initial dose of 250 to 500 mg may be administered slowly during several minutes. It may be repeated as necessary at 10-minute intervals if strong indications exist.

Precautions for calcium use include the need for slow injection without extravasation. If bicarbonate has been administered through the same line, it must be cleared before introducing the calcium. If the patient has a rhythm, rapid injection may result in bradycardia. Calcium salts must be used with caution in patients receiving digitalis.

Sodium Nitroprusside

This is a rapidly acting dilator of both arteries and veins. Systemic arterial dilatation decreases impedance to left ventricular outflow (afterload reduction), thereby diminishing resistance to left ventricular ejection and improving cardiac output. Venous dilatation simultaneously provides preload reduction by withholding blood from the central circulation and reducing left ventricular filling pressure and volume. Myocardial oxygen consumption drops and subendocardial blood flow may rise as the ventricular wall stress is lowered. In addition, the lowered left ventricular filling pressures cause a decrease in pulmonary capillary pressure and pulmonary congestion. Although vasodilators are most commonly used in the critical care unit, they are occasionally needed in the emergency room to aid in the stabilization of the resuscitated patient with severe left ventricular dysfunction.

Nitroprusside is indicated in any situation in which cardiac output is severely reduced, causing either cardiogenic shock with elevated systemic vascular resistance or pulmonary congestion from elevated left ventricular filling pressure. Patients with aortic or mitral regurgitation or a left-to-right shunt from a ventricular septal rupture are apt to respond well especially to nitroprusside infusion. Nitroprusside has also become a preferred treatment for patients in hypertensive crisis.

Nitroprusside is administered by IV infusion. The onset of action is rapid so that the effects of dose change become apparent within several minutes. For patients with severe left ventricular failure, infusion should begin at 10 μg per minute, with increments of 5 to 10 μg per minute at 5-minute intervals. Most patients respond to a total dose of 50 to 100 μg per minute, although an occasional patient requires a significantly higher dose. Patients in hypertensive crisis may be started at 50 μg per minute and may require as much as 400 to 1,000 μg per minute. Nitroprusside is available in 50-mg vials of dihydrate. The drug should be dissolved in 5 mL of D_5W and diluted to a volume of 250 to 1,000 mL in D_5W. Because of the instability of the reconstituted solution, it is recommended that it be used within 4 hours. The solution should be wrapped in opaque material because nitroprusside will deteriorate more rapidly with exposure to light.

Precautions for nitroprusside include hypotension, usually secondary to excessive dosage. Although most patients with hypotension cannot tolerate nitroprusside, some can be given nitroprusside with volume repletion. Nitroprusside is converted to cyanide in the blood, which is metabolized to thiocyanate by the liver. Thiocyanate is cleared by the kidney and can accumulate in renal failure. Signs and symptoms of thiocyanate toxicity (more likely in liver failure) include nausea, tinnitus, blurred vision, and delirium; signs of cyanide toxicity include elevated superior vena cava, or mixed venous oxygen saturation and a lactic acidosis. Nitroprusside should be discontinued if the latter two signs are observed.

Nitroglycerin

Like nitroprusside, nitroglycerin is a vasodilator that may prove to be useful in the emergency treatment of the postresuscitation patient. It may be given sublingually, transdermally, or IV, depending on the situation and desired dose. Unlike nitroprusside, nitroglycerin is a more potent dilator of venous capacitance vessels than of arterioles; therefore, it is more a preload reducer than an afterload reducer. Coronary dilatation does occur and may be particularly beneficial in patients with coronary spasm and acute ischemia. Myocardial ischemia is reversed through the lowering of preload and myocardial oxygen consumption as well as by coronary dilatation.

Sublingual or transdermal nitroglycerin is indicated for angina. The sublingual route is preferable. For persistent or frequently recurring ischemia unrelieved by other routes of administration, an infusion of nitroglycerin is often effective. It is useful for suspected coronary spasm. An infusion of nitroglycerin may also be used for preload reduction in patients with left ventricular failure. It may be given together with an infusion of nitroprusside, especially if ischemia has not been reversed by the hemodynamic effects of nitroprusside alone.

Nitroglycerin is administered by a sublingual tablet or spray (0.3 to 0.4 mg) or by a transdermal patch or ointment. For rapid effect, the sublingual route should be used. It may be repeated every 3 to 5 minutes, if pain relief or ST-segment deviation has not occurred. If ischemia persists, an infusion should be started and titrated to achieve the desired result. A 50-mg bolus of nitroglycerin may be given before the initiation of an IV drip. Two 20-mg vials may be diluted in 250 mL D_5W for a concentration of 160 μg per mL. The infusion is started at 10 to 20 mg per minute and increased by 5 to 10 μg every 5 to 10 minutes until the desired effect is achieved (e.g., fall in left ventricular pressure to 15 to 18 mm Hg, relief of chest pain, or return of ST segments to baseline). Although most patients respond to 50 to 200 μg per minute, an occasional patient will require 500 μg per minute or more; however, the maintenance of high plasma levels of nitroglycerin may induce

tolerance. *Whenever possible, intermittent dosing with nitrate-free periods is recommended, and the use of the lowest effective dose is advised.*

Precautions for nitroglycerin use include hypotension and syncope, especially if the patient has had an acute myocardial infarction, is volume depleted, has either restriction to left ventricular filling (e.g., pericardial constriction or tamponade, hypertrophic disease, mitral stenosis, pulmonic stenosis, or pulmonary hypertension) or obstruction to left ventricular outflow (e.g., aortic stenosis, pulmonic stenosis, or hypertrophic obstructive cardiomyopathy). Rapid titration of IV nitroglycerin in patients with left ventricular failure requires careful hemodynamic monitoring to ensure efficacy and safety. The hypotensive patient may be placed in the Trendelenburg position and given volume replacement. Rarely, a patient with severe obstructive coronary disease develops worsened ischemia with nitroglycerin through a coronary steal mechanism. If ischemia is persistent in spite of maximal tolerated nitroglycerin dose, attempts should be made to decrease the dose, and other modalities of therapy, including heparin or cardiac catheterization, should be considered with a view to early revascularization.

CLINICAL SETTINGS

The procedures involved in the resuscitation of a person who has experienced cardiovascular or respiratory collapse are all part of a continuum progressing from the initial recognition of the problem and the institution of CPR to intervention with defibrillators, drugs, pacemakers, transport, and postresuscitative evaluation and care (Figs. 23.14 to 23.17). The following sections focus on the pharmacologic and electric interventions appropriate to various clinical settings common in cardiac arrest.

Ventricular Fibrillation and Pulseless Ventricular Tachycardia

Electric defibrillation is the most important intervention in treating these arrhythmias (see Chapter 6). The sooner it is administered, the more likely it is to succeed. If a defibrillator is not immediately available and an adult cardiac arrest is witnessed, a precordial thump is recommended by some authors [97]; however, no recommendation for or against its use is made in the recent AHA guidelines [57]. Many witnessed arrests in the emergency room will be in monitored patients; the rescuer, however, must never rely solely on the monitored signal but must always confirm the need for CPR by determining the absence of a pulse. Quick-look paddles or pads should confirm the diagnosis of VF or VT and a countershock should be attempted (120 to 200 J for biphasic defibrillators and 360 J for monophasic defibrillators). CPR should be resumed without rechecking the rhythm or a pulse. After 2 minutes or about 5 cycles of CPR, the rhythm should be rechecked. If VF or VT is still present, another shock is applied at the same energy level. CPR is again resumed immediately, and if an IV line is

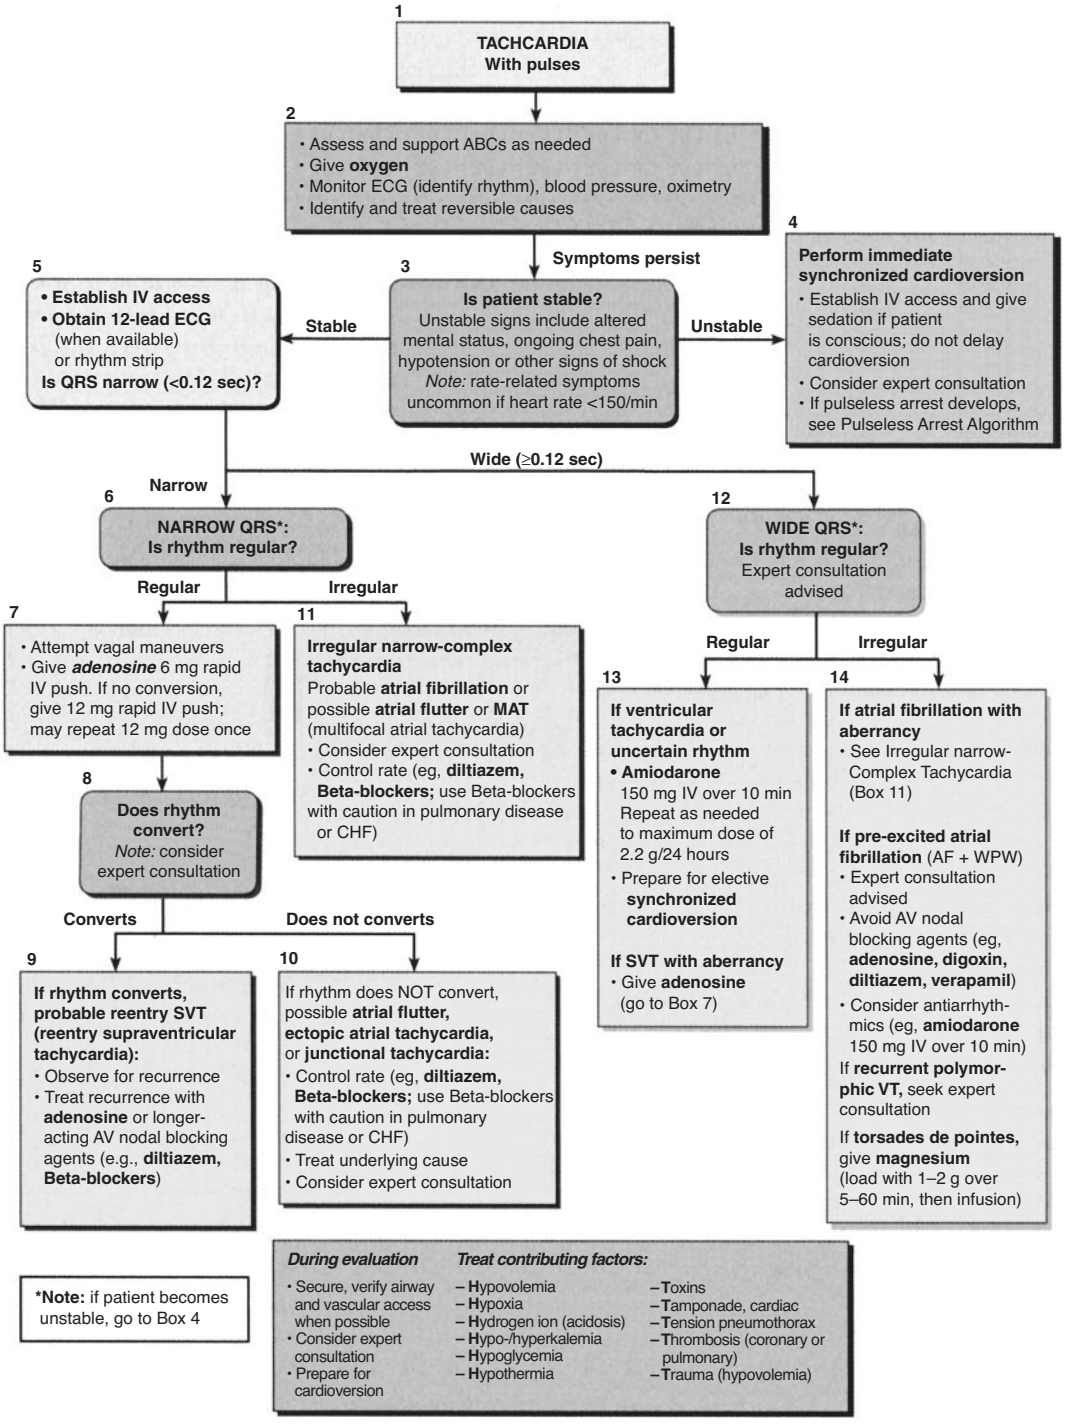

FIGURE 23.16. Advanced cardiac life support tachycardia algorithm. [From *Circulation* 112[Suppl 24]:IV-67–77, 2005, with permission. Copyright 2005, American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care.]

available, vasopressors (epinephrine, 1 mg IV, or IO every 3 to 5 minutes, or vasopressin 40 units, IV/IO) are administered. After another 5 cycles of CPR, the rhythm is checked again. If VF or VT is still present, another shock is applied.

After the second shock, if the patient remains in VF or VT, consideration should be given to the administration of an antiarrhythmic agent: amiodarone (300 mg IV/IO once with an additional dose of 150 mg IV/IO if necessary) or lidocaine (1.0 to 1.5 mg per kg IV/IO followed by additional doses of 0.5 to 0.75 mg per kg, if necessary, up to a total dose of 3 mg per kg).

Adequacy of ventilation should be assessed with an arterial blood gas determination, if possible. Sodium bicarbonate is of questionable value during cardiac arrest but should be administered if the patient is known to have preexisting hyperkalemia.

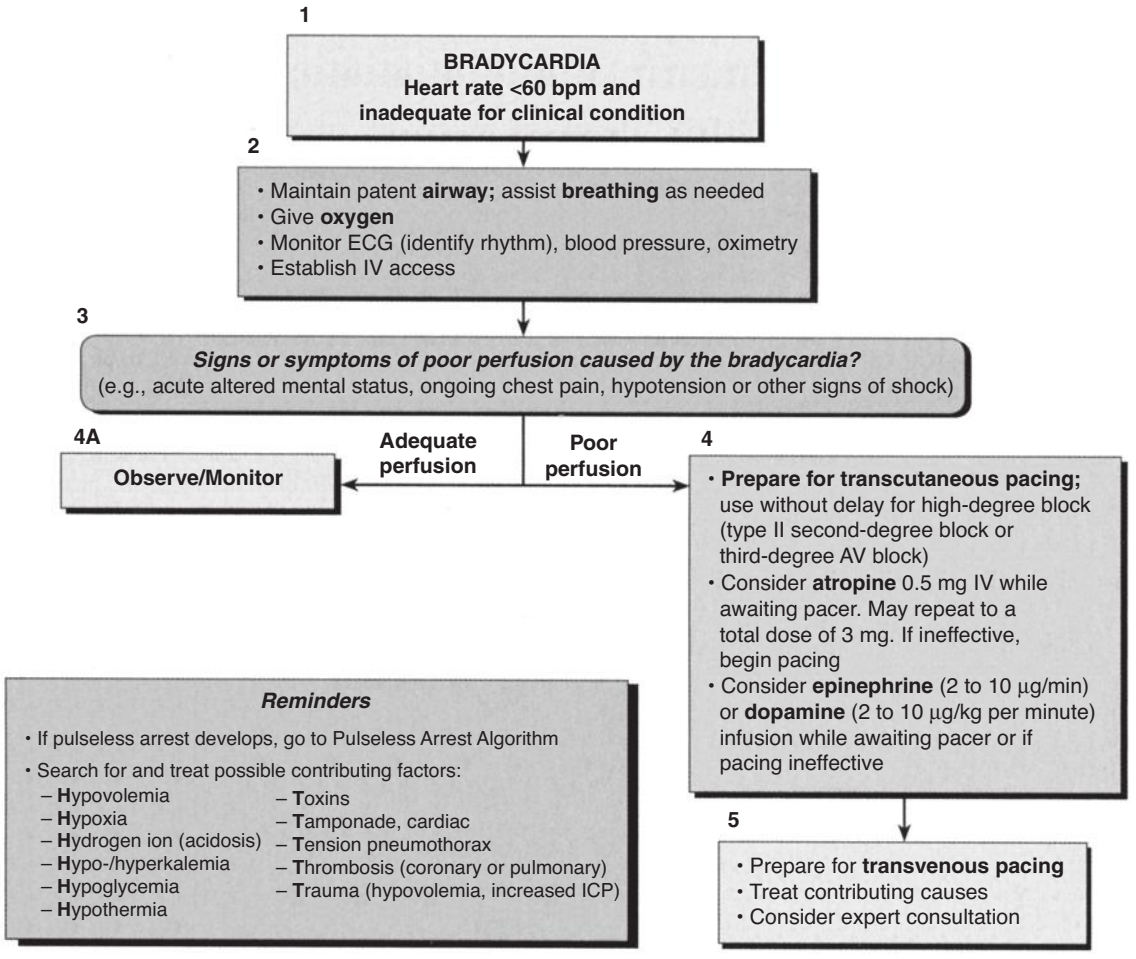

FIGURE 23.17. Bradycardia algorithm. [From *Circulation* 112[Suppl 24]:I-V-67–77, 2005, with permission. Copyright 2005, American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care.]

Asystole

Asystole is obviously the end result of any pulseless rhythm. When asystole is the presenting rhythm, it is often the termination of untreated VF. In the prehospital setting, many cases of asystole are related to delayed initiation of BLS or ACLS. Primary asystole associated with increased parasympathetic tone is less common, but does occur. Whether this rhythm occurs as the initial rhythm or follows on VT or fibrillation, it carries a very poor prognosis. Less than 1% to 2% of patients can be expected to revert successfully to a perfusing rhythm. Even more rarely will such patients leave the hospital with reasonable neurologic integrity or significant long-term survival; their best hope lies in the early discovery and treatment of a reversible cause for cardiovascular collapse, such as hypovolemia. Occasionally, asystole develops due to excessive vagal tone, such as is seen with induction of anesthesia, during surgical procedures, or with stimulation of the carotid body, bladder, biliary, or gastrointestinal tract. Unfortunately, most patients with asystole have severe coronary artery disease and are unlikely to be saved.

In patients with apparent asystole, CPR is initiated and an IV line is established as soon as possible (Fig. 23.15). Either epinephrine (1 mg IV/IO and repeated every 3 to 5 minutes) or vasopressin (1 dose of 40 U IV/IO to replace the first or second dose of epinephrine) is administered. Atropine at a dose of 1 mg IV/IO may also be considered. After 5 cycles of CPR, the rhythm is rechecked. If asystole persists, the aforementioned sequence is repeated.

It has been demonstrated that VF may masquerade as asystole in several leads and for minutes at a time [98]. It is therefore important to check at least two different lead configurations at 90-degree orientation to confirm the diagnosis of asystole. Routine shocking of asystole, however, is discouraged because of the possibility of increasing parasympathetic tone and thus decreasing further any chance of return of spontaneous rhythm. No improvement in survival has been demonstrated with the use of shocks for presumed asystole [99].

As in other forms of arrest, neither sodium bicarbonate nor calcium has been shown to be of benefit; these agents should be considered only under specific circumstances (see previous discussion).

Temporary artificial pacing is of no likely benefit in asystole—either primary or that following countershock. Pacing with endocardial, percutaneous transthoracic, or external transcutaneous electrodes has led to pitifully few long-term survivals in these cases.

The use of isoproterenol in an attempt to stimulate pacemakers through its β-adrenergic agonist effects has not proved to be beneficial. Indeed, its peripheral β-stimulation produces a decrease in arterial resistance and perfusion pressure that is

likely to be detrimental, whereas α-agonists seem to increase myocardial and cerebral perfusion.

Pulseless Electric Activity

PEA is present when an arrest patient is found to have organized ECG ventricular complexes (QRS) not associated with a palpable pulse (Fig. 23.15). Pulseless VT is not considered a form of PEA. Electromechanical dissociation is a form of PEA in which the QRS is unaccompanied by any evidence of ventricular contraction and the emergency response is the same. Bradyasystolic rhythms and severe wide-complex bradycardias may be considered along with PEA. These arrhythmias may be associated with specific clinical states that if reversed early, may lead to the return of a pulse. It is, therefore, best to consider them together. When PEA is encountered, severe hypovolemia, hypoxia, acidosis, hyperkalemia or hypokalemia, hypoglycemia, hypothermia, drug overdose, cardiac tamponade, massive pulmonary embolism, tension pneumothorax, and severe myocardial contractile dysfunction should be considered.

With the diagnosis of PEA, CPR is initiated and, as soon as possible, volume is administered in the form of IV crystalloid or colloid. If PEA is indeed caused by intravascular volume depletion, a fluid challenge may return a pulse. As described in the section "Asystole," vasopressors should be administered every 3 to 5 minutes if a pulse has not returned. In bradycardic PEA, atropine is given as in asystole. Bicarbonate is used for preexisting hyperkalemia and is acceptable for known preexisting bicarbonate-responsive acidosis, tricyclic overdose, to alkalinize the urine with other drug overdoses and in intubated and well-ventilated patients with prolonged arrest intervals.

In patients at high risk for pericardial effusions (i.e., patients hospitalized with known malignancy, severe renal failure, recent myocardial infarction, or recent cardiac catheterization), pericardiocentesis should be attempted early in the course of CPR if the patient is not responding to volume administration and α-agonists. In prehospital arrests, pericardial tamponade is rare, but an attempt at pericardiocentesis is warranted if there is no favorable response to volume or α-agonists. Echocardiography, when available, almost always confirms or excludes the possibility of tamponade and may be useful in delineating the volume status as well as the function of the ventricles.

Special Situations

Patients who have nearly drowned in cold water may recover after prolonged periods of submersion. Apparently, the hypothermia and bradycardia of the diving reflex may serve to protect against organ damage [100]. Successful resuscitation has been described after considerable periods of submersion [100]. Because it is often difficult for bystanders and rescuers to estimate the duration of submersion, in most cases it is warranted to initiate CPR at the scene, unless physical evidence exists of irreversible death, such as putrefaction or dependent rubor.

Hypothermia may occur with environmental exposures other than cold-water drowning. The body's ability to maintain temperature is diminished by alcohol, sedation, antidepressants, neurologic problems, and advanced age. Because of the associated bradycardia and oxygen-sparing effects, prolonged hypothermia and arrest may be tolerated with complete recovery. A longer period may be needed to establish breathlessness and pulselessness because of profound bradycardia and slowed respiratory rate. Resuscitative efforts should not be abandoned until near-normal temperature has been reestablished.

Electric shock and lightning strike may lead to tetanic spasm of respiratory muscles or convulsion, causing respiratory arrest. VF or asystole may occur from the electric shock or after prolonged respiratory arrest. Before initiating assessment and CPR, the potential rescuer must ascertain whether the person who has been shocked is still in contact with the electric energy and that live wires are not in dangerous proximity. If the individual is located at the top of a utility pole, CPR is best instituted after the person is lowered to the ground [101].

Open-chest CPR with thoracotomy should be applied early in cases of penetrating chest trauma associated with cardiac arrest (see previous discussion). In such patients, thoracotomy by trained personnel allows for the relief of pericardial tamponade and possible control of exsanguinating hemorrhage. Well-equipped trauma centers should have multidisciplinary teams that can provide early, definitive surgical treatment. The unanswered question is whether another subgroup of patients who have not responded to conventional ACLS techniques (including defibrillation attempts and drugs) would benefit from thoracotomy and open-chest CPR. Animal studies suggest that survival may be improved over closed-chest compression if open-chest CPR is used within the first 15 minutes of arrest [102]. If open-chest CPR is delayed until 20 minutes or more of closed-chest CPR, there is no improvement in outcome despite improved hemodynamics. In patients with out-of-hospital arrest in whom open-chest CPR was attempted after 30 minutes of conventional CPR, survival did not improve [103].

Open-chest CPR may also be indicated in blunt trauma with cardiac arrest and cardiac arrest due to hypothermia, pulmonary embolism, pericardial tamponade, or abdominal hemorrhage in which initiation of conventional therapy and closed-chest CPR is not proving effective. In the aforementioned cases, the decision to use open-chest CPR presupposes quick availability of definitive surgical intervention. Early surgical exploration is indicated in penetrating abdominal trauma with deterioration and cardiac arrest in which aortic cross-clamping may provide temporary control of abdominal hemorrhage.

Induced therapeutic hypothermia (32°C to 34°C) for 12 to 24 hours improves survival and neurologic outcome in comatose patients who have survived an out-of-hospital VF arrest [104,105]. Hypothermia may also be beneficial for in-hospital arrests. Lower cardiac index and hyperglycemia tend to occur more frequently in hypothermic patients. Shivering must be prevented to reduce metabolic rate. Please see Chapter 64 on hypothermia for an in-depth discussion of induced therapeutic hypothermia.

CHAPTER 24 ■ MANAGEMENT OF PAIN IN THE CRITICALLY ILL PATIENT

ARMAGAN DAGAL, MARIO DE PINTO AND W. THOMAS EDWARDS

Pain in critically ill patients should be systematically observed and regularly assessed. All means of analgesic interventions should be evaluated in a coordinated, individualized, and goal-oriented interdisciplinary manner.

Pain may stem from acute medical or surgical illness as well as preexisting medical conditions. Mechanical ventilation, placement of indwelling tubes and catheters, procedures performed such as placement of chest tubes, intracranial pressure (ICP) monitors, and turning and suctioning are also causes of pain [1,2]. Exposure to high levels of pain has negative psychologic and physiologic consequences, and its effective management is important in the maintenance of patient's dignity [3–5].

Despite numerous improvement initiatives over the past two decades, pain is very common and often not treated appropriately in critically ill patients. It is estimated that as many as 70% of patients experience moderate-intensity procedure-related or postoperative pain during their stay in the hospital intensive care unit (ICU) [6–9]. Pain is frequently treated inappropriately because of fears of depressing spontaneous ventilation, inducing opioid dependence, and precipitating cardiovascular instability. Moreover, many clinicians often poorly understand the methods for assessing pain, the techniques for optimally treating it, and the benefits of its effective management. State-of-the-art pain management means not only decreasing pain intensity, but also reducing analgesics' side effects, which may indeed facilitate patient recovery and is likely to shorten ICU and hospital stay [10–12]. Recent studies also suggest that effective acute pain management may help in reducing the development of chronic pain [13].

In 2005, the American Pain Society (APS) published the following guidelines for quality improvement in acute and cancer pain management [14]:

- Recognize, identify, and treat pain promptly.
- Involve patients and families in the pain management plan.
- Improve treatment patterns.
- Reassess and adjust the pain management plan as needed.
- Monitor processes and outcomes of pain management.

The primary goal of this structured approach to pain management was to prevent pain through the administration of analgesics at regular intervals and before performing potentially painful procedures.

Implementation of the APS guidelines in 120 postcardiac surgery patients over a 3-month period revealed that 95% of them had effective pain relief during every ICU staff shift for the first 6 days after surgery [15]. Data also revealed dramatically improved side-effect profile and reduced length of hospital stay. Implementation of a similar pain management protocol in a medical ICU resulted in a decrease in ventilator days (from 10.3 to 8.9) and significant reductions of average hospital costs.

ICU pain management strategies may also incorporate the application of regional analgesia techniques (neuraxial and peripheral nerve blocks) when possible. Regional analgesia, when used appropriately, helps reduce the total amount of opioid analgesics necessary to achieve adequate pain control and the development of potentially dangerous side effects.

EVALUATION OF PAIN

It is difficult to perform assessment of pain in the ICU. Structured approaches to pain assessment are mandatory for favorable patient outcome.

Pain assessment tools are useful to monitor for deterioration or improvements over time, and evaluate and titrate analgesic therapy appropriately [5,16].

There are several newly proposed methods available for pain assessment in the ICU. The chosen strategy should be adapted to the patient's capacity to interact with the practitioner in order to provide assessment of static (rest) and dynamic pain (while moving the affected part or while taking deep breaths or coughing).

Assessment of pain should include determining cause, type, intensity, duration, site, and prior response to therapy. Categorization of pain into somatic, visceral, neuropathic in nature, or identification of specific sites, such as focal bone pain as opposed to allodynia or diffuse bowel distention, is important because it helps in determining the most effective type of intervention.

In general, appropriate assessment of pain improves the overall quality of pain management.

Subjective Pain Assessment

The Visual Analog Scale (VAS) is a 10-cm horizontal line, anchored by textual descriptors and/or pictures at each end. An end-point descriptor such as "no pain" (a score of 0) is marked at the left end and "worst pain imaginable" (a score of 10) is marked at the right end.

The Numerical Rating Scale (NRS) is a horizontal line with a scale from 0 to 10. Patients are asked to choose a number that relates to their pain intensity, where 0 represents no pain and 10 the worst imaginable pain. The NRS can be administered verbally or visually.

The Faces Pain Scale (FPS) was first developed by Wong and Baker and is recommended for those aged 3 and older. An explanation is given to the patient that each face is a person who feels happy because he or she has no pain or sad because he or she has some or a lot of pain. The patient is then asked to choose the face that best describes how they feel from six possible options.

It has been shown that the NRSs have the least variance and may be the preferred tool overall. Mechanically ventilated and sedated patients will be unable to use the VAS ruler or other self-report pain assessment tools. Once sedation has ceased, some patients may be alert enough to use a VAS ruler. This should be attempted as an option for these patients. If psychomotor abilities are impaired at this point, an NRS or FPS may prove to be more helpful.

Objective Pain Assessment

When the patient is critically ill, sedated, and/or ventilated, pain severity can be estimated only by observing the behavioral and physiologic responses to pain:

- The Behavioral Pain Scale (BPS) is the earliest and most widely tested pain assessment tool for sedated patients. The BPS was developed by Payen et al. There are three component domains: "facial expression," "upper limb movement," and "compliance with ventilation." Patients are scored from 1 to 4 on each section, giving a total score between 3 (no pain) and 12 (maximum pain) [17].
- The Critical Care Pain Observation Tool (CPOT) was designed by Gelinas et al. The CPOT has four domains: "facial expression," "body movement," "muscle tension," and "compliance with ventilation." Patients are scored in each section between 0 and 2, giving an overall score of 0 (no pain) to 8 (maximum pain).
- The Non-Verbal Pain Scale (NVPS) was developed by Odhner et al. The NVPS incorporates three behavioral domains and two physiologic domains. The behavioral domains are "face," "activity (movement)," and "guarding." The first physiologic domain considers vital signs and the second incorporates other physiologic indicators including skin color and temperature, perspiration, and pupillary changes. Again, specific descriptors are given to enable the assessors to rate a patient's pain from 0 to 2 within each domain, giving a total pain score between 0 (no pain) and 10 (maximum pain).

None of these tools can be regarded as gold standard and they require further evaluation and research to investigate the impact of their use on pain management in clinical practice. Nonetheless, they offer a consistent and systematic approach that might improve pain management in ICUs.

Analgesic trials can be another assessment tool if pain is suspected in ICU patients. They involve administration of a low dose of an analgesic followed by observation of the patient's pain-related behavior [5,18].

FORMULATION OF A TREATMENT PLAN

It is important to understand the characteristics of the pathologic process responsible for pain in order to establish the most effective therapy.

Character and Site

Pain can be categorized as follows:

- *Nociceptive pain:* It occurs in response to a noxious stimulus and continues only in the presence of a persistent noxious

stimulus. It is transmitted through nonmyelinated C-sensory fibers and small myelinated A-fibers via the dorsal root ganglion and spinothalamic pathways in the spinal cord to the thalamus, periaqueductal gray, and other centers in the brain [19]. Nociceptive pain is often dull, aching, sharp, or tender.

- *Somatic pain:* It is due to nociceptive signals arising from the musculoskeletal system.
- *Visceral pain:* It is due to a disease process or abnormal function of an internal organ or its covering (parietal pleura, pericardium, and peritoneum). It can be frequently associated with nausea, vomiting, sweating, and changes in heart rate and blood pressure.

Inflammatory pain occurs in response to tissue injury and the subsequent inflammatory reaction. In order to help healing of the injured body part, the sensory nervous system undergoes a profound change as a result; normally innocuous stimuli now produce pain, and responses to noxious stimuli are both exaggerated and prolonged [20]. This is secondary to plasticity in nociceptors and central nociceptive pathways [21,22]. Ablation of a specific set of nociceptor neurons, such as the one expressing the tetrodotoxin-resistant sodium channel Nav1.8, eliminates inflammatory pain, but leaves neuropathic pain intact, indicating a fundamental difference in the neuronal pathways responsible for these pain states [23,24].

- *Neuropathic pain:* It can be burning, tingling, or electric in character. Patients with neuropathic pain may describe positive or negative neurologic phenomena. Positive phenomena include spontaneous pain (arising without stimulus) and evoked pains (abnormal response to stimulus). Negative phenomena include impaired sensation to touch or thermal stimuli. Neuropathic pain is initiated or caused by a primary lesion or dysfunction in the central or peripheral nervous system (CNS or PNS).

Central neuropathic pain most commonly results from spinal cord injury, stroke, or multiple sclerosis [25].

Peripheral neuropathic pain can be caused by [26] the following:

- Trauma (e.g., complex regional pain syndrome (CRPS) and chronic postsurgical pain)
- Infection (e.g., postherpetic neuralgia and HIV-induced neuropathy)
- Ischemia (e.g., diabetic neuropathy and central "poststroke" pain)
- Cancer (e.g., invasion and compression of peripheral nerve structures)
- Chemically induced (e.g., chemotherapy-induced neuropathy)

Neural damage to either the PNS or the CNS provokes maladaptive responses in nociceptive pathways that drive spontaneous pain and sensory amplification. This maladaptive plasticity leads to persistent changes and, therefore, needs to be considered a disease state of the nervous system in its own right, independent of the etiologic factor(s) that triggered it. Studies suggest that peripheral and central sensitization mechanisms are also involved. In the PNS, they include altered gene expression and changes in ion channels that lead to ectopic activity. In the CNS, the regulation of many genes also changes. In addition, synaptic facilitation and loss of inhibition at multiple levels of the neuraxis produce central amplification. Neuronal cell death and aberrant synaptic connectivity provide the structural basis for persistently altered processing of both nociceptive and innocuous afferent input. Highly organized neuroimmunologic interactions as a result of neural damage play an important part in the development of persistent neuropathic pain. Genetically determined susceptibility is also likely to unveil the risk of developing neuropathic pain [24].

Hyperalgesia (the lowering of pain threshold and an increased response to noxious stimuli), allodynia (the evocation of pain by non-noxious stimuli), hyperpathia (explosive pains evoked in areas with an increased sensory threshold when the stimulus exceeds the threshold), dysesthesia (spontaneous or evoked unpleasant abnormal sensation), and paresthesia (spontaneous or evoked abnormal sensation) are typical elements of neuropathic pain.

MEDICAL MANAGEMENT

Consequences of inadequate sedation and analgesia in the ICU may result in excessive pain and anxiety, agitation, self-removal of tubes and catheters, violence toward caregivers, myocardial ischemia, patient-ventilator asynchrony, hypoxemia, and pain-related immunosuppression. In contrast, excessive and/or prolonged sedation can lead to skin breakdown, nerve compression, delirium, unnecessary testing for altered mental status, prolonged mechanical ventilation and associated problems such as ventilator-associated pneumonia (VAP), and perhaps post-traumatic stress disorder (PTSD). Balanced treatment using both nonpharmacologic and pharmacologic methods are imperative for pain management in the ICU [27,28]. Improvement in quality of care results in a reduction of the time spent on mechanical ventilation and length of stay in the ICU.

Nonpharmacologic Treatments

Nonpharmacologic interventions are easy to provide, safe, and economical. They may include attention to proper positioning of patients to avoid pressure points, stabilization of fractures, and elimination of irritating physical stimulation (e.g., avoiding traction on the endotracheal tube).

Several mechanisms have been proposed to explain how to inhibit or modulate the ascending transmission of a noxious stimulus from the periphery or, conversely, to stimulate descending inhibitory control from the brain [29].

They include the following:

1. Gate control theory
2. "Busy-line" effect
3. Production of endogenous opioids at the periaqueductal gray, reticular activating system, and spinal gate
4. Activation of monoaminergic neurons in the thalamus, hypothalamus, and brain stem
5. Activation of second-order neurons in the dorsal horn, selective inhibition of abnormally hypersensitive neurons in the dorsal horn, and increased release of γ-aminobutyric acid (GABA) in spinal neurons
6. Descending inhibition from supraspinal centers via the pretectal zone and posterior columns

Stimulation-produced analgesia (SPA) is a term that describes noninvasive or minimally invasive techniques such as acupuncture, electroacupuncture (EA), transcutaneous electric nerve stimulation (TENS), acupressure and spinal cord stimulation (SCS), peripheral nerve stimulation (PNS), deep-brain stimulation, and motor cortex stimulation. Evidence suggests that these modalities are useful as a sole or supplementary analgesic technique for both acute and chronic painful conditions [29].

Peripherally applied heat causes local vasodilation that promotes circulatory removal of biomediators of pain from the site of injury, whereas cold application decreases the release of pain-inducing chemicals [30].

Modifications of the ICU environment, such as creating units with single rooms, decreasing noise, and providing music and appropriate lighting that better reflect a day–night

orientation [31], may help patients achieve normal sleep patterns and also improve pain control. For the cognitively intact ICU patients, provision of sensory and procedural information may improve their ability to cope with the discomfort.

Pharmacologic Treatments

The pharmacologic characteristics of the ideal analgesic medication include easy titration, rapid onset and offset of action without accumulation, and no side effects.

Nonsteroidal Anti-Inflammatory Drugs

Cyclooxygenase (COX) is located in all cells. It metabolizes arachidonic acid to generate prostaglandin H_2. A number of enzymes further modify this product to generate bioactive lipids (prostanoids) such as prostacyclin, thromboxane A_2, and prostaglandins D_2, E_2, and F_2. Three isoforms COX-1, COX-2, and COX-3 have been described. COX-1 is ubiquitous and constitutive. COX-2 is present in areas of inflammation and located in inflammatory cells. COX-3 is a splice variant, found centrally, and its inhibition is thought to be responsible for the action of acetaminophen [32].

It is now recognized that COX-2 is expressed in normal endothelial cells in response to shear stress and its inhibition is associated with suppression of prostacyclin synthesis. Inhibition of COX-2 results in prothrombotic inclination on endothelial surfaces and an increase in sodium and water retention, leading to edema, as well as exacerbations of heart failure and hypertension. Loss of the protective effects of COX-2 upregulation in the setting of myocardial ischemia and infarction leads to a larger infarct size, greater thinning of the left ventricular wall in the infarct zone, and an increased tendency to myocardial rupture [33,34].

Blockade of the proinflammatory mediators by nonsteroidal anti-inflammatory drugs (NSAIDs) reduces the inflammatory response (and subsequent pain). Classically, their effect is anti-inflammatory, analgesic, and antipyretic because of the direct inhibition of prostaglandin production. Adding NSAIDs to intravenous (IV) opioid-based patient-controlled analgesia (PCA) reduces opioid consumption by 30% to 50% and results in a significant reduction in the incidence of nausea, vomiting, and sedation [35].

On the other hand, the nonspecific blockade of COX inhibits the physiologic role of COX-1 and results in clinically significant deterioration of renal function and risk of development of peptic ulceration and upper gastrointestinal (GI) hemorrhage, bronchospasm, and platelet dysfunction. A meta-analysis published in 2002 showed that the risk of GI hemorrhage is related to the patient and drug-related factors, and is irrespective of the type of NSAID used. Patients who smoke, those with history of GI hemorrhage, and those taking anticoagulants are at increased risk [36].

Current evidence indicates that selective COX-2 inhibitors have important adverse cardiovascular effects that include increased risk for myocardial infarction, stroke, heart failure, and hypertension. The risk for these adverse effects is likely to be greatest in patients with a history of or at high risk for cardiovascular disease. In these patients, COX-2 inhibitors for pain relief should be used only if there are no alternatives and then only in the lowest dose and shortest duration necessary [37]. Currently, celecoxib is available for clinical use worldwide, whereas parecoxib is available only outside the United States.

Opioid-sparing properties of NSAIDs have not been studied in critically ill patients, so it is unclear if potential benefits outweigh potential risks such as GI bleeding or renal failure. Therefore, until more evidence for such agents becomes available, the clinician must carefully judge the risks and benefits on an individual basis.

Acetaminophen

Acetaminophen is an analgesic and antipyretic. It may also have anti-inflammatory properties. The mechanism of action of acetaminophen remains unknown. The greater sensitivity of cells containing COX-3 to acetaminophen is frequently cited as indicating that the target of action of acetaminophen is COX-3. Recent research indicates that acetaminophen inhibits prostaglandin synthesis in cells that have a low rate of synthesis and low levels of peroxide. When the levels of arachidonic acid are low, acetaminophen appears to be a selective COX-2 inhibitor. Acetaminophen has predominant effects on the CNS because the peroxide and arachidonic acid levels in the brain are lower than at peripheral sites of inflammation [38]. It is available in oral, rectal, and parenteral formulations. The parenteral formulation is not yet available in the United Sates although approval of the Food and Drug Administration (FDA) is pending. Acetaminophen is an effective adjuvant to opioid analgesia, and a reduction in opioid requirement by 20% to 30% can be achieved when combined with a regular regimen of oral or rectal acetaminophen.

It has been shown that 1 g of acetaminophen significantly reduces postoperative morphine consumption over a 6-hour period. Doses greater than 1,000 mg have been reported to have a superior effect when compared to lower doses. IV acetaminophen has been shown to reduce PCA morphine requirements after spinal surgery [39] and hip arthroplasty.

Its side-effect profile is comparable to placebo [40]; hypersensitivity reactions are rare. Major concerns with acetaminophen administration relate to the potential for hepatotoxicity, which, however, is extremely rare following therapeutic dosing [41]. In patients with severe liver disease, the elimination half-life can be prolonged. A reduced dose of 1 g three times a day with short duration of therapy is recommended. Prospective studies administering acetaminophen to patients consuming alcohol have found no increased evidence of liver injury [42]. In a recent study, nonallergic hypotension has been reported in a cohort of ICU patients on therapeutic doses of acetaminophen. The authors indicated brain injury and sepsis as the potential risk factors for this type of hypotensive reaction [43].

Opioids

For the critically ill patient, opioids remain the main pharmacologic method for the treatment of pain. Despite their extensive side-effect profile, there are no therapeutic alternatives available currently (Table 24.1).

Opiates refer to the nonpeptide synthetic morphine-like drugs while the term opioid is more generic, encompassing all substances that produce morphine-like actions. Opioids can be loosely divided into four groups:

- Naturally occurring, endogenously produced opioid peptides (e.g., dynorphin and Met-enkephalin)
- Opium alkaloids, such as morphine, purified from the poppy (*Papaver somniferum*)
- Semisynthetic opioids (modifications to the natural morphine structure) such as diacetylmorphine (heroin), hydromorphone, oxycodone, and oxymorphone
- Synthetic derivatives with structure unrelated to morphine, which include the phenylpiperidine series (e.g., pethidine and fentanyl), methadone series (e.g., methadone and dextropropoxyphene), benzomorphan series (e.g., pentazocine), and semisynthetic thebaine derivatives (e.g., etorphine and buprenorphine)

TABLE 24.1

GUIDELINES FOR FRONT-LOADING INTRAVENOUS ANALGESIA

Drug	Total front-load dose	Increments	Cautions
Morphine	0.08–0.12 mg/kg	0.03 mg/kg q 10 min	Bradycardia/hypotension (histamine) Nausea/vomiting Biliary colic Acute/chronic renal failure Elderly Bronchospasm
Methadone	0.08–0.12 mg/kg	0.03 mg/kg q 15 min	Accumulation/sedation Elderly
Hydromorphone	0.02 mg/kg	25–50 μg/kg q 10 min	Same as morphine Dosing errors
Fentanyl	1–3 μg/kg	0.5–2.00 μg/kg/h	Accumulation/sedation Elderly skeletal muscle rigidity
Remifentanil	0.25–1.00 μg/kg	0.05–2.00 μg/kg/min	Bradycardia/hypotension Pain on discontinuation Skeletal muscle rigidity
Ketamine	0.2–0.5 mg/kg	0.5–2.0 mg/kg/h	Delirium Increased ICP High myocardial O_2 requirement Hypotension Decreased CO

CO, cardiac output; ICP, intracranial pressure; q, every.

Snyder et al. in 1973 reported on the presence of specific binding sites for opioids, providing the first evidence of distinct receptors for opioids. There are several types of opioid receptors. They differ in their potency, selective antagonism, and stereospecificity of opiate action. With a recent addition, the opioid receptor subtypes are listed as μ (MOP), κ (KOP) and δ (DOP) and nociception/orphanin FQ (N/OFQ) peptide receptor (NOP).

Opioids bind to the CNS and peripheral tissue receptors. μ1-Receptors mediate analgesia, whereas μ2-receptor binding produces respiratory depression, nausea, vomiting, constipation, and euphoria. κ-Receptor activation causes sedation, miosis, and spinal analgesia. In addition to analgesia, opioid receptors may provide mild-to-moderate anxiolysis. Opioids have no reliable amnestic effect on patients. Opioid administration is associated with a dose-dependent, centrally mediated respiratory depression. The respiratory rate is reduced, whereas the tidal volume is initially preserved. The ventilatory response to hypoxia is eradicated and the CO_2–response curve is shifted to the right. Opioids facilitate patients' compliance to the ventilator due to their cough-suppressant effects. Despite minimal cardiovascular effects in normovolemic patients, they may generate hypotension via decreased sympathetic tone, and thus may decrease heart rate and systemic vascular resistance in critically ill patients. Additionally, opioids increase venous capacitance, thereby decreasing venous return. Hypotension clearly is more pronounced in hypovolemic patients.

Opioid-induced ileus is a common problem in critically ill patients.

Morphine

Morphine has poor lipid solubility and thus has a relatively slow onset of action (5 to 10 minutes). The standard IV dose is 5 to 10 mg and the approximate half-life is 3 hours. However, with repeated dosing or continuous infusions, half-life kinetics become unreliable. Morphine is conjugated by the liver to metabolites that include morphine-6-glucuronide, a potent metabolite with 20 times the activity of morphine. Both morphine and morphine-6-glucuronide are eliminated by the kidney; therefore, renal dysfunction results in a prolonged drug effect.

Morphine may also cause hypotension due to vasodilatation (secondary to the release of histamine).

Fentanyl

Fentanyl is highly lipid soluble with rapid onset of action (1 minute) and rapid redistribution into peripheral tissues, resulting in a short half-life (0.5 to 1.0 hour) after a single dose. The duration of action with small doses (50 to 100 μg) is short as a result of redistribution from the brain to other tissues. Larger or repeated doses, including the doses delivered via a continuous infusion, alter the context-sensitive half-time and result in drug accumulation and prolonged effects of the drug. The hepatic metabolism of fentanyl creates inactive metabolites that are renally excreted, making this drug a more attractive choice in patients with renal insufficiency. Fentanyl causes minor hemodynamic changes and does not affect inotropy.

Hydromorphone

Hydromorphone is a semisynthetic opioid that is five- to tenfold more potent than morphine, but with a similar duration of action. It has minimal hemodynamic effects, lacks a clinically significant active metabolite, and causes minor to no histamine release [44]. Recently published data (Chang et al.) suggest

that patients who received IV hydromorphone have a greater decrease in pain than those given an equianalgesic dose of IV morphine [45].

Methadone

Methadone is a synthetic opioid agent with properties similar to morphine. It can be given enterally and parenterally. Methadone is an attractive choice for opioid analgesia due to its long half-life and low cost. It produces *N*-methyl-D-aspartate (NMDA) antagonism, which makes it ideal for neuropathic pain. Although methadone is not the drug of choice for an acutely ill patient whose hospital course is rapidly changing, it is a good alternative for the patient who has preexisting opioid tolerance or prolonged ventilatory wean. It may help facilitate the tapering of opioid infusions [46,47]. Metabolized in the liver, 40% of the drug is eliminated from kidney and free from active metabolites. It does not accumulate in renal failure.

Oxycodone

Oxycodone is effective for postoperative pain management. It has a higher bioavailability and a slightly longer half-life than oral morphine. When transferring patients from parenteral morphine to oral oxycodone, the dose should be based on a 1:1.5 ratio (i.e., 1 mg IV morphine = 0.5 to 0.7 mg oral oxycodone). Individual patient variability and incomplete cross-tolerance requires careful titration [48].

The use of controlled-release oxycodone (OxyContin) is indicated for the treatment of moderate-to-severe pain when continuous analgesia is required for prolonged periods. The release of oxycodone from the OxyContin capsule is biphasic; there is a rapid initial absorption phase within 37 minutes followed by a slow absorption phase over 6.2 hours. Peak pain relief for OxyContin capsules occurs at approximately 1 hour and lasts for 12 hours, with peak plasma concentrations at 2 to 3 hours after administration.

Remifentanil

Remifentanil (a derivative of fentanyl) is a powerful analgesic with ultrashort duration of action. It is metabolized by nonspecific esterases to remifentanil acid, which has negligible activity in comparison. Its metabolism is independent from hepatorenal function. The context-sensitive half-time of remifentanil is consistently short (3.2 minutes), even after an infusion of long duration up to 72 hours [49].

In terms of safety, efficacy, and speed of onset and offset, remifentanil has been reported to have a better profile when compared to fentanyl [50]. When a morphine-based pain and sedation regimen was compared to another based on remifentanil, the mean duration of mechanical ventilation and extubation time were significantly shorter in the remifentanil group [51]. Breen et al. [52] compared a remifentanil-based analgesia–sedation regimen with a midazolam-based one, to which fentanyl or morphine could be added for analgesia, in a group of critically ill patients requiring prolonged mechanical ventilation for up to 10 days. The remifentanil-based sedation regimen was associated with significantly reduced duration of mechanical ventilation by more than 2 days.

Rozendaal et al. reported that in patients with anticipated short-term mechanical ventilation, a remifentanil–propofol analgesia–sedation regimen provides better control of sedation and agitation and reduces weaning time compared to conventional regimens. In addition, patients on a remifentanil–propofol-based regimen are almost twice as likely to be extubated and discharged from the ICU within the first 3 days of treatment than patients on conventional regimens [53].

In addition, remifentanil does not exert significantly prolonged clinical effects when it is administered to ICU patients with renal failure or chronic liver disease [49]. On the basis of these studies, it can be concluded that remifentanil is effective for providing both analgesia and sedation in critically ill patients, even those suffering from multiple organ failure. However, further data are needed to better guide clinicians on the use of this drug in ICU patients.

OPIOID SIDE EFFECTS

Opioid-related adverse effects occur commonly in the ICU [54].

Opioid-induced respiratory depression is generally dose related and is most deleterious for the spontaneously breathing ICU patients. Incidence of opioid-induced nausea and vomiting is low in the ICU. High-dose fentanyl may cause muscle rigidity. Opioid-induced hypotension occurs most commonly in patients who are hemodynamically unstable, are volume depleted, or have a high sympathetic tone. The use of morphine is associated with histamine release; therefore, hypotension, urticaria, pruritus, flushing, and bronchospasm are possible. Fentanyl can safely be used in patients with a suspected allergy to morphine. Excessive sedation from opioids is most often seen with the use of continuous infusions, particularly in patients with end-stage renal disease who are receiving fentanyl or morphine. Methadone may cause excessive sedation if the dose is not titrated downward after the first 5 days of therapy or if a human cytochrome P450 inhibitor is concomitantly administered. QTc-interval prolongation and the risk of development of torsades de pointes can occur with high doses of methadone because of its effects on the hERG channel, particularly if the chlorbutanol-containing IV formulation is used. Opioids may cause hallucinations, agitation, euphoria, sleep disturbances, and delirium [55]. Methadone may be the least likely drug to cause delirium because of its antagonistic activity at the NMDA receptor [56]. The effects of opioids on ICP in patients with traumatic brain injury remain unclear. Gastric retention and ileus are common in patients who are critically ill and receiving opioids, with prokinetic therapy and/or postpyloric access required in patients prescribed enteral nutrition. Prophylactic use of a stimulant laxative reduces the incidence of constipation. Methylnaltrexone, an opioid antagonist specific to peripheral receptors, may have a role in treating opioid-induced constipation that fails to respond to laxative therapy [57]. The possibility of developing an addiction problem in adult patients receiving long-term opioids is extremely low.

OPIOIDS ADMINISTRATION METHODS

Opioid analgesics administered by either continuous infusion or titration to effect provide better pain control and less drug-related adverse effects. "As needed" protocols make it difficult to achieve adequate analgesic plasma concentrations with resultant poor pain control.

When a continuous infusion is used, a sedation vacation protocol allows more effective analgesic titration with a lower total dose of opioid used. Daily awakening may also be associated with a shorter duration of ventilation and ICU stay. For patients in whom a long recovery and a prolonged ventilatory wean are anticipated, it is appropriate to use a long-acting

medication (e.g., methadone) to achieve adequate background pain control in combination with bolus doses of a short-acting opioid for management of breakthrough pain.

Conventional Routes of Administration (Oral, Intramuscular, and Subcutaneous)

Because of first-pass metabolism in the liver, larger doses of medications are required when oral preparations are used. Immediate-release oral opioids (e.g., morphine, oxycodone, and hydromorphone) are preferred because onset analgesia is obtained in 45 to 60 minutes. Fixed-interval dosing (e.g., every 4 hour) is preferable to a "when required" regimen to ensure adequate relief of moderate-to-severe pain.

The rectal route is rarely used in the ICU. Drugs absorbed from the lower half of the rectum bypass the portal vein and first-pass metabolism in the liver. Suppository formulations containing morphine, oxycodone, hydromorphone, and oxymorphone are available.

Intramuscular injections of opioids are useful if there is a lack of personnel trained to administer IV injections or if venous access is difficult. The intramuscular injection of morphine takes 30 to 60 minutes to be effective. Absorption of intramuscular opioids is variable and depends on the injection site, especially in the critically ill patients.

Subcutaneous injection via an indwelling cannula in the subcutaneous tissue of the upper outer aspect of the arm or thigh is a useful alternative route of administration. The rate of absorption of morphine after subcutaneous injection is similar to that of an intramuscular injection; therefore, the guidelines for titration are the same (Fig. 24.1).

Advanced Methods of Administration

The *IV route* is the preferred route of administration. There is less variability in blood levels when the IV route is used, making it easier to titrate the drug to effective analgesia concentration.

IV infusions are a commonly used method. An opioid infusion at a fixed rate takes five half-lives of the drug to reach 98% of a steady-state concentration. Therefore, a front-loading dose is needed to achieve adequate pain relief more rapidly before starting the infusion. If breakthrough pain occurs, more IV bolus doses may be needed to reestablish pain relief before the infusion rate is increased.

FIGURE 24.1. Several scales that can be useful for the evaluation of patient "self-reports" of pain before and after treatment. [From Stevens DS, Edwards WT: Management of pain in the critically ill. *J Intensive Care Med* 5:258, 1990, with permission.]

IV PCA allows the patient to self-administer a predetermined dose of opioid within the limits of a lockout period. This results in less variability in the blood levels of the drug, thereby enabling titration of the drug to effect [58].

The *epidural* and *intrathecal* routes of administration provide a more rapid analgesia due to the application of the drug directly within the CNS.

Patient-controlled epidural analgesia (PCEA) regimens allow better titration of the medication. In general, the analgesic efficacy of neuraxial opioids is greater than that achieved with parenteral opioid administration, resulting in superior pain relief despite the smaller doses used in the subarachnoid or epidural space (e.g., subarachnoid morphine 0.1 mg = epidural morphine 1 mg = IV morphine 10 mg). Opioid solutions with preservative-free formulations should be used for neuraxial administration to avoid potential neurotoxicity.

Highly lipid-soluble opioids (e.g., fentanyl and buprenorphine) have been formulated as a skin patch for transdermal delivery, especially in the management of severe pain in chronic and palliative care. Fentanyl patches are usually not a recommended modality for acute analgesia because of their 12- to 24-hour delay to peak effect and similar lag time to complete offset once the patch is removed. However, it is appropriate to continue its use in the ICU if the patient has a known history of using this formulation of the medication prior to admission.

Technological advances have led to the development of a transdermal delivery system that uses ionophoresis for the management of acute postoperative and post-trauma pain. This is a compact, self-contained, and self-adhesive system, which is applied to the patient's upper arm or chest. The system is preprogrammed and uses an imperceptible electric field to deliver 40 μg of fentanyl over 10 minutes and is unresponsive to additional dose requests during this time; patients can initiate up to 6 doses per hour for a 24-hour period or a maximum of 80 doses per system, whichever occurs first. Numerous trials have already demonstrated fentanyl iontophoretic transdermal system (ITS) to be better than placebo and therapeutically comparable with a standard morphine IV PCA. The pharmacokinetics is similar to those of IV fentanyl [59,60]. Its release waits completion of further clinical trials.

Other Drugs

Adjuvants are compounds which by themselves have undesirable side effects or low potency, but in combination with opioids, allow a reduction of opioid dosing for pain control.

Ketamine

Ketamine is a dissociative anesthetic also used for sedation. It possesses strong analgesic properties. It acts both centrally and peripherally by inhibition of glutamate activation via noncompetitive antagonism at the phencyclidine receptor of the NMDA channel. Nitric oxide (NO) synthase inhibition also contributes to its effects.

Water- and lipid-soluble characteristics of ketamine hydrochloride enable the IV, intramuscular, subcutaneous, epidural, oral, rectal, and transnasal routes of administration. It has a rapid onset and short duration of action [61]. Following metabolism in the liver, norketamine is produced, which is significantly less potent (20% to 30%) when compared to ketamine.

In subanesthetic or low doses (0.1 to 0.5 mg per kg IV), ketamine demonstrates significant analgesic efficacy without significant adverse pharmacologic effects. There is evidence that low-dose ketamine may play an important role in postoperative pain management when used as an adjunct to

opioids, local anesthetics, and other analgesic agents [62–64]. Administration of regular benzodiazepines should be considered to minimize the psychomimetic side effects associated with its use.

Subhypnotic doses of ketamine administered as infusions have been used for critically ill ICU patients who are very difficult to sedate with opioid and benzodiazepine infusions. Because of its potential adverse effects, ketamine is not recommended for routine sedation and analgesia of the critically ill patient, but it can be useful for more difficult situations and/or when short surgical procedures with intense pain, such as placement of chest tubes, dressing changes, and/or wound debridement in burn patients, are necessary.

α_2-Adrenergic Agonists

α_2-Adrenergic activation represents an intrinsic mechanism of pain control at the level of the CNS. α_2-Adrenergic receptors exist in large numbers in the substantia gelatinosa of the spinal cord dorsal horn in humans. Agonists produce their pain control effect on those receptors.

Clonidine

Clonidine produces analgesia after systemic, epidural, or intrathecal administration. It has a short duration of action after a single dose and may produce sedation, bradycardia, and hypotension. Clonidine improves opioid analgesia and potentiates the effect of local anesthetic [65,66].

Dexmedetomidine

Dexmedetomidine is a centrally acting α_2-agonist with sedative and analgesic properties. It has a much greater affinity for α_2-receptors than clonidine. The sedative properties are facilitated through the locus coeruleus in the CNS. Analgesic effects occur via activation of the α_2-receptors and through potentiation of the action of opioids [67]. The drug causes no significant effect on the respiratory drive even when used with opioids. Dexmedetomidine has a biphasic effect on the cardiovascular system. The initial bolus injection is associated with vasoconstrictive effects, causing bradycardia and hypertension. Continuous infusion is associated with hypotension secondary to vasodilation caused by central sympatholysis. Studies conducted in postoperative ICU patients demonstrated successful short-term sedation and analgesic sparing [68]. There are a few studies examining long-term administration to critically ill, mechanically ventilated patients with encouraging results [69]. Suggested dosing recommendation would be a loading dose of 1 μg per kg over 10 minutes followed by an infusion at a rate of 0.2 to 0.7 μg per kg per hour.

Anticonvulsants

Gabapentin and *pregabalin* are licensed for the management of neuropathic pain.

Despite its structural similarity to GABA, gabapentin does not bind to GABA receptors. It has a high affinity for α_2/δ-subunits of voltage-dependent calcium channels, resulting in postsynaptic inhibition of the calcium influx and thereby reducing the presynaptic excitatory neurotransmitter release [70]. It markedly decreases postoperative opioid consumption when given at the time of anesthetic induction [71]. Several randomized controlled trials (RCTs) using different pain models have shown a positive effect of the gabapentinoids on postoperative pain in humans. Single doses of gabapentin up to 1,200 mg have been shown to reduce pain scores and/or morphine consumption after abdominal and vaginal hysterectomy, lower limb arthroplasty, and laparoscopic cholecystectomy. Different meta-analyses have confirmed these effects, which persist for up to 24 hours after surgery [72]. Common side effects of these medications include dizziness and drowsiness, which should not limit its use in ICU. Gabapentin has minimal drug interactions.

Pregabalin has the same mechanism of action as that of gabapentin. It has higher efficacy due to its linear pharmacokinetics. In addition, pregabalin appears to have a faster onset of action, which is due in part to its smaller volume of distribution.

Perioperative gabapentinoids (gabapentin/pregabalin) reduce postoperative pain, opioid requirements, and the incidence of opioid-related adverse effects, but increase the risk of sedation.

REGIONAL ANALGESIA TECHNIQUES

Recent studies suggest that advances in perioperative anesthesia and analgesia improve pain relief, patient satisfaction, and outcome in surgical and trauma patients. Neuraxial anesthesia and peripheral nerve blockade have the potential to reduce or eliminate the physiologic stress response to surgery and trauma, decreasing the possibility of surgical complications and improving outcomes.

When used alone or in combination with other treatment modalities, regional analgesia techniques are an invaluable tool to address pain-related problems in critically ill patients, but the indications for their use must be established correctly. ICU patients are at risk for numerous complications and the use of an inappropriate regional analgesia technique can cause a deterioration of the patient's clinical status, affecting a potentially favorable outcome.

The purpose of this section is to discuss risk and benefits of neuraxial and peripheral nerve blockade for the management of pain in the critically ill patient.

General Considerations

The use of ultrasound (US) technology in regional anesthesia allows a easier and more reliable identification of neural structures, the safe administration of lower doses of local anesthetic, and the insertion of nerve catheters even in the heavily sedated ICU patients. Ultrasound-guided (USG) techniques have reduced misplacement and failure rates in clinical practice. Effective identification of the needle allows for the reduction of the amount of administered drug volumes, which may be of importance in the critically ill, children, and patients who need more than one block, especially for those who have undergone multisite surgery or sustained multitrauma [73].

Regional analgesia techniques also effectively block sympathetic outflow. Many studies show that surgically related stress is reduced when regional anesthesia and analgesia techniques are used, neuraxial techniques in particular. The use of neuraxial analgesia has also been reported to decrease the rate of postoperative myocardial infarctions, shorten postoperative and post-traumatic ileus, improve the outcome, and shorten the length of ICU stay [74].

The use of such techniques may also reduce the incidence of chronic pain in patients undergoing surgical procedures, such as limb amputations and thoracotomies, two procedures in

particular associated with the development of chronic persistent postsurgical pain [75].

Nerve Blocks for Thoracic and Abdominal Wall

Intercostal Nerve Blocks

Single and continuous intercostal nerve blocks are used to provide analgesia in patients with thoracic injuries and rib fractures and for the treatment of postoperative pain. Excellent pain relief and improvement in pulmonary mechanics have been reported [76].

Intercostal nerve blocks are associated with risk of pneumothorax and systemic local anesthetic toxicity. The patient's coagulation status must be checked to prevent the risk of bleeding and hematoma formation subsequent to the laceration of an intercostal vessel.

Continuous intercostal nerve blockade after thoracotomy using an extrapleural catheter consistently results in better pain relief and preservation of pulmonary function than the use of systemic opioids and appears to be at least as effective as the relief provided by the epidural approach. The ease of the extrapleural approach and the low incidence of complications suggest that this technique should be used more frequently. Other methods of intercostal nerve blockade appear to be less effective. The use of a multifaceted approach to postthoracotomy analgesia that includes intercostal nerve blockade has been shown to be beneficial in the immediate postoperative period, as well as reduce the incidence of chronic pain.

Major pulmonary resections, which have been managed with a minithoracotomy and intrapleural intercostal nerve blocks, have been shown to be associated with reduced postoperative pain and improved outcome. However, a recently published study in thoracotomy patients did not find a measurable difference in pain relief between intercostal catheters and epidural analgesia [77].

Although not frequently used, intercostal nerve blocks can be extremely useful in the ICU patient, especially when used as a single injection for painful procedures (e.g., placement of chest tubes), or as an infusion when the patient's hemodynamic conditions do not allow the use of thoracic epidural analgesia (TEA).

Paravertebral Block

Paravertebral nerve blocks (PVBs) provide analgesia for thoracic and upper abdominal pain. Paravertebral nerve blockade can be performed with a single injection or a continuous catheter technique [78]. Injection of contrast material into a paravertebral catheter shows flow of the dye laterally into the intercostal space, as well as up and down the ipsilateral paravertebral space, leading to the spreading of local anesthetics over several dermatomal levels.

The advantages of PVBs are similar to those of the intercostal nerve block technique. Analgesia can be obtained without widespread cardiovascular effects because only unilateral sympathetic blockade is produced.

Because the site of injection is medial to the scapula, this block is easier to perform at high thoracic levels than the intercostal nerve blocks. In contrast to routine intercostal blocks, the posterior primary ramus of the intercostal nerve is also covered with the paravertebral approach, providing analgesia of the posterior spinal muscles and the costovertebral ligaments.

Failure rate after PVB in adults varies from 6.1% to 10.7% and compares favorably with other regional procedures. In a prospective study of 319 adult patients, the incidence of complications after thoracic or lumbar PVB was reported to be as follows: hypotension 5%, vascular puncture 3.8%, pleural puncture 0.9%, and pneumothorax 0.3% [79,80].

Interpleural Analgesia

Interpleural blockade is a technique by which an amount of local anesthetic is injected into the thoracic cage between the parietal and visceral pleura to produce ipsilateral somatic block of multiple thoracic dermatomes. Local anesthetic solutions can be administered as single or intermittent boluses, or as continuous infusions via an indwelling interpleural catheter. It has been shown to provide safe, high-quality analgesia after cholecystectomy, thoracotomy, renal surgery, breast surgery, and some invasive radiologic procedures of the renal and hepatobiliary system. It has also been used successfully in the treatment of pain from multiple rib fractures, herpes zoster, CRPS, thoracic and abdominal cancer, and pancreatitis [80].

There are several methods proposed for the detection of the entry of the needle into the pleural space. All of them involve the detection of the "negative pressure" of the intrapleural space [81]. If a posterior approach is not possible, an anterior approach could be used. The catheter may also be positioned in the interpleural space under direct vision during surgery.

The risk of pneumothorax is 2%. The risk of systemic local anesthetic toxicity is 1.3%. Pleural inflammation increases the risk of toxicity. Interpleural blocks have no clinically significant adverse effect on respiratory muscle function; on the contrary, they are more likely to be beneficial in the presence of painful conditions compromising pulmonary function.

It has been suggested that local anesthetic solution diffuses outward with the interpleural technique blocking multiple intercostal nerves, the sympathetic chain of the head, neck and upper extremity, the brachial plexus, splanchnic nerves, the phrenic nerve, the celiac plexus, and ganglia. As the injected local anesthetic diffuses out through both layers of the pleura, direct local effects on the diaphragm, lung, pericardium, and peritoneum may also contribute to some of its analgesic activity [81].

Transversus Abdominis Plexus Block

Incisional pain represents a considerable portion of postoperative pain following abdominal operations. The abdominal wall consists of three muscle layers: external oblique, internal oblique, transversus abdominis, and their corresponding fascial sheaths. The skin, muscles, and parietal peritoneum of the anterior abdominal wall are innervated by the lower six thoracic nerves and the first lumbar nerve. The anterior primary rami of these nerves exit their respective intervertebral foramina and extend over the vertebral transverse process. They then pierce the musculature of the lateral abdominal wall to travel through a neurofascial plane between the internal oblique and transversus abdominis muscles.

Deposition of local anesthetic dorsal to the midaxillary line blocks both the lateral cutaneous branch and the lateral cutaneous afferents, thus facilitating blockade of the entire anterior abdominal wall. The transversus abdominis plane (TAP) thus provides a space into which local anesthetic can be deposited to achieve myocutaneous sensory blockade.

This regional technique has been shown to provide good postoperative analgesia for a variety of procedures involving the abdominal wall [82]. The use of a fine-gauge, blunt-tipped, short-bevel needle, and USG has been proposed to reduce the incidence of possible complications (intraperitoneal injection with bowel injury/hematoma, liver laceration, transient femoral nerve palsy, accidental intravascular injection, infection, and catheter breakage). In addition, with USG

techniques, upper and lower portions of the abdominal wall can be preferentially blocked [83].

Peripheral Nerve Blocks for the Upper Extremities

Severe trauma to the shoulders and arms is frequently present in acutely injured ICU patients. These injuries may be associated with blunt chest trauma requiring mechanical ventilation; they usually augment pain overall, especially during positioning [84]. If the orthopedic injury is part of a complex trauma with closed-head injury causing alterations of the mental status so that opioid-based analgesia regimens may mask the underlined neurologic condition, adequate analgesia can be provided with blocks of the brachial plexus.

Continuous brachial plexus blocks consistently provide superior analgesia with minimal side effects, promoting earlier hospital discharge and possibly improving rehabilitation after major surgery [85].

Peripheral nerve injury is a rare complication of regional anesthesia for the upper extremities. A large study from France reported 0.04% overall risk of a serious adverse event after peripheral nerve block [86]. Several retrospective studies reported the incidence to be between 0.5% and 1.0%, whereas prospective studies published higher incidence rates between 10% and 15% [87].

Current evidence suggests that peripheral nerve blocks should not be routinely performed in most adults during general anesthesia (GA) or heavy sedation especially when using the interscalene approach. However, the risk-to-benefit ratio of performing a peripheral nerve block under these conditions versus using high doses of opioids to maintain adequate analgesia should be carefully considered in select ICU patients [88].

Furthermore, the advent of USG techniques, in combination with injection pressure monitoring and electric nerve stimulation, may help to significantly minimize possible serious complications in heavily sedated patients with increased success rate and potential benefits overall.

Peripheral Nerve Blocks for the Lower Extremities

Lower extremity injuries are also commonly present in critically ill ICU patients.

Reid et al. recently conducted a study to compare the accuracy, success rates, and complications of USG femoral nerve blocks (FNBs) with the fascial pop (FP) technique in an emergency department. The result of this study favors the use of USG FNB. A similar study, conducted by Marhofer et al. has demonstrated a clear benefit in the use of US over a peripheral nerve stimulator when performing a three-in-one nerve block.

FNB is the preferred analgesic technique following injuries of the knee. Compared to epidural analgesia, it has a favorable morbidity profile, it allows early mobilization, and there is no need for urinary catheterization. In addition, with USG, the technique is simple and easy to perform compared to the epidural blocks [89]. FNB and catheters are helpful in the management of acute pain following femoral fractures as well as after surgical stabilization [90].

Easy visualization of the sciatic nerve proximal to the popliteal fossa, before it divides into common peroneal nerve medially and tibial nerve laterally with USG, makes the lateral approach to the sciatic nerve an ideal approach for management of pain secondary to distal tibia, ankle, and foot fractures [91]. This block can be conveniently performed in the supine position and enables more secure placement of a peripheral nerve catheter with high success rate.

Epidural Analgesia

Epidural analgesia is the most frequently used regional anesthesia technique in the ICU [92] and has been reported to provide better pain relief than parenteral opioid administration [93]. However, literature data report conflicting evidence regarding reduction of mortality with the use of epidural analgesia. The largest meta-analysis (CORTRA) [74] to date and analysis of the Medicare claims database [94] indicate a reduction in perioperative mortality with perioperative neuraxial anesthesia. Procedure-specific meta-analyses and specific RCTs, however, have not demonstrated benefit from epidural anesthesia and analgesia regarding reduction in mortality. It is important to note that these specific meta-analyses and individual RCTs lack sufficient sample size due to the relatively low incidence of mortality (0.2% to 5%) overall [95].

A meta-analysis of more than 5,000 surgical patients [96] has shown that postoperative epidural analgesia reduces the time to extubation, length of ICU stay, incidence of renal failure, morphine consumption during the first 24 hours, and maximal glucose and cortisol blood concentrations, and improves forced vital capacity. Many of these benefits may be relevant to ICU patients; they have been demonstrated to be actually beneficial in cardiac surgery [97] and thoracic trauma patients [98], as well as patients with severe acute pancreatitis [99].

Whether sepsis, with or without positive blood cultures, should be an absolute contraindication for the use of epidural analgesia is still a matter of debate [100]. In patients with ischemic heart disease, high thoracic epidural analgesia (HTEA) has been shown to improve systolic and diastolic myocardial function [101]. Furthermore, Ferguson et al. have concluded, in a recently published prospective randomized trial, that PCEA offers superior postoperative pain control after laparotomy for gynecologic surgery compared to traditional IV PCA [102].

TEA exerts a remarkable influence on the cardiovascular system. It reduces the risk of perioperative dysrhythmias except postoperative atrial fibrillation. In cardiac surgical patients, with improved left ventricular function, the left ventricular global and regional wall motions are better preserved. TEA has been associated with a reduction of cardiac oxygen consumption without jeopardizing coronary perfusion pressure with an increase of the diameter of stenotic coronary segments. As a result, TEA reduces the overall incidence of myocardial infarction. It produces functional hypovolemia by inhibiting the vasoconstrictor sympathetic outflow; moreover, it interferes with the integrity of renin–angiotensin system, but increments vasopressin plasma concentration. Despite causing hypotension, TEA has a beneficial outcome during hemorrhagic shock [103].

Issues of consent, coagulopathy, and infection can be addressed easily in elective conditions; they become a major problem in patients with multiple trauma or extremely painful conditions (e.g., acute pancreatitis).

A study published in Sweden reports the risk of hematoma to be 1.3 to 2.7 per 100,000 [104]. The current recommendations of the American Society of Regional Anesthesia should be followed [105].

Placing epidural catheters safely and confirming the presence of an adequate sensory block can be difficult in critically ill, sedated, and anesthetized patients. Awake and cooperative patients usually facilitate the placement of an epidural catheter, minimizing the possibility of undesirable complications. Current recommendations suggest that the possibility to miss systemic local anesthetic toxicity under GA or heavy sedation is

not a valid reason not to perform a neuraxial block in this group of patients. However, neuraxial regional anesthesia should be performed rarely in patients whose sensorium is compromised by GA or heavy sedation [88]. The overall risk of neuraxial anesthesia should be weighed against its expected benefit.

Positioning the patient for the procedure may also represent a challenge depending on the underlying injury and the number and position of tubes, catheters, or external fixation devices present. Strict asepsis should always be maintained for neuroaxial procedures.

Bolus injections of long-acting local anesthetics, such as bupivacaine and ropivacaine, or the discontinuation of continuous infusions every morning can help neurologic and sensory assessment.

The most common side effects of thoracic epidural blocks are bradycardia and hypotension related to sympathetic block; this can be more pronounced with intermittent bolus dosing in patients with hypovolemia or shock. Continuous low-rate local anesthetic and/or opioid (morphine) infusions can be safely used in this particular clinical setting.

Currently, sepsis and bacteremia are considered contraindications to neuraxial blockade. Fever and increased white blood cell count alone in the absence of positive blood cultures do not provide a reliable diagnosis of bacteremia. High levels of the serum markers C-reactive protein, procalcitonin, and interleukin-6/8 have been shown to indicate bacterial sepsis with a high degree of sensitivity and specificity and can guide the decision as to whether or not to place an epidural catheter [106].

Because high-risk patients seem to profit most from epidural analgesia and the current literature does not address the specific problem of the critically ill patient with multiple comorbidities and organ failure, logic suggests that in carefully selected and closely monitored patients epidural analgesia may have significant benefits. Further research is needed before clear recommendations can be made.

INFLUENCE OF PAIN MANAGEMENT ON COMPLICATIONS, OUTCOME, LENGTH OF HOSPITAL STAY, AND CHRONIC PAIN

Pain leads to development of increased catabolism, immunosuppression, and prolonged sympathetic response as a result of the combination of tissue injury and pain that leads to increased morbidity and mortality. These effects can be subclassified as follows.

Cardiovascular Effects

- Increased heart rate
- Increased blood pressure
- Increased stroke volume
- Increased myocardial O_2 demands and reduced supply leading to myocardial ischemia

Respiratory Effects

- Stimulation of respiration causing initial hypocapnia and respiratory alkalosis
- Diaphragmatic splinting and hypoventilation, atelectasis, hypoxia, and hypercapnia
- Development of chest infection

Endocrine Effects

- Catabolic and anabolic changes
- Decrease in insulin production
- Reduction in testosterone level
- Fluid retention

Metabolic Effects

- Raised blood sugar level

Gastrointestinal effects

- Delayed gastric emptying
- Nausea
- Reduced GI motility and ileus

Coagulation

- Immobility
- Increased blood viscosity
- Hypercoagulability and deep vein thrombosis (DVT)

A meta-analysis published in the year 2000 has concluded that epidural analgesia prevents postoperative major complications and may decrease postoperative mortality [74]. Other studies have reported that epidural anesthesia may selectively prevent the occurrence of respiratory and cardiovascular complications [107–109].

Recent prospective trials, including a significant number of patients, have failed to confirm the beneficial effect of epidural anesthesia on postoperative morbidity and mortality after major abdominal or orthopedic surgery. Such a discrepancy is thought to be the result of improved postoperative medical care. As an example, previously reported 50% reduction in DVT with epidural analgesia is no longer a valid criterion due to the recent introduction of low-molecular-weight heparin (LMWH) for management of DVT prophylaxis, which decreases the risk by more than 80%. Similarly, the use of prophylactic antibiotics and aggressive physiotherapy significantly reduces the postoperative pulmonary complications, and the preventive effect of epidural analgesia on chest infections has become less important.

Consequently, there is no significant evidence to consider epidural analgesia beneficial for the prevention of morbidity, but as part of a multimodal pain management process, it may facilitate recovery from surgery. The superior quality of pain relief provided by epidural analgesia combined with parenteral analgesia does indeed have a positive impact on mobilization, bowel function, and early food intake that results in a significant improvement in postoperative quality of life [110]. In orthopedic surgery, regional analgesia may provide a functional benefit, allowing better patient involvement with physical therapy and shorter recovery.

Hebl et al. [111] have published their findings on the improvements in perioperative outcomes following peripheral nerve block after major orthopedic surgery. These include significantly shorter hospital stay, earlier ambulation, improved joint range of motion, lower perioperative pain scores, and a reduction in postoperative nausea and vomiting when compared with patients treated with traditional postoperative IV opioids (PCA). These patients also had significantly lower opioid requirements when compared with controls, as well as significant reduction in urinary retention and postoperative ileus [111].

Although the risk factors are difficult to identify, patients who experience severe pain and, above all, persistence of

postoperative pain several days after the expected duration are prone to develop chronic pain.

Postoperative chronic pain is defined as persisting pain, without relapse or pain-free interval, 2 months after the surgical insult. Chronic pain syndromes have been described commonly after breast surgery, inguinal hernia repair, cholecystectomy, thoracic surgery, cardiac surgery, and limb or organ amputation. Its incidence has been recorded to be up to 60% [112]. With such a high incidence, it is very important to provide good postoperative and post-trauma pain control to prevent the occurrence of chronic pain syndromes.

CONCLUSIONS

Pain control in critically ill patients is of paramount importance. Achieving adequate levels of analgesia in trauma and surgery patients decreases the stress response and improves morbidity and mortality.

Individual units and acute pain teams should employ pain assessment techniques for patients with cognition impairment.

Lack of education, fear of possible side effects, and inappropriate use of medications contribute to the ineffective treatment of pain in critically ill ICU patients. The expertise of pain management specialists and anesthesiologists is often necessary for the management of these complex situations.

Choosing the treatment plan that best fits the patient's clinical conditions is mandatory. A potentially favorable outcome can be altered if inappropriate pain modalities are chosen and used.

A rational multimodal approach including the use of nonpharmacologic, pharmacologic, and regional analgesia techniques is desirable and often needed. The continued use of these techniques extended into the postoperative period may shorten recovery time and speed discharge.

Always assess and monitor the effects of a treatment modality on the patient's pain and clinical conditions as well. Be prepared to make changes in therapy as needed.

Regional analgesia techniques (epidural and peripheral nerve blockade), although proved to be safe and effective, are underused in the management of pain in critically ill patients. They allow a decrease in the overall use of opioid analgesics and sedatives and reduce the possibility of developing potentially dangerous side effects. A correct indication, as well as an appropriate timing for their use, is required in order to increase their beneficial effects.

The availability of new technologies (e.g., ultrasonography) improves the quality and safety of upper and lower extremity peripheral nerve blocks even in heavily sedated ICU patients.

CHAPTER 25 ■ THERAPEUTIC PARALYSIS

KHALDOUN FARIS

The most common indications for the use of neuromuscular blocking agents (NMBAs) in the intensive care unit (ICU) include emergency or elective intubations, optimization of patient–ventilator synchrony, management of increased intracranial pressure, reduction of oxygen consumption, and treatment of muscle spasms associated with tetanus. According to the American College of Critical Care Medicine and the Society of Critical Care Medicine clinical practice guidelines for sustained neuromuscular blockade in the adult critically ill patient, these medications should be used only when all other means of optimizing a patient's condition have been used. This recommendation is based on the concern that the administration of NMBAs may worsen patient outcome when administered during a course of critical illness, particularly if the patient is receiving systemic steroids at the same time [1]. In a recent international multicenter trial, 13% of patients on mechanical ventilation received NMBAs for at least 1 day, which was associated with a longer duration of mechanical ventilation, longer weaning time and stay in the ICU, and higher mortality [2].

In addition to the pharmacology of the most commonly administered agents, we briefly review the biology of the neuromuscular junction (NMJ), its alterations during the course of critical illness, and the resulting implications for the use of depolarizing and nondepolarizing NMBAs. Recommendations for administration of NMBAs to ICU patients on based on available evidence are provided.

PHARMACOLOGY OF NMBAS

The NMJ consists of the motor nerve terminus, acetylcholine (ACh), and muscle end plate. In response to neuronal action potentials, ACh is released from presynaptic axonal storage vesicles into the synapse of the NMJ. Both the presynaptic membrane and the postsynaptic end plate contain specialized nicotinic ACh receptors (nAChRs). The chemical signal is converted into an electric signal by binding of two ACh molecules to the receptor ($\alpha\delta$- and $\alpha\varepsilon$-subunits), causing a transient influx of sodium and calcium, and efflux of potassium from muscle cells. This depolarization propagates an action potential that results in a muscle contraction. Unbound ACh is quickly hydrolyzed in the synapse by the enzyme acetylcholinesterase to acetic acid and choline, thus effectively controlling the duration of receptor activation. A repolarization of the motor end plate and muscle fiber then occurs.

THE NICOTINIC ACETYLCHOLINE RECEPTOR

The nAChR is built of five subunit proteins, forming an ion channel. This ionic channel mediates neurotransmission at the NMJ, autonomic ganglia, spinal cord, and brain. During early development, differentiation and maturation of the NMJ and transformation of the nAChR take place: fetal nAChRs gradually disappear with a rise of new, functionally distinct, mature nAChRs.

These mature nAChRs (also termed *adult*, *innervated*, ε-*containing*) have a subunit composition of two α, β, ε, *and* δ in the synaptic muscle membrane. The only structural difference from the fetal nAChR is in substitution of the γ for the ε-subunit, although functional, pharmacologic, and metabolic characteristics are quite distinct. Mature nAChRs have a shorter burst duration and a higher conductance to Na^+, K^+, and Ca^{2+} and are metabolically stable with a half-life averaging about 2 weeks. The two α-, β-, δ-, and ε/γ-subunits interact to form a channel and an extracellular binding site for ACh and other mediators as well. As mentioned previously,

simultaneous binding of two ACh molecules to $\alpha\delta$- and $\alpha\varepsilon$-subunits of an nAChR initiates opening of the channel and a flow of cations down their electrochemical gradient. In the absence of ACh or other mediators, the stable closed state (a major function of ε/γ-subunits) normally precludes channel opening [3].

Adult skeletal muscle retains the ability to synthesize not only adult, but also fetal (often called *immature* or *extrajunctional*)-type nAChRs. The synthesis of fetal nAChRs may be triggered in response to altered neuronal input, such as loss of nerve function or prolonged immobility, or in the presence of certain disease states. The major difference between fetal- and adult-type nAChRs is that fetal receptors migrate across the entire membrane surface and adult ones are mostly confined to the muscle end plate. In addition, these fetal nAChRs have a much shorter half-life, are more ionically active with prolonged open channel time that exaggerates the K^+ efflux, and are much more sensitive to depolarizing agents such as succinylcholine and resistant to nondepolarizing neuromuscular blockers.

The functional difference between depolarizing and nondepolarizing neuromuscular blockers lies in their interaction with AChRs. Depolarizing neuromuscular blockers are structurally similar to ACh and bind to and activate AChRs. Nondepolarizing neuromuscular blockers are competitive antagonists.

DEPOLARIZING NEUROMUSCULAR BLOCKERS

Succinylcholine is the only depolarizing neuromuscular blocker in clinical use. Its use is limited to facilitating rapid-sequence intubation in the emergency setting. Succinylcholine mimics the effects of ACh by binding to the ACh receptor and inducing a persistent depolarization of the muscle fiber. Muscle contraction remains inhibited until succinylcholine diffuses away from the motor end plate and is metabolized by serum (pseudo-) cholinesterase [4]. The clinical effect of succinylcholine is a brief excitatory period, with muscular fasciculations followed by neuromuscular blockade and flaccid paralysis. The intravenous dose of succinylcholine is 1 to 1.5 mg per kg and offers the most rapid onset of action (60 to 90 seconds) of the NMBAs. Recovery to 90% muscle strength after an intravenous dose of 1 mg per kg takes from 9 to 13 minutes. Succinylcholine is also suitable for intramuscular administration, most frequently for the treatment of laryngospasm in pediatric patients without intravenous access; however, there are several limitations. First, the required dose is higher (4 mg per kg) and time to maximum twitch depression is significantly longer (approximately 4 minutes). Second, the duration of action of succinylcholine after intramuscular injection is prolonged.

Potential adverse drug events associated with succinylcholine include hypertension, arrhythmias, increased intracranial and intraocular pressure, hyperkalemia, malignant hyperthermia, myalgias, and prolonged paralysis. Neuromuscular blockade can persist for hours in patients with genetic variants of pseudocholinesterase isoenzymes [5]. Contraindications to succinylcholine use include major thermal burns, significant crush injuries, spinal cord transection, malignant hyperthermia, and upper or lower motor neuron lesions. Caution is also advised in patients with open-globe injuries, renal failure, serious infections, and near-drowning victims [6].

NONDEPOLARIZING NMBAS

Nondepolarizing NMBAs function as competitive antagonists and inhibit ACh binding to postsynaptic nAChRs on the motor end plate. They are categorized into two classes on the basis of chemical structure: benzylisoquinoliniums and aminosteroids. Within each of these classes, the therapeutic agents may further be categorized as short-acting, intermediate-acting, or long-acting agents. The benzylisoquinolinium agents commonly used in the critical care setting include atracurium, cisatracurium, and doxacurium, whereas the aminosteroid agents include vecuronium, rocuronium, pancuronium, and pipecuronium.

The nondepolarizing NMBAs are administered by the intravenous route and have volumes of distribution (V_ds) ranging from 0.2 to 0.3 L per kg in adults.

A clinical relationship exists between the time to onset of paralysis and neuromuscular blocker dosing, drug distribution, and ACh-receptor sensitivity. An important factor to consider is V_d, which may change as a result of disease processes. Cirrhotic liver disease and chronic renal failure often result in an increased V_d and decreased plasma concentration for a given dose of water-soluble drugs. However, drugs dependent on renal or hepatic excretion may have a prolonged clinical effect. Therefore, a larger initial dose but smaller maintenance dose may be appropriate.

Alterations in V_d affect both peak neuromuscular blocker serum concentrations and time to paralysis. The pharmacokinetic and pharmacodynamic principles of commonly used NMBAs are summarized in Table 25.1.

Atracurium

Atracurium is an intermediate-acting nondepolarizing agent. Neuromuscular paralysis typically occurs between 3 and 5 minutes and lasts for 25 to 35 minutes after an initial bolus dose. Atracurium undergoes ester hydrolysis as well as Hofmann degradation, a nonenzymatic breakdown process that occurs at physiologic pH and body temperature, independent of renal or hepatic function. Renal and hepatic dysfunction should not affect the duration of neuromuscular paralysis. The neuroexcitatory metabolite laudanosine is renally excreted. Laudanosine is epileptogenic in animals and may induce central nervous system (CNS) excitation in patients with renal failure who are receiving prolonged atracurium infusions. Atracurium may induce histamine release after rapid administration.

Cisatracurium

Cisatracurium and atracurium are similar intermediate-acting nondepolarizing agents. A bolus dose of 0.2 mg per kg of cisatracurium usually results in neuromuscular paralysis within 1.5 to 2.5 minutes and lasts 45 to 60 minutes. When compared with atracurium, cisatracurium is three times as potent and has a more desirable adverse drug event profile, including lack of histamine release, minimal cardiovascular effects, and less interaction with autonomic ganglia. It also undergoes ester hydrolysis as well as Hofmann degradation. However, plasma laudanosine concentrations after cisatracurium administration are five to ten times lower than those detected after atracurium administration [7,8].

Rocuronium

Rocuronium is the fastest onset, shortest acting aminosteroidal NMBA. A bolus dose of 0.6 mg per kg usually results in neuromuscular paralysis within 60 to 90 seconds. It may be considered an alternative to succinylcholine for rapid-sequence intubation (0.8 to 1.2 mg per kg), although, even with large doses, the onset of action is slower as compared to succinylcholine [9]. Rocuronium is primarily eliminated in the liver and

TABLE 25.1

PHARMACOKINETIC AND PHARMACODYNAMIC PRINCIPLES OF NONDEPOLARIZING NEUROMUSCULAR BLOCKERS[a]

	Benzylisoquinolinium agents		
	Cisatracurium (Nimbex)	**Atracurium (Tracrium)**	**Doxacurium (Nuromax)**
Introduced	1996	1983	1991
95% Effective dose (mg/kg)	0.05	0.25	0.025–0.030
Initial dose (mg/kg)	0.1–0.2	0.4–0.5	Up to 0.1
Onset (min)	2–3	3–5	5–10

[a]Modified from Grenvik A, Ayres SM, Holbrook PR, et al: *Textbook of Critical Care*. 4th ed. Philadelphia, WB Saunders, 2000; Watling SM, Dasta JF: Prolonged paralysis in intensive care unit patients after the use of neuromuscular blocking agents: a review of the literature. *Crit Care Med* 22(5):884, 1994.

bile. Hepatic or renal dysfunction may reduce drug clearance and prolong recovery time.

Vecuronium

An initial intravenous bolus dose of 0.1 mg per kg of vecuronium typically results in neuromuscular paralysis within 3 to 4 minutes and lasts for 35 to 45 minutes. Vecuronium lacks vagolytic effects, such as tachycardia and hypertension, and produces negligible histamine release. Hepatic metabolism produces three active metabolites, the most significant being 3-desacetyl vecuronium, with 50% to 70% activity of the parent drug. Both vecuronium and its active metabolites are renally excreted. There is potential for prolonged neuromuscular paralysis in patients with renal dysfunction receiving vecuronium by continuous infusion [10].

Pancuronium

Pancuronium is a long-acting nondepolarizing agent that is structurally similar to vecuronium. Unique features of pancuronium are its vagolytic and sympathomimetic activities and

potential to induce tachycardia, hypertension, and increased cardiac output. Pancuronium is primarily excreted unchanged (60% to 70%) in the urine and bile, whereas the remaining 30% to 40% is hydroxylated by the liver to 3-hydroxy pancuronium. It has 50% activity of the parent drug and is renally eliminated. Renal dysfunction may result in the accumulation of pancuronium and its metabolites [11].

Doxacurium

Doxacurium is the most potent nondepolarizing agent available, but it has the slowest onset (as long as 10 minutes). It is practically devoid of histaminergic, vagolytic, or sympathomimetic effects. Doxacurium undergoes minimal hepatic metabolism, and excretion occurs unchanged in both the urine and the bile, with significantly prolonged effects seen in patients with renal dysfunction and, to a lesser extent, hepatic disease [12,13].

Pipecuronium

Pipecuronium is structurally related to pancuronium and its duration of action is 90 to 100 minutes, making it the longest acting NMBA. It is metabolized to 3-desacetyl pipecuronium by the liver, and both the parent compound and the metabolite are renally excreted. When compared with pancuronium, pipecuronium has a longer duration of action, less histamine release, and minimal cardiovascular effects [14].

REVERSAL AGENTS

The clinical effects of nondepolarizing neuromuscular blockers can be reversed by acetylcholinesterase inhibitors (anticholinesterases). These agents increase the synaptic concentration of ACh by preventing its synaptic degradation and allow it to competitively displace nondepolarizing NMBAs from postsynaptic nAChRs on the motor end plate. Because anticholinesterase drugs (e.g., neostigmine, edrophonium, and pyridostigmine) also inhibit acetylcholinesterase at muscarinic receptor sites, they are used in combination with the antimuscarinic agents (e.g., atropine or glycopyrrolate) to minimize adverse muscarinic effects (e.g., bradycardia, excessive secretions, and bronchospasm) while maximizing nicotinic effects. Typical combinations include neostigmine and glycopyrrolate (slower acting agents) and edrophonium and atropine (faster acting agents). The depth of neuromuscular blockade determines how rapidly neuromuscular activity returns [15,16].

Sugammadex is a new and novel agent (modified γ-cyclodextrin) that reverses rocuronium and other aminosteroid NMBAs by selectively binding and encapsulating the NMBA [16]. One of the advantages of sugammadex is the rapid reversal of the profound neuromuscular block, induced by the high dose of rocuronium needed for the rapid-sequence induction [17,18]—an effect that is equivalent to, if not better than, the spontaneous recovery from succinylcholine. Hence, rocuronium/sugammadex may prove to be an effective and safer alternative to succinylcholine in cases of the difficult airway and contraindications to the use of succinylcholine. Sugammadex is also useful as a reversal agent whenever the blockade is profound and there is an advantage for a timely reversal [18]. It is approved for use in Europe, but not in the United States. The nonapproval of the Food and Drug Administration (FDA) was based on concerns related to hypersensitivity and allergic reactions. However, a recently published *Cochrane* systemic review concluded that sugammadex was not only effective but also equally safe when compared with placebo and neostigmine [19].

DRUG INTERACTIONS

A substantial number of medications commonly used in clinical practice have the potential for interaction with NMBAs. These interactions typically influence the degree and duration of clinical effects through either potentiation of or resistance to neuromuscular blockade. The most clinically relevant drug interactions with NMBA are discussed here and summarized in Table 25.2.

Aminoglycosides and other antibiotics (e.g., tetracyclines, clindamycin, and vancomycin) have the ability to potentiate neuromuscular blockade and prolong the action of nondepolarizing agents through mechanisms including the inhibition of presynaptic ACh release, reduction of postsynaptic receptor sensitivity to ACh, blockade of cholinergic receptors, and impairment of ion channels. Penicillin and cephalosporin antibiotics do not interact with NMBAs and thus do not influence the degree of neuromuscular blockade.

Local, inhalational, and intravenous anesthetic and sedative agents may potentiate neuromuscular blockade. Local anesthetics reduce ACh release and decrease muscle contractions through direct membrane effects, whereas inhalational anesthetics desensitize the postsynaptic membrane and also depress muscle contractility.

Cardiovascular drugs such as furosemide, procainamide, quinidine, beta-blockers, and calcium channel blockers have the ability to potentiate neuromuscular blocking effects. The role of the calcium ion in the release of ACh from vesicles into the synapse has been well established, although the exact interaction between calcium channel blockers and NMBAs remains to be determined. Verapamil, a calcium channel blocker, has local analgesic effects and direct skeletal muscle effects, but its significance in drug interaction with NMBAs remains to be defined.

Chronic antiepileptic therapy, specifically phenytoin and carbamazepine, can increase the resistance to neuromuscular blocking effects, whereas the acute administration of phenytoin potentiates neuromuscular blockade. Chronic phenytoin therapy appears to induce an upregulation of ACh receptors, resulting in decreased postsynaptic sensitivity. Carbamazepine has been shown to induce resistance and shorten recovery times in combination with both pancuronium and vecuronium, possibly resulting from competition at the NMJ [4,20].

MONITORING OF NMBAS

Current guidelines recommend the routine monitoring of depth of neuromuscular blockade in critically ill patients [1]. It is important to remember that NMBAs have no analgesic and sedative effect. Careful clinical monitoring of the patient for signs consistent with inadequate sedation or analgesia—such as tachycardia, hypertension, salivation, and lacrimation—while receiving NMBAs is important. A recommendation to use monitors such as the Bispectral Index or the Patient State Index to ensure adequate depth of sedation while receiving NMBAs seems plausible; however, more studies are needed to determine whether these monitors are reliable and cost-effective in the critical care setting and whether they contribute to improved outcomes [21–23]. The modality of choice to monitor the depth of nondepolarizing neuromuscular blockade at present is train-of-four (TOF) monitoring. To determine the depth of blockade, four supramaximal stimuli are applied to a peripheral nerve (ideally, the ulnar nerve to assess an evoked response of the adductor pollicis muscle) every 0.5 seconds (2 Hz). Each

TABLE 25.2

DRUG INTERACTIONS WITH NEUROMUSCULAR BLOCKING AGENTS[a]

Therapeutic agent	Potential interaction
Antibiotics	
Aminoglycosides	Potentiate blockade; decreased acetylcholine release
Tetracyclines	Potentiate blockade
Clindamycin and lincomycin	Potentiate blockade
Vancomycin	Potentiate blockade
Sedative/anesthetics	Potentiate blockade
Cardiovascular agents	
Furosemide	Low doses: potentiate blockade; high doses: antagonize blockade
Beta-blockers	Potentiate blockade
Procainamide	Potentiate blockade
Quinidine	Potentiate blockade
Calcium channel blockers	Potentiate blockade
Methylxanthines	Antagonize blockade
Antiepileptic drugs	Acute: potentiate blockade; chronic: resistance to blockade
Phenytoin	
Carbamazepine	Resistance to blockade
Ranitidine	Antagonize blockade
Lithium	Potentiate blockade
Immunosuppressive agents	
Azathioprine	Mild antagonism; phosphodiesterase inhibition
Cyclosporin	Potentiate blockade
Corticosteroids	Potentiate steroid myopathy
Local anesthetics	Potentiate blockade

[a] Adapted from Buck ML, Reed MD: Use of nondepolarizing neuromuscular blocking agents in mechanically ventilated patients. *Clin Pharm* 10(1):32, 1991.

stimulus in the train causes the muscle to contract, and "fade" in the response provides the basis for evaluation. To obtain the TOF ratio, the amplitude of the fourth response is divided by the amplitude of the first response. Before administration of a nondepolarizing muscle relaxant, all four responses are ideally the same: the TOF ratio is 1 to 1. During a partial nondepolarizing block, the ratio decreases (fades) and is inversely proportional to the degree of blockade [24].

Three prospective clinical trials have examined the question whether the routine use of TOF monitoring in the ICU will increase the cost-effectiveness and decrease the incidence of prolonged neuromuscular weakness. TOF monitoring for vecuronium appears to improve the outcome and decrease the cost of therapy. However, these outcomes could not be demonstrated for the benzylisoquinolinium agents, atracurium, and cisatracurium [25–27].

ADVERSE EFFECTS OF DEPOLARIZING AND NONDEPOLARIZING NMBAS IN CRITICALLY ILL PATIENTS

Significant progress has been made in the recent past in our understanding of the changes in regulation and distribution of ACh receptors during a course of critical illness. The majority of patients hospitalized in an ICU will undergo postsynaptic upregulation of nAChRs due to immobility, upper and/or lower motor neuron lesions, and/or pharmacologic denervation (such as NMBAs and aminoglycoside antibiotics). As previously outlined, immature receptors are not confined to the NMJ proper, but can be found over the entire surface of skeletal muscle (Fig. 25.1). This will lead to increased sensitivity to depolarizing NMBAs and decreased sensitivity to nondepolarizing NMBAs. Furthermore, these changes in receptor distribution and physiology put the patient at a heightened risk for succinylcholine-induced hyperkalemia. This is based on the fact that immature (fetal) and α7nAChRs are low conductance channels with prolonged opening times and significantly higher potassium efflux into the systemic circulation as compared to mature (adult) nAChRs. Furthermore, succinylcholine is metabolized more slowly as compared to ACh, thus prolonging the "open" state of the immature receptors. Upregulation of receptors during periods of immobilization has been described as early as 6 to 12 hours into the disease process. Therefore, it seems advisable to avoid succinylcholine in critically ill patients beyond 48 to 72 hours of immobilization and/or denervation. In contrast, a reduction in the number of postsynaptic nAChRs will result in resistance to depolarizing and increased sensitivity to nondepolarizing NMBAs. For conditions associated with the potential for ACh receptor upregulation, see Table 25.3.

INTENSIVE CARE UNIT–ACQUIRED WEAKNESS

ICU-acquired weakness (ICUAW) is a relatively new term used to describe all weaknesses developed in critically ill patients after the onset of illness and in the absence of any identifiable causes. ICUAW is further classified into three entities:

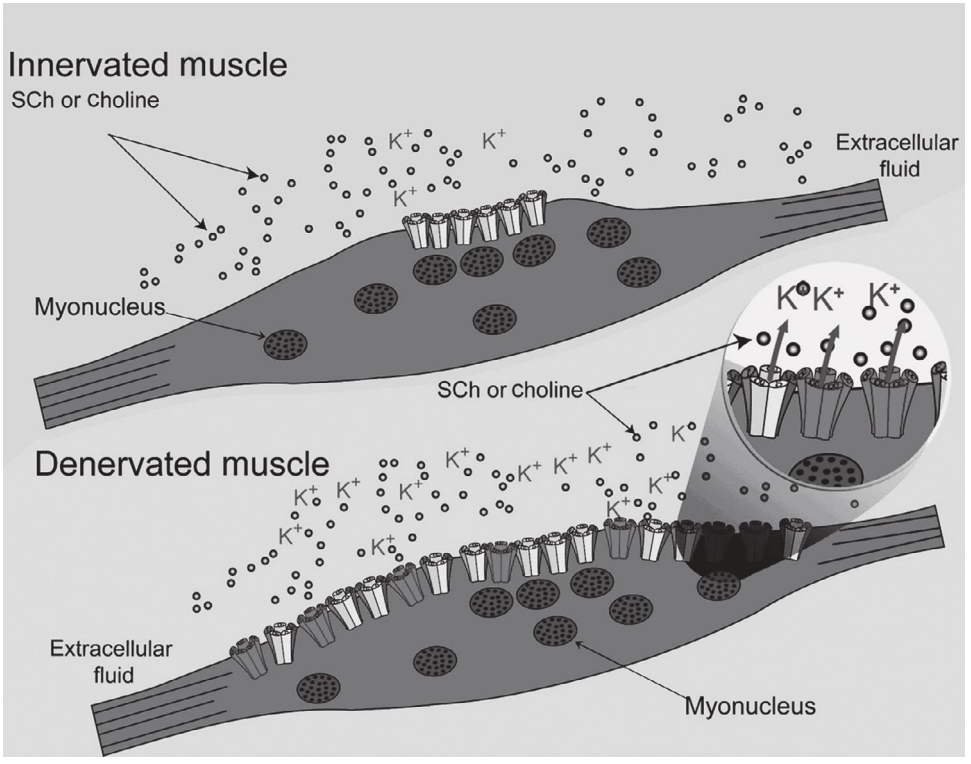

FIGURE 25.1. Schematic of the succinylcholine (SCh)-induced potassium release in an innervated (*top*) and denervated (*bottom*) muscle. In the innervated muscle, the systemically administered SCh reaches all of the muscle membrane, but depolarizes only the junctional ($\alpha 1$, $\beta 1$, δ, ε) receptors because acetylcholine receptors (AChRs) are located only in this area. With denervation, the muscle (nuclei) expresses not only extrajunctional ($\alpha 1$, $\beta 1$, δ, γ) AChRs, but also $\alpha 7$AChRs throughout the muscle membrane. Systemic succinylcholine, in contrast to acetylcholine released locally, can depolarize all of the upregulated AChRs, leading to massive efflux of intracellular potassium into the circulation, resulting in hyperkalemia. The metabolite of SCh, choline, and possibly succinylmonocholine can maintain this depolarization via $\alpha 7$AChRs, enhancing the potassium release and maintaining the hyperkalemia. [From Martyn JA, Richtsfeld M. Succinylcholine-induced hyperkalemia in acquired pathologic states: etiologic factors and molecular mechanisms. *Anesthesiology* 104:158, 2006, with permission.]

critical illness polyneuropathy (CIP), critical illness myopathy (CIM), and critical illness neuromyopathy (CINM) [28,29] (See Chapter 180). These conditions occur in up to 50% to 70% of patients meeting diagnostic criteria for the systemic inflammatory response syndrome as well as in patients immobilized and on mechanical ventilation for more than a week [30]. They manifest as limb weakness and difficulty in weaning from the mechanical ventilator. Nondepolarizing muscle relaxants of both classes, aminosteroids and benzylisoquinoliniums, have been associated with the development of these neuromuscular disorders [31]; however, the etiology appears to be multifactorial and includes alterations in microvascular blood flow in conditions of sepsis/systemic inflammatory response syndrome and the concomitant administration of corticosteroids [30]. There is evidence suggesting that high-dose corticosteroids have direct physiologic effects on muscle fibers, resulting in a typical myopathy with loss of thick-filament proteins. Atrophy and weakness are observed primarily in muscles of trunk and extremities, and functional denervation of muscle with NMBAs in conjunction with corticosteroid therapy seems to heighten the risk of myopathy [31]. Furthermore, both methylprednisolone and hydrocortisone antagonize nAChRs, possibly potentiating the effects of NMBAs [32]. A differential diagnosis of weakness in ICU patients is presented in Table 25.4.

TABLE 25.3

CONDITIONS ASSOCIATED WITH THE POTENTIAL FOR NICOTINIC ACETYLCHOLINE RECEPTOR UPREGULATION

Severe infection/SIRS
Muscle atrophy associated with prolonged immobility
Thermal injury
Upper and/or lower motor neuron defect
Prolonged pharmacologic or chemical denervation (e.g., NMBAs, magnesium, aminoglycoside antibiotics, and clostridial toxins)

NMBAs, neuromuscular blocking agents; SIRS, systemic inflammatory response syndrome.

Critical Illness Polyneuropathy

Electrophysiologic findings of CIP are consistent with a primary, axonal degeneration, resulting in reduction in amplitudes of the compound muscle action potential and sensory

TABLE 25.4

WEAKNESS IN INTENSIVE CARE UNIT PATIENTS: ETIOLOGIES AND SYNDROMES[a]

Prolonged recovery from neuromuscular blocking agents (secondary to parent drug, drug metabolite, or drug–drug interaction)
Myasthenia gravis
Eaton–Lambert syndrome
Muscular dystrophy
Guillain–Barré syndrome
Central nervous system injury or lesion
Spinal cord injury
Steroid myopathy
Mitochondrial myopathy
Human immunodeficiency virus–related myopathy
Critical illness myopathy
Disuse atrophy
Critical illness polyneuropathy
Severe electrolyte toxicity (e.g., hypermagnesemia)
Severe electrolyte deficiency (e.g., hypophosphatemia)

TABLE 25.5

RECOMMENDATIONS FOR ADMINISTRATION OF NEUROMUSCULAR BLOCKING AGENTS (NMBAS) TO ICU PATIENTS[a]

1. Develop, use, and document a standardized approach for administering and monitoring NMBA
2. Use NMBA only after optimizing ventilator settings and sedative and analgesic medication administration
3. Establish the indications and clinical goals of neuromuscular blockade, and evaluate at least daily
4. Select the best NMBA on the basis of patient characteristics:
   A. Use intermittent NMBA therapy with pancuronium, doxacurium, or other suitable agent if clinical goals can be met
   B. If continuous infusion is required and renal or hepatic dysfunction is present, select atracurium or cisatracurium, and avoid vecuronium
5. Use the lowest effective dose for the shortest possible time (<48 h if possible), particularly if corticosteroids are concomitantly administered
6. Administer adequate analgesic and/or sedative medication during neuromuscular blockade, and monitor clinically and by bispectral array EEG if available
7. Systematically anticipate and prevent complications, including provision of eye care, careful positioning, physical therapy, and DVT prophylaxis
8. Avoid the use of medications that affect NMBA actions. Promptly recognize and manage conditions that affect NMBA actions
9. Adjust NMBA dosage to achieve clinical goals (i.e., patient–ventilator synchrony, apnea, or complete paralysis)
10. Periodically (i.e., at least once or twice daily) perform NMBA dosage reduction, and preferably cessation (drug holiday) if clinically tolerated, to determine whether neuromuscular blockade is still needed and to perform physical and neurologic examination
11. Periodically perform and document a clinical assessment in which spontaneous respiration, as well as limb movement, and/or the presence of DTRs are observed during steady-state infusion and/or during dosage reduction/cessation. With deep blockade, muscle activity may be present only during dosage reduction/cessation
12. Perform and document scheduled (i.e., every 4–8 h) TOF testing for patients receiving vecuronium NMBA and/or undergoing deep neuromuscular blockade (i.e., apnea or complete paralysis), and adjust dosage to achieve one-fourth or more twitches. If clinical goals cannot be met when one-fourth or more twitches are present during steady-state infusion, demonstrate one-fourth or more twitches during dosage reduction/cessation. Consider TOF testing in all patients

DTR, deep tendon reflexes; DVT, deep venous thrombosis; EEG, electroencephalogram; TOF, train of four.
[a]Modified from Gehr LC, Sessler CN: Neuromuscular blockade in the intensive care unit. *Semin Respir Crit Care Med* 22:175, 2001, with permission.

nerve action potential. Although several case reports have suggested that NMBAs are causative agents in the etiology of this disorder, prospective studies of CIP have not confirmed a correlation between the use of NMBAs, steroids, and CIP [33]. It seems plausible, however, that NMBAs contribute to nerve and muscle damage during a course of critical illness. Their use should be avoided whenever possible until more prospective data demonstrating their safety in critically ill patients are available [34] (See Chapter 180).

Critical Illness Myopathy

CIM can occur in association with, or independently from, CIP. A group of several myopathies of critical illness are now thought to be part of the same syndrome; these include acute quadriplegic myopathy, critical care myopathy, acute corticosteroid myopathy, acute hydrocortisone myopathy, acute myopathy in severe asthma, and acute corticosteroid and pancuronium-associated myopathy [35]. The major feature of this syndrome is flaccid, diffuse weakness, involving all limb muscles and neck flexors, and often the facial muscles and diaphragm. As with CIP, this can result in difficulty to wean from the mechanical ventilator. The syndrome is more difficult to diagnose than CIP, and diagnostic evaluations include electrophysiologic studies, muscle biopsy, and laboratory evaluations (plasma creatine kinase levels). Again, there is no definitive evidence suggesting that NMBAs are causative agents for this syndrome, but rather a component in a multifactorial etiology. However, the incidence of CIP and CIM appears to be higher in ICUs where these agents are more frequently used [36].

The question whether CIP and CIM increase hospital mortality was recently addressed by Latronico et al. [37]. Although only limited data are available suggesting that CIP increases ICU and hospital mortality in critically ill patients, CIP and CIM appear to be important causes of increased morbidity during and after acute care hospital stay [37] (See Chapter 180).

SUMMARY AND RECOMMENDATIONS

Although there is currently insufficient evidence to demonstrate an unequivocal link between the use of NMBAs and an increase in morbidity and mortality in critically ill patients, it seems prudent to perform a careful risk–benefit analysis prior to the administration of this class of drugs in the ICU setting. Indeed, a recent prospective, randomized study of patients in the early stage of the acute respiratory distress syndrome demonstrated that use of cisatracurium was associated with improved survival without an increase in ICUAW [38]. Nonetheless, more prospective data are needed to identify proper indications, selection of agents, and doses in the ICU setting. Concomitant use of drugs predisposing patients for the development of CIM-like steroids and aminoglycoside antibiotics should alert the clinician for the increased risk of CIP/CIM in this setting. Succinylcholine can subject patients who are immobilized with upper and lower motor neuron lesions or with burns to a markedly increased risk for succinylcholine-induced hyperkalemia, and should be avoided in the ICU whenever possible. For recommendations for the administration of NMBAs to ICU patients, please see Table 25.5.

ACKNOWLEDGMENTS

We thank Dr. Jerry D. Thomas and Dr. Greg A. Bauer for the significant contributions to previous revisions of this chapter.

ALAN LISBON

CHAPTER 26 ■ ROUTINE MONITORING OF CRITICALLY ILL PATIENTS

PATRICK TROY, NICHOLAS A. SMYRNIOS AND MICHAEL D. HOWELL

A key difference between intensive care units (ICUs) and other hospital units is the level of detail with which patients are routinely monitored. This careful monitoring alerts the health care team to changes in the patient's severity of illness—helping to both diagnose disease and assess prognosis. Careful monitoring also helps the health care team safely apply therapies such as volume resuscitation, vasoactive infusions, and mechanical ventilation.

This chapter deals with the routine, predominantly noninvasive monitoring that is often done for many patients in ICUs. It examines the indications for, the technology of, and problems encountered in the routine monitoring of temperature, blood pressure, ECG rhythm, ST segments, respiratory rate, and oxygen and carbon dioxide levels. In addition, it reviews noninvasive monitoring of tissue perfusion, with particular attention to gastric tonometry, sublingual capnometry, and transcutaneous oxygen and carbon dioxide monitoring.

MONITORING SYSTEMS

When ICUs came into being in the late 1950s, nurses monitored patients' vital signs intermittently. Continuous measurement was either unavailable or necessitated invasive procedures. Now, however, nearly all routine vital signs can now be monitored accurately, noninvasively, and continuously. As a result, patients now are monitored more intensively and continuously in the ICU than in any other part of the hospital, with the possible exception of the operating room.

Over the past decades, the trend in monitoring systems has been toward multipurpose systems that integrate monitoring of a variety of parameters. Multipurpose systems eliminate the need for multiple, freestanding devices—reducing clutter and improving workflow ergonomics at the bedside. These systems also interface critical care information systems to provide more efficient data management, quality improvement reports, and in some cases prospective data-driven alerts.

TEMPERATURE MONITORING

Temperature changes in the critically ill are associated with significant morbidity and mortality [1] (see Chapters 65 and 66)—making it clinically important to recognize an abnormal temperature. In one surgical ICU study, rectal temperatures on admission were normal in only 30% of patients, were above 37.6°C in 38%, and were below 36.8°C in 32% [2]. An abnormal temperature is frequently the earliest clinical sign of infection, inflammation, central nervous system dysfunction, or drug toxicity. Unfortunately, the type of thermometer and the site where the temperature is taken can affect the accuracy of this vital measurement. Clinicians should understand the impact of the thermometer type and the measurement site on how to interpret the patient's reported temperature.

Indications for Temperature Monitoring

The Society of Critical Care Medicine's Task Force on Guidelines' recommendations for care in a critical care setting grades temperature monitoring as an essential service for all critical care units [3]. Critically ill patients are at high risk for temperature disorders because of debility, impaired control of temperature, frequent use of sedative drugs, and a high predisposition to infection. All critically ill patients should have core temperature measured at least intermittently. Patients with marked temperature abnormalities should be considered for continuous monitoring; patients undergoing active interventions to alter temperature, such as breathing heated air or using a cooling–warming blanket, should have continuous monitoring to prevent overtreatment or undertreatment of temperature disorders.

Measurement Sites

The goal of temperature measurements is generally to estimate *core temperature*—the deep body temperature that is carefully regulated by the hypothalamus so as to be independent of transient small changes in ambient temperature. Core temperature exists more as a physiologic concept than as the temperature of an anatomic location. An ideal measurement site would be protected from heat loss, painless and convenient to use, and would not interfere with the patient's ability to move and communicate. No one location provides an accurate measurement of core temperature in all clinical circumstances.

Sublingual Temperature Measurements

Sublingual temperature measurements are convenient, but suffer numerous limitations. Although open-mouth versus closed-mouth breathing and use of nasogastric tubes do not alter temperature measurement [4], oral temperature is obviously altered if measured immediately after the patient has consumed hot or cold drinks. Falsely low oral temperatures may occur because of cooling from tachypnea. Sixty percent of sublingual temperatures are more than 1°F lower than simultaneously measured rectal temperatures; 53% differ by 1° to 2°F, and 6% differ by more than 2°F. Continuous sublingual measurement is not generally practical. Sublingual measurement is best suited for intermittent monitoring when some inaccuracy can be tolerated.

Axillary Temperature Measurements

Axillary temperatures are commonly used as an index of core temperature. Although some studies indicate close approximation of the axillary site with pulmonary artery temperatures [5], temperatures average 1.5° to 1.9°C lower than tympanic temperatures [6]. Positioning the sensor over the axillary artery may improve accuracy. The accuracy and precision of axillary temperature measurements are less than at other sites [6], perhaps due in part to the difficulty of maintaining a good probe position.

Rectal Temperature Measurements

Rectal temperature is the most widely accepted standard of measuring core temperature in clinical use. Before a rectal thermometer is inserted, a digital rectal examination should be performed because feces can blunt temperature measurement. Readings are more accurate when the sensor is passed more than 10 cm (4 in) into the rectum. Rectal temperature correlates well in most patients with distal esophageal, bladder, and tympanic temperatures [7]. Rectal temperatures typically respond to induced changes in temperature more slowly than other central measurement sites [8]. Reusable, electronic, sheath-covered rectal thermometers have been associated with the transmission of *Clostridium difficile* and vancomycin-resistant *Enterococcus,* so disposable probes are generally preferred.

Esophageal Temperature Measurements

Esophageal temperature is usually measured with an electric, flexible temperature sensor. On average, esophageal temperatures are 0.6°C lower than rectal temperatures [9]. However, the measured temperature can vary greatly depending on the position of the sensor in the esophagus. In the proximal esophagus, temperature is influenced by ambient air [10]. During hypothermia, temperatures in different portions of the esophagus may differ by up to 6°C [10]. Because of the proximity of the distal esophagus to the great vessels and heart, the distal esophageal temperature responds rapidly to changes in core temperature [11]. Changes in esophageal temperature may inaccurately reflect changes in core temperature when induced temperature change occurs because of the inspiration of heated air, gastric lavage, or cardiac bypass or assist [11].

Tympanic Temperature Measurements

Health care providers can measure tympanic temperature with specifically designed thermometers that are commonly used in the ICU. However, several studies have demonstrated poor correlation with ICU patients' core temperatures [12,13]. Accuracy depends in part on operator experience—but even when trained, experienced ICU nurses use tympanic thermometers, the variability in repeated measurements was more than 0.5°F in 20% of patients [14]. Unlike temporal artery measurements, which are not known to have complications, tympanic temperature measurements come with some risk. Perforation of the tympanic membrane and bleeding from the external canal due to trauma from the probe have been reported.

Temporal Artery Measurements

Temporal artery measurements are not known to have complications. Their accuracy is reviewed later.

Urinary Bladder Temperature Measurements

Providers can easily measure the urinary bladder temperature with a specially designed temperature probe embedded in a Foley catheter [6–8]. In patients undergoing induced hypothermia and rewarming, bladder temperatures correlate well with great vessel and rectal temperatures [7,8]. Bladder temperature under steady-state conditions is more reproducible than that taken at most other sites [7].

Central Circulation Temperature Measurements

ICU practitioners can measure the temperature of blood in the pulmonary artery using a thermistor-equipped pulmonary artery catheter. The temperature sensor is located at the distal tip and can record accurate great vessel temperatures once the catheter is in place in the pulmonary artery. Pulmonary artery temperatures have generally been accepted as the gold standard for accurate measures of core temperature, although readings might be expected to differ from core temperature when heated air was breathed or warm or cold intravenous fluids were infused. However, this understanding may not be true in neurosurgical patients. A study in patients undergoing neurosurgical procedures with induced hypothermic circulatory arrest found that pulmonary arterial temperature measurement was not effective in assessing core brain temperature with a correlation coefficient of 0.63. A greater degree of correlation was found in bladder temperature [15]. Inserting a central venous thermistor specifically to monitor temperature is probably warranted only when other sites are felt to be unreliable and accurate, rapid, continuous temperature measurements are critical to the patient's management.

Types of Thermometers

Mercury Thermometers

Although mercury thermometers were historically been the most common type in clinical use, environmental and health concerns related to mercury have resulted in several state and local legislative efforts to phase out this type of thermometer. Mercury and other liquid–expansion-based thermometers can give a falsely low measurement when the thermometer is left in place for too short a period; falsely high temperatures result from failure to shake the mercury down.

Liquid Crystal Display Thermometers

Liquid crystal display (LCD) thermometers contain liquid crystals embedded in thin adhesive strips that are directly attached to the patient's skin. LCD thermometers are most commonly applied to the forehead for ease of use and steady perfusion, but can be applied to any area of the skin. Like all skin temperature measurements, they may poorly reflect core temperature when the skin is hypoperfused or patients have vasomotor instability. Forehead skin temperature is typically lower than core temperatures by 2.2°C [16], and changes in LCD forehead temperature lag behind changes in core temperature by more than 12 minutes [17]. LCD skin thermometry is probably best used in patients with stable, normal hemodynamics who are not expected to experience major temperature shifts and in whom the trend of temperature change is more important than the accuracy of the measurement.

Standard Digital Thermometers: Thermocouples and Thermistors

Electric thermometers convert an electrical temperature signal into digital displays, frequently by use of thermocouples and thermistors as probes. Thermocouples and thermistors can be fashioned into thin wires and embedded in flexible probes that are suitable for placing in body cavities to measure deep temperature.

Thermocouples consist of a junction of two dissimilar metals. The voltage change across the junction can be precisely related to temperature. The measuring thermocouple must be calibrated against a second constant-temperature junction for absolute temperature measurements. In the range of 20° to 50°C, thermocouples may have a linearity error of less than 0.1 [18].

Thermistors consist of semiconductor metal oxides in which the electrical resistance changes inversely with temperature. A linearity error of up to 4°C may occur over the temperature range of 20° to 50°C, but this can be substantially reduced by mathematical adjustments and electrical engineering techniques [18]. Semiconductors measure temperature by taking advantage of the fact that the base-to-emitter voltage change is temperature dependent, whereas the collector current of the silicon resistor is constant. Thermistors are more sensitive, faster responding, and less linear than thermocouples or semiconductors [18].

Infrared Emission Detection Thermometers

Tympanic Thermometers. Commonly used in a hospital setting, infrared emission detection tympanic thermometers use a sensor that detects infrared energy emitted by the core-temperature tissues behind the tympanic membrane. Infrared emissions through the tympanic membrane vary linearly with temperature. Operator technique is important: errors due to improper calibration, setup, or poor probe positioning can significantly alter temperatures [19]. Measurements are most accurate when the measuring probe blocks the entrance of ambient air into the ear canal and when the midposterior external ear is tugged posterosuperiorly so as to direct the probe to the anterior, inferior third of the tympanic membrane. Studies are mixed on whether tympanic thermometers provide accurate core temperature measurements, ranging from a 4% clinically meaningful error rate [14] to a finding that 21% of tympanic readings might result in delays in therapy for or evaluation of fever [20].

Temporal Artery Thermometers. Infrared technology can also measure temperature over the temporal artery. A probe is passed over the forehead and searches for the highest temperature; some systems also scan the area behind the ear. An algorithm estimates ambient heat loss and blood cooling to calculate core temperature. The device is convenient, painless, and provides a rapid reading. Although one small study of normothermic patients found good correlation with pulmonary artery temperatures [5], another study in patients with a broader temperature range found that 89% of measurements differed from pulmonary artery temperatures by more than 0.5°C, the amount the author's had specified a priori as clinically significant [21].

Selecting the Measurement Site

The site used to monitor temperature must be an individualized choice, but certain generalizations can be made. When intermittent temperature measurement is all that is clinically needed (e.g., in routine monitoring), or the consequences of inaccurate measurement are low, rectal or sublingual measurement may be preferred. If less accuracy is required, tympanic, temporal, or axillary sites may be chosen. When more accurate measurement is needed, bladder, esophageal, and rectal temperatures in general appear to be most accurate and reproducible—although rectal temperatures may lag behind other temperatures when the patient's status is changing quickly [7,13]. However, routine measurement of esophageal temperatures would necessitate inserting an esophageal probe in all patients. In addition, small changes in probe position can affect the accuracy of esophageal measurements, so this mode is probably best used in patients undergoing active, aggressive temperature management in centers with substantial experience with the modality. Meanwhile, rectal probes may be extruded or may be refused by patients. The third option, bladder temperature monitoring, is simplified by the fact that most critically ill patients have an indwelling Foley catheter. Monitoring the bladder temperature in these patients requires only a thermistor-equipped catheter. Patients with a thermistor-tipped pulmonary artery catheter already in place require no additional temperature monitoring.

Patient Safety and Temperature Monitoring

Therapeutic hypothermia is increasingly prevalent in ICU settings (Chapter 65]). Some devices used to induce hypothermia are closed-looped systems. Since core temperature probes can fail (for example, dislodgement of a rectal probe to a position outside the patient), practitioners should consider monitoring core temperature from two sites when temperature is being actively manipulated.

ARTERIAL BLOOD PRESSURE MONITORING

The first recorded blood pressure measurement occurred in 1733 and—somewhat surprisingly—was intra-arterial pressure monitoring. The Reverend Stephen Hales placed a 9-foot brass tube in a horse's crural artery and found a blood pressure of about 8 feet 3 inches. This was obviously not clinically applicable. In the mid-1800s, Carl Ludwig recorded the first arterial pressure waveforms, but it was not until 1881 that the first noninvasive blood pressure recordings were made. In 1896, Riva-Rocci developed and popularized the mercury sphygmomanometer, which was then adopted and disseminated at least in part by Harvey Cushing. In 1905, Korotkoff developed techniques for detecting diastolic pressure by listening for what are now called Korotkoff sounds. More clinical techniques of direct blood pressure measurement by intra-arterial cannula were initially developed in the 1930s and popularized in the 1950s [22]. These measurements were soon accepted as representing true systolic and diastolic pressures.

Since that time, a variety of invasive and alternative indirect methods have been developed that equal and even surpass auscultation in reproducibility and ease of measurement. This section examines the advantages and disadvantages of various methods of arterial pressure monitoring and provides recommendations for their use in the ICU.

Noninvasive (Indirect) Blood Pressure Measurement

Providers can indirectly monitor blood pressure using a number of techniques, most of which describe the external pressure applied to block flow to an artery distal to the occlusion. These methods therefore actually detect blood *flow*, not intra-arterial pressure, although one method describes the pressure required to maintain a distal artery with a transmural pressure gradient of zero. These differences in what is actually measured are the major points of discrepancy between direct and indirect measurements.

Indirectly measured pressures vary depending on the size of the cuff used. Cuffs of inadequate width and length can provide falsely elevated readings. Bladder width should equal 40% and bladder length at least 60% of the circumference of the extremity measured [23]. Anyone who makes indirect pressure

measurements must be aware of these factors and carefully select the cuff to be used.

Manual Methods

Auscultatory (Riva-Rocci) Pressures

The traditional way to measure blood pressure involves inflating a sphygmomanometer cuff around an extremity and auscultating over an artery distal to the occlusion. Sounds from the vibrations of the artery under pressure (Korotkoff sounds) indicate systolic and diastolic pressures. The level at which the sound first becomes audible is taken as the systolic pressure. The point at which there is an abrupt diminution in or disappearance of sounds is used as diastolic pressure. This method, still commonly used in the ICU, yields an acceptable value in most situations. Its advantages include low cost, time-honored reliability, and simplicity. Disadvantages include operator variability, susceptibility to environmental noise, and the absence of Korotkoff sounds when pressures are very low. Auscultatory pressures also correlate poorly with directly measured pressures at the extremes of pressure [24].

Manual Oscillation Method

When a cuff is slowly deflated and blood first begins to flow through the occluded artery, the artery's walls begin to vibrate. This vibration can be detected as an oscillation in pressure and has served as the basis for the development of several automated blood pressure monitoring devices. However, it also continues to be used in manual blood pressure measurement. The first discontinuity in the needle movement of an aneroid manometer indicates the presence of blood flow in the distal artery and is taken as systolic pressure [25]. The advantages of the oscillation method are its low cost and simplicity. The disadvantages include the inability to measure diastolic pressure, poor correlation with directly measured pressures [25], and lack of utility in situations in which Riva-Rocci measurements are also unobtainable. Aneroid manometers may also be inaccurate: in one study, 34% of all aneroid manometers in use in one large medical system gave inaccurate measurements, even when more lenient standards were used than those advocated by the National Bureau of Standards and the Association for the Advancement of Medical Instrumentation [26]. In the same survey, 36% of the devices were found to be mechanically defective—pointing out the need for regular maintenance. Although the manometers themselves can also be used for auscultatory measurements, oscillometric readings probably provide no advantage over auscultation in the ICU.

Palpation, Doppler, and Pulse-Oximetric Methods

Systolic pressures can be measured any method that detects flow in a distal artery as the blood pressure cuff is slowly deflated. Palpation of the radial artery is the most commonly used technique; it is most useful in emergency situations in which Korotkoff sounds cannot be heard and an arterial line is not in place. The inability to measure diastolic pressure makes the palpation method less valuable for ongoing monitoring. In addition, palpation obtains no better correlation with direct measurements than the previously described techniques. In one study, variation from simultaneously obtained direct pressure measurements was as high as 60 mm Hg [24]. Like other indirect methods, palpation tends to underestimate actual values to greater degrees at higher levels of arterial pressure. Any method which detects blood flow distal to a sphygmomanometer cuff may be used in this fashion. Doppler machines are commonly used and may be particularly useful in situations where the pulse is not palpable or environmental noise precludes auscultation. Pulse oximeters have been similarly used and correlate well with other methods; the point at which a plethysmographic trace appears is taken as the systolic pressure [27].

Automated Methods

Automated indirect blood pressure devices operate on one of several principles: Doppler flow, infrasound, oscillometry, volume clamp, arterial tonometry, and pulse wave arrival time.

Doppler Flow

Systems that operate on the Doppler principle take advantage of the change in frequency of an echo signal when there is movement between two objects. Doppler devices emit brief pulses of sound at a high frequency that are reflected back to the transducer [28]. The compressed artery exhibits a large amount of wall motion when flow first appears in the vessel distal to the inflated cuff. This causes a change in frequency of the echo signal, known as a *Doppler shift*. The first appearance of flow in the distal artery represents systolic pressure. In an uncompressed artery, the small amount of motion does not cause a change in frequency of the reflected signal. Therefore, the disappearance of the Doppler shift in the echo signal represents diastolic pressure [29].

Infrasound

Infrasound devices use a microphone to detect low-frequency (20 to 30 Hz) sound waves associated with the oscillation of the arterial wall. These sounds are processed by a minicomputer, and the processed signals are usually displayed in digital form [30].

Oscillometry

Oscillometric devices operate on the same principle as manual oscillometric measurements. The cuff senses pressure fluctuations caused by vessel wall oscillations in the presence of pulsatile blood flow [31]. Maximum oscillation is seen at mean pressure, whereas wall movement greatly decreases below diastolic pressure [32]. As with the other automated methods described, the signals produced by the system are processed electronically and displayed in numeric form.

Volume Clamp Technique

The volume clamp method avoids the use of an arm cuff. A finger cuff is applied to the proximal or middle phalanx to keep the artery at a constant size [33]. The pressure in the cuff is changed as necessary by a servocontrol unit strapped to the wrist. The feedback in this system is provided by a photoplethysmograph that estimates arterial size. The pressure needed to keep the artery at its *unloaded volume* can be used to estimate the intra-arterial pressure [34].

Arterial Tonometry

Arterial tonometry provides continuous noninvasive measurement of arterial pressure, including pressure waveforms. It slightly compresses the superficial wall of an artery (usually the radial). Pressure tracings obtained in this manner are similar to intra-arterial tracings. A generalized transfer function can convert these tracings to an estimate of aortic pressure [35]. This method has not yet achieved widespread clinical use. One available system studied in ICU patients had approximately one third of MAP readings which differed by $\geq$10 mm Hg compared with intra-arterial pressure measurements and was associated with significant drift during the course of the study [36]. However, more studies of a different system reported more

accurate readings in patients undergoing anesthesia [37], including those with induced hypotension [38].

Utility of Noninvasive Blood Pressure Measurements

Only four of the methods described previously (infrasound, oscillometry, Doppler flow, volume clamp) are associated with significant clinical experience. Of these, methods that use infrasound technology correlate least well with direct measures of arterial blood pressure [31,39]. Therefore, infrasound is rarely used in systems designed for critical care.

Although they have not been consistently accurate, automated methods have the potential to yield pressures as accurate as values derived by auscultation. Commonly used oscillometric methods can correlate to within 1 mm Hg of the directly measured group average values [31] but may vary substantially from intra-arterial pressures in individual subjects, particularly at the extremes of pressure. One study revealed as good a correlation with directly measured pressures as Riva-Rocci pressures have traditionally obtained [31]. Another study demonstrated that mean arterial pressures determined by auscultation were extremely close to those measured by automated devices [40].

When volume clamp methods using a finger cuff have been compared with standard methods [41,42], these devices have been found to respond rapidly to changes in blood pressure and give excellent correlation in group averages. In one study looking at a large number of measurements, 95% of all measurements using this method were within 10 mm Hg of the directly measured values [43]. Studies by Aitken et al. [42] and Hirschl et al. [41] demonstrated acceptable correlation of volume clamp technique with systolic pressures measured directly. However, other studies have shown clinically significant differences between the volume clamp technique and invasively measured pressures in patients undergoing anesthesia [44].

One of the proposed advantages of automated noninvasive monitoring is patient safety. Avoiding arterial lines eliminates the risk of vessel occlusion, hemorrhage, and infection. Automated methods, however, have complications of their own. Ulnar nerve palsies have been reported with frequent inflation and deflation of a cuff [45]. Decreased venous return from the limb and eventually reduced perfusion to that extremity can also be seen when the cuff is set to inflate and deflate every minute [45,46].

In summary, automated noninvasive blood pressure forms a major component of modern critical care monitoring. Oscillometric and Doppler-based devices are adequate for frequent blood pressure checks in patients without hemodynamic instability, in patient transport situations in which arterial lines cannot be easily used, and in the severely burned patient, in whom direct arterial pressure measurement may lead to an unacceptably high risk of infection [47]. Automated noninvasive blood pressure monitors have a role in following trends of pressure change [48] and when group averages, not individual measurements, are most important. In general, they have significant limitations in patients with rapidly fluctuating blood pressures and may diverge substantially from directly measured intra-arterial pressures. Given these limitations, critical care practitioners should be wary of relying solely on these measurements in patients with rapidly changing hemodynamics or in whom very exact measurements of blood pressure are important.

Direct Invasive Blood Pressure Measurement

Direct blood pressure measurement is performed with an intra-arterial catheter. Chapter 3 reviews insertion and maintenance of arterial catheters. Here, we discuss the advantages and disadvantages of invasive monitoring compared with noninvasive means.

Arterial catheters contain a fluid column that transmits the pressure back through the tubing to a transducer. A low-compliance diaphragm in the transducer creates a reproducible volume change in response to the applied pressure change. The volume change alters the resistance of a Wheatstone bridge and is thus converted into an electrical signal. Most systems display the pressure in both wave and numeric forms.

Problems in Direct Pressure Monitoring

System-Related Problems. Several technical problems can affect the measurement of arterial pressure with the arterial line. Transducers must be calibrated to zero at the level of the heart. Improper zeroing can lead to erroneous interpretation. Thrombus formation at the catheter tip can occlude the catheter, making accurate measurement impossible. This problem can be largely eliminated by using a 20-gauge polyurethane catheter, rather than a smaller one, with a slow, continuous heparin flush [49], although this may be associated with heparin-induced thrombocytopenia [50]. Because movement may interrupt the column of fluid and prevent accurate measurement, the patient's limb should be immobile during readings.

The frequency response of the system is a phenomenon not only of transducer design but also of the tubing and the fluid in it. The length, width, and compliance of the tubing all affect the system's response to change. Small-bore catheters are preferable because they minimize the mass of fluid that can oscillate and amplify the pressure [51]. The compliance of the system (the change in volume of the tubing and the transducer for a given change in pressure) should be low [51]. In addition, bubbles in the tubing can affect measurements in two ways. Large amounts of air in the measurement system damp the system response and cause the system to underestimate the pressure [52]. This is usually easily detectable. Small air bubbles cause an increase in the compliance of the system and can significantly amplify the reported pressure [51,52].

Arterial Catheter Infections. Recent data challenge the classical perception that that arterial catheters are less likely to become infected [53] than central venous catheters. A prospective cohort study examined 321 arterial and 618 central venous catheters and found that arterial catheter colonization occurred with similar incidence to central venous catheter colonization [54]. Another recent study found similar results [55]. There is good evidence to support a link between the incidence of catheter colonization and catheter related blood stream infections [56]. Although one study suggested that full barrier precautions did not reduce the incidence of arterial line infection, interpretation of this trial is complex [57]. Taken together, the weight of evidence suggests that arterial catheters are an important potential source for infection in the critically ill patient and should be treated similar to central venous catheters in this setting.

Finally, the location within the hospital where the procedure is performed is important as catheters placed in non-ICU locations may be associated with an increased risk of colonization versus those placed in the ICU [54].

Site Selection. The radial artery is the most common site of arterial cannulation for pressure measurement. This site is accessible and can be easily immobilized to protect both the catheter and the patient. The major alternative site is the femoral artery. Both sites are relatively safe for insertion [58,59]. The ulnar, brachial, dorsalis pedis, and axillary arteries are also used with some frequency [60]. Mechanical complications such as bleeding and nerve injury are discussed in Chapter 11. How should a

provider choose a site? Although there are a number of theoretical considerations about comparing blood pressures from one site to another, there is little data in critically ill patients. A systematic review of 19,617 radial, 3,899 femoral, and 1,989 axillary cannulations found that serious complications occurred infrequently (<1% of cannulations) and were similar between the sites [60]. In 14 septic surgical patients on vasopressors, radial pressures were significantly lower than femoral arterial pressures. In 11 of the 14 patients, vasopressor dose was reduced based on the femoral pressure without untoward consequences; after vasopressors were discontinued, radial and femoral pressures equalized. The authors concluded that clinical management based on radial artery pressures may lead to excessive vasopressor administration [61]. Similar significant differences in systolic pressures between the radial and femoral sites were found in the reperfusion phase of liver transplantation, although MAPs did not differ [62]. However, another somewhat larger observational study in critically ill patients [63] found no clinically meaningful differences in blood pressures between the sites. Although data are sparse, mean arterial pressure readings between the radial and femoral sites are probably interchangeable in many or most patients. There may be a preference toward using femoral arterial pressure readings in patients with vasopressor resistant shock, but this decision should be balanced by the risks of the femoral approach.

Should the risk of infection drive site selection? The data are mixed. Earlier work suggested that there was no difference in infection rates between the femoral and radial sites [60]. More recently, a prospective observational study of 2,949 catheters in the intensive care unit found the incidence of catheter related blood stream infection was significantly higher for femoral access (1.92/1,000 catheter-days) than for radial access (0.25/1,000 catheter-days) (odds ratio, 1.9; $p = 0.009$]. Localized skin infections were also significantly increased in femoral versus radial arterial catheters. In addition, femoral arterial catheter blood stream infections may have an increased association with gram negative bacteria when compared to the radial site, similar to previous data from central venous catheters [64].

Advantages

Despite technical problems, direct arterial pressure measurement offers several advantages. Arterial lines actually measure the end-on pressure propagated by the arterial pulse. In contrast, indirect methods report the external pressure necessary either to obstruct flow or to maintain a constant transmural vessel pressure. Arterial lines can also detect pressures at which Korotkoff sounds are either absent or inaccurate. Arterial lines provide a continuous measurement, with heartbeat-to-heartbeat blood pressures. In situations in which frequent blood drawing is necessary, indwelling arterial lines eliminate the need for multiple percutaneous punctures. Finally, analysis of the respiratory change in systolic or pulse pressure may provide important information on cardiac preload and fluid responsiveness.

Conclusions

Indirect methods of measuring the blood pressure estimate the arterial pressure by reporting the external pressure necessary to either obstruct flow or maintain a constant transmural vessel size. Arterial lines measure the end-on pressure propagated by the arterial pulse. Direct arterial pressure measurement offers several advantages in many but not all patients. Although an invasive line is required, the reported risk of complications is low [60]. Arterial lines provide a heartbeat-to-heartbeat measurement, can detect pressures at which Korotkoff sounds are either absent or inaccurate, and do not require repeated inflation and deflation of a cuff. In addition, they provide easy access for phlebotomy and blood gas sampling, and they may provide additional information about cardiac status. However, particular care should be taken with aseptic technique and line site maintenance, since the reported incidence of arterial line infection approaches that of central venous catheterization. Regardless of the method used, the mean arterial pressure should generally be the value used for decision making in most critically ill patients.

ELECTROCARDIOGRAPHIC MONITORING

Almost all ICUs in the United States routinely perform continuous electrocardiographic (ECG) monitoring. Continuous ECG monitoring combines the principles of ECG, which have been known since 1903, with the principles of biotelemetry, which were first put into practical application in 1921 [65]. Here we review the principles of arrhythmia monitoring, automated arrhythmia detection, and the role of automated ST segment analysis.

ECG monitoring in most ICUs is done over hard-wired apparatus. Skin electrodes detect cardiac impulses and transform them into an electrical signal, which is transmitted over wires directly to the signal converter and display unit. This removes the problems of interference and frequency restrictions seen in telemetry systems. Although this comes at the cost of reduced patient mobility, mobility is often not an immediate concern for this group of patients.

Arrhythmia Monitoring in the ICU

The American Heart Association's Practice Standards guideline considers continuous ECG monitoring a Class I intervention for all patients with indications for intensive care, regardless of whether the patient's primary admitting diagnosis related to a cardiac problem [66]. Approximately 20% of ICU patients in a general ICU have significant arrhythmias, mostly atrial fibrillation or ventricular tachycardia [67]. There is also a substantial incidence of arrhythmia following major surgery [68]. Although no studies address whether monitoring for arrhythmias in a general ICU population alters outcomes, this monitoring is generally accepted and considered standard care [66]. In postmyocardial infarction patients, on the other hand, the data is compelling. Arrhythmia monitoring was shown to improve the prognosis of patients admitted to the ICU for acute myocardial infarction (AMI) many years ago [69]. It has been a standard of care in the United States since that time. Although ventricular tachycardia and fibrillation after myocardial infarction have declined in frequency over the years, they still occur in about 7.5% of patients [70]. Monitoring enables the rapid detection of these potentially lethal rhythms.

Evolution of Arrhythmia Monitoring Systems for Clinical Use

After ICUs implemented continuous ECG monitoring, practitioners recognized some deficiencies with the systems. Initially, the responsibility for arrhythmia detection was assigned to specially trained coronary care nurses. Despite this, several studies documented that manual methods failed to identify arrhythmias, including salvos of VT, in up to 80% of cases [71]. This failure was probably due to an inadequate number of staff nurses to watch the monitors, inadequate staff education, and

faulty monitors [72]. Subsequently, monitors equipped with built-in rate alarms that sounded when a preset maximum or minimum rate was detected proved inadequate because some runs of VT are too brief to exceed the rate limit for a given time interval [71,73]. Ultimately, computerized arrhythmia detection systems were incorporated into the monitors. The software in these systems is capable of diagnosing arrhythmias based on recognition of heart rate, variability, rhythm, intervals, segment lengths, complex width, and morphology [74]. These systems have been validated in coronary care and general medical ICUs [71,75]. Computerized arrhythmia detection systems are well accepted by nursing personnel, who must work most closely with them [76].

Ischemia Monitoring

Just as simple monitoring systems can miss episodes of VT and ventricular fibrillation, they can fail to detect significant episodes of myocardial ischemia. This is either because the episode is asymptomatic or because the patient's ability to communicate is impaired by intubation or altered mental status. ECG monitoring systems with automated ST segment analysis have been devised to attempt to deal with this problem.

In most ST segment monitoring systems, the computer initially creates a template of the patient's normal QRS complexes. It then recognizes the QRS complexes and the J points of subsequent beats and compares an isoelectric point just before the QRS with a portion of the ST segment 60 to 80 milliseconds after the J point [77]. It compares this relationship to that of the same points in the QRS complex template. The system must decide whether the QRS complex in question was generated and conducted in standard fashion or whether the beats are aberrant, which negates the validity of comparison. Therefore, an arrhythmia detection system must be included in all ischemia monitoring systems. Standard systems can monitor three leads simultaneously. These leads are usually chosen to represent the three major axes (anteroposterior, left-right, and craniocaudal]. The machine can either display these axes individually or sum up the ST segment deviations and display them in a graph over time [77].

Automated ST segment analysis has gained widespread popularity among cardiologists. Since 1989, the American Heart Association has recommended that ischemia monitoring be included in new monitoring systems developed for use in the coronary care unit [78]. In patients admitted for suspected acute coronary syndromes, ischemia is both frequently silent and strongly associated with adverse events after discharge [66]. Although noting that no randomized clinical trials document improved patient outcomes when automated ST segment monitoring is used to detect ischemia, the American Heart Association recommends ST segment monitoring for patients with a number of primary cardiac issues (for example, acute coronary syndromes), based on expert opinion. The guidelines make no statement regarding ST segment monitoring for ICU patients [66].

Newer Techniques

Because conventional three-lead monitoring detects only about one third of transient ischemic events in patients with unstable coronary syndromes [79], some authors have advocated the use of continuous 12-lead ECG systems in the care of acute coronary syndromes. However, continuous 12-lead ECG monitoring can be impractical given the large number of leads required, patient discomfort, interference with medical procedures and proclivity to motion artifact. Some systems based on the dipole hypothesis of vectorcardiography allow the derivation of a 12-lead ECG from four recording electrodes and a reference electrode. Good correlation has been demonstrated between the EASI system and traditional 12-lead ECG in detection of ST segment deviation in acute myocardial ischemia and also in analyzing cardiac rhythm [80]. Other proposed enhancements to continuous ECG monitoring include signal-averaged ECG, QT dispersion, QT interval beat-to-beat variability, and heart rate variability [81]. Although associated with subsequent arrhythmic events, these have not yet reached common clinical use.

Technical Considerations

As with any other biomedical measurement, technical problems can arise when monitoring cardiac rhythms. Standards have been devised to guide manufacturers and purchasers of ECG-monitoring systems [82].

The possibility of electrical shock exists whenever a patient is directly connected to an electrically operated piece of equipment by a low-resistance path. Electrical shocks would most commonly occur with improper grounding of equipment when a device such as a pacemaker is in place. Necessary precautions to avoid this potential catastrophe include (a) periodic checks to ensure that all equipment in contact with the patient is at the same ground potential as the power ground line; (b) insulating exposed lead connections; and (c) using appropriately grounded plugs [83]. Each hospital's biomedical engineering department should have a documented preventive maintenance plan for all equipment in the unit.

The size of the ECG signal is important for accurate recognition of cardiac rate and rhythm. Several factors may affect signal size. The amplitude can be affected by mismatching between skin-electrode and preamplifier impedance. The combination of high skin-electrode impedance, usually the result of poor contact between the skin and electrode, with low-input impedance of the preamplifier can decrease the size of the ECG signal. Good skin preparation, site selection, and conducting gels can promote low skin-electrode impedance. A high preamplifier input impedance or the use of buffer amplifiers can also improve impedance matching and thereby improve the signal obtained. Another factor that affects complex size is critical damping, the system's ability to respond to changes in the input signal. An underdamped system responds to changes in input with displays that exaggerate the signal, called *overshoot*. An overdamped system responds slowly to a given change and may underestimate actual amplitude. The ECG signal can also be affected by the presence of inherent, unwanted voltages at the point of input. These include the common mode signal, a response to surrounding electromagnetic forces; the direct current skin potential produced by contact between the skin and the electrode; and a potential caused by internal body resistance. Finally, the ECG system must have a frequency response that is accurate for the signals being monitored. Modern, commercially available systems have incorporated features to deal with each of these problems.

Personnel

The staff's ability to interpret the information received is crucial to effective ECG monitoring [78]. Primary interpretation may be by nurses or technicians under the supervision of a physician. All personnel responsible for interpreting ECG monitoring should have formal training developed cooperatively by the hospital's medical and nursing staffs. At a minimum, this training should include basic ECG interpretation skills and arrhythmia recognition. Hospitals should also establish and adhere to formal protocols for responding to and verifying

alarms. Finally, a physician should be available in the hospital to assist with interpretation and make decisions regarding therapy.

Principles of Telemetry

Intensive care patients frequently continue to require ECG monitoring after they are released from the ICU, and many postoperative critical care patients begin mobilization while in the ICU. At this point, increased mobility is important to allow physical and occupational therapy as well as other rehabilitation services. Telemetry systems can facilitate this.

Telemetry means measurement at a distance biomedical telemetry consists of measuring various vital signs, including heart rhythm, and transmitting them to a distant terminal [84]. Telemetry systems in the hospital consist of four major components [84]: (a) A signal transducer detects heart activity through skin electrodes and converts it into electrical signals; (b) a radio transmitter broadcasts the electrical signal; (c) a radio receiver detects the transmission and converts it back into an electrical signal; and (d) the signal converter and display unit present the signal in its most familiar format. Continuous telemetry requires an exclusive frequency so the signal can be transmitted without interruption from other signals, which means the hospital system must have multiple frequencies available to allow simultaneous monitoring of several patients. The telemetry signal may be received in one location or simultaneously in multiple locations, depending on staffing practices. The signal transducer and display unit should also be equipped with an automatic arrhythmia detection and alarm system to allow rapid detection and treatment of arrhythmias. Notably, telemetry systems may be subject to interference by cellular phones [85] or other radio equipment.

Summary

The American Heart Association recommends continuous ECG monitoring for the detection of arrhythmias as a Class I intervention for all ICU patients [66]. Because ICU staff can miss a large percentage of arrhythmias when they use monitors without computerized arrhythmia detection systems, these computerized systems should be standard equipment in ICUs, especially those which care for patients with AMI. It appears that computerized monitoring devices can also detect a significant number of arrhythmias not noted manually in noncardiac patients. A large percentage of these lead to an alteration in patient care. Automated ST segment analysis facilitates the early detection of ischemic episodes. Telemetry provides close monitoring of recuperating patients while allowing them increased mobility.

RESPIRATORY MONITORING

Critical care personnel should monitor several primary respiratory parameters, including respiratory rate, tidal volume or minute ventilation, and oxygenation in critically ill patients. Routine monitoring of carbon dioxide levels would be desirable, but the technology for monitoring these parameters is not yet developed enough to consider mandatory continuous monitoring. In mechanically ventilated patients, many physiologic functions can be monitored routinely and continuously by the ventilator. This section does not discuss monitoring by the mechanical ventilator (see Chapter 31) but examines devices that might be routinely used to monitor the aforementioned parameters continuously and noninvasively.

Respiratory Rate, Tidal Volume, and Minute Ventilation

Clinical examination of the patient often fails to detect clinically important changes in respiratory rate and tidal volume [86]. Physicians, nurses, and hospital staff frequently report inaccurate respiratory rates, possibly because they underestimate the measurement's importance [87]. In another study, ICU staff had a greater than 20% error more than one-third of the time when the recorded respiratory rate was compared with objective tracings [88]. This is particularly surprising since the respiratory rate is an especially important predictor of outcome in many severity of illness scores such as the APACHE series [89]. In fact, respiratory rate has been called "the neglected vital sign [90]." Providers' clinical assessment of tidal volume and minute ventilation is similarly inaccurate [91]. Therefore, objective monitoring must be used because clinical evaluation is inaccurate.

Impedance Monitors

ICUs commonly use impedance monitors to measure respiratory rates and approximate tidal volume. These devices typically use ECG leads and measure changes in impedance generated by the change in distance between leads as a result of the thoracoabdominal motions of breathing. Obtaining a quality signal requires placing the leads at points of maximal change in thoracoabdominal contour or using sophisticated computerized algorithms. Alarms can then be set for a high and low rates or for a percentage drop in the signal that is thought to correlate with a decrease in tidal volume.

In clinical use, impedance monitors suffer confounding problems. They have failed to detect obstructive apnea when it has occurred and falsely detected apnea when it has not [92,93]. About one third of all apnea alarms from this technology are false-positives [94]. In situations with moving patients, they are even less accurate for the quantification of respiratory rate [95]. Impedance monitors are poor detectors of obstructive apnea because they may count persistent chest wall motion as breaths when the apneic patient struggles to overcome airway obstruction [92,93]. In general, respiratory rate monitoring in the ICU therefore results in a very high fraction of clinically irrelevant alarms: in one study, only 4% of respiratory alarms were deemed clinically relevant [96]. Although impedance monitors offer the advantage of being very inexpensive when ECG is already in use, they lack accuracy when precise measurements of apnea, respiratory rate, or tidal volume are required.

Respiratory Inductive Plethysmography

Respiratory inductive plethysmography (RIP) measures changes in the cross-sectional area of the chest and abdomen that occur with respiration and processes these signals into respiratory rate and tidal volume. This technology may be familiar to providers and patients because it is often used in polysomnograms. Typically, two elastic bands with embedded wire are placed above the xiphoid and around the abdomen. As the cross-sectional area of the bands changes with respiration, the self-inductance of the coils changes the frequency of attached oscillators. These signals are generally calibrated to a known gas volume, or may be internally calibrated so that further measurements reflect a percentage change from baseline rather than an absolute volume. RIP can accurately measure respiratory rate and the percentage change in tidal volume, as well as detect obstructive apnea [97–99]. RIP has been used to follow lung volumes in patients undergoing high-frequency oscillatory ventilation [100]. These measurements are more accurate than impedance measurements [93]. However, some studies have

found problems with RIP's estimation of lung volumes. Notably, RIP must be calibrated against a known gas volume in order to provide tidal volume estimates. This calibration is not always accurate and may result in errors of >10% in 5% to 10% of patients even in highly controlled circumstances [97,101]. In mechanically ventilated patients, RIP had significant measurement drift (25 cm^3/min) and imprecise volume estimates. Only about two thirds of tidal volume estimates were accurate to within 10% of the reference value [102].

In addition to displaying respiratory rate and percentage change in tidal volume, RIP can provide asynchronous and paradoxical breathing measurements and alarms, which are common during early weaning and may be helpful in predicting respiratory failure [103]. The noninvasive nature of the tidal volume measurement may be helpful in patients in whom technical problems or leaks make it difficult to directly measure expired volume (e.g., patients with bronchopleural fistulas]. In addition, RIP can display changes in functional residual capacity, which permits health care providers to assess the effect of changing positive end-expiratory pressure (PEEP). Providers can determine the presence and estimation of the amount of auto (intrinsic) PEEP by observing the effect of applied (extrinsic) PEEP on functional residual capacity [104], with the caveats noted earlier regarding possible inaccuracy of volume measurements.

RIP systems are available with central station configurations, which have been used in noninvasively monitored respiratory care units; these units have allowed ICU-level patients to be safely moved to a less-expensive level of care [105]. Compared with impedance methods, RIP is more accurate and offers a variety of other useful measurements but is less convenient and more expensive.

Other Methods

Although health care providers can also use pneumotachometers, capnographs, and electromyography to accurately measure respiratory rate, these methods are not commonly used in the ICU. A pneumotachometer requires complete collection of exhaled gas and, therefore, either intubation or use of a tight-fitting face mask is not practical simply for monitoring. A second alternative, capnography, works exceedingly well as a respiratory rate monitor. Because it does not require intubation or a face mask, it can be a useful tool in many circumstances. Capnography is discussed in more detail later. A third option, surface electromyography of respiratory muscles can be used to calculate respiratory rate accurately [106] but cannot detect obstructive apnea or provide a measure of tidal volume. Electromyography works well in infants but presents difficulties in adults, especially in obese adults and those with edema.

Recently, substantial research has focused on better ways to noninvasively monitor respiratory rate. All of these need clinical validation in a critical care setting, but examples of potentially emerging technologies include mechanical contact sensors placed in either patient beds or pillows, acoustical respiratory monitoring, and photoplethysmography.

Measurements of Gas Exchange

Pulse Oximetry

Clinical estimation of hypoxemia is exceptionally unreliable [107,108]. Pulse oximeters measure the saturation of hemoglobin in the tissue during the arterial and venous phases of pulsation and mathematically derive arterial saturation. Meta-analysis of 74 oximeter studies suggests that these estimates are usually accurate within 5% of simultaneous gold standard measurements [109]. However, up to 97% of physicians and nurses who use pulse oximeters do not understand their underlying fundamental principles [110]. This section reviews the essential technology involved in pulse oximetry and practical problems that limit its use.

Theory. Oximeters distinguish between oxyhemoglobin and reduced hemoglobin on the basis of their different absorption of light. Oxyhemoglobin absorbs much less red (±660 nm) and slightly more infrared (±910 to 940 nm) light than nonoxygenated hemoglobin. Oxygen saturation thereby determines the ratio of red to infrared absorption. When red and infrared light are directed from light-emitting diodes (LEDs) to a photodetector across a pulsatile tissue bed, the absorption of each wavelength by the tissue bed varies cyclically with pulse. During diastole, absorption is due to the nonvascular tissue components (e.g., bone, muscle, and interstitium) and venous blood. During systole, absorption is determined by all of these components and arterialized blood. The pulse amplitude accounts for only 1% to 5% of the total signal [111]. Thus, the difference between absorption in systole and diastole is in theory due to the presence of arterialized blood. The change in ratio of absorption between systole and diastole can then be used to calculate an estimate of arterial oxygen saturation. Absorption is typically measured hundreds of times per second. Signals usually are averaged over several seconds and then displayed numerically. The algorithm used for each oximeter is determined by calibration on human volunteers. Most oximeters under ideal circumstances measure the saturation indicated by the pulse oximeter (SpO_2) to within 2% of arterial oxygen saturation [112].

Cooximeters perform measurements on whole blood obtained from an artery or a vein. They frequently measure absorbance at multiple wavelengths and compute the percentage of oxyhemoglobin, deoxyhemoglobin, methemoglobin, and carboxyhemoglobin (COHb) in total hemoglobin based on different absorption spectra. They are mostly free of the artifacts that limit the accuracy of tissue oximeters and are regarded as the gold standard by which other methods of assessing saturation are measured.

Technology. Many manufacturers market pulse oximeters. Because of the variety of manufacturers, the numerous algorithms used, and the diverse patient populations studied, it is difficult to generalize the studies performed with one particular instrument, with its specific version of software, in one defined group of patients, to critically ill patients in general. The reader should always check with an oximeter's manufacturer before generalizing the following discussion to his or her oximeter and patient population.

Problems Encountered in Use. Because pulse oximeters are ubiquitous, all ICU providers must understand their limitations. A meta-analysis of problems encountered in pulse oximetry trials found that severe hypoxemia, dyshemoglobinemia, low perfusion states, skin pigmentation, and hyperbilirubinemia may affect the accuracy of pulse oximeter readings [109]. Any process that affects or interferes with the absorption of light between the LEDs and photodetector, alters the quality of pulsatile flow, or changes the hemoglobin may distort the oximeter's calculations. Pulse oximeters should be able to obtain valid readings in 98% of patients in an operating room or postanesthesia care unit [113]. Table 26.1 lists the problems that must be considered in clinical use.

Calibration. Manufacturers use normal volunteers to derive pulse oximeter calibration algorithms. This creates three problems. First, manufacturers use different calibration algorithms, which results in a difference in SpO_2 of up to 2.7% between different manufacturers' oximeters used to measure the same

TABLE 26.1

CONDITIONS ADVERSELY AFFECTING ACCURACY OF OXIMETRY

May result in poor signal detection	
Probe malposition	No pulse
Motion	Vasoconstriction
Hypothermia	Hypotension
Falsely lowers SpO_2	**Falsely raises SpO_2**
Nail polish	Elevated carboxyhemoglobin
Dark skin	Elevated methemoglobin
Ambient light	Ambient light
Elevated serum lipids	Hypothermia
Methylene blue	
Indigo carmine	
Indocyanine green	

SpO_2, saturation indicated by the pulse oximeter.

patient [114]. Second, manufacturers define SpO_2 differently for calibration purposes. Calibration may or may not account for the interference of small amounts of dyshemoglobinemia (e.g., methemoglobin or COHb). For example, if an oximeter is calibrated on the basis of a study of nonsmokers with a 2% COHb level, the measured SpO_2 percentage would differ depending on whether the value used to calibrate SpO_2 included or excluded the 2% COHb [114]. Third, it is difficult, for ethical reasons, for manufacturers to obtain an adequate number of validated readings in people with an SpO_2 of less than 70% to develop accurate calibration algorithms in this saturation range. Most oximeters give less precise readings in this saturation range [115]. Unless better calibration algorithms become available, oximeters should be considered unreliable when SpO_2 is less than 70%, although this may have little clinical impact since emergent intervention is usually required for all SpO_2 readings <70%.

Measurement sites. Careful sensor positioning is crucial to obtaining accurate results from a pulse oximeter [116]. Practitioners can obtain accurate measurements from fingers, forehead, and earlobes. The response time from a change in the partial pressure of arterial oxygen (PaO_2) to a change in displayed SpO_2 is delayed in finger and toe probes compared with ear, cheek, or glossal probes [117,118]. Forehead edema, wetness, and head motion may result in inaccurate forehead SpO_2 values [119]. Motion and perfusion artifacts are the greatest problems with finger or toe measurements. The earlobe is believed to be the site least affected by vasoconstriction artifact [120], but paradoxically the finger may give a better signal in times of hypoperfusion [109].

Fingernails. Long fingernails may prevent correct positioning of the finger pulp over the LEDs used in inflexible probes and therefore produce inaccurate SpO_2 readings without affecting the pulse rate [121]. Synthetic nails have produced erroneous results [112]. Adhesive tape, even when placed over both sides of a finger, did not affect measured SpO_2 [122]. Since pulse oximetry depends fundamentally on color, nail polish may falsely lower SpO_2. In a 1988 study, blue, green, and black polish showed greater decreases than red or purple [123]. However, a 2002 study with a newer-generation oximeter did not find this effect [124]. In addition, placing the probe sideways across the fingernail bed appeared to ameliorate any effect of fingernail polish in one study [125].

Skin color. The effect of skin color on SpO_2 was assessed in a study of 655 patients [126]. Although patients with the darkest skin had significantly less accurate SpO_2 readings, the mean inaccuracy in SpO_2 (compared with cooximetry) between subjects with light skin and those with the darkest skin was only 0.5%, a clinically insignificant difference. Pulse oximeters, however, encountered difficulties in obtaining readings in darker-skinned patients; 18% of patients with darker skin triggered warning lights or messages versus 1% of lighter skinned patients. A study of 284 patients with a newer generation oximeter also found that skin color did not affect measurement accuracy. Poor-quality readings were found more often in darker skinned patients, although this was a rare event (<1% of all patients) [127]. Thus, dark skin may prevent a measurement from being obtained, but when the oximeter reports an error-free value, the value is generally accurate enough for clinical use [128].

Ambient light. Ambient light that affects absorption in the 660- or 910-nm wavelengths, or both, may affect calculations of saturation and pulse. Xenon arc surgical lights [129], fluorescent lights [130], and fiberoptic light sources [131] have caused falsely elevated saturation but typically obvious dramatic elevations in reported pulse. An infrared heating lamp [132] has produced falsely low saturations and a falsely low pulse, and a standard 15-W fluorescent bulb resulted in falsely low saturation without a change in heart rate [133]. Interference from surrounding lights should be suspected by the presence of pulse values discordant from the palpable pulse or ECG, or changes in the pulse-saturation display when the probe is transiently shielded from ambient light with an opaque object. Most manufacturers have now modified their probes to minimize this problem. Studies report that ambient lighting has little or no effect on newer generation oximeters [134], although this varies among manufacturers [135].

Hyperbilirubinemia. Bilirubin's absorbance peak is maximal in the 450-nm range but has tails extending in either direction [136]. Bilirubin, therefore, does not typically affect pulse oximeters that use the standard two-diode system [136,137]. However, it may greatly interfere with the measurement of saturation by cooximeters. Cooximeters typically use four to six wavelengths of light and measure absolute absorbance to quantify the percentage of all major hemoglobin variants. Serum bilirubin values as high as 44 mg per dL had no effect on the accuracy of pulse oximeters but led to falsely low levels of oxyhemoglobin measured by cooximetry [136].

Dyshemoglobinemias. Conventional (two-diode) pulse oximeters cannot detect the presence of methemoglobin, COHb, or fetal hemoglobin. Fetal hemoglobin may confound readings in neonates but is rarely a problem in adults. On the other hand, acquired methemoglobinemia—although uncommon—is seen in routine practice, largely due to the use of methemoglobinemia-inducing drugs such as topical anesthetics [138]. Because methemoglobin absorbs more light at 660 nm than at 990 nm, it affects pulse oximetry readings [139]. Moreover, higher levels of methemoglobin tend to bias the reading toward 85% to 90% [140]. COHb is typically read by a two-diode oximeter as 90% oxyhemoglobin and 10% reduced hemoglobin [141], resulting in false elevations of SpO_2. A gap between pulse oximetry and pO_2 or cooximetrically measured oxygen saturation may suggest elevated COHb levels, particularly in patients with smoke inhalation or potential carbon monoxide poisoning [142]. Because COHb may routinely be 10% in smokers, pulse oximetry may fail to detect significant desaturation in this group of patients. Oxygen saturation in smokers, when measured by cooximetry, was on average 5%

lower than pulse oximetric values [143]. Hemolytic anemia may also elevate COHb up to 2.6% [144]. Because other etiologies of COHb are rare in the hospital and the half-life of COHb is short, this problem is unusual in the critical care setting except in newly admitted patients, patients with active hemolysis, or those on COHb-inducing drugs such as sodium nitroprusside [145]. More recently, some pulse oximeters that use multi-wavelength technology have been able to successfully report methemoglobin and COHb levels [146].

Anemia. Few clear data are available on the effect of anemia on pulse oximetry. In dogs, there was no significant degradation in accuracy until the hematocrit was less than 10% [147]. In one study of humans who had hemorrhagic anemia, there appeared to be little effect on pulse oximetry accuracy [148].

Lipids. Patients with elevated chylomicrons and those receiving lipid infusions may have falsely low SpO_2 because of interference in absorption by the lipid [149]. This also affects cooximetry and may lead to spurious methemoglobin readings [150].

Hypothermia. Good-quality signals may be unobtainable in 10% of hypothermic patients [151]. The decrease in signal quality probably results from hypothermia-induced vasoconstriction. When good-quality signals could be obtained, SpO_2 differed from cooximetry-measured saturation by only 0.6% [151] in one series.

Intravascular dyes. Methylene blue, used to treat methemoglobinemia, has a maximal absorption at 670 nm and therefore falsely lowers measured SpO_2 [152]. Indocyanine green and indigo carmine also lower SpO_2, but the changes are minor and brief [153]. Fluorescein has no effect on SpO_2 [153]. Because of the rapid vascular redistribution of injected dyes, the effect on oximetry readings typically lasts only 5 to 10 minutes [154]. Patent V dye, which is used to visualize lymphatics in sentinel node mapping, confounds pulse oximetry, an effect which may persist for more than 90 minutes [155].

Motion artifact. Shivering and other motions that change the distance from diode to receiver may result in artifact. Oximeters account for motion by different algorithms. Some oximeters display a warning sign, others stop reporting data, and others display erroneous values. The display of a plethysmographic waveform rather than a signal strength bar helps to indicate to providers that artifact has distorted the pulse signal and lowered the quality of the SpO_2 reading. Newer generation oximeters appear to have significantly less susceptibility to motion artifact than earlier models [156].

Hypoperfusion. During a blood pressure cuff inflation model of hypoperfusion, most oximeters remained within 2% of control readings [157]. Increasing systemic vascular resistance and decreasing cardiac output can also make it harder to obtain a good-quality signal. In one series, the lowest cardiac index and highest systemic vascular resistance at which a signal could be detected were 2.4 L per minute per m^2 and 2,930 dynes second per cm^5 per m^2, respectively [158]. Warming the finger [159] or applying a vasodilating cream [158] tended to extend the range of signal detection in individual patients. The oximeter's ability to display a waveform and detect perfusion degradation of the signal was crucial in determining when the readings obtained were valid [157].

Pulsatile venous flow. In physiologic states in which venous and capillary flows become pulsatile, the systolic pulse detected by the oximeter may no longer reflect the presence of just arterial blood. In patients with severe tricuspid regurgitation, the measured saturation may be falsely low, especially with ear probes [160].

Indications. The Society of Critical Care Medicine considers pulse oximetry (or transcutaneous oxygen measurement) essential monitoring for all ICU patients receiving supplemental oxygen [161]. Unsuspected hypoxemia is common in critically ill patients. Sixteen percent of patients not receiving supplemental oxygen in the recovery room have saturations of less than 90% [162]. In 35% of patients, saturations of less than 90% develop during transfer out of the operating room [163]. Because of the high frequency of hypoxemia in critically ill patients, the frequent need to adjust oxygen flow, and the unreliability of visual inspection to detect mild desaturation, oximeters should be used in most critically ill patients for routine, continuous monitoring. In one study that randomized more than 20,000 operative and perioperative patients to continuous or no oximetric monitoring, the authors concluded that oximetry permitted detection of more hypoxemic events, prompted increases in the fraction of oxygen in inspired air, and significantly decreased the incidence of myocardial ischemia but did not significantly decrease mortality or complication rates [164].

Oximeters have been used in the ICU for reasons other than continuous monitoring. For example, oximeters may be helpful during difficult intubations. Once desaturation occurs, attempts to intubate should be postponed until manual ventilation restores saturation. Note, however, that oximetry is not helpful in promptly detecting inadvertent esophageal intubation because desaturation may lag significantly behind apnea in preoxygenated patients [165]. Oximeters can be useful in detecting systolic blood pressure (see arterial pressure monitoring earlier), and have been used in other clinical applications with varying degrees of success. Notably, a normal SpO_2 reading should *not* be used to exclude pulmonary embolism [166].

Capnography

Capnography involves the measurement and display of expired PCO_2 concentrations. This section reviews the technology, the sources of difference between end-tidal PCO_2 ($EtCO_2$) and $PaCO_2$, and the indications for capnography in the ICU.

Technology. Expired PCO_2 concentration is usually determined by infrared absorbance or mass spectrometry. The infrared technique relies on the fact that carbon dioxide has a characteristic absorbance of infrared light, with maximal absorbance near a wavelength of 4.28 mm. A heated wire with optical filters is used to generate an infrared light of appropriate wavelength. When carbon dioxide passes between a focused beam of light and a semiconductor photodetector, an electronic signal can be generated that, when calibrated, accurately reflects the PCO_2 of the tested gas.

A mass spectrometer bombards gas with an electron stream. The ion fragments that are generated can be deflected by a magnetic field to detector plates located in precise positions to detect ions that are characteristic of the molecule being evaluated. The current generated at the detector can be calibrated to be proportional to the partial pressure of the molecule being evaluated.

The two techniques have different strengths. Mass spectrometers can detect the partial pressures of several gases simultaneously and can monitor several patients at once. Infrared techniques measure only PCO_2 and are usually used on only one patient at a time. The calibration and analysis time required for mass spectrometry is significantly longer than with infrared techniques. Infrared systems respond to changes in

approximately 100 milliseconds, whereas mass spectrometers take 45 seconds to 5 minutes to respond [167]. Although costs vary widely, mass spectrometers are in general far more expensive and are most frequently purchased to be the central component of a carbon dioxide monitoring system. In the operating room, mass spectrometry has the advantage of being able to measure the partial pressure of anesthetic gases, and the need for a technical specialist to oversee its operation can be more easily justified. For these reasons, mass spectrometry has achieved much more popularity in the operating room than in the ICU.

Gases can be sampled by mainstream or sidestream techniques. Mainstream sampling involves placing the capnometer directly in line in the patient's respiratory circuit. All air leaving the patient passes through the capnometer. The sidestream sampling techniques pump 100 to 300 mL expired air per minute through thin tubing to an adjacent analyzing chamber.

The mainstream method can be used only on patients who are intubated or wearing a tight-fitting face or nose mask. Mainstream sampling offers the advantage of almost instantaneous analysis of sampled air, but it increases the patient's dead space and adds weight to the endotracheal tube. Sidestream sampling removes air from the expiratory circuit, altering measurement of tidal volume. Slower aspirating flow rates and longer tubing lengths significantly worsen the ability to detect a rapid rise in carbon dioxide and cause delay between physiologic changes in the patient and the display of changes on the monitor [168]. When the delay exceeds the respiratory cycle time, the generated data are inaccurate [168]. Located near the mouth or nose, sidestream sampling lines are also prone to clogging with secretions, saliva, or water condensation. Sidestream sampling can be used in nonintubated patients to detect cyclic changes in carbon dioxide concentrations. Because of these issues, accurate sidestream sampling requires short sampling tubes and attention to the possibility of clogged sample lines.

Differences Between End-Tidal and Arterial Carbon Dioxide. The PCO_2 in exhaled air measured at the mouth changes in a characteristic pattern in normal people that reflects the underlying physiologic changes in the lung (Fig. 26.1). During inspiration, the PCO_2 is negligible, but it rises abruptly with expiration. The rapid rise reflects mixing and the washout of dead-space air with air from perfused alveoli, which contain higher levels of CO_2. A plateau concentration is reached after dead-space air has been exhaled. The plateau level is determined by the mean alveolar PCO_2, which is in equilibration with pulmonary artery PCO_2. The end-alveolar plateau level of PCO_2 measured during the last 20% of exhalation is the $EtCO_2$. In normal people at rest, the difference between $EtCO_2$ and $PaCO_2$ is ± 1.5 mm Hg. A difference exists because of the presence of dead space and a normal physiologic shunt. Changes in dead space or pulmonary perfusion alters ventilation–perfusion ratio and changes the relationship between end-tidal and arterial PCO_2 values. As dead space increases, the $EtCO_2$ represents more the (lower) PCO_2 of nonperfused alveoli, thereby diverging from the $PaCO_2$ value. As perfusion decreases, fewer alveoli are perfused, creating a similar effect.

In most equipment, the $EtCO_2$ level is determined by a computerized algorithm. Because algorithms are imperfect, a waveform display is considered essential for accurate interpretation of derived values [168]. In slowly breathing patients, cardiac pulsations may cause the intermittent exhalation of small amounts of air at the end of the lungs' expiratory effort. This results in oscillations that may obscure the plateau phase. An irregular respiratory pattern or large increases in dead space can also distort the plateau phase. Visual inspection of traces can detect situations in which algorithms are prone to produce errors [167].

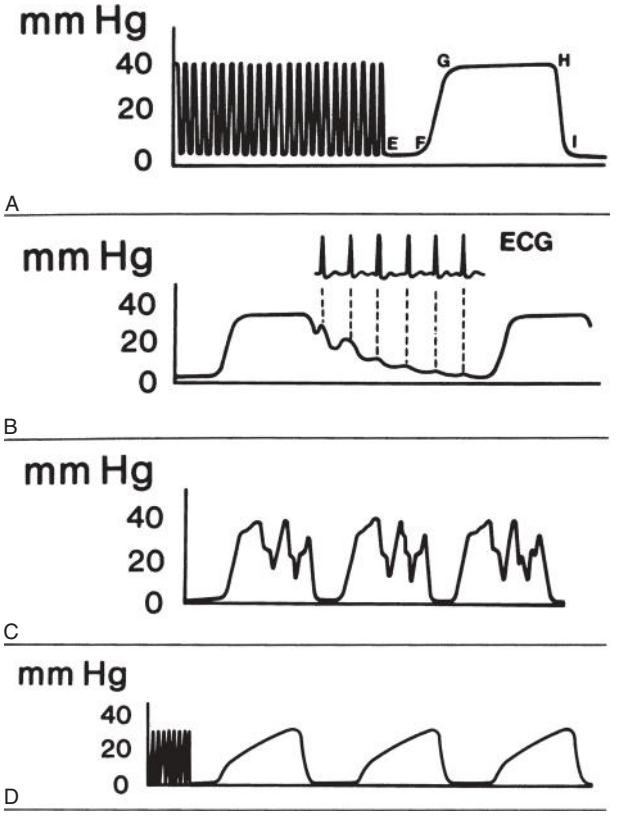

FIGURE 26.1. Normal and abnormal capnograms. In the normal capnogram (**A**), on the right of the trace, the paper speed has been increased. The *EF* segment is inspiration. The *FG* segment reflects the start of expiration with exhalation of dead space gas. The *GH* segment is the alveolar plateau. End-tidal values are taken at point *H*. *HI* is the beginning of inspiration. In the abnormal capnograms, the alveolar plateau is distorted and the end-tidal point cannot be clearly determined because of cardiac oscillations (**B**), erratic breathing (**C**), and obstructive airway disease (**D**). ECG, electrocardiogram. (Modified from Stock MC: Noninvasive carbon dioxide monitoring. *Crit Care Clin* 4:511, 1988.)

Indications. In the ICU, capnography is most useful for (1) detection of extubation, (2) determining the presence or absence of respiration, and (3) detecting return of spontaneous circulation after cardiac arrest. Such determinations do not require that $EtCO_2$ be measured accurately, only that changes be detected reliably. Alarms for apnea and tachypnea can be set and relied on, although capnography cannot discriminate between obstructive and central apnea. Capnography is a useful adjunct for detecting unintentional extubation, malposition of the endotracheal tube, or absence of perfusion. Cyclic variation of $EtCO_2$ is absent in esophageal intubation or disconnection from the ventilator [169]. Although pharyngeal intubation with adequate ventilation may produce a normal capnogram. Capnography can demonstrate the return of circulation after cardiopulmonary arrest or bypass. In full cardiac arrest, $EtCO_2$ is low because of lack of perfusion; a rapid rise in $EtCO_2$ indicates return of circulation and successful delivery of CO_2 to the alveoli [170]. Capnography or capnometry is also frequently used to help detect esophageal intubation [171].

$EtCO_2$ measurements are unreliable indicators of $PaCO_2$ in critically ill patients. Since these patients undergo rapid changes

in dead space fraction and pulmonary perfusion, the relationship of $EtCO_2$ to arterial $PaCO_2$ may change rapidly and unpredictably. In one study of anesthetized, stable, generally healthy adults, $PaCO_2$ could not be reliably determined from end-tidal values [172]. In patients undergoing weaning from mechanical ventilation, $EtCO_2$ was also shown to have no predictable relationship to $PaCO_2$[173]. Although end-tidal and arterial values correlated well ($r = 0.78$) and rarely differed by more than 4 mm Hg, changes in $EtCO_2$ correlated poorly with changes in arterial PCO_2 ($r^2 = 0.58$]. Because of changes in dead space and perfusion, arterial and end-tidal measurements at times moved unpredictably in opposite directions. Although theoretically attractive, the use of end-tidal carbon dioxide measurements to evaluate changes in ventilation-perfusion mismatch in response to ventilator changes has failed to yield consistent clinical benefits [174].

Capnography has been helpful in the operating room in detecting air and pulmonary embolism as well as malignant hyperthermia [167]. In these situations, the capnograph does not provide a diagnosis; it records a change that, if limits are exceeded, signals an alarm. The responsibility for accurately interpreting the subtleties of changes in the capnogram remains the task of an experienced physician.

Conclusions. Capnography is of limited use in the critically ill patient. In any patient with changing cardiac output, fluctuating respiratory function, or chronic lung disease, it should not be used to replace $PaCO_2$ monitoring. It has been used to assess correct endotracheal tube placement (or inadvertent extubation) and offers rapid information about the return of spontaneous circulation after cardiac arrest. It does, however, monitor respiratory rate accurately and may be useful in some circumstances for that function. Capnography may be better suited to the operating room, where its value is increased because of its ability to help detect endotracheal tube malposition, air embolism, pulmonary embolism, and malignant hyperthermia, and where there is a highly skilled anesthesiologist immediately available to interpret subtle changes in the capnogram.

NONINVASIVE TISSUE PERFUSION MONITORING

Bedside providers usually monitor tissue perfusion based on clinical signs such as skin temperature and capillary refill time. However, several noninvasive technologies provide quantitative data about overall or regional tissue perfusion. Unlike most of the other monitoring technologies described in this chapter, clinical adoption of these techniques has been relatively limited and heterogeneous [175]. This section reviews three such technologies that measure local pCO_2 or pO_2: gastric tonometry, sublingual capnometry, and transcutaneous oxygen and carbon dioxide monitoring. Measurements from each of these techniques correlate meaningful clinical outcomes such as patient survival.

Physiology: Why Regional pO_2 and pCO_2 Reflects Tissue Perfusion and Not Just Global Gas Exchange

At first glance, it would appear that measurement of pO_2 or pCO_2 in the skin, stomach, or tongue would reflect global gas exchange and might be used for noninvasive blood gas estimation. In some cases, this is true. In healthy adults, for example, transcutaneously measured pO_2 and CO_2 ($PtcO_2$ and $PtcCO_2$) accurately reflect PaO_2 and $PaCO_2$ [176]. The measured transcutaneous values of oxygen and carbon dioxide are typically 10 mm Hg lower [177] and 5 to 23 mm Hg higher [178] than arterial values, respectively.

However, local pO_2 and pCO_2 therefore depend not only on global gas exchange, cardiac output, and oxygen content, but also on regional blood flow and oxygen delivery to the site of measurement. Under normal circumstances, oxygen delivery far exceeds consumption. In critical illness, however, regional hypoperfusion or inadequate regional delivery of oxygen may occur for any number of reasons: hypotension, regional vasoconstriction, low cardiac output states, anemia, vascular occlusion, etc. If there is no flow to the region, there can be no delivery of oxygen and no elimination of carbon dioxide by the vasculature—thus creating lower local pO_2 and higher local pCO_2 than in the arterial circulation. When tissue is hypoperfused, local metabolism then further alters local pO_2 and pCO_2. As cellular processes use available oxygen for the production of adenosine triphosphate (ATP), local pO_2 falls. When these cells use ATP faster than they replenish it, they liberate hydrogen ions (H^+) and reduce local pH. (Alternatively, cells may produce lactic acid through the anaerobic metabolic pathway.) These addition hydrogen ions are then buffered by tissue bicarbonate, generating CO_2: $H^+ + HCO_3^- \rightarrow H_2O_3 \rightarrow H_2O + CO_2$. This increases local pCO_2 above corresponding global/arterial values [179]. For these reasons, local pO_2 and pCO_2 therefore vary not only with global gas exchange, but also with local tissue perfusion.

Gastric Tonometry

Gastric tonometry, probably the most commonly used of the three perfusion monitoring techniques discussed in this section, assesses regional splanchnic perfusion based on the stomach's mucosal pCO_2. The splanchnic circulation has several properties which make this region particularly useful to assess in critically ill patients. Early in the development of shock states, the splanchnic circulation vasoconstricts, shunting cardiac output toward other core organs. Although this helps to prevent circulatory collapse, it may also result in intestinal mucosal ischemia—increasing the risk of gastric stress ulceration, mesenteric ischemia, and translocation of gut bacteria into the systemic circulation [180]. The gut is particularly sensitive to hypoperfusion and so may provide earlier warning of occult hypoperfusion than other vascular beds—leading some to liken it to a coal miner's canary [181]. Gastric tonometry measures gastric luminal pCO_2 and estimates gastric intramucosal pCO_2 and pH (pHi).

Technical Considerations

Development. Early measurements of visceral mucosal pH required operative implantation of monitors and focused on the gallbladder, urinary bladder, and small bowel [182,183]. Development of silastic tubing [184]—which is exceptionally permeable to O_2 and CO_2—and confirmation that gases in tissue equilibrate rapidly with fluid in the lumen of a hollow viscus [185] allowed development of the modern gastrointestinal tonometer.

Technique. The upper gastrointestinal catheter is inserted with standard technique for nasogastric tube placement, and placement is confirmed radiographically. The stopcock is flushed with fluid to eliminate any trapped air, the balloon is filled to the manufacturer's specifications with fluid, and the tonometer lumen is closed to the outside environment. The fluid is allowed to equilibrate with the fluid in the lumen of the organ being monitored, a process believed to require approximately

90 minutes, although formulas are available to correct the values obtained with 30 to 90 minutes of equilibration [186]. After adequate time for equilibration, the dead space (usually 1.0 mL) is aspirated and discarded, and the fluid in the balloon is completely aspirated under anaerobic conditions. An ABG sample is taken simultaneously, and both samples are sent for analysis. The pCO_2 of the tonometer sample is measured directly. Providers can then calculate an arterial/mucosal pCO_2 gap or, using the HCO_3^- of arterial blood and the modified Henderson–Hasselbalch equation, pHi [187,188].

An air-based tonometer has also gained popularity. This device operates on the same principles as the saline-based tonometer, but automatically aspirates small amounts of air from a semipermeable balloon. This is substantially more convenient than the saline-based device, and allows semicontinuous measurement of gastric mucosal pCO_2. Results are generally similar to saline-based tonometry [189].

Technical Limitations. Several issues may confound the clinical use of gastric tonometry. Two of these apply only to saline-based tonometry. The fluid in the tonometer balloon requires 90 minutes for full equilibration with the fluid in the stomach. In a rapidly changing patient, this time window may not be appropriately timely. In addition, manufacturers calibrate blood gas analyzers to measure pCO_2 in blood, not saline. pCO_2 measurements in tonometer saline, therefore, may vary based on the blood gas analyzer used [190]. Other limitations apply to the general principle of measure gastric luminal pCO_2 to estimate mucosal perfusion. Tonometrically derived gastric pHi can be affected by the acid-secretory status of the stomach. In one study, mean gastric pHi was 7.30 in untreated normal volunteers but 7.39 in a similar group treated with ranitidine [191]. This was because the pCO_2 in the gastric fluid of the treated patients was 42 ± 4 mm Hg, compared with 52 ± 14 mm Hg in the untreated group. The difference in carbon dioxide content of the fluid is thought to be due to production of carbon dioxide by the conversion of secreted H^+ and HCO_3^- into water and carbon dioxide. Enteral feeding may also affect pHi reading. Tube feedings may lead to increased production of carbon dioxide through the interaction of secreted hydrogen ions and HCO_3^-. Some suggest temporarily discontinuing tube feeds before doing pHi measurements [192], although the pCO_2 affect appears to diminish after 24 hours of continuous feeding [193]. Finally, pHi is a calculated variable which uses the systemic arterial bicarbonate value; this probably does not reflect regional perfusion [188]. The present consensus favors the use of arterial-gastric pCO_2 gap rather than pHi [189,194].

Clinical Usefulness and Limitations. pHi correlates well with a number of clinically important endpoints. Changes in pHi during weaning from mechanical ventilation predict weaning failure [195]. Intraoperative and postoperative cardiac surgery patients have been particularly well studied, and in that group gastric pHi appears to predict complications well [196,197]. Most importantly, pHi predicts mortality in septic [198], acutely injured [199], and general ICU patients [200].

For a diagnostic tool to be *therapeutically* useful, however, we must be able to act on its results in a way that improves patient outcome [201]. Therapeutic protocols based on gastric tonometry have produced conflicting results. A randomized, controlled trial of 260 ICU patients, reported in 1992, found that gastric pHi-based therapy had no effect on mortality of patients with a low admission pHi but was associated with reduced mortality in patients with a normal admission pHi [202]. However, interpretation of this finding is severely limited because the authors did not analyze the results in an intention-to-treat fashion, thus abandoning many of the benefits of randomization [203], and 21 patients were withdrawn from the study due to protocol noncompliance by treating physicians. A subsequent randomized, controlled trial of 210 general ICU patients, reported in 2000, found no difference between intervention and control arms [204]. In patients with a normal initial pHi, there was a nonsignificant trend toward increased 30-day mortality in the group treated based on pHi. One patient in the intervention group was excluded from analysis due to a conversion to comfort-measures-only status 5 hours after enrollment. A 2005 study randomized 151 trauma patients to pHi-driven therapy, splanchnic ischemia/reperfusion-based protocol, or usual care. The authors found no significant differences in mortality, organ dysfunction, ventilator days, or length of stay. Analysis was intention-to-treat [205]. Other, smaller randomized trials have generally found no effect [206].

Alternative Regional pCO_2 Measurement: Sublingual Capnometry. Sublingual capnometry operates on the same fundamental principles as gastric tonometry. A sensor is placed under the tongue and CO_2 diffuses across a semipermeable membrane into a dye, which fluoresces differently based on CO_2 concentration. A fiberoptic cable transmits light of the appropriate wavelength and detects the resulting fluorescence, which is proportional to CO_2 concentration in the sensor [175]. Results from this technique correlate with gastric tonometry [207] and patient outcome [208]. No randomized intervention trials based on sublingual capnometry have yet been published. Although sublingual capnometry was entering nonresearch clinical use, the manufacturer recalled the commercially available sublingual capnometry device in 2004 after an outbreak of *Burkholderia cepacia* related to contaminated sublingual probes [209].

Summary. Although gastric tonometry predicts many important clinical outcomes, high-quality data does not support gastric-tonometry–based resuscitation. The Surviving Sepsis Campaign's 2004 guidelines for hemodynamic management of septic shock—representing eleven international professional societies—concludes that these results make gastric tonometry "of interest largely as a research tool rather than as a useful clinical monitor for routine use [194]." Researchers are actively investigating the use of sublingual capnometry, a similar technology, as a potential resuscitation endpoint.

Transcutaneous Oxygen and Carbon Dioxide Measurement in Adults

Transcutaneous measurements of the partial pressures of oxygen ($PtcO_2$) and carbon dioxide ($PtcCO_2$) are frequently used for neonatal blood gas monitoring but have not gained widespread clinical acceptance in adult ICUs [175]. In adults, similar to gastric tonometry, $PtcO_2$ and $PtcCO_2$ reflect *local* tissue oxygen and carbon dioxide levels and therefore blur the boundary between assessment of global gas exchange and regional tissue perfusion monitoring. More recently, measurements of transcutaneous hemoglobin oxygen saturation (StO_2) have entered the research and clinical realms.

This section refers only to transcutaneous monitoring in adults.

Technique

Oxygen and carbon dioxide diffuse out of the capillaries, into the interstitium, and through the skin. The skin usually resists O_2 and CO_2 diffusion, but heating the skin promotes diffusion by changing the structure of the stratum corneum, shifting the oxygen dissociation curve, and promoting arterialization of dermal capillaries [175]. Transcutaneous systems take advantage of these properties to measure partial pressures of oxygen ($PtcO_2$) and carbon dioxide ($PtcCO_2$). Typically, a unit less

than 1 inch in diameter is attached with an airtight seal to the skin with an adhesive. An electrode heats the skin to improve gas exchange; a temperature sensor measures skin temperature at the skin surface and adjusts the heater to provide a constant temperature—typically about 44°C. Oxygen and carbon dioxide diffuse out of the capillaries into the interstitium and through the skin to measuring electrodes.

Technical Limitations

Because units use electrodes for partial pressure measurement, problems with calibration and electrode drift during prolonged monitoring can clearly alter measurements. Drift may alter readings by up to 12% over a 2-hour period [210]. Because of the heating requirement, probe sites must be changed at least every 4 hours to prevent burns [211]. Units must be recalibrated whenever the probe temperature is changed and every 4 to 6 hours to prevent artifact from electrode drift. Many units take 15 to 60 minutes to warm the skin and establish stable readings. Probes must be firmly attached to the skin, or leaks from the surrounding atmosphere lower $PtcCO_2$ and alter $PtcO_2$ values. Adhesion is a problem in diaphoretic patients.

Thick or edematous skin provides a diffusion barrier that amplifies differences between arterial and transcutaneous pO_2 and pCO_2. The longer the distance the gases must diffuse to be measured, the more important are the effects of temperature, perfusion, and local metabolism. This appears to be the fundamental reason why transcutaneous measurements are usually more closely related to arterial values in neonates than in adults. Edema, burns, abrasions, or scleroderma would all be expected to alter transcutaneous values.

Clinical Usefulness and Limitations

Because $PtcO_2$ and $PtcCO_2$ reflect local pO_2 and pCO_2, they change in response both to regional perfusion/oxygen delivery and to global derangements. In stable, healthy adults without hemodynamic or respiratory instability, $PtcO_2$ and $PtcCO_2$ accurately reflect PaO_2 and $PaCO_2$ [176,210]. The measured transcutaneous values of oxygen and carbon dioxide are typically 10 mm Hg lower [177] and 5 to 23 mm Hg higher [212] than arterial values, respectively. In stable patients, it may be reasonable to use transcutaneously measured values as surrogates for arterial pO_2 and pCO_2. However, systemic hypoperfusion due to low cardiac output, regional hypoperfusion due to sepsis or shock, and local hypoperfusion due to cutaneous vasoconstriction caused by medication or cold produces discrepancies. In these cases, transcutaneous measurements cease to reflect arterial values and better track oxygen delivery and tissue metabolism [213]. For these reasons, many authors have argued against relying on $PtcO_2$ and $PtcCO_2$ to estimate arterial pO_2 and pCO_2 in critically ill adults [213,214].

Several studies have demonstrated the value of transcutaneous oxygen measurements as indices of perfusion or oxygen delivery. When PaO_2 remains constant, a decrease in $PtcO_2$ is probably due to changes in perfusion. Changes in local perfusion and metabolism may cause $PtcO_2$ values to fall to zero and $PtcCO_2$ values to climb to more than 30 mm Hg above arterial values [212]. During cardiac decompensation and arrest, $PtcO_2$ correlates best with cardiac output [215]. In hemorrhagic shock, the ratio of $PtCO_2$ to PaO_2 decreases, even though PaO_2 may remain normal [216]. Because the measurements are very sensitive to changes in flow, they can be useful in predicting or warning of imminent change before a blood pressure response is seen. In a small series of high-risk perioperative patients, declines in the $PtCO_2/PaO_2$ ratio predicted subsequent hemodynamic collapse [217]. Transcutaneous $PtcO_2$ also correlates with mortality. In emergency department patients with severe sepsis or septic shock, $PtcO_2$ was lower in nonsurvivors than survivors [218]. In trauma patients, $PtcO_2$ values were significantly higher in survivors than nonsurvivors ($p < 0.001$) with an area under the receiver operating characteristics curve of 0.74 for predicting in-hospital mortality [219].

Ongoing Development

More recent work has focused on the use of near-infrared spectroscopy to measure tissue hemoglobin oxygen saturation. This technique, rather than quantifying partial pressures of oxygen, instead measures the percent of microvascular hemoglobin saturated with oxygen. It has shown clinical correlations with invasive hemodynamic measures in sepsis [220] and severity of shock in trauma [221]. Further research is required to define the role of StO_2 as a potential resuscitation endpoint.

Summary

Transcutaneous monitors have little role in the ICU as simple tools to replace other means of measuring arterial gas. They predictably reflect arterial pO_2 and pCO_2 values only in hemodynamically stable patients, who are least likely to demand intensive care or to benefit from ICU monitoring. As monitors of trends in PCO_2 and PO_2, they can be regarded as effective only in the sense that they typically do not produce false-negative alarms—that is, if the arterial values change, the transcutaneous values reflect the change. So many other factors, such as changes in tissue edema and perfusion, may result in alterations in transcutaneous trends that the supervising staff can initially determine only that *something* has changed. An accurate interpretation of the clinical event usually requires reassessment of either cardiac status or arterial gases.

Therefore, transcutaneous monitors are inadequate cardiac monitors and inadequate pulmonary monitors but are good cardiopulmonary monitors. When perfusion is stable, values reflect gas exchange. When gas exchange is stable, values reflect perfusion. When both are unstable, the results cannot be interpreted without additional information. The use of near infrared spectroscopy to measure tissue hemoglobin oxygenation—StO_2—is a promising development, but one that requires further clinical study.

CHAPTER 27 ■ MINIMALLY INVASIVE HEMODYNAMIC MONITORING

ANDREW J. GOODWIN, EDNAN K. BAJWA AND ATUL MALHOTRA

INTRODUCTION

The assessment of cardiac output (CO) has historically been vital to the management of critically ill patients. The underlying nature of shock in a hypotensive patient may not be obvious clinically and is often multifactorial. In these circumstances, it is crucial to characterize what type of shock (i.e., distributive, cardiogenic, hypovolemic) is playing a role in a patient's presentation as well as how they will respond to interventions, such as volume loading. Determination of CO is thought to be a critical component of this process and thus has long been a matter of interest to clinicians.

The physical exam can be unreliable in assessing hemodynamics in systolic heart failure [1] and in critically ill patients without recent myocardial infarction [2]. As such, more dependable measurements may be required to treat such patients optimally. Since its introduction [3], the flow-directed pulmonary artery catheter (PAC) has been useful in obtaining measurements of CO and has been used both diagnostically as well as to gauge response to treatment. For many years, the PAC thermodilution technique was considered to be the "gold standard" of ICU hemodynamic measurement. This philosophy has been called into question over the last several years in light of mounting evidence that clinicians may be using the PAC ineffectively [4] and that morbidity and mortality in a variety of clinical situations are not improved with its use [5–7], but instead may be worsened [8,9].

In light of these studies, many clinicians have begun to question the importance and the credibility of the PAC. Some postulate that the lack of improvement in morbidity and mortality stems from the deleterious complications that are inherent to an invasive procedure. Others have shown that even when oxygen delivery in critically ill patients is known and is optimized or even increased to supranormal levels, there is no corresponding improvement in outcomes [10]. This gives rise to the notion that once tissue hypoperfusion results in organ dysfunction, a cycle of inflammation ensues which leads to irreversible organ damage if not corrected early. This concept has been described as "cytopathic hypoxia" where hypoperfusion leads to the disruption of the intracellular utilization of oxygen such that delivery of normal or supranormal amounts of oxygen to a cell will not restore its function [11,12]. More recently, some intensivists have questioned the notion of "cytopathic hypoxia" although the concept of mitochondrial failure in some ICU patients is relatively well accepted. Some data have emerged that suggest that correction of hypoperfusion and inadequate oxygen delivery early in the course of sepsis improves outcomes [13,14]. Interestingly, these studies did not use PACs, but instead used central venous oxygen saturation as a surrogate for CO and oxygen utilization. Two other possibilities may explain the failure of RCTs to show benefit to the PAC. Considerable data suggest inadequate knowledge among practitioners regarding the optimal use of PAC, making any hope of improving outcome unlikely under such circumstances. Alternatively, the failure of PAC trials may reflect failure of the protocols used to guide PAC treatment rather than failure of the PAC per se [15].

Many are focusing on alternative and less invasive methods of determining cardiac function. These methods can be divided into two broad categories: measurements of cardiac function and measurements of indices of oxygen delivery and/or tissue

perfusion as surrogates for CO. The goal of this research has been to develop feasible minimally invasive techniques that provide accurate measurements in the ICU patient. In some cases, these studies have focused on adapting monitoring technology that is already routinely used in this patient population.

In this chapter, we focus on several emerging technologies being used to determine CO and tissue perfusion in the ICU. The methods of Doppler echocardiography, pulse contour analysis, partial carbon dioxide rebreathing, and gastric tonometry represent the modalities best studied to date. Consideration will also be given to new and developing methods such as sublingual capnometry and biomarkers. Given its known limitations in critically ill patients, thoracic bioimpedance will not be discussed in detail in this chapter. We will conclude with a summary of practice recommendations and future directions.

CARDIAC OUTPUT

CO is the amount of blood flow through the cardiovascular system over a period of time. Traditionally, it is reported in liters per minute and can be normalized for body surface area to provide the cardiac index. In the normal subject, CO is directly related to a subject's metabolic rate and oxygen consumption ($\dot{V}O_2$). The fundamental principles of CO will be described in more detail elsewhere in this text. The therapy for a hypotensive patient with diminished CO (cardiogenic shock) is fundamentally different from the therapy for a patient with diminished vascular tone (distributive shock). Therefore, an accurate knowledge of these variables is vital to the effective treatment of hypotension. The systemic vascular resistance is calculated from the ratio of pressure gradient (mean arterial pressure minus central venous pressure) to flow rate (CO). This formula assumes an Ohmic resistor (i.e., one with a linear pressure flow relationship). Because a fall in systemic vascular resistance could represent a decrease in blood pressure or a rise in CO, we favor the use of the primary measured variables in hemodynamic assessments. We would also suggest caution in the interpretation of changes in systemic vascular resistance in isolation, without consideration for underlying mechanism (e.g., changes in CO).

Traditionally, a number of techniques have been used for the assessment of cardiac function. Jugular venous pulsations, S3 gallop, and skin temperature have all been used to estimate CO with mixed results [16–18]. The pulmonary artery occlusion pressure (PAOP) and central venous pressure (CVP) have also been used as surrogates for left and right ventricular function, respectively. The PAOP is commonly used to establish the diagnosis of left heart failure in the hypotensive patient and is often used to guide resuscitation. Magder et al. demonstrated that the CVP could provide useful information about the volume status of critically ill patients [19,20]. Because the majority of the blood volume is in the systemic veins, and the right ventricle is the major determinant of CO, some would argue that the CVP should receive more attention as the focus of hemodynamic resuscitation protocols [21]. Unfortunately, PAOP and CVP only represent the end-diastolic pressures of their respective chambers. These variables do not always accurately translate into systolic function and CO. In addition, invasive assessment of PAOP [22,23] and clinical assessment of CVP [24] have been notoriously difficult to assess accurately and reliably.

Over the last few decades, considerable research has been devoted to the accurate measurement of CO by minimally invasive means. At present, there exist several modalities that are able to provide estimates of CO on a continuous or near-continuous basis. As described later, some have been established enough to warrant increasing use in clinical settings (esophageal Doppler, pulse contour analysis) while the clinical usefulness of others is still unclear (partial carbon dioxide rebreathing).

Esophageal Doppler

Background

To date, the esophageal Doppler (ED) has been one of the most rigorously studied noninvasive CO measurement modalities. Side et al. described ED in 1971 and it was later refined by Singer et al. [25,26]. This technique uses a Doppler probe placed in the esophagus to measure blood flow in the descending thoracic aorta. The ED uses the Doppler Shift principle, which implies that when a transmitted sound wave is impeded by a structure, the reflected sound wave will vary in a frequency dependent manner with the structure's characteristics. In the case of a fluid filled tube, such as the aorta, the magnitude of Doppler shift will vary in direct proportion to the velocity of flow in the tube (Fig. 27.1). Thus, the reflected sound wave can be used to determine flow velocity in the descending aorta. Multiplying this flow velocity by the ejection time and the cross-sectional area of the aorta provides an estimate of the stroke volume (SV). As this measurement does not account for the component of total stroke volume that travels to the coronary, carotid, and subclavian arteries, a correction factor must be applied to estimate the total SV. CO is then calculated by multiplying corrected stroke volume by the heart rate. The original versions of the ED system provided only Doppler shift data; therefore, the cross-sectional area of the aorta was estimated from a nomogram based on a patient's height, weight, and age. Subsequently, a combined Doppler and ultrasound probe has been introduced to provide estimates of both aortic flow velocity and cross-sectional area [27]. The descending aortic cross-sectional area measured by this model correlated very well with that measured by transesophageal echocardiography. In addition, aortic blood flow measured with this model was well correlated with CO as measured by thermodilution [27].

Beyond providing an estimate of CO, ED systems can provide information about the preload and the contractility of the heart. Singer et al. analyzed the flow-velocity waveform derived from an ED system and discovered that the corrected flow time (FT_c) correlated with preload [26,28] (Fig. 27.2). These studies further demonstrated that as preload was increased or

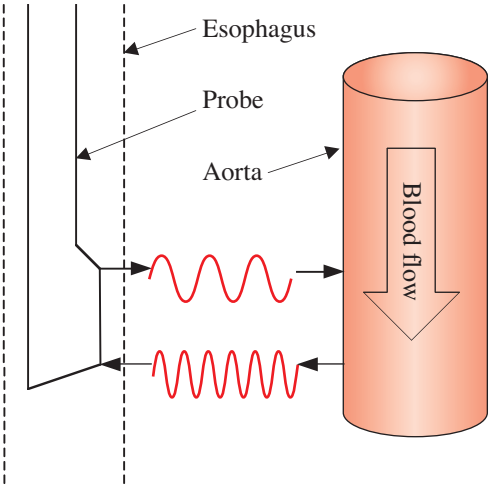

FIGURE 27.1. Esophageal Doppler probe using the Doppler Shift principle. Transmitted ultrasound waves are reflected back at varying frequencies, which depend on the velocity of flow of the red blood cells they encounter.

TABLE 27.1

ADVANTAGES AND DISADVANTAGES OF THE ESOPHAGEAL DOPPLER SYSTEM FOR CARDIAC OUTPUT MONITORING

Concept: Doppler probe in the esophagus measures stroke volume in the descending aorta to estimate cardiac output.
Advantages
Continuous
Short set-up time
Low incidence of iatrogenic complications
Ability to leave in place for extended periods
Minimal training period required
Minimal infection risk
Disadvantages
High up-front cost
Can only be used in the intubated patient
May require frequent repositioning if patient is moved
High interobserver variability

decreased, the corrected flow time increased or decreased, respectively [26,28]. It is not clear, however, if following trends in FT_c in response to volume loading is superior to following trends to SV [29]. Wallmeyer et al. described a correlation between the peak velocity measured by Doppler and contractility measured by electromagnetic catheter measured flow [30]. Singer et al. further substantiated this finding by demonstrating that dobutamine infusions increased peak flow velocities measured by an ED system in a dose-dependent fashion [31]. These observations suggest that an experienced operator may be able to extrapolate useful hemodynamic parameters beyond the CO, through careful data synthesis.

Clinical Utility

The clinical usefulness of the ED system is still being determined. The majority of recent studies that have compared this system to the "gold standard" of thermodilution have been performed in either intraoperative or postoperative settings and have revealed mixed results. One single-center study of 35 patients that compared ED measurements of CO to simultaneous measurements of CO by thermodilution during off-pump coronary artery bypass graft showed very poor correlation between the two techniques [32]. Other studies, including a meta-analysis of 11 trials, have shown that ED systems are better at following changes in CO in response to fluid challenges than they are at measuring the absolute CO [33–35]. The authors of the meta-analysis also made an important point when discussing the reliability of comparing ED systems to thermodilution. They argued that the poor reproducibility inherent in the thermodilution technique will likely affect the limits of agreement between ED systems and thermodilution even if ED systems were reliable [33]. This concept was described by Bland and Altman [36] and has important implications when comparing the accuracy of absolute CO measured by any system when compared to thermodilution.

Advantages and Disadvantages

While comparing ED systems to thermodilution, technical advantages and disadvantages deserve consideration (Table 27.1). One advantage of the ED system is that it is continuous. Unlike the traditional bolus thermodilution techniques, an ED system can continuously display CO, which allows earlier recognition of hemodynamic deterioration or improvement in system responsiveness to a therapeutic intervention. In addition, an ED probe can be placed in minutes and has been associated with a low incidence of major iatrogenic complications [37–39]. Some data suggest that once inserted, an esophageal probe can be left in situ safely for more than 2 weeks [40]. One study determined that the training required to become proficient in the use of ED consisted of no more than 12 patients [41]. Furthermore, as the esophagus is a nonsterile environment, it is logical to assume that the infectious risk of ED probe use is less than that of a PAC placed percutaneously.

There are also technical disadvantages to the ED system. One is the high up-front cost of the system itself as compared to the PAC apparatus. This cost may represent a very real limitation in the number of systems that a facility can purchase and maintain. This financial obstacle must be balanced with the likelihood that multiple patients would have need of this system simultaneously, which would necessitate multiple systems. Another disadvantage of this system is that it can only be used in the intubated patient. Although a large percentage of critically ill and/or surgical patients who would benefit from this system fit this criterion, the nonintubated patient would be more problematic. Additional concerns would include the likely need for repositioning or recalibration in the ICU patient. Though surgical patients are often immobile, ICU patients are often repositioned frequently to prevent skin breakdown or to facilitate improved oxygenation. Such movements will increase the chance of probe position changes that will require frequent calibration and repositioning. Finally, Roeck et al. suggested that there is significant interobserver variability when measuring changes in stroke volume in response to fluid challenges with ED [35]. Poor reproducibility may limit the utility of this system.

Future Research

As the ED is used more widely, outcome data will be crucial. To date, the majority of research has focused on the technique's validity and feasibility. One notable study which compared intraoperative ED use with conventional monitoring during femoral neck fracture repair found a faster recovery time and significantly shorter hospital stay in the ED group [42]. Similarly, Gan et al. demonstrated in a prospective randomized trial of patients undergoing major elective surgery that stroke volume optimization using ED shortened hospital length of stay and resumption of PO intake as compared to conventional intraoperative care [43]. This latter finding may be due to less gut hypoperfusion which has also been demonstrated with the use

of ED [44]. A recent meta-analysis of nine trials of perioperative ED use also found improvements in length of stay as well as time to resuming an oral diet [45].

Although the above-mentioned data suggest that perioperative outcomes are improved with the use of ED, there are no robust parallel data for nonoperative ICU patients. The ultimate use of ED will depend on further outcome data, availability of equipment and local experience and expertise.

Pulse Contour Analysis

Background

Pulse Contour Analysis (PCA) is another modality for measuring CO noninvasively that has been extensively studied. This method relies on the theory, first described by Frank in the early part of the twentieth century, that SV and CO can be derived from the characteristics of an aortic pressure waveform [46]. Wesseling et al. eventually published in 1983 an algorithm to link mathematically SV and the pressure waveform [47]. This original version calculated SV continuously by dividing the area under the curve of the aortic pressure waveform by the aortic impedance. As aortic impedance varies between patients, it had to be measured using another modality to initially calibrate the PCA system. The calibration method usually employed was arterial thermodilution. Aortic impedance, however, is not a static property. It is based on the complex interaction of the resistive and compliant elements of each vascular bed, which are often dynamic, especially in hemodynamically unstable patients. Since the first PCA algorithm was introduced, several unique algorithms have been created to model accurately the properties of the human vascular system for use in PCA systems.

PCA involves the use of an arterial placed catheter with a pressure transducer, which can measure pressure tracings on a beat-to-beat basis. Such catheters are now routinely used in operating rooms and ICUs as they provide a continuous measurement of blood pressure that is superior to intermittent noninvasive measurements in hemodynamically unstable patients. These catheters are interfaced with a PCA system, which uses its unique algorithm as well as the initial aortic impedance calibration data from a thermodilution measurement of CO to provide a continuously displayed measurement of CO. Obviously, the reliability of a PCA system depends upon the accuracy of the algorithm that it employs. Because each algorithm is unique in the weight that it ascribes to each element of vascular conductivity, it is impossible to ensure that a system will be able to reproduce the results of another system under similar conditions [48]. Keeping this in mind, one cannot conclude that all systems are equally reliable.

PiCCO (Pulsion SG, Munich, Germany) is a PCA system that has received considerable attention in the literature. Numerous studies have demonstrated good correlation between this system and pulmonary thermodilution in both critically ill and surgical patients [49–53]. Notably, this system did not require recalibration during these study periods, which were performed under static ventricular loading conditions. The system involves the placement of a femoral arterial catheter that is passed into the abdominal aorta. In addition to a pressure transducer, the catheter also contains a thermistor for arterial thermodilution. The system is calibrated by injecting cold saline via a central venous catheter at the right atrium in a manner similar to pulmonary arterial thermodilution. Instead of using a thermistor in the pulmonary artery, however, the thermistor on the femoral arterial catheter allows calculation of CO. This initial value of CO is then used to calibrate the PCA system that is attached to the arterial catheter. Because the arterial catheter is used for calibration, a PAC is not necessary. When compared with pulmonary artery thermodilution, the arterial thermodilution method was found to be accurate, implying that it is an acceptable method for calibration of a PCA system [49–51].

More recently, a novel PCA system known as the Flotrac (Edwards Lifesciences, LLC, Irvine, CA) has been introduced. It is designed to "autocalibrate" on a continuous basis. It calculates stroke volume using a general equation: $SV = K \times$ pulsatility, where K is a constant including arterial compliance and vascular resistance [54]. This constant is initially derived by patient variables such as height, weight, sex, and age by using a method described by Langewouters et al. [55] and is subsequently adjusted once per minute using arterial waveform characteristics. Pulsatility is determined by analyzing the standard deviation of the arterial pressure waveform over preceding 20-second intervals. Thus, the variables used to calculate SV are updated at least once per minute. This algorithm offers the advantage of not needing an alternative method for calculating CO for calibration purposes. When compared to pulmonary artery catheter thermodilution in a postcardiac surgery setting, this system showed good correlation over a wide range of COs. In addition, it appears that a radial artery catheter is just as accurate as a femoral artery catheter in this setting, which is another advantage of this system [54].

Clinical Utility

As mentioned earlier, the initial trials studying PCA systems used data from static ventricular loading conditions. Both the critically ill and the intraoperative patient, however, often experience rapid changes in ventricular preload. The accuracy of the PiCCO system with dynamic changes in preload was addressed in a subsequent study, which used a modified algorithm. Felbinger et al. showed that changes in CO in response to preload could be accurately measured in a cardiac surgical ICU population when compared to pulmonary thermodilution [56].

Although being able to monitor changes in CO during volume loading is important, being able to predict *a priori* when a patient would benefit from volume loading is perhaps more useful. Pulse pressures commonly vary throughout the respiratory cycle. Pulse pressure variation (PPV) is defined as the result of the minimum pulse pressure subtracted from the maximum pulse pressure divided by the mean of these two pressures.

$$\mathrm{PPV} = \frac{\text{Pulse Pressure}_{\max} - \text{Pulse Pressure}_{\min}}{\text{Pulse Pressure}_{\text{mean}}} \quad (1)$$

The magnitude of the PPV in a patient can predict preload responsiveness [57–59]. Analogous to PPV, an additional piece of data that PCA systems can provide is the stroke volume variation (SVV). The SVV represents the change in percentage of SV over a preceding time period as a result of changes in SV due to ventilation. So far, the ability to use SVV to determine preload responsiveness has yielded mixed results. Reuter et al. found that SVV reliably decreased as cardiac index increased in response to preloading with colloids in ventilated postoperative cardiac surgical patients [60]. This finding supports the argument that the magnitude of SVV may be used to predict preload responsiveness. It is important to note that the tidal volumes used in this study were supraphysiologic (15 mL per kg), which results in a larger SVV and a resultant increase in the accuracy of this approach. Subsequently, another study used a smaller tidal volume (10 mL per kg) in a similar patient population and could not demonstrate a reliable relationship between SVV and an increase in cardiac index in response to preloading [61]. This finding suggests that when using lower tidal volume ventilation strategies, which are optimal for acute respiratory

TABLE 27.2

ADVANTAGES AND DISADVANTAGES OF THE PULSE CONTOUR ANALYSIS METHOD FOR CARDIAC OUTPUT MONITORING

Concept: Arterial catheter used to determine stroke volume from aortic pressure waveforms.
Advantages
Continuous
Uses catheters that are already commonly used in ICU patients
Does not require calibration with pulmonary artery catheter
Disadvantages
Likely unable to determine preload responsiveness during low tidal volume ventilation
Questionable accuracy during large changes in blood pressure
Questionable accuracy during vasoconstrictor use

distress syndrome (ARDS), PCA-derived SVV should not be used to estimate preload responsiveness.

Advantages and Disadvantages

Overall, the pulse contour analysis system offers several advantages over the traditional "gold standard" of pulmonary artery thermodilution (Table 27.2). Depending on the system, only an arterial catheter (Flotrac) or an arterial catheter and a central venous catheter (PiCCO) are required, both of which are commonly in place in critically ill and surgical patients. Thus, PACs and their possible risks can be avoided when using these systems. The PCA systems also provide a continuous measurement of CO as opposed to the intermittent nature of traditional thermodilution systems.

As with any system, there are disadvantages to the PCA system as well. The ability to use this system to determine preload responsiveness is questionable in patients who are being managed with recommended ventilatory strategies. In addition, some data suggest that in patients who have marked changes in blood pressure, the algorithm is not able to model adequately the changes in vascular resistance and compliance and, therefore, the accuracy of the measured CO declines [62]. Furthermore, a similar breakdown in the accuracy of measured CO has been suggested during the administration of vasoconstrictors [63], which are common in the critically ill patient.

Future Research

The clinical utility of the pulse contour analysis system is still being determined. Future studies that may help in defining the system's clinical role could focus on several points. First, a better understanding of how changes in blood pressure and vasoconstrictor use affect the accuracy of a particular system's algorithm will help to determine when a system needs to be recalibrated to maintain its accuracy. In addition, an analysis of how SVV predicts preload responsiveness at lower tidal volumes will provide more applicable information. Finally, a paucity of data regarding how PCA systems affect patient outcomes exists at present. Comparisons between the outcomes seen with this system and pulmonary artery thermodilution may provide convincing evidence about the real usefulness of PCA. In particular, the common question "will the patient respond to fluids?" may be replaced by the question "should the patient be given fluids?" once adequate outcome data are available.

Partial Carbon Dioxide Rebreathing Method

Background

The Fick equation for calculating CO has been known for over a 100 years. Its underlying principle states that for a gas (X) whose uptake in the lung is transferred completely to the blood, the ratio of that gas's consumption (VX) to the difference between the arterial (C_aX) and venous (C_vX) contents of the gas will equal the CO. In its original form, Fick used the example of oxygen (O_2) and described the following equation:

$$\text{Cardiac Output} = \frac{\dot{V}O_2}{C_aO_2 - C_vO_2} \quad (2)$$

For this equation to be accurate, several conditions must exist. The first is that blood flow through the pulmonary capillaries must be constant. In order for this to occur, the right and left ventricular outputs must be equal (i.e., steady state) and there must be no respiratory variation of pulmonary capillary flow. Another condition critical to this method's accuracy is an absence of shunts. As this method is dependent upon using gas exchange to calculate CO, any blood that does not participate in gas exchange will result in underestimation of CO. Furthermore, oxygen uptake by the lung itself must be minimal to maintain the integrity of this equation.

Although possible, the accurate measurement of $\dot{V}O_2$ is clinically challenging, especially in patients who require high FiO_2 [64]. This prompted investigators to focus on using carbon dioxide production ($\dot{V}CO_2$) in place of $\dot{V}O_2$ [65–67]. As $\dot{V}O_2$ is equal to $\dot{V}CO_2$ divided by the respiratory quotient, they determined that CO could be calculated by $\dot{V}CO_2$ divided by the arteriovenous difference between O_2 concentrations as well as the respiratory quotient (R). To measure O_2 concentrations continuously, arterial and venous oximeters were used to measure oxygen saturation (SO_2) and concentration was determined based on measured hemoglobin (Hgb) levels. This technique, therefore, relied upon the assumption that both R and hemoglobin levels remained constant during the measurement period.

$$\dot{V}O_2 = \frac{\dot{V}CO_2}{R} \quad (3)$$

$$C_aO_2 = 13.4 \times \text{Hgb} \times S_aO_2 \quad (4)$$

$$CO = \frac{\dot{V}CO_2}{13.4 \times \text{Hgb} \times R \times [S_aO_2 - S_vO_2]} \quad (5)$$

Using this method, one study found good correlation with CO determined by thermodilution [67]. The drawback to this approach, however, is the need for an invasive central venous catheter to measure accurately venous oxygen saturations as well as initially to calibrate the system and determine R. Subsequently, the partial carbon dioxide rebreathing method was introduced in an attempt to avoid the need for such catheters.

The partial CO_2 rebreathing method is based upon the Fick equation for CO_2 [68]:

$$CO = \frac{\dot{V}CO_2}{C_vCO_2 - C_aCO_2} \quad (6)$$

When using this method, a disposable rebreathing loop is placed between the endotracheal tube and the ventilator resulting in the rebreathing of carbon dioxide. A carbon dioxide sensor, an airflow sensor, and an arterial noninvasive pulse oximeter are then used to gather data before and after a period of CO_2 rebreathing. The CO_2 sensor and airflow monitor allow for the calculation of produced carbon dioxide ($\dot{V}CO_2$) both

before and during the rebreathing period. Because CO does not change from baseline during rebreathing conditions [69], one can generate the following equation [68]:

$$CO = \frac{\dot{V}CO_{2_{baseline}}}{C_vCO_{2_{baseline}} - C_aCO_{2_{baseline}}} = \frac{\dot{V}CO_{2_{rebreathing}}}{C_vCO_{2_{rebreathing}} - C_aCO_{2_{rebreathing}}} \quad (7)$$

Gedeon et al. [70] determined that subtracting the rebreathing ratio from the baseline ratio yields the following equation [68]:

$$CO = \frac{\dot{V}CO_{2_{baseline}} - \dot{V}CO_{2_{rebreathing}}}{\left[C_vCO_{2_{baseline}} - C_aCO_{2_{baseline}}\right] - \left[C_vCO_{2_{rebreathing}} - C_aCO_{2_{rebreathing}}\right]} \quad (8)$$

As CO_2 diffuses rapidly into the blood, one can further assume that the mixed venous CO_2 concentration (C_vCO_2) remains unchanged between baseline and rebreathing conditions, that is, $C_vCO_{2_{baseline}} = C_vCO_{2_{rebreathing}}$. This allows for further simplification of the equation to the following [68]:

$$CO = \frac{\Delta\dot{V}CO_2}{\Delta C_aCO_2} \quad (9)$$

C_aCO_2 can be estimated from end-tidal carbon dioxide ($etCO_2$) and the carbon dioxide dissociation curve. Therefore, ΔC_aCO_2 can be substituted for by $\Delta etCO_2$ multiplied by the slope (S) of the dissociation curve [68]:

$$CO = \frac{\Delta\dot{V}CO_2}{\Delta etCO_2 \times S} \quad (10)$$

An estimate of CO can now be calculated using data that can be measured before and after a period of rebreathing, in addition to S, which can be determined from a carbon dioxide dissociation curve. It is important to note that the estimate of CO calculated using equation 10 only accounts for the blood that is able to participate in gas exchange. Any blood involved in a right to left intrapulmonary shunt is not considered by this equation; therefore, a correction factor must be incorporated to account for this shunted blood. This is determined by a partial rebreathing system by using the data collected from the noninvasive arterial oximeter, the FiO_2, and the PaO_2 as determined by arterial blood gases. These data allow one to determine an estimate of shunted blood using Nunn's iso-shunt tables [71].

Clinical Utility

So far, the results of comparisons between partial CO_2 rebreathing techniques and alternative methods of measuring CO have been mixed at best. Although some studies have demonstrated reasonable agreement with the "gold standard" of thermodilution [72–74], others have shown poor agreement [52,75,76]. One of these studies [76] did demonstrate good reproducibility of the results obtained from the partial rebreathing method despite the fact that they did not correlate with results obtained by thermodilution. One could infer from this that the method may have been appropriately precise but that something in its algorithm, that is, estimation of shunt or estimation of C_aCO_2 from $etCO_2$, prevented it from obtaining accurate results. This may be encouraging evidence that the partial rebreathing method can be an acceptable technique in certain clinical situations as the accuracy of currently marketed systems is improved.

Determining which clinical situations are appropriate for the partial rebreathing method is critical when considering its use. Because the method's accuracy depends upon an estimate of C_aCO_2 from $etCO_2$ as well as an estimate of shunt, clinical situations that affect these estimates may not be appropriate for using this method. For instance, post-operative cardiac surgical patients tend to have increased pulmonary dead space and shunt [77] and may not be an appropriate population for partial CO_2 rebreathing monitor use [76]. In addition, some data suggest that the correlation between this method and thermodilution declines as the amount of venous admixture from shunting increases in animal models [78]. In order for C_aCO_2 to be estimated accurately by $etCO_2$, gas exchange needs to be somewhat homogenous throughout the lung. One of the hallmarks of acute lung injury (ALI) and ARDS is a heterogeneous pattern of injury and fibrosis. This heterogeneity results in a large variation of gas exchange throughout the lung. Consequently, the $etCO_2$ may be a poor estimate of C_aCO_2 leading to an important source of error. Indeed, one study, which compared the partial CO_2 rebreathing method to thermodilution in patients with varying degrees of ALI, found poor agreement between the two methods [79]. The disagreement intensified with worsening severity of ALI. Finally, significant variations in tidal volume during a period of measurement will often markedly affect the accuracy of $\dot{V}CO_2$ on a breath-to-breath basis. Consequently, the accuracy of measured CO is limited in situations of varying tidal volume such as pressure support ventilation [80].

Advantages and Disadvantages

The most notable advantage of the partial CO_2 rebreathing method is its true noninvasive nature. With the exception of the arterial blood gases used to estimate shunt, this method does not require any additional invasive procedures. In addition, CO can be measured on a near-continuous basis. However, the disadvantages of the system are substantial (Table 27.3). It is challenging to use in patients who are not intubated or in intubated patients with spontaneous ventilation. Its accuracy is questionable in patients with intrapulmonary shunt and lung injury, which are both common findings in the ICU. Because the technique raises arterial PCO_2, its safety in patients with hypercapnia or increased intracranial pressure is unknown. Each system also represents an important fixed cost but can only be used by one patient at any given time. The limited clinical utility of these systems may not justify this expenditure.

TABLE 27.3

ADVANTAGES AND DISADVANTAGES OF THE PARTIAL CARBON DIOXIDE REBREATHING METHOD FOR CARDIAC OUTPUT MONITORING

Concept: Using exhaled carbon dioxide to determine cardiac output using a modified Fick equation

Advantages
- Truly noninvasive
- Nearly continuous

Disadvantages
- High up-front cost
- Can only be used in the intubated patient
- Questionable accuracy in patients with lung injury
- Unclear risk in patients with hypercapnia or increased intracranial pressure

Future Research

At present, the clinical applicability of partial CO_2 rebreathing systems is not completely known. Future research should focus on further examining the accuracy of these systems in patients with lung injury as the current data are limited. Improvements of existing algorithms for shunt and C_aCO_2 estimation could also aid in increasing this method's generalizability. Finally, determining if this method's noninvasive nature truly makes a difference in clinical outcomes should be an important focus of upcoming investigation. In critically ill patients, there may be no major advantage to using monitoring techniques that avoid central lines and arterial lines since these are nearly ubiquitous in the ICU.

OXYGEN DELIVERY AND TISSUE PERFUSION

Although directly measuring CO can provide information vital to the management of critically ill patients, one can also argue that accurate knowledge of oxygen delivery and/or adequacy of tissue perfusion can be similarly useful. Proponents of this concept are less interested in the absolute CO as long as adequate oxygen is delivered to tissues. One of the traditional techniques used to assess oxygen delivery is the mixed venous oxygen saturation ($S_{mv}O_2$). The $S_{mv}O_2$ is measured by sampling blood from the pulmonary artery, which is representative of the venous return from both the superior and inferior vena cava after sufficient mixing. $S_{mv}O_2$ is dependent on both systemic oxygen delivery (DO_2) as well as systemic oxygen consumption ($\dot{V}O_2$). Because $\dot{V}O_2$ does not dramatically change in the absence of major metabolic derangements, decreases in $S_{mv}O_2$ can be considered to be due to decreases in DO_2 (and, thereby, CO) in many patients. As a result, investigators have focused on the clinical utility of measuring $S_{mv}O_2$ as a surrogate means of monitoring CO [81,82]. Pearson et al. found that $S_{mv}O_2$ monitoring did not improve length of ICU stay or length of vasopressor requirement when compared to traditional pulmonary artery catheter use and CVP monitoring. In addition, $S_{mv}O_2$ monitoring cost more [83].

Another potential drawback of $S_{mv}O_2$ monitoring is the need for PAC and the possible associated risks. Because many critically ill patients receive central venous catheters, some research has focused on using central venous oxygen saturations ($S_{cv}O_2$) rather than $S_{mv}O_2$. One early study found that $S_{cv}O_2$ tended to be approximately 5% to 10% lower than $S_{mv}O_2$ in humans [84]. While studying dogs, Reinhart et al. found good correlation ($r = 0.96$) between the two [85]. So far, clinical data using this variable are limited, however, the previously mentioned landmark trial by Rivers et al. used $S_{cv}O_2$ among other variables with success [13,14].

In addition to estimating oxygen delivery, recent research has focused on estimating tissue perfusion as a guide for resuscitative therapy. With this approach, the adequacy of blood and oxygen delivery is assessed by measuring markers of hypoperfusion of accessible organs. We will focus on three modalities that have demonstrated considerable promise in this field to date: gastric tonometry, sublingual capnometry, and cardiac biomarkers.

Gastric Tonometry

Background

Mounting evidence that early correction of hypoperfusion in shock improves mortality [13,14,86] has led investigators to focus on the development of methods for its early detection. Tissue levels of CO_2 rise early in the setting of hypoperfusion [87–89]. The level of CO_2 in a tissue is determined by the balance between the concentration of arterial CO_2 (C_aCO_2), blood flow to the tissue, and CO_2 production by the tissue. In a state of hypoperfusion, CO_2 increase is thought to be multifactorial. Carbon dioxide production increases in hypoperfused tissue to buffer the increase in hydrogen ions generated by the hydrolysis of ATP during glycolysis [90]. In addition, the low flow state seen in hypoperfusion results in an impaired clearance of CO_2 causing a further increase in tissue CO_2 concentrations [91]. This impaired clearance is likely the largest contributor to tissue hypercapnia in states of hypoperfusion [92]. The complex mucosal circulation of the gut results in the recirculation of CO_2 as well as arteriovenous O_2 shunting, which is exacerbated by the low-flow state of hypoperfusion. As a result, the gut mucosa is one of the earliest regions in the body affected by hypoperfusion. This characteristic combined with the relatively easy accessibility of the gut makes gastric tonometry an appealing choice for the early detection of shock [93].

Tonometry is based on the principle that gases will equilibrate between semipermeable compartments over time. Gastric tonometry involves placing a nasogastric tube tipped with a fluid or air filled balloon into the lumen of the stomach and allowing its contents to equilibrate with the fluid in the stomach. This gastric fluid, in turn, is in equilibrium with the mucosal lining the stomach. Therefore, by sampling the steady state contents of the balloon, one can estimate the partial pressure of CO_2 in the gastric mucosa ($P_{gm}CO_2$). The original set-ups used saline in the balloon, which required approximately 90 minutes for equilibration. Once equilibrated, the saline was aspirated and its PCO_2 was determined. Newer automated models use air in place of saline, which results in shorter equilibration times (less than 20 minutes) and improved precision [94–96]. Many of the early studies performed with gastric tonometry used the $P_{gm}CO_2$ to determine the intramucosal pH (pH_i) by estimating the tissue bicarbonate levels from serum bicarbonate and solving the Henderson–Hasselbach equation. Recent focus has shifted away from this approach due to the introduction of error by estimating intramucosal bicarbonate from serum bicarbonate. Instead, the PCO_2 gap ($P_{gm}CO_2$–P_aCO_2) has been proposed as an alternative measure of tissue perfusion that is less influenced by the systemic acid–base status [97].

Clinical Utility

Given its relatively noninvasive nature, gastric tonometry would be an ideal candidate for a safe modality for the guidance of resuscitation in shock. Indeed, many studies have attempted to explore this technique's ability to guide therapy in situations of hypoperfusion. Silva et al. measured changes in PCO_2 gap in addition to changes in systemic hemodynamic variables in response to fluid challenges in septic patients. They found that while cardiac index increased in response to fluid loading, indices of global oxygen delivery such as $S_{mv}O_2$ did not. The PCO_2 gap, however, was noted to significantly fall in response to fluid challenges [98]. This implies that gastric tonometry may provide a more reliable and less invasive means of monitoring response to resuscitation than monitoring traditional global variables of oxygenation such as $S_{mv}O_2$. Jeng et al. monitored $P_{gm}CO_2$ in a small series of burn patients and found that changes in $P_{gm}CO_2$ often preceded more traditional signs of hypoperfusion such as changes in mean arterial pressure and urine output [99].

In perhaps the best-known trial using this modality, Guitierrez et al. randomized 260 critically ill patients in the ICU to a standard therapy arm and a protocol arm in which patients received additional therapy aimed at improving oxygen delivery whenever pH_i fell below 7.35 [100]. These authors found a significant increase in 28-day survival in a subset of the

protocol group whose pH_i was greater than 7.35 on admission. Although this study suggested that gastric tonometry could be used to improve survival in a select group of patients, perhaps its most relevant point is that early correction of hypoperfusion is crucial to improving survival. Barquist et al. compared the effects of a pH_i guided splanchnic therapy with that of a non-pH_i–guided therapy in trauma patients. They found that patients in the splanchnic therapy group had fewer organ failures, which was associated with shorter length of both ICU and hospital stays [101]. Unfortunately, a similar "splanchnic-oriented therapy" failed to show significant clinical benefit when compared to conventional therapy in trauma patients in a more recent study [102].

Not all studies, however, have demonstrated the usefulness of gastric tonometry as a resuscitative guide. In one notable article comparing pH_i-guided therapy with therapy guided by global oxygen delivery indices in trauma patients, Ivatury et al. did not find any significant difference in overall mortality [103]. In their analysis, however, they pointed out that the time to optimization of pH_i was significantly longer in nonsurvivors. This implies that the resuscitative therapy used or the clinical condition of the nonsurvivors likely resulted in a delay of pH_i optimization and that this delay was most responsible for their outcome. Gomersall et al. also compared pH_i-guided therapy with conventional treatment in 210 ICU patients [104]. They, too, found no significant change in mortality although this study may have been underpowered [105].

Although the ideal use of gastric tonometry is guidance of resuscitation in shock, many studies using this modality have demonstrated its prognostic utility. Levy et al. analyzed how pH_i and PCO_2 gap on admission to the ICU and at 24 hours correlated with outcome in 95 critically ill patients [86]. They found that the nonsurvivor group had significantly lower pH_i values on admission and at 24 hours as compared to the survivor group. In addition, the PCO_2 gap at 24 hours independently predicted 28-day survival. These findings supported those of Maynard et al. who compared pH_i with other global measures of perfusion in 83 patients with acute circulatory failure. In their study, pH_i was found to be a better predictor of outcome than lactate and other global measures of perfusion [106]. Interestingly, mortality may not be the only outcome that can be predicted through the use of gastric tonometry. Lebuffe et al. demonstrated that the intraoperative gap between gastric and end-tidal CO_2 can predict postoperative morbidity in high-risk patients undergoing major surgery [107]. The relationship between pH_i and outcome of ventilator weaning has also been studied [108–111]. In these studies, a low baseline pH_i and a significant drop in pH_i during weaning were associated with failure to wean and failed extubations. It is not entirely clear if the witnessed drop in pH_i is due to splanchnic ischemia from diverted blood flow to facilitate increased work of breathing or if it is related to increased P_aCO_2.

Thus far, studies have suggested that gastric tonometry may be a promising modality for the treatment and prognosis of shock with numerous advantages over traditional methods (Table 27.4). It is relatively noninvasive and can provide early information regarding the development of hypoperfusion that may be more reliable than global indices of oxygen delivery. Insufficient sample sizes and the inability of some treatment protocols to raise pH_i may explain some of the negative results derived from the studies performed to date. Critics of this modality question the validity of using gastric intramucosal pH as a surrogate for the entire splanchnic circulation [112]. Others wonder if the information obtained from gastric tonometry could be determined less invasively by the base deficit/excess [113]. This particular question was partially addressed by Totapally who showed that base excess responded very slowly to changes in intravascular changes in hemorrhagic shock in rats. Alternatively, esophageal PCO_2 gap was seen to reflect changes in intravascular volume more closely [114]. One major concern for this modality is its inability to accurately measure $P_{gm}CO_2$ during enteral feeding. This may limit gastric tonometry's use in patients with protracted critical illness.

TABLE 27.4

ADVANTAGES AND DISADVANTAGES OF GASTRIC TONOMETRY

Concept: Using a semipermeable balloon in the lumen of the stomach to estimate gastric mucosal perfusion
Advantages
Low risk of infection
May provide signs of early shock before traditional methods
Provides evidence of response to therapy before traditional markers
Disadvantages
Not continuous, takes up to 20 min per measurement
Does not reveal the cause of hypoperfusion (i.e., cardiogenic vs. distributive)

Future Research

The future study of gastric tonometry should focus in several directions. First, it should be used to help determine effective protocols for increasing gut mucosal perfusion. Poorly outlined and/or ineffective protocols were potential flaws in both the Guitierrez and the Ivatury studies [100,103]. A clearly delineated and effective protocol for optimizing pH_i or PCO_2 gap would allow for a more meaningful comparison between conventional and gastric-tonometry–guided treatment. Furthermore, once a reliable protocol has been determined, gastric tonometry may be used to validate further the increasing evidence that early restoration of perfusion and oxygen delivery in shock is crucial to outcomes. Finally, the ability of gastric tonometry to predict not only mortality but also ability to wean from mechanical ventilation should be further explored as this may help to guide determining goals of care and family decision making.

Sublingual Capnometry

Background

In attempts to further explore the clinical utility of guiding resuscitative therapy by tissue CO_2 levels, investigators have begun to focus on using alternative sites for measurement. One site that appears to be particularly promising due to its easy accessibility and, thus far, its accuracy, is the sublingual mucosa. After Sato et al. demonstrated that esophageal pH_i correlated well with gastric pH_i in a rodent model [115], Jin revealed that the more proximal sublingual mucosa developed hypercapnia to a similar degree as gastric mucosa in a model of hemorrhagic shock [116]. These authors went on to show not only a close correlation between increases in sublingual PCO_2 ($P_{sl}CO_2$) and decreases in arterial pressure and cardiac index [117] but also demonstrated that reversal of shock led to a correction of $P_{sl}CO_2$ comparable to that of $P_{gm}CO_2$ and more rapidly than the traditional marker of hypoperfusion, lactate [118].

The most widely clinically studied sublingual capnometry system is the Capnoprobe SL Monitoring System (Nellcor; Pleasanton, CA) which is a CO_2-sensing optode. This device is a CO_2-permeable capsule filled with a buffered solution of fluorescent dye. The capsule is attached to an optic fiber and

is placed under the tongue. As CO_2 diffuses into the capsule, the pH of the buffered solution is altered by production of carbonic acid (H_2CO_3). This change in pH results in an alteration of the fluorescent emissions from the solution, which is ultimately sensed as a change in projected light by the attached optic fiber. Hence, by calibrating wavelengths of light with known partial pressures of CO_2, one can measure PCO_2 with this system. To ensure the highest possible accuracy of the device, it must be placed securely under the tongue with the mouth closed. An open mouth allows the entrance of light and ambient air to the optode, which can significantly alter accuracy. The reliable range of a well-seated and calibrated probe is 30 to 150 mm Hg [119].

Clinical Utility

Using this probe, researchers began to further investigate the comparability of sublingual capnometry and gastric tonometry as well as the clinical utility of capnometry. In one validation study, Marik demonstrated close correlation between $P_{gm}CO_2$ and $P_{sl}CO_2$ ($r = 0.78$; $p < 0.001$) in a heterogeneous population of 76 ICU patients [120]. Furthermore, Marik and Bankov went on to show that in another ICU population of 54 patients, $P_{sl}CO_2$ and $P_{sl}CO_2$–P_aCO_2 gap were better predictors of outcome than lactate or $S_{mv}O_2$. These authors specifically found that a $P_{sl}CO_2$–P_aCO_2 gap greater than 25 mm Hg was the best discriminator of outcome. In addition, they found that $P_{sl}CO_2$ and $P_{sl}CO_2$–P_aCO_2 gap were more responsive to treatment measures than were lactate and $S_{mv}O_2$ [121]. Weil et al. also demonstrated the prognostic abilities of sublingual capnometry when they found that a $P_{sl}CO_2$ <70 mm Hg had a positive predictive value of 93% for survival [122].

Unfortunately, in 2004 Nellcor initiated a voluntary recall of the Capnoprobe device after reports of Burkholderia cepacia being cultured from patients using this device as well as from unused devices themselves. As such, there is currently no system commercially available for sublingual capnography. Further insight into its clinical utility will have to wait until this technology is again available for clinical use.

Conclusion

In summary, the existing research regarding the clinical utility of sublingual capnometry appears promising. This technique may provide similar accuracy to gastric tonometry while being less invasive and providing results on a more instantaneous basis. In addition, it does not require discontinuation of enteral feeding during measurement periods, as some have advocated for gastric tonometry. If sublingual capnography is safely made available again, it may replace the use of lactate and $S_{mv}O_2$ as markers of hypoperfusion and as resuscitative guides. Further research into this technique's effect on patient outcome would also be warranted in the future.

Cardiac Biomarkers

Background

Cardiac biomarkers are molecules, usually proteins, which are specifically released from the heart into the blood and can be used to judge both cardiac function and dysfunction. Myocardial dysfunction is commonly seen early in the course of sepsis [123] and may be related to elevated levels of proinflammatory cytokines such as interleukin-1 and tumor necrosis factor-α, which have been shown to be cardiodepressant [124]. However, due to a concomitant increase in left ventricular ejection fraction (LVEF) caused by afterload reduction from systemic vasodilation, diagnosis of myocardial dysfunction early in sepsis can be difficult by traditional echocardiography. The study of cardiac biomarkers in the ICU setting is becoming an increasingly popular method of determining early cardiac dysfunction. As they can be obtained from a peripheral venous blood sample, they represent completely noninvasive and potentially valuable data that may assist in prognostication as well as in guiding management. To date, research has focused primarily on two proteins: troponin and B-type natriuretic peptide (BNP).

Troponin

Troponin T (TnT) and Troponin I (TnI) are cardiac-specific contractile proteins that have been studied extensively in the context of myocardial ischemia. Both have been shown to be superior to the traditional creatinine kinase MB (CK-MB) in diagnosing myocardial injury in certain clinical contexts [125–127]. As such, they have become part of the mainstay for diagnosing acute myocardial infarction today. Less is known about their role in the ICU in patients who are not undergoing myocardial infarction due to coronary plaque rupture. Several authors have observed an elevated level of troponin in ICU patients who are not undergoing an acute coronary syndrome [128,129]. One recent prospective case control study showed that 17 out of 20 patients (85%) with systemic inflammatory response syndrome (SIRS), sepsis, or septic shock had elevations in TnI. Furthermore, of the six patients who died in the study, five had elevated TnI levels. Ten of the seventeen patients with elevated TnI levels had no evidence of important coronary artery disease by coronary angiography, stress echocardiography, or autopsy [130]. Interestingly, in this study there were patients with a normal LVEF by echocardiography who had increased TnI levels. This suggests that TnI may be able to detect myocardial dysfunction even when echocardiography cannot. Troponin has also been studied as a prognostic marker in sepsis. Spies et al. measured serum TnT levels in 26 septic patients in a surgical ICU. They found that elevated TnT levels within the first 24 hours of sepsis were associated with a significantly higher mortality rate when compared to normal TnT levels [131]. Thus, troponin may be useful for detection of occult myocardial dysfunction as well as for prognostication in ICU patients in the absence of an acute coronary syndrome. These promising early findings as well as the development of more sensitive troponin assays [132] should lead to further research into the utility of troponin in the ICU.

BNP

The natriuretic peptides are a family of hormones that exert a wide range of biologic functions including diuresis and vasodilation. Two members of this family, atrial natriuretic peptide (ANP) and B-type (or brain) natriuretic peptide (BNP), are secreted by the atria and the ventricles, respectively. Their secretion is stimulated by myocardial stretch induced by increased filling volumes. Each hormone is derived from a prohormone that is cleaved into the biologically active C-terminal component and the biologically quiescent but longer lasting N-terminal component. In recent years, research has suggested that BNP can be a valuable surrogate for left ventricular end-diastolic pressure and left ventricular ejection fraction and can correlate with New York Heart Association heart failure class in patients with congestive heart failure (CHF) [133–137]. Until recently, however, little was known about the role of BNP as a marker of myocardial dysfunction in the critically ill population. Prompted by data that suggest that BNP can correlate with pulmonary artery occlusion pressure (PAOP) in patients with severe CHF [138,139], Tung et al. investigated the utility of using BNP as a surrogate for pulmonary artery catheter placement in a heterogeneous population in shock. Although BNP levels did not correlate with cardiac index or PAOP in this study, they did find that a BNP level of

<350 pg per mL had a 95% negative predictive value for the diagnosis of cardiogenic shock [140]. This suggests that although BNP should not be used in place of PAOP, a low BNP level may obviate the need for PAC placement.

This study also demonstrated that BNP levels have prognostic significance among the critically ill. The median BNP level at the time of PAC placement was significantly higher in the nonsurvivor population as compared with survivors. In addition, a multivariate analysis showed that a BNP concentration in the highest log-quartile was the strongest predictor of mortality with an odds ratio of 4.5. This was an even stronger predictor of mortality than the APACHE II scores [140]. The prognostic utility of BNP was further validated by Brueckmann et al. when these authors found that elevated N-terminal proBNP (NT-proBNP) levels on day 2 were significantly correlated with an increased mortality rate in patients with severe sepsis. These authors did not, however, find prognostic significance with N-terminal proANP (NT-proANP). Interestingly, the levels of NT-proBNP, NT-proANP, and troponin I were all found to be significantly lower in patients being treated with drotrecogin alfa (activated) than in those not receiving it [141]. This suggests that drotrecogin alfa (activated) may provide some cardioprotective effect in severe sepsis, perhaps through its proposed anti-inflammatory properties [142]. However, the sample size did not allow assessment of mortality benefit from APC.

Conclusion

In summary, the study of cardiac biomarkers in the ICU is still in the early stages. Till date, the majority of data suggests that troponin and BNP may have some prognostic significance in critically ill patients without CHF. Neither has been shown to be able to guide management, so far, although some data suggest that low BNP levels may exclude cardiogenic shock thereby preventing the need for a diagnostic PA line. Larger trials may further prove this concept in the future allowing for less invasive management of a select population of patients. Furthermore, a better understanding of the effect of drotrecogin alfa (activated) on cardiac biomarkers may provide some insight into the nature of the myocardial dysfunction seen in sepsis.

PRACTICE RECOMMENDATIONS

Independent of which cardiac monitoring technique is employed, a strategy that should be utilized in all patients with shock is early intervention. Mounting evidence suggests that mitochondrial failure may play a role in late shock [11,12] and efforts to correct hemodynamic derangements and augment oxygen delivery early in shock have shown promising results, thus far [13]. The optimal method for cardiac monitoring, however, is yet to be determined. At present, pulmonary artery thermodilution remains the "gold standard"; however, increasing interest has been given to less invasive monitoring modalities. Till date, the most substantial research has focused on ED, pulse contour analysis (Table 27.5), and gastric tonometry systems. Although there remains some question whether the absolute CO determined by ED is accurate, most studies have proven its reliability in monitoring trends in CO in response to therapeutic interventions. This ability to monitor trends may be sufficient for the management of patients in shock. Pulse contour analysis systems have also proven to be useful in monitoring trends in response to interventions. In addition, PCA systems do not require additional invasive procedures other than an arterial catheter, which is commonly used in patients with shock.

Despite these positive attributes, both ED and PCA systems do not provide a direct measure of tissue perfusion, which is, arguably, the most important variable to follow. Alternatively, gastric tonometry, and by extension sublingual capnometry, do not focus on the absolute CO but instead measure indices of tissue perfusion. This quality combined with noninvasiveness, makes these techniques appealing as replacements of thermodilution. The partial carbon dioxide rebreathing method has not yet sufficiently demonstrated its applicability to the critically ill patient. Confounding clinical features such as ALI are commonly found in this population and would likely impair the validity of existing systems. Finally, although BNP has not shown the ability to replace the PAC to date, there is some evidence that suggests that patients with a low BNP may not need one for diagnostic purposes. At present, use of any of these modalities must be performed cautiously. The majority of data available regarding these techniques has focused on comparing their accuracy with that of thermodilution. Few studies have addressed patient outcomes. Ultimately, before definite recommendations can be made, further research focusing on clinical outcomes will be necessary.

TABLE 27.5

SUMMARY OF RECOMMENDATIONS BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

Early intervention in shock is beneficial
Esophageal Doppler can be used to follow trends in cardiac output
Pulse contour analysis can reliably estimate cardiac output in perioperative patients
Stroke volume variation cannot reliably be used to estimate preload responsiveness during low tidal volume ventilation

FUTURE DIRECTIONS

As medical technology continues to advance at an explosive rate, it is easy to imagine that ICU practice will completely change in the not too distant future. The next generation of intensivists and likely younger members of this generation may find themselves looking back with awe at the "archaic" methods of current practice. At present, there are many technologies that are still in their early stages but may one day provide useful clinical information. A few of these deserve mention.

Magnetic resonance imaging (MRI) has become a common fixture in many large hospitals and is routinely used in a variety of clinical settings due to its improved accuracy over computed tomography (CT) in defining soft tissue structure. The role of MRI continues to expand as clinicians and researchers develop new ways to use its capabilities. One area in which MRI has shown particular promise is that of cardiac MRI. Although this technique is still being primarily used experimentally, early results have demonstrated its ability to assess both cardiac function as well as viability [143–145]. As more data become available, one can envision the possibility of more routine use of MRI to assess cardiac function in the ICU. In addition, advances in nuclear magnetic resonance (NMR) spectroscopy have made it possible to estimate arterial oxygen supply (DO_2) as well as skeletal muscle reoxygenation, mitochondrial ATP production, and oxygen consumption($\dot{V}O_2$) [146]. Although cost and the technical difficulties of using MRI in the ICU may be prohibitive, there clearly exists potential in this arena.

Although traditional two-dimensional transthoracic echocardiography is certainly not a new technology, recently there has been new interest in this technique among intensivists. Echocardiography has historically fallen under the domain of cardiologists who are formally trained to perform and interpret

these useful studies. This technique can provide a wealth of information about systolic function, valvular dysfunction and pericardial disease in critically ill patients [147]. More and more, noncardiology intensivists are now learning how to perform, at least, basic exams to help quickly guide initial management decisions. For example, some bedside ultrasound devices used for central line placement, also have probes, which allow at least cursory examination of cardiac function (e.g., to exclude pericardial tamponade). However, the authors are aware of instances of erroneous information being gathered from such devices when used in untrained hands. Therefore, a more formal education in echocardiography would likely be beneficial for intensivists who do not have access to immediate echocardiography by an expert.

Finally, as in other areas of medicine, in the coming years emerging technology may substantially impact critical care through insights gained in the fields of proteomics, genomics, and metabolomics. These techniques use next-generation technologies of mass spectroscopy and microarray analysis to isolate and compare which proteins, genes, and other molecular markers are preferentially expressed during different disease states. Through analysis of these patterns, it may be possible to better understand the mechanisms behind diseases such as sepsis and ARDS. Ultimately such technologies could theoretically be used in the field of hemodynamic monitoring if such patterns could be associated with specific hemodynamic states. Ideally, for example, a simple blood or urine test could reveal a biomarker pattern consistent with cardiogenic shock that would take the place of invasive measuring of CO. Determining these expression patterns as well as refining the technique such that the information could be obtained in a timely manner will be important and challenging obstacles to overcome.

CHAPTER 28 ■ NEUROLOGIC MULTIMODAL MONITORING

RAPHAEL A. CARANDANG, WILEY R. HALL AND DONALD S. PROUGH

Neurologic function is a major determinant of quality of life. Injury or dysfunction can have a profound effect on a patient's ability to be alert, communicate, and interact with his or her environment meaningfully, and function as an independent human being. The brain is a highly complex organ with specialized areas of function and is exquisitely sensitive to metabolic and physical insults such as hypoxemia, acidosis, trauma, and hypoperfusion. The goal of neurocritical care is to protect the brain and preserve neurologic functions in the critically ill patient. The impetus for multimodal monitoring of brain function arises from both its importance and vulnerability and also the difficulty in obtaining a satisfactory assessment of function in the setting of numerous insults and processes including toxic and metabolic encephalopathy, sedation and chemical restraints, and primary central nervous system (CNS) processes like stroke and traumatic brain injury.

There has been rapid growth and there continues to be much interest in the field as numerous devices and modalities are developed to monitor brain function and processes including intracranial pressure (ICP) monitoring, electroencephalography, and corticography, global and regional brain tissue oxygen monitoring, cerebral blood flow measurements, and neurochemical and cellular metabolism assessment with microdialysis.

As with any diagnostic or therapeutic tool, an understanding of the indications, limitations, risks and benefits of an intervention are essential in the effective utilization, interpretation, and application of the obtained information to the management of the individual patient. Important characteristics of monitoring devices include the ability to detect important abnormalities (sensitivity), to differentiate between dissimilar disease states (specificity), and to prompt changes in care that alter long-term prognosis (Table 28.1). Limitations of techniques include risks to patients (during placement, use, and removal), variability errors in generation of data (e.g., calibration and drift), and inherent trade-offs between specificity and sensitivity. Monitors with high specificity—values fall outside of threshold levels only when a disease state is unequivocally present—are unlikely to detect less profound levels of disease, while monitors with high sensitivity (will detect any value outside of the normal range) are likely to demonstrate small deviations from normal, which may be trivial in individual patients. The advantage of multimodal monitoring is it increases the sensitivity and accuracy of our detection of physiologic and cellular changes that signal further impending clinical deterioration by using different monitoring modalities in a complementary fashion. A legitimate concern raised by some is that the vastly larger amounts of data generated by these devices requires computer-supported data analyses which is costly and time-consuming and may overwhelm the ill-prepared clinician and detract whatever benefits may be gained from the new technology [1]. Most agree that careful consideration should go into selecting the appropriate patient to monitor, the modalities to use, and that determining the most beneficial application of these technologies requires further prospective study.

The compelling theoretical importance of brain monitoring is based on the high vulnerability of the brain to hypoxic and ischemic injuries. The brain uses more oxygen and glucose per weight of tissue than any large organ, yet has no appreciable reserves of oxygen or glucose. The brain is thus completely dependent on uninterrupted cerebral blood flow (CBF) to supply metabolic substrates that are required for continued function and survival and to remove toxic byproducts. Even transient interruptions in CBF, whether local or global, can injure or kill neural cells. These perturbations may not result in immediate cell death, but can initiate metabolic or cellular processes (e.g., gene transcription, secondary injury) that may lead to cell death days, months, or years after the insult. Therefore, clinical monitoring of neuronal well-being should emphasize early detection and reversal of potentially harmful conditions. Although there is limited conclusive data to demonstrate that morbidity and mortality are reduced by the information gathered from current neurologic monitoring techniques, most clinicians caring for patients with critical neurologic illness have confidence that their use improves management. In this chapter, we review currently available techniques with emphasis on the current scientific literature and indications for utilization.

GOALS OF BRAIN MONITORING

Monitoring devices cannot independently improve outcome. Instead, they contribute physiologic data that can be integrated into a care plan that, while frequently adding risks (associated with placement, use, and removal), may lead to an overall decrease in morbidity and mortality.

Neurologic monitoring can be categorized into three main groups: (i) Monitors of neurologic function (e.g., neurologic examination, EEG, evoked potentials, functional MRI), (ii) Monitors of physiologic parameters (e.g., ICP, cerebral blood flow, transcranial Doppler), and (iii) Monitors of cellular metabolism (e.g., $SjvO_2$, NIRS, Brain tissue oxygen tension, Microdialysis, PET, MRSPECT). Most categorizations are arbitrary and obviously overlaps and inter-relationships between modalities (e.g., blood flow and electrical activity, oxygenation, and perfusion) blur the lines of distinction. All categories provide information that may be useful in assessing the current status of the brain and nervous system and in directing therapies as well as monitoring responses to interventions, but it cannot be overemphasized that the data obtained from these monitoring devices should always be interpreted in relation to the overall clinical picture of the individual patient.

TABLE 28.1

GLOSSARY OF NEUROLOGIC MONITOR CHARACTERISTICS

Term	Definition
Bias	Average difference (positive or negative) between monitored values and "gold standard" values
Precision	Standard deviation of the differences (bias) between measurements
Sensitivity	Probability that the monitor will demonstrate cerebral ischemia when cerebral ischemia is present
Positive predictive value	Probability that cerebral ischemia is present when the monitor suggests cerebral ischemia
Specificity	Probability that the monitor will not demonstrate cerebral ischemia when cerebral ischemia is not present
Negative predictive value	Probability that cerebral ischemia is not present when the monitor reflects no cerebral ischemia
Threshold value	The value used to separate acceptable (i.e., no ischemia present) from unacceptable (i.e., ischemia present)
Speed	The time elapsed from the onset of actual ischemia or the risk of ischemia until the monitor provides evidence

CEREBRAL ISCHEMIA

Given the brain's dependence and sensitivity to perturbations in oxygenation many if not all monitors are concerned with the detection of cerebral ischemia defined as cerebral delivery of oxygen (CDO_2) insufficient to meet metabolic needs. Cerebral ischemia is traditionally characterized as global or focal, and complete or incomplete (Table 28.2). Systemic monitors readily detect most global cerebral insults, such as hypotension, hypoxemia, or cardiac arrest. Brain-specific monitors can provide additional information primarily in situations, such as stroke, SAH with vasospasm, and TBI, in which systemic oxygenation and perfusion appear to be adequate but focal cerebral oxygenation may be impaired.

The severity of ischemic brain damage has traditionally been thought to be proportional to the magnitude and duration of reduced CDO_2. For monitoring to influence long-term patient morbidity and mortality, prompt recognition of reversible cerebral hypoxia/ischemia is essential. Numerous animal studies and human studies using different imaging techniques such as PET, MRI, and SPECT have concluded that the ischemic threshold for reversible injury or penumbra is a cerebral blood flow of 20 mL per 100 g per minute below which tissue is at risk for irreversible damage [2,3]. The tolerable duration of more profound ischemia is inversely proportional to the severity of CBF reduction (Fig. 28.1). Ischemia and hypoxemia initiate a cascade of cellular reactions that involve multiple pathways including energy failure from anaerobic glycolysis with accumulation of lactic acid and increase in lactate/pyruvate ratios, loss of ion homeostasis and failure of ATP-dependent ion pumps to maintain ion gradients. This leads to sodium and calcium influx into the cell and activation of enzymes such as phospholipases that result in further membrane and cytoskeletal damage, glutamate release and excitotoxicity, lipoperoxidases and free fatty acid breakdown, and free-radical formation and inflammation with microvascular changes. Endonucleases which alter gene regulation and protein synthesis and activate the caspase pathways that trigger apoptosis are also released [4,5]. Other proteins synthesized in response to altered oxygen delivery, such as hypoxia inducible factors (HIF), have been identified as adaptive mechanisms that respond to variations in oxygen partial pressure [6] and may be protective. These multiple pathways and cellular mediators and their interactions are potential areas for therapeutic intervention. Byproducts of these reactions provide potential biomarkers for secondary injury that can be used for monitoring. Our current understanding of the utility of this data is still evolving and currently when a cerebral monitor detects ischemia, the results must be carefully interpreted. Often, all that is known is that cerebral oxygenation in the region of the brain that is assessed by that monitor has fallen below a critical threshold. Such information neither definitively implies

TABLE 28.2

CHARACTERISTICS OF TYPES OF CEREBRAL ISCHEMIC INSULTS

Characteristics	Examples
Global, incomplete	Hypotension, hypoxemia, cardiopulmonary resuscitation
Global, complete	Cardiac arrest
Focal, incomplete	Stroke, subarachnoid hemorrhage with vasospasm

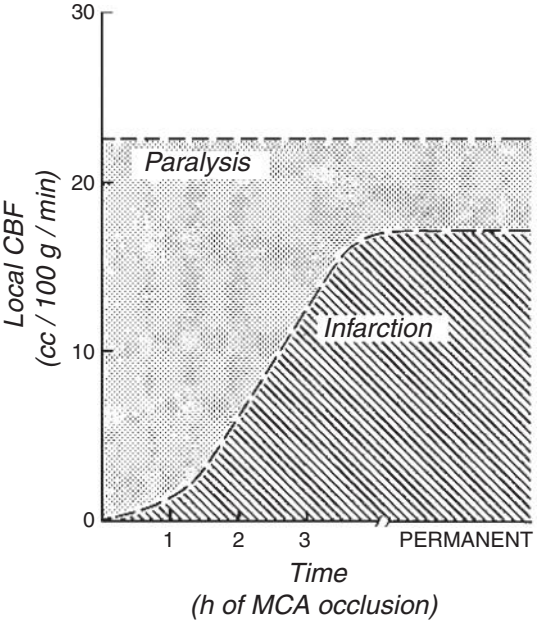

FIGURE 28.1. Schematic representation of ischemic thresholds in awake monkeys. The threshold for reversible paralysis occurs at local cerebral blood flow (local CBF) of approximately 23 mL/100 m/min. Irreversible injury (infarction) is a function of the magnitude of blood flow reduction and the duration of that reduction. Relatively severe ischemia is potentially reversible if the duration is sufficiently short. (From Jones TH, Morawetz RB, Crowell RM, et al: Thresholds of focal cerebral ischemia in awake monkeys. *J Neurosurg* 54:773–782, 1981, with permission.)

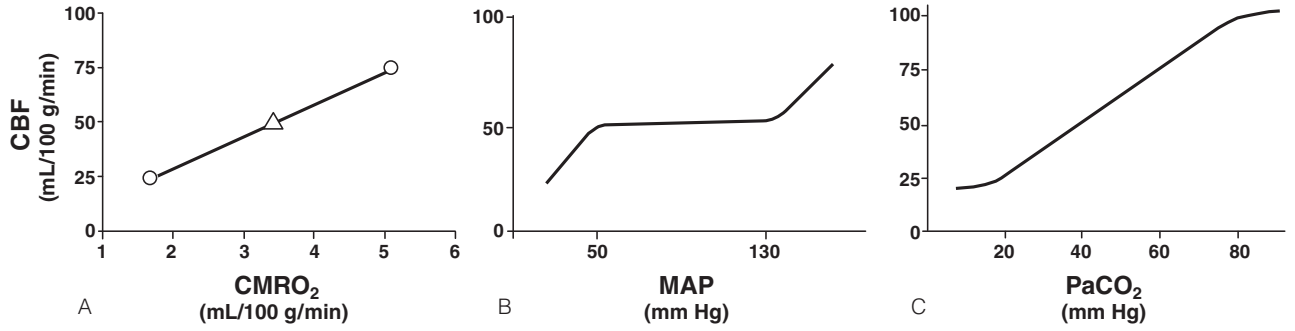

FIGURE 28.2. A: The normal relationship between the cerebral metabolic rate of oxygen consumption ($CMRO_2$) and cerebral blood flow (CBF) is characterized by closely couple changes in both variables. Normally, CBF is 50 mL per 100 g per minute in adults (*open triangle*). As $CMRO_2$ increases of decreases, CBF changes in a parallel fashion (*solid line*). **B:** Effect of mean arterial pressure (MAP) on CBF. Note that changes in MAP produce little change in CBF over a broad range of pressures. If intracranial pressure (ICP) exceeds normal limits, substitute cerebral perfusion pressure on the horizontal axis. **C:** Effect of $PaCO_2$ on CBF. Changes in $PaCO_2$ exert powerful effects on cerebral vascular resistance across the entire clinically applicable range of values.

that ischemia will necessarily progress to infarction nor does it clearly define what biochemical or genetic transcriptional changes may subsequently occur. Also, because more severe ischemia produces neurologic injury more quickly than less severe ischemia, time and dose effects must be considered. More important, if regional ischemia involves structures that are not components of the monitored variable, then infarction could develop without warning.

In healthy persons, CBF is tightly regulated through multiple pathways such that CDO_2 is adjusted to meet the metabolic requirements of the brain. In the normal, "coupled" relationship, CBF is dependent on the cerebral metabolic rate for oxygen ($CMRO_2$), which varies directly with body temperature and with the level of brain activation (Fig. 28.2A). As $CMRO_2$ increases or decreases, CBF increases or decreases to match oxygen requirements with oxygen delivery. Pressure autoregulation maintains CBF at a constant rate (assuming unchanged metabolic needs) over a wide range of systemic blood pressures (Fig. 28.2B). If pressure autoregulation is intact, changes of cerebral perfusion pressure (CPP) do not alter CBF over a range of pressures of 50 to 130 mm Hg. CPP can be described by the equation CPP = MAP − ICP, where MAP equals mean arterial pressure. After neurologic insults (e.g., TBI), autoregulation of the cerebral vasculature may be impaired such that CBF may not increase sufficiently in response to decreasing CPP [7]. This failure to maintain adequate CDO_2 can lead to ischemia and add to preexisting brain injury, a process termed secondary injury, at blood pressures that would not normally be associated with cerebral ischemia/injury. Normally, arterial partial pressure of carbon dioxide, ($PaCO_2$) significantly regulates cerebral vascular resistance over a range of $PaCO_2$ of 20 to 80 mm Hg (Fig. 28.2C). CBF is acutely halved if $PaCO_2$ is halved, and doubled if $PaCO_2$ is doubled. This reduction in CBF (via arteriolar vasoconstriction) results in a decrease in cerebral blood volume and a decrease in ICP. Conceptually, decreasing $PaCO_2$ to decrease ICP may appear to be desirable. Hyperventilation as a clinical tool was described by Lundberg et al. [8] in 1959 as a treatment for increased ICP and was a mainstay of treatment for over 40 years. However, in healthy brain, there are limits to maximal cerebral vasoconstriction with falling $PaCO_2$ (as well as vasodilation with increasing $PaCO_2$), such that, as CBF decreases to the point of producing inadequate CDO_2, local vasodilatory mechanisms tend to restore CBF and CDO_2. As a consequence, in healthy brain, hyperventilation does not produce severe cerebral ischemia; however, after TBI, hypocapnia can generate cerebral ischemia as reflected in decreased $PbtO_2$ and $SjvO_2$ [9,10]. For this reason, hyperventilation has fallen out of favor as a treatment modality for intracranial hypertension. If hyperventilation is required to acutely reduce ICP to bridge a patient to emergent surgery for example, administration of an increased inspired oxygen concentration can markedly increase $SjvO_2$ (Fig. 28.3). In response to decreasing arterial oxygen content (CaO_2), whether the reduction is secondary to a decrease of hemoglobin (Hgb) concentration or of arterial oxygen saturation (SaO_2), CBF normally increases, although injured brain tissue has impaired ability to increase CBF [11].

TECHNIQUES OF NEUROLOGIC MONITORING

Neurologic Examination

Frequent and accurately recorded neurologic examinations are an essential aspect of medical care, but are often limited in patients with moderate-to-severe neurologic compromise. Neurologic examination quantifies three key characteristics: level of consciousness, focal brain dysfunction, and trends in neurologic function. Recognition of changing consciousness or new focal deficits may warn of a variety of treatable conditions, such as progression of intracranial hypertension, new mass lesions such as expansion of intraparenchymal contusions or subdural hematoma and systemic complications of intracranial pathology, such as hyponatremia.

The GCS score, originally developed as a tool for the assessment of impaired consciousness [12], has also been used as a prognostic tool for patients with TBI [13]. The GCS score at the time of initial hospitalization is used to characterize the severity of TBI, with severe TBI defined as a GCS score less than or equal to 8, moderate TBI as a GCS score of 9 to 12, and mild TBI as that associated with a GCS score greater than 12. Lower GCS scores are generally associated with poorer long-term outcomes, although correlation to individual patients with TBI is difficult because of the significant variations in mortality rates and functional outcome [14]. Significant concern has arisen regarding the validity of the initial GCS score on presentation given the aggressive prehospital management of these patients over the last decade or so, that includes sedation and intubation in the field or the administration of paralytics and sedatives in

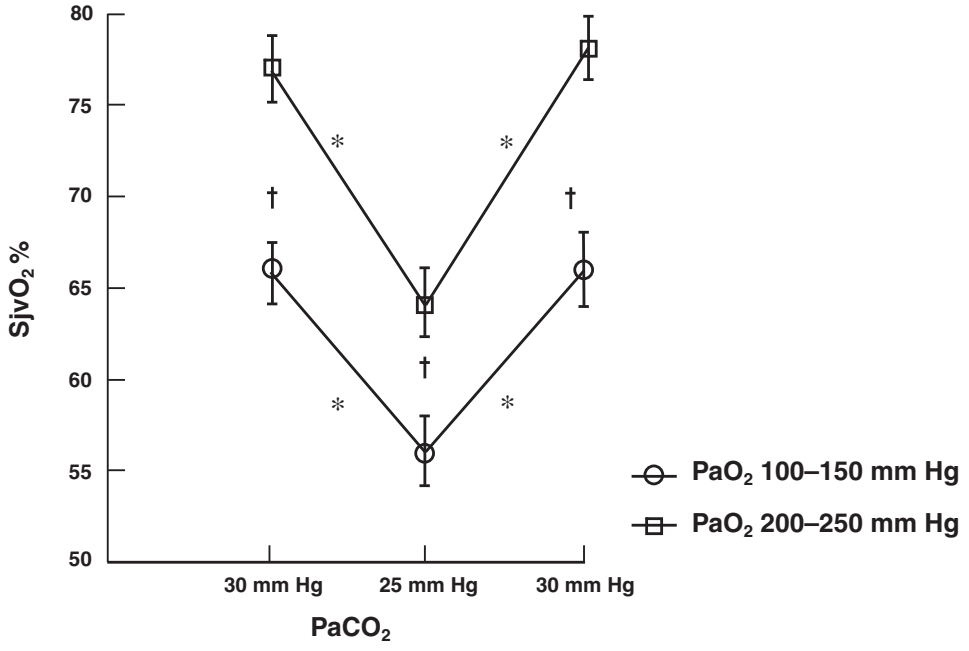

FIGURE 28.3. The effect of hyperoxia on percentage of oxygen saturation of jugular venous blood ($SjvO_2$) at two levels of $PaCO_2$. $^*p < 0.001$ for $SjvO_2$ at $PaCO_2$ 25–30 mm Hg at each PaO_2. $^\dagger p < 0.001$ for $SjvO_2$ between PaO_2 at each $PaCO_2$ level. (From Thiagarajan A, Goverdhan PD, Chari P, et al: The effect of hyperventilation and hyperoxia on cerebral venous oxygen saturation in patients with traumatic brain injury. *Anesth Analg* 87:850–853, 1998, with permission.)

the emergency room. Some authors have reported a loss of predictive value of the GCS score from 1997 onwards and call for a critical reconsideration of its use [15]. Other studies done have looked at GCS in the field versus GCS upon arrival and have found good correlation and prognostic value in predicting outcome and have even found the changes in scores from field GCS to arrival GCS to be highly predictive of outcome in patients with moderate to severe TBI [16]. Many centers use the best GCS or postresuscitation GCS in the first 24 hours or just the motor component of the GCS instead of initial GCS given these issues. Nevertheless, the GCS score is popular as a quick, reproducible estimate of level of consciousness (Table 28.3), has become a common tool for the serial monitoring of consciousness, and has been incorporated into various outcome models, such as the Trauma score, APACHE II, and the Trauma-Injury Severity score. The GCS score, which includes eye opening, motor responses in the best functioning limb, and verbal responses is limited and by no means replaces a thoughtful and focused neurologic examination. It should be supplemented by recording pupillary size and reactivity, cranial nerve examination and more detailed neurologic testing depending on the relevant neuroanatomy involved in the disease process. Even so, the use of serial GCS determinations remains a common tool in the management of patients with neurologic dysfunction.

Systemic Monitoring

Although not specific to neurologic monitoring, systemic parameters, including blood pressure, arterial oxygen saturation (SaO_2), $PaCO_2$, serum glucose concentration, and temperature, have clinical relevance in the management of patients with neurologic dysfunction or injury. The relationships between these systemic variables and long-term outcome after neurologic insults are closely linked and are subject to continuing research.

Perhaps the most important systemic monitor is blood pressure, as CBF is dependent on the relationship between CPP and cerebral vascular resistance (CVR), and can be modeled generally by the equation: CBF = CPP/CVR. As previously discussed, CBF is maintained relatively constant over a wide range of blood pressures (pressure autoregulation) through arteriolar changes in resistance (assuming no change in brain metabolism) in healthy individuals. After brain injury, autoregulation may become impaired, especially in traumatically brain-injured patients. Chesnut et al. [17,18] reported that even brief periods of hypotension (systolic blood pressure less than 90 mm Hg) worsened outcome after TBI, and recommended that systolic blood pressure be maintained greater than 90 mm Hg (with possible benefit from higher pressures). These recommendations have also been promoted by the Brain Trauma Foundation for patients with severe TBI [19]. To achieve this goal, the use of vasoactive substances, such as norepinephrine, may be required [20]. Nevertheless, optimal blood pressure management

TABLE 28.3

GLASGOW COMA SCALE

Component	Response	Score
Eye opening	Spontaneously	4
	To verbal command	3
	To pain	2
	None	1
		Subtotal: 1–4
Motor response (best extremity)	Obeys verbal command	6
	Localizes pain	5
	Flexion-withdrawal	4
	Flexor (decorticate posturing)	3
	Extensor (decerebrate posturing)	2
	No response (flaccid)	1
		Subtotal: 1–6
Best verbal response	Oriented and converses	5
	Disoriented and converses	4
	Inappropriate words	3
	Incomprehensive sounds	2
	No verbal response	1
		Subtotal: 1–5
		Total: 3–15

for patients with TBI has yet to be defined. Some clinical data suggest that the influence of hypotension on outcome after TBI is equivalent to the influence of hypotension on outcome after non-neurologic trauma [21]. Proposed treatment protocols include CPP greater than 70 mm Hg [22], greater than 60 mm Hg [23], or greater than 50 mm Hg [24]. The augmentation of CPP above 70 mm Hg with fluids and vasopressors has, however, been associated with increased risk of acute respiratory distress syndrome and is not universally recommended [23].

Another essential step in insuring adequate CDO_2 is the maintenance of adequate CaO_2, which in turn is dependent on Hgb and SaO_2; therefore, anemia and hypoxemia can reduce CDO_2, which would normally result in compensatory increases in CBF. However, these compensatory mechanisms are limited. As SaO_2 (or PaO_2) decreases below the compensatory threshold, $SjvO_2$ and jugular venous oxygen content ($CjvO_2$), which reflect the ability of CDO_2 to supply $CMRO_2$, also decrease. The correlation is most evident below a PaO_2 of approximately 60 mm Hg, the PaO_2 at which SaO_2 is 90% and below which SaO_2 rapidly decreases. In contrast, as Hgb is reduced by normovolemic hemodilution, $SjvO_2$ remains relatively constant unless severe anemia is produced [25].

The management of arterial CO_2 in patients with neurologic injury has changed dramatically in the past 10 years. Although hyperventilation as a management strategy for increased ICP was routine in the 1990s, it is now reserved for acute or life-threatening increases in the intensive care unit (ICU) and is no longer recommended for routine use. Having been associated with cerebral ischemia in children and adults [9,10] with severe TBI, hyperventilation is least likely to be harmful when combined with monitoring, such as $SjvO_2$ or $PbtO_2$, that can identify cerebral ischemia.

Hyperglycemia increased injury in experimental TBI [26] and was associated with worse outcome in clinical TBI [27,28], although it is difficult to distinguish between elevated glucose causing worsened outcome versus increased severity of TBI inducing more elevated glucose levels [29]. In critically ill patients requiring mechanical ventilation, elevated glucose levels were associated with worsened outcomes [30], and current recommendations are to tightly control serum glucose in critically ill patients in the medical and surgical ICU [31]. Caution must be exercised in the brain injured patient as there is also evidence to suggest that hypoglycemia can be more detrimental than hyperglycemia and microdialysis studies in traumatic brain injury patients found that extracellular glucose concentration is low after TBI and is associated with markers for tissue distress and poor outcome [32].

The monitoring and management of body temperature remains an important aspect of care for critically ill patients. Hypothermia and hyperthermia should be considered separately in this context. The use of hypothermia as a treatment for brain injury, while demonstrating benefit in animals [33] and in some phase II human studies, has not shown consistent benefit in larger studies [34] and is not recommended for general use in TBI [35,36]. Although the largest clinical trials (NABISH-1 and Hypothermia Pediatric Head Injury Trial Investigators and the Canadian Critical Care Trials Group) were negative [37,38], there were numerous smaller human trials and meta-analyses that suggested improved neurologic outcomes with hypothermia in TBI. Some authors suggest that the failure of these trials was because of poor protocol design and lack of proper management of the side effects of hypothermia [39,40]. In contrast, induced hypothermia after resuscitation from cardiac arrest (secondary to ventricular tachycardia or fibrillation) has improved outcome in some trials [41,42]. Research into this complex area is ongoing, and clinical practice is likely to undergo further refinement.

Hyperthermia is common in critically ill patients, occurring in up to 90% of patients with neurologic disease, related to both diagnosis and length of stay [43,44]. Hyperthermia is generally associated with poorer outcome when associated with neurologic injury in adults and children [45], but a causal link with adverse outcome (as with serum glucose levels) is lacking. It is unclear whether increased temperatures result in worsened long-term neurologic outcome, or whether a greater severity of brain injury is associated with more frequent or severe increases in systemic temperature.

The method of temperature monitoring is important. Thermal gradients exist throughout the body, and the site of measurement influences the diagnosis of hypothermia, normothermia, or hyperthermia. Measurements of systemic temperature may underestimate brain temperature. In studies of temperature monitoring by site, variations of up to 3°C have been identified between the brain and other routinely used monitoring sites, emphasizing the importance of monitoring site selection in patients with neurologic injury and the need to appreciate the difference between brain temperature and the active site of measurement used clinically for a given patient.

EEG/Electrocorticography

Electroencephalographic (EEG) monitoring has long been used in neurology for diagnosis and intraoperative monitoring, but has less frequently been used as a neurologic monitoring technique in critically ill patients. EEG is indicated in response to suspicion of a new or progressive abnormality such as cerebral ischemia or new onset of seizures. The cortical EEG or electrocorticography, which is altered by mild cerebral ischemia and abolished by profound cerebral ischemia, can be used to indicate potentially damaging cerebral hypoperfusion. More recent research has documented its utility in the detection of cortical spreading depression and peri-infarct depolarizations (proposed to be early indicators of delayed ischemic injury) in the acutely injured human cortex in traumatic brain injury and subarachnoid hemorrhage [46,47]. The EEG can document seizures, either convulsive or nonconvulsive, and provide information as to the efficacy of antiseizure therapy. Other functions include defining the depth or type of coma, documenting focal or lateralizing intracranial abnormalities, and the diagnosis of brain death.

If the EEG is to be used for monitoring, care must be taken and weaknesses of the technique appreciated [48]. In the ICU, electrical noise from other equipment may produce artifacts and interfere with technically adequate tracings. Continuous EEG recording was cumbersome in the past owing to the sheer volume of data (300 pages per hour of hard copy on as many as 16 channels), but techniques for digital recording and networking direct computer recording of EEG data are now available given adequate computer power and storage. Scalp fixation has also been a significant limiting factor, although newer fixation techniques are easier to apply and more stable. Techniques of mathematical data analysis, such as rapid Fourier analysis, can be used to determine the relative amplitude in each frequency band (delta—less than 4 Hz, theta—4 to 8 Hz, alpha—8 to 13 Hz, beta—greater than 13 Hz), which can then be displayed graphically in formats such as the compressed spectral array or density spectral array. Alpha variability has been found to predict vasospasm/delayed cerebral ischemia in subarachnoid hemorrhage patients [49] and the percentage of alpha variability was found to have prognostic value in traumatic brain injury [50]. Analytic software has been developed that processes the raw EEG signal to provide single number interpretation of the "depth of sedation." These devices have been recommended for use during general anesthesia as a means to reduce the risk of awareness [51], although the scientific justification for this claim is not conclusive. The American Society of Anesthesiologists has developed a practice advisory on this issue [52]. Use of

this type of monitoring has also been implemented by some for use in the ICU for monitoring sedation levels in the critically ill, the utility of which has yet to be proven [53,54]. All devices use proprietary analysis of an EEG signal (either spontaneous or evoked, with or without electromyogram monitoring), which is converted to a single number that is intended to correspond to an awareness level based on an arbitrary scale. The future role and evidence of improved patient outcomes with this monitoring modality remain unclear. A more detailed discussion of the clinical indications, technical aspects, and limitations can be found in a recent review [55].

EVOKED POTENTIALS

Sensory-evoked potentials (EPs), which include somatosensory-evoked potentials (SSEPs), brainstem auditory EPs, and visual EPs, can be used as qualitative threshold monitors to detect severe neural ischemia. Unlike EEG that records the continuous, spontaneous activity of the brain, EPs evaluate the responses of the brain to specific stimuli. To record SSEPs, stimuli are applied to a peripheral nerve, usually the median nerve at the wrist or posterior tibial nerve at the ankle, by a low-amplitude current of approximately 20 milliseconds in duration. The resultant sensory (afferent) nerve stimulation and resultant cortical response to the stimulus are recorded at the scalp. Repeated identical stimuli are applied and signal averaging is used to remove the highly variable background EEG and other environmental electrical noise and thereby visualize reproducible evoked responses (Fig. 28.4).

EPs are described in terms of the amplitude of cortical response peaks and the conduction delay (latency) between the stimulus and the appearance of response waveform. Because peripheral nerve stimulation can be uncomfortable, SSEPs are usually obtained from sedated or anesthetized patients. SSEPs are unaffected by neuromuscular blocking agents but may be significantly influenced by sedative, analgesic, and anesthetic agents, often in a dose-dependent manner. In general, however, the doses of drugs required to influence EPs are sufficient to produce general anesthesia and are not usually clinically important in the ICU. If a patient is undergoing EP monitoring and requires large doses of analgesic or sedative agents, potential impairment of monitoring should be considered. Motor EPs represent a method of selectively evaluating descending motor tracts. Stimulation of proximal motor tracts (cortical or spinal) and evaluation of subsequent responses yield information that can be used for intraoperative and early postoperative neurosurgical management. Induction of motor EP and its interpretation is exquisitely sensitive to sedative, analgesic, and anesthetic drugs, making clinical use difficult when drugs are given concurrently. Despite these limitations, motor EP evaluation has been successfully used for the management of neuro-ICU patients and may become more common as techniques and equipment improve [56,57].

The sensitivity of EP monitoring is similar to that of EEG monitoring. EPs, especially brainstem auditory EPs, are relatively robust, although they can be modified by trauma, hypoxia, or ischemia. Because obliteration of EPs occurs only under conditions of profound cerebral ischemia or mechanical trauma, EP monitoring is one of the most specific ways in which to assess neurologic integrity in specific monitored pathways. However, as with the discussion of cerebral ischemia, there is a dose–time interaction that ultimately determines the magnitude of cerebral injury. As a result, neurologic deficits occur that have not been predicted by changes in EPs, and severe changes in EPs may not be followed by neurologic deficits. The most definitive indication for SSEPs is in the prognostication of anoxic brain injury from cardiac arrest. The absence of the N20 response on bilateral SSEPs of the median nerve within 3 days postarrest has been found to be a reliable predictor of negative outcome or recovery of consciousness in anoxic postarrest coma and is part of the AAN practice parameter in the prognostication of postanoxic coma [58].

INTRACRANIAL PRESSURE MONITORING

The symptoms and signs of intracranial hypertension are neither sensitive nor specific. Usually, the physical findings associated with increasing ICP (e.g., Cushing's response–hypertension and Cushing's triad–hypertension, reflex bradycardia, and alterations in respiratory function) become apparent only when intracranial hypertension has become sufficiently severe to injure the brain. Likewise, papilledema is a late development and is often difficult to identify clinically. Because ICP cannot otherwise be adequately assessed, direct

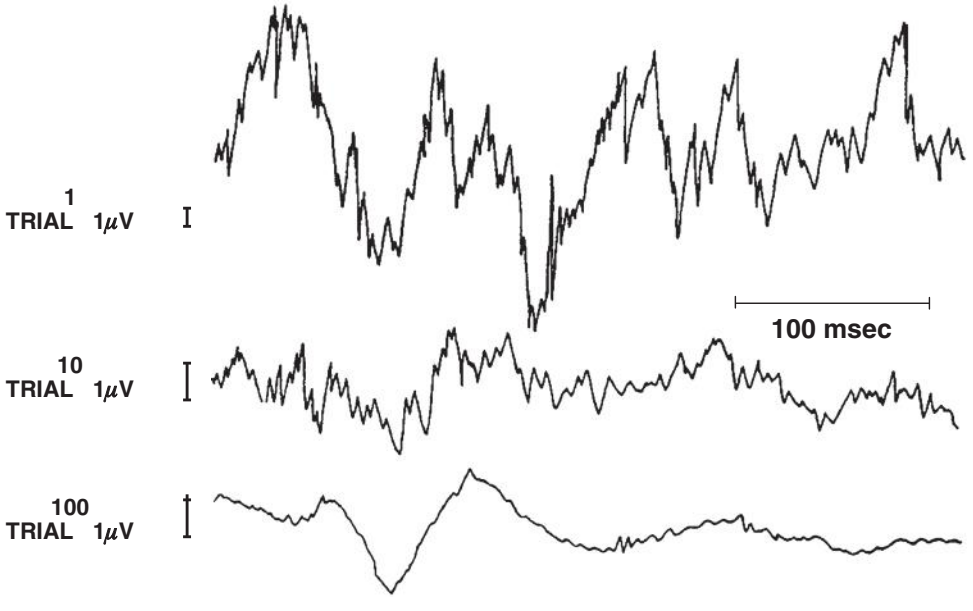

FIGURE 28.4. Averaging reduces background noise. After 100 trials, this visual evoked potential (EP) is relatively noise-free. The same EP is hard to distinguish after only 10 trials and would be impossible to find in the original unaveraged data. (From Nuwer MR: *Evoked Potential Monitoring in the Operating Room*. New York, Raven Press, 1986, p 29, with permission.)

measurement and monitoring of ICP has become a common intervention, especially in the management of TBI [59], and less commonly after critical illnesses such as SAH or stroke. Although there is no class 1 evidence that the use of this technique improves outcomes, there is a large body of clinical evidence supporting its use to guide therapeutic interventions in traumatic brain injury that have potential risks (such as aggressive osmotherapy, induced hypothermia and barbiturate coma), to aid in the detection intracranial mass lesions and to provide prognostic data [60]. ICP monitoring has been found to improve outcome prediction in TBI and next to clinical parameters such as age, GCS motor score and abnormal pupillary responses, the proportion of hourly ICP recordings greater than 20 mm Hg was the next most significant predictor of outcome in an analysis done of the National Traumatic Coma Data Bank [61]. Despite this, the debate continues on how to use ICP data to change patient care and reduce morbidity and mortality. It is unlikely that a large randomized clinical trial will ever be done given the lack of clinical equipoise. The Brain Trauma Foundation/American Association of Neurosurgeons Guidelines recommend ICP monitoring in all patients with severe TBI (GCS <8) and an abnormal CT scan or a normal scan with patients who are greater than 40 years old, have motor posturing, or a systolic BP <90 mm Hg [62,63]. Because pressure gradients may exist among various sites within the calvarium, it may be advantageous to monitor in or adjacent to the most severely damaged hemisphere [64], some even recommend bilateral ICP monitoring to circumvent this problem [65].

ICP functions as the outflow pressure apposing MAP (CPP = MAP − ICP) when ICP exceeds jugular venous pressure. Because the skull is not distensible, the brain, cerebrospinal fluid (CSF), and cerebral blood volume have little room to expand without increasing ICP. It is important to appreciate that some increase in intracranial volume is possible without much change in ICP, but when the compensatory mechanisms are exhausted, even small changes in volume can lead to significant increases in pressure. Although CBF cannot be directly inferred from knowledge of MAP and ICP, severe increases in ICP reduce CPP and CBF. ICP monitoring provides temporally relevant, quantitative information. The problems associated with ICP monitoring fall generally into three categories: direct morbidity due to monitor placement (e.g., intracranial hemorrhage, cortical damage, and infection), inaccurate measurement, and misinterpretation or inappropriate use of the data. Clinically, one of three sites is used to measure ICP: a lateral ventricle, the brain parenchyma, and much less commonly the subdural space. Ventricular catheterization, when performed using strict asepsis, is the method of choice for ICP monitoring and CSF drainage [66] in patients with acute intracranial hypertension and excess CSF (i.e., acute hydrocephalus). In practice, intraventricular catheters may be difficult to place if cerebral edema or brain swelling has compressed the ventricular system. Intraventricular pressure monitoring can also be performed with fiber-optic catheters (instead of a hollow catheter) that use a variable reflectance pressure sensing system (transducer tip) to measure pressure (Camino Laboratories, San Diego, CA). These fiber-optic catheters are less susceptible to short-term malfunction than conventional, fluid-filled catheters but may slowly and unpredictably drift over days to weeks [67].

Pressure monitoring from the subdural space may use a fluid-coupled bolt (simple transcranial conduit), fluid-coupled subdural catheters (or reservoirs), or fiber-optic transducer-tipped catheters (see earlier). Because subdural bolts are open tubes facing end-on against the brain surface, brain tissue may herniate into the system, obstructing the system, distorting measurements, and potentially damaging the cerebral cortex. Reservoir systems require surgical placement into the subdural space. Fiber-optic systems do not have these specific problems, but fixation and equipment reliability are practical issues. This technique is used uncommonly for these reasons.

Intraparenchymal placement of a fiber-optic catheter is also possible and is associated with complications similar to ventricular fiber-optic catheters. Complications are generally noted to be highest with ventriculostomies (when compared with fiber-optic catheter usage), and complications of ICP monitoring are associated with a worse GCS score.

Management decisions based on ICP data are the focus of ongoing debate and study. Clinical studies after TBI have demonstrated that increased ICP is associated with worsened outcome [68]. Therefore, control of ICP has been considered by some clinicians to be the primary focus of treatment [24], while other clinicians have considered restoration of CPP (by increasing MAP) to be the primary goal of medical management [21]. To date, the ideal approach has not been established by outcome trials; therefore, practice patterns remain variable [69]. Clinical experience with ICP monitoring of head-injured patients has resulted in publication of clinical guidelines using an evidence-based approach (Fig. 28.5) [70].

CEREBRAL BLOOD FLOW MONITORING

The first quantitative clinical method of measurement of CBF, the Kety–Schmidt technique, calculated global CBF from the difference between the arterial and jugular bulb concentration curves of an inhaled, inert gas as it equilibrated with blood and brain tissue. Later techniques used extracranial gamma detectors to measure regional cortical CBF from washout curves after intracarotid injection of a radioisotope such as 133-xenon (Xe 133). Carotid puncture was avoided by techniques that measured cortical CBF after inhaled or intravenous administration of Xe 133, using gamma counting of exhaled gas to correct clearance curves for recirculation of Xe 133. Because Xe is radiodense, saturation of brain tissue increases radiographic density in proportion to CBF. Imaging of the brain after equilibration with stable (nonradioactive) Xe provides a regional estimate of CBF that includes deep brain structures. Clinical studies of CBF after TBI performed using stable xenon computed tomography (CT) have prompted a radical revision of conventional understanding by demonstrating that one third of patients had evidence of cerebral ischemia within 8 hours of trauma. Although slow in becoming a routine clinical tool, Xe CT is becoming a more common technique for monitoring CBF in patients. The use of helical and spiral CT scanners (with very short acquisition times) reduces the radiation exposure to the patient and decreases the time needed for a scan, improving clinical utility [71]. A newer method of measuring CBF that provides continuous bedside quantitative measurements is the thermal diffusion technique. This consists of the insertion of a microprobe into the brain parenchyma with a thermistor at the tip and a temperature sensor proximal to it. The thermistor is heated to 2 degrees above tissue temperature and CBF is calculated using the thermal gradient and provides a quantified regional CBF measurement in mL per 100 g per minute. Some studies suggest a correlation with regional brain tissue oxygenation and possible role in guiding management of ICP. Technical issues such as the invasive nature of the device, frequent calibration, and the limitations seen in the febrile patient have kept this method from becoming more widely adopted [72]. Another CT-based technique, perfusion CT, uses iodinated contrast infusion with repeated images to calculate local CBF. This technique is limited to smaller regions and may not provide uniform results between brain regions [73]. Other techniques, such as single-photon emission CT (SPECT) and magnetic resonance perfusion imaging also can provide

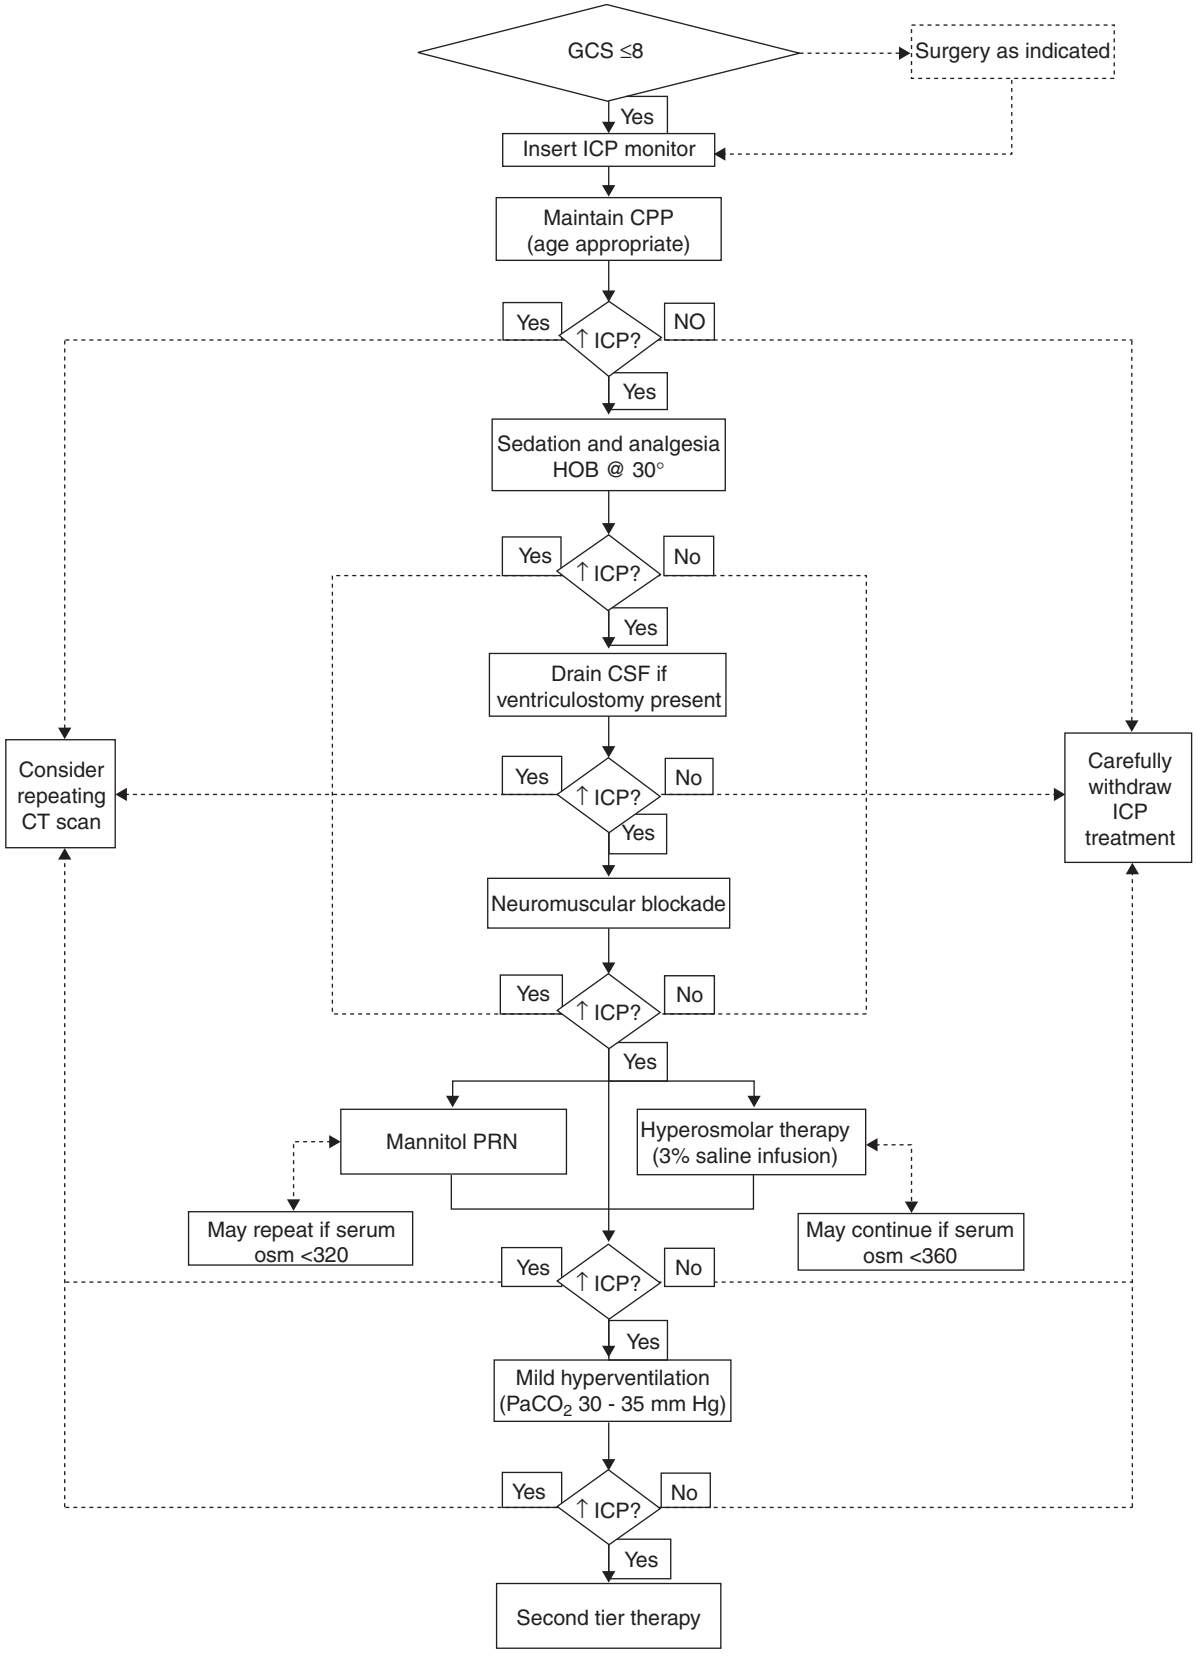

FIGURE 28.5. Critical pathway for treatment of intracranial hypertension in the pediatric patient with severe head injury. ICP, intracranial pressure. FIGURE 28.6. Mean flow velocity (FV, in cm/sec) curves of 18 patients with laterally localized aneurysms (arising from the internal carotid and middle cerebral arteries). The side of the ruptured aneurysm (*continuous line*) shows a higher FV than the unaffected side (*dotted line*). SAH, subarachnoid hemorrhage. (From Seiler RW, Grolimund P, Aaslid R, et al: Cerebral vasospasm evaluated by transcranial ultrasound correlated with clinical grade and CT-visualized subarachnoid hemorrhage. *J Neurosurg* 64:594–600, 1986, with permission.)

information about CBF, but their clinical utility is still currently being studied [71]. Transcranial Doppler ultrasonography can be used to estimate changes in CBF. In most patients, cerebral arterial flow velocity can be measured easily in intracranial vessels, especially the middle cerebral artery, using transcranial Doppler ultrasonography. Doppler flow velocity uses the frequency shift, proportional to velocity, which is observed when sound waves are reflected from moving red blood cells. Blood moving toward the transducer shifts the transmitted frequency to higher frequencies; blood moving away, to lower frequencies. Velocity is a function of both blood flow rate and vessel diameter. If diameter remains constant, changes in velocity are proportional to changes in CBF; however, intersubject differences in flow velocity correlate poorly with intersubject differences in CBF. Entirely noninvasive, transcranial Doppler measurements can be repeated at frequent intervals or even applied continuously. The detection and monitoring of post-SAH vasospasm remains the most common use of transcranial Doppler (Fig. 28.6) [74]. However, further clinical research is necessary to define those situations in which the excellent capacity for rapid trend monitoring can be exploited including assessment of vascular autoregulation, ancillary testing to detect intracranial hypertension and brain death.

JUGULAR BULB VENOUS OXYGEN SATURATION

Several measurements of cerebral oxygenation are clinically useful, including measurement of $SjvO_2$. To insert a retrograde jugular venous bulb catheter, the internal jugular vein can be located by ultrasound guidance or by external anatomic landmarks and use of a "seeker" needle, namely, the same technique used for antegrade placement of jugular venous catheters. Once the vessel is identified, the catheter is directed cephalad, toward the mastoid process, instead of centrally. A lateral cranial radiograph can confirm the position just superior to the base of the skull. The decision to place a jugular bulb catheter in the left or right jugular bulb is important. Simultaneous measurements of $SjvO_2$ in the right and left jugular bulb demonstrate differences in saturation [75], suggesting that one jugular bulb frequently is dominant, carrying the greater portion of cerebral venous blood. Differences in the cross-sectional areas of the vessels that form the torcula and the manner in which blood is distributed to the right and left lateral sinus contribute to differences between the two jugular bulbs. Ideally, a jugular bulb catheter should be placed on the dominant side, which can be identified as the jugular vein that, if compressed, produces the greater increase in ICP or as the vein on the side of the larger jugular foramen as detected by CT [76].

In general $SjvO_2$ reflects the adequacy of CDO_2 to support $CMRO_2$, but mixed cerebral venous blood, like mixed systemic blood, represents a global average of cerebral venous blood from regions that are variably perfused and may not reflect marked regional hypoperfusion/ischemia of small regions. In contrast to ICP and CPP, which provide only indirect information concerning the adequacy of CDO_2 to support $CMRO_2$, $SjvO_2$ directly reflects the balance between these variables on a global or hemispheric level. CBF, $CMRO_2$, CaO_2, and $CjvO_2$ are modeled by the equation: $CMRO_2 = CBF\ (CaO_2 - CjvO_2)$. In healthy brain, if $CMRO_2$ remains constant as CBF decreases, $SjvO_2$ and $CjvO_2$ decrease [25]. If flow-metabolism coupling is intact, decreases in $CMRO_2$ result in parallel decreases in CBF while $SjvO_2$ and $CjvO_2$ remain constant [25]. Abnormally low $SjvO_2$ (i.e., less than 50%, compared to a normal value of 65%) suggests the possibility of cerebral ischemia; but normal or elevated $SjvO_2$ does not prove the adequacy of cerebral perfusion because of possible saturation averaging between normal and abnormal areas of perfusion. This is especially true for focal areas of hypoperfusion. Therefore, the negative predictive value of a normal $SjvO_2$ is poor. After placement of a jugular catheter, monitoring of $SjvO_2$ can be achieved through repeated blood sampling. However, repeated blood sampling yields only "snapshots" of cerebral oxygenation and thus provides discontinuous data that may miss rapid changes in saturation. To achieve continuous monitoring of $SjvO_2$, indwelling fiber-optic oximetric catheters have been used. Because oxyhemoglobin and deoxyhemoglobin absorb light differently, $SjvO_2$ can be determined from differential absorbance. Oximetric jugular bulb catheters have proven somewhat challenging to maintain, requiring frequent recalibration, repositioning, and confirmation of measured saturation by analyzing blood samples in a cooximeter. The highest frequency of confirmed desaturation episodes occurs in patients with intracerebral hematomas, closely followed by those with SAH. In patients with TBI, the number of jugular desaturations is strongly associated with poor neurologic outcome; even a single desaturation episode is associated with a doubling of the mortality rate [77]. Clinical application of jugular venous bulb cannulation has been limited, perhaps in part because the technique is invasive, although the risks of cannulation injury, including hematoma and injury to the adjacent carotid, are low. Several modifications of jugular venous oxygen monitoring have been proposed. Cerebral extraction of oxygen, which is the difference between SaO_2 and $SjvO_2$ divided by SaO_2, is less confounded by anemia than the cerebral A-VDO_2 [78]. Another concept, termed cerebral hemodynamic reserve, is defined as the ratio of percentage of change in global cerebral extraction of oxygen (reflecting the balance between $CMRO_2$ and CBF) to percentage of change in CPP [79]. This equation attempts to integrate cerebral hemodynamics and metabolism with intracranial compliance. Cruz et al. [78] found that cerebral hemodynamic reserve decreased as intracranial compliance decreased, even as a consequence of minor elevations in ICP. Theoretically, this variable may allow more precise management of cerebral hemodynamics in patients with decreased intracranial compliance.

BRAIN TISSUE OXYGEN TENSION

Another promising technique for monitoring the adequacy of CDO_2 is direct assessment of $PbtO_2$. Monitoring of $PbtO_2$ overcomes one important limitation of $SjvO_2$ monitoring,

which is that the global saturation measurements provide no information about regional or focal tissue oxygenation. Only relatively profound focal global ischemia causes $SjvO_2$ to decrease to less than the accepted critical threshold of 50%. Even severe regional ischemia may not result in desaturation if venous effluent from other regions is normally saturated, in part because the absolute flow of poorly saturated blood returning from ischemic regions is by definition less per volume of tissue than flow from well-perfused regions, resulting in a smaller percentage of poorly oxygenated to well-oxygenated blood. Intracranial, intraparenchymal probes have been developed that monitor only $PbtO_2$ or that also monitor brain tissue PCO_2 and pH [79]. Modified from probes designed for continuous monitoring of arterial blood gases, intraparenchymal probes can be inserted through multiple-lumen ICP monitoring bolts. Although these probes provide no information about remote regions, they nevertheless provide continuous information about the region that is contiguous to the probe. They also carry the theoretical risk of hematoma formation, infection, and direct parenchymal injury. Evaluation of $PbtO_2$ after severe TBI has shown that low partial pressures ($PbtO_2$ less than 10 mm Hg for greater than 15 minutes) powerfully predict poor outcomes and that $PbtO_2$ probes are safe [80,81]. Both $PbtO_2$ and $SjvO_2$ may reflect changes in cerebral oxygenation secondary to alterations in CBF (Fig. 28.7) [82]. However, comparisons of simultaneous $PbtO_2$ and $SjvO_2$ monitoring suggest that each monitor detects cerebral ischemia that the other fails to detect. In 58 patients with severe TBI, the two monitors detected 52 episodes in which $SjvO_2$ decreased to less than 50% or $PbtO_2$ decreased to less than 8 mm Hg; of those 52 episodes, both monitored variables fell below the ischemic threshold in 17, only $SjvO_2$ reflected ischemia in 19, and only $PbtO_2$ reflected ischemia in 16 (Fig. 28.8) [83]. Ongoing research will determine the role of $PbtO_2$ monitoring and the relationship between $PbtO_2$ monitoring and $SjvO_2$ monitoring in critical neurologic illness. Recent single-center prospective studies comparing brain tissue oxygen directed protocols in traumatic brain injury with historical controls report reduced mortality as well as improved 6-month clinical outcomes [84,85]. A randomized multicenter clinical trial is in the planning stages but has not started recruiting patients yet (BOOST-2).

NEUROCHEMICAL MONITORING

Neuronal injury is associated with the release or production of chemical markers such as free radicals, inflammatory mediators, metabolic products, and excitatory amino acids [4]. Neurochemical monitoring via microdialysis allows assessment of the chemical milieu of cerebral extracellular fluid, provides valuable information about neurochemical processes in various neuropathologic states, and is used clinically in the management of severe TBI [86] and SAH [87,88]. There is data to suggest that chemical changes detected by microdialysis precede secondary neurologic injury and clinical worsening in intracranial hypertension, subarachnoid hemorrhage, and ischemic stroke. Substances monitored via microdialysis include energy-related metabolites such as glucose, lactate, pyruvate, adenosine, and xanthine; neurotransmitters such as glutamate, aspartate, gamma-amino butyric acid; markers of tissue damage such as glycerol and potassium [89], and alterations in membrane phospholipids by oxygen radicals [90]. Lactate levels and lactate/pyruvate ratios are reliable markers of ischemia and have been found to correlate well with PET, cerebral perfusion pressure and jugular venous bulb oxygen saturation values and associated with outcome in traumatic brain injury and subarachnoid hemorrhage. Elevations of the excitatory neurotransmitter glutamate have been found in hypoxic-ischemic injury seen in low CBF, jugular venous bulb desaturation, seizures and low CPP, and correlated with poor outcome in TBI. The magnitude of release of these substances correlates with the extent of ischemic damage. The time-dependent changes of these substances and the clinical implications are being evaluated, and their incorporation into standard practice is being studied. Certain issues related to quantification, bedside presentation of data, implantation strategies, and standardization of protocols need to be addressed. An excellent review of the current status, issues surrounding potential future developments and

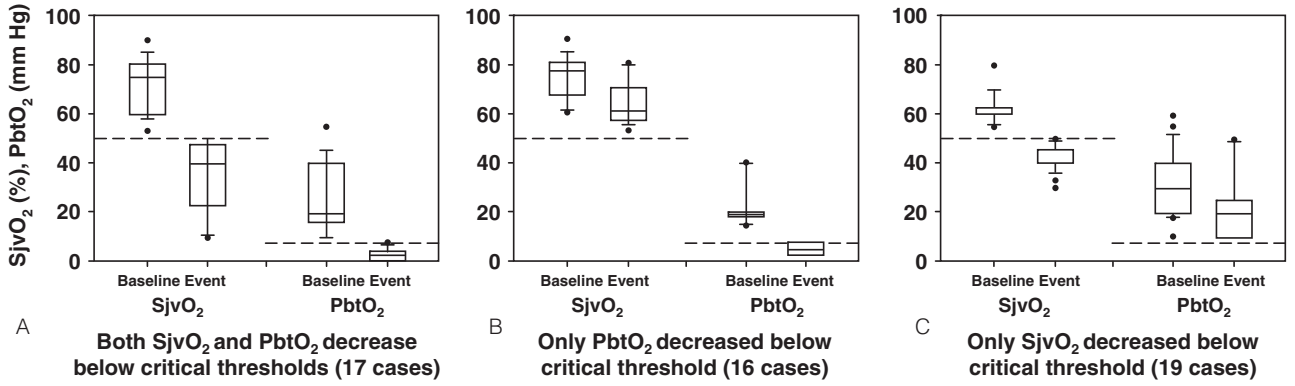

FIGURE 28.8. Changes in jugular venous oxygen saturation ($SjvO_2$) and brain tissue PO_2 ($PbtO_2$) during 52 episodes of cerebral hypoxia/ischemia. The horizontal line across the box plot represents the median, and the lower and upper ends of the box plot are the 25th percentile and 75th percentile, respectively. The error bars mark the 10th and 90th percentiles. The closed circles indicate any outlying points. **A:** Summary of the 17 cases in which both $SjvO_2$ and $PbtO_2$ decreased to less than their respective thresholds, as defined in the text. **B:** Summary of the 16 cases in which $PbtO_2$ decreased to less than the defined threshold; but $SjvO_2$; although decreased, did not decrease to less than 50%. **C:** Summary of the 19 cases in which $SjvO_2$ decreased to less than the threshold, but $PbtO_2$ remained at greater than 10 torr. (From Gopinath SP, Valadka AB, Uzura M, et al: Comparison of jugular venous oxygen saturation and brain tissue PO_2 as monitors of cerebral ischemia after head injury. *Crit Care Med* 27:2337–2345, 1999, with permission.)

methodological aspects of microdialysis are discussed in detail in a recent article [91].

NEAR-INFRARED SPECTROSCOPY

Theoretically, the best monitor of brain oxygenation would be a noninvasive device that characterizes brain oxygenation in real time: near-infrared spectroscopy (NIRS) might eventually offer the opportunity to assess the adequacy of brain oxygenation continuously and noninvasively, although to date the use of the technique in adults has been limited.

Near-infrared light penetrates the skull and, during transmission through or reflection from brain tissue, undergoes changes in intensity that are proportional to the relative concentrations of oxygenated and deoxygenated hemoglobin in the arteries, capillaries, and veins within the field [92]. The absorption (A) of light by a chromophore (i.e., hemoglobin) is defined by Beer's Law: $A = abc$, where a is the absorption constant, b is the path length of the light, and c is the concentration of the chromophore, namely, oxygenated and deoxygenated hemoglobin. Because it is impossible to measure the path length of NIRS light in tissue, approximations as to relative lengths and arterial versus venous contribution must be made.

Extensive preclinical and clinical data demonstrate that NIRS detects qualitative changes in brain oxygenation [93]. Studies have been done comparing NIRS to other technologies and assessing its correlation with EEG, transcranial Doppler, $PbtO_2$ and jugular venous O_2 saturation changes. NIRS was found to correlate with EEG, TCD, and PtO_2 in transient cerebral hypoxia, subarachnoid hemorrhage, and during intraoperative monitoring for carotid endarterectomy. It did not correlate well with $SjvO_2$ [94] values but was thought to provide complementary focal oxygenation data to $SjvO_2$'s global oxygenation assessment. Clinical applications include traumatic brain injury where an rSO_2 of less than 55% was thought to suggest inadequate CPP and NIRS values were lower in the high ICP group of patients vasospasm detection in the setting of subarachnoid hemorrhage, and the detection of intracranial hemorrhages such as subdural and epidural hematomas but studies are not definitive [95]. Despite the promise and enthusiasm generated by NIRS, many problems remain with the technology including tissue penetration, spatial and temporal resolution, artifacts from subcutaneous blood flow and methods of quantitative analysis which need to be resolved [96]. Therefore, validation studies suggest that NIRS may be more useful for qualitatively monitoring trends of brain tissue oxygenation than for actual quantification and its current clinical use is limited to a few centers and is adjunctive at best [93,97]. Some of the liabilities of near-infrared spectroscopy may be overcome by optoacoustic monitoring of cerebral venous saturation. Optoacoustic monitoring of cerebral venous saturation depends on the generation by near-infrared light of ultrasonic signals in blood. The acoustic signals are then transmitted linearly through tissue and bone and provide a focused, depth-resolved signal that reflects venous oxygenation [98].

NEUROIMAGING

Magnetic resonance imaging (MRI), positron emission spectroscopy (PET) scans, cerebral angiography, and radionuclide scans do not function as monitors per se. Rather, they are indicated in response to suspicion of a new or progressive anatomic lesion, such as a subdural or intracerebral hematoma or cerebral arterial vasospasm, that requires altered treatment. Most neuroimaging modalities provide static, discontinuous data and require moving a critically ill patient from the ICU to a remote location. Even so, these techniques play an important role in the overall management of patients with brain injury [99]. With the introduction of portable CT scanners and the development of ultrafast helical and spiral CT scanners, availability and acquisition time for evaluations have significantly decreased and can now be used for serial monitoring of ongoing neurologic processes and for evaluation of changes in CBF (see above).

CT scans obtained at the time of admission to the hospital can provide valuable prognostic information. Marshall et al. [100] predicted outcome of head-injured patients in relation to four grades of increasingly severe diffuse brain injury and

TABLE 28.4

OUTCOME AT DISCHARGE IN RELATION TO INTRACRANIAL DIAGNOSIS (% OF PATIENTS)

Outcome	DI I	DI II	DI III	DI IV	Evacuated mass	Nonevacuated mass

the presence of evacuated or nonevacuated intracranial mass lesions (Table 28.4). Normal CT scans at admission in patients with GCS scores less than 8 are associated with a 10% to 15% incidence of ICP elevation [101,102]; however, the risk of ICP elevation increases in patients older than age 40 years, those with unilateral or bilateral motor posturing, or those with systolic blood pressure less than 90 mm Hg [101].

Although MRI often provides better resolution than CT scans, the powerful magnetic fields make the use of ferrous metals impractical (and dangerous), a ubiquitous component of life-support equipment. To address this issue, MRI-compatible ventilators, monitors, and infusion pumps have been developed, although the logistics of transport and the time required for scans continues to make this technique difficult for repeated monitoring. Recent advances in MRI technology, such as diffusion-weighted imaging, magnetic resonance spectroscopy (carbon labeled, phosphorus labeled, and nitrogen labeled), phase-contrast angiography, and functional MRI provide information about oxidative metabolic pathways, cerebral blood volume, functional CBF, and neuronal activation [99,103,104]. These techniques, while undergoing further evaluation and validation, may one day prove useful in evaluating brain injury and its management. Recent clinical evidence of brain mitochondrial dysfunction after TBI, despite apparently adequate CDO_2, suggests that functional cellular evaluation and associated therapy may someday be as important as maintaining CDO_2 [105]. In addition to providing information regarding ischemia and defining tissue at risk, MRI-based Diffusion Tensor Imaging has been found to be helpful in further defining the anatomy of fiber tracts that have been damaged and has also been found to have prognostic value in severe TBI [106]. Functional MRI provides information regarding neural activity, localization and the physiology of brain function but is currently in use only for neurosurgical planning, brain mapping and in the investigation of neurobehavioral aspects and neuropsychologic sequelae of disorders such as Alzheimer's disease, stroke, multiple sclerosis, brain tumors, and traumatic brain injury.

MULTIMODAL MONITORING STRATEGIES

With technological advances and active ongoing research the field of neurologic monitoring is developing rapidly. Multimodal monitoring takes into account the limitations of each monitoring modality and compensates by combining different techniques into a generalized strategy that help to further elucidate the pathophysiology and underlying cellular mechanisms of disease and focuses care on the physiologic aspects of disease. This concept is not new (consider the operating room and the role of the anesthesiologist) and is becoming more common in the management of brain injury [107] as well as other neurologic diseases. It is hoped that the use of these regimented techniques will lead to improvements in patient outcome [108].

CHAPTER 29 ■ ECHOCARDIOGRAPHY IN THE INTENSIVE CARE UNIT

ACHIKAM OREN-GRINBERG, SAJID SHAHUL AND ADAM B. LERNER

INTRODUCTION

Echocardiography was introduced to the operating suite in the 1970s, with epicardial echocardiography as its initial application. Transesophageal echocardiography (TEE) during surgery was first described in 1980 but did not become commonplace until the mid-1980s. Since then, TEE has evolved to become a widely used and versatile modality for diagnosis and monitoring of critically ill patients. As such, its use has expanded into the perioperative period and the intensive care unit (ICU). Echocardiography provides both anatomic and functional information about the heart; systolic and diastolic function, cavity size, and valvular function [1].

Ease of use, availability of diagnostic information within 10 to 15 minutes from the start of examination, high-quality imaging in most patients, and low complication rates have all led to the pervasive use of echocardiography in the perioperative environment and increasing use in the ICU [2–8]. However, patient safety and optimal outcome depend heavily on a thorough understanding of both the strengths and limitations of the available technologies and their applications.

BASIC TERMINOLOGY OF ECHOCARDIOGRAPHY TECHNIQUES

A sonographer must use different echocardiographic imaging techniques and hemodynamic modalities to achieve a diagnosis or management plan. The following is a list of the basic techniques used during an echocardiographic study.

Two-Dimensional Echocardiography

Two-dimensional (2D) echocardiography is the backbone of the echocardiographic examination [9]. Using 2D, a complete visualization of the beating heart is achieved by displaying anatomic structures in real-time tomographic images. By aiming the ultrasound probe at the heart, exactly oriented anatomic "slices" are obtained. Information acquired includes cardiac chamber sizes, global and regional systolic function, and valvular anatomy.

M-Mode Echocardiography

M-mode or motion-mode images are a continuous 1D graphic display that can be derived by selecting any of the individual sector lines from which a 2D image is constructed [9]. It is useful for quantification of myocardial wall and chambers sizes, which in turn can be used to estimate left ventricle (LV) mass and chamber volumes, respectively. Though very limited, M-mode can also be used to determine fractional shortening, a rough estimate of left ventricular systolic function. In addition, since it has high temporal resolution, M-mode is helpful in assessing the motion of rapidly moving cardiac structures such as cardiac valves.

Doppler Echocardiography

Doppler echocardiography is used to supplement 2D and M-mode echocardiography. It can provide functional information regarding intracardiac hemodynamics; systolic and diastolic flows, blood velocities and volumes, severity of valvular lesions, location and severity of intracardiac shunts, and assessment of diastolic function. The four types of Doppler modalities used include continuous-wave, pulsed-wave, color flow mapping, and tissue Doppler [9]. Continuous-wave Doppler is used for measuring high-pressure gradient/high-velocity flows such as seen in aortic stenosis. When using continuous wave Doppler, the ultrasound probe continuously transmits and receives sound waves. This increases the maximum limit of blood velocity that can be evaluated before exceeding the Nyquist limit. The Nyquist limit represents the maximum flow velocity that can be evaluated by Doppler and is dependent on both equipment and imaging variables. Continuous wave Doppler can evaluate higher flows but does so at the expense of spatial specificity. This is referred to as "range ambiguity." Pulsed-wave Doppler is used for measuring lower-pressure gradient/lower-velocity flows such as in mitral stenosis. In this mode, the ultrasound probe sends out a pulse of sound and then waits to receive reflected waves. This lowers the Nyquist limit and the maximum velocities that can be interrogated but allows for precise spatial resolution. Color flow mapping is useful for screening valves for stenosis or regurgitation, quantifying the degree of valvular regurgitation, imaging systolic and diastolic flow, and detection of intracardiac shunts. Doppler tissue imaging has been introduced as a new method of quantifying segmental and global left ventricular function. It records systolic and diastolic velocities within the myocardium and at the corners of the mitral annulus and is useful for studying diastolic function and contractile asynchrony of the LV [10].

Contrast Echocardiography

Contrast echocardiography is used to enhance the diagnostic quality of the echocardiogram [11]. It may be used to improve assessment of global function and regional wall motion abnormalities by 2D echocardiography. Although approved only for LV opacification, recent clinical studies suggest a potential use in assessing myocardial perfusion [12,13].

Transesophageal Versus Transthoracic Echocardiography

Although transthoracic echocardiography (TTE) is a less invasive way to image cardiac structures, suboptimal acoustic windows lead to low-quality images in many critically ill patients. These suboptimal acoustic windows are due to obesity, pulmonary disease, the presence of chest tubes, drains and wound dressings, and limitations on patient positioning. Using TTE in the ICU can be challenging; one study found the echocardiographic examination to be inadequate in approximately 50% of patients on mechanical ventilation and 60% of all ICU patients [8]. The relatively low percentage of adequate imaging improves when TTE is used as a **monitoring tool**, which does not require the same quality of images, and not as a diagnostic tool. In a report of more than 200 ICU patients, TTE used as a monitoring tool provided 2D images of acceptable quality in 97% of patients [14].

In contrast to TTE, TEE is more invasive but consistently provides images of better quality. In up to 40% of patients, TEE may provide additional unexpected diagnoses that are missed by TTE [4,15]. Recent advances in ultrasound imaging, which include harmonic imaging, digital acquisition, and contrast endocardial enhancement, have improved the diagnostic yield of TEE [16,17].

CONTRAINDICATIONS TO PERFORMING TEE

Although TEE is safe [18,19], there are several contraindications to probe insertion. These include significant esophageal or gastric pathology; mass or tumors, strictures, diverticulum, Mallory-Weiss tears, recent esophageal or gastric surgery, upper gastrointestinal bleeding, and dysphagia or odynophagia not previously evaluated. Esophageal varices are not an absolute contraindication, and a risk–benefit analysis of each case must be carried out before performing TEE in any individual patient [20]. Practitioners must be aware of the potential for severe bleeding, in particular when a coagulation abnormality exists. Cervical spinal injury is another relative contraindication requiring careful risk–benefit analysis.

COMPLICATIONS AND SAFETY OF TEE

TEE is considered a moderately invasive procedure and complications are rare. In one study of ICU patients, complication rates reached 1.6% and included hypotension following sedation for probe insertion, oropharyngeal bleeding in a coagulopathic patient, and aspiration during tracheal intubation performed prior to TEE [19]. Another study in 2,508 ICU patients reported a complication rate of 2.6%. In this study, there was no examination-related mortality. Complications included

transient hypotension or hypertension, circulatory deterioration, hypoxemia, arrhythmias, vomiting, coughing, superficial mucous membrane lesions, displacement of a tracheostomy tube and accidental removal of a duodenal feeding tube [18]. A large European multicenter study of 10,419 examinations reported a complication rate of 2.5% with one (0.01%) case of fatal hematemesis due to a malignant tumor [2]. In addition, in 0.88% of the reported cases, the TEE exam had to be prematurely terminated due to either patient intolerance or because of cardiac, pulmonary, or bleeding events [2].

Common Indications for TEE in the ICU

In 1996, a task force created by the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists published guidelines regarding the indications for TEE [21]. Three categories of evidence-based clinical indications were identified. For indications grouped into category I, TEE was judged to be *frequently* useful in improving clinical outcomes. To date, there is only a single category I indication for TEE in the ICU. That indication is for "unstable patients with unexplained hemodynamic disturbance, suspected valve disease, or thromboembolic problems (if other tests or monitoring techniques have not confirmed the diagnosis or patients are too unstable to undergo other tests)" [21]. This indication, however, encompasses a significant proportion of ICU patients and in practice, clinicians use echocardiography in the ICU for many other indications. These are summarized in Table 29.1.

ECHOCARDIOGRAPHIC EVALUATION OF HEMODYNAMIC INSTABILITY

Hemodynamic instability is an extremely common event in every ICU. Determining the cause of such can sometimes be more challenging than one would expect. Echocardiography can be used successfully in the diagnosis, monitoring, and management of the unstable patient in the ICU. Using echocardiography to determine the etiology of hemodynamic instability requires assessment of cardiac function, volume status, valvular function, and extracardiac processes.

ASSESSMENT OF CARDIAC FUNCTION

Systolic dysfunction of either ventricular chamber must be considered in every unstable patient. The etiology of dysfunction may often times be discerned from the echocardiographic evaluation allowing for appropriate therapy to be initiated.

TABLE 29.1

COMMON INDICATIONS FOR PERFORMING TEE IN THE ICU

Assessment of LV systolic function	Evaluation of valvular pathology
Hemodynamic management	Determination of source of emboli
Evaluation of pericardial tamponade	Evaluation of endocarditis
Evaluation of pulmonary embolism	Evaluation of chest trauma
Evaluation of aortic dissection	Evaluation of hypoxemia

Assessment of Left Ventricular Systolic Function

Use of several echocardiographic assessment modalities is necessary for evaluation of left ventricular systolic function. These modalities include quantitative as well as qualitative assessments.

Quantitative Assessment of Left Ventricular Systolic Function

Volumetric Method Using Geometric Models. Quantitative assessment of left ventricular systolic function relies on volume assessment using 2D tomographic images. To determine the volume at end diastole (LVEDV) and end systole (LVESV), the endocardial borders in two orthogonal tomographic planes are traced at end diastole and end systole. Several geometric assumptions and formulas have been developed (e.g., truncated ellipse, "bullet" formula, cylinder, and cone) to determine the LVEDV and LVESV based on these 2D images. Once LVEDV and LVESV have been determined, the stoke volume, and thus cardiac output (CO) can be calculated:

$$SV = LVEDV - LVESV$$
$$CO = SV \times HR$$

In addition, ejection fraction (EF) can be calculated from these volumes using the formula:

$$EF = SV/LVEDV \times 100\%$$

These formulas work optimally in a symmetrically contracting ventricle; the presence of regional wall motion abnormalities decreases accuracy. In addition, foreshortening of the LV cavity is a common source of underestimation of LV end-diastolic and end-systolic volumes and can similarly impact the accuracy of systolic function assessment with these formulas [1,22]. Lastly, since the models depend on accurate endocardial border definition, their use requires adequate visualization. Incomplete endocardial definition is described in 10% to 20% of routine echocardiographic studies [23] and may reach 25% in ICU patients [24]. This challenge is even greater in patients requiring mechanical ventilation in which imaging can be particularly challenging. These challenges have limited the use of the geometric models and formulas for assessment of LV systolic function.

Discs Method (Simpson's Rule). Another method for volumetric assessment of LV systolic function is the discs method, which may be more accurate than the other volumetric methods described above, particularly in the presence of distorted LV geometry [9]. In this method the ventricle is divided into a series of discs of equal height and each disc volume is calculated as follows:

$$\text{Disc volume} = \text{disc height} \times \text{disc area}$$

The ventricular volume can be calculated from the sum of the volumes. This technique requires true apical images, which in clinical practice may be difficult to achieve. Foreshortening of the ventricular apex will result in inaccurate assessment of the left ventricular EF and CO (Fig. 29.1).

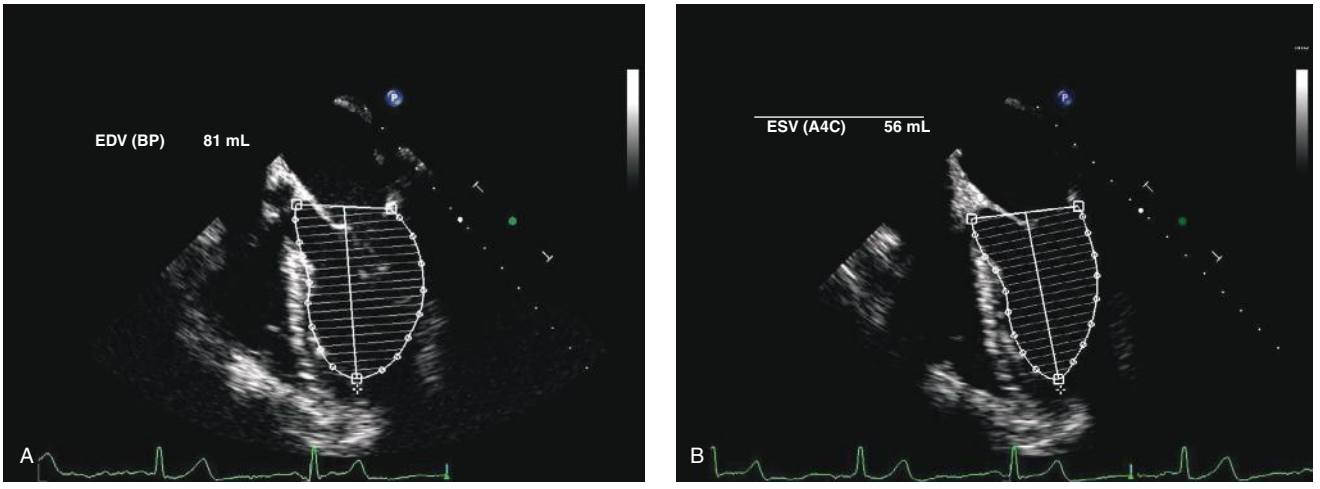

FIGURE 29.1. Calculation of cardiac output using the disc method (Simpson's rule). TEE Mid-esophageal 4-chamber view in diastole (**A**) and systole (**B**) is shown. Using the Simpson's rule, LVEDV (81 mL) and LVESV (56 mL) were calculated by the echocardiographic computer. From these volumes, the cardiac output was calculated to be 1.7 L/min (81–56 mL) × 69 beats per minute.

Qualitative Assessment of Left Ventricular Systolic Function

2D Evaluation of Ventricular Systolic Function. Using 2D imaging, two of the most important questions regarding hemodynamic stability can be rapidly answered; are the ventricles contracting well and are they adequately filled. Using 2D, an experienced observer can qualitatively evaluate systolic function. This should be assessed from multiple tomographic planes and attention must be given to obtaining adequate endocardial definition. Normal ventricular contraction consists of simultaneous myocardial thickening and endocardial excursion toward the center of the ventricle. It is important to look for this myocardial thickening; infarcted myocardium may be pulled inward by surrounding, normal myocardium. There is some regional heterogeneity of normal wall motion with the proximal lateral and inferolateral (or posterior) walls contracting somewhat later than the septum and inferior wall [25]. For qualitative assessment of overall systolic function, the echocardiographer integrates the degree of wall thickening and endocardial motion in all tomographic views and reaches a conclusion about overall LV systolic function and EF. Although different institutions use different standards, severe LV systolic dysfunction is usually defined as an EF <30%, moderate dysfunction 30% to 45%, mild depression 45% to 55%, and normal >55%. This method of EF estimation is of great clinical utility and can be performed with good correlation to quantitative measurements. There are however, a few potential pitfalls to 2D assessment of EF that must be considered:

1. Accurate assessment requires satisfactory endocardial border definition. Qualitative EF estimation becomes inaccurate when the endocardium is inadequately defined.
2. Accurate estimation of EF depends on the experience of the echocardiographer.
3. In asynchronous contraction (paced-rhythm, conduction defects, etc.), assessment of EF is more difficult.

Despite its limitations, 2D qualitative assessment is the most widely used technique for assessment of LV systolic function due to its ease of application in the clinical setting. In the operating room, after completing the TEE exam, most physicians monitor LV systolic function continuously with 2D imaging using the transgastric (TG) midpapillary short-axis view. This allows for quick assessment of regional wall motion abnormalities in all coronary arterial circulatory beds as well as rudimentary evaluation of volume status [26]. However, it is important to remember that this view alone is never satisfactory for assessing overall systolic function.

Regional Left Ventricular Function

Most commonly, abnormal regional wall motion is the result of coronary artery disease and resultant ischemia/infarction. Abnormal wall motion is a continuum of conditions consisting of hypokinesis, akinesis, and dyskinesis. With dyskinesis, the affected wall segment moves away from the center of the ventricle during systole. To standardize echocardiographic evaluations of wall motion, a 17-segment model of the LV has been defined [25]. These 17 segments are evaluated separately for the presence and degree of regional wall motion abnormality. When the etiology of the wall motion abnormality is CAD, the location of the coronary lesion can be usually predicted from the location of the regional wall motion abnormality.

Contrast Echocardiography

Recent innovations have been made to overcome some of the technical obstacles related to endocardial border detection and image quality. Intravenous echocardiographic contrast agents that opacify the left side of the heart can markedly improve visualization of the LV cavity and enhance endocardial definition. These agents can aid assessment of regional and global LV functions [27–30]. They also have the potential to "salvage" nondiagnostic TTEs in ICU patients. One study demonstrated a "salvage" rate of 51% [31] and another 77% of nondiagnostic TTEs [32]. In addition to improving visualization and assessment of LV function, assessment of myocardial perfusion defects with intravenous contrast has been reported with various imaging techniques and modalities [33–35].

Doppler Assessment of Left Ventricular Systolic Function

Doppler spectral profiles can be used to evaluate left ventricular function quantitatively. This evaluation of left ventricular

systolic function is based on calculation of stroke volume (SV) and CO.

Stroke Volume—the volume of blood ejected during each cardiac cycle is a key indicator of cardiac performance. SV can be calculated by using pulse wave Doppler (PWD) to measure the instantaneous blood velocity recorded during systole from an area in the heart where a cross-sectional area (CSA) can be easily determined. The left ventricular outflow tract (LVOT) is most commonly used because its cross section is essentially a circle. By measuring the diameter of the LVOT and assuming a circular geometry, the CSA is calculated as $\pi(D/2)^2$. Any cardiac chamber or structure that has a measurable CSA may be used; mitral valve annulus, right ventricular outflow tract outflow, and tricuspid annulus are some examples. By tracing the outline of the PWD profile, the echocardiographic computer can calculate the integral of velocity by time or the velocity–time integral (VTI). The VTI is the distance (commonly referred as the *stroke distance*) that the average red cell has traveled during the systolic ejection phase. SV (cm^3) is then calculated by multiplying the VTI (stroke distance in cm) by the CSA in cm^2 of the conduit (i.e., LVOT, aorta, mitral valve annulus, pulmonary artery) through which the blood has traveled [36–42]; SV = CSA × VTI. CO is then easily derived by multiplying the calculated SV by the heart rate: CO (cm^3/min) = SV × HR (Fig. 29.2).

This approach to SV and CO calculations has shown very good correlation with thermodilution-derived CO measurements [43]. There are however, several potential sources of error:

1. CSA determination often leads to the greatest source of error. When using any diameter for CSA determination, any error in measurement will be squared (CSA = $\pi(D/2)^2$). This translates to a 20% error in calculation of CO for each 2-mm error when measuring a 2.0-cm diameter LV outflow tract [25]. Studies have shown that while the Doppler velocity curves can be recorded consistently with little interobserver measurement variability (2% to 5%), the variability in 2D LVOT diameter measurements for CSA is significantly greater (8% to 12%) [44].
2. The Doppler signal is assumed to have been recorded at a parallel or near parallel intercept angle, called θ, to blood flow. The Doppler equation has a cos θ term in its denominator. With an intercept angle of 0 degree, the cos θ term equals 1. Deviations up to 20 degrees in intercept angle are acceptable since only a 6% error in measurement is introduced.
3. Velocity and diameter measurements should be made at the same anatomic site. When the two are measured at different places, the accuracy of SV and CO calculations is decreased.
4. Although the pattern of flow is assumed to be laminar, in reality the flow profile is parabolic. This does have some impact on velocity-based calculations [25]. However, in routine clinical practice this factor is of little significance and can be essentially ignored.

Determination of Left Ventricular *dP/dt*

The changing rate of left ventricular pressure (dP/dt) is an important parameter in the assessment of myocardial systolic function. Traditionally, dP/dt was derived from the left ventricular pressure curve acquired at cardiac catheterization using a micromanometer catheter recording. It has been shown that echocardiography can be used accurately and reliably to assess dP/dt by performing Doppler assessment of mitral regurgitant jet [45,46]. Using continuous wave Doppler, a spectral display of the mitral regurgitation (MR) jet is obtained. From the spectral display, information about the rate of pressure development within the LV can be derived using measurements undertaken in the early phase of systole (the upstroke of the velocity curve is used for calculations). Determination of dP/dt using the MR spectral jet is done by calculation of the time required for the MR jet velocity to go from 1 m per second to 3 m per second. The time between these two points represents the time that it takes for a 32 mm Hg pressure change to occur in the left ventricular cavity. This is based on the modified Bernoulli equation ($P = 4v^2$), which relates pressure to velocity. Thus, in going from 1 m per second to 3 m per second:

$$P = 4v_B^2 - 4v_A^2(4(3^2) - 4(1^2) = 32)$$

where v_B is velocity of 3 m/s.

dP/dt is then is calculated using the formula:

$$dP/dt = 32\,\text{mm Hg} \div \text{time (seconds)}.$$

A depressed ventricle will take a longer time to develop this pressure gradient—a lower dP/dt. Normal dP/dt value is >1,200 mm Hg per second (or time ≤27 milliseconds),

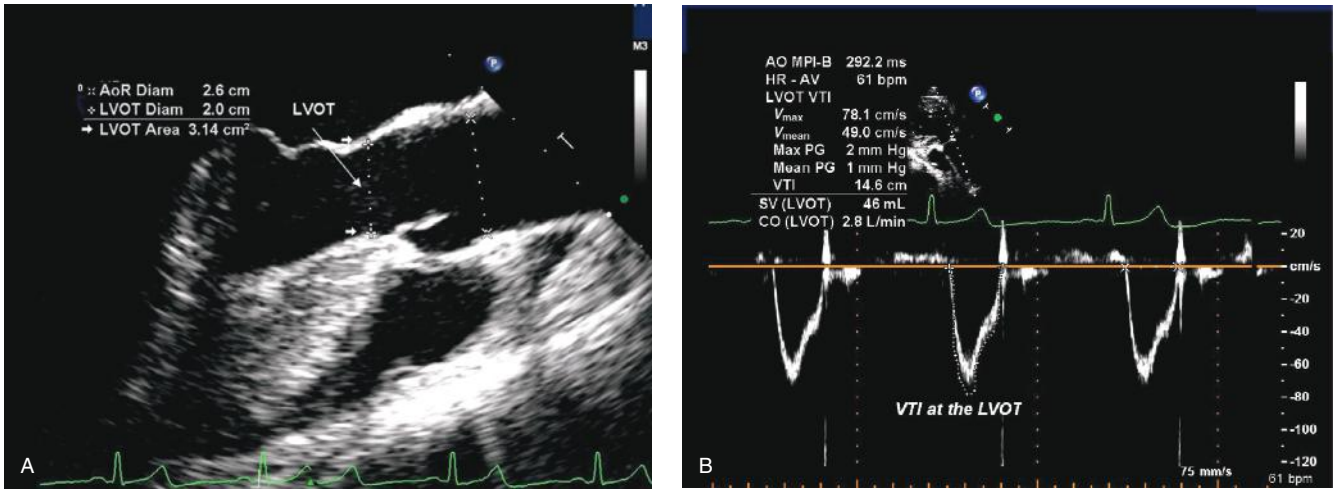

FIGURE 29.2. Calculation of CO using spectral Doppler approach. **A**: Mid-esophageal long-axis view of LVOT. LVOT measurement is 2.0 cm. The CSA is calculated as $\pi(D/2)^2$ to be 3.14 cm^2. **B**: Transgastric long-axis view using a PWD directed through the aortic valve opening. VTI is calculated by the computer through tracing the outer envelope of the spectral signal and is determined to be 14.6 cm. **SV** is the product of CSA and VTI: 3.14 × 14.6 = 46 mL. **CO** = SV × HR: 46 × 61 = 2.8 L/min.

moderately depressed systolic function value range between 1,000 and 1,200 mm Hg per second, and when dP/dt is decreased bellow 1,000 mm Hg per second, left ventricular systolic function is severely depressed [47,48].

ASSESSMENT OF PATIENT VOLUME STATUS

One of the most challenging and crucial tasks in the management of a hemodynamically unstable patient is to predict accurately whether the patient would benefit from fluid therapy. Overhydration may lead to pulmonary edema, hypoxia, and worsening outcome and therefore should be avoided. A novel and effective method for determining this "fluid responsiveness" is through the assessment of "dynamic parameters." Examples of such dynamic parameters are stroke volume variation (SVV) and pulse pressure variation (PPV). These parameters can be readily assessed with echocardiography.

SVV and PPV are caused by the interaction of the cardiac and respiratory systems; that is, the changes in intrathoracic pressure during controlled ventilation have an impact on SV and therefore, arterial pressure. The increase in intrathoracic pressure during the inspiratory phase of positive pressure ventilation leads to simultaneous but different physiologic effects on the left and right sides of the heart. In the left side, SV increases as blood is pushed forward out of the pulmonary veins into the LV. In addition, the increased intrathoracic pressure leads to improved "afterload matching" for the LV, which increases SV by functionally decreasing afterload. The interventricular septum is shifted toward the right ventricle (RV) also increasing LV SV. On the right side, right ventricular inflow decreases secondary to compression of the inferior vena cava (IVC). The rightward shift of the septum also decreases RV SV. At the beginning of the exhalation phase, SV decreases since both the pulmonary veins and the RV are relatively "empty." In hypovolemic patients, the magnitude of these cyclical or dynamic changes is increased and this serves as the basis for the accurate assessment of fluid responsiveness using these parameters [49–54].

In addition to preload, other factors affecting SVV and PPV include chest wall compliance and ventilation parameters, including tidal volumes and airway pressures. In situations wherein chest wall compliance and respiratory parameters are held relatively constant, SVV can be used as a guide to establishing whether a given patient will respond to fluid loading by increasing CO.

Limitations to this technique include the following:

1. Need for positive pressure ventilation with either total paralysis or heavy sedation preventing from the patient to initiate the ventilator.
2. Effect of cardiac rhythm. In patients with cardiac arrhythmia, the beat-to-beat variation in SV and hence in BP may no longer reflect the effects of mechanical ventilation. This is particularly true in patients with atrial fibrillation or frequent extrasystoles. In patients with few-and-far-between extrasystoles, the arterial pressure curve can still be analyzed if the cardiac rhythm is regular during at least one respiratory cycle.
3. Effect of tidal volume. Increasing tidal volume will result in increasing the mean airway pressure and, hence, in decreasing the mean cardiac preload (leftward shift on the Frank–Starling curve). Therefore, a patient operating on the flat portion of the Frank–Starling curve (i.e., insensitive to changes in preload) may operate on the steep portion and hence become sensitive to changes in preload (in essence leading to false-positive reading of this index) if the tidal volume is increased. Conversely, using lung-protective ventilation with low tidal volume may lead to minimal pleural pressure changes over a single respiratory cycle. In this case, inspiration will not induce any significant change in LV SV, even in fluid-responsive patients (leading to a false-negative reading). This may explain why the SVV has been found to be a reliable predictor of fluid responsiveness in patients with tidal volume ranging between 8 and 15 mL per kg [49,55,56].

Three echocardiographic indices have been shown to reliably assess fluid responsiveness based on the dynamic parameter approach:

1. ***Aortic Flow Index***: The increase in SV during positive pressure ventilation as described earlier leads to increased peak flow across the LVOT, the aortic valve and descending aorta. Similarly, the decrease in SV during exhalation leads to decrease in peak flow across these structures. The aortic flow index can efficiently predict fluid responsiveness in patients ventilated with positive pressure. To calculate the aortic flow index, one has to use the pulse wave Doppler to sample flow at the ascending aorta. This will generate a series of peak flow spectral displays that are increased during inspiration and decreased during exhalation (Fig. 29.3). The formula to calculate the aortic flow index is

$$\text{Aortic flow index} = (\text{PEAK max}_{\text{ins}} - \text{PEAK min}_{\text{exp}})/\text{mean} \times 100$$

   An index of >12% has been shown to discriminate between fluid responders and nonresponders with high sensitivity and specificity (100% and 89%, respectively) [57]. This index can be calculated rapidly by either TTE or TEE.
2. ***Superior Vena Cava Collapsibility Index***: This concept is similar to other dynamic parameters. During the inspiratory phase of positive pressure ventilation, the superior vena cava (SVC) collapses due to increase in the intrathoracic pressure. The SVC re-expands back to its baseline during exhalation. The degree of collapsibility depends on the degree of hypovolemia; as less volume circulates in the intravascular compartment the SVC will be susceptible to the increase in intrathoracic pressure, and thus this phenomenon is exacerbated in a state of hypovolemia. The SVC index can be calculated with TEE only by using either 2D or M-mode modality to measure the SVC diameter during PPV (Fig. 29.4). The formula to calculate this index is

$$\text{SVC collapsibility index} = (D\text{max}_{\text{exp}} - D\text{min}_{\text{ins}})/D\text{max}_{\text{exp}} \times 100$$

   An index of >36% has been shown to predict fluid responsiveness with high sensitivity and specificity (90% and 100%, respectively) [58] and can be very useful in predicting the need for fluid therapy in hemodynamically unstable patients.
3. ***Inferior Vena Cava Collapsibility Index***: The rationale behind the IVC collapsibility index is similar to other dynamic parameters. The physiology, however, is slightly different. The increased intrathoracic pressure during positive pressure ventilation as compared to the extrathoracic pressure leads to reduced pressure gradient to venous return. This, in turn, leads to decrease in systemic venous return and as a consequence to increase in the volume of the extrathoracic venous blood. The end result is an increase in extrathoracic IVC diameter during positive pressure breath, followed by a decrease in its diameter during exhalation [59,60]. Recently, IVC collapsibility during positive pressure ventilation has been used to predict fluid responsiveness similar to the

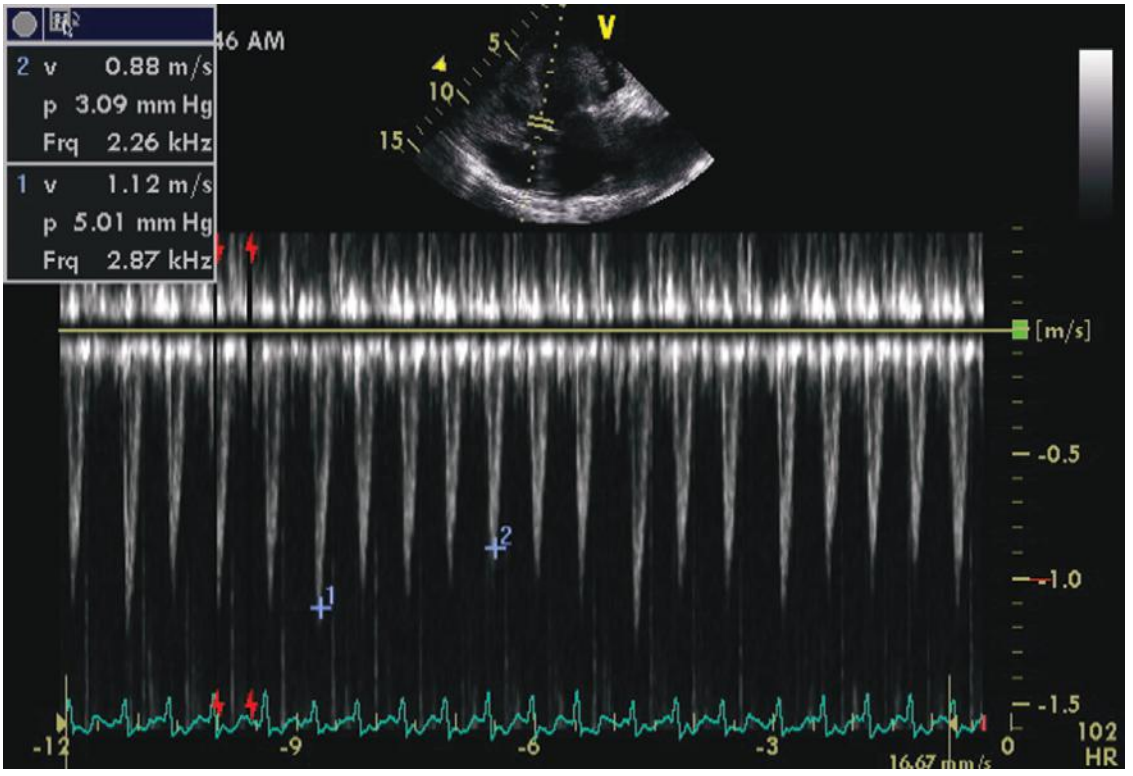

FIGURE 29.3. TEE deep transgastric view assessment of aortic flow index. The pulse-wave Doppler sample volume is positioned at the LVOT level, demonstrating spectral displays of peak flows during PPV. The peak flows vary with respiration; increased during positive pressure breath (1) and decreased during exhalation (2). The aortic flow index is calculated as the difference between the peaks flows divided by their mean. In this example, the aortic flow index = (PEAK $\max_{ins}$ − PEAK $\min_{exp}$)/mean × 100 = (1.12 − 0.88/1) × 100 = 24%. This indicated severe hypovolemia and fluid resuscitation initiated.

aortic flow index and other dynamic parameters [61]. In this study, the change in IVC diameter during positive pressure ventilation (ΔD_{IVC}) was defined as the difference between the maximum and the minimum IVC diameter over the mean and expressed as percentage: $\Delta D_{IVC} = (D_{IVCmax} - D_{IVCmin})$/mean × 100%. In this study, a threshold ΔD_{IVC} value of 12% allowed identification of fluid responders with positive and negative predictive values of 93% and 92%, respectively. To assess for IVC collapsibility, the IVC is visualized in the subcostal view, and the IVC diameter is measured 3 cm from the right atrium by either 2D or M-mode technique.

ASSESSMENT OF LEFT VENTRICULAR PRELOAD

Preload is defined as the myocardial fiber length at end diastole [43]. LV end-diastolic volume (LVEDV) is one of several clinical variables used to assess preload. Accurate preload estimation is one of the main challenges faced when caring for critically ill patients, even to the most experienced physician. Traditionally, preload has been assessed using physical examination, clinical assessment of end-organ perfusion, and direct measurement of intravascular pressures. Echocardiography can be used efficiently to supplement clinical assessment.

A. ***2D Echo Method***: LV diameter measured with 2D echo can be used to extrapolate LV volume at end-diastole, and thus estimate preload. These measurements can be compared with reported estimates of normal ventricular dimensions to define degrees of ventricular enlargement. A single measurement, however, is of limited value in defining the preload state of any given patient. A patient with a history of cardiomyopathy, as an example, will have an increased LV end-diastolic diameter compared to a normal patient. To define such a patient as having adequate or excess preload is not justifiable. Serial measurements of LV diameter are more useful clinically in assessing changes over time and in response to therapies such as intravenous fluid challenge or diuresis. A number of studies that have compared echocardiographic estimates of preload with PAOP have shown the potential superiority of the echocardiographic method [62–64]. This method seems to perform well in detecting decreased end-diastolic volumes and hypovolemia. However, when used to diagnose high preload or fluid overload, they may not be as reliable [43]. In the operating room, both end-diastolic areas and volumes correlated well with thermodilution cardiac index in patients undergoing coronary artery bypass grafting [65] and liver transplantation [66], while PAWP showed no correlation.

B. ***Pulsed Wave Doppler Method***: Preload estimation can be assessed by Doppler echocardiography. The velocity profile of blood flow through the mitral valve during diastole is normally biphasic. In a young individual with normal LV compliance and relaxation, the early, passive filling phase, represented by the *E*-wave, exceeds the component of filling due to atrial contraction, represented by the A-wave. The

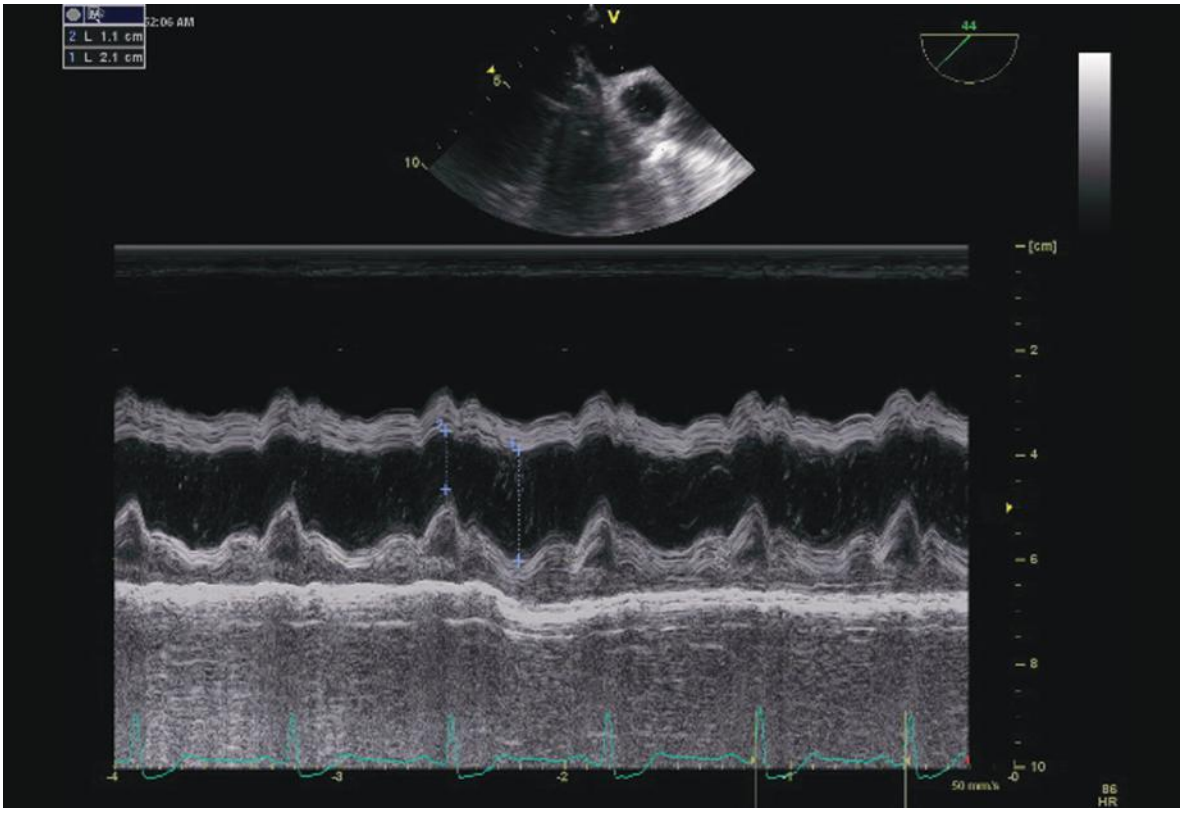

FIGURE 29.4. TEE upper esophageal view of the superior vena cava M-mode. SVC collapsibility index $= (D\text{max}_{\text{exp}} - D\text{min}_{\text{ins}})/D\text{max}_{\text{exp}} \times 100 = (2.1 - 1.1)/2.1 \times 100 = 47\%$, indicating hypovolemia and fluid responsiveness.

magnitude of theses flows and their ratio varies with age in normal individuals [25] (Fig. 29.5).

Using the peak *E/A velocity* ratio, LV end-diastolic pressure (LVEDP) can be roughly estimated. With this technique, a ratio >2 is associated with LVEDP >20 mm Hg [67]. It is possible to estimate PAWP more accurately by using the equation [68]:

$$\text{PAWP} = 18.4 + [17.1 \cdot \ln(E\,\text{peak}/A\,\text{peak})]$$

One study demonstrated that measurement of transmitral and pulmonary venous flows by Doppler can be used to estimate LV-filling pressure in critically ill patients under mechanical ventilation [69]. In this study, an E/A ratio >2 had a positive predictive value of 100% for a PAWP value >18 mm Hg. However, a large E/A ratio may also be seen in young healthy subjects. In this population, LV elastic myocardial relaxation is rapid, which allows for almost complete LV filling during early diastole. This can lead to high E/A ratio without elevation of left atrial (LA) pressure [70]. Therefore, any interpretation of transmitral flow must take into account the patient's age. In addition, heart rate also modifies the transmitral flow pattern. Since tachycardia shortens diastolic filling time, atrial contraction may occur before early filling is completed. This will potentially result in a higher peak *A*-wave velocity than when the heart rate is slower. Furthermore, the transmitral *E*- and *A*-waves can overlap, making interpretation of the transmitral indices impossible [71]. Thus, in tachycardic patients a low *E/A*ratio does not necessarily relate to a low PAOP.

EVALUATION OF RIGHT VENTRICULAR FUNCTION AND PRELOAD

Right ventricular systolic dysfunction is another potential cause of hypotension. In practice, estimates of RV function are made from qualitative assessments of 2D imaging. Using either TEE (mid-esophageal four-chamber view) or TTE (apical and subcostal views), the right ventricular free wall can be visualized and its thickening and displacement can be noted. In situations where right ventricular dysfunction is the sole cause of hypotension, whether directly from states causing myocardial dysfunction or as a result of a secondary issue such as a pulmonary embolus, the LV is typically underfilled. Preload of the RV is also estimated from either qualitative or quantitative assessment of ventricular size while again understanding that single measurements of such dimensions are of limited usefulness.

ASSESSMENT OF VALVULAR ETIOLOGIES OF HEMODYNAMIC INSTABILITY

Abnormalities of valvular function can, on occasion, be the primary cause of hypotension. Although valvular stenoses can certainly have impact on hemodynamics in the ICU patient, they are rarely the direct cause of hypotension. For this

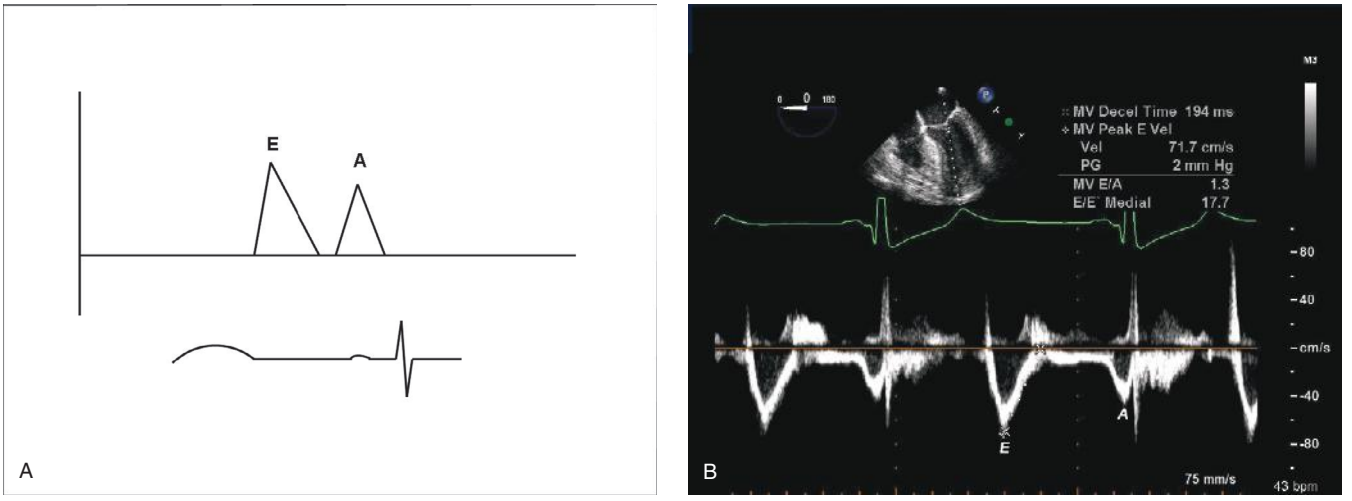

FIGURE 29.5. A: Schematic representation of transmitral inflow profile showing *E*- and *A* waves during diastole. **B**: TEE mid-esophageal four-chamber view of transmitral inflow showing *E*- and *A* waves.

reason, this section will concentrate on evaluation of regurgitant valvular lesions.

Echocardiographic Evaluation of Mitral Regurgitation

Echocardiographic evaluation of MR includes assessment of valve anatomy, severity of regurgitation, LA enlargement due to volume overload, ventricular function, and the severity of pulmonary arterial hypertension. The mitral apparatus includes the anterior and posterior leaflets, the annulus, chordae tendineae, and the papillary muscles with their supporting LV walls. The etiology of MR could be a result of anatomical or functional changes in the mitral valve and its supporting structures. Anatomical changes in mitral valve leaflet pathology can be caused by rheumatic disease, endocarditis, myxomatous disease, infiltrative diseases, such as amyloid, sarcoid, mucopolysaccharidosis, and collagen-vascular disorders, such as systemic lupus erythematosus and rheumatoid arthritis. Functional changes in the mitral annulus leading to dilation, secondary to LA as well as LV dilation, may result in MR due to incomplete leaflet coaptation. MR can also occur as a result of chordal tear or elongation, which leads to inadequate tensile support of the closed leaflet(s) in systole with prolapse of the leaflet(s) into the left atrium [44]. Papillary muscle rupture can occur in the setting of acute myocardial infarction and frequently leads to cardiogenic shock from acute, severe MR. Partial rupture is more common and better tolerated.

The Carpentier classification is commonly used to define the pathophysiologic mechanism leading to the regurgitation: normal, restrictive, or excessive leaflet motion [72].

- *Class I—Normal leaflet motion*: the most common cause of MR wherein leaflet motion is normal and there is mitral annular dilation and papillary muscle dysfunction due to myocardial ischemia. In most cases, the MR jet is centrally directed into the left atrium.
- *Class II—Excessive leaflet motion*: Characterized by excessive leaflet motion ranging from leaflet *billowing* wherein a portion of a leaflet projects above the annulus in systole while the coaptation point remains below the mitral annulus, to *prolapse* wherein the excursion of a leaflet tip is above the level of the mitral annulus during systole, to *flail*, where a leaflet flows freely into the left atrium, frequently as a consequence of ruptured chordae tendineae. Typically, the MR jet is eccentrically directed away from the affected leaflet.
- *Class III—Restrictive leaflet motion*: Characterized by restriction of the leaflet, most commonly as a result of left ventricular dilation that displaces the papillary muscle away from the mitral valve annulus and in this way prevents leaflet coaptation. The direction of the MR jet may be central or eccentrically directed toward the side of the more affected leaflet. Mitral valvular systolic anterior motion (SAM), which is discussed later, is also considered as an example of restricted leaflet motion

Mitral Regurgitation Assessment

1. ***2D Examination***: Basic 2D assessment may provide clues for the presence of MR. Structural leaflet abnormality or coaptation defects may be obvious in some cases. Indirect signs of MR should also be sought. These include LV and LA enlargement and signs of pulmonary arterial hypertension; elevated PA pressures estimated from Doppler interrogation of Tricuspid regurgitation (TR) jets as an example.
2. ***Doppler Flow Examination***: Doppler flow examination is the most common method used to screen and evaluate MR. MR is graded as trivial, mild, moderate, or severe, which corresponds to the angiography scores of 1+, 2+, 3+, and 4+. A visual assessment of the area of the MR color map provides a rough estimate of the severity of regurgitation. However, this simple visual assessment has limitations. As an example, eccentric MR jets that run along an LA wall may appear less severe (the Coanda effect). In addition, color gain settings—a technical issue—can have significant impact on the size of the MR color map. Low color gains will increase the size where as high gains will reduce it. This is sometimes referred to as the "dial-a-jet" phenomenon. Typically, color flow velocity limits should be set in the 50 to 60 cm per second range when evaluating MR. As mentioned in the prior section, MR jet direction has important clinical implications. Centrally directed jets usually result from annular dilation or ischemic and dysfunctional

papillary muscle. Eccentric jets are caused almost exclusively by structural abnormalities of the mitral apparatus. As a consequence, eccentric jets are unlikely to improve after improving myocardial ischemia.

Quantification of Mitral Regurgitation

A. ***Vena Contracta Width***: The vena contracta is the narrow contracted portion of the MR jet seen just below the mitral leaflets. The width of this jet has been shown to correlate well with the severity of MR [73]. Widths of <3 mm correspond to mild MR, 3 to 5 mm with moderate MR, and more than 7 mm with severe MR [74]. Limitation includes the situation where there are multiple MR jets or the presence of eccentric jets.
B. ***Pulmonary Vein Flow Reversal***: Blunting or reversal of the systolic component of pulmonary venous inflow is one of the most reliable signs of hemodynamically significant MR. Systolic flow reversal is associated with severe MR whereas blunting is usually associated with moderate or moderate-to-severe MR. Limitations includes the inability to use this in the presence of atrial fibrillation where there is systolic blunting of flow due to loss of atrial relaxation, independent of the degree of MR.
C. ***Proximal Isovelocity Surface Area Method (PISA)***: The PISA method is based on the principle that a regurgitant jet accelerates in layers of concentric shells proximal to the regurgitant orifice. Immediately adjacent to the orifice, these shells have small area with high-velocity flow and at increasing distance from the orifice they have larger area and lower velocities [44]. By interrogating this area with color Doppler, the regurgitant volume can be calculated. The regurgitant volume of blood is the product of the shell area (PISA) and the aliasing velocity. Since this regurgitant volume is passing through a defect in the mitral valve, the regurgitant orifice area (ROA) can be calculated as follows: ROA = regurgitant volume ÷ VTI_{MRjet}.

Systolic Anterior Motion: SAM of the mitral valve represents an important diagnosis that must be considered in the unstable patient. MV SAM is caused when a venturi effect of blood flow at high velocity through a narrowed space between the anterior mitral valve leaflet and LV septum causes the MV leaflet(s) to be displaced toward the LVOT, causing obstruction to systolic flow. Patients at risk for developing SAM include those with hypertrophied LV septums, whether asymmetric or symmetric, patients with small LV diameters, patients with redundant mitral apparatus tissue and patients with hypercontractile left ventricles. 2D imaging of the mitral leaflet and LVOT will show movement of the leaflet into the path of blood flow. Color Doppler imaging will reveal "color aliasing" of blood flow, the Doppler equivalence of turbulence, in the LVOT. In addition, SAM frequently prevents normal coaptation of the mitral leaflets resulting in significant, usually anteriorly directed, eccentric MR. Continuous wave Doppler interrogation of the outflow tract from deep gastric windows will reveal a high-velocity flow profile, often "dagger" shaped, which can be used to quantify a pressure gradient across the obstruction. The response of this process to therapeutic interventions can be followed using these echocardiographic assessments.

Assessing Aortic Regurgitation

Causes of aortic regurgitation (AR) can be divided into abnormalities of the aortic valve leaflets and the aorta. Primary diseases of the valve leaflets include degenerative calcification, rheumatic fever, infective endocarditis, and congenital bicuspid aortic valve (which is usually associated with aortic stenosis) [75]. Dilation of the ascending aorta and aortic root may be due to chronic hypertension, aortic dissection, degenerative diseases of the aorta, cystic medial necrosis, Marfan's syndrome, and several rare conditions including ankylosing spondylitis, and syphilitic disease.

Evaluation of Aortic Regurgitation Severity

A. ***Jet Width/LVOT Diameter Ratio***: By viewing the LVOT in the long axis, the regurgitant jet width can be qualitatively compared with the diameter of the LVOT. A ratio of 1% to 24% is considered trivial AR (0 to 1^+), 25% to 46% mild AR (1^+ to 2^+), 47% to 64% moderate (2^+ to 3^+), and >65% severe (3^+ to 4^+) AR [76]. An alternate method is the use of M-mode, where the Doppler beam is placed perpendicular to the outflow tract. The regurgitant jet can be seen within the LVOT boundaries during diastole. Dividing the regurgitant jet width by the LVOT width can then be used as outlined to grade the AR.
B. ***Jet Area/LVOT Area Ratio***: Using a short-axis view of the aortic valve, the area of the regurgitant jet can be compared with the area of the LVOT. A ratio of <4% is considered trivial AR (0 to 1^+), 4% to 24% mild (1^+ to 2^+), 25% to 59% moderate (2^+ to 3^+), and >60% severe (3^+ to 4^+) AR [77].
C. ***Vena Contracta***: The vena contracta width of an aortic insufficiency (AI) jet can be measured in the long-axis view of the jet. A vena contracta width of more than 6 mm has been associated with severe AR [78].
D. ***Slope of Aortic Regurgitant Jet Velocity Profile***: The velocity of the regurgitant jet is directly correlated to the pressure gradient between the aorta and the LV in diastole. The more severe the AR, the faster the velocity profile will approach zero as the gradient between the aorta and the LV decreases rapidly. Using this principle, the slope of the rate of decay of the velocity jet can be used as a measure of regurgitation severity. A measurement of the pressure half time of this decay (the time interval between maximal AR gradient and the time it takes to half the maximal gradient). A pressure half-time of less than 200 ms corresponds to severe, 200 to 500 ms moderate, and >500 ms mild AR [79,80]. A potential pitfall of this grading technique is that it may be influenced by other pathologies that influence the gradient between the aorta and LV, such as diastolic dysfunction.

Assessing Tricuspid Regurgitation

Tricuspid regurgitation may be the result of leaflet abnormalities due to myxomatous disease or destruction from endocarditis. More frequently, increases in TR may be secondary to processes that impact right ventricular and tricuspid annular dimensions. Such examples include both acute and chronic volume overload and acute and chronic increases to RV afterload. Examples of the latter include pulmonary embolus and primary or secondary pulmonary artery hypertension. TR is typically quantified by assessing color map area and with vena contracta width as described in the assessment of MR. Evaluation for RV enlargement and systolic function is important. Continuous wave Doppler interrogation of the TR jet allows for quantification of systolic pulmonary arterial pressures and partial assessment of RV afterload. This is performed by adding

an actual or estimate of CVP to the maximum pressure of the TR jet.

EXTRACARDIAC CAUSES OF HEMODYNAMIC INSTABILITY

Pericardial Tamponade

Cardiac tamponade is a clinical and hemodynamic diagnosis; echocardiography may however, be assistance in equivocal cases. Chronic, or slowly accumulating effusions can become very large (>1,000 mL) without significant increase in pericardial pressures. In the acute setting, however, even a small volume of fluid (50 to 100 mL) may lead to significant increase in pericardial pressure and tamponade physiology. The echocardiographic diagnosis of tamponade first requires demonstration of an effusion. From there, the examination should focus on identifying cardiac chamber collapse. As the pericardial pressure increases, the cardiac chambers will show collapse in sequence from lowest pressure to highest; the atria will collapse first, followed by the RV and then LV. Furthermore, the collapse of each chamber will be most pronounced during the portion of the cardiac cycle during which the pressure is the lowest in that chamber; ventricular systole for the atria and ventricular diastole for the ventricles. This collapse can be evaluated with M-mode interrogation of the chamber walls. Pulsed-wave Doppler echocardiographic interrogation of ventricular inflow, across both the mitral and tricuspid valves, can also be used to assess for the effects of respiratory variation on ventricular filling—the echocardiographic equivalent of pulsus paradoxus. In the setting of tamponade, the peak LV inflow velocities will decrease by more than 25% with spontaneous inspiration while peak RV velocities will decrease by more than 25% during expiration [44] (Fig. 29.6).

Pulmonary Embolus

Diagnosis of pulmonary embolism (PE) in ICU patients can be extremely challenging. TTE has been described as a routine screening test in patients with suspected PE. When TTE is nondiagnostic and the clinician has high level of suspicion, or there is evidence of RV overload or hemodynamic instability, TEE examination is indicated [81]. In these circumstances, TEE has a sensitivity of 80% and a specificity of 100%. 2D echo visualization of the main and proximal right and left pulmonary arteries may allow visualization of an embolus lodged in those locations. The left pulmonary artery may be difficult to visualize as the left bronchus is frequently interposed between the TEE probe and the artery. When the PE is not extensive and easily diagnosed by echocardiography, several indirect echocardiographic signs may suggest the presence of one. These include evidence of acute right ventricular pressure overload with elevated PA pressures, right ventricular dilation, right ventricular systolic dysfunction, and increased tricuspid regurgitation. In situations where the echocardiogram can not definitively make the diagnosis of PE, the exam findings can aid the clinician in guiding therapy (Fig. 29.7).

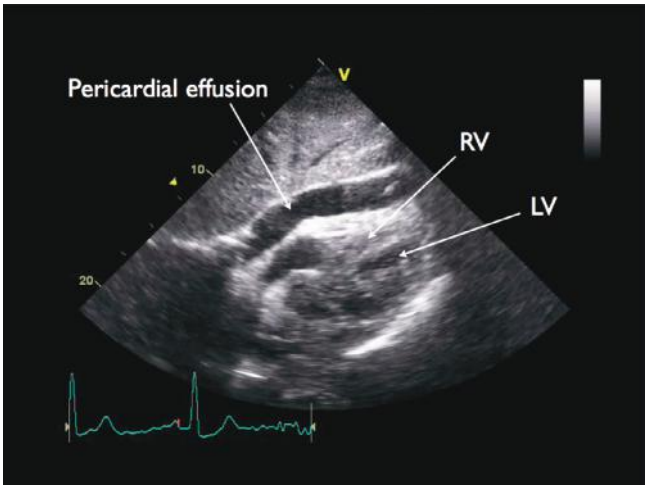

FIGURE 29.6. Transthoracic subcostal view demonstrating large pericardial effusion with end-diastolic right-ventricular chamber collapse making the echocardiographic diagnosis of tamponade. RV, right ventricle; LV, left ventricle.

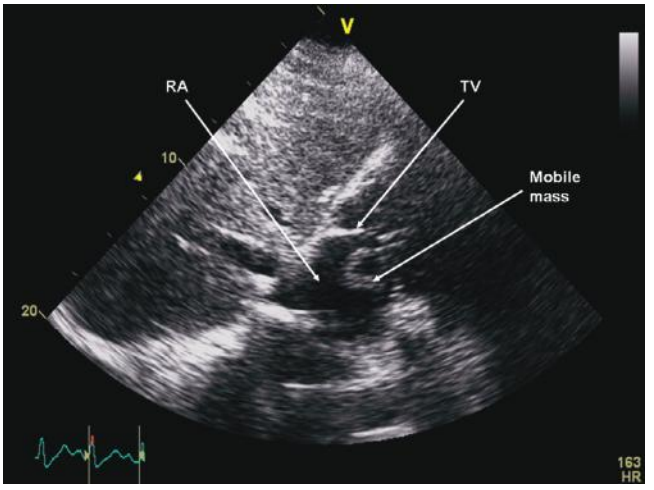

FIGURE 29.7. Transthoracic echocardiography subcostal view focusing on the right atrium demonstrating a mobile mass in the atrium making the diagnosis of emboli in transit in a patient with acute cardiovascular collapse. RA, right atrium; TV, tricuspid valve.

Aortic Dissection

Aortic dissection is a life-threatening condition where an intimal tear in the aortic wall allows passage of blood into a "false" lumen between the intima and the media. The mortality rate for acute aortic dissection is as high as a 1% per hour among untreated patients in the first 48 hours [82]. A rapid and correct diagnosis is paramount for improving survival rate. TEE has become a standard modality for the evaluation of suspected aortic dissection due to its availability, low cost, and noninvasiveness [83]. In addition, TEE can be used to diagnose other dissection-related cardiac and noncardiac complications such as AI, coronary occlusion, pericardial effusion with or without tamponade, and hemothorax.

Diagnosis of an ascending aortic dissection can prove to be very challenging due to imaging-related issues. The ascending aorta and aortic arch are areas where imaging artifacts due to reverberation and refraction are common. These artifacts can mimic the appearance of dissection flaps. Furthermore, at the level of the distal ascending aorta and proximal arch, the left mainstem bronchus crosses between the esophagus and aorta, causing image degradation. As an end result, imaging from different tomographic planes and angles is mandatory to insure accurate reporting. To distinguish artifact from dissection

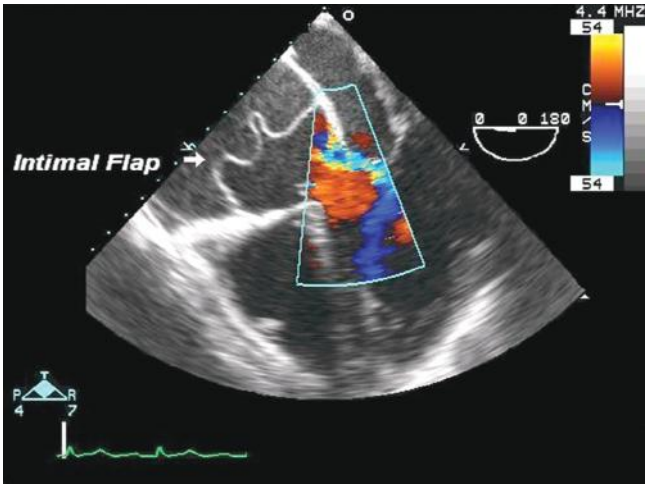

FIGURE 29.8. TEE mid-esophageal four chamber view (zooming on the aortic valve) showing acute aortic dissection with an intimal flap (arrow). The color Doppler showing severe aortic regurgitation.

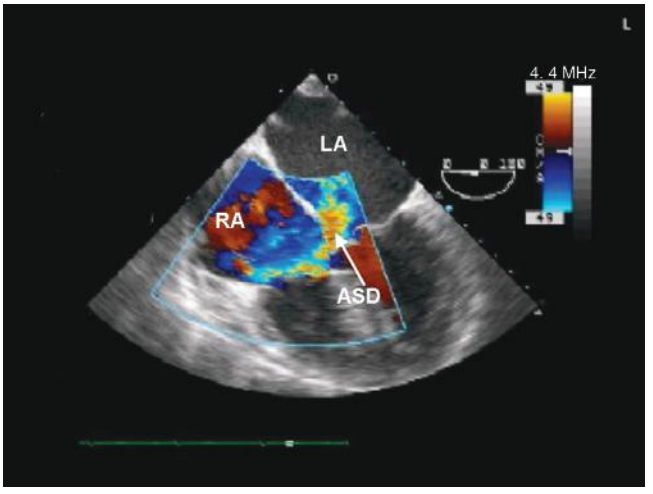

FIGURE 29.9. TEE mid-esophageal four chamber view showing a left to right shunt through an atrial septal defect (*arrow*). LA, left atrium; RA, right atrium; ASD, atrial septal defect.

flap, the echocardiographer should establish whether or not the linear echodensity conforms to the limits of the aorta or if it seems to disregard such anatomic boundaries as would an artifact. Color Doppler imaging can be used to establish whether or not blood flow respects or ignores the echodensity.

Usually, an intimal flap creates a true and false lumen. Identification of these lumina is frequently an important goal of TEE evaluation but can create a diagnostic challenge for the sonographer. There are several indirect findings that can help differentiate the lamina. First, the true lumen usually expands during systole and is slightly compressed during diastole [84]. Second, spontaneous echo contrast or thrombus may be seen in the false lumen as a result of stagnant flow; however, this may occasionally be misleading as in some instances it may be the true lumen where flow is stagnant. In addition, the true lumen is usually smaller than the false lumen, especially in chronic dissection [85,86]. Several communications between the true and false lamina can often be identified by color Doppler. Although some of these communications represent entry sites allowing blood to flow from the true to the false lumen, others are exit sites with bidirectional flow. Identification of the starting point of a dissection can have ramifications for deciding therapy (Fig. 29.8).

ECHOCARDIOGRAPHIC EVALUATION OF HYPOXEMIA

Assessment of unexplained hypoxemia and the inability to wean from ventilatory support is another potential use of echocardiography in the ICU. Etiologies of hypoxemia that can be diagnosed by echocardiography include intracardiac right to left shunting, pulmonary embolus, and LV pathologies such as LV systolic and/or diastolic dysfunction and mitral valvular abnormalities which can lead to pulmonary edema. The echocardiographic evaluation of pulmonary embolus and of LV and mitral valvular pathologies has been discussed earlier.

Intracardiac shunt is defined as an abnormal communication between two cardiac chambers and is characterized by blood flow across the defect [44]. The direction and volume of flow is determined by the pressure gradient across the defect and the size of the defect. A chronic left-to-right shunt may lead to right-sided volume overload and, over time, right-sided pressure overload from irreversible pulmonary arterial hypertension. This right-sided pressure increase may then lead to right-to-left shunting through the same defect. In clinical practice, right-to-left shunt is more commonly seen in settings where right-sided pressure acutely increases over left-sided pressures and typically involves defects in the interatrial septum. The diagnosis of an intracardiac shunt can be made with color flow Doppler. Typically, the flow across an atrial septal defect (ASD) is of low velocity because of the small pressure difference between the chambers. A significant right-to-left shunt will occur when right atrial pressure exceeds LA as with severe pulmonary arterial hypertension. Other echocardiographic signs consistent with an ASD are biatrial and RV enlargement. The ratio of pulmonary to systemic blood flow, Q_p/Q_s, can be determined by Doppler flow measurements. To calculate Q_p/Q_s, it is necessary to measure SV form the left and right sides of the heart. Transpulmonary flow, Q_p, can be calculated by measurement of the pulmonary artery CSA and VTI at the same site. Systemic flow, Q_s, is calculated from the measurement of LVOT CSA and VTI as outlined earlier (Fig. 29.9).

$$Q_p/Q_s = \frac{CSA_{PA} \times VTI_{PA}}{CSA_{LVOT} \times VTI_{LVOT}}$$

ECHOCARDIOGRAPHIC ASSESSMENT FOR SOURCES OF EMBOLI

Several disease processes, including intracardiac mass and shunt, are potential sources of systemic emboli leading to acute vascular occlusive events. Echocardiography can be very useful in the diagnosis or exclusion of the heart as a source of systemic emboli.

Cardiac masses: the three basic types of cardiac masses include vegetation, thrombus, and tumor, all of which are known causes of emboli.

A. ***Vegetation***: suspected infective endocarditis is a common indication for a TEE in the ICU, since critically ill patients are at a high risk for bacteremia. Endocarditis is a diagnosis based on a combination of findings from physical examination, laboratory findings (most importantly bacteremia), and echocardiographic examination. The purpose of the

echocardiographic exam is to identify valvular lesions that may be consistent with endocarditis, to evaluate any functional abnormality associated with the affected valve, to assess the impact of the valvular disease on chamber function and dimensions, and to discover other complications of endocarditis such as paravalvular abscess and pericardial effusion. All valves have to be carefully inspected as more than one valve can be involved. Echocardiographic evaluation of valvular endocarditis involves multiple acoustic windows and 2D views, since the vegetation may be seen only in a certain tomographic planes. Most commonly, the vegetation is attached to the upstream, lower pressure side of the valve leaflet. It appears as an abnormal, echogenic, irregular mass attached to a leaflet [44]. Although vegetations can be attached to any part of the leaflet, attachment to the coaptation point is most common.

B. ***Thrombus***: Intracardiac thrombi form in areas of blood stasis or low flow. Examples of this within the ventricles include ventricular aneurysm, pseudoaneurysm, and areas adjacent to severely hypokinetic or akinetic wall segments. LA thrombi are usually associated with atrial enlargement, mitral stenosis, and atrial fibrillation. Most LA thrombi are found in the LA appendage, which is best visualized by TEE. Thrombi are usually more echogenic than the underlying myocardium and have a shape distinct from the endocardial border. Imaging from several tomographic planes is frequently necessary to rule out artifact that may mimic thrombus. Again, color Doppler can be used to establish whether or not blood flow respects the apparent boundaries of the suspected thrombus to attempt to distinguish it from an echo artifact.
C. ***Cardiac Tumors***: Nonprimary tumors, which are about twenty times more common than primary cardiac tumors, can involve the heart by either metastatic or lymphatic spread, or invasion from neighboring malignancies. They can invade all structures of the heart; the pericardium, epicardium, myocardium and endocardium. About 75% of metastatic cardiac tumors involve the pericardium and epicardium and most commonly present as pericardial effusion. A definite diagnosis usually cannot be made from the echocardiographic images alone. A probable diagnosis can sometimes be made by incorporating the clinical information along with the echocardiographic images. Renal cell carcinoma has a propensity to develop "finger-like" projections that may extend up the IVC into the right atrium. Occasionally, uterine tumors may present in a similar manner
D. ***Shunts***: As described earlier, right-to-left shunting can play a role in hypoxemia. In addition, any right to left communications can allow for paradoxical emboli to travel from the systemic venous to arterial circulation. This can lead to stroke or vascular occlusive disease of one or several organs.

IMPACT OF ICU ECHOCARDIOGRAPHY ON PATIENT MANAGEMENT

Indications for performing a TEE study vary significantly depending on patient type: for patients in the medical and neurosurgical ICUs, most TEE studies are performed to rule out or confirm bacterial endocarditis (medical ICU) and/or a cardiac source of emboli (neurosurgical ICU). In contrast, in medical-surgical and coronary ICU patients the most common indications are for diagnosing aortic dissection, valvular dysfunction, or hemodynamic instability [18].

A recent review of 21 studies evaluating the impact of TEE on patient management demonstrated that out of 2,508 critically ill patients, TEE findings had therapeutic implications, either surgical interventions or changes in medical therapy, in 68.5% of patients. [18] 5.6% of patients underwent a surgical intervention without additional investigations following their TEE. In 62.9% of patients, the TEE study had a therapeutic, nonsurgical impact. Included within this group was the institution or dose adjustment of inotropic or vasopressor drugs, antibiotics, anticoagulation, thrombolysis, fluid administration, and the initiation of advanced hemodynamic monitoring. This represents the largest reported series evaluating the use of TEE in a noncardiac surgical ICU setting.

The current body of literature that focuses on the use of echocardiography in the ICU lacks prospective, randomized controlled studies demonstrating efficacy in decreasing morbidity and mortality and cost-effectiveness. However, this literature does point to the potential benefits that may be gained by the availability of echocardiography in ICUs. It also demonstrates the potential benefit of more widespread and advanced training in echocardiography for intensive care physicians.

FUTURE POTENTIAL USE OF ECHOCARDIOGRAPHY IN TRAUMA PATIENTS IN THE ICU

Recently, hand-carried ultrasound (HCU) devices have been introduced into clinical use [87–89]. These devices are attractive because of their size, portability, and cost. They may be easily stored in the ICU, which makes them immediately available for bedside use. Portable echocardiograms performed at the bedside can help the physician to diagnose and manage critically ill patients. Although overall image and color flow qualities of hand-carried echocardiographic devices are not equivalent to the standard full-featured machines, they have been found to compare well with standard platforms for the identification of cardiac pathology [90]. Reports in the literature regarding the use of these devices are mixed. Early reports showed favorable results in the outpatient setting [88], when used on hospital rounds [89], and in a small cohort of ICU patients [87]. Some of these reports have shown a good correlation between these devices and standard echocardiographic equipment for the evaluation of wall motion abnormalities and valvular regurgitation. [91,92] In addition, data from a few studies have shown a high level of agreement between hand-carried device examination and standard echocardiographic examination [87,89,93–95]. In one study, examination with a HCU device was able to evaluate and answer 85% of clinical questions presented by the referring physician. Of those questions, 86% were later confirmed as correctly answered [96]. Although one study has demonstrated the relative equivalence of the HCU device with regards to 2D imaging, even in mechanically ventilated patients [97], other studies have shown it to be inferior to standard echocardiography when comparing spectral Doppler capabilities [98]. Other reports have shown that HCU imaging may lead to inadequate evaluation of pulmonary hypertension, valvular disease, and LV outflow tract obstruction in severely ill patients [96,97]. In ICU cohorts, several reports have demonstrated similar shortcomings. [96,98]

In addition to cardiac evaluation, the HCU can be used in the ICU to aid in placing central venous catheters and arterial lines as well as for ultrasound guidance of pleurocentesis and paracentesis. The day when the HCU becomes an extension of the traditional physical exam may not be far off. It is also not unreasonable to imagine the HCU used by the hospital code team for better diagnosis and patient management during resuscitative efforts.

CONCLUSION

Echocardiography is an important tool for diagnosis and monitoring of the critically ill. With time, utilization of echocardiography is likely to become even more widespread. It is quickly establishing itself as a highly efficient and reliable clinical tool. The echo examination can be performed in numerous clinical settings and in a diverse patient population, including the most complex. Technical advancements in this field will potentially improve the imaging quality and clinical capabilities and allow for implementation of this tool in new situations and settings. With this in mind, proper education and implementation of utilization guidelines becomes increasingly important. To achieve optimal clinical results, clinicians must be well aware of the limitation as well as the benefits of each modality and when and how they should be used. An important step toward achieving this will be inclusion of echocardiographic training within critical care fellowships.

CHAPTER 30 ■ MONITORING GASTROINTESTINAL TRACT FUNCTION

RUBEN J. AZOCAR, LAURA SANTOS PAVIA AND SURESH AGARWAL

Gastrointestinal system function is of paramount importance for the maintenance of the body's homeostasis, which is not only limited to the important functions of digestion and absorption but also closely related to immune function. Monitoring the gastrointestinal tract function remains largely based on clinical exam and a few diagnostic tests. The majority of the tests that are available have been primarily used for research purposes and are not available at the bedside of the critically ill patient (Table 30.1).

This chapter examines the diagnostic modalities available, on an organ system basis, for assessing abnormalities in the critically ill patient.

ESOPHAGUS

Tests of Esophageal Motility and Lower Esophageal Sphincter Function

Impaired tubular esophageal motility is involved in the pathogenesis of gastroesophageal reflux disease (GERD) which might cause nosocomial pneumonias in the critically ill.

Esophageal manometry has been used extensively to study GERD in critically ill patients. One study, of 15 critically ill patients, demonstrated that low esophageal sphincter (LES) pressure (mean 2.2 ± 0.4 mm Hg) and poor motor response to reflux correlated with the presence of GERD. Furthermore, low LES pressures were associated with frequent reflux episodes (60% of untreated patients) and decreased esophageal motility [1].

In a more recent 24-hour manometric study, the authors demonstrated that propulsive esophageal motility is impaired in critically ill patients receiving sedation and postulated that 24-hour motility studies appear to be a valuable and feasible method to analyze and quantify esophageal motor disorders in critically ill patients [2].

Twenty-four–hour pH and impedance monitoring further elucidates the function of the LES and the amount of gastric reflux a patient is experiencing. Over a 24-hour period, the pH should not drop below 4 frequently or for a prolonged duration (6% of total time in the supine patient, 10% of total time in the upright patient).

Both barium swallow and real-time fluoroscopy yield functional and anatomic data about the esophagus and the swallowing mechanisms. Similarly, an isotope swallow, using a technetium-99 colloid and a gamma camera, may provide data regarding esophageal physiology.

STOMACH

Tests of Gastric and Duodenal Motility

Delayed gastric emptying (GE) is common during critical illness. Patients receiving enteral nutrition are frequently assessed to evaluate feeding tolerance and prevent nosocomial pneumonias.

Traditionally this is done by quantification of gastric residual volumes (GRV), which despite being easy to perform, are a poor predictor of the patient's ability to tolerate enteral nutrition. In addition, a recent article suggests that the use of residual volumes as a marker of risk for aspiration in critically ill patients has poor validity [3].

Reflectometry (RFT) of gastric contents seems to provide complementary information on the adequacy of gastric emptying [4] by differentiating gastric contents from feeding formula when measuring GRVs. This model implies the measurement of the Brix value (BV) of the gastric aspirate at several time points. The BV is the refractive index of a substance, which is the degree of deviation or refraction of a beam of light when passing obliquely through a solution [5]. Chang et al. [6] studied 36 patients receiving continuous enteral nutrition. Based on the data collected, the authors created and algorithm using BVs and GRV, which suggest values at which enteral feedings can be safety continued. RFT uses an inexpensive handheld instrument (refractometer) similar to a small telescope. A drop of the solution is placed in the viewing window and the BV is read thought the eyepiece. The use of RFT is simple, inexpensive, and quick, but it has not been compared with what is consider the gold standard, gamma scintigraphy.

Gamma scintigraphy is a quantitative method to measuring gastric motility by administering radiolabeled solid food (usually greater than 200 kcal) and measuring transit after 2 to 4 hours. The administration of liquids may not be relevant as liquids may empty from the stomach even as solid food remains behind. The feasibility of scintigraphy testing for the critically ill patient makes is difficult as it is often impractical to transport these individuals to the nuclear radiology suite for this study.

Breath tests are a novel and useful bedside technique to assess gastric emptying of both solids and liquids by using ^{13}C- or ^{14}C-labeled octanoic acid. The absorption of the labeled octanoic acid in the small intestine and subsequent metabolism in the liver produce $^{13}CO_2$, which can be measured in the exhaled air. The delivery of the 13-octanoic acid into the duodenum is the rate-limiting step for these processes. As such, measurement of $^{13}CO_2$ levels correlates with the rate of gastric emptying. Ritz et al. [7] founded that gastric emptying of a caloric-dense liquid meal is slow in 40 to 45 of unselected mechanically ventilated patients by using the 13-octanoic acid breath test. They concluded that this test is a useful bedside adjunct to measure gastric emptying in ventilated, critically ill patients.

Gastroduodenal manometry has also been used to study the effects of critical illness in gastric motor activity. Nguyen demonstrated that in critical illness in addition to impaired proximal and distal gastric motor activity, the association between the two regions was also abnormal which interferes with meal distribution and affects GE [8]. Similar data was observed by Chapman et al. who noted that in critical illness there is slower GE probably associated by fewer anterograde waves

TABLE 30.1

TESTS FOR MONITORING GASTROINTESTINAL FUNCTION

Organ	Function	Test
Esophagus	Motility/LES function	Barium swallow Isotope swallow Esophageal manometry Esophageal pH and impedance
Stomach	Motility	Gastric residuals Refractometry Gastroduodenal manometry Breath tests Acetaminophen absorption test
	Mucosal permeability and ischemia	Gastric tonometry Laser Doppler flowmetry Near-infrared spectrometry Positron emission tomography Microdialysis Orthogonal polarization spectrometry Sidestream Dark Field
Small intestine	Absorption	Stool analysis: fecal pH, fecal osmotic gap, steatorrhea Carbohydrates absorption tests (D-xylose, L-rhamnose) Acetaminophen absorption test Breath tests
Pancreas	Exocrine functions	Fecal fat concentration Amylase/lipase Secretin tests
Liver	Liver function test	**Static tests** Transaminases Bilirubin Albumin Lactate Coagulation tests **Dynamic test** MEGX ICG Breath tests
	Hepatic blood flow tests	ICG MEGX
	Cholestasis	Transaminases Bilirubin Alkaline phosphatase Gamma glutamyl transpeptidase Ultrasound HIDA

HIDA, hepatic iminodiacetic acid; ICG, indocyanine green; LES, low esophageal sphincter; MEGX, monoethylglycinexylidide.

and more retrograde waves as recorded when measuring the antroduodenal motility [9].

The acetaminophen absorption test may also be used to assess gastric emptying, by administering 1,000 mg of acetaminophen and measuring serum concentrations of acetaminophen over a 1-hour period to construct an area under the curve (AUC) absorption model. This AUC is then compared to a known AUC model constructed from healthy volunteers. The utility of this test may be quite variable in the critically ill patient given differences in volume of distribution, hepatic metabolism, and renal clearance [5].

Other novel methods to assess GE include the use of ultrasound and gastric impedance monitoring (GIM). Ultrasound has used different equipment and different methods to assess GE, which has not allowed standardization or validation despite its obvious benefits of availability, lack of radiation and good interobserver agreement. GIM, which measures increases in impedance as the stomach fills, and declines as it empties, seems to be a promising tool. However, the time needed to complete and the requirement of a fasting state for baseline may interfere with its use in the clinical setting.

Tests of Mucosal Permeability and Ischemia

Microcirculatory dysfunction plays an important role in the pathogenesis of the systemic inflammatory response, sepsis, and shock. Global hemodynamic measurements do not assess

oxygen delivery at the microcirculatory level. Gut ischemia at this level causes changes in permeability leading to bacterial translocation that may initiate, perpetuate, and aggravate sepsis and multisystem organ failure (MOF). Many methods have been used to study the gut microcirculation. Unfortunately, most of them have failed to be applicable in the clinical setting or have flaws in the data collected.

Tonometry

Although the diagnosis of bowel ischemia may be done by a variety of different methods, gastric tonometry is the simplest, most practical, and least invasive [10]. It attempts to determine the perfusion status of the gastric mucosa by measuring the local PCO_2 [11]. As perfusion to the stomach decreases, the PCO_2 in the tonometer will increase. Once cellular anaerobic respiration starts, the hydrogen ions titrate with bicarbonate, with the end result of more CO_2 production by mass action. By estimating the PCO_2 gap (the difference between gastric mucosa and arterial CO_2) the gastric perfusion can be assessed [12]. Unfortunately, the use of the technique has not gained widespread popularity despite many clinical studies that have validated gastric tonometry as a valuable and easily accessible prognostic tool [13,14]. This may be explained by the possibility of error in the determination of the PCO_2 and interoperator variability [15,16]. Other pitfalls include multiple local effects, including increased gastric secretions and refluxed duodenal contents; both of which can increase CO_2 measurement and lead to false PCO_2 measurement, and that this technique may only represent one region of perfusion [11].

Recently, the measurement of carbon dioxide in the sublingual mucosa by sublingual capnometry has been advocated as a monitor for tissue oxygenation and as an end-point for resuscitation [17]. Studies have demonstrated a good correlation between gastric mucosal and sublingual mucosa PCO_2. In addition, sublingual mucosa PCO_2 seems to respond faster to therapeutic interventions [18].

Laser Doppler Flowmetry

Laser Doppler flowmetry (LDP), which estimates gastric and jejunal blood perfusion by integrating red blood cell content and velocity, correlates well with absolute blood flow. The flowmeter consists of a laser source, a fiberoptic probe, and a photodetector with a signal-processing unit. The laser conducts through the tissue by a flexible fiberoptic guide. The probe contains an optic fiber for transmission of laser light to the tissue and two fibers for collecting the reflected scattered light. The signal-processing unit consists of a photodetector and an analog circuit to analyze the frequency spectrum of the scattered light. By determining the instantaneous mean Doppler frequency and the fraction of backscattered light that is Doppler shifted, the signal-processing unit provides a continuous output proportional to the number of red blood cells moving in the measuring volume and the mean velocity of these cells. Measurements are considered satisfactory if (a) the measurement is stable for 15 seconds; (b) the measurement is free of motion artifacts; (c) pulse waves can be clearly identified; and (d) the reading is reproducible. Although LDP is relatively easy to use and it is noninvasive, it does not account for blood flow heterogeneity, a major parameter of microcirculation [19].

Near-Infrared Spectometry

Near-infrared spectrometry (NIRS) has been used to measure local tissue blood flow and oxygenation at the cellular level [20]. Local oxygen delivery and oxygen saturation can be determined by comparing the differences in the absorption spectrum of oxyhemoglobin with its deoxygenated counterpart, deoxyhemoglobin [21]. Puyana et al. [22] reported using NIRS to measure tissue pH in a model of experimental shock and showed that NIRS gut pH correlated with the pH obtained by microelectrodes. This technology has progressed to the measurement of muscle tissue oxygenation and microcirculation by measuring thenar muscle oxygenation saturation with promising results [23].

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography may also be used to evaluate regional blood flow. Fluoromisonidazole accumulation has been used to demonstrate abdominal splanchnic perfusion and regional oxygenation of the liver in pigs; however, the lack of portability of this technique makes it difficult to use for monitoring in the intensive care unit (ICU) [14].

MICRODIALYSIS

Microdialysis measurement of mucosal lactate is a novel way to assess gut mucosal ischemia. Tenhunen et al. [24] inserted microdialysis catheters into the lumen of the jejunum, the jejunal wall, and the mesenteric artery and vein of pigs. Subsequently, the animals were subjected to nonischemic hyperlactataemia or an episode of mesenteric ischemia and reperfusion. The lactate levels from the jejunal wall and the jejunal lumen were compared. The gut wall lactate was increased in both the nonischemic and the ischemic lactataemia whereas the lactate measured from the jejunal lumen only was altered significantly during true ischemia.

Microdialysates of other substances have also been measured, including glucose and glycerol, showing that, while lactate levels increase with ischemia, intestinal wall glucose levels drop with the same stressor. Glycerol was increased, but the changes were seen later than the changes in lactate [25]. Similarly, increases in the lactate/pyruvate ratio in both intraperitoneal or intraluminal placed microdialysis catheters have correlated with hypoperfusion [26]. As glucose from the splanchnic circulation is inhibited, pyruvate accumulates in the tissue and, in the setting of inadequate oxygen delivery, is broken down to lactate. Using glycerol as a marker, Sollingard et al. [27] suggested that gut luminal microdialysis could serve as a valuable tool for surveillance not only during ischemia, but also after the ischemic insult. This group has also suggested that gut luminal lactate measured by this technique correlates well with changes in the permeability of the intestinal mucosa after ischemia [28].

The assessment of the barrier function using colon submucosal microdialysis with a radioactive tracer substance has also been reported. No data comparing these results with local tissue chemistry have been reported [29].

These data support the idea that microdialysis could be a potentially useful method to monitor gut ischemia. However, even under investigational conditions, technical difficulties were reported in up to 15% of cases by either damage to the microdialysate membrane, dislocation of the probe, or incorrect placement [30].

ORTHOGONAL POLARIZATION SPECTROMETRY AND SIDESTREAM DARK FIELD

Recently devices able to allow the microcirculation to be visualized directly have been used clinically [31]. Orthogonal polarization spectrometry (OPS) and the sidestream dark field

provide high-contrast images of the microvasculature. Both devices are based on the principle that green light penetrates a tissue and that then green light is absorbed by red blood cells (RBCs) hemoglobin contained in superficial vessels. Therefore, capillaries and venules can be visualized if they contain RBCs. The easiest assessment method is the microvascular flow index. The image is divided into four quadrants and the flow is characterized and scored as absent (0), intermittent (1), sluggish (2), or normal (3). The values of the quadrants are then averaged. Clinical studies suggest that this is a good method to assess microcirculation in critically ill patients. Those patients with more severe alterations have a higher mortality and that if these alterations persist they may lead to MOF [32–34]. In most studies, the sublingual circulation has been the site chosen. An attempt to use this method for gut ischemia by assessment of the villi microvasculature per se was not successful. Likely causes include blood flow redistribution, heterogenicity of the intestine microcirculation, and suboptimal OPS imaging, which resulted in large interobserver differences in the quantification of vessel density [35].

SMALL INTESTINE

Tests of Intestinal Absorption

Clinically, the recognition of malabsorption in the ICU is associated with a variety of signs and symptoms. On physical exam, abdominal distention, abdominal pain, and increased flatulence may be present. Isolated carbohydrate malabsorption may result in increased gas production, which can lead to flatulence, bloating, and abdominal distention. Likewise, diarrhea may indicate a problem with absorption of nutrients, but again it is nonspecific and other potential causes should be examined. Steatorrhea may indicate pancreatic insufficiency. It is also important to elicit the past medical history since it can provide useful information in regards to primary (i.e., lactose intolerance) or secondary (i.e., chronic pancreatitis) malabsorptive problems.

Malabsorption can be detected by a variety of tests. Stool analysis may provide information regarding carbohydrate and fat malabsorption. Bacterial fermentation of malabsorbed carbohydrates may result in an acidic fecal pH. Eherer and Fordtran [36] found that when diarrhea was caused by carbohydrate malabsorption (lactulose or sorbitol), the fecal fluid pH was always less than 5.6 and usually less than 5.3. Other causes of diarrhea rarely caused fecal pH to be as low as 5.6 and never caused a pH less than 5.3.

Another measurement is of fecal osmolarity. Assuming the fecal osmolality is similar to that of the serum, the fecal osmotic gap can be calculated. A sample is taken from the stool supernatant and if the value is greater than 50 to 100 mOsm, it would suggest the presence of an unmeasured solute. Although this solute may be a malabsorbed carbohydrate, other compounds, such as sorbitol, or ions, such as sulfates, may yield similar results.

Steatorrhea is defined as the presence of at least 7 g of fat in a 24-hour stool collection [37]. Sudan II stain is a simple screen testing and it is helpful to detect those patients with mild degrees of steatorrhea (7 to 20 g per 24 hours). The gold standard is represented by quantitative fecal fat analysis [38]. Stool is collected over 2 to 3 days while the patient ingests 75 to 100 g of fat within 24 hours. Normal values are less than 7 g per day. However, this test is laborious and may not help with differentiating diagnoses.

D-Xylose Uptake

The D-xylose test has been used in the diagnosis of malabsorption. This pentose sugar of vegetable origin is incompletely absorbed in the small intestine by a passive mechanism. The test consists in the ingestion of a 25 g dose of D-xylose and the subsequent measurement of the levels in the serum or urine. In normal individuals, a serum sample taken 1 to 2 hours after ingestion will reveal a level of 25 mg per dL and a 5-hour urine collection will result in at least 4 g of this substance. Many entities such celiac disease, alterations in gastrointestinal motility, and impaired function of the pylorus will result in abnormal results. In the critically ill, renal function may be altered and may alter the results of the urine test. Chiolero et al. [39] studied the intestinal absorption of D-xylose in critically ill patients that were tolerating enteral feeding. They introduced D-xylose to the stomach or the jejunum and found that although the levels in plasma in all patients in the study increased indicating proper gastric emptying, in those receiving the compound in the stomach, the levels of D-xylose were lower than normal, indicating delays or depression in absorption. These results were similar to a prior study in trauma and septic patients. In that study, in both groups the D-xylose test showed abnormal results at the onset of the illness with resolution by 1 to 3 weeks after trauma or resolution of sepsis. Interestingly, enteral feedings were tolerated by these patients before the test results returned to normal [40]. As the patients in both studies were tolerating tube feeds even with abnormal D-xylose test results, Chiolero et al. [39] suggested that this test may not be a good indicator to determine the capacity of patients to tolerate enteral feeds. This does confirm that absorption of D-xylose stays depressed for a prolonged period of time in the critically ill.

Johnson et al. [41] also found decreased absorption in the septic population when compared with healthy individuals. They used an oral test solution that contained 5 g of lactulose, 1 g of L-rhamnose, 0.5 g of D-xylose, and 0.2 g of 3-*O*-methyl-D-glucose. L-rhamnose is absorbed by passive diffusion and therefore particularly sensitive to changes of the absorptive capacity of the gut when compared with D-xylose and 3-*O*-methyl-D-glucose, which depend on specific carrier mechanisms. The authors found that septic patients had decreased L-rhamnose/3-*O*-methyl-D-glucose ratios when compared with normal individuals, a result consistent with decrease absorptive capacity during sepsis. They also used the lactulose/L-rhamnose ratio to assess permeability of the gut. This group concluded that the changes in the absorptive capacities of the gut may contribute to the pathophysiology of sepsis.

Other Tests

The rapid absorption of acetaminophen at the jejunal level can also aid the assessment of the absorptive capacity of the gut. It has, however, been used more to assess gastric emptying [5] and tube feeding location for enteral feeding [42]. From these data, it appears that either carbohydrate absorption tests or the acetaminophen test could be used to a monitor absorption in the critically ill. No correlation has been established between tolerating tube feeds and the degree of absorption. The role of this test may be to monitor improvement of absorptive function of the gastrointestinal tract after critical illness.

Breath tests are a simple and safe alternative to diagnose many gastrointestinal conditions including malabsorption. Most of the data are from the gastroenterology literature and are used to diagnose specific gastrointestinal pathologies. However, it seems feasible to apply this test to the critically ill population. These tests are based on the appearance of a metabolite of a specific test substance in the breath [43]. Both hydrogen gas excretion and carbon dioxide appearance on breath tests are available.

If carbohydrates are not absorbed in the small intestine, they are fermented in the colon by colonic bacteria. This process results in the production of hydrogen. For example, in cases of lactose intolerance, this disaccharide will reach the colon and a peak on the end-expiratory hydrogen of more of

20 ppm over baseline by either gas chromatography or portable hydrogen analyzers at 2 to 3 hours indicates malabsorption for this carbohydrate [44]. A similar test using a nonabsorbable carbohydrate, such as lactulose, has been used for the diagnosis of bacterial overgrowth in which the peak of hydrogen occurs earlier but is less pronounced. The use of carbon dioxide that results from the fermentation of labeled substances has also been reported. The use of both radioactive ^{14}C and stable ^{13}C compounds has been described. However, since the nonradioactive substances can be detected by mass spectrometry and do not involve radiation exposure, they seem to be preferred over the radioactive ones [45].

In critically ill patients ^{13}C-acetate has been studied to evaluate intestinal absorption [12]. Acetate possesses interesting properties that allow its use for absorption purposes since it is readily absorbed by the intestinal mucosa and it is metabolized through oxidative metabolism by nearly all body tissues. Acetate is converted into acetyl–CoA and then oxidized to CO_2. When marked acetate is provided, the $^{13}CO_2$ is then measured in the breath by mass spectometry. ^{13}C-acetate was provided by intravenous infusion and enterally at both gastric and jejunal levels. Surprisingly, the kinetics of all three routes was similar (the gastric group was delayed but probably secondary to the time for gastric emptying), indicating a rapid absorption and metabolism. The authors concluded that further studies are needed in this area before this particular breath test can be used to assess tolerance of enteral feeding [15]. C-octanoic acid has been used to assess gastric emptying in the critically ill and was discussed in the motility section [3]. Other breath tests have been use to assess absorption anomalies [44]. In the case of bile acid malabsorption and bacterial overgrowth, cholylglycine (glycocholic acid) is not absorbed at the ileum and the glycine is cleaved from the labeled cholylglycine by colonic bacteria. Glycine is then absorbed and metabolized into CO_2. The CO_2 can be detected in the breath and 4.5% of the radioactivity is seen in the breath over the subsequent 6 hours. To differentiate between bacterial overgrowth and bile acid malabsorption a stool collection is needed to detect bile acid losses.

In pancreatic insufficiency mixed triglycerides that are hydrolyzed to glycerol and fatty acid are then absorbed and finally metabolized in the liver where they release labeled CO_2. This test indirectly measures intraluminal fat digestion by pancreatic enzymes. Other substances such as triolein, hiolein, tripalmitin, and labeled starch have been use for this purpose but are not sensitive enough for patients with mild disease [44].

PANCREAS

Although the pancreas performs both endocrine and exocrine functions, only the functions affecting the digestive tract are discussed here. Although diabetes mellitus may decrease gastric motility, the diagnosis and management of endocrine disorders will be dealt with elsewhere (see Section VIII).

Fecal Fat Concentration

As discussed in the digestion and absorption section, in the presence of pancreatic steatorrhea, fecal fat concentration is elevated [37,38]. Diarrhea resolves and fecal fat concentration abates once the individual is challenged with enzyme replacement therapy.

Amylase/Lipase

These simple blood tests are elevated in the presence of acute pancreatic inflammation. Although not indicative of the severity of injury, they do indicate that injury is present. Pancreatitis will be covered in other portions of this text (see Chapter 99).

Secretin Test

The secretin test is a direct measurement of pancreatic exocrine function that measures the intraduodenal secretion of bicarbonate, amylase, and trypsin after exogenous administration of secretin. Generally, bicarbonate and amylase secretion will increase in adults, whereas the increase of bicarbonate, amylase, and trypsin will increase in children. In the presence of chronic pancreatitis, concentrations and quantity will be diminished; in contrast to pancreatic cancer, which presents with diminished volume but normal concentration. The maintenance of normal concentrations in pancreatic cancer is attributed to normal pancreatic function in the nonmalignant portions of the pancreas.

LIVER

Liver function includes vital functions of metabolism, synthesis, detoxification, and excretion. It is then, not surprising that patients with deteriorating liver function will have a more complex course during critical illness. Traditionally, tests related to measuring the products of liver synthesis have been use to assess liver function and damage in a static fashion, but as it will be discussed, tests that evaluate the liver function in a more dynamic fashion are also available.

Tests of Liver Injury and Static Function

In the critically ill, different levels of dysfunction can be manifest ranging from mild elevation of the transaminases to profound hepatic failure. It is difficult to separate completely those tests that assess liver injury from those that are related to its function as some will suggest the insult to the organ as well as the alteration on its function, particularly in the acute setting. The tests described in this section are considered "static" and will reflect an injury that has occurred and changes on the liver's function, but they do not assess current functionality, particularly in the patient with chronic liver failure. However, in a critically ill patient with no prior liver problems these tests are helpful in detecting an ongoing morbid process in the liver.

Transaminases

Serum glutamic-oxaloacetic transaminase (SGOT), or aspartate aminotransferase (AST), and serum glutamate-pyruvate transaminase (SGPT), or alanine aminotransferase (ALT), are enzymes that are present in all organism cells; however, they are found in highest concentration in the hepatocyte: SGPT in the cytoplasm and SGOT in the cytoplasm as well as the mitochondria. Therefore, as injury and necrosis of the hepatocyte occurs the enzymes levels in the plasma will increase reflecting the damage to this organ. The rate and the level of the elevation are usually related to the onset of the dysfunction and its severity. Severe ischemic hepatitis is characterized by an acute elevation of the aminotransferases to at least 20 times the upper limit of normal [45].

Bilirubin

One of the main functions of the liver is to conjugate and excrete bilirubin, a product of erythrocyte breakdown. Therefore, either elevations of the bilirubin clinically (jaundice, icterus, dark urine) or by laboratory testing should raise the clinical

suspicion of liver dysfunction or injury. It is possible to determine if the bilirubin has already been conjugated, and this helps in searching for the causes of the hyperbilirubinemia. Unconjugated (or indirect) hyperbilirubinemia is the result of excess production of bilirubin (e.g., hemolysis) or decreased hepatic uptake. Conjugated hyperbilirubinemia results when intrinsic parenchymal injury or biliary obstruction exists. Acute changes of the conjugated bilirubin levels are related to acute hepatocyte injury in situations such as viral hepatitis or ischemic hepatitis and will be related to the increase in the transaminases. This should alert the clinician of injury and dysfunction of the liver. Tests to study cholestasis are described in a separate section of this chapter. However, it should be remembered that biliary obstruction may also lead to hepatic dysfunction.

Lactate

The ability of the liver to clear lactate is profound. Greater than 99% of lactate is cleared by first pass metabolism by a healthy liver. Inability to clear lactate may be an indicator of poor organ perfusion and anaerobic metabolism, and this metabolite can be used as a resuscitation parameter. If other indicators of resuscitation are optimized and the arterial lactate levels remain elevated, this may indicate severe liver dysfunction and injury, particularly in patients in shock.

Albumin

Liver function may also be evaluated by measuring its ability to synthesize a variety of proteins. Albumin is the most common protein measured when evaluating liver synthetic ability. Although hepatocellular dysfunction may be the cause of hypoalbuminemia, the protein concentration also varies in a variety of diseases/acute injury phases (e.g., burns, nephrotic syndrome, etc.) and can be nonspecific. It is a better marker to assess the degree of chronic hepatic failure than acute dysfunction and it does not reflect injury.

Coagulation Studies

More sensitive and specific measurements of hepatic function include evaluation of the coagulation cascade and the production of specific coagulation factors. If the prothrombin time (PT) is elevated, one of two conditions exists: vitamin K deficiency or deficiency in vitamin K dependent factors (II, VII, IX, and X). If vitamin K has been replaced and the PT remains elevated, this is very specific for liver dysfunction. This is not a sensitive test, as the PT remains normal as long as 20% of the liver remains intact. Far more sensitive, although more time consuming and costly, is the measurement of factor V levels. Factor V, produced in the liver, is not vitamin K dependent, and its deficiency is both sensitive and specific for hepatocellular synthetic dysfunction.

Dynamic or Qualitative Tests of Liver Function

Although the tests discussed in the earlier section are very important in detecting and helping the clinician assess liver dysfunction, they are not perfect as some are nonspecific (lactate, coagulation disorders, albumin levels) or reflect past damage (transaminases) in assessing the current state of liver functionality. Figg et al. [46] compared the Pugh's classification, which is based in clinical and laboratory data, with dynamic or qualitative methods of hepatic function and found that the Pugh's classification seemed to be a reliable indicator of the degree of chronic liver disease but could not replace qualitative metabolic markers particularly isozyme-specific markers. Although the quantitative tests may be more complicated to perform and more expensive than conventional tests, they may prove superior in monitoring the degree of liver dysfunction by monitoring the liver's metabolic or clearance functions [47]. Different tests have been used in an attempt to have a dynamic or "real-time" assessment of the liver's metabolic or clearance functions and complement the information provided by the static tests.

Monoethylglycinexylidide

The hepatic metabolism of lidocaine by sequential oxidative *N*-dealkylation by the cytochrome P450 system into its major metabolite; monoethylglycinexylidide (MEGX) is a dynamic liver function test [48]. Because of the high extraction ratio of lidocaine by the liver, this test not only evaluates liver metabolic capacity but also hepatic blood flow [49]. Detection of this metabolite can be accomplished by different techniques such as immunoassay based on the fluorescence polarization immunoassay technique, high performance liquid chromatography, and gas liquid chromatography [49]. Fluorescence polarization immunoassay technique may cross react with another metabolite (3-OH-MEGX). The other two tests are specific for MEGX.

This test has been useful in patients with end-stage liver disease in which a MEGX level at 15 or 30 minutes of less than 10 mg per L indicates poor 1-year survival. In liver transplant recipients, a change in the levels may indicate a deterioration of the graft function. In critically ill patients, a rapid decrease in MEGX test values have been associated not only with liver dysfunction but with the development of multisystem organ failure and an enhanced systemic inflammatory response [49]. McKindley et al. [50] reported on the pharmacokinetics of lidocaine and MEGX in a rat model of endotoxic shock. They found that the metabolism of both compounds was altered and attributed the results to both the reduced hepatic blood flow and altered function of the cytochrome P450 system, particularly cytochrome P450–3A4. Chandel et al. [51] also report the use of this test in an animal model of hypovolemic shock. They found that the MEGX levels were significantly lower in shocked animals. Once the animals were resuscitated with Ringer's lactate, the MEGX levels were higher but still lower than the control group. They concluded that shock produced significant depression of hepatocyte function and that MEGX seemed a suitable tool for clinical evaluation and therapeutic intervention after shock.

Dyes

Another dynamic test of liver function is related to the rate of elimination of dyes such as indocyanine green (ICG) and/or bromsulphthalein [52]. Most of the data in the critically ill come from the use of ICG. This dye is a water-soluble inert compound that is injected intravenously. In the plasma, it binds to albumin and is then selectively taken up by hepatocytes. The ICG is then excreted into the bile via an adenosine triphosphate (ATP)-dependent transport process. This compound is not metabolized and does not undergo enterohepatic recirculation. The excretion rate of ICG into the bile reflects the hepatic excretory function and the hepatic energy status and justifies its use as a tool for assessment of liver function [53]. In a study comparing cirrhotic and noncirrhotic patients, Hashimoto and Watanabe [54] found that ICG clearance was proportional to liver parenchymal cell volume and is related to the hepatic dysfunction in cirrhotic patients. Traditionally, the ICG clearance has been measured by a series of blood samples and subsequent laboratory analysis. NIRS has also been used to measure hepatic ICG clearance with promising results in the assessment of hepatic parenchymal dysfunction [55].

Fortunately, bedside techniques have become available to measure the plasma disappearance rate (PDR) of ICG.

Von Spiegel et al. [56] compared the clearance method of a transpulmonary indicator dilution technique with an arterial fiberoptic thermistor catheter that assessed the ICG-circulating curve in patients undergoing liver transplantation. They found that both methods were effective in detecting onset and maintenance of graft function in these patients. Newer technology allows the use of assessment of ICG PDR transcutaneously. In two separate publications, Sakka et al. [57,58] suggested that this technology, when compared with invasive methods, reflected ICG blood clearance with sufficient accuracy in critically ill patients to be used as a surrogate. In contrast, in a model of hyperdynamic porcine endotoxemia the PDR of ICG failed to accurately substitute for direct short-term measurements of ICG excretion [59]. The authors suggested that normal values of PDR of ICG should be interpreted with caution in early, acute inflammatory conditions. As mentioned before, ICG clearance also aids with the evaluation of the hepatic energy status since the excretion into bile is energy dependent. Chijiiwa et al. [60] correlated the biliary excretion of ICG with the ATP levels in liver samples obtained from patients with biliary obstruction, and in a second study, they were able to correlate those variables with the biliary acid output [61]. They concluded that biliary bile acid output and ICG excretion are valuable parameters of hepatic energy status, which is essential for organ viability. ICG can be considered a valuable tool to assess liver function in patients after liver transplantation, at risk to develop, or with ongoing liver injury to assess damage and recovery and to assess the energy status of the liver.

Radiological Studies

Another method to assess functional liver reserve is with the use of technetium-99 diethylenetriamine penta-acetic acid galactosyl human serum albumin (99mTc-DTPA-GSA) clearance. Studies using hepatic scintigraphy and more recently single-proton emission computer tomography (SPECT) scan have been described [62,63]. Hwang et al. [63] demonstrated the use of this test as a reflection of hepatic function and also suggested that predicting residual hepatic values was a good indicator of postoperative hepatic function and early prognosis after liver resection. Kira et al. [62] showed that using this test before and after transjugular intrahepatic portosystemic shunt was useful to evaluate changes in hepatic functional reserve and evaluate the degree of portosystemic shunt. At this time, the test is mostly used as a predictor of liver function after liver resection and not used in the critically ill [64].

Breath Tests

The use of breath tests as qualitative measurement of liver function has also been described. The principle behind these tests is similar to the description of breaths tests used for monitoring of gut absorption described earlier. As the carbon marked compound is metabolized, the resulting marked carbon dioxide can be measured in the breath. As liver function declines, less of the marked CO_2 will be detected in the breath. In an animal model of hepatectomy, Ishii et al. [65] injected L-[1-(13)C] methionine and L-[1-(13)C] phenylalanine intravascularly and measured the exhaled $^{13}CO_2$ over 15 minutes. They concluded that this test could qualitatively evaluate liver dysfunction. In a human study, Kobayashi et al. [66] demonstrated that the use of the ^{13}C phenylalanine test correlated well with ICG clearance test, Child Pugh's classification, and standard liver blood tests, suggesting that this test is a useful noninvasive method to determine liver functional reserve. Koeda et al. [67] studied the validity of the ^{13}C phenylalanine breath test in both chronic cirrhosis and acute hepatitis patients and concluded that in both groups this test allows the noninvasive evaluation of hepatic function. Hepatic dysfunction associated with obstructive jaundice in a rat model was also evaluated using this test. As similar results were achieved, the authors concluded that this test could be used to measure hepatic dysfunction associated with obstructive jaundice [68]. Reports of the use of other marked compounds to assess liver function using the breath test principles, such as ^{13}C-methacetin [69], L-[1,2–13C] Ornithine [70], and L-[1–130 C] alanine [71] have been described with promising results.

Other dynamic tests that are available include the antipyrine clearance test [46,47], the caffeine clearance test [47], and the pharmacokinetics of acetaminophen. Zapater et al. [72] reported a higher AUC concentration and lower clearance and higher elimination half-life in cirrhotics when compared with healthy volunteers.

Blood Flow Tests

Tests to determine hepatic blood flow are also useful. Xylocaine metabolism also evaluates hepatic blood flow [35]. The use of ICG has also been described for this purpose. The use of intravenous infusions of ICG seemed more reliable and accurate in evaluation of hepatic blood flow than with the use of boluses or intravenous injections of galactose [59]. Apparently with the use of boluses, extrahepatic accumulation of the dye occurs and alters the results [60]. More recently, pulse dye-densitometry (PDD) has been used in the critically ill patient instead of blood tests. Mizushima et al. [61] measured effective hepatic blood volume (EHBV) and cardiac output (CO) using ICG-PDD [61]. They found that in septic patients, the EHBF/CO ratio was lower than that of nonseptic patients, suggesting that inadequate splanchnic perfusion or metabolic changes occur in septic patients. In addition, the lower EHBF/CO ratio was related to a fatal outcome in septic patients. The authors concluded that PDD could be a clinically useful method of assessing splanchnic conditions in critically ill patients. Dysfunction in one of the components of the gastrointestinal system, in this case the liver, manifested by decreased metabolic [35–37] capacities or hepatic blood flow [36,61] are related to shock states and are probably an integral part of the multiorgan system failure (MOSF) cascade, highlighting the relationship of the gastrointestinal system with immunity.

Tests of Cholestasis

In patients with conjugated hyperbilirubinemia but without other indicators of liver dysfunction or injury, biliary obstruction should be suspected. Alkaline phosphatase (AP), like SGOT and SGPT, is found in a variety of different organs, but has its highest concentration in the liver. As such, it is most often elevated in situations where cholestasis is present. AP is more specific than gamma glutamyl transpeptidase (GTT) for biliary tree inflammation, as GGT is sensitive to even mild liver inflammation and/or activation of the cytochrome P-450 enzymes.

Further workup may include radiological evaluation. Hepatic iminodiacetic acid (HIDA) scan may also prove valuable in differentiating the cause of cholestasis. The test reveals many facets of hepatic function with respect to its ability to conjugate bile: If the liver does not actively uptake tracer, than its ability to conjugate bile must be questioned. In addition, when conjugation is not an issue, definitive anatomic localization of biliary obstruction is possible. In addition, in the presence of a functional sphincter of Oddi, it is possible to diagnose acute cholecystitis. Further assessment of biliary architecture can be made with ultrasonography. Not only can one determine the architecture of the liver and gallbladder, but one can also determine the amount of intra- and extrahepatic biliary dilatation, further delineating the source of biliary obstruction.

CONCLUSIONS

Gastrointestinal function is of vital importance in the critically ill patient. These functions are not limited to the mere absorption of nutrients but are closely related with the immune system, particularly in the critically ill patient. Despite its importance, monitoring of intestinal function is limited, providing anatomic and physiologic information rather than an assessment of pathophysiologic change. Assessment of absorption by sugar absorption tests and breath tests, of motility by manometry, and of ischemia by tonometry and microdialysis are promising modalities that may help monitor the functions of the gastrointestinal tract.

CHAPTER 31 ■ RESPIRATORY MONITORING DURING MECHANICAL VENTILATION

TODD W. SARGE, RAY RITZ AND DANIEL TALMOR

Respiratory function may be simply classified into ventilation and oxygenation, where ventilation and oxygenation are quantified by the ability of the respiratory system to eliminate carbon dioxide and form oxyhemoglobin, respectively. The goal of respiratory monitoring in any setting is to allow the clinician to ascertain the status of the patient's ventilation and oxygenation. The clinician must then use the data appropriately to correct the patient's abnormal respiratory physiology. As with all data, it is imperative to remember that interpretation and appropriate intervention are still the onus of the clinician, who must integrate these data with other pieces of information (i.e., history and physical examination) to make a final intervention. In the acutely ill patient, the principal intervention with regard to respiratory function and monitoring usually involves the initiation, modification, or withdrawal of mechanical ventilatory support. This chapter focuses on respiratory monitoring for the mechanically ventilated patient.

Mechanical ventilation entails the unloading of the respiratory system by the application of positive pressure to achieve the goal of lung insufflation (i.e., inspiration) followed by the release of pressure to allow deflation (i.e., expiration). These simplified goals of mechanical ventilation are achieved in spite of complex and dynamic interactions of mechanical pressure with the physical properties of the respiratory system, namely elastance (E_{rs}) and resistance (R_{rs}). Furthermore, the patient's neurologic and muscular conditions can also affect the goals of respiration, and they need to be monitored and evaluated as well. This chapter focuses on three specific areas in monitoring the mechanically ventilated patient: (a) the evaluation of gas exchange, (b) respiratory mechanics, and (c) respiratory neuromuscular function.

GAS EXCHANGE

Basic Physics of Gas Exchange

As mentioned earlier, the primary function of the respiratory system is gas exchange (i.e., elimination of carbon dioxide while instilling oxygen to form oxyhemoglobin). Inadequate ventilation and oxygenation within the intensive care setting are typically caused by hypoventilation, diffusion impairment, or shunt and ventilation–perfusion (V–Q) mismatch.

Hypoventilation is defined as inadequate alveolar ventilation, and it is commonly caused by drugs, neurologic impairment, or muscle weakness/fatigue, which results in hypercarbia, according to the following equation:

$$P_aCO_2 = (\dot{V}_{CO_2} / V_A)k$$

where P_aCO_2 is the arterial partial pressure of carbon dioxide, $\dot{V}_{CO_2}$ the production of carbon dioxide in the tissues, $\dot{V}_A$ the alveolar ventilation, and k the constant. Fortunately, the institution of mechanical ventilatory support readily corrects hypoventilation while the underlying cause is determined and corrected.

Diffusion impairment is a result of inadequate time for the exchange of oxygen across the capillary–alveolar membrane. This may occur due to pathologic thickening of the membrane or high-output cardiac states such as sepsis. However, the relative clinical significance of diffusion impairment in the intensive care unit (ICU) is debatable. This is because the hypoxemia that results from the acute exacerbation of diffusion impairment

is usually corrected by supplemental oxygen therapy. Furthermore, P_aCO_2 is rarely affected by diffusion impairments because it is highly soluble and is eliminated in multiple forms, such as bicarbonate.

The most common cause of hypoxemia in the ICU is ventilation–perfusion ($\dot{V}$–$\dot{Q}$) mismatch. One manifestation of $\dot{V}$–$\dot{Q}$ mismatch is shunting. The true shunt fraction is the amount of cardiac output that results in venous blood mixing with end-arterial blood without participating in gas exchange. This has little effect on carbon dioxide tension; however, increases in shunt can lead to hypoxemia. The true shunt is expressed by the shunt equation as follows:

$$Q_s/Q_t = (C_c - C_a)/(C_c - C_v)$$

where Q_s and Q_t are the shunt and total blood flows, and C_c, C_a, and C_v represent the oxygen contents of pulmonary end-capillary, arterial, and mixed venous blood, respectively. The absolute oxygen content of arterial and mixed venous blood is calculated according to the oxygen content equation:

$$C_x = (1.34 \times Hb \times S_xO_2) + (P_xO_2 \times 0.003)$$

where C_x, S_xO_2, and P_xO_2 are the oxygen content, saturation, and partial pressure of oxygen within arterial and mixed venous blood, respectively. The oxygen content of end-capillary blood is estimated by the alveolar gas equation as follows:

$$C_c = (P_{atm} - P_{H_2O}) \times F_iO_2 + P_aCO_2/RQ$$

where P_{atm} and P_{H_2O} are the partial pressures of the atmosphere and water (typically 760 and 47 at sea level), respectively; while F_iO_2 is the concentration of inspired oxygen; P_aCO_2 the arterial partial pressure of carbon dioxide; and RQ the respiratory quotient. The significance of true shunt is the fact that it is not amenable to supplemental oxygen therapy. Shunted blood reenters the circulation and dilutes oxygenated blood, resulting in a lower partial pressure of oxygen (P_aO_2) in the arterial system. Increasing the F_iO_2 will not improve oxygenation since the shunted fraction of blood does not meet alveolar gas.

V–Q mismatch is the result of inequality of the normal ventilation/perfusion ratio within the lung. V–Q mismatch is a spectrum of abnormal ratios signifying inadequate gas exchange at the alveolar level. It is possible with supplemental oxygen to overcome hypoxemia that is caused by an abnormal ratio of ventilation and perfusion, which differentiates this form of hypoxemia from true shunt. However, in the extreme, as the V–Q ratio in any alveolus approaches zero (i.e., ventilation approaches zero), it approaches true shunt as described above. At the other end of the spectrum, as the ratio in any alveolus approaches infinity (i.e., as perfusion approaches zero), it becomes physiologic "dead space," which denotes alveoli that are ventilated but not perfused. Dead space is described in greater detail later in this chapter.

Direct Blood Gas Analysis

Monitors of gas exchange in the mechanically ventilated patient are typically directed at measurements of gas content and their gradients from the ventilator circuit to the alveolus and from the alveolus to the end-artery. As with most monitors, sources of error abound at many points as gases flow down their concentration gradients. The most accurate assessment of gas exchange is direct measurement from an arterial blood sample. This provides the partial pressures of carbon dioxide (P_aCO_2) and oxygen (P_aO_2) in the blood as well as the pH, base deficit, and co-oximetry of other substances such as carboxyhemoglobin and methemoglobin. Advantages of arterial blood gas (ABG) analysis include the fact that it is a fairly exact representation of the current state of the patient with regard to acid–base status, oxygenation, and ventilation. However, the limitations of blood gas analysis as a tool for monitoring gas exchange are numerous, including the fact that it is invasive, wasteful (blood), and noncontinuous (i.e., it is only a snapshot of the patient's condition at the time the ABG is drawn).

Central and peripheral venous blood gas sampling has been proposed as an acceptable surrogate to arterial blood for monitoring pH, P_aCO_2, and base deficit [1]. The obvious advantage is mitigation of the invasiveness (i.e., patients are not required to have arterial access or punctures), while the disadvantages are the need for correlation and inability to assess oxygenation. With the exception of patient's undergoing cardiopulmonary resuscitation [2], good correlation has been observed between arterial and venous pH and P_aCO_2 in patients with acute respiratory disease, with one study noting an average difference of 0.03 for pH and 5.8 for P_aCO_2 [1]. Another study in mechanically ventilated trauma patients also demonstrated good correlation between arterial and central venous pH, P_aCO_2, and base deficit; however, the authors concluded that the limits of agreement (−0.09 to 0.03 for pH and −2.2 to 10.9 for P_aCO_2) represented clinically significant ranges that could affect management and therefore should not be used in initial resuscitation efforts of trauma patients [3].

Pulse Oximetry

Without question, pulse oximetry has been the most significant advance in respiratory monitoring in the past three decades. On the basis of established oxyhemoglobin dissociation curve (Fig. 31.1), pulse oximetry allows for the continuous, noninvasive estimate of a patient's oxyhemoglobin and is expressed as a percentage of total hemoglobin. A detailed explanation of pulse oximetry including the physics and limitations is provided in Chapter 26.

Expired Carbon Dioxide Measurements

Capnometry is the quantification of the carbon dioxide concentration in a sample of gas. Capnography is the continuous

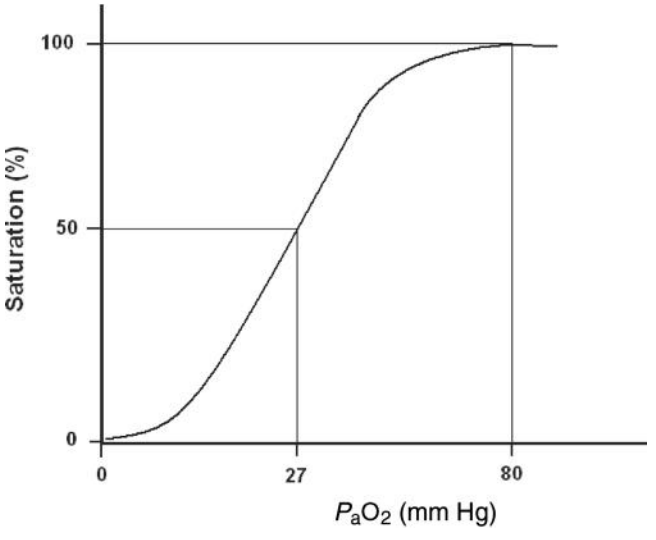

FIGURE 31.1. This is a schematic demonstrating a normal hemoglobin dissociation curve with 50% saturation at P_aO_2 of 27 mm Hg and approaching 100% saturation at a P_aO_2 of 80 mm Hg.

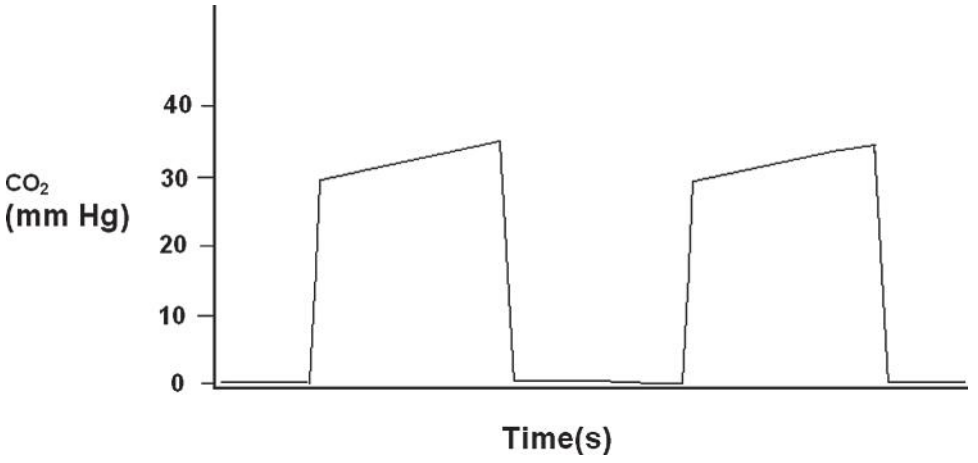

FIGURE 31.2. This is a schematic representation of a capnograph waveform with the expiratory plateau delineating the end-tidal CO_2 between 30 and 40 mm Hg.

plotting of carbon dioxide over time to create a waveform (Fig. 31.2). When capnography is performed on continuous samples of gas from the airway circuit, a waveform is created whereby the plateau is reported as the maximum pressure in millimeters Hg and termed end-tidal carbon dioxide, or $P_{et}CO_2$. Although continuous capnography has limited usefulness in the ICU, capnometry has many clinical uses such as early detection of esophageal intubation. For a detailed explanation of capnography and its uses, please refer to Chapter 26.

Dead Space Measurements

Dead space is defined as any space in the respiratory system that is ventilated but not perfused, such that no gas exchange can occur. Measurement of dead space is a marker of respiratory efficiency with regard to carbon dioxide elimination. Dead space can be subdivided into several categories including alveolar and anatomic. Anatomic dead space is the sum of the inspiratory volume that does not reach the alveoli and, therefore, participate in gas exchange. For mechanically ventilated patients, the anatomic dead space includes the proximal airways, trachea, endotracheal tube, and breathing circuit up to the Y-adapter. In normal human subjects, anatomic dead space in cubic centimeters is approximately two to three times the ideal body weight in kilograms, or 150 to 200 cm^3. Alveolar dead space is the conceptual sum of all alveoli that are ventilated but not participating in gas exchange, otherwise described as "West Zone 1" [4]. Physiologic dead space (V_d) is the sum of anatomic and alveolar dead space and is usually expressed as a ratio of the total tidal volume (V_t) and can be calculated at the bedside using the modified Bohr equation:

$$V_d/V_t = P_aCO_2 - P_{exp}CO_2/P_aCO_2$$

where P_aCO_2 is the partial pressure of carbon dioxide and $P_{exp}CO_2$ the partial pressure of carbon dioxide in the expired tidal volume of gas. The $P_{exp}CO_2$ is difficult to measure, often requiring metabolic monitoring systems. However, v*olume capnography* is a novel and simple approach to estimating $P_{exp}CO_2$, involving measurements of carbon dioxide at the Y-adapter, and has been shown to correlate with more complex methods of metabolic monitoring [5]. The P_aCO_2 is often estimated as end-tidal carbon dioxide, $P_{et}CO_2$, however this is known to be inaccurate in disease states. Therefore, determination of the P_aCO_2 is most often measured directly by an ABG.

Physiologic dead space, V_d/V_t, is often increased in critical illnesses that cause respiratory failure, such as acute respiratory distress syndrome (ARDS) and chronic obstructive pulmonary disease (COPD). V_d/V_t can also increase with dynamic hyperinflation or auto-PEEP, as well as with overaggressive application of extrinsic positive end-expiratory pressure (PEEP) due to overinflation of alveoli impeding pulmonary artery blood flow—effectively increasing the West Zone 1 volume. Serial measurements of V_d/V_t have been shown to correlate with outcome in ARDS [6] and have been used to monitor the degree of respiratory compromise in critically ill patients [7]. However, these data have not translated into changes in treatment. Furthermore, Mohr et al. [8] found no appreciable difference in V_d/V_t while studying a series of posttracheostomy patients successfully weaned from mechanical ventilation compared with those who had failed weaning.

PULMONARY MECHANICS

Basic Pulmonary Variables

Modern ventilators allow manipulation and measurement of the airway pressures (P_{aw}), including peak, plateau, mean and end-expiratory; volumes (V); and flows ($\dot{V}$). Integration of these measurements allows assessment of the mechanical components of the respiratory system. The mechanical components are influenced by various disease states, and understanding these relationships may allow delivery of more appropriate ventilator support. The airway pressure (P_{aw}) is described by the equation of motion and must be equal to all opposing forces. For the relaxed respiratory system ventilating at normal frequencies, the major forces that oppose P_{aw} are the elastive and resistive properties of the respiratory system as they relate to the tidal volume (V_t) and flow ($\dot{V}$), respectively:

$$P_{aw} = E_{rs}\, V_t + R_{rs}(\dot{V})$$

where E_{rs} and R_{rs} are the elastance and resistance of the respiratory system, respectively.

Constant flow inflation in a relaxed, ventilator-dependent patient produces a typical picture as depicted in Figure 31.3 [9]. The rapid airway occlusion method at end inflation results in zero flow and a drop in P_{aw} from the peak value (peak inspiratory pressure, PIP) to a lower initial value and then a gradual decrease over the rest of the inspiratory period until a plateau pressure (P_{plat}) is observed. The P_{plat} measured at the airway represents the static end-inspiratory recoil of the entire respiratory system [10].

Measurement of the pleural pressures would allow further partitioning of these pressures into the lung (i.e., transpulmonary pressure, P_L) and chest wall (i.e., pleural pressure, P_{pl})

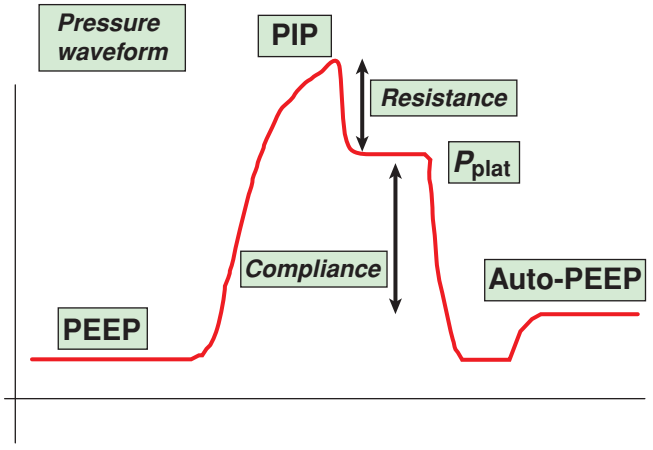

FIGURE 31.3. Schematic drawing of an airway pressure waveform delineating PEEP, auto-PEEP, peak inspiratory pressure (PIP), plateau pressure (P_{plat}), resistance, and compliance.

components using the equation:

$$P_{aw} = P_L + P_{pl}$$

Unfortunately, direct measurements of pleural pressure are not practical in the intensive care setting. Therefore, pleural pressures have often been estimated by esophageal balloon catheters measuring the pressure in the esophagus (P_{es}), which lies in the proximity of the pleura at mid-lung height. This alters the earlier equation as follows:

$$P_{aw} = P_L + P_{es}$$

where P_{es} is esophageal pressure.

These partitioned pressures are presented graphically in Figure 31.4.

Compliance and Elastance

The static compliance ($C_{st,rs}$) of the respiratory system and its reciprocal, elastance ($E_{st,rs}$), are easily measured at the bedside using the aforementioned end-inspiratory airway occlusion method to produce zero flow and thus negate the resistive forces within the system. The elastance of the respiratory system ($E_{st,rs}$) is simply the pressure gradient between the total PEEP ($PEEP_t$) and the plateau pressure (P_{plat}) divided by the tidal volume (V_t) to yield the following equation:

$$E_{st,rs} = (P_{plat} - PEEP_t)/V_t$$

$E_{st,rs}$ may also be separated into its lung (E_L) and chest wall (E_{cw}) components by applying this equation to the P_L and P_{es} tracings obtained using P_{es} tracings (see Fig. 31.4) and by the equation:

$$E_{st,rs} = E_L + E_{cw}$$

The relative contributions of the lung and chest wall to the total elastance may be dependent on the etiology of respiratory failure. By way of example, pulmonary edema, either cardiogenic or as a result of ARDS, will lead to an elevated lung E_{st} and reduced compliance. ARDS of a nonpulmonary origin, for example, sepsis, may also lead to edema of the chest wall and abdominal distension. Both of these will lead to an additional increase in the $E_{st,rs}$ as a result of an increase in the elastance of the chest wall.

Resistance

According to Ohm's law, resistance is a function of the airway pressure gradient (ΔP_{aw}) divided by flow ($\dot{V}$). Airway resistance can be measured in ventilator-dependent patients by using the technique of rapid airway occlusion during constant flow

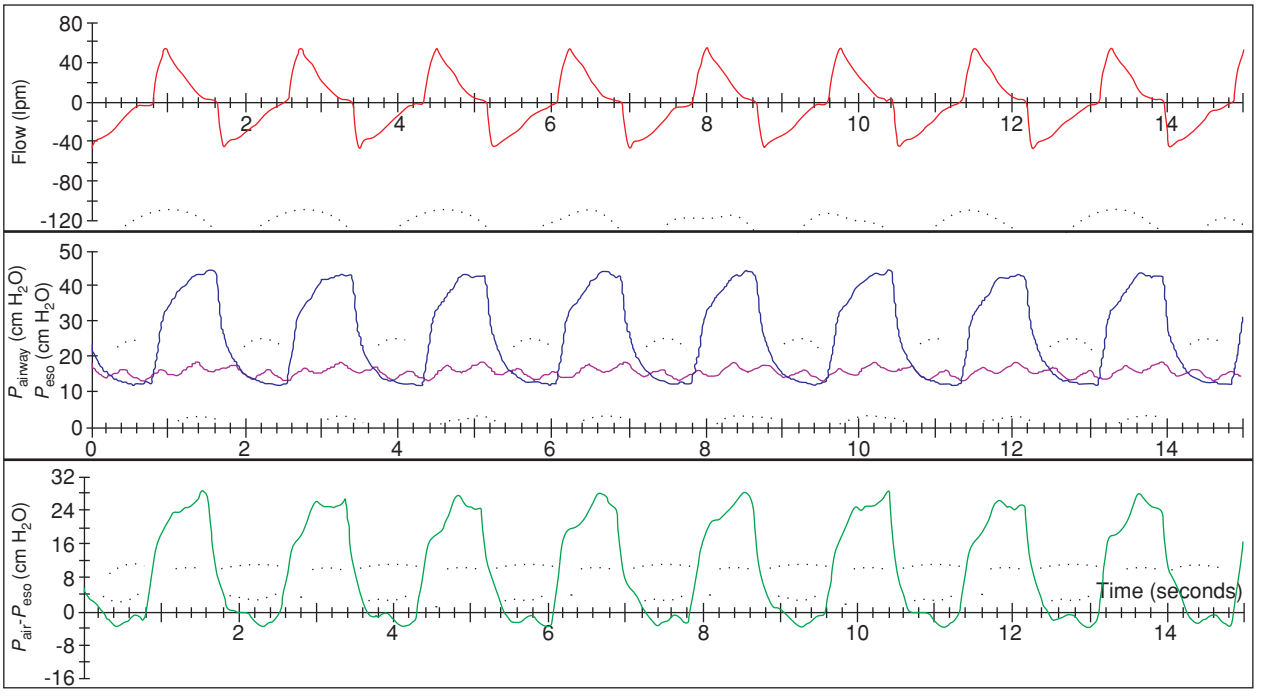

FIGURE 31.4. Esophageal pressure tracing (P_{eso}) can be seen superimposed on the airway pressure tracing (P_{air}) during pressure control ventilation (PCV). Transpulmonary pressure has been estimated as the difference between these pressures with specific assumptions.

inflation. The maximum resistance (R_{max}) of the respiratory system is calculated by

$$R_{max} = [P_{peak} - P_{plat}]/\dot{V}$$

And the minimum resistance (R_{min}) of the respiratory system can be computed by dividing

$$R_{min} = [P_{peak} - PEEP_t]/\dot{V}$$

R_{min} reflects ohmic airway resistance, while the difference between R_{max} and R_{min} (ΔR) reflects both the viscoelastic properties (stress relaxation) and the time–constant variability within the respiratory tissues (*pendelluft effect*).

Pressure–Volume Curves

Static Measurements of the Pressure–Volume Curve

The gold standard of pressure–volume (P–V) curve measurement is the super-syringe method. Using a large calibrated syringe, increments of volume of 50 ± 100 mL gas are used to inflate the lung up to a total volume of 1,000 ± 2,000 mL. After each increment, the static airway pressure is measured during a pause lasting a few seconds during which there is no flow, and the pressure is the same in the entire system from the super-syringe to the alveoli. The lung is then deflated in the same manner and the pressure at each decrement of gas is recorded and the inspiratory and expiratory P–V curves are plotted. Continued oxygen uptake from the blood during this slow inflation–deflation cycle, coupled with equalization of the partial pressure of CO_2 in the blood and alveoli, will lead to a decrease in the deflation volume as compared with the inflation volume of gas. This artifact may appear to contribute to the phenomena of hysteresis. The more important mechanical cause of hysteresis is based on the slow inflation of the lung during the P–V curve maneuver. This slow inflation recruits or opens up areas of the lung with slow time constants and collapsed alveoli. This again will lead to a decreased expiratory volume and hysteresis.

Semistatic Measurements of the Pressure–Volume Curve

There are two methods for obtaining semistatic measurements of the P–V curve. These methods do not require the specialized skill and equipment needed for the super-syringe technique. The *multiple occlusion technique* uses a sequence of different-sized volume-controlled inflations with an end-inspiratory pauses [11,12]. Pressure and volume are plotted for each end-inspiratory pause to form a static P–V curve. If expiratory interruptions are also done, the deflation limb of the P–V curve may also be plotted. This process may take several minutes to complete, but yields results close to those obtained by static measurements. The second method is the *low-flow inflation technique*. This technique uses a very small constant inspiratory flow to generate a large total volume. The slope (compliance) of the curve is parallel with a static P–V curve only if airway resistance is constant throughout the inspiration. This is likely not the case as the low flow lessens airway resistance. The low flow also causes a minimal but recognizable pressure decrease over the endotracheal tube, which means that the dynamic inspiratory pressure–volume curve will be shifted to the right [13,14]. The long duration of the inspiration produces the same artifacts as the super-syringe technique, which is represented as hysteresis. Another drawback of static and semistatic methods is that they require stopping therapeutic ventilation while the maneuver is performed. The question has been raised, therefore, if these maneuvers are relevant in predicting the mechanical behavior of the lung under dynamic conditions, where resistance and compliance depend on volume, flow, and respiratory frequency.

Dynamic Measurements of the Pressure–Volume Curve

Dynamic measurement of the P–V curve allows continuous monitoring of the respiratory mechanics and in particular of the response to ventilator changes. These measurements are done with the patient on therapeutic ventilator settings and therefore may reflect more accurately the complex interaction of patient, endotracheal tube, and ventilator. A continuous display of pressure may be obtained either proximal to the endotracheal tube (at the patient connector or from the ventilator itself) or distal to the endotracheal tube. This pressure may then be plotted against tidal volume to produce a dynamic P–V curve. Each of these methods has advantages; however, the more commonly used proximal method suffers from the disadvantage of being heavily influenced by the resistance of the endotracheal tube. Neither the peak pressure nor the end-expiratory pressures are accurately recorded, and this will lead to an underestimation of compliance [12].

Clinical Use of the Pressure–Volume Curve

There is a characteristic shape to the static respiratory system P–V curve of patients with injured lungs. This shape includes an S-shaped inflation curve with an upper and lower inflection point (UIP and LIP, respectively; Fig. 31.5), an increased recoil pressure at all lung volumes, and reduced compliance (Fig. 31.6), which is seen in the slope of the inflation curve between LIP and UIP. The LIP has often been considered the critical opening pressure of collapsed lung units and has been used as a method of setting the optimal PEEP in patients with acute lung injury (ALI). The pressure at UIP, in turn, was considered to indicate alveolar overdistension that should not be exceeded during mechanical ventilation [15]. These ideas have been challenged for multiple reasons. Accurate identification of the LIP and UIP is challenging even for experienced clinicians [16]. In addition, changes in the P–V curve are not specific for alveolar collapse and have been observed in saline-filled lungs, such as would be seen in patients with pulmonary edema [17,18]. When applied clinically to patients mechanically ventilated with ARDS, Amato et al. [19] demonstrated that use of the P–V curve and titration of PEEP to a level that exceeds the LIP may be part of a successful lung-protective strategy. It is unclear from this study, however, what the relative importance of the higher levels of PEEP was in the context of the ventilatory strategy, which included delivery of low tidal volumes and the use of intermittent recruitment maneuvers. Subsequent trials have confirmed the survival benefit in patients ventilated using low tidal volumes but not in those ventilated with a higher level of PEEP [20,21].

Separating the Lung and Chest Wall Components of Respiratory Mechanics

Esophageal Pressure Monitoring

Ventilator-induced damage to the lungs arguably depends on the transpulmonary pressure ($P_{aw} - P_{pl}$), whereas current recommendations for management of ARDS specify limits for pressure applied across the whole respiratory system and are based on pressures measured at the airway. This approach could be seriously misleading if P_{pl} were to vary substantially among patients. In healthy subjects and upright spontaneously breathing patients, P_{pl} is often estimated by measuring esophageal pressure (P_{es}); however, this is rarely done in patients with acute injury, possibly because of a widespread, but

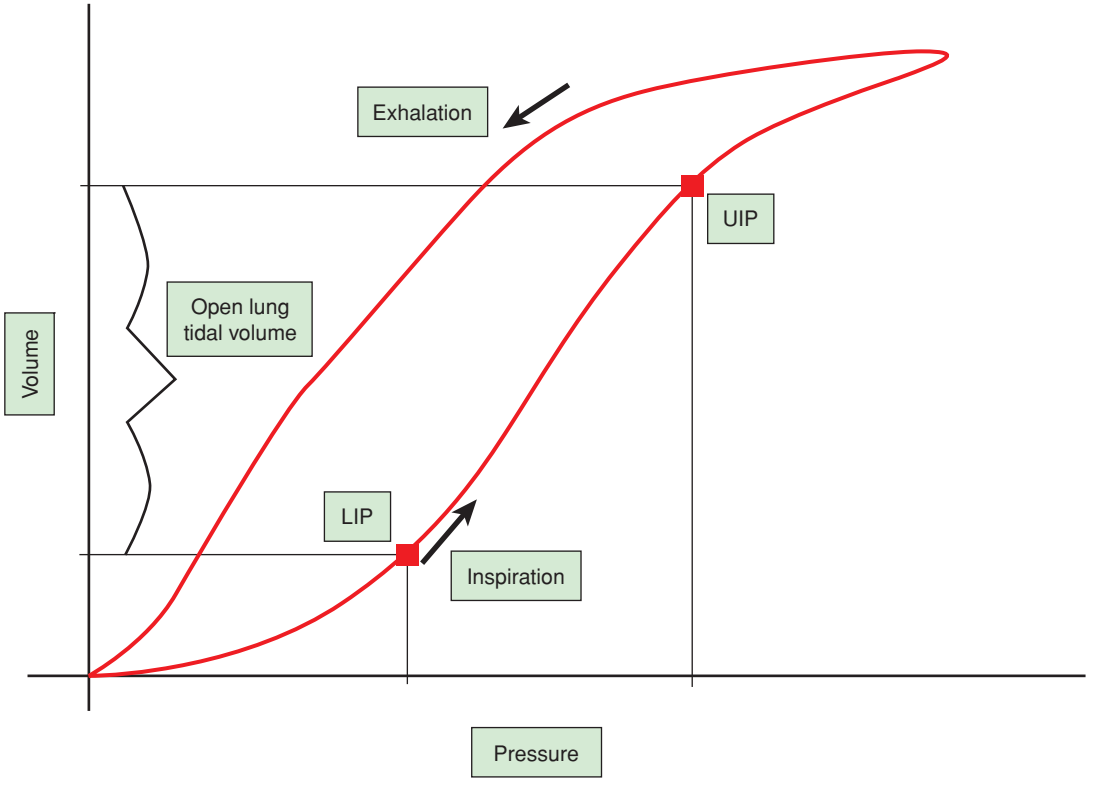

FIGURE 31.5. Schematic representation of normal pressure–volume curve (PV curve) with upper and lower inflection points (UIP and LIP, respectively) delineating the more compliant portion of the inspiratory limb and corresponding tidal volume that has been proposed as an "open lung" approach to ventilation in ARDS.

untested, belief that artifacts make P_{es} unreliable as an estimate of P_{pl} [22]. However, in a lung-injured canine model, Pelosi et al. [23] demonstrated good correlation at mid-lung height between an esophageal balloon catheter measuring the pressures in the esophagus (P_{es}) and the pleural pressures measured by pressure-transducing wafers inserted directly in the thorax. Although the absolute values of the esophageal pressures were not identical with the pleural pressures, Pelosi noted the excursions of esophageal pressure were the same as those observed in the directly measured pleural pressures. The authors therefore concluded that the changes in esophageal pressures were accurate, but the absolute values were not [23]. Others have postulated the explicit assumption that absolute values of P_{es}, corrected for a positional artifact, may reliably reflect an effective P_{pl} in critically ill patients [24].

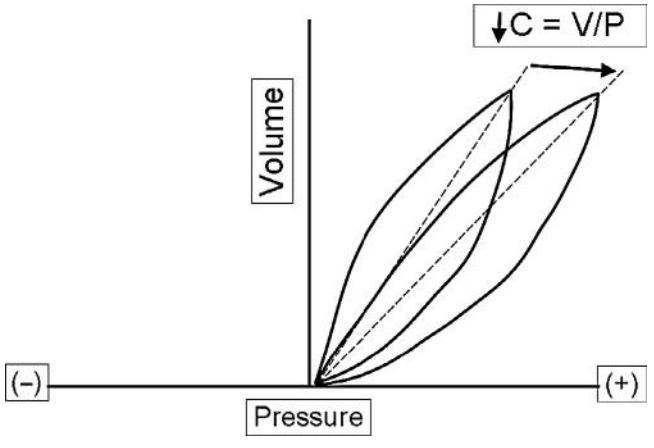

FIGURE 31.6. Schematic representation of altered compliance (C) and the effect on the volume–pressure (V/P) curve as occurs with pulmonary edema.

Variations in P_{pl} may have contributed to inconsistent outcomes among clinical trials of ventilation strategies in ARDS. Although one large-scale randomized trial demonstrated a survival benefit from use of low tidal volume ventilation, results from other studies have been equivocal [20,25,26]. It is possible that in some patients with high P_{pl}, low tidal volume ventilation coupled with inadequate levels of PEEP results in cyclic alveolar collapse at end-expiration. In such cases, resulting atelectrauma might negate the benefit of limiting tidal volume. Similarly, higher levels of PEEP have been shown to be lung protective in numerous animal models of ARDS but have demonstrated inconsistent benefit in clinical investigations [19,21]. This too may reflect failure to account for P_{pl}, leading to under- or overapplication of PEEP in some patients as well as misinterpretation of high-plateau airway pressures as evidence of lung overdistension [27,28]. Measuring P_{es} to estimate transpulmonary pressure may allow mechanical ventilator settings to be individualized to accommodate variations in lung and chest wall mechanical characteristics. Such an individual approach may reduce the risk of further lung injury in ARDS [22,27,29]. This was the hypothesis of a recent single-center, randomized control trial (EPVENT Trial) of 61 patients by Talmor et al. in which ARDS and ALI patients with low tidal lung-protective ventilation were randomized to a high or low PEEP. Unique when compared with prior trials, the intervention group received PEEP based on the contribution of the chest wall as measured by esophageal pressure manometry. The control group received PEEP based on the PEEP/F_iO_2 tables from earlier trials that were created from expert opinion

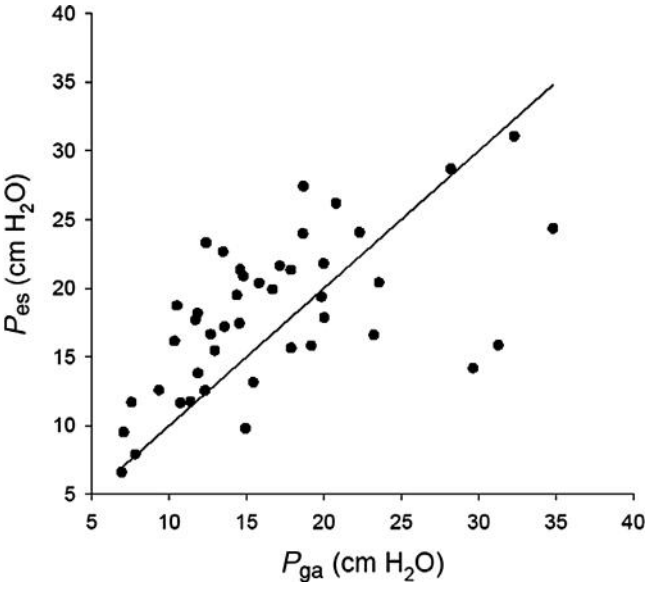

FIGURE 31.7. This graph demonstrates the correlation between pressures measured in the esophagus (P_{es}) and gastric pressure (P_{ga}).

and without individualization based on physiologic measurements. The primary end point was oxygenation (P_aO_2/F_iO_2). The authors demonstrated that ventilation with a strategy that used esophageal pressures measurements to determine PEEP settings was superior as evidenced by improved oxygenation, compliance, and a trend toward improved mortality [30].

Gastric Pressure

Esophageal pressure monitoring is not a trivial task, requiring specialized equipment and experienced operators. Gastric pressure may provide a reasonable surrogate measure for P_{pl}. In an earlier study, Talmor et al. [24] have demonstrated that there is a correlation between pressure measured in the esophagus and gastric pressures (Fig. 31.7). This relationship may be particularly important in patients having ARDS with extrapulmonary causes, where abdominal distension may contribute significantly to alveolar collapse.

Bladder Pressure

An alternative measurement of intra-abdominal pressure may be obtained by measuring pressure in the urinary bladder [31]. Instilling 50 to 100 mL of sterile water through the Foley catheter, clamping the catheter, and measuring the resulting bladder pressure has been shown to correlate well with intra-abdominal pressure measured through a gastric tube [32]. These pressures have also been shown to correlate well with esophageal pressures [33]. Studies are still required to validate use of any of these measurements in the clinical care of patients with respiratory failure.

Respiratory Neuromuscular Function

During mechanical ventilation, the goal of the clinician is to unload the patient's failing respiratory system and thereby reduce the work of breathing in the setting of respiratory failure [34]. Obviously, this goal is temporary with the later goal of weaning mechanical ventilation once the patient begins to recover from his or her disease process. To accomplish these goals, the clinician needs to have an understanding of the patient's respiratory function, which impacts each of these goals differently. For example, complete unloading of the respiratory system is common in the surgical operating room with general anesthesia, muscle relaxants, and controlled mechanical ventilation. However, the use of deep sedation and muscle relaxants for prolonged periods in the ICU has deleterious effects on the latter goal of ultimately preparing critically ill patients for extubation with several studies demonstrating increases in ventilator days, hospital length of stay, and associated costs [35–37]. Furthermore, assisted modes of ventilation with partial unloading have been surmised as beneficial for maintaining the conditioning of the diaphragm and reducing sedation requirements in the critical care setting [34,38]. No one has defined the ideal degree of unloading [34], which would presumably vary by individual and disease state. Nevertheless, it is helpful to understand and quantify the patient's neuromuscular function to facilitate unloading of the respiratory system, minimize patient–ventilator dyssynchrony, and ultimately wean the difficult patient from ventilatory support. This requires an understanding of respiratory neuromuscular physiology and how it cooperates with the ventilator. This relationship has been termed *patient–ventilator interaction*.

Respiratory Neuromuscular Anatomy

The respiratory system is involuntarily controlled by specialized neurons in the pons and medulla oblongata that control both inspiration and expiration. These neurons in the brainstem coordinate many inputs and feedback loops to control respiration and ensure adequate gas exchange. The specific types of feedback can be mechanical, chemical, reflex, and behavioral, all of which directly affect the neurons rate and intensity of neural firing [39]. Together these neurons and their feedback loops constitute the respiratory control center. Under normal resting conditions, neurons in the inspiratory center stimulate contraction of the diaphragm and intercostal muscles through the phrenic and spinal nerves, which creates a negative force in the chest cavity relative to the airway (i.e., a pressure gradient), thus allowing air to flow into the lungs (Fig. 31.8). Subsequent exhalation is typically passive, and air is exhaled as a consequence of lung and chest wall elastance. However, when the respiratory center is stimulated in the presence of carbon dioxide, acidosis, or hypoxemia, exhalation can be made more active by contraction of abdominal and chest wall muscles. The cerebral cortex has the ability to take control of the respiratory system by overriding the brainstem to change the frequency, depth, and rhythm of respirations. This is of minimal concern in the mechanically ventilated patient, whose cerebral cortex is sedated, by either medications or illness, such that respiratory neuromuscular function is typically under the control of the brainstem as described earlier.

The muscular component of the respiratory system has been described as a pump that when stimulated creates a pressure, P_{mus} [39]. During assisted mechanical ventilation, this pressure can be added to a second pump, which is the airway pressure generated by the ventilator, P_{aw}. The sum of these two pressures, P_T, provides the total driving pressure for inspiratory flow [39]. Although neglecting inertia, the equation for motion in the respiratory system states that P_T is dissipated while overcoming the elastive and resistive properties of the lungs as follows:

$$P_T = P_{mus} + P_{aw} = (E_{rs} \times V_t) + (R_{rs} \times \dot{V}) \quad (1)$$

where the variables represent elastance (E_{rs}), tidal volume (V_t), resistance (R_{rs}), and flow ($\dot{V}$) in the respiratory system [39]. Since the ventilator-generated pressure, P_{aw}, is intended to unload the patient's respiratory muscles, it should be synchronous with the neural impulses generated by the respiratory center and thus P_{mus}. To be synchronous with the patient's neural

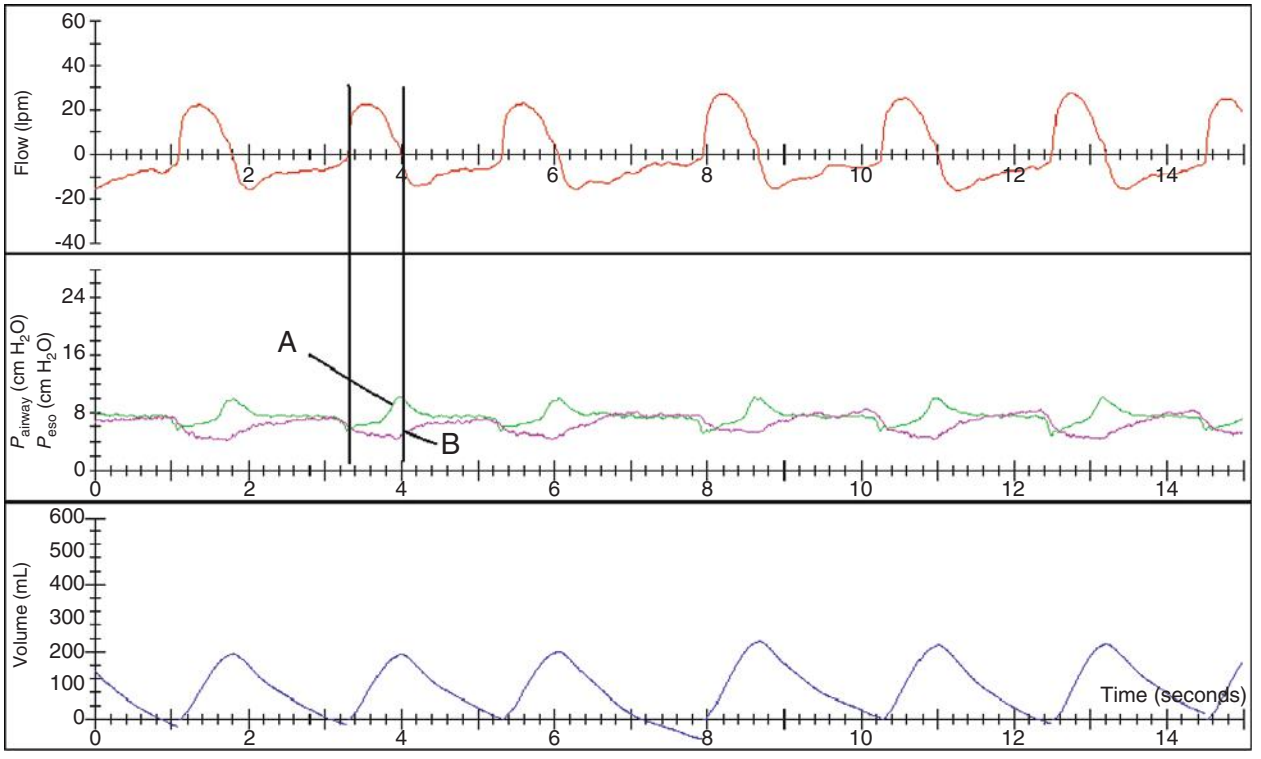

FIGURE 31.8. Spontaneous ventilation with continuous positive airway pressure (CPAP) at 7.5 mm Hg. Airway and esophageal pressure tracings are superimposed and marked as A and B, respectively. Note the onset of inspiration and flow, marked by the first vertical line, as esophageal (P_{eso}) and airway (P_{air}) pressures separate, creating a pressure gradient. Flow then ceases, as marked by the second vertical line, when the expiratory valve is opened on the ventilator and airway pressure quickly decreases.

inspiration, the ventilator would need to initiate support simultaneously with the patient's neural firing at the onset of inspiration, continue this support throughout the neural firing, and stop support at the end of neural firing. In reality, this goal is virtually impossible, as currently there is no practical monitor for efferent motor neurons of the respiratory system. Rather than monitoring neural impulses, modern ventilators sense changes in pressure and flow within the circuit in an effort to match the patient's respiratory cycle. The variables that we discuss regarding the patient–ventilator interaction include ventilator triggering, cycling-off, and delivery of gas between these two events (i.e., the posttrigger phase). However, it is essential to first define some of the measures of respiratory drive and effort that are commonly used to assess patient–ventilator interaction and weaning such as work of breathing, pressure–time product (PTP), airway occlusion pressure, maximal inspiratory force, vital capacity (VC), and rapid shallow breathing index (RSBI).

Work of Breathing

Patient respiratory effort is typically discussed and quantified via some measure of the patient's "work of breathing." *Work* is defined as the force acting on an object to cause displacement of that object. Therefore, mechanical work of breathing includes the measurement of a force required to create a change in volume of gas and is expressed in Joules per liter. However, measurements that are based on volume frequently fail to account for the work done by the diaphragm and respiratory muscles during isometric contraction against a closed valve [40], as occurs before triggering in some assisted modes of ventilation. The PTP, which measures swings in intrathoracic pressure by an esophageal pressure monitor and correlates with oxygen requirements of breathing, is considered superior for quantifying a patient's effort and degree of unloading [34]. This is a calculation of the difference in the time integrals between esophageal pressure, P_{es}, during assisted breathing and the recoil pressure of the chest wall during passive breathing at a similar tidal volume and flow [40].

Airway Occlusion Pressure

Airway occlusion pressure at 0.1 seconds ($P_{0.1}$) is an indicator of respiratory drive and is determined by measuring the pressure in the airway a tenth of a second after the onset of inspiration beginning at functional residual capacity (FRC). This has been shown to correlate well with work of breathing during pressure support ventilation [40]. Therefore, several authors have advocated its use as a potential predictor for discontinuation of mechanical ventilation [41–44]. The threshold value for $P_{0.1}$ of 6 cm H_2O appeared to delineate success versus failure in one such study, although this value was variable among authors. Although the utility of this measurement is still debated, it has been incorporated into several commercially available ventilators.

Maximal Inspiratory Force

Maximal inspiratory pressure (MIP), also known as negative inspiratory force, is another marker of respiratory muscle function and strength and is determined by measuring the maximum pressure that can be generated by the inspiratory muscles against an occluded airway beginning FRC. A normal value is

considered to be approximately 80 cm H_2O, with respiratory compromise typically observed at values less than 40% of normal. The major disadvantage and limitation of this measurement is the fact that it is extremely effort dependent, which can make interpretation difficult in severely ill, sedated, and neurologically impaired patients.

Vital Capacity

Vital capacity is the sum of tidal volume, inspiratory reserve volume, and expiratory reserve volume. Forced vital capacity (FVC) is measured by instructing a patient to inspire maximally to total lung capacity (TLC), followed by forced expiration while measuring the expired volume as the integral of the flow rate. FVC has also been used as an indicator of respiratory muscle function. However, similar to MIP, FVC is also effort dependent and therefore can lead to variable results. With limited success, it has been used to monitor trends in respiratory muscle strength in patients with neurologic impairment and muscle disorders such as cervical spine injury, myasthenia gravis, and Guillain-Barre [45–47].

Frequency/Tidal Volume Ratio

Respiratory distress is typically marked by tachypnea and decreased tidal volumes, leading to inadequate ventilation and increases in P_aCO_2 secondary to disproportionate ventilation of anatomic dead space and inadequate alveolar ventilation. Therefore, the ratio of frequency to tidal volume, also known as the RSBI, has been used to gauge respiratory distress and facilitate weaning and readiness for extubation [43,48–50]. As a criterion for extubation, the RSBI has had mixed success. Values of 100 to 105 breaths per minute per liter are typically used as a cutoff to predict extubation success from failure. The RSBI is limited by the fact that rapid and shallow breathing, although sensitive indicators of respiratory distress, are not specific. For example, pain and anxiety are also consistent with an abnormally high RSBI and are commonplace among critically ill patients weaning from mechanical ventilation.

PATIENT VENTILATOR INTERACTION

Ventilator–Triggering Variable

During assisted modes of ventilation, the patient's inspiratory effort is sensed by the ventilator, which is then "triggered" to deliver support at a preset volume or pressure (Fig. 31.9). There are two distinct methods of triggering the ventilator—pressure and flow. *Pressure triggering* depends on patient inspiratory effort, creating a change in pressure that exceeds a preset requirement (typically—2 cm H_2O) to open the inspiratory valve on the ventilator and initiate ventilator support. Likewise, *flow triggering* depends on patient inspiratory effort, creating flow detected by a flow meter within the inspiratory limb that exceeds a preset threshold (typically 2 L per minute) for triggering the ventilator support. The significant difference between these two triggering criteria is the presence of a closed demand valve in the inspiratory limb in pressure-triggered ventilators. In general, flow triggering has been considered superior to pressure-triggered algorithms in that it is believed that the

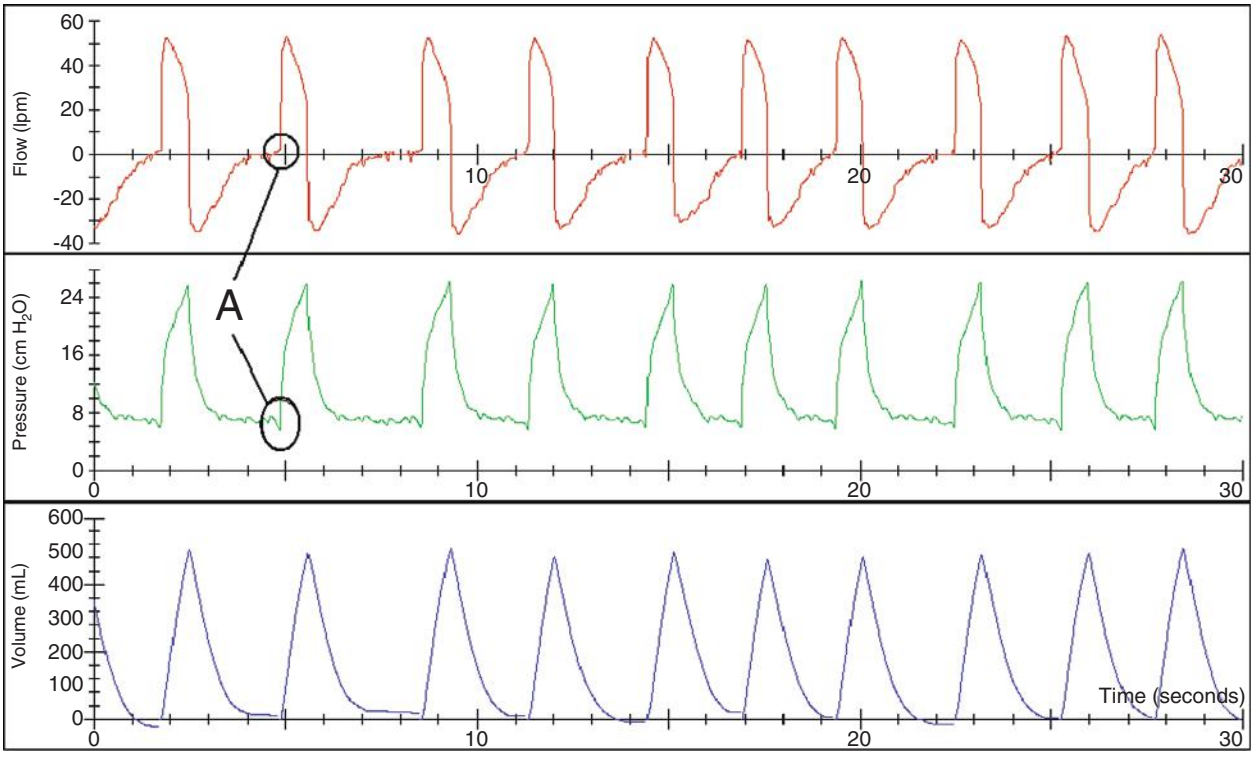

FIGURE 31.9. Normal triggering in assisted-control ventilation. The circles marked A denote the pressure and flow that correspond to patient neural inspiration that is detected by the ventilator and leads to delivery of a mechanical breath.

work of breathing is less in a system that does not require an initial inspiratory effort against this closed valve. Many studies have compared flow triggering and pressure triggering with respect to work of breathing with most showing significant advantages in favor of flow-triggered systems [51–53]. This is partially explained by the fact that flow-triggering results in improved responsiveness with shorter delay between onset of diaphragm contraction and ventilator triggering [53].

The main variable that can be controlled on the ventilator with regard to triggering is termed *sensitivity*. Typical values for pressure triggering are 1 to 2 cm H_2O, while those for flow triggering are 2 to 3 L per minute. The sensitivity threshold is important because it is required to strike a balance between two main problems associated with triggering. First, if the sensitivity is set too low, patients may experience autotriggering, in which pressure and flow changes that occur from sources of artifact such as cardiac oscillations, water in the circuit, patient movement, or resonance within the system lead to irregular breathing patterns and dyssynchrony. Second, sensitivity settings that are too high will lead to ineffective triggering, which has the consequences of increased and wasted work and energy (Fig. 31.10). Ineffective triggering is also common in the setting of dynamic hyperinflation, as seen in obstructive disorders such as asthma and COPD. In the setting of obstructive diseases, dynamic hyperinflation leads to elevations in the intrinsic PEEP ($PEEP_i$) above a critical threshold such that the patient's respiratory drive is insufficient to overcome the elastic recoil of the lung and chest wall and trigger the ventilator [34]. Clearly, this is also disadvantageous to the patient in terms of work of breathing and may contribute to ventilator dyssynchrony. Leung et al. [54] demonstrated that ineffective trigger attempts required 38% increases in patient effort as compared to successfully triggered breaths. Obviously, autotriggering and ineffective triggering can create a challenge to the clinician when attempting to optimize the ventilator settings. In general, it is helpful to reduce the trigger threshold to a point where the delay between neural firing and ventilator support is minimized without allowing autotriggering to occur.

Cycle-Off Variable

Neurons in the respiratory center continue firing beyond ventilator triggering and throughout inspiration. The cessation of firing is an important time point in the respiratory cycle and marks the beginning of expiration. The neural inspiratory time is often variable from breath to breath [34]. This can lead to considerable dyssynchrony in controlled modes of ventilation such as assisted-control, pressure-control, and intermittent mandatory ventilation, where "cycling-off" of the ventilator into expiration is a function of the inspiratory time (T_i) and is generally constant from one breath to the next. This can lead to increased sedation requirements that are inconsistent with the goal of ventilator weaning, as mentioned earlier. Ideally, the ventilator should be able to detect the end of neural firing and react accordingly to halt the inspiratory pressure supplied. This is one of the goals and advantages of the "supportive" modes of ventilation such as "pressure support ventilation." That is, supportive modes of ventilation have the ability to detect patient expiration and stop ventilator inspiration such that the T_i is variable. This can be accomplished by measuring flow or pressure changes within the circuit. As neural firing ceases and P_{mus} decreases to baseline with muscle relaxation, total pressure and thus flow should decrease according to the elastive and resistive properties of the lung according to the equation of motion previously described. Typically, support modes have

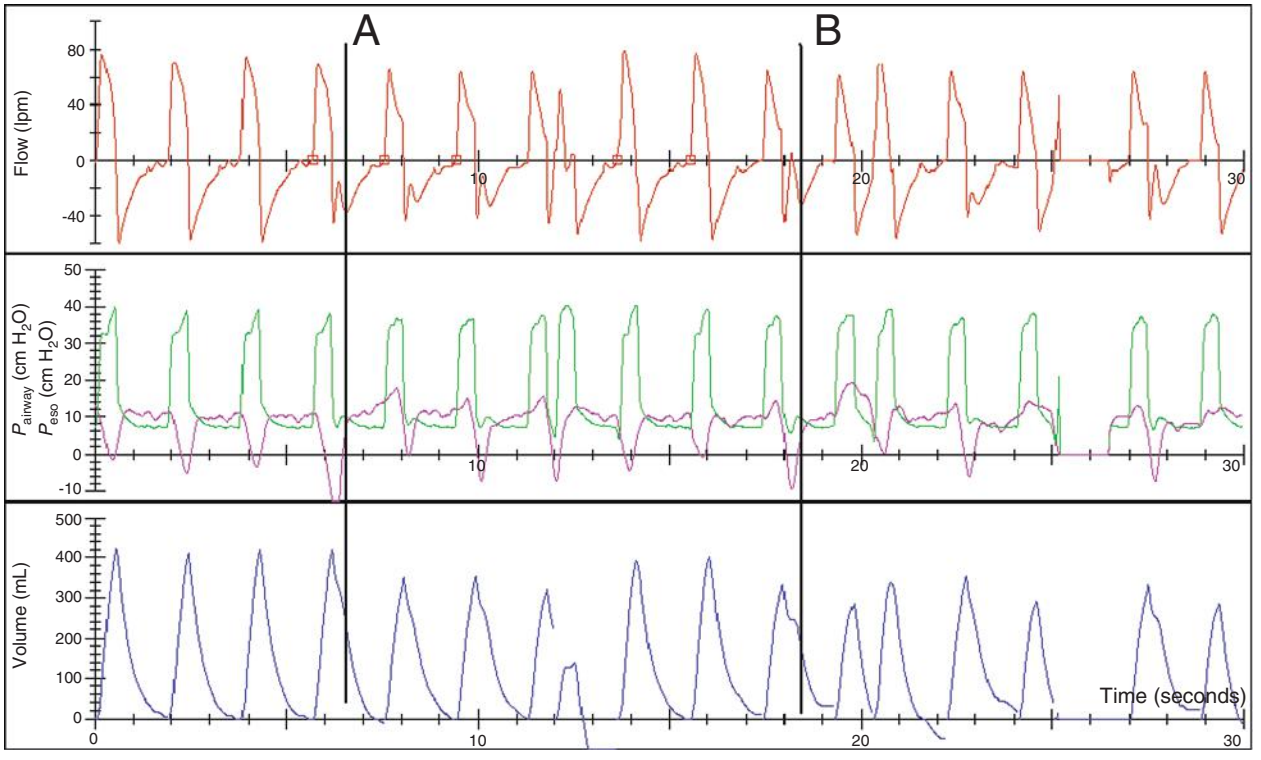

FIGURE 31.10. This pressure and flow tracing demonstrated failed trigger attempts that can be appreciated by the negative deflections in the expiratory limbs in the flow waveform and delineated by lines A and B.

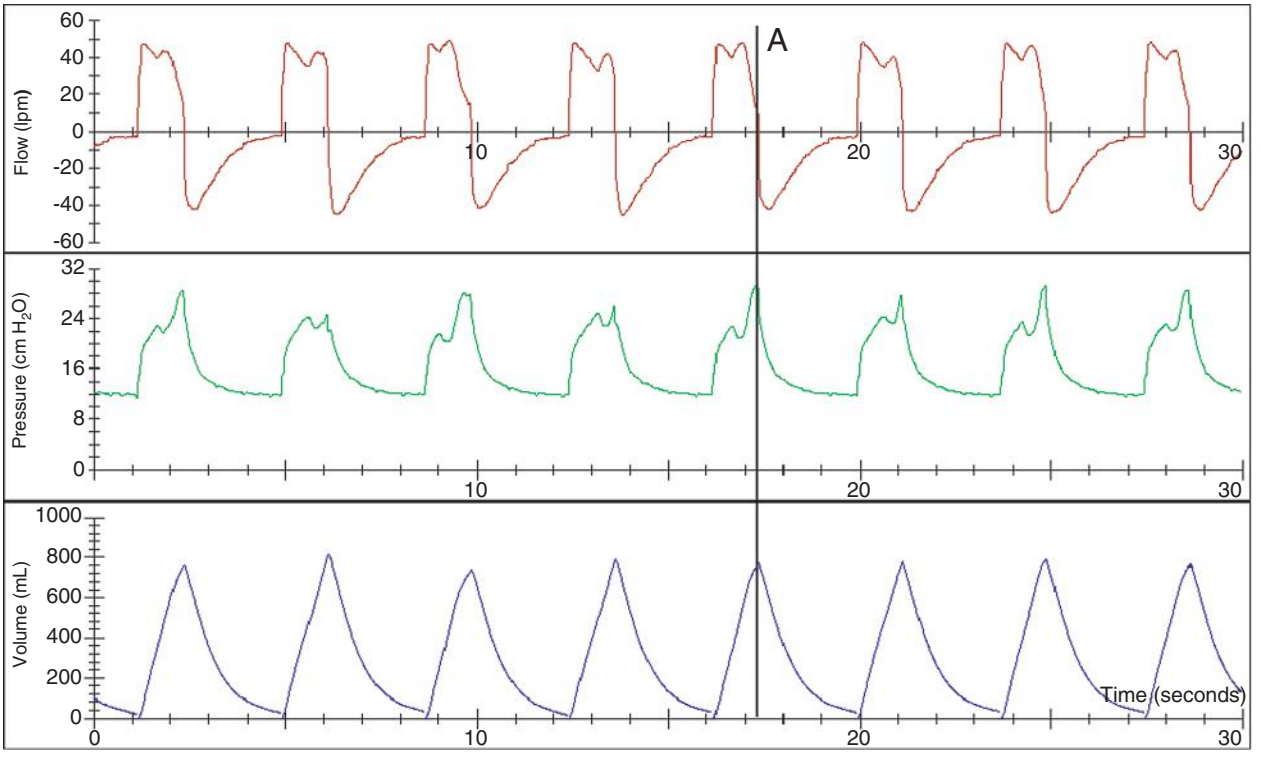

FIGURE 31.11. The pressure and flow waveforms demonstrate active recruitment of expiratory muscles to terminate ventilator inspiration. Note the time point marked by line A in which flow decreases rapidly corresponding to a sharp increase in the airway pressure due to active exhalation.

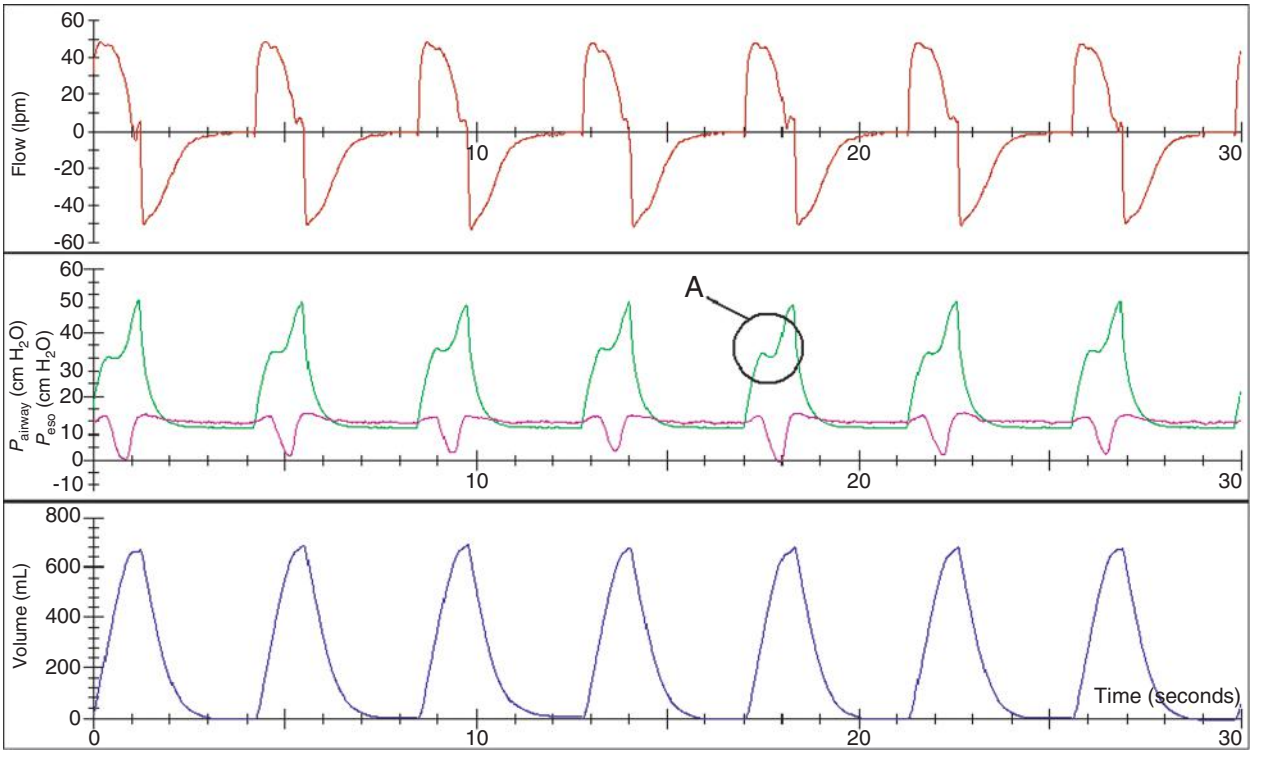

FIGURE 31.12. The pressure and flow waveforms above demonstrate the classic depressions on the inspiratory airway (P_{air}) pressure tracing in a patient with an elevated respiratory drive as highlighted by circle A. P_{eso}, esophageal pressure.

software that detects a preset decrement in flow, which in turn leads to cycling off the inspiratory support. This preset threshold can be an absolute value of flow or a percentage of maximum flow in the circuit, or both. Often, an increase in pressure that exceeds the programmed support level will also signal the ventilator to stop inspiration and open the expiratory valve as well.

Just as with triggering, the cycle-off variable can be a source of serious tribulations with the patient–ventilator interaction. For example, in the setting of decreased lung elastance, such as emphysematous lung disease, flow may not diminish enough to be detected properly despite a drop in P_{mus} at the end of neural inspiratory time. This can lead to patient discomfort and was studied by Jubran et al. [55], who noticed that 5 out of 12 patients with COPD required active exhalation to cycle off the ventilator during pressure support ventilation at 20 cm H_2O. Active exhalation is counterproductive to both the primary goal of respiratory muscle unloading and ventilator synchrony (Fig. 31.11). Furthermore, active exhalation will increase transpulmonary pressure, which can lead to premature airway closure and increased intrinsic $PEEP_i$ as closing capacity increases.

Inspiratory Flow Variable

Inspiratory flow is now being recognized as an important parameter in assisted modes of ventilation. Critically ill patients in acute respiratory failure often have elevated respiratory drives that appear to demand greater flow to overcome the resistance of the failing respiratory system and ventilator breathing circuit [34]. Classically, this appears as a depression on the inspiratory limb of the airway pressure tracing and has been described by some practitioners as "flow hunger" (Fig. 31.12). Clinically, the response has been to increase flow, which typically ranges between 30 and 80 L per minute during assisted modes of mechanical ventilation in an effort to decrease the work of breathing and intrinsic PEEP in these situations. However, a recent series of studies has shown that this may in fact be counterproductive due to a phenomenon now recognized as "flow-associated tachypnea" [34]. Puddy and Younes [56] demonstrated this phenomenon by adjusting inspiratory flow in awake volunteers breathing on a volume-cycled ventilator in assisted-control mode in which inspiratory T_i was variable. Laghi et al. [57] later delineated the contributions of flow, tidal volume, and inspiratory time in their study in which flow was increased from 60 to 90 L per minute and balanced with tidal volume settings of 1.0 and 1.5 L to maintain a constant inspiratory time, where frequency did not change. Furthermore, they were able to show that imposed ventilator inspiratory time during mechanical ventilation can determine frequency independently of delivered inspiratory flow and tidal volume. Therefore, the clinician must consider the counteracting variables of flow, tidal volume, and inspiratory time when attempting to ventilate patients with elevated respiratory drive in acute respiratory failure and how one may negatively influence the other.

SUMMARY

Respiratory monitoring is a complicated task in the critically ill patient who requires mechanical ventilation. The clinician must carefully balance a plethora of data acquired from studying variables of gas exchange, pulmonary mechanics, neuromuscular function, and patient ventilator interactions. Skilled intensive-care–trained personnel must then process these data so that a plan of respiratory support, often with mechanical ventilation, can be instituted. This plan must proceed in such a way that the patient is safely ventilated and oxygenated without imposing the undue harm that is associated with injurious and careless methods of ventilation.

CHAPTER 32 ■ APPROACH TO THE PATIENT WITH HYPOTENSION AND HEMODYNAMIC INSTABILITY

MICHAEL M. GIVERTZ AND JAMES C. FANG

Hypotension and hemodynamic instability are frequently encountered clinical problems in the intensive care setting. When the mean arterial blood pressure falls below approximately 60 mm Hg, end-organ perfusion becomes compromised and is manifested clinically as cool skin, decreased urine output, and altered mental status. Cornerstones of management include volume resuscitation and therapy directed toward the underlying cause of hypotension (e.g., cardiac pacing for bradycardia, cardioversion or defibrillation for tachyarrhythmias, blood transfusion for gastrointestinal bleeding, corticosteroids for adrenal insufficiency). When these measures fail to restore blood pressure and vital organ perfusion or while awaiting their availability, administration of intravenous vasoactive agents may be necessary. This chapter reviews the general management of the hypotensive patient with an emphasis on coronary care and the pharmacologic properties of commonly used vasopressor and positive inotropic agents. An overview of shock (see Chapter 157), volume resuscitation (see Chapter 158), sepsis (see Chapter 159), the use of intra-aortic balloon counterpulsation and mechanical circulatory support devices (see Chapter 45) are discussed elsewhere.

GENERAL APPROACH TO THE HYPOTENSIVE PATIENT IN THE CORONARY CARE UNIT

The assessment of the hypotensive patient begins with accurate measurement of the blood pressure and rapid correlation with clinical signs of hypoperfusion. Blood pressure should be measured in both arms and confirmed by another examiner. This practice is especially important when automated devices are used to make these measurements in the setting of tachyarrhythmias or respiratory distress. In patients with peripheral arterial disease, upper extremity blood pressure should also be compared to measurements in the legs in the supine position. In rare circumstances, true central aortic pressure may differ significantly from peripherally obtained blood pressures and can only be confirmed by invasive measurement during diagnostic catheterization. This situation should be suspected when clinical features of hypoperfusion do not accompany low blood pressure.

Hypotension is generally defined as a mean arterial pressure of less than 60 mm Hg and/or a systolic blood pressure less than 100 mm Hg. However, higher values may be consistent with clinically relevant hypotension if there are concomitant clinical signs of hypoperfusion such as mental confusion, oliguria, pallor, and cool extremities. If clinically relevant hypotension cannot be rapidly corrected, invasive monitoring with an arterial line should be considered, especially if vasoactive medications are employed. Central venous catheterization should also be considered to monitor intravascular volume, since volume status is often dynamic in the hypotensive patient and multiple mechanisms of hypotension may be simultaneously present. Foley catheterization should also be employed to assess hourly urine output as a surrogate for end-organ perfusion.

The history and physical examination should be directed toward establishing the primary mechanism and etiology of hypotension. Primary mechanisms include hypovolemia, low cardiac output, and vasodilation. Assessing volume status is critical; if not discernible from the bedside evaluation (jugular venous pressure, skin turgor, urine output, orthostasis), invasive measurement of the central venous pressure should be obtained with placement of a central venous catheter. If there are clinical reasons to suggest a dissociation of right and left ventricular hemodynamics (i.e., right ventricular infarction), pulmonary artery catheterization may be required to measure the left ventricular filling pressure. Warm well-perfused skin and extremities despite hypotension may suggest low systemic vascular resistance and a vasodilatory state, whereas cool clammy skin and extremities suggest vasoconstriction as a compensatory response to a low output syndrome. A narrow pulse pressure may also suggest reduced cardiac output. If a putative mechanism of hypotension cannot be ascertained from bedside assessment, pulmonary artery catheterization can be used to characterize the hemodynamic profile. This strategy is especially useful when more than one mechanism is present (for example, a large myocardial infarction complicated by pneumonia, leading to cardiogenic and vasodilatory shock).

Initial management strategies are directed at the primary etiology of hypotension and addressed later in this chapter. In general, therapy is guided by the primary pathophysiologic mechanism underlying the hypotension (e.g., volume resuscitation for hypovolemia, positive inotropes for low cardiac output, vasopressors for vasoplegia). The pace and aggressiveness of therapeutic intervention are guided by the presence or absence of clinical signs of hypoperfusion. For example, holding vasodilators may be sufficient in the hypotensive patient without changes in mental status or urine output. In contrast, the acutely hypotensive patient with clinical shock needs rapid resuscitation with intravascular volume expansion and usually vasoactive therapy.

ADRENERGIC RECEPTOR PHYSIOLOGY

Most vasopressor and positive inotropic agents currently available for use are sympathomimetic amines that exert their action

by binding to and stimulating adrenergic receptors. To better understand the similarities and differences among these agents, a basic knowledge of adrenergic receptor distribution and function is required [1].

The adrenergic receptors that are most relevant to the management of hypotension are the α_1, β_1, and β_2 receptors. α_1-Adrenergic receptors are present in smooth muscle cells of many vascular beds, including the arterioles supplying the skin, mucosa, skeletal muscle, and kidneys, as well as the peripheral veins. α_1-Adrenergic stimulation causes vasoconstriction and is the most common mechanism of vasopressor action. The presence of α_1 receptors has also been demonstrated in the myocardium, where stimulation appears to result in a positive inotropic effect with little change in heart rate. β_1-Adrenergic receptors are the predominant adrenergic receptor type in the heart and they mediate positive inotropic, chronotropic and lusitropic responses. Stimulation of β_2-adrenergic receptors causes relaxation of smooth muscle cells in bronchial, gastrointestinal, and uterine muscle, as well as vasodilation in skeletal muscle. β_3-adrenergic receptors, which are located mainly in adipose tissue, are involved in the regulation of lipolysis and thermogenesis and do not play a role in hemodynamic stability. Other relevant receptors are the dopaminergic receptors (DA_1 and DA_2), which mediate renal, coronary, cerebral, and mesenteric vasodilation, and cause a natriuretic response.

The receptor selectivity of sympathomimetic amines can be drug and dose dependent. For example, β_2 receptors are more sensitive to epinephrine than are α_1 receptors. Thus, at low doses of epinephrine, the vasodilatory effect of β_2 receptors predominates, whereas at high doses, α_1-mediated vasoconstriction overcomes the β_2 effect and increases systemic vascular resistance. The dose-dependent actions of dopamine have also been well established.

The overall clinical effects of vasoactive agents depend not only on the outcome of direct adrenergic receptor stimulation, but also on the reflex response of homeostatic forces. For example, stimulation of β_1-adrenergic receptors by norepinephrine would be expected to cause an increase in heart rate; however, norepinephrine-mediated α_1-adrenergic stimulation induces a reflex increase in vagal tone that cancels out its positive chronotropic effects. The action of some drugs (e.g., dopamine and ephedrine) is further complicated by their ability to stimulate release of stored endogenous catecholamines.

COMMONLY USED VASOPRESSORS AND POSITIVE INOTROPES

The armamentarium of vasoactive agents has changed little since the 1980s. Commonly used drugs with vasopressor activity are dopamine, epinephrine, norepinephrine, phenylephrine, and ephedrine. Vasopressin is a newer alternative to adrenergic vasopressors. Agents with positive inotropic activity that are useful for the treatment of hypotension include dobutamine, dopamine, epinephrine, and isoproterenol. Table 32.1 summarizes the receptor activity and hemodynamic effects of these drugs.

Dopamine

Dopamine is an endogenous catecholamine that functions as a central neurotransmitter and a synthetic precursor of norepinephrine and epinephrine. When administered intravenously, the effects of dopamine are mediated by dose-dependent stimulation of dopaminergic and adrenergic receptors, and by stimulation of norepinephrine release from nerve terminals.

At low doses (less than 5 μg per kg per minute), dopamine predominantly stimulates dopaminergic receptors in renal, mesenteric, and coronary vessels with minimal adrenergic effects. In normal subjects, so-called renal-dose dopamine augments renal blood flow, glomerular filtration rate, and natriuresis, with little effect on blood pressure. Low-dose dopamine has frequently been used by itself or in combination with other drugs as a renoprotective agent. However, the efficacy and safety of this strategy remain controversial [2]. Although a recent study demonstrated renal vasodilatory effects of dopamine in patients with heart failure [3], a randomized placebo-controlled trial in 328 critically ill patients with evidence of early renal dysfunction demonstrated no protective effect of low-dose dopamine on renal function and no difference in ICU or hospital length of stay [4]. Moderate doses of dopamine (5 to 10 μg per kg per minute) stimulate β_1-adrenergic receptors in the myocardium, augmenting cardiac output by increasing contractility and, to a lesser extent, heart rate (Fig. 32.1). In addition, venoconstriction mediated by serotonin and dopaminergic receptors may occur [5]. At higher doses (greater than 10 μg per kg per minute), α_1-adrenergic

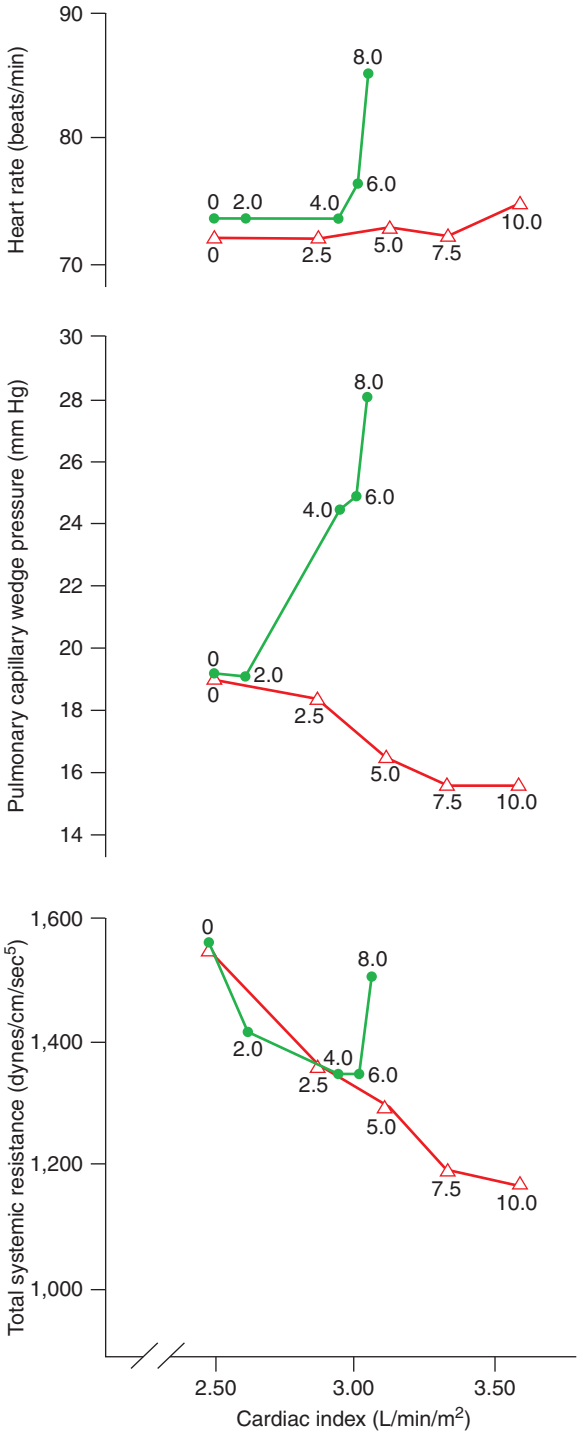

FIGURE 32.1. Comparative effects of dopamine (*closed circles*) and dobutamine (*open triangles*) on heart rate, pulmonary capillary wedge pressure, and total systemic resistance in patients with advanced heart failure. The numbers shown on the figures are infusion rates in μg per kg per minute. These data demonstrate that dopamine at doses greater than 2 to 4 μg/kg/min exerts a vasoconstrictor effect and increases heart rate and left ventricular filling pressure. [Adapted from Leier CV, Heban PT, Huss P, et al: Comparative systemic and regional hemodynamic effects of dopamine and dobutamine in patients with cardiomyopathic heart failure. *Circulation* 58:466–475, 1978, with permission.]

receptor stimulation predominates, resulting in systemic arteriolar vasoconstriction. The overall effects of dopamine at the highest doses resemble those of norepinephrine (see later). However, it should be remembered that there is a great deal of overlap in the dose-dependent effects of dopamine in critically ill patients [1,2].

Moderate- to high-dose dopamine is a mainstay in the treatment of hypotension. In studies of fluid-resuscitated patients with septic shock, dopamine produced a mean increase in mean arterial pressure of approximately 25%, primarily owing to an increase in cardiac index and, to a lesser extent, systemic vascular resistance [2]. In the setting of hyperdynamic septic shock when excessive vasodilation is the primary source of hypotension, addition or substitution of a more potent α-adrenergic agonist such as norepinephrine may be more effective. Moreover, evidence of worsening splanchnic oxygen utilization with the use of high-dose dopamine has made it a less attractive agent.

By itself or in combination with other agents, dopamine may be used at moderate doses in the management of patients with acute decompensated heart failure and hypotension. Venodilating agents (e.g., nitroprusside and nitroglycerin) may be added to moderate the tendency of dopamine to increase cardiac-filling pressures [6]. Dopamine may also be combined with dobutamine for added inotropic effects or used at low doses to augment diuresis [7], although the benefits of "renal-dose" dopamine remain controversial and other agents may be more effective for preserving renal function in critically ill patients [8].

The use of dopamine is associated with several adverse effects, including tachycardia, tachyarrhythmias, and excessive vasoconstriction. Although these effects are generally dose dependent, in individual patients there may be substantial overlap of receptor affinity such that even at low doses dopamine may result in toxicity. In patients with ischemic heart disease, increased myocardial oxygen consumption coupled with some degree of coronary vasoconstriction with high-dose dopamine can result in myocardial ischemia. As with other positive inotropes, dopamine can increase flow to poorly oxygenated regions of the lung and cause shunting and hypoxemia. In addition, dopamine has been shown to depress minute ventilation in normoxic heart failure patients [9]. When dopamine is used in patients with acute decompensated heart failure, increased venous tone and pulmonary arterial pressure may exacerbate pulmonary edema in the setting of already high cardiac filling pressures. Despite these caveats, oxygen saturation generally remains constant due to improved hemodynamics.

There is mounting evidence that dopamine adversely effects splanchnic perfusion at doses usually required to treat septic shock. A small, randomized study of patients with sepsis using selective splanchnic and hepatic cannulation showed that infusion of dopamine was associated with a disproportionate increase in splanchnic oxygen delivery compared with oxygen extraction (65% vs. 16%). In contrast, norepinephrine produced better-matched increases in oxygen delivery and extraction (33% vs. 28%) [10]. Another study showed that in patients with septic shock randomly assigned to treatment with norepinephrine or dopamine, gastric intramucosal pH worsened significantly in patients treated with dopamine despite similar improvements in mean arterial pressure [11]. Thus, the use of dopamine in septic shock may be associated with splanchnic shunting, impairment of gastric mucosal oxygenation, and increased risk of gastrointestinal bleeding [2].

Epinephrine

Epinephrine is an endogenous catecholamine that is a potent nonselective agonist of α- and β-adrenergic receptors.

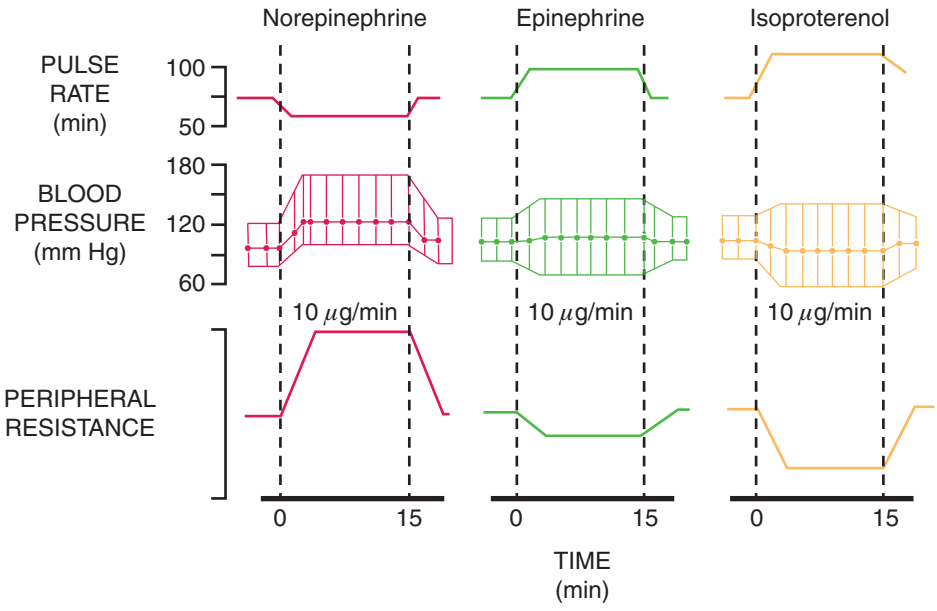

FIGURE 32.2. Cardiovascular effects of intravenous infusions of norepinephrine, epinephrine, and isoproterenol in normal human subjects. [Modified from Westfall TC, Westfall DP: Adrenergic agonists and antagonists, in Brunton LL (ed): *Goodman & Gilman's The Pharmacological Basis of Therapeutics*. 11th ed. New York, McGraw-Hill, 2005, pp 237–295, with permission.]

Stimulation of myocardial β_1 and β_2 receptors increases contractility and heart rate, resulting in a rise in cardiac output (Fig. 32.2). Cardiac output is further augmented by an increase in venous return as a result of α_1-mediated venoconstriction. Blood flow to skeletal muscles is increased owing to β_2-mediated vasodilation. With very low-dose infusions of epinephrine (0.01 to 0.05 μg per kg per minute), β-adrenergic–mediated positive chronotropic and inotropic effects predominate. Diastolic blood pressure and overall peripheral vascular resistance may actually decrease owing to vasodilation in skeletal muscle. With higher doses of epinephrine, stimulation of α-adrenergic receptors in precapillary resistance vessels of the skin, mucosa, and kidneys outweighs β_2-mediated vasodilation in skeletal muscle, causing increased mean and systolic blood pressure [1].

Epinephrine plays a central role in cardiovascular resuscitation (see Chapter 23) and the management of anaphylaxis (see Chapter 194). Epinephrine is also used to reverse hypotension with or without bradycardia after cardiopulmonary bypass or cardiac transplantation [12]. Because of its adverse effects on splanchnic and renal blood flow and potential for inducing myocardial ischemia and tachyarrhythmias, epinephrine has generally been regarded as a second-line agent in the management of septic shock [2,13]. However, a recent randomized trial showed no difference in efficacy or safety between epinephrine alone versus norepinephrine plus dobutamine in patients with septic shock [14]. For patients with symptomatic bradycardia and hypotension who have failed atropine or external pacing, epinephrine may be used to stabilize the patient while awaiting more definitive therapy (e.g., transvenous placement of a temporary or permanent pacemaker) [15]. When used to treat hypotension, epinephrine is given as a continuous infusion starting at a low dose (0.5 to 1.0 μg per minute) and titrating up to 10 μg per minute as needed. Continuous infusions of epinephrine may cause restlessness, tremor, headache, and palpitations. Epinephrine should be avoided in patients taking β-adrenergic antagonists, as unopposed α-adrenergic vasoconstriction may cause severe hypertension and cerebral hemorrhage.

Norepinephrine

Norepinephrine is an endogenous catecholamine that is a potent β_1- and α_1-adrenergic agonist, with little β_2 activity. The main cardiovascular effect of norepinephrine is dose-dependent arterial and venous vasoconstriction owing to α-adrenergic stimulation (Fig. 32.2). The positive inotropic and chronotropic effects of β_1 stimulation are generally counterbalanced by the increased afterload and reflex vagal activity induced by the elevated systemic vascular resistance. Thus, heart rate and cardiac output usually do not change significantly, although cardiac output may increase or decrease depending on vascular resistance, left ventricular function, and reflex responses [5].

Norepinephrine, when infused at doses ranging from 0.5 to 30.0 μg per minute, is a potent vasopressor. Although generally reserved as a second-line agent or used in addition to other vasopressors in cases of severe distributive shock, norepinephrine is emerging as an agent of choice for the management of hypotension in hyperdynamic septic shock [14,16]. In a small, prospective double-blind trial, Martin et al. [17] randomized patients with hyperdynamic septic shock to dopamine or norepinephrine titrated to a mean arterial pressure greater than or equal to 80 mm Hg or systemic vascular resistance greater than 1,100 dynes per second per cm^{-5}, or both. Although only 5 of 16 patients randomized to dopamine were able to achieve these endpoints, 15 of 16 patients randomized to norepinephrine were successfully treated with a mean dose of 1.5 μg per kg per minute. Moreover, 10 of the 11 patients who remained hypotensive on high-dose dopamine improved with the addition of norepinephrine. A subsequent prospective, nonrandomized, observational study suggested that in adults with septic shock treated initially with high-dose dopamine or norepinephrine, the use of norepinephrine was associated with improved survival [18]. In the setting of sepsis, norepinephrine improves renal blood flow and urine output [19], although large doses may be required to achieve these effects due to α-receptor downregulation [2].

Adverse effects of norepinephrine include increased myocardial oxygen consumption causing ischemia and renal and mesenteric vasoconstriction. Renal ischemia, may be of particular concern in patients with hemorrhagic shock. Norepinephrine can also cause necrosis and sloughing at the site of intravenous injection owing to drug extravasation. Norepinephrine is relatively contraindicated in patients with hypovolemia. As previously discussed, the overall effect of norepinephrine on gut mucosal oxygenation in septic patients compares favorably with that of high-dose dopamine.

Phenylephrine

Phenylephrine is a synthetic sympathomimetic amine that selectively stimulates α_1-adrenergic receptors. When administered intravenously, phenylephrine causes dose-dependent arterial vasoconstriction and increases peripheral vascular resistance. As blood pressure rises, activation of vagal reflexes causes slowing of the heart rate.

Phenylephrine, infused at 40 to 180 μg per minute, is commonly used in the management of anesthesia-induced hypotension [20,21] and hyperdynamic septic shock. Its rapid onset of action, short duration, and primary vascular effects make it an ideal agent for treating hemodynamically unstable patients in the intensive care setting. However, there are few data regarding its relative efficacy compared with older vasopressors such as norepinephrine and dopamine. In one small study of fluid-resuscitated patients with septic shock, the addition of phenylephrine to dobutamine or dopamine increased mean arterial pressure and systemic vascular resistance without a change in heart rate [22]. In addition, urine output improved while serum creatinine remained stable. The absence of β-adrenergic agonist activity at usual doses (phenylephrine activates β receptors only at much higher doses) makes phenylephrine an attractive agent for the management of hypotension in clinical situations where tachycardia or tachyarrhythmias, or both, limit the use of other agents [2]. As with other vasopressors, high-dose phenylephrine may cause excessive vasoconstriction. In addition, patients with poor ventricular function may not tolerate the increased afterload induced by α_1-stimulation [22]. Compared to epinephrine and norepinephrine, phenylephrine is less likely to decrease microcirculatory blood flow in the gastrointestinal tract [23].

Ephedrine

Ephedrine is a naturally occurring sympathomimetic amine derived from plants. Its pharmacologic action results from direct nonselective activation of adrenergic receptors, as well as stimulation of norepinephrine release from storage sites. Although ephedrine is less potent and longer acting (half-life, 3 to 6 hours) than epinephrine, its hemodynamic profile is similar and includes cardiac stimulation and peripheral vasoconstriction.

Ephedrine is rarely used in the critical care setting except in the temporary treatment of hypotension induced by spinal anesthesia [20]. Ephedrine does not appear to compromise uterine blood flow and is considered by some to be the vasopressor of choice in the treatment of anesthesia-induced hypotension in the obstetric patient [24]. However, prophylactic use in pregnant woman undergoing Caesarian section is not recommended as it may cause hypertension and tachycardia [25]. Ephedrine can be administered in doses of 10 to 25 mg, given as an intravenous bolus every 5 to 10 minutes, with the total dose not to exceed 150 mg in 24 hours. In healthy women undergoing elective cesarean delivery that develop hypotension, pharmacogenomic data suggests that β_2-adrenoceptor genotype may affect dose requirements [26]. Adverse effects of ephedrine include myocardial ischemia and excessive vasoconstriction.

Isoproterenol

Isoproterenol is a synthetic sympathomimetic amine with potent nonselective β-adrenergic activity and little effect on α-adrenergic receptors. Its major cardiovascular effect is increased cardiac output owing to direct positive inotropic and chronotropic effects (Fig. 32.2). Isoproterenol also increases heart rate by increasing atrioventricular nodal conduction. Systemic and pulmonary vascular resistances decrease owing to β_2-mediated vasodilation in skeletal muscle and pulmonary vasculature, respectively. Reduced peripheral resistance typically causes a fall in mean arterial and diastolic blood pressure, whereas systolic blood pressure is unchanged or rises modestly owing to increased cardiac output. Coronary blood flow remains unchanged, which in the face of increased myocardial oxygen demand can produce ischemia in patients with ischemic heart disease. In addition, stimulation of myocardial β_2-receptors can cause arrhythmias via increased dispersion of repolarization [27].

Stimulation of β-adrenergic receptors in the heart by isoproterenol increases the risk of excessive tachycardia, tachyarrhythmias, and myocardial ischemia. Given the likelihood of toxicity and the availability of alternative drugs, isoproterenol is no longer used as an inotropic agent; rather, its use is limited to the temporary treatment of hemodynamically significant bradycardia unresponsive to atropine while awaiting more definitive treatment with an external or transvenous pacemaker. The starting infusion rate for isoproterenol is 1 μg per minute, and this can be titrated up to 10 μg per minute to achieve the desired response (e.g., for bradycardia, titrated to a heart rate of 60 beats per minute or higher, depending on the blood pressure response). Other uses for isoproterenol include "chemical" overdrive pacing for torsades de pointes refractory to magnesium [28], and temporary inotropic and chronotropic support after cardiac transplantation [29]. Side effects of isoproterenol include palpitations, headache, flushing, and rarely paradoxical bradycardia [30].

Dobutamine

Dobutamine is a synthetic sympathomimetic amine that was derived from isoproterenol in an attempt to create a less arrhythmogenic positive inotrope with minimal vascular effects. Although initially thought to be a selective β_1-adrenergic agonist, its mechanism of action appears to be more complex. Dobutamine is available for clinical use as a mixture of two enantiomeric forms with different pharmacologic properties. Ruffolo et al. [31] showed that although both stereoisomers are nonselective β-agonists, the positive isomer is several times more potent. In addition, the two isomers have opposing effects on α-adrenergic receptors: the positive isomer is an α-antagonist and the negative isomer is a potent α_1-agonist. The overall effect of the racemic mixture is potent nonselective β- and mild α-adrenergic stimulation [31].

Cardiac contractile force is enhanced by β_1- and α-adrenergic stimulation. Heart rate may also increase, but to a lesser extent than occurs with isoproterenol or dopamine (Fig. 32.1). In contrast to dopamine, dobutamine decreases cardiac filling pressures, making it a preferred agent in the treatment of patients with acute decompensated heart failure [32]. Systemic vascular resistance is modestly reduced or may remain unchanged, as α_1-mediated vasoconstriction is counterbalanced by β_2-mediated vasodilation and reflex withdrawal of sympathetic tone that typically occurs in response to increased cardiac output. Dobutamine has no effect on dopaminergic receptors; however, renal blood flow often increases in proportion to the increase in cardiac output [33].

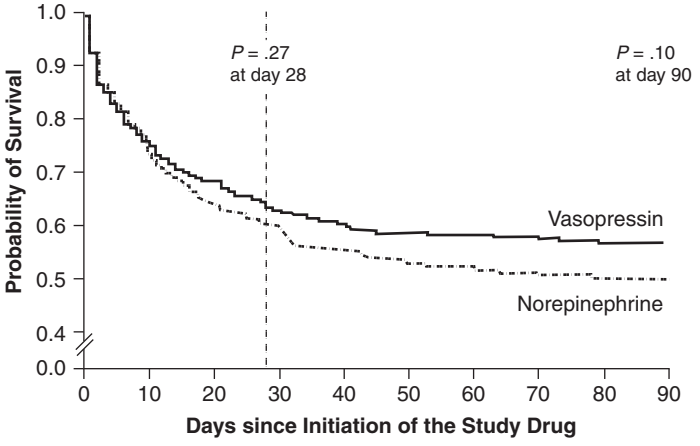
Dobutamine, by itself or in combination with other vasoactive drugs, is useful in the temporary support of myocardial function in patients with hypotension and poor end-organ perfusion, including those with acute decompensated heart failure as well as patients with concomitant septic shock and depressed cardiac function. In patients with cardiogenic shock, the effect of dobutamine on systemic vascular resistance and blood

pressure is difficult to predict. Therefore, when used in this setting, it is often administered in combination with dopamine [7].

Dobutamine is generally initiated at an infusion rate of 2 μg per kg per minute and can be titrated up to 15 μg per kg per minute or higher to achieve the desired hemodynamic or clinical effects, or both. Side effects that may limit dose titration include increased heart rate and exacerbation of supraventricular and ventricular arrhythmias. As with other positive inotropic agents, increased myocardial oxygen consumption can worsen cardiac ischemia, and short-term dobutamine therapy has been associated with excess mortality [34]. Although systolic and mean arterial blood pressures typically increase, hypotension may occur if dobutamine is administered to a volume-depleted patient. Some patients with advanced heart failure may be resistant to dobutamine owing to β-receptor hyporesponsiveness or may develop tolerance after several days of a continuous infusion [35]. Chronic dobutamine therapy may also cause an eosinophilic or hypersensitivity myocarditis [36], leading to further hemodynamic deterioration.

TABLE 32.2

SUMMARY OF ADVANCES IN THE MANAGEMENT OF HYPOTENSION



- Vasopressin improves blood pressure in patients with sepsis [37] or vasodilatory shock after cardiopulmonary bypass [38].
- Methylene blue is effective for refractory hypotension following cardiopulmonary bypass [53] and may be useful in preventing vasoplegia in high-risk patients [54].
- Recombinant human activated protein C (drotrecogin alfa activated) is indicated for severe sepsis (Apache II score >25) in the absence of bleeding [2,55–57].
- Stress-dose steroids improve hemodynamics and may reduce mortality in septic shock if adrenocortical insufficiency is present [62]. Doses of hydrocortisone should not exceed 200–300 mg/day [2].

Vasopressin
